For fluorescence microscopy in particular, it is important that the microscope is optimized for maximum collection and transmission of light. The single most important parameter in determining the amount of image forming light that reaches the camera is the numerical aperture of the objective lens (Murphy, 2001; Abramowitz *et al*., 2002). The brightness of an image formed by an objective lens can be defined by $B = 10^4 NA^4/M^2$, where NA and M refer to the numerical aperture and the magnification of the objective lens, respectively (Abramowitz *et al*., 2002). The numerical aperture, which is usually marked on the barrel of an objective lens just to the right of the magnification, is a measure of the half angle of the cone of light accepted by the objective lens times the refractive index of the medium between the lens and the specimen. The higher the numerical aperture, the more light the lens is capable of collecting. Conversely, the brightness of an image is inversely proportional to the square of the magnification. Therefore, a 60×/1.4 NA objective lens will create a brighter image than a 100×/1.4 NA objective, while having the same optical resolution. The actual light transmission of a lens is also affected by the extent to which the lens is corrected for aberrations, a highly corrected plan apochromat objective with many internal lens elements transmitting less light than a more simple fluorite lens (Abramowitz *et al*., 2002). Phase-contrast objective lenses are not optimal for low-light fluorescence imaging, as these objectives have a light-attenuating

phase annulus in the back focal plane that decreases the intensity of the signal by 10–15%.

To perform fluorescence microscopy effectively, the optimal fluorophore, filters, and illuminator should be chosen for a given application (Kinoshita, 2002; Reichman, 2000). It is also important to minimize the number of filters and prisms in the light path that absorb the excitation or emission light and decrease the intensity of the signal. For example, on a microscope with both fluorescence and DIC optics, the polarization analyzer (Murphy, 2001) is usually situated in the shared light path just behind the objective lens and should be removed when using the microscope for fluorescence to prevent attenuation of the signal.

D. Automated Live Cell Image Acquisition

Motorized microscope components allow the user to automate image acquisition and are particularly useful for live cell time-lapsed studies (Salmon and Waters, 1996; Mason, 1999). Components such as electronic shutters, filter wheels, motorized stages, and focus motors can be attached to a research grade microscope and controlled through a computer using image acquisition software. Electronic shutters, which are used to block the light source from illuminating the specimen between camera exposures, are particularly important for fluorescence specimens as a means of minimizing photobleaching and phototoxicity, thereby increasing image quality and cell viability over long periods of time-lapse recording. For live cell studies in which the localization of more than one fluorophore is to be time-lapse recorded, automated switching between fluorescence filter sets is necessary. Microscopes are now available that come equipped with a motorized fluorescence filter set slider or turret; however, they tend to be too slow for live cell applications in which the time between acquisition of the different fluorophores needs to be minimized. A faster solution is the addition of motorized filter wheels to the fluorescence light path (Salmon and Waters, 1996; Mason, 1999). In this setup, the standard fluorescence filter set (Herman, 1998) is replaced with a multiple band-pass dichroic mirror (Reichman, 2000). Excitation illumination is then controlled with a motorized wheel filled with single band-pass excitation filters placed in front of the light source. Either a single multiple band-pass emission filter or a set of single band-pass emission filters in a second motorized wheel (placed just before the camera) is then used to select emission wavelengths. Filter wheels are available that can move between adjacent positions in 30–50 ms, allowing rapid switching between fluorophores.

Focus motors attach to the fine focus mechanism of the microscope and allow automated focus control through image acquisition software. Focus motors can be used in conjunction with autofocus functions in the software or to collect a stack of optical sections for subsequent deconvolution and/or 3D reconstruction. Motorized stages can be used with image acquisition software to automate movement of the stage between more than one field of view or between wells in a culture dish. An image acquisition system equipped with a focus motor, a motorized stage, and advanced image acquisition software can be used for "4D" (*x*, *y*, *z* and *time*), "5D" (*x*, *y*, *z*, *time*, and *wavelength*), and "6D" (multiple *x*, *y* areas, *z*, *time*, and *wavelength*) live cell imaging.

It is often useful to collect both fluorescence and bright-field transmitted light images of the same specimen (Salmon and Waters, 1996). For many experiments, it is sufficient to acquire a phase or DIC image at the beginning and end of the fluorescence time lapse. When automated switching between fluorescence and bright field is required, both illumination pathways must have an electronic shutter in front of the light source. For DIC and fluorescence microscopy, a motorized polarization analyzer is also desirable so that this light-attenuating filter can be automatically removed from the light path while the fluorescence image is acquired. This DIC analyzer can alternatively be placed into a motorized wheel in front of the camera, alongside fluorescence emission filters.

IV. PREPARING YOUR SPECIMEN FOR IMAGING

An important part of generating excellent images of fluorescence specimens is to learn to evaluate critically the quality of the fluorescence signal relative to background fluorescence. It is difficult, and in many cases impossible, to use subsequent image processing to remove noise that comes from nonspecific fluorescence staining from the collected image. Fluorophores with high quantum efficiency and low photobleaching should be chosen whenever possible (Herman, 1998). It is well worth the time and effort of optimizing your labeling protocol to maximize signal while minimizing background fluorescence (Harper, 2001).

For high-resolution fluorescence work it is also important that specimens are mounted properly for viewing. The majority of high numerical aperture objectives are marked "0.17" on the objective barrel, indicating that they are designed to image through a 0.17-μm-thick coverslip (Murphy, 2001; Abramowitz

et al., 2002). This means that there should be nothing between the specimen and the front of the objective lens except a 0.17-µm-thick glass coverslip and the appropriate immersion medium (usually immersion oil). This means that the specimen to be imaged must be located adjacent to the coverslip, not at a great distance into its aqueous support medium. If the latter situation is unavoidable, a suitable water-immersion objective designed for confocal imaging deep within the aqueous specimen should be used. High-resolution light microscopy cannot be performed through a plastic petri dish or 16-well plate. Live cells should instead be grown in petri dishes or welled chambers that have a glass coverslip cemented into the bottom. There are also commercially available viewing chambers for live cell work that are designed to hold a coverslip and a volume of media. Similar chambers can be built with the help of a clever machine shop (for one such design, see Rieder and Cole, 1998). Fixed fluorescence specimens should be mounted in a glycerol-based media with an antiphotobleaching reagent. There are many commercially available mounting media, but it is also easy and inexpensive to make your own (one reliable recipe is a 1:1 mixture of double-strength phosphate-buffered saline and glycerol containing 0.5% *n*-propyl gallate). For live cell work, reducing the concentration of oxygen in media will also help prevent photobleaching. The product Oxyrase (http://www.oxyrase.com) works very well when used with a closed viewing chamber. However, it should be realized that lack of oxygen may compromise the long-term survival of the cells.

Focus drift while filming live cells can be disruptive and frustrating. A small amount of focus drift (1–2 µm per hour) is usual and must be tolerated, but steps can be taken to minimize the amount of focus drift in your image acquisition system. It is important to be sure that coverslips are mounted securely to the slide or viewing chamber and that the slide or viewing chamber itself is clamped tightly onto the microscope stage. With oil objectives, some amount of focus drift will occur within the first few minutes of viewing as the oil settles across the objective lens. It is thus often preferable to wait several minutes after placing a specimen on the microscope before beginning filming. Heated stage chambers can also lead to focus drift by causing fluctuations in temperature that make microscope components expand. Heated incubation chambers that totally enclose and heat the entire body of the microscope as well as the specimen are often the best way to maintain temperature and focus during image acquisition, especially during long-term experiments. Use of a fixed, permanently mounted specimen and monitoring focus over time will help determine whether focus drift is coming from your equipment or your specimen.

CHAPTER

6

Video-Enhanced Contrast Microscopy

Dieter G. Weiss

I. INTRODUCTION

Video contrast enhancement is a technique that considerably improves images obtained by a large variety of video-based imaging systems used in light, electron, and confocal microscopy. It requires a camera system with manually adjustable "gain" and "offset" (also called "pedestal" or "black level" by some manufacturers). Much better results are obtained if digital image processing can be applied in addition. In light microscopy the most striking image improvements are possible if the technique is applied to images obtained by polarized light methods. In such cases the improvement in true resolution is almost 2-fold and in visualization is 10-fold over conventional light microscopy by eye. The specimens most suitable for observation by this technique are unstained, low-contrast objects, such as living cells, uncontrasted semithin electron-microscopic sections, or gels and colloidal material. The objects made additionally accessible to observation include organelles, especially small vesicles, isolated microtubules (25 nm), latex beads 20 nm in size and larger, and colloidal gold particles of 5 nm in diameter and larger. The basic principles and theory are described in detail elsewhere (Weiss *et al*., 1999; Weiss and Maile, 1993).

II. EQUIPMENT

Video-enhanced contrast (VEC) microscopy requires the combination of a versatile, high-quality research microscope with an analog and digital real-time image processor. The parts required were discussed in detail elsewhere (Inoué and Spring, 1997; Weiss *et al*., 1999; Weiss and Maile, 1993) so that a short summary may suffice here.

To utilize the technique to its full extent, a massive, stable microscope preferably equipped with differential interference contrast (DIC), and if required additional epi-illumination fluorescence, transmitted light bright-field, dark-field, or other techniques, is used. The illumination should be as bright and even as possible to provide enough light for working at the highest magnifications. A stabilized DC mercury arc or xenon lamp with a narrow band filter (e.g., green 546 ± 10 nm for mercury arc lamps) is recommended; with some microscopes it may preferably be equipped with a light-scrambling fiber optic connection (Ellis, 1985; Inoué, 1986) (Technical Video Ltd.). The condenser and objective should be of the oil immersion type when working with objective magnifications of 40× and more. The numerical aperture (NA) of the condenser front lens must match that of the objective; for 60 and 100× objectives, a 1.4 NA oil condenser front lens is required. An exit port projecting 100% of the light to the video camera is essential for fluorescence and high magnification DIC work. In order to visualize objects of sizes near and below the limit of resolution, optical magnification of 2 or 4× is in addition to 100 or 60X, NA 1.3–1.4 objectives required and is obtained by the use of high oculars (16, 25×) and a video camera objective (50 or 63 mm) or, preferably, by direct projection of the image to the camera and additional magnification changers. This yields magnifications on a monitor with a 25-cm screen width of 10,000× and more. A temperature-controlled box is needed for work with cultured cells. The use of at least one heat-absorbing and one heat-reflecting filter is essential; a narrow band green filter and a UV filter are recommended for DIC work with most cell types.

Because VEC microscopy is best applied with DIC, it should be noted that DIC microscopes differ in the separation of the two orthogonally polarized wave trains. If this so-called shear is high (250 nm) the bright and dark rims of the object are also wide and have high contrast differences so that a crisp, very high contrast image appears when inspected by eye. However, in this case the true resolution cannot be increased over 250 nm, which is also the conventional limit. Most high magnification oil optics are designed with medium shear so that there will be a gain in resolution with VEC-DIC. Low-shear DIC optics would yield poor visual contrast but best improvement of resolution with VEC microscopy. Although microscope manufacturers intended up to now to design their DIC prism systems for bright shadow-cast visual contrast, Nikon was the first to offer a design better suitable for VEC-DIC in their new line of Eclipse microscopes with low-shear Wollaston prisms and the de Sénarmont compensator recommended by Allen *et al.* (1981a,b).

The image is picked up by a high-quality video camera, usually a chalnicon or newvicon tube camera. Charge-coupled device (CCD) cameras are equally suitable only if they have a comparable dynamic range. The cameras need to have a manually adjustable offset (black level) and gain to allow for analog contrast enhancement. Automatic gain control (AGC), if present, must be disabled. The digital image processor needs to have the following features to be performed in real time, i.e., at video rate: digitization with 512 × 512 pixels of 256 possible gray levels or better, arithmetic frame operations such as subtraction of the out-of-focus background (mottle) pattern, accumulation, rolling averaging (recursive filtering) of images in order to increase the signal-to-noise ratio, scaling, frame counting, and finally selecting of the desired range of gray levels (histogram stretching or digital contrast enhancement). In addition, controls signaling camera saturation and excessively high light levels, digital filters, or pseudo-color option are also useful. The cameras and processors developed for microscopy from Hamamatsu Photonics (e.g., Hamamatsu Photonics Deutschland) and Dage-MTI, Inc. are the most widely used ones.

III. STRATEGY OF IMAGE GENERATION

Video contrast enhancement of microscopic images obtained using bright-field, dark-field, anaxial illumination including Varel contrast, fluorescence, reflected light confocal, or fluorescence confocal optics, rather than DIC and polarization optics, is very straightforward. It is performed by following the steps in Table I with the exception of step 4.

For special aspects of video enhancement **in** fluorescence microscopy, refer to Lange *et al.* (1996). High-resolution VEC microscopy can also be used simultaneously with fluorescence if appropriate beam

TABLE I Steps in AVEC-DIOC Microscopy[a]

Step		Manipulation	Result
1[b]	M[c]	Focus specimen	Image appears
2	M	Adjust microscope correctly for Köhler illumination	Image improves
3	M	Open iris diaphragm fully	Optical image becomes too bright
4	M	Set compensator up to 20° from extinction[d]	Optical image worsens
5	C	Analog enhance by manually adjusting gain and offset	High-contrast video image with often disturbing mottle pattern appears
6	M	Defocus or move specimen laterally out of field of view	Object disappears, mottle remains
7	P	Average and store mottle image, then subtract mottle image from incoming video images	Absolutely homogeneous, light gray ("empty") image appears
8	M	Return specimen to focal plane	Clear image appears; if contrast is weak go to step 9
9	P	Contrast enhance digitally (histogram stretching)	Contrast becomes optimal; if pixel noise is high go to step 10
10	P	Use rolling or jumping averaging or digital filtering	Clear, low noise, and high-contrast image appears

[a] Reprinted from Weiss and Maile (1993) by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

[b] Before step 1, one should set the "brightness" and "contrast" controls of the monitor showing the processed image to their intermediate positions because the degree of enhancement will not be adequate in the recorded sequence if the monitor had been adjusted to an extreme setting. To use VEC microscopy to its full extent, make sure that the microscope objective and condenser front lenses are absolutely clean (check at least once daily) and that the lamp is always optimally adjusted and centered.

[c] Manipulations are performed at the microscope (M), camera control (C), or image processor (P), respectively.

[d] Particles need to appear in DIC microscopy images as if illuminated from above, i.e., with their bright part up, whereas vacuoles have the opposite shadows. If this is not the case, the camera has to be rotated 180° or the compensator or Wollaston prism has to be set to the opposite side with respect to the extinction position.

splitters and filters are used. When applied to live cells stained with vital dyes, this allows observation of organelle morphology and dynamics in parallel with the identification of the types of organelles or with measurements of ion concentrations (Foskett, 1993).

Most striking image improvements are usually gained with DIC and polarization microscopy, but special attention and some explanations are required for step 4. Allen *et al.* (1981a,b) and lnoué (1981, 1989; Inoué and Spring, 1997) simultaneously developed procedures of video contrast enhancement for polarized-light techniques that differed considerably in their approach but yielded very similar results. Although this is not the place to judge which one is more appropriate, we have to distinguish clearly between the two strategies to avoid confusion.

Allen named his techniques "Allen video-enhanced contrast" differential interference contrast and polarization (AVEC-DIC and AVEC-POL, respectively) microscopy. AVEC techniques involve the introduction of additional bias retardation by setting the polarizer and analyzer relatively far away from extinction to gain a high specimen signal. Allen suggested the use of a de Sénarmont compensator (Bennett, 1950), which consists of a quarter-wave plate (specific for the wavelength used) in front of a rotatable analyzer. In DIC microscopy, alternatively but less accurately, the desired bias retardation can also be introduced by shifting the adjustable Wollaston prism. Allen recommended a bias retardation of one-quarter to one-ninth of a wavelength away from extinction, with one-ninth (20°) as the best compromise between high signal and minimal diffraction anomaly of the Airy pattern (Allen *et al*., 1981b). The enormous amount of stray light introduced at such settings is removed by an appropriately large setting of analog and/or digital offset.

The technique recommended by lnoué, which in this article is called IVEC microscopy for distinction, aims to optically reduce stray light and diffraction anomaly arising from curved lens surfaces and other sources by employing selected, extremely strain-free objectives and the special rectifying lenses developed by Inoué (1961). The latter are available commercially only for few microscopes (some lines of Nikon) and are expensive. Inoué's special optimized microscope (Inoué and Spring, 1997) is used at a polarizer setting very close to extinction, which cannot be used for VEC micro-scopy with many other instruments because insuf-ficient light is passed for near-saturation of the video camera.

Thus in IVEC microscopy, stray light is not admitted, as the polarizers stay close to extinction and the special rectifying optics further reduce the stray light. Consequently, filters to reduce brightness are not required. On the contrary, a very bright arc lamp, ideally with a fiber-optic illuminator, is necessary to saturate the camera. The AVEC technique, however, electronically improves primary optical images characterized by low contrast and relatively high stray light content, arising from a "non-optimal" optical arrangement. In IVEC microscopy, no compromise is made regarding the optics, and consequently less demanding electronic steps are required to rescue the image. The AVEC technique is, however, one that can be used with any good research microscope equipped with commercial film polarizers.

The steps required for image generation and improvement by VEC microscopy are summarized in Table I and are explained later. They include procedures different from those used in conventional microscopy, which are, however, required for the highest resolution and visualization of subresolution objects. The procedure described is that for AVEC-DIC, but if DIC or other polarized light techniques are not required, step 4 should simply be omitted. Steps 1–5 of the procedure given here yield the final image if digital processing is not possible or if only analog enhancement is required. In this situation, analog enhancement has to be stopped just before mottle or uneven illumination becomes annoying. Analog shading correction and other types of analog image improvement may be applied if the camera control unit offers them. The use of a light scrambler and meticulous cleaning of the microscope and the lens surfaces in the projecting system to the camera (see step 5) help considerably in permitting high levels of analog enhancement.

Generally, it is most desirable in video microscopy to obtain near-saturation of the video camera prior to applying analog or digital enhancement. *If there is insufficient light*, the following measures are recommended: use brighter lamps (mercury or xenon lamp); redo the illumination adjustments such as setting Köhler illumination and centering the filament or arc, possibly while observing the image on the monitor to improve; remove ground glass diffusers from the light path; make sure that the video exit port receives 100% of the light; reduce magnification slightly; or replace the otherwise highly recommended narrow band-pass filter by a wider one.

In AVEC microscopy, near-saturation should be reached at a retardation setting of about one-ninth of a wave (20°), as this provides the best resolution (Hansen *et al*., 1988). Further opening of the crossed polarizers far beyond 20° will rarely improve the image further, but it may introduce amounts of stray light no longer manageable by offset, leading to a bright-field type of appearance.

In the case of excessive light reaching the camera, the following steps are recommended: apply weak neutral density gray filters, employ high-power light sources that can be attenuated (e.g., the Atto-Arc system from Carl Zeiss or metal halide burners, e.g., from Nikon), or increase magnification slightly.

Reducing light intensity by closing diaphragms is not recommended as it reduces resolution. In AVEC microscopy, if the one-ninth setting yields too much light for the camera, this could be reduced by setting the compensator or Wollaston prism to a position of less than 20°. Although widely used, this does somewhat compromise image quality, especially if settings of less than 15° or 10° are used (Allen *et al*., 1981a,b; Hansen *et al*., 1988).

IV. SAMPLE PREPARATION

Live cells from tissue cultures should preferentially be grown on a cover glass. The specimen's region of interest should be close to the cover glass surface, where the best image is obtained. If the highest magnifications are intended, it may be that the optics can be adjusted for Köhler illumination only at this surface and a few tens of micrometers below (upright microscope), as high-magnification objectives are usually designed for best optical imaging of objects only near a distance of 170 µm from the front element, i.e., 10–20 µm from the inner surface of a regular cover glass (No. I glasses, approximately 170 µm thick). To identify objectives for which this distance and the presence of a 170-µm-thick cover glass is critical, look for the "0.17" engraved or refer to the manufacturer's data sheet. If thick cells or other extended specimens must be observed with such objectives, No. 0 cover glasses (80–120 µm thick) and/or thinner glass slides (0.9 instead of 1 mm) (both available from O. Kindler GmbH or Scholt North America) may have to be used instead of the regular ones to allow the setting up of Köhler illumination with oil immersion of both condenser and objective lens and to permit a greater working distance within the specimen. The use of a slide preparation made of two cover glasses mounted in a frame as depicted in Fig. I would serve the same purpose.

Note, however, that if the oil immersion objectives are focusing through water rather than through glass and oil only, spherical aberration will be introduced. The use of monochromatic illumination or of immersion oils of different refractive indices (R. P. Cargille Laboratories) is recommended to overcome this problem. Alternatively, for imaging deep within an aqueous sample, water immersion objectives must be used. Special water immersion objectives have become available from major manufacturers for confocal microscopy. They combine high numerical aperture (e.g., 60×, NA 1.2) with correction for extreme working distances of up to 220 µm below the cover glass (Brenner, 1994).

Aqueous samples have to be prevented from drying out by completely sealing the cover glass to the microscope slide. Nail polish may be used for this or, if live or other solvent-sensitive specimens, such as microtubules, extruded cytoplasm, or cultured cells, are being observed, VALAP is recommended. This consists of equal parts by weight of Vaseline, lanolin, and paraffin (MP 51–53°C); it liquefies at around 65°C. It may be applied around the cover glass with a cotton tip applicator or fine paint brush and hardens rapidly. If the specimen is small enough or in suspension, sample volumes of no more than 5–10 µl should be used with 22 × 22-mm cover glasses and without spacers to produce very thin specimens (ca. 10 µm thick) for best image quality.

If working with an inverted microscope, the specimen slide has to be inverted for fitting to the microscope with the cover glass underneath. With most microscope stages, this will interfere with the VALAP sealant, and flat positioning of the slide will not be possible. Instead, use of a metal frame the size of a regular slide and 0.8 to 1 mm thick to hold a sandwich of two cover glasses of dissimilar sizes separated by tape or cover glass spacers is recommended (Schnapp, 1986; Weiss *et al*., 1999, 1990) (Fig. 1).

If thick specimens, such as tissue slices, vibratome sections, or nerve bundles, are to be observed at high magnifications that require oil immersion, only contrasting techniques that allow optical sectioning such as DIC, Hoffman modulation contrast, or anaxial illumination (including Varel) contrast are recommended. Only the first 10 or 20 µm behind the cover glass will yield perfect images. However, even if expensive long working distance water immersion objectives are not available, part of the loss of image quality can be compensated for by video enhancement with good results down to a depth of 100 µm or more, with respect to both visibility and contrast, sometimes also to resolution (Kachar, 1985). The opacity of live tissues such as brain slices is reduced greatly when 700 to 800 nm light is used because they are transparent for infrared or near-infrared light (Dodt and Zieglgänsberger, 1990).

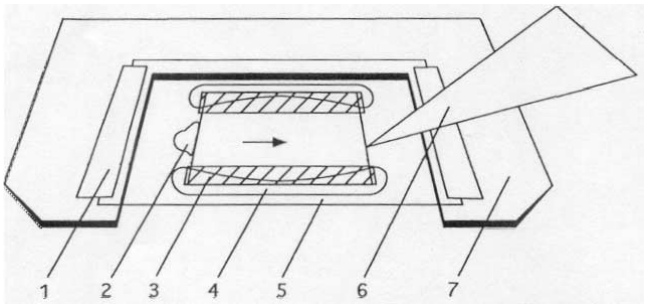

FIGURE 1 Slide preparation suitable for highest magnification VEC microscopy with upright and inverted microscopes and for superfusion of live cells or suspension specimens: (1) adhesive tape attaching the cover glass to the metal frame (7); (2) drop of medium to replace the original medium; (3) VALAP sealant; (4) small cover glasses or thin adhesive tape as spacers (e.g., double-sticky Scotch Tape); (5) carrier cover glass [e.g., No. 2 (extra thick) 24 × 50 or 60 mm]; (6) filter paper wick to induce medium flow (arrow); and (7) metal frame of the size of regular microscope slides made of brass or aluminum 0.8 to 1 mm thick and absolutely flat. For use with inverted microscopes the preparation should be mounted on the lower side of the carrier glass (5). Reproduced from Weiss *et al*. (1990) with permission by Plenum Press.

V. GENERATION OF THE IMAGE

Step 1: Focusing the Specimen

We find the specimen preferably by looking through the oculars or, alternatively, by looking at reduced magnification at the monitor. Only if the entire specimen consists of subresolution size material (density gradient fractions, microtubule suspensions, unstained EM sections) will it be difficult to find the specimen plane. Use a relatively dark setting of the condenser diaphragm and/or polarizers or prisms and look for contaminating larger particles. If there are none, routinely apply a fingerprint to one corner of the specimen side of the cover glass and use this for focusing.

Step 2: Adjusting Köhler Illumination

After finding a coarse setting for the illumination, the desired plane for the specimen is selected exactly. Then the condenser is finely adjusted, but now in relation to the image on the monitor (make sure the light is reduced to avoid damage of the camera!). The field diaphragm must be centered on the monitor and opened until it becomes just invisible. If the field diaphragm is opened too much, most microscope–camera adapter tubes or high-power projectives and oculars will create a very annoying central hot spot. If this persists at the adjustment for proper illumination, closing the projective diaphragm or inserting a self-made diaphragm cutting the peripheral light at the microscope exit usually helps. Note that at the high magnifications and numerical apertures used here, Köhler illumination has to be readjusted once the focus is changed more than a few micrometers.

As we will apply extreme contrast enhancement later, we have to start out with as even an illumination setting as possible (Fig. 2a). Proper centering of the lamp and setting of the collector lens are therefore important. At high magnifications as much light as possible needs to be collected. Some workers have therefore used critical illumination, i.e., focusing the light source onto the specimen plane instead of Köhler illumination (Schnapp, 1986). This is counter to good microscopical practice and can lead to very uneven illumination as the filament or arc a will be superimposed onto the image of the specimen and, subsequently, has to be subtracted digitally by mottle subtraction. Critical illumination might be useful, however, in those cases where the illuminating light is made extremely homogeneous by light scrambling with a light fiber device (Ellis, 1985; Inoué, 1986; Schnapp, 1986) (Technical Video Ltd.).

Step 3: Full Numerical Aperture for Highest Resolution

Open the condenser diaphragm fully in order to utilize the highest possible numerical aperture to obtain highest resolution. Also, any iris diaphragm of the objective should be opened fully. The result of opening the condenser diaphragm will usually be that the optical image worsens because it becomes too bright and flat for the eye. This setting will result in a small depth of focus, especially with DIC (optical sections of 0.3 µm or less with 100× NA 1.4 oil objectives). If collection of information from a large depth of focus is desired (e.g., viewing very dilute suspensions) and resolution can be sacrificed, the condenser diaphragm may be closed down as desired.

Be careful to protect the camera from too high light intensity prior to this step. However, at this point you have to make sure that the camera receives the proper amount of light to work near its saturation end. Some manufacturers have red and green control lamps built in to indicate this. In any case you should see a moderately modulated image on the monitor, whereas a very flat or no image indicates insufficient light. In this case, follow the recommendations on how light intensity can be increased (see Section III). If the illumination has to be reduced to protect the camera, this should not be done by closing diaphragms, as this compromises resolution (see Section III).

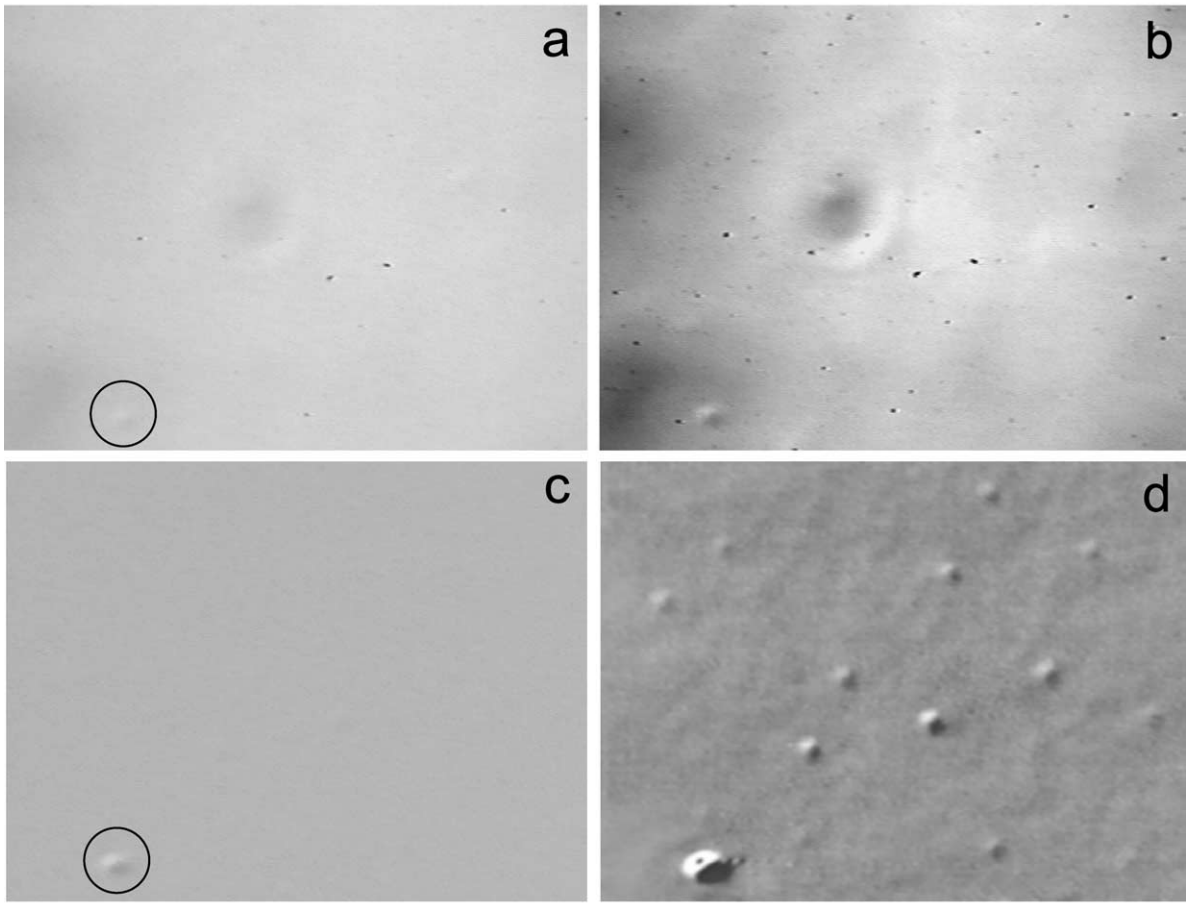

FIGURE 2 VEC microscopy of a specimen with very weak contrast. The steps of image generation and contrast enhancement in VEC microscopy are demonstrated using subresolution size latex beads (50 nm diameter). (a and b) Analog contrast enhancement. (c and d) Digital background subtraction and digital contrast enhancement. (a) In focus, not enhanced; only the large aggregate of a size above the limit of resolution is visible (circle); (b) in focus, analog-enhanced; the mottle becomes annoying; (c) in focus, mottle subtracted; (d) the same digitally enhanced. Microscope: Reichert-Leica Polyvar; image processor: Hamamatsu Argus 10; width of frames: 22 µm.

Step 4: Setting the Compensator (Polarized Light Techniques Only)

Set the compensator or main prism (AVEC-DIC) or the polarizer (AVEC-POL) to about 1/9 λ, i.e., one-ninth of a wavelength. The optical image, i.e., that seen in the oculars, will disappear due to excessive stray light.

If you have the accessories for de Sénarmont compensation as recommended by Allen *et al*. (1981a,b; see also Weiss and Maile, 1993; Weiss *et al*., 1999), set them at 20'° off extinction. The basic setup for the de Sénarmont compensator is as follows: Remove both Wollaston prisms and quarter-wave plate from the light path; set analyzer and polarizer to best extinction; insert quarter-wave plate at 0° (best extinction); insert Wollaston prisms and set the adjustable one to best symmetrical extinction (if possible, check with a phase telescope for symmetry of the pattern); and use the rotatable analyzer as a compensator and set it as desired (one-ninth of a wave is 20°, one-quarter is 45°).

If you do not have such a calibrated system, first determine the distance between extinction (0°) and maximum brightness (90° or one-half of a wavelength)

by moving the adjustable Wollaston prism and then estimate and select approximately the ninth of a wave or 20° position. Many microscopes equipped with DIC for biological applications do not allow a phase shift of 90° and some may not even allow 20° because for observation by eye, phase shifts of a few degrees already yield good contrast. Microscope manufacturers will, however, have the proper parts in their mineralogy programs.

At this point you have to again make sure that the camera is protected from excessive light but receives enough light to work near its saturation end. Ideally this should be near the one-ninth setting. Light adjustment should be done as explained in Section III. Opening the compensator or the crossed polarizers beyond 20°, although perhaps leading to a better saturation of the camera, will hardly improve the resolution of DIC or polarization images and will yield a poor image resembling the bright-field type.

In IVEC microscopy, stray light is not admitted, i.e., the polarizers stay close to extinction and the special rectifying optics further reduce the stray light. Filters to reduce brightness will not be required, but very bright lamps will be necessary to saturate the camera.

Step 5: Analog Enhancement

Increase the gain on the camera to obtain good contrast. Then apply offset (pedestal). Always stop before you lose parts of the image that become too dark or too bright. Repeat this procedure several times, if necessary and helpful. Make sure that the monitor for watching the changes is not set to extreme contrast or brightness and is terminated properly (75 Ω setting). Analog enhancement improves the contrast of the specimen, but unfortunately also emphasizes dust particles, uneven illumination, and optical imperfections. These artifacts, called "mottle," are superimposed on the image of the specimen and may, in some cases, partially or totally obscure it (Fig. 2). Disturbing contributions from fixed pattern noise (mottle) or excessive amounts in unevenness of illumination (Fig. 2b) can, however, be tolerated if digital processing is performed later (Fig. 2c and d).

If digital processing is not possible, stop enhancement just before mottle or uneven illumination becomes annoying. Optimal adjustment of the lamp and thorough cleaning of the inner optical surfaces of the microscope, oculars, and camera lens usually result in images that allow the application of considerably higher analog contrast enhancement. Apply analog shading correction and other types of analog image improvement if your camera control unit offers these features.

Finding Dust When the imaged dust particles or the mottle pattern rotates when the camera head is rotated, they are in the optical path before the camera, while the immobile dust is to be found on the camera face plate. Rotate the ocular or camera objective lens to find dust located there. Dust should be removed with a low-pressure air gun or an optical cleaning brush. If this does not help, use lens paper or a fat-free cotton tip applicator (wooden stick, no plastic!) with ethanol or ether (in the fume hood only!). Work from the center to the periphery in a circular fashion while carefully avoiding to apply any pressure. Dust or mottle that is defocused if the specimen is defocused is part of the specimen.

Step 6: Finding a "Background" Scene

Try removing the specimen laterally out of the field of view or (when using DIC) defocus to render it just invisible (preferably toward the cover glass). The result is an image containing only the imperfections of your microscope system (mottle pattern). This step may not be satisfactory, however, with such techniques as phase contrast or bright field.

Step 7: Background (Mottle) Subtraction

Freeze, i.e., store, the mottle image, preferably averaged over several frames, and subtract it from all incoming video frames.

Step 8: Return Specimen to Focal Plane

When returning the specimen to the focal plane, you should see an absolutely even and clean image, which may, however, be weak in contrast (Fig. 2c). If there are regions "missing" that are gray and flat, there is too much contrast in the mottle of the raw image to be subtracted properly. Reduce gain, adjust offset, and repeat the procedure.

Step 9: Digital Enhancement

This is done in a similar manner to step 5. Alternate between stretching a selected range of gray levels (setting "width") and shifting the image obtained up and down the scale of gray levels (setting "level" or "lower level") until a pleasing result is found (Fig. 2d). If available on your equipment, display the gray level histogram and select the upper and lower limits, which are to be defined as bright white and saturated black, respectively. If the image is noisy (pixel noise), go to step 10.

Step 10: Temporal Filtering (Frame Averaging)

Use an averaging function in a rolling (recursive filtering) or jumping mode over two or four frames. This

will still allow the observation of fairly rapid movements in your specimen, whereas very fast motions and noise due to pixel fluctuations will be averaged out. Averaging over a large number of frames will filter out all undesired motion and may be used with a fixed specimen or in order to remove, for example, distracting Brownian motion of small particles in suspension. The image will then contain the immobile parts of the object exclusively.

Please note that not all image processors are capable of performing background subtraction and the rolling average function simultaneously, as desired here. In this case, averaging generally yields the better image improvement for low light applications (fluorescence), whereas background subtraction is more advantageous in VEC microscopy, although this should be determined experimentally.

Step 11: Spatial Filtering

A large number of digital procedures for spatial filtering are available that can be used to reduce noise, to enhance edges of objects, or to reduce shading (Shotton, 1993; Russ, 1995). Some image processors offer such filters at video rate so that live sequences can be accentuated by filtering prior to recording.

Step 12: Printing Pictures

For publication purposes, pictures may be photographed or filmed off the video screen by observing special procedures and hints to remove video lines as discussed in detail by Inoué and Spring (1997) or Weiss *et al*. (1999). Alternatively, video printers are available with near-photographic or, at higher cost, with true pho-tographic quality that can be directly connected to the analog video output. Very good results are also obtained if all analog and photographic steps for printing can be avoided and the selected frame is directly transferred in digital form to a computer and from there to a high-resolution printer.

VI. INTERPRETATION OF IMAGES

Unlike in EM images, which truly resolve the submicroscopic objects depicted, the sizes of objects seen by AVEC-DIC microscopy may not necessarily reflect their real size. When AVEC-DIC is used, the limit of true resolution is shifted to almost one-half of that obtained conventionally. Objects smaller than the limit of resolution, i.e., 100–250 nm, depending on the optics and the wavelength of light used, are inflated by diffraction to the size of the resolution limit. The orientation of birefringent objects may also somewhat affect their apparent thickness if they are oriented at angles very close to 45° or 135°. Whereas the size of the image does not enable a decision on whether one or several objects of a size smaller than the limit of resolution are pre-sent, the contrast sometimes permits this judgment to be made. A pair of microtubules would, for example, have the same thickness as a single one, but the contrast would be about twice as high. If large numbers of subresolution objects are separated by distances of less than 200 nm from each other (e.g., microtubules in concentrated suspensions or vesicles in a synapse), they will remain invisible, but they will be depicted clearly if they are separated by more than the resolution limit.

Also remember that if in-focus subtraction or averaging over time is used, the immobile or the moving parts of the specimen, respectively, may have been completely removed from the image.

Confocal Microscopy of Living Cells and Fixed Cells

CHAPTER

7

Spinning Disc Confocal Microscopy of Living Cells

Timo Zimmermann and Damian Brunner

I. INTRODUCTION

Confocal laser-scanning microscopy (CLSM) has in the last decade significantly extended our ability to visualise highly complex biological samples as multi-dimensional datasets (with dimensions of space and time, and different pseudocolours representing monochrome images collected from different fluorophores emitting at different wavelengths). In parallel, the introduction of fluorescent proteins such as green fluorescent protein (GFP) and its variants, as tags for structures of interest, has opened up new ways to observe intracellular processes *in vivo*. This article presents and discusses a variant of confocal microscopy, the spinning disc microscope, which is particularly well suited for fast three-dimensional (3D) real-time imaging of living cells, and describes its application to the imaging of yeast cells.

The most common type of confocal microscope uses a single focused laser beam to sequentially point scan a region of a sample. Spinning disc confocal microscopes (SDCMs) instead use a parallelised scanning approach with multiple confocal beams that simultaneously illuminate the sample. This overcomes the severe speed disadvantage that is inherent in the approach of sequentially scanning with a single beam. SDCM has thus become a powerful tool, especially for the time-limited requirements of *in vivo* imaging in combination with GFP technology.

A spinning disc confocal microscope consists of the confocal scanning unit containing the light source (a laser or fluorescence lamp), a rotating Nipkow disc with thousands of pinholes arranged in a geometric spiral, and a CCD camera, all of which are attached to a conventional light microscope (Fig. 1A). The light passes through the pinholes and then, when focused into the specimen by the objective lens, creates a set of confocal minibeams that sweep the chosen focal plane of the specimen as the disc rotates. The pinholes all have an identical, fixed aperture, and, in most commonly used setups, the excitation and emission light of each minibeam passes through the same pinhole (Inoué and Inoué, 2002; Kino, 1995). Because the pinholes only cover a small percentage of the disc surface, most of the excitation light would normally not pass the disc to reach the sample. This has for a long time been a limitation in the applicability of SDCM for weak fluorescence signals. However, Yokogawa Corp. overcame this problem by attaching a second disc on top of the pinhole disc that contains an identical array of microlenses, each of which covers a pinhole on the lower disc (Fig. 1A). Because each microlens focuses the excitation light of a larger region into its corresponding pinhole, this increases the efficiency of use of the excitation light from 1–4% (pinhole area) to 40–60% (Inoué and Inoué, 2002). This results in higher fluorescence emission signals due to the significant increase in excitation.

The fluorescence emission passes the pinholes and is then deflected onto the camera by a dichroic beam splitter, which is situated inbetween the two discs (Fig. 1A). Furthermore, because the unused excitation light is rejected already by the microlens disc, it cannot interfere with the detection signal, as would be the case in single disc designs.

In the Yokogawa scan unit, approximately 1000 of the 20,000 pinholes in the Nipkow disc cover the field of view of the microscope at any one time (Fig. 1B). The pinholes are arranged such that every region of the image is covered during one-twelfth of a disc rotation. Because the disc rotates at 1800 rpm, 360 full

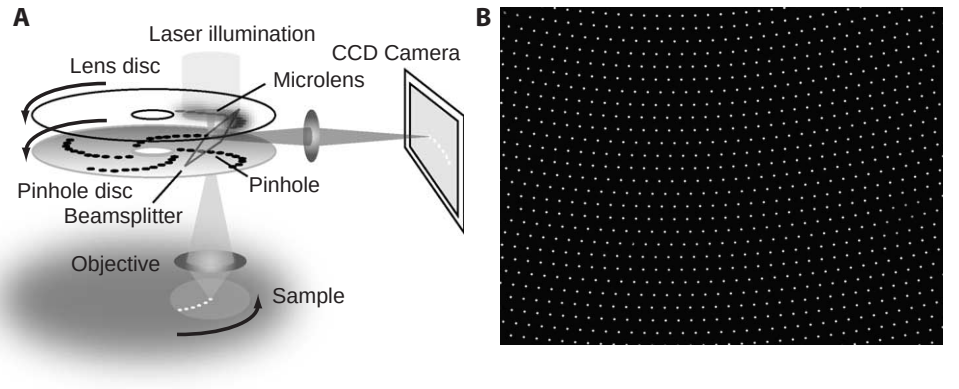

FIGURE 1 (A) Schematic of an SDCM setup. (B) Approximately 1000 of the 20,000 pinholes on the Nipkow disc cover the field of view of the microscope at any one time.

frames are scanned per second. This fast image acquisition rate means that two features of the CCD camera used for image detection become limiting: the sensitivity of the camera and its readout time.

Two alternative spinning disc designs use xenon or mercury arc lamps instead of laser light for excitation (ATTO Bioscience, Olympus). They can be added onto existing wide-field microscope systems and can be switched easily between wide-field and confocal imaging modes. Because they use lamps with a continuous emission spectrum, the excitation light can be controlled and varied with excitation filters. This flexibility is not available with systems employing lasers because there the excitation is limited to lines provided by the installed lasers.

II. MATERIALS AND INSTRUMENTATION

A. Materials

1. Media

All cell culture media are prepared in bulk and sterilised by autoclaving at 10 psi for 20 min. At this pressure, very little caramelisation of glucose takes place, which can cause background fluorescence. However, for live imaging we alternatively use sterile filtered medium to keep background fluorescence to an absolute minimum. The media is stored in 500-ml bottles, and agar is remelted in a microwave oven before using.

Yeast extract (YE): 0.5% (w/v) yeast extract (Bio 101 Systems—Q Biogene, 4018-022); 3.0% (w/v) glucose (Merck, 104074.1000)

Yeast extract + supplements (YES): YE plus 225 mg/l each of adenine, histidine, leucine, uracil, and lysine hydrochloride (all Sigma, A 9126, H 8125, 61820, U 0750, L 5626).

Edinburgh minimal medium (EMM 2): 3 g/liter potassium hydrogen phthallate (14.7 m*M*) (Sigma, P 3792); 2.2 g/liter Na_2HPO_4 (15.5 m*M*) (Merck, 106586.0500); 5 g/liter NH_4Cl (93.5 m*M*) (Merck, 101145.1000); 2% (w/v) glucose (111 m*M*) (Merck, 104074.1000); 20 ml/liter salts (stock "salts ×50"); 1 ml/liter vitamins (stock "vitamins ×1000"); and 0.1 ml/liter minerals (stock "minerals ×10,000").

"Salts ×50": 52.5 g/liter $MgCl_2{\cdot}6H_20$ (0.26 *M*) (Merck, 105833.1000); 0.735 mg/liter $CaCl_2{\cdot}2H_20$ (4.99 m*M*) (Merck, 102382.1000); 50 g/liter KCl (0.67 *M*) (Merck, 104936.1000); and 2 g/liter Na_2SO_4 (14.1 m*M*) (Merck, 106649.1000)

"Vitamins ×1000": 1 g/liter pantothenic acid (4.20 m*M*) (Sigma, P 2250); 10 g/liter nicotinic acid (81.2 m*M*) (Sigma, N 0761); 10 g/liter inositol (55.5 m*M*) (Sigma, P 7508); and 10 mg/liter biotin (40.8 µ*M*) (Sigma, B 4639)

"Minerals ×10,000": 5 g/liter boric acid (80.9 m*M*) (Merck, 100165.1000); 4 g/liter $MnSO_4$ (23.7 m*M*) (Sigma, M 1144); 4 g/liter $ZnSO_4{\cdot}7H_2O$ (13.9 m*M*) (Sigma, Z 0251); 2 g/liter $FeCl_2{\cdot}6H_2O$ (7.40 m*M*) (Sigma, F 2130); 0.4 g/liter molybdic acid (2.47 m*M*) (Sigma, M 1019); 1 g/liter KI (6.02 m*M*) (Sigma, P 5686); 0.4 g/liter $CuSO_4{\cdot}5H_2O$ (1.60 m*M*) (Merck, 1027900250); and 10 g/liter citric acid (47.6 m*M*) (Merck, 100244).

Minimal supplemented medium (used for vegetative growth): EMM2 plus 225 mg/liter each of adenine, histidine, leucine, uracil, and lysine hydrochloride (all Sigma, A 9126, H 8125, 61820, U 0750, L 5626), as described earlier for YES

Solid media: add 2% Difco Bacto agar (BD, 214010) to the appropriate liquid media before autoclaving

These media, and the fission yeast growth conditions employed, are described online under http://www-rcf.usc.edu/~forsburg/lab.html and in H. Gutz (1974) and Moreno *et al*. (1991).

2. *Other Materials*

Culture dishes (MatTec Corporation, P35G-1.5-10-C). Lectin BS-1 from *Bandeiraea simplicifolia* (Sigma, L-2380). Flow chamber (EMBL custom made, can be ordered from EMBL workshop). Silicon paste (Baysilone-Paste 35 g, hochviskos, GE Bayer Silicones).

B. Instrumentation

Spinning Disc Setups

Yokogawa scanheads: Two confocal scanning unit (CSU) designs by Yokogawa Corp. are available in our laboratory. The CSU-10 (Inoué and Inoué, 2002) is incorporated into several commercially available spinning disc setups (Perkin Elmer, VisiTech/Solamere). In addition to the CSU-10, we now also use a CSU-21 unit with higher and variable disc rotation speeds and with switchable filter sets. In our experiments, we use two Perkin Elmer setups with Hamamatsu Orca-ER CCD cameras and a 488/568/647-nm argon krypton laser, or 488/568/647-nm argon krypton, 442 helium/cadmium, and 488/514-nm Argon lasers, respectively. For switching between fluorescence channels, we use filter wheels (Ultraview LCI system) or acousto-optical tunable filters (AOTFs, Ultraview RS system).

III. PROCEDURES

In principle, there are no SDCM-specific restrictions, with respect either to the cell type or organism used or to the preparation/mounting procedures applied. Whatever specimen is mountable on an epifluorescence microscope or a single beam laser-scanning confocal setup can also be imaged using an SDCM. Here we present the mounting methods used for live imaging of fission yeast cells that express tubulin or microtubule-associated proteins tagged with GFP, CFP, and YFP (Brunner and Nurse, 2000; Ding *et al*., 1998; Drummond and Cross, 2000; Busch *et al*., 2004) and we describe the way we usually approach the task. To a large extent this approach would also be applicable to live imaging of yeast with epifluorescence and single beam confocal microscope setups.

A. Mounting Cells

Fission yeast cells can be mounted in a variety of ways for live imaging. However, for 3D imaging of intracellular structures over extended periods of time, it is important that the cells are absolutely immobile. Special attention therefore has to be given to immobilising the cells such that movements that would otherwise be created by medium flow cannot displace the cells during the acquisition process.

1. *Mounting Cells in Petri Dishes*

This method of adhering yeast cells to a coverslip allows imaging over short and intermediate time periods in liquid medium. Dividing cells will often disconnect from the glass surface and move out of the focal plane.

Steps

1. Use culture dishes with glass bottoms formed by 0.17-mm-thick microscope coverslips of 10 mm diameter. Be aware that their use is restricted to inverted microscopes! Wipe the glass surface inside the dish with a "cotton-bud" stick soaked in 70% ethanol containing one drop of glacial acetic acid per milliliter to remove the oil coating that is present on most glass surfaces. Rinse with double distilled water and dry with a Kimwipe.
2. Coat the cleaned glass surface by distributing 0.5 µl of 2 mg/ml lectin in H_2O with a pipette tip and allow to air dry.
3. Pipet 300 µl of cell suspension onto the coated glass and allow 5–10 min for cells to adhere to the lectin-treated glass surface.
4. Remove the medium and any unattached cells with a pipette, wash with 2 ml of fresh medium, and finally add 200 µl fresh medium for imaging.

2. *Mounting Cells on Solid Medium*

This method of embedding yeast cells in agar medium allows imaging over long time periods. Dividing cells will remain in the selected focal planes.

Steps

1. Stick one or more layers of narrow adhesive tape along the long axis of two slides, near one of their edges. The thickness of the tape will define the thickness of the agar pad and thus the amount of nutrients available. We usually make pads of about 0.25 mm thickness.
2. Place the slides on a flat surface to the left and the right of a third clean untreated, empty slide, leaving small gaps between the parallel slides (Fig. 2).

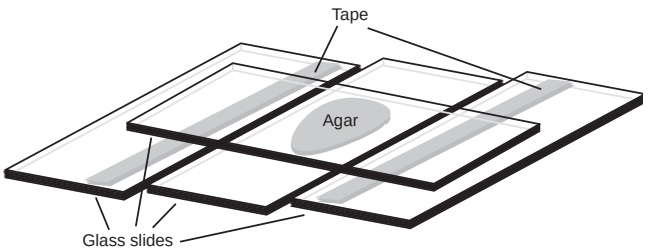

FIGURE 2 Setup for making agar pads.

3. Melt previously prepared agar medium in the microwave (open the lid of the container as it may explode) and apply a drop of the hot medium onto the middle of the central slide.

4. Place a fourth slide perpendicular to the other three, centred on top of the agar drop, and push its ends down onto the flanking slides in the taped area (Fig. 2). Keep pressing for about 30 s to allow cooling and repolymerisation of the agar.

5. Carefully remove the top slide (slow sideward sliding helps) and then, with a scalpel, trim away the edges of the remaining agar pad to make it slightly smaller than the square coverslip that will be used subsequently to cover the preparation.

6. Add a drop of yeast cell suspension onto the agar pad. Make sure that the cells are not too dense. Usually, the aim is to have isolated single cells distributed all over the agar surface, with clear areas between them.

7. Let the preparation stand until the agar has absorbed the fluid medium. Place a coverslip on top of the agar (avoid trapping air bubbles) and seal between the edges of the coverslip and the slide with a preparation of melted VALAP (a 1:1:1 mixture of vaseline, lanolin, and paraffin wax). The duration of usage of such a preparation depends on the thickness of the agar pad and on the density of the cells.

3. Mounting Cells in a Flow Chamber

This method allows imaging of cells over short and intermediate time periods. It is particularly suitable for applications where media are exchanged during image acquisition (i.e., drug wash-in/wash-out experiments).

Steps

1. The flow chamber (Fig. 3) consists of a closed cylindrical space (0.5 mm high) with connected inlet and outlet tubes for medium exchange, the ends of which, separated by 10 mm, can be sealed by circular coverslips of 15 mm diameter that form observation windows through which cells attached to the lower or upper coverslip can be observed using an inverted or upright microscope, respectively. Prepare the flow chamber for adhesion of the coverslips by covering the edges that will support them with silicon paste.

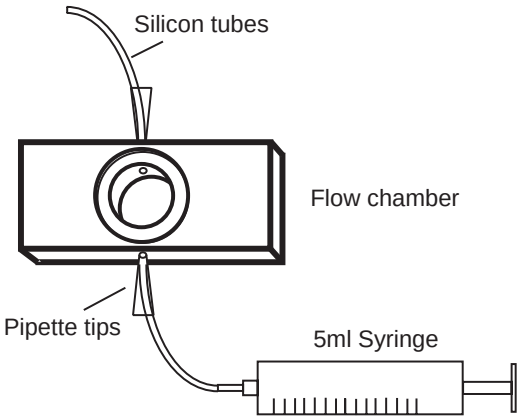

FIGURE 3 Design of a simple flow chamber. The core made of aluminium has the size of a standard microscopy slide except that it is slightly thicker. However, multiple sizes are available to suit the experimental requirements.

2. Clean two coverslips in 70% ethanol containing a drop or two of glacial acetic acid/ml as described previously. Rinse slides with water and dry with a Kimwipe.

3. Coat one coverslip with lectin as described earlier and place it on the silicon paste to form a window on the lower surface of the flow chamber, with the lectin-coated side facing inward.

4. Apply the cell suspension to the lectin-coated surface of the coverslip, let cells settle for 5 min, remove the medium, and wash once with fresh medium.

5. Immediately proceed to close the chamber by applying the second clean coverslip to form the upper window and flow in the required medium to fill the chamber and prevent the cells from drying out.

6. Exchange the medium as desired during image acquisition using the attached syringe.

B. Imaging Procedure

Several requirements have to be carefully considered to optimally resolve a dynamic process of interest in space and time. Above all, the total amount of light required for imaging should be kept to a minimum because the strong illumination needed for fluorescence microscopy observation will invariably affect the living sample, particularly if of a wavelength below 500 nm. The microscope setup should therefore be optimised to collect as much of the fluorescence signal as possible. Use high NA objectives and match

the refractive indices of the sample and the objective. Also the selected camera type is important. The more sensitive it is, the less excitation light is required for a viable signal. What should also be considered in the choice of camera is that for imaging very fast events, its readout time can become a limiting factor.

After optimizing the microscope setup, the first challenge is to set the imaging parameters such that your structure of interest can be unambiguously detected with sufficient contrast for the duration of the experiment, during which the signal intensity will decrease over time due to photobleaching. The observation intervals and the total experiment duration will therefore influence the initial image acquisition settings. Setting up such *in vivo* experiments thus means finding an optimal compromise between these variables.

Four relevant imaging parameters can be manipulated on an SDCM. (1) The excitation intensity defines the amount of photons that reach the sample and excite the fluorophores. (2) The exposure time defines the amount of emission light being collected by the CCD camera prior to each image readout. (3) The degree of CCD binning defines how many photons are sampled into a single image point (pixel), and also the spatial resolution. (4) Finally, the camera gain setting defines the overall sensitivity of the camera. How changing these parameters affects the image acquisition is shown in Fig. 4A. Figure 4B illustrates the interdependence of the parameters for three-dimensional (*x*, *y*, and *time*) temporal imaging experiments. For example, if the amount of excitation light (*n* photons) to be used for the complete duration of the experiment is defined, an increase in the number of time points has to be compensated for by decreasing the amount of excitation per image, either by shortening each exposure time or by reducing the excitation intensity. This will be perceived as a lower signal (compare a and b). If the signal level cannot be reduced, an increase in the number of time points for an experiment will be brought about by an increase in total irradiation (compare a and c), with concomitant increases in photobleaching (not shown in Fig 4B) and phototoxicity. An alternative possibility, which is not demonstrable in the illustration, is to increase CCD binning, which allows one to keep the irradiation dose low, but results in a loss of spatial resolution and thus of structural information.

The considerations we have discussed can be easily extended to four-dimensional (*x*, *y*, *z*, and *time*) temporal imaging, which is one of the strong points of SDCM. To collect a *z* stack of confocal *x*, *y* images spanning the relevant *z*-axis range of an object at each of several time points, three simple points have to be considered. (1) The range along the *z* axis should be set according to the thickness and expected movement of

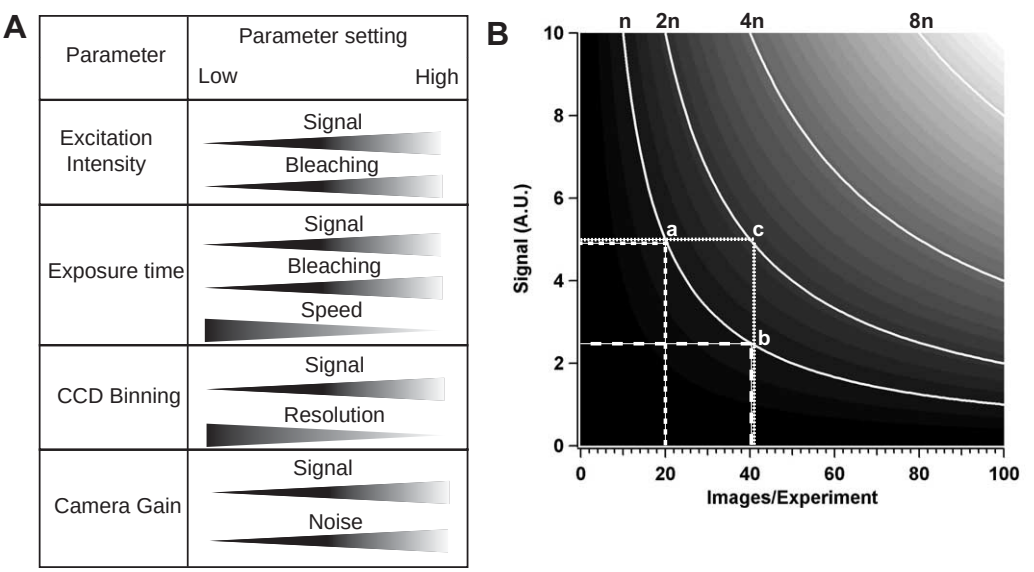

FIGURE 4 (A) Variables that can be changed on an SDCM and effects of the respective changes on other parameters that are relevant for live imaging. (B) The diagram shows interdependence among the number of frames taken in an experiment (*X* axis), the signal intensity per image (a function of exposure time and excitation intensity; *Y* axis), and the number of photons exciting the sample (*n* curves). A.U., arbitrary units of signal intensity.

the structures of interest. (2) It should not cover non-relevant regions. (3) The number of optical sections should be set according to the required z axis resolution and, to avoid unnecessary oversampling, should not be set smaller than half the z axis resolution of the confocal microscope itself. It is possible that ones initial ideal image acquisition settings have to be adjusted if the number of exposures required for the complete time series would otherwise result in unacceptable levels of photobleaching.

Steps for Setting up a SDCM in Vivo Experiment

1. Plan all general settings (time intervals, duration, camera settings) for the experiment using existing comparable images and sequences before putting the sample on the microscope. This minimises setup and fine-tuning time.
2. Use as little light as possible for finding the sample! Find the focal plane and, if possible, also your object of interest using phase contrast or DIC. This reduces unnecessary photobleaching prior to imaging. If you need to see the fluorescence to identify your object, first reduce the fluorescence excitation as much as possible.
3. Optimise the settings for image acquisition on the chosen object as discussed earlier and illustrated in Fig. 4A.
4. Once you find the optimal conditions, choose a new object. Set upper and lower z limits. With sufficient preexisting knowledge of the sample (e.g., the diameter of fission yeast cells is around 4 µm), upper and lower z limits can be set by focusing on the middle of the sample and setting the z limits around it without further imaging (e.g.) ±2.2 µm for fission yeast cells).
5. Always store all the raw image data before further processing the images.

C. Multicolor Imaging

SDCMs allow multicolor imaging from multiple fluorochromes. This is usually done by sequentially acquiring the appropriate fluorescence channel images. The switching between different detection settings can be done with filter wheels or (just for the excitation) with acousto-optical tunable filters. AOTFs are provided by the manufacturers of some of the new spinning disc setups (Perkin Elmer, VisiTec/Solamere). Sequential "multichannel" image acquisition at multiple wavelengths involves a significant reduction in the frame rate (at least by a factor of two) because at least two wavelength-specific images have to be acquired for every time point. This can be a limitation when observing very fast processes. Furthermore, fast structures might move during the time intervals between acquisition of the different wavelength images, leading to spatial mismatches between the different image channels. If this is the case, an alternative parallel acquisition approach, where the image channels are detected simultaneously, has to be implemented. For this, the emitted fluorescence is split into longer and shorter wavelength components by an appropriate dichroic beam splitter and is projected either onto separate CCD cameras or onto different regions of the same CCD chip. The recent introduction of sensitive color CCD cameras (such as the Orca 3CCD camera by Hamamatsu Photonics) increases the potential for fast multichannel imaging (T. Nagai, personal communication).

IV. COMMENTS

In imaging, as in all experiments, the tools should match the task. It is therefore important to understand the specific properties and advantages of the available imaging approaches. The following discussions highlight the abilities and shortcomings of SDCM versus single beam confocal and wide-field microscopes.

A. SDCM versus Single Beam Scanning Confocal Microscopy (see Table I)

1. Sensitivity

An essential point to be taken into consideration is the sensitivity of the detection devices. These are CCD cameras for SDCMs and PMTs for single beam confocal microscopes. CCD cameras have higher intrinsic quantum efficiencies than PMTs and therefore collect the available emission photons more efficiently, resulting in increased sensitivity (Inoué and Inoué, 2002). In practice, this significantly reduces the required exposure times in SDCM experiments, permitting higher frame rates and accordingly a speed advantage for equivalent signals when compared to single beam systems. This makes SDCM more suitable for imaging fast phenomena, although both types of confocal microscope are equally suited for time-lapse applications, where observations may be extended over several hours, with significant pauses between the acquisition of each 2D (x, y) image or each 3D (x, y, z) image stack.

2. Imaging Speed

SDCMs are particularly well suited for fast 3D (x, y, and *time*) and 4D (x, y, z, and *time*) temporal imaging. This is due to the almost instantaneous image generation by the spinning disc and the very sensitive CCD

TABLE I Comparison of Single and Multibeam Confocal Microscopes for *in Vivo* Imaging

	Single beam scanning confocal microscope	Multibeam scanning confocal microscope
Speed and temporal resolution	Frame rate limited to ~1 Hz at maximal spatial resolution +	High frame rate +++
Detection sensitivity	Photomultiplier tube +	CCD camera ++
Avoidance of photobleaching for equal image signals	More excitation required +	Less excitation required ++
Multichannel imaging	Simultaneous detection ++	Sequential detection usual +
Region bleaching or photoactivation	Possible ++	Not possible without additional hardware –
Optical sectioning efficiency (*z* resolution)	Adjustable pinhole diameter, giving optimal exclusion of out-of-focus blur ++	Fixed pinhole diameter, allowing possible contribution of unwanted out-of-focus blur +

cameras that can be used. The frame acquisition rate is determined by the exposure time required by the CCD camera. With sensitive cameras this can be lowered considerably. In this way, the high frame rates required for resolving fast events can be achieved. Generally, an image of equal quality and resolution can be generated significantly faster on an SDCM than on a single beam scanning confocal microscope. The speed disadvantage of single beam systems can, however, be partially overcome by scanning only a small subregion of the total image field. Furthermore, if only a single line is read out [e.g., acquisition of a 2D (*x* and *time*) image, suitable for certain types of Ca^{2+} imaging], the scan rate of a single beam confocal microscope can significantly exceed the frame rate of an SDCM.

3. *Photobleaching and Phototoxicity*

An observation made by many researchers working with both single beam and multibeam confocal systems is that photobleaching seems to be reduced in multibeam systems, permitting the same kind of sample to be observed over a longer period of time. However, it has been shown that the absolute rate of bleaching in SDCMs is similar to that using other confocal microscopes (Inoué and Inoué, 2002). The difference seems to be mainly due to the increased sensitivity of detection, which allows less excitation light to be used in SDCM.

4. *Optical Sectioning*

Adjusting the diameter of the detection pinhole varies the thickness of an optical section in a single beam confocal microscope, and hence *z* resolution. This is not possible with an SDCM. Here, the pinhole diameter is fixed because the holes in the disc cannot be modified. The numerical aperture of the objective employed therefore defines the thickness of the optical section. With high NA objectives (>1.3), this is in the range of <1 µm at 488 nm excitation. Furthermore, when imaging within thick specimens, out-of-focus fluorescence from an excitation minibeam can reach into neighbouring pinholes, which will compromise confocality (Inoué and Inoué, 2002). For such specimens, the optical sectioning will therefore be better if a single beam confocal microscope is used. For dynamic *in vivo* applications, however, these sectioning considerations are usually outweighed by the superior acquisition performance of multibeam systems.

B. SDCM versus Wide-Field Microscopy

Almost all of the mentioned positive features of SDCM (speed, sensitivity) also apply to wide-field microscope setups, which in principle are even faster due to the fact that the entire field of view is illuminated simultaneously. In addition, wide-field systems collect more of the emission light than SDCMs (since no emitted light is rejected by the disc of confocal pinholes), which is important for extremely weak fluorescence signals. However, due to the lack of confocality, deconvolution has to be applied to images generated on wide-field systems in order to gain a reasonable 3D resolution. Deconvolution is time-consuming and is

not trivial, as it critically depends on optimised system setups and image acquisition parameters in order to avoid the creation of artefacts, as well as requiring careful measurement of the point spread function of the microscope.

Furthermore, a z stack of wide-field images has to be acquired to enable deconvolution to be applied, and motion artefacts can be created in such a z stack when imaging fast processes. This is not the case for SDCM, as a single unprocessed image already constitutes a reasonably blur-free optical section. This means that SDCM has a significant speed and sample illumination advantage over a conventional wide-field microscope for fast temporal imaging of a single focal plane.

It should be noted that deconvolution can also be applied to z stacks acquired by SDCM, which can further increase the z resolution.

V. PITFALLS

Although most SDCMs use laser light for excitation, the laser cannot be used for spot or region bleaching as in single beam confocal microscopes. Powerful applications such as fluorescence recovery after photobleaching, photoconversion, or photoactivation, which are used to analyze protein dynamics in living cells, are therefore not possible. However, regional bleaching could, in principle, be made possible by implementing an additional positionable laser.

CHAPTER

8

Confocal Microscopy of *Drosophila* Embryos

Maithreyi Narasimha and Nicholas H. Brown

I. INTRODUCTION

The genetically tractable organism *Drosophila melanogaster* is proving to be an excellent model system for cell biological analysis in the context of the whole organism. The relative ease with which embryos can be obtained in large numbers and processed for high-resolution light microscopy has facilitated many recent advances at the interface between cell and developmental biology. Fine subcellular structures previously impossible to visualise by conventional fluorescence microscopy, on account of high noise resulting from out-of-focus signals, are revealed with clarity on a confocal microscope.

There are several reasons why scientists who have not used *Drosophila* before may wish to use Drosophila embryos for the analysis of protein localisation and expression. The embryo contains representatives of each cell type and is small enough ($500 \times 100\,\mu m$) to fit within the field of view of a 20X objective lens. The embryos are nearly transparent, permitting visualisation of all cells in whole mount preparations. These features allow one to assay the tissue distribution of a particular protein in a single specimen. The tissues have a relatively simple structure, with the epithelia being made up of a single layer of cells. In general, there are fewer copies of each protein encoded by the genome compared with vertebrates, e.g., one α-actinin rather than four, further simplifying the analysis of the distribution of a particular kind of protein. Injection of double-stranded RNA can be an effective way to knock down protein expression, provided the bulk of the protein in the embryo comes from new synthesis. Sophisticated manipulation of the proteins is possible using the powerful molecular genetic techniques available in this organism.

While *Drosophila* has many advantages for cell biological analysis, it also has some drawbacks. The cells are small: an embryonic epidermal cell, for example, has dimensions of only $2 \times 5\,\mu m$ compared to a vertebrate epidermal cell of $10 \times 20\,\mu m$, which can make it difficult to resolve different intracellular compartments. The embryo is the only stage where the whole animal can be stained in its entirety; at late stages of development, antibody penetration is blocked by the secreted exoskeleton [although the use of proteins tagged with green fluorescent protein (GFP) circumvents this problem]. Therefore, the most easily generated samples for analysis are the embryo or tissues, that are easily dissected from the larva or adult, such as the imaginal discs and ovaries. Only a small number of *Drosophila* cell lines are available for *in vitro* culture and experimentation. These represent just a few cell types and are also small. Finally, antibodies raised against vertebrate proteins rarely bind to *Drosophila* orthologues, even when they are highly conserved. Therefore, new antibodies need to be raised to see the distribution of a given protein in *Drosophila*. An important exception to this are antibodies raised to specific motifs of proteins, such as those recognising particular phosphorylated residues. A growing number of antibodies against *Drosophila* proteins are available, either from the Developmental Studies Hybridoma Bank or directly from the laboratory that has generated them; few are available commercially.

This article describes the techniques used to look at cell junctions and cytoskeletal structures in the developing embryo, using both antibodies against

Drosophila proteins and GFP-tagged proteins expressed from transgenes.

The embryo is surrounded by two proteinaceous layers: the egg shell or chorion, which is removed easily; and the vitelline membrane, which is impermeable and more difficult to remove. The vitelline membrane can be permeabilised by treatment with heptane, permitting fixatives to reach the embryo. The vitelline membrane is generally removed by "popping" the embryos with a rapid osmotic shock produced by adding methanol to create a heptane–methanol interface and shaking vigorously. The fixation/devitellinisation steps are the part of the procedure most likely to go wrong, but with practice become routine. Once the embryos are fixed and the vitelline membrane removed, antibody staining is straightforward. Simple mounting of embryos is sufficient in most cases, which, due to the elongated shape of the embryo, allows many optical section views except a cross section of the embryo (i.e., cutting a slice from the middle of loaf of bread). As this can be very informative, we also describe a more labour-intensive method that allows such a view. We also make some recommendations for getting the best confocal images of *Drosophila* embryos. Additional references describing these methods are found in Davis (1999), Hazelrigg (2000), and Rothwell (2000).

II. INSTRUMENTATION AND MATERIALS

A. Equipment

Fly bottles or vials (250-ml bottles and 30/40 ml vials, Scientific Lab Supplies)
Egg collection cages (see Fig. 1, I)
Apple juice agar plates (see solutions)
Embryo collection baskets (see Fig. 1, I)
Scintillation vials (4 ml, 908-054, Jencons; 20 ml, 215/0079/00, BDH)
Rollers (Denley Spiramix 5 or equivalent)
Rotary shakers (Labinco BV or equivalent)
Microscope glass slides 76 × 26 mm (Menzel Glaeser, Superfrost Color)
Coverslips 22 × 22 mm, 22 × 40 mm (Menzel Glaeser)
Forceps (Watkins and Doncaster)
A001 size dissecting tungsten needles (E6871, Watkins and Doncaster)
Needle holder (Watkins and Doncaster)
$26G^{3/8}$, 0.45 × 10 syringe needle (Industrial and Scientific)
Artist's paintbrushes 00, 000

B. Reagents

Bleach (commercial)
Heptane (27051-2, Sigma)
Methanol (M/4000/PC17, Fischer Chemicals)
Ethanol (E/0555DF/17, Fischer Chemicals)
Formaldehyde (37–40%, 101134-A, AnalaR /BDH, reagent grade)
Paraformaldehyde (40% EM grade, 15715, Electron-microscopy Sciences)
Triton X-100 (T-9284, Sigma)
Bovine serum albumin (BSA) fraction IV (A-2153, Sigma)
NaCl (102415K, AnalaR/BDH)
KCl (101984L, AnalaR/BDH)
NaH_2PO_4 (301324Q, AnalaR/BDH)
Na_2HPO_4 (S-9390, Sigma)
KH_2PO_4 (102034B, AnalaR/BDH)
$MgCl_2$ (63064 Fluka Biochemika)
EGTA (E-4378, Sigma)
PIPES (P-8203, Sigma)
SDS (Ultrapure, Melford Labs Ltd.)
Glycerol (101184K, AnalaR/BDH)
Sucrose (S-0389, Sigma)
Apple juice (commercial)
Bactoagar (0140-01, Difco laboratories)
Nipagin (Nipa Laboratories Inc.)
Baker's yeast blocks (Commercial)
Vectashield (H-1000,Vector Labs, Burlingame)
Voltalef H10S Halocarbon oil (Elf Atochem, France)
Fly food (Instant *Drosophila* medium, Phillip Harris Scientific)

C. Solutions

1. *10× phosphate-buffered saline (PBS) (1 litre) (adapted from Sambrook and Russell, 2001):* 80 g (137 m*M* final) NaCl, 2 g (2.7 m*M* final) KCl, 14.4 g (10 m*M* final) Na_2HPO_4, 2.4 g (2 m*M* final) KH_2PO_4, and distilled water up to 1 litre. Dissolve all components in 800 ml of H_2O and make volume up to 1 litre. Adjust pH to 7.4 with HCl/NaOH. Sterilise by autoclaving.

2. *PBT (500 ml) PBS with 0.3% Triton X-100:* 50 ml 10× PBS, 750 µl Triton X-100 (0.3% v/v), 0.1 g (optional) sodium azide, and distilled water to 500 ml

3. *PBTB (500 ml) PBS with 0.3% Triton X-100 and 0.5% BSA:* 50 ml 10× PBS, 2.5 g BSA (0.5% w/v), 750 µl Triton X-100 (0.3% v/v), 0.1 g (optional) sodium azide, and distilled water to 500 ml.

4. PB: 77.4 ml (100 m*M* final) Na_2HPO_4 (1 *M*) and 22.6 ml (100 m*M* final) NaH_2PO_4 (1 *M*). Dissolve in distilled water to 1000 ml. Adjust pH to 7.4.

5. *PEM (4 ml) (adapted from Ashburner, 1989)*: 400 µl (100 m*M* final) 1 *M* PIPES (pH 6.9), 4 µl (1 m*M* final)

1 *M* $MgCl_2$, and 20 µl (1 m*M* final) 200 m*M* EGTA (pH 8.0). Adjust to pH 6.9 with 10 *M* KOH to final volume of 4 ml.

6. *4% formaldehyde in PBS (100 ml)*: 10 ml 10× PBS, 10.8 ml 37% formaldehyde, and 79.2 ml distilled water.

7. *Apple juice agar plates (1.6 litre)*: 36 g Bactoagar and 1200 ml distilled water. Dissolve the agar in a microwave oven or on a heating pad until the solution is clear. Dissolve 40 g sucrose in 400 ml apple juice in a microwave oven or on a heating pad until the solution is clear. Mix the two solutions once clear on a stirrer. Add 20 ml of 20% Nipagin when the solution has cooled below 60°C. Stir again and pour while still liquid into 5-cm/9-cm petri dishes. When set, store at 4°C. Allow to reach room temperature before use.

III. PROCEDURES

A. Producing Embryos for Confocal Microscopy

Steps

1. Grow up flies. If you are not a fly laboratory, try to obtain a few bottles from a fly colleague. Alternatively, make simple bottles with instant fly food, topped with cotton or a foam plug. Try to get the density of flies such that they are neither under- nor overcrowded. For 250-ml bottles, 20 females and 10 males will lay the ideal number of eggs per bottle in a 24-h period, after an initial lag of a couple of days while they feed and mate. Such a bottle will produce about 500 flies after 10 days at 25°C, depending on the food and the fly strain. Ideally, collect adult flies within 1–2 days after eclosion from the pupal case. For the egg collection cages described later, 25–200 females and about half the number of males is a good number.

2. Set up an egg collection cage containing an apple juice agar plate at the bottom, fixed on with tape, and a ventilation screen at the top (Fig. 1, IA). The plate should have an approximately 50 µl dab of yeast paste in the centre. Make yeast paste by stirring in a bit of water into the baker's yeast to make it the consistency of toothpaste. This is the food for the flies and is essential for the females to lay large numbers of eggs. Ensure that there is no excess moisture in the cage or plate (usually resulting from condensation on the plate). Put the flies into the cage and incubate at the desired temperature (usually 25°C). It will take a couple of days before the females lay substantial numbers of eggs, but once they get going each female can lay 100 eggs a day. Replace the yeasted apple juice plates at least once a day. To do this, invert the cage and peel back the tape holding the plate. Gently tap the flies down on the bench and quickly swap the plate. Even for the most practiced of us, this usually results in a few flies gaining freedom.

3. Collect embryos for analysis. Place a new yeasted apple juice plate on the cage. After the appropriate time period (e.g., 4 hs), remove the plate from the cage, replacing with a fresh one, and age the plate containing the embryos at 25°C for the desired length of time. Such short collections are an advantage when one is interested in a particular developmental event (for staging, see Wieschaus and Nuesslein-Volhard, 1998; Campos-Ortega and Hartenstein, 1997), and for the novice who has not yet learned how to stage embryos by visual examination. Embryogenesis lasts 22 h at 25°C, but the exoskeleton becomes secreted at about 16 h, making embryos older than this inaccessible to antibody staining using standard methods. Development takes twice as long at 18°C, allowing some adjustment to more convenient hours. The embryo plates can also be stored at 4°C for up to 24 h, but this has been known to cause subtle phenotypes. Overnight collections allow the examination of all stages of embryogenesis, but the distribution of embryos at the different stages is rarely even.

B. Removal of Chorion (Dechorionation)

In this step, the embryos are collected from the plate, washed well to remove yeast and other detritus from the plate and the eggshell (chorion) removed. You should prepare vials ready for the fixation step (**C**1) before starting this step.

Steps

1. Add about 2 ml water to each plate and, with the aid of a paintbrush, gently release the embryos from the agar (the eggs are usually partially pushed into the agar when they are laid).

2. Rinse/pour embryos into a meshed basket, made as shown in Fig. 1, IB.

3. Place the basket in a dish (the lids from the apple juice plates are useful for this) containing 50% bleach (1:1, water:commercial bleach). It should be made fresh and can be used for a maximum of 2 days. If older, the bleach still removes the chorion, but affects devitellinisation adversely. Swirl the basket in the dish and add more bleach into the basket. After 2–5 mins, most embryos will have risen to the surface, indicative of successful dechorionation. Do not extend the period in bleach beyond 5 min; prolonged exposure can destroy tissue architecture.

4. Wash the embryos thoroughly while in the basket by swirling embryos under running tap water or water from a squirt bottle.

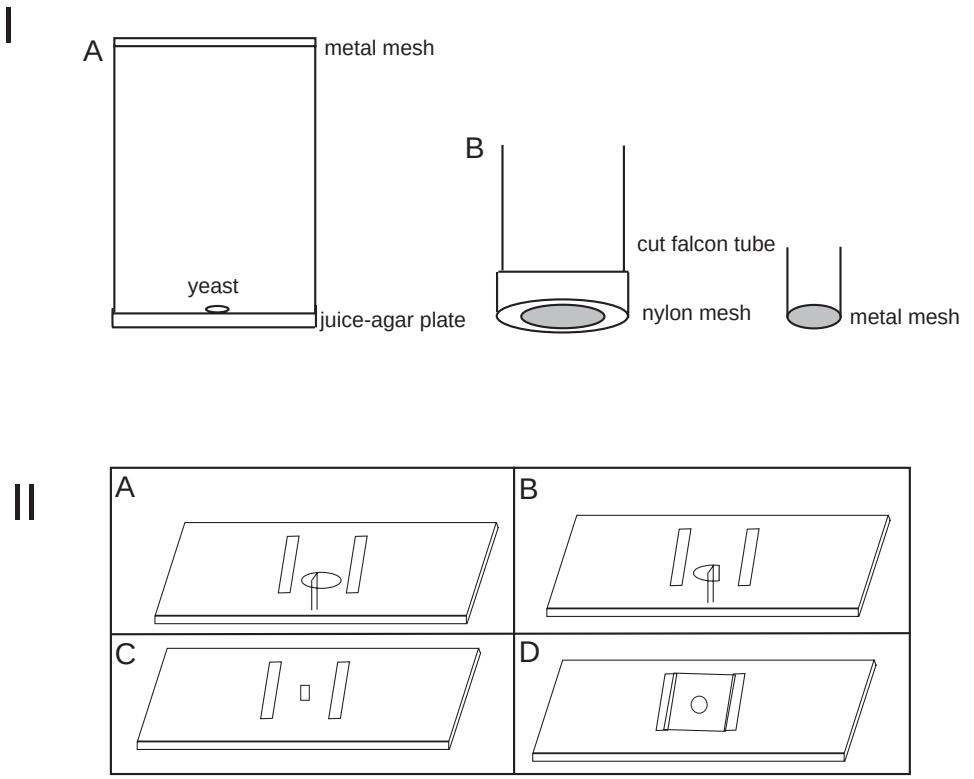

FIGURE 1 Schematic showing the parts that make up an egg-laying cage (IA). Apple juice agar is poured and allowed to set in petri plates. A dab of yeast is placed on warmed plates that are placed on top of cages containing flies. The plate is strapped onto the cage and the contraption is placed inverted in an incubator. The parts that make up an egg collection basket are shown in IB. A nylon mesh/sieve is screwed onto a cut 50-ml Falcon tube by the cap in which a hole has been cut using a hot scalpel blade. A 15-ml cut Falcon tube can also be used to make smaller baskets using metal wire mesh that is cut into rounds of the appropriate diameter and fastened onto the tube by melting the end of the tube with a hot scalpel blade. (II) Schematic showing how sections are cut. See text for details.

5. Briefly dry embryos by placing them on a paper towel. Do not overdry.

C. Standard Fixation and Removal of Vitelline Membrane (Devitellinisation)

Steps

1. Label a scintillation vial for each different sample of embryos (stage or genotype) and add 0.8 ml of 4% formaldehyde in PBS.

2. Transfer the basket of embryos into a dish containing heptane. Using a Pasteur pipette, transfer the embryos with the heptane into the scintillation vial containing 4% formaldehyde in PBS. The amount of heptane should be equal to or greater than the volume of fixative solution. Mix for 20–30 mins at room temperature or at 37°C on a roller or other device.

3. Remove the aqueous phase from the bottom with a Pasteur pipette and then remove the heptane. Add 1 ml of new heptane and then rapidly add 1–3 ml of methanol and shake by vigorous inverting/vortexing for 1 min. (If you want to stain the embryos with phalloidin, use 80–90% ethanol rather than methanol at this and the next two steps; this has the disadvantage that reduced number of embryos are successfully devitellinised.)

4. Let the embryos settle for about 10 s and then transfer the embryos from the bottom of the vial to an Eppendorf tube with a Pasteur pipette. Any embryos still at the interface between the heptane and the methanol have not popped out of the vitelline membrane and therefore will not stain well and should be left behind. An alternative method for this step is remove all of the liquid phase, including embryos that have not settled, leaving only the devitellinised embryos at the bottom of the vial. Add 1–2 ml of methanol to the embryos and vortex/shake for 30 s. Remove methanol.

5. Wash in methanol three times. For each wash, squirt in 1 ml of methanol so that the embryos disperse. Let the embryos settle by gravity and remove the methanol (this is called a gravity wash). Either proceed to the next step or add 1 ml methanol and store at –20°C (for embryos that will be stained with phalloidin store in 100% ethanol).

Comments

Embryos can be stored in methanol or ethanol at –20°C for several months and will continue to be successfully stained by most antibodies. However, detection of some antigens and GFP fluorescence are affected adversely by exposure to ethanol or methanol. In these cases, do steps 3–5 as rapidly as possible and proceed quickly to step **D**1. Some antibodies will not recognise their antigen in embryos fixed by this method, but will when one of the alternative methods described in Section III,**G** is used.

D. Antibody Staining of Embryos

Steps

1. Wash embryos in PBT (PBS with 0.3% Triton X-100): First give three to five quick washes, where 1 ml is squirted in so the embryos are dispersed, the embryos are allowed to settle by gravity, and then the PBT is removed (a gravity wash) and then give one longer wash (15 mins) with mixing. We use a device that gently inverts the tubes for this and all subsequent steps, but a variety of mixing devices should work. If mixing is not sufficient, it will result in variable staining of embryos in the tube.

2. (Optional) Staining with some antibodies is improved by a 15-min incubation in 0.1% SDS with mixing, followed by three washes in PBT. This may help those antibodies raised against bands from SDS gels.

3. Block nonspecific binding sites on the embryos by incubating in PBTB for 30 min. Transfer 15 µl (5–20 µl) of embryos to a 0.5-ml Eppendorf tube for each staining with a Pipetteman and a yellow tip with the last couple of millimeter of the end cut off with a razor blade. Rinse the tip with some PBT before taking up the embryos. While the volume of embryos is not critical, larger volumes can result in uneven staining. The volume of 15 µl of embryos corresponds to about 100 embryos, which is sufficient for most purposes. If more embryos are desired, use multiple tubes or a larger tube for staining.

4. Incubate embryos with 250–500 µl of PBTB containing an appropriate dilution of each primary antibody at 4°C overnight. Optimal timing depends on the antibody and whether staining of internal tissues is important, in which case longer incubations are recommended. We have successfully used a range from 2 h at room temperature to 2 days at 4°C. If the appropriate dilution is not known, a good starting point is 1 : 1000 for antisera and 1 : 10 for monoclonal antibody supernatants.

5. Wash off the primary antibody with PBT with three to five gravity washes and one to three longer (at least 15 min) washes.

6. Incubate with fluorochrome-conjugated secondary antibodies diluted in PBTB as suggested by the manufacturer (usually 1 : 100–300) at room temperature for 2 h or overnight at 4°C. The choice of fluorochrome coupled will depend on the laser lines of the confocal you are using. Our preferred ones are Alexa488, Alexa568 or Cy3, and Cy5. We tend to keep the embryos in the dark during the incubation.

7. Wash secondary antibodies off with three to five gravity washes and three longer (5–30 min each) washes in PBT. Washing overnight is also fine. The embryos can be left for a day or two in PBT at 4°C, but it is better to store them after step **F**1 or once mounted on microscope slides.

E. Staining with Phalloidin to Visualise Actin

Steps

1. Embryos that have been exposed to methanol will not stain with phalloidin, so use 90% ethanol rather than methanol during devitellinisation.

2. Dissolve rhodamine-conjugated phalloidin in methanol (methanol harms the actin, not the phalloidin) and store at –20°C in aliquots of 6 units. To stain embryos, vacuum dessicate the required number of aliquots and resuspend in PBTB at 1 unit/100 µl.

3. Follow sections **D**1 and **D**2. (If phalloidin staining is to be combined with antibody staining, proceed through sections **D**3 to **D**5 and then go to **E**4. Phalloidin can be combined with the secondary antibodies at **D**6, at the concentration described later.

4. Incubate embryos with 1 unit of phalloidin (100 µl of the aforementioned solution, plus 400 µl PBT or PBTB)/0.5 ml tube containing approximately 20 µl of embryos for at least 30 min.

5. Wash twice with PBT (if combined with secondary antibodies, wash more thoroughly).

F. Standard Mounting on a Microscope Slide

Steps

1. After the final wash, replace PBT with 50–200 µl of Vectashield or similar glycerol-based mounting

medium containing antibleaching agents. The embryos can be stored at 4°C for a couple of days or, for longer periods, allow 30 min to equilibrate in the Vectashield and store at –20°C.

2. Using a Pipetteman and a yellow tip with the end cut off, transfer some of the embryos onto a slide. First suck up approximately 5 µl of Vectashield alone and then the embryos, as this reduces sticking of the embryos to the inside of the yellow tip. For a 22 × 22-mm coverslip, use 20–30 µl per slide. The lower volume will lead to a mild flattening of the embryos, which can be an advantage, but is trickier to mount without air bubbles. As you add the embryos to the slide, move the tip to spread them out over a square region a bit smaller than the coverslip. Using a needle or similar instrument (such as plastic Pipetteman tip with a very small diameter), gently distribute the embryos more evenly and separate them from each other. (Do not fiddle too long with this, as they will generally distribute into a monolayer when the coverslip is placed on top, but this step helps reduce or eliminate the number of embryos lying on top of each other.) The goals of the experiment will dictate the optimal number of embryos per slide. For staged embryos, it is better to have fewer embryos, less than 30 per slide. You can then in a single session on the confocal completely examine all embryos on the slide and start a new session with a new slide. This is helpful because it is easier to find the best embryos at low power and then add oil for the image collection. If you have embryos from an overnight collection, a larger number of embryos improves the chance of finding each stage on a given slide. With a forceps, gently place a coverslip over the embryos, starting at one end to avoid introducing air bubbles and gently let go of the forceps as the Vectashield spreads. If a small volume has been used to flatten the embryos, let sit for 10 min and then if there is still air under the coverslip, add a little more Vectashield to an edge.

3. (Optional) Seal the edges with nail varnish (but see Section III,G,5).

General Comments

Almost every aspect of this procedure will vary from fly laboratory to fly laboratory and even within our laboratory there are a number of variations. None of the following are critical: which recipe is used for the egg collection plates (some laboratories prefer grape juice), the tubes used for fixation and staining, the solutions used for antibody staining, the timing of the incubations and the number of washes, and the medium for mounting the embryos. As mentioned at the beginning, the key steps are fixation and devitellinisation. Again there are many variants of this, and the important thing is to get a method that works well for the antibodies you are using. Once you have a method that works, try to do this step as identically as possible each time. This will give you reproducibly good staining. Generally, the first time a new person in the laboratory does this technique it does not work well. However, after a few times, it is hard to understand how you could have failed the first time. A simple check is to look at a few embryos at step **C**4 or **D**1 down a dissecting microscope. If the embryos are still surrounded by the transparent shiny vitelline membrane, throw them away and try again. Before moving onto microscopy, we will mention some useful variants of this technique.

G. Alternative Methods for Embryo Fixation and Devitellinisation

1. Alternative Fixation Solutions

In these the method is identical to that described earlier, but instead of 1:1 4% formaldehyde in PBS:heptane, and 20–30 min at room temperature, use the following alternatives.

1:1 4% formaldehyde in PEM:heptane, 20–30 min at room temperature.
1:1 4% formaldehyde in PB:heptane, 20–30 minutes (Uemura *et al*., 1996).
1:1 37% formaldehyde:heptane, 2–5 min at 25–37°C with gentle mixing

This can improve the preservation of cytoskeletal structures present in membrane compartments [e.g., scribble, β-heavy spectrin (Bilder *et al*., 2000)] and gives the best preservation of microtubules (Foe *et al*., 2000).

2. Heat Fixation (Muller et al., 1996)

Heat fixation improves the penetration of antibodies into late stage embryos and larvae (when the exoskeleton normally blocks antibodies).

Steps

1. With a paintbrush, transfer dechorionated embryos from the dechorionation basket into a scintillation vial containing 1–2 ml of 0.4% NaCl and 0.3% Triton X-100 solution that has been heated in a boiled, but no longer boiling, water bath with its cap half screwed on.
3. Pull the vial out of the hot water bath, screw cap tightly, and shake once vigorously.
4. Uncap the vial and fill up with ice-cold 0.4% NaCl and 0.3% Triton X-100.
5. Leave on ice until cooled.

6. Pour off the solution, add heptane and methanol in equal volumes, and vortex to devitellinize.
7. Remove embryos from bottom, transfer to new tube, and wash twice with methanol.
8. Incubate in methanol for an additional hour and proceed as usual for antibody staining.

3. Fixation Conditions for Visualising Nonmuscle Myosin (Foe et al., 2000)

Steps

1. Transfer dechorionated embryos to 4 ml of fixation solution: 1 volume 40% formaldehyde (EM grade) and 3 volumes PBS.
2. Vortex for 45 s and add 4 ml heptane.
3. Shake vigorously for 25 min.
4. To devitellinise the embryos, use either 80–90% ethanol (as for phalloidin described earlier) or hand peel embryos after replacing the fixation solution with PBS many times (see Section III,J,1).

4. Methanol Fixation

Steps

1. Transfer dechorionated embryos to 1:1 heptane: (97% methanol, 3% 0.5 *M* NaEGTA, pH 8.0)
2. Shake hard for 2 min.
3. Transfer embryos from the bottom of the vial to a 1.5-ml Eppendorf tube.
4. Wash three times with methanol
5. Incubate in methanol overnight at 4°C.

This is a good alternative when a new antibody fails to stain embryos fixed under standard conditions, as a number of antibodies have been found to only work on embryos prepared by this method. Other antibodies will work with both this method and standard fixation, while some will not stain with this method.

5. Fixation Conditions for Visualising GFP

If you are planning to visualise GFP fluorescence, keep exposure of the embryos to methanol or ethanol to a minimum and do not seal the slides with clear nail varnish. Organic solvents quench GFP fluorescence or severely affect its ability to fluoresce.

H. Embryo Thick Sections (Adapted from Grosshans and Wieschaus, 2000)

To get a good cross-sectional view of the embryo by confocal microscopy it is necessary to cut sections. They give far better resolution than optical *X-Z* scans (see later and Figs. 2E and 2F). We have used a relatively crude method that does not require a microtome and is compatible with our standard methods for antibody staining. These sections are particularly useful for the visualisation of morphogenetic events that occur in the midline and in the interior of the embryo, such as invagination of the mesoderm, formation of the midgut, and dorsal closure.

Steps

1. Fix and stain the embryos according to the desired protocol. It is hard to combine this method on phalloidin-stained embryos, because the ethanol (rather than methanol) treatment results in embryos that are harder to cut and the morphology is not as well preserved.

2. Follow the antibody staining protocol described in Section III,**C**. Keep embryos in PBT after the secondary antibody has been washed off.

3. Refix the stained embryos in 4% formaldehyde in PBT for 30–60 min at 37°C.

4. Wash the embryos in PBT, do three gravity washes, and one 15-min wash with mixing.

5. Take the embryos through a glycerol series comprising of 10, 20, and 30% glycerol in PBT for 1 h each followed by 40% overnight. (This is the optimal concentration, do not go higher.)

6. On clean dusted microscope slides, make bridges with strips of coverslips cut using a diamond knife. These are stuck to the slide using clear nail varnish.

7. Place an embryo on the slide in a drop of Vectashield between the bridges (see Fig. 1, IIA).

8. To cut the embryo, use a $26G^{3/8}$ hypodermic needle fitted to a 2.5-ml syringe whose plunger has been removed. Cut at one end in one clean sweep with the bevelled edge facing away from the slice you wish to keep. Turn the embryo around with the dissecting needle. Once again, with the bevelled edge of the needle pointing away from the slice you want to keep, cut the embryo to obtain a slice of the desired region (Fig. 1, IIB). The thickness of the section must be approximately the same thickness as the bridges; that is the thickness of a coverslip, which is about one-fifth the length of the embryo. If the sections are thinner, they are hard to orient and most of the section is beyond the depth of focus of the 60× objective; if they are thicker, the morphology is distorted by the resulting squashing. With practice you can cut more than one section from the same embryo, but each should be mounted on a separate slide due to slight differences in thickness.

9. Remove the undesired embryo pieces with the dissecting needle (Fig. 1, IIC) and orient the desired slice so that it lies at the bottom of the drop of Vectashield with its anterior face up.

10. Place a 22 × 22-mm coverslip over the section and the bridges (Fig. 1, IID). Do not seal the sides to

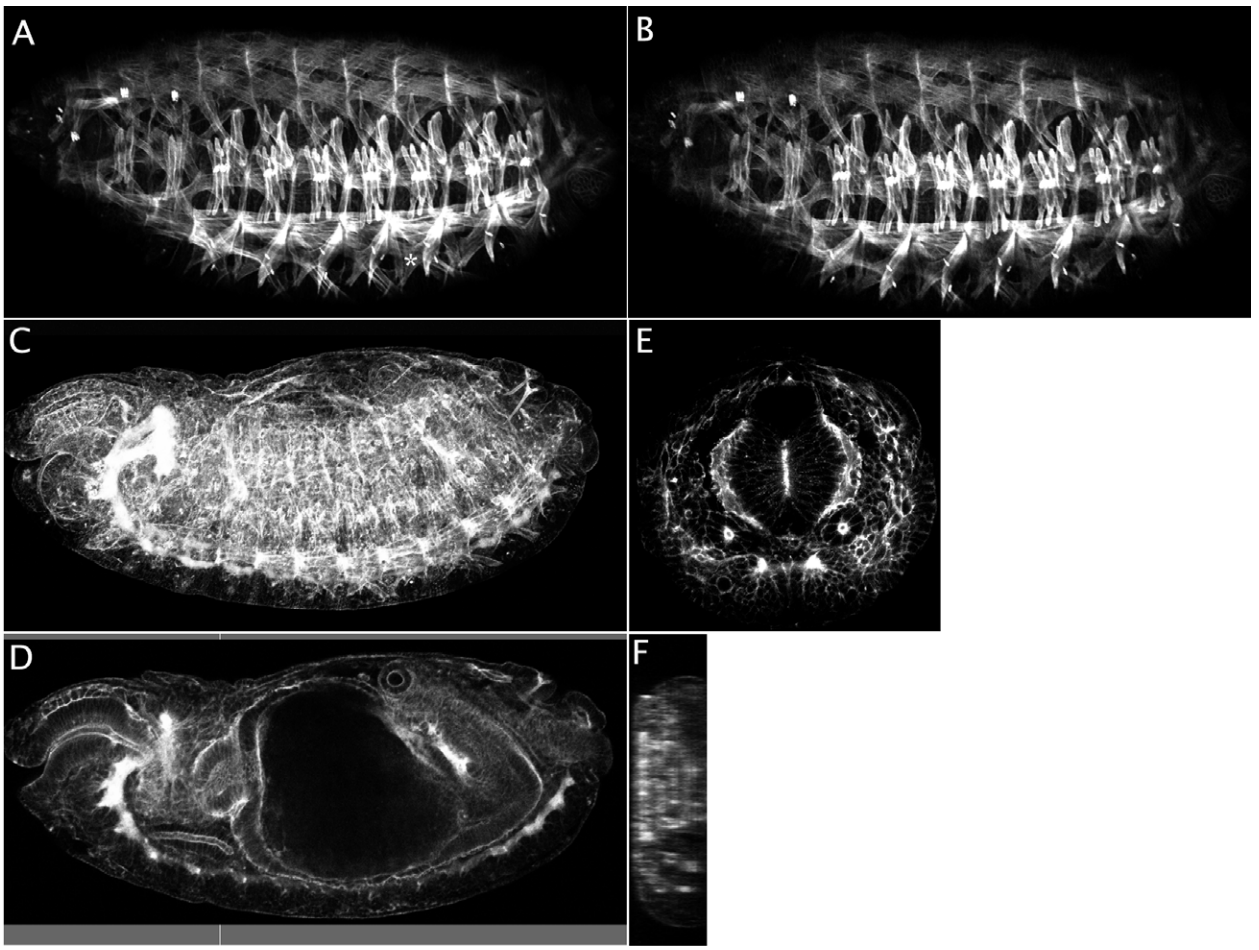

FIGURE 2 A projection of four optical sections of a late *Drosophila* embryo stained with phalloidin to highlight actin in somatic muscles (A) is compared to a single optical section (B). Note that some muscles (asterisk in A) are not visualised in the single optical section. A projection of 42 sections of a *Drosophila* embryo stained with phalloidin is used to visualise actin in the whole embryo (C). A single optical section through the same embryo (D) reveals staining in internal structures that are obscured by the extensive surface staining in C. A confocal generated *X*–*Z* section along the *Z* axis depicted by the white line in D is shown in F. Such a scan provides very poor resolution. A single optical section of a thick section cut (as described in Section III,H) to include the same region of the embryo as shown in D is shown in E. Such a section resolves the apicobasal extension of actin especially in internal organs that are obscured in whole embryos. In all images, the dorsal surface of the embryo is on top. In A–D, the anterior end of the embryo is on the left.

allow for reorientation. If the section is slightly thinner than the thickness of the coverslip, it may move/turn in the drop of Vectashield. Slight pressure on the corner of the coverslip can then bring the section back to its right orientation. If the section moves under the coverslip during imaging, abandon that section and proceed to the next.

11. View under a 60× oil immersion objective lens.

I. Confocal Microscopy

Drosophila embryos can be examined with a variety of confocal microscope setups. Both inverted and upright microscopes are appropriate. The key variable is the available laser lines; this will dictate the optimal choice of fluorochrome-conjugated secondary antibodies that one should use. A detailed description of confocal microscopy is clearly beyond the scope of this article (a good reference is Centonze and Pawley, 1995), but we hope to provide a few helpful hints.

Once one has obtained an initial quick view of the result of the staining, which is often possible by conventional fluorescence microscopy if the signal is strong, the usual goal is to produce a set of images for publication. The biggest challenge is to produce a set of comparable images of different embryos. For

example, for a general description of the distribution of a new protein one would like comparable views of embryos at different stages; generally a lateral view. There is a strong convention in the fly field regarding images of embryos: they should always have anterior to the left and dorsal up. Similarly, for a comparison of staining in different mutants, it is essential to obtain a suitable micrograph from wild type and each mutant at the same stage and with the same view: this can often require looking through many embryos. Clearly, to be able to achieve this you must be able to tell the stage of the embryo and which way is up, which is not as easy as it sounds. The only way to achieve this is to spend time looking at embryos down the microscope. To learn your way around embryonic development, it helps to examine embryos that are stained with antibodies that highlight the development of a particular tissue. The following antibodies are recommended for this: Fasciclin III (available from the Developmental Studies Hybridoma Bank) and phosphotyrosine (available from Sigma). For an overall view of the embryo, phalloidin (rhodamine conjugated, Molecular Probes) is very useful (see Fig. 2).

In general, we start our confocal session by first scanning through the slide by conventional fluorescence, taking note of the approximate position on the slide of embryos of the right stage and orientation that have stained well. Next we find a well-stained embryo that is not one of the best ones and use it to work out the appropriate settings for each channel on the confocal. When it is essential that there is minimal mixing between the outputs of each channel, then it is advisable to do sequential scanning rather than simultaneous. Use the channel with the brightest signal to get started. In most cases we use a collection area of 1024 $\times$ 768 pixels. Using rapid scanning, find the best focal plane, adjusting the focus by hand (adjustments to the eyepieces often result in the view by eye being at a different focal plane than the resultant scan). Using intermediate scan rates, set the laser power, iris, gain, and background levels appropriately for the first channel and then proceed to the next channel. We keep the iris similar in the different channels so that they all capture the same depth of focus. Some confocal setups have this feature built into the software.

Once all channels are set up, adjust the focus to obtain the optimal image. Collect images using Kalman scanning to improve the signal-to-noise ratio. We use either 166 lines per second with three to five scans or 50 lines per second and two scans. Make a note of the orientation of the embryo, especially if you are just focused on a small region.

Because the embryo is curved, in many cases a single section will not capture all of the relevant tissue. In this case, collect a series of sections at different focal planes and combine them into a single image using the projection software. The first step is to find the top and bottom of the series you wish to collect. Turn on the focus motor, doing fairly rapid scans in a channel with the most robust signal, and vary the focal plane to find the top and bottom. Be aware that with an oil objective lens, the new focal plane can take a minute to "settle." Set up the software to collect the Z series. Generally we use a step of 1 µm, with a range from 0.5 to 2.0 µm. Collect the Z series and project the image. For some tissues, e.g., the somatic muscles, it helps if the embryos are mildly flattened by mounting in a minimal amount of Vectashield, as described in Section III,**F**,2; then fewer scans are required to visualise all the muscles (Figs.2A and 2B).

One other variable to keep an eye on is the zoom. We standardly keep this at 1 (no zoom), and it is helpful to check that it has not been varied by a previous worker, as your images from session to session will not be comparable. Some judicious use of the zoom function can improve resolution. In practice we have found that a zoom factor of greater than two provides no further improvement in resolution and may even lead to loss of resolution.

J. Examination of GFP in Living Embryos

Steps

1. For imaging live embryos, briefly dry embryos over a paper towel after dechorionation. Alternatively, the embryos can be dechorionated by hand by gently rolling on double-stick 3MM Scotch tape with a forceps.
2. Transfer embryos in their vitelline membranes with a paintbrush or forceps to a drop of halocarbon oil. Cover with a coverslip and leave the slides unsealed. For time-lapse analysis it is essential to use a method that allows better access of air to the embryo. We use a microscope slide consisting of an air-permeable Teflon membrane in a holder (Edwards *et al.*, 1997; Kiehart *et al.*, 1994).

IV. COMMON PROBLEMS

A. Nonstaining Embryos

The most common causes are (i) use of inappropriate fixation method, (ii) inefficient devitellinisation, (iii) inappropriate primary and/or secondary antibody, and (iv) faulty laser, either nonfunctioning or unsuitable for the fluorochrome coupled to the secondary antibody.

B. Bleaching

This is a common problem inherent to confocal microscopy, especially during the acquisition of a Z series at high laser power and high magnification. It can be reduced by ensuring that the laser power is set to the minimum value that is optimal for the image.

C. Low-Resolution Images

Low-Resolution Images can result from faulty image processing of the original image. Obtain the highest resolution image possible on the confocal. Information that does not exist in the acquired data cannot be added by image processing software. Too high a gain can result in too much noise. Such noisy images may be improved by increasing either the iris or the laser power. Out of focus signals resulting from inappropriate mounting and from inappropriate thickness of sections are the cause of low-resolution images from sections.

Ultraviolet Laser Microbeam for Dissection of *Drosophila* Embryos

Daniel P. Kiehart, Yoichiro Tokutake, Ming-Shien Chang, M. Shane Hutson, John Wiemann, Xomalin G. Peralta, Yusuke Toyama, Adrienne R. Wells, Alice Rodriguez, and Glenn S. Edwards

I. INTRODUCTION

Laser microbeams provide a unique opportunity to augment traditional genetic and cell biological analysis of biological phenomena with surgical studies that selectively damage cells, allowing us to "interrogate" the mechanical properties of adjacent tissues. By applying biophysical and quantitative reasoning to the results of microbeam surgery on wild-type and mutant embryos, we gain insight into the molecular basis of changes in cell and tissue structure during processes such as morphogenesis and wound healing. Previously, microbeams have been used for a wide variety of applications, including surgery, ablation, chromophore-assisted laser inhibition, and molecular uncaging (e.g., Berns *et al*., 1991, 1998; Bargmann and Avery, 1995; Lin *et al*., 1995; Skibbens *et al*., 1995; Wang and Augustine, 1995; Buchstaller and Jay, 2000; Grill *et al*., 2003). This article describes the use of ultraviolet (UV) laser microbeam interrogation strategies, combined with confocal microscopy, to investigate the developmental process of dorsal closure (Figs. 1 and 2; see also Kiehart *et al*., 2000; Harden, 2002; Jacinto *et al*., 2002; Hutson *et al*., 2003).

Dorsal closure can be summarized as follows. In the early stages of closure, the dorsal surface of the embryo is covered by the large, flat polygonal cells of the amnioserosa. The rest of the embryo is covered by smaller, cuboidal-to-columnar cells of the lateral and ventral epidermis. The visible area of the amnioserosa is shaped roughly like a human eye, with a wide central section that tapers to canthi, the corners of the eye (see Kiehart *et al*., 2000; Bloor and Kiehart, 2002). With time, this eye-like structure "closes." A single row of amnioserosa cells is tucked under the lateral epidermis throughout closure (Kiehart *et al*., 2000). Where these cell sheets overlap, the dorsalmost row of lateral epidermis cells comprise a third, distinct tissue known as the leading edge of the lateral epidermis (see later and Foe, 1989; Kiehart *et al*., 2000; Stronach and Perrimon, 2001). The cells of the leading edge on each flank of the embryo contain an actomyosin-rich "purse string" or "actin cable" (Young *et al*., 1993; Kiehart, 1999; Kiehart *et al*., 2000). In addition, these cells extend dynamic finger-like filopodia ~10 μm in length (Jacinto *et al*., 2000). At the canthi, pairs of these filopodia can span the gap between opposing leading edges. As dorsal closure progresses, the actin cytoskeleton is remodeled and each structure changes (Young *et al*., 1993; Jacinto *et al*., 2000; Kiehart *et al*., 2000; Wood *et al*., 2002). Cells of the lateral epidermis are stretched (or elongate) toward the dorsal midline; the purse string contracts along their length; and cells of the amnioserosa actively change shape as their apical surfaces contract to help draw the lateral epidermal sheets together. The two flanks of the lateral epidermis adhere to one another or are zipped together—filopodia and lamellipodia from opposing leading edges interdigitate and a seam is formed (Jacinto *et al*., 2000; Bloor and Kiehart, 2002). At the end stages, the arcs flatten out and closure occurs "edge to edge" as numerous contacts are made simultaneously between the opposing sheets. Once the tissues from opposing flanks are sutured together, the actin-rich purse string dissolves. Ultimately, the dorsal surface is covered by

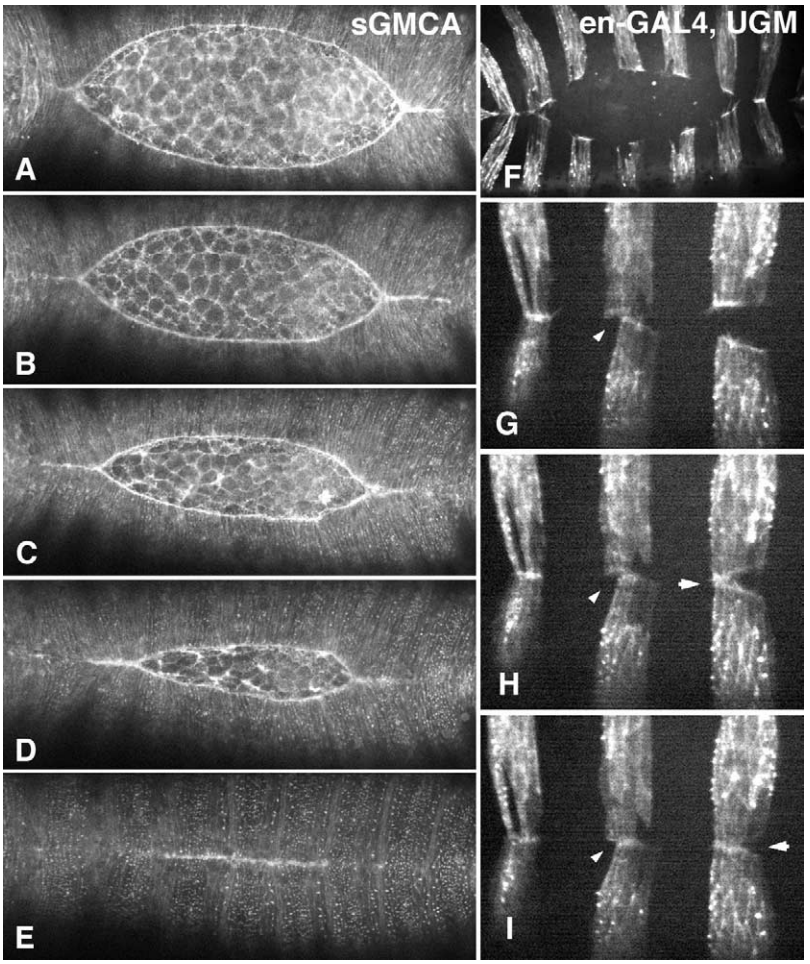

FIGURE 1 Native dorsal closure. (A–E) A time-lapsed sequence of dorsal closure in an embryo that expresses GFPmoe ubiquitously under the control of the heterologous *spaghetti-squash* (encodes nonmuscle myosin regulatory light chain) promoter/enhancer cassette (from Kiehart *et al*., 2000). (F–I) A time-lapsed series from an embryo in which the GFPmoe is expressed in epidermal stripes. The yeast transcriptional activator GAL4 was expressed under the control of an *engrailed* enhancer/promoter cassette, which in turn drives the expression of UAS-GFPmoe (Bloor and Kiehart, 2002). The GAL4/UAS expression system was developed by Brand and Perrimon (1994).

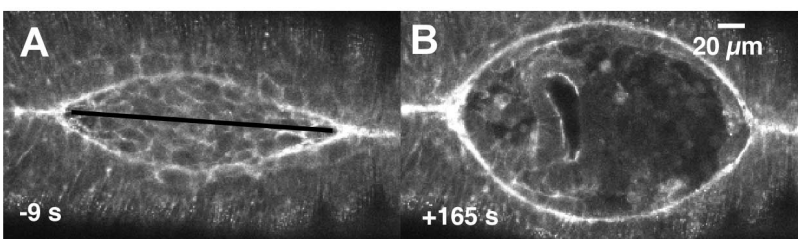

FIGURE 2 Confocal fluorescent images of native and laser perturbed dorsal closure. (A) An image of the dorsal opening just prior to laser surgery. (B) The full recoil of the dorsal opening, which occurs 165 s after a mechanical jump experiment, i.e., where the laser microbeam cuts from canthus to canthus (along black line in A) to remove the force due to the amnioserosa. Taken from Hutson *et al*. (2003).

a continuous epithelium that appears seamless. The main process of closure requires ~2–3 h. The focus of our research is to understand the molecular basis of force production and regulation for these movements that are well choreographed in space and time.

We perform laser surgery on fly embryos that carry green fluorescent protein (GFP) transgenes and can be imaged by confocal microscopy (see Hutson *et al*., 2003). Hutson *et al*. (2003) used optical methods to generate a near diffraction-limited spot of UV light and added the capability of steering that beam under computer control that is detailed later. By modifying our imaging systems, we can record high-resolution, time-lapsed image sequences of embryos before, during, and after UV surgery. We detail methods for automated processing of digitally acquired images and describe analytic strategies designed to reduce large data sets in the form of high-resolution image stacks to a small number of geometric parameters. With the help of QuickTime videos of the time-lapsed image stacks, changes in specimen morphology that result from laser surgical interrogation are therefore described both qualitatively and quantitatively. This provides unique insight into the morphogenic process and tissue response to laser surgery. By using these approaches and comparing wild-type and mutant embryos, we gain insight into the molecular basis of cell and tissue structure and behavior.

II. GFPMOE EMBRYOS

*Drosophil*a embryos that carry GFP-fusion transgenes are mounted to allow high spatial and temporal resolution imaging under conditions that allow development to proceed unimpeded. We use GFP fused to the actin-binding region of moesin (here called GFPmoe; Edwards *et al*., 1997; Kiehart *et al*., 2000; Bloor and Kiehart, 2002; Dutta *et al*., 2002; Hutson *et al*., 2003), which functions as a fluorescent marker for F-actin-rich regions of cells in the embryos. We can express these GFPmoe transgenes under the control of a variety of different promoter/enhancer cassettes (Fig. 1) and find that they are benign under all conditions examined so far: fly development is completely normal from egg lay to the formation of healthy, fertile adults such that we can maintain homozygous stocks of the fluorescently marked flies. Because of the high concentration of filamentous actin in the cortex of virtually all fly cells, these constructs provide a particularly efficacious way of imaging cell boundaries, thereby revealing the structural complexity of the embryo at the cellular level. Other GFP-fusion constructs (e.g., GFP–α-catenin, GFP–actin, GFP–src, GFP–DE-cadherin, Oda and Tsukita 1999; Verkhusha *et al*., 1999; Kaltschmidt *et al*., 2000; Oda and Tsukita, 2001) are applicable to imaging and may even prove superior for certain applications, but the GFPmoe has the advantage of being stable, bright, and benign.

III. EMBRYO OBSERVATION CHAMBER

We mount specimens in an environment that does not perturb progress in development (i.e., allows ready access to oxygen, prevents dessication) yet allows for high-resolution imaging (Fig. 3). We sandwich specimens between a gas-permeable membrane (a thin sheet of transparent Teflon that is available commercially and inexpensive, Fisher Scientific, Cat. No. 13-298-82) and a glass coverslip (Kiehart *et al*., 1994). The most recent version of our chamber allows the embryo, surrounded by inert, nontoxic halocarbon oil, to be

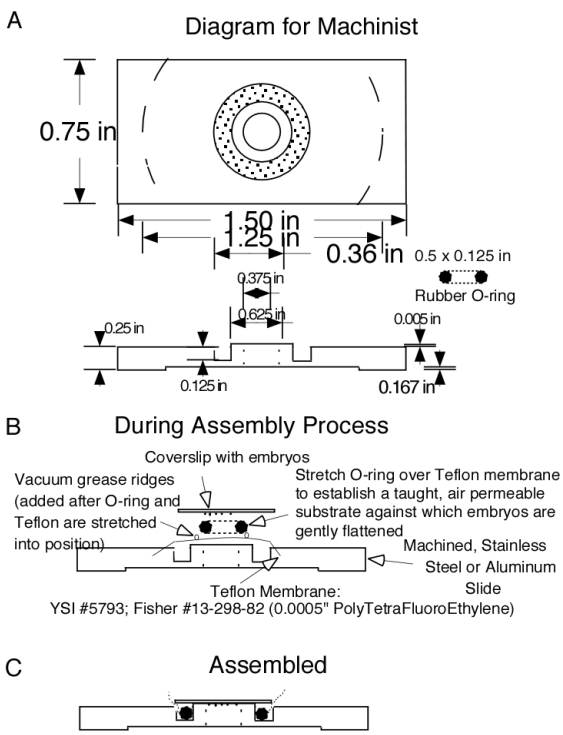

FIGURE 3 Teflon window chamber for the observation of embryos. The chamber is as described in the text. (A) A mechanical drawing to scale that can be used by an appropriately skilled shop to machine the stainless steel or aluminum chamber required to hold the gas-permeable membrane and the coverslip with embryos affixed. (B and C) How the chamber looks during and after assembly with a coverslip and embryos.

gently and slightly flattened, thereby improving our ability to image movements in a single (or relatively few) optical sections. These slightly flattened embryos hatch into larvae and, if removed from the halocarbon oil, proceed through development to form healthy and fertile flies.

IV. CONFOCAL MICROSCOPY

We perform laser surgery using one of three commercially available confocal microscope systems in which visible [e.g., continuous wave (CW) argon ion, krypton–argon ion, HeCd], lasers excite GFP (or its spectral variants, e.g., Heim and Tsien, 1996; Ormo *et al*., 1996; Miyawaki *et al*., 1997) and provide imaging contrast. We have mounted the surgical UV lasers on both upright and inverted microscope systems. Thus far we have used a Zeiss Axioscope (upright) microscope equipped with a Bio-Rad 600 scanning laser confocal imaging system (Kiehart *et al*., 2000), a Zeiss Axiovert (inverted) outfitted with a Zeiss 410 scanning laser confocal imaging system (Hutson *et al*., 2003), and a Zeiss Axioplan (upright) outfitted with a Perkin Elmer/Yokogawa spinning disk confocal imaging system using a Hamamatsu Orca ER camera (unpublished). Confocal microscopy is essential for imaging the thick (150 µm diameter; 450 µm long), optically challenging (yolky and light scattering) embryos.

For each confocal microscope system, modifications to the optical path of the microscope were necessary to allow *simultaneous* imaging and laser surgery. Thus, at an appropriate location (see later), we introduced a dichroic filter that reflects UV ablating light and passes visible imaging light (or *vice versa*), depending on the microscope system. This allows the morphology of the embryos before, during, and after a laser incision to be observed and recorded at image acquisition frequencies of 0.1 to 1 Hz with scanning laser confocals, or better than 1 Hz with spinning disk confocals.

For the Zeiss Axioscope/Bio-rad 600 system and the Zeiss Axioplan/spinning disk system, which are both upright microscopes, the imaging systems are introduced from above, through the trinocular heads. As a consequence, on these systems we required a long-pass dichroic filter that transmits the 488-nm excitation light and the 508-nm light emitted from EGFP and reflects the 337.1- or 355-nm ablating wavelengths (Model 400DCLP, Chroma Technology Corp., Rockingham, VT). On the Axioscope/Bio-rad system, the UV laser was introduced through the epiport (the mercury arc illuminator and associated collectors and diaphragms used conventionally for wide-field fluorescence work having been removed) so that the unmodified 337.1-nm surgical laser beam illuminated first the dichroic and then the objective, in that order. Unfortunately, the epiport on the Zeiss Axioplan includes a "drop-down" prism that does not transmit or transmits only poorly in the UV so we had to devise an alternate strategy for introducing the ablating beam. We modified an epifilter holder to accept light orthogonal to the nominal axis of incidence by drilling out the end of an epi slider and rotating the dichroic filter holder about the optic axis so that it remains positioned at 45° to the optic axis, but can reflect the UV light passing through the end of the slider onto the optic axis (Fig. 4). Most competent university machine shops should be able to modify an existing Zeiss slider in this manner satisfactorily. More recent Zeiss microscopes do not have this transmission problem, so that the standard epiport can be used to introduce the ablating beam—one of the fluorescent filter sets is simply replaced with the appropriate dichroic filter.

For the Zeiss 410 scanning laser confocal system mounted on the Zeiss Axiovert inverted scope, we required two modifications. Normally, a first surface mirror mounted in the epifluorescence filter slider is designed to reflect the imaging beam path. Our first modification was to replace this mirror with a short-pass dichroic filter (Model 360DCSX, Chroma Technology Corp.) that reflects 488- and 508-nm imaging wavelengths but transmits the 355-nm UV ablating beam. In practice, we left the first surface mirror in place and inserted the required dichroic in one of the other filter positions. To image from a nonstandard filter slider position, we defeated the interlocking system, which prevents the imaging laser from accidentally being projected through the binocular eyepieces, by taping two rare earth magnets (Cat. No. 64-1895, RadioShack Corp.) over the detector that senses the position in which the slider is located. This allows imaging with the slider in any position. The second modification was to the mount of the tube lens required for image formation by the binocular eyepieces and the Keller port (an optical port on the bottom of the Zeiss Axiovert that allows a straight optical path through the bottom of the inverted scope). This tube lens does not transmit UV and is mounted in a fixed position between the Keller port and the objective. We removed the lens from its fixed mount, machined a new mount for it, and attached the mounted lens to the sliding first surface mirror that is used to select between access to the Keller port and access to the binocular eyepieces. Thus, this modification allows imaging with the binocular eyepieces, but the tube lens slides out of the way when the Keller port

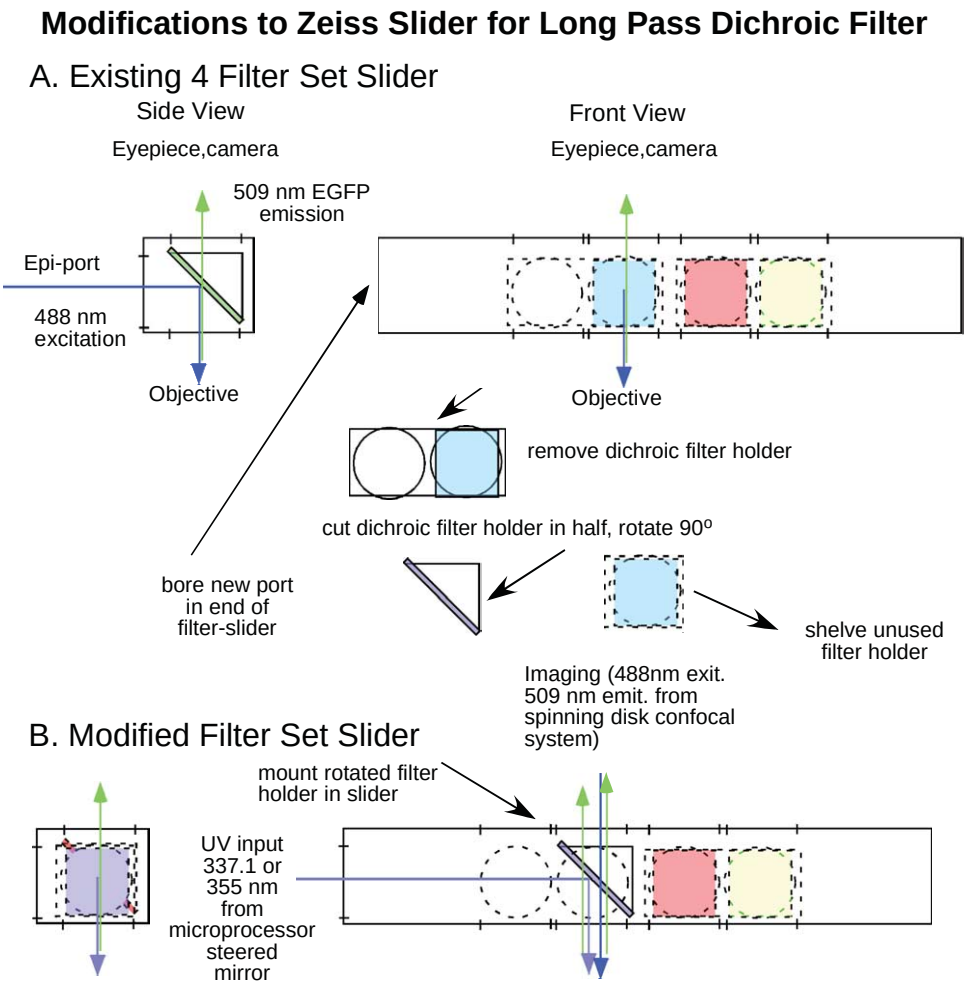

FIGURE 4 Modifications required so that a Zeiss epifluorescent filter holder/slider can be used to introduce UV ablating light onto the optic axis of a Zeiss Axioplan microscope (see text). (A) A schematic of the unmodified four-position slider with filter sets. It diagrams removal and modification of one of the dichroic filter mounts. (B) A schematic of the modified holder with the appropriate dichroic mounted. UV ablating light enters through a hole bored in the end of the slider.

is selected. With these modifications in place, the first optical components encountered by the expanded, UV ablating beam are the dichroic and the objective, in that order. Clearly, the configuration we describe is independent of the use of laser scanning versus spinning disk microscope technology. The advent of spectral variants of GFP mentioned earlier, the proliferation of other unrelated fluorescent proteins, each with different excitation and emission characteristics (Lippincott-Schwartz and Patterson, 2003), and the use of UV microbeams over a range of wavelengths may require selection of dichroic filters with different spectral characteristics.

V. ULTRAVIOLET MICROBEAM

Originally, we used a nitrogen laser to produce a UV beam on the Zeiss Axioscope/Bio-rad 600 imaging system that, as implemented, can be described more appropriately as a "UV macrobeam" (see later). The N_2 laser (Model VSL-337ND-S, 337.1 nm, 300 µJ, 75-kW peak power, 4-ns pulse width, 0–60 Hz repetition rate, Laser Science, Inc., Franklin, MA) was introduced without modification through the wide-field epiport of our microscope as described earlier. The beam produced by this laser does not have a Gaussian spatial

profile nor did it fill the back aperture of the 25× (NA 0.8) or 40× (NA 0.9, 1.0, 1.2, or 1.3) objectives commonly used for our experiments. As a consequence, lesions that result are larger than 5–10 µm in diameter. Furthermore, the N_2 laser is an unstable resonator. Consequently, introduction of a spatial filter designed to produce a Gaussian spatial profile proved impractical due to damage to the spatial filter and insufficient transmitted intensity for microsurgery. Nevertheless, the original system provided a useful tool for introducing spot lesions and did yield biologically significant observations (Kiehart *et al.*, 2000). Fiber adapters that couple this N_2 laser to various microscope systems are available commercially through Laser Science, Inc. However, we have found that the flexibility offered by individual optical components offsets the disadvantage of the extra space they require. Thus, we chose an alternate strategy to improve the quality of our microbeam.

To achieve the near diffraction-limited spot that we required, we upgraded to a Q-switched Nd:YAG laser, operating at the third harmonic, with considerably more power and an extremely stable Gaussian output (Model MiniLight II, 355 nm, 8 mJ, 1.0 MW peak power, 3–5 ns pulse duration, 1–15 Hz repetition rate; Continuum, Santa Clara, CA). We had previously used earlier Nd:YAG laser technology manufactured by Continuum (Model Quantel YSG571C, 355 nm, 300–700 nJ, 10 MW peak power, 8 ns pulse duration, 10 Hz repetition rate, no longer available commercially), but this laser was relatively large, required a spatial filter (R1,2 in Fig. 6), and required daily, tedious alignment. In contrast, the Minilite II is substantially easier to maintain and is essentially a turnkey system. Moreover, it has improved beam quality, thereby eliminating the need for a spatial filter. Currently we have two complete Minilite II laser surgical systems set up, one mounted on the Zeiss Axiovert/410 imaging system and the other on the Zeiss Axioplan/spinning disk system. The optical trains for the two systems are essentially identical and are detailed later.

To produce a near diffraction-limited spot, the laser beam is steered into the optical path of the microscope using an "optical train" that consists of individual

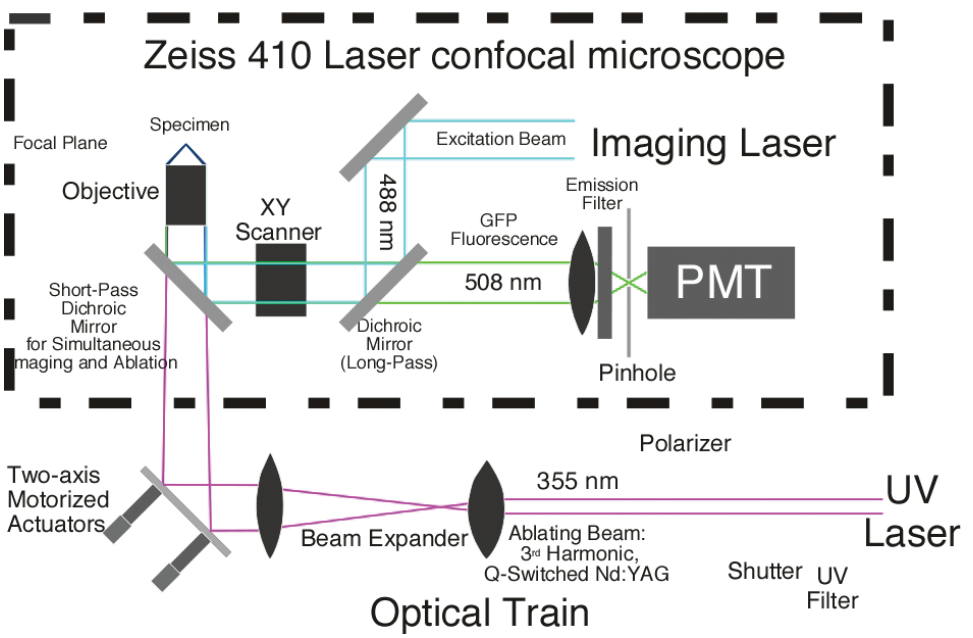

FIGURE 5 Schematic diagram of the Zeiss 410 scanning laser confocal microscope/UV laser surgical system. Part of the interior of the microscope (dotted box) showing how the internal excitation beam (visible argon ion laser) and the external microbeam (third harmonic of a Nd:YAG laser) are combined by a short-pass dichroic mirror to simultaneously direct both laser beams onto the sample. In order that the visible and UV focal planes coincide, the microbeam converges slightly in this case to compensate for the chromatic aberration of the microscope objective (see text). The long-pass dichroic mirror shown is an integral part of the Zeiss 410 imaging system and is left unmodified. It reflects excitation light scattered from the specimen while transmitting fluorescent light to the pinhole and onto the photomultiplier tube (PMT). Note that our laser confocal system utilizes an inverted microscope, with the specimen set above the objective. A comparable system, mounted on a standard upright microscope, is very similar and is described in the text.

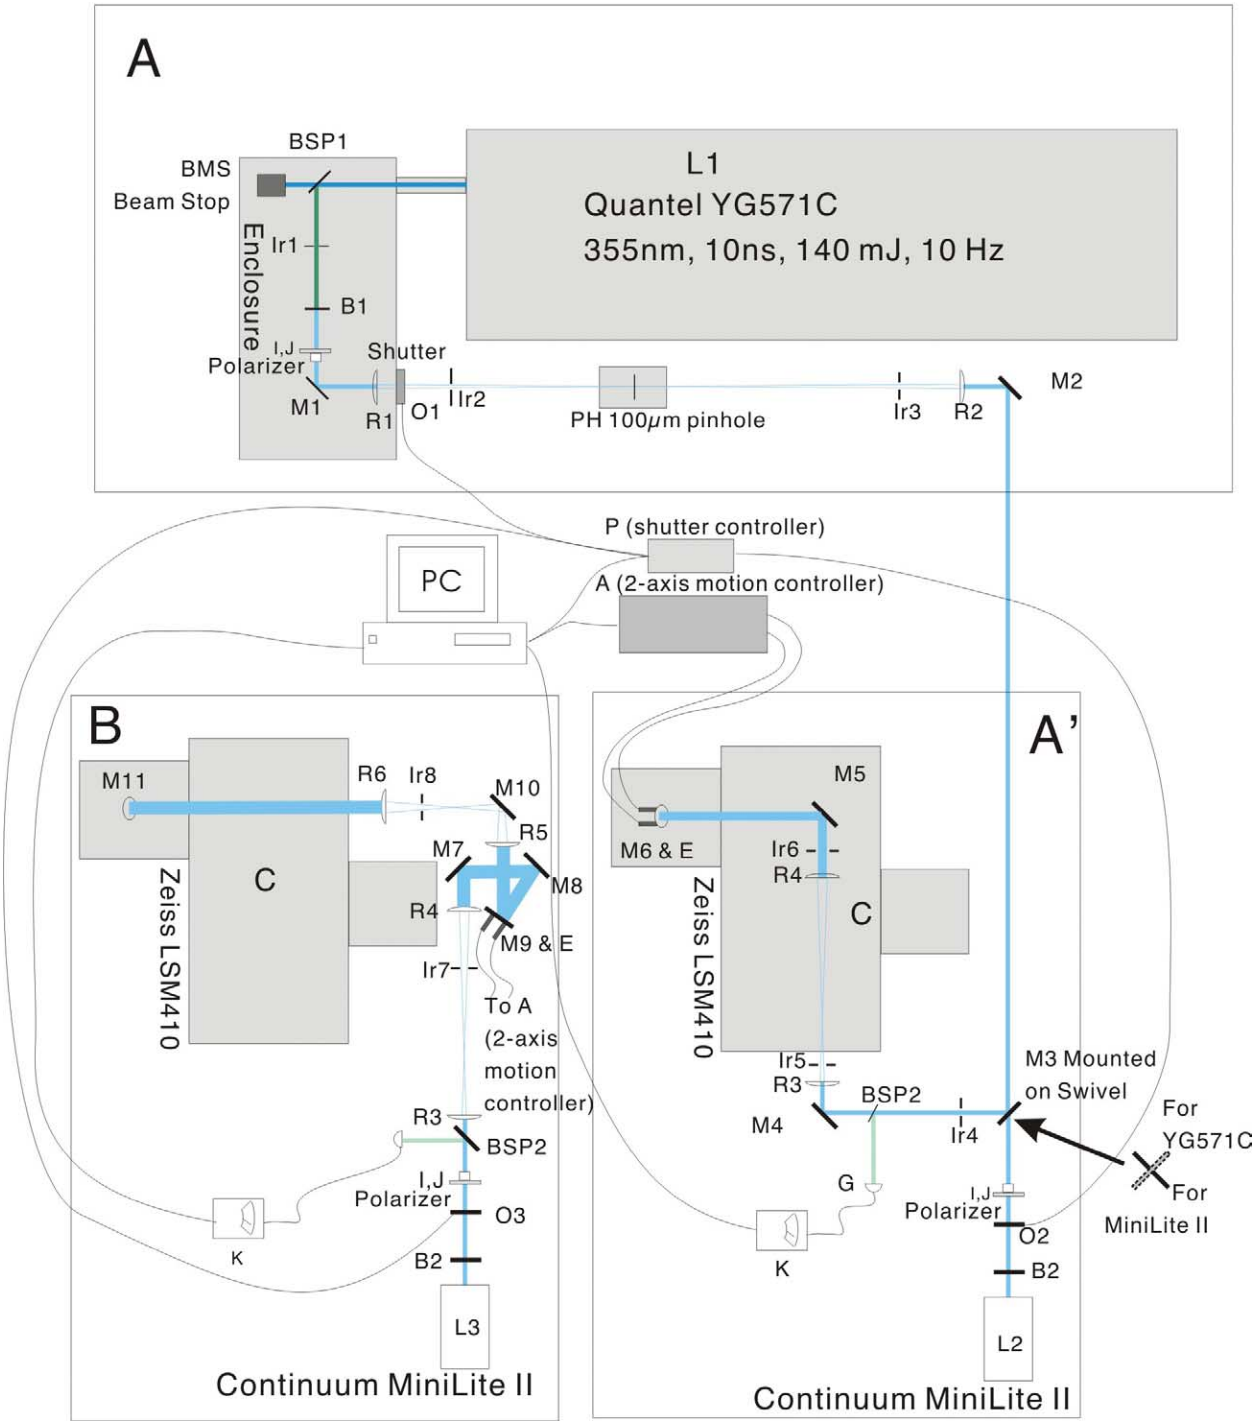

FIGURE 6 Optical layout for the UV microbeam, scanning laser confocal microscope system. Sketch of the optical train of the UV ablating laser system mounted on the Zeiss 410 imaging system is drawn roughly to scale. (A and A′) Layout for Quantel and Minilite II. components (mirrors, lenses, filters, and diaphragms) mounted on an vibration isolation table (e.g., Micro-G, Technical Manufacturing Corp., Peabody, MA). By implementing a beam expander, the back aperture of the objective can be filled and a near diffraction-limited microbeam generated so that the area of a lesion can be reduced to the submicrometer scale, achieving our goal of ablating a single cell (Figs. 5 and 6).

VI. ASSEMBLY OF THE OPTICAL TRAIN

The optical train required to achieve a near diffraction-limited spot in the specimen plane is shown schematically and approximately to scale for the two generations of Continuum Nd:YAG lasers that we used (Fig. 6). The individual components are described later, their position is specified by an appropriate letter in Fig. 6, and the suppliers and part numbers for the various components are specified in Table I. The specific components were chosen based on a number of factors, including compatibility with other components, cost, and availability. In most if not all cases, equivalent lenses, mirrors, and filters and ancillary components such as rails, sliders, posts, lens, and mirror mounts are available from any one of a number of suppliers (e.g., Melles Griot, www.mellesgriot.com; Oriel, www.oriel.com, Newport, www.newport.com; Edmund Industrial Optics, www.edmundoptics.com; CVI Laser, www.cvilaser.com; Chroma, www.chroma.com; and Omega, www.omegafilters.com). Lenses and mirrors were mounted in appropriate mounts and positioned via posts, sliders, and optical rails as shown schematically.

To set up the optical train, we first mount the laser on the optical table at an appropriate height (beam approximately 18 cm from the table surface) and then position the shutter. Next we mount and align individual mirrors in order to maintain the UV beam parallel or perpendicular to the surface of the table and guide it to the dichroic filter that merges the optic axis of the UV optical train with the visible light optic axis of the imaging microscope. Mirrors closest to the laser are added first. Many commercially available white index cards, business cards, or "post it" notes fluoresce sufficiently to allow the beam to be visualized during this alignment process. Alternatively, cards can be doped with a dilute solution of DAPI to improve visualization of the beam. Once the mirrors are aligned properly to guide the unmodified beam through the objective, the polarizer, the individual lenses that comprise the beam expander and the telescope are added, in that order. In each case, one needs to verify that they are mounted centrally and orthogonal to the optical train. Again, the lens closest to the laser is inserted first.

Downstream of the laser and upstream of the beam expander are the following key components: A UV band-pass filter (B1 and B2 in Fig. 6, peak transmission

TABLE I Optical Instrumentation

The following is a list of the optical components comprising the optical trains shown in Fig. 6.

A	Two-axis motion controller (Newport ESP300-11N11N) to operate the motorized actuators
B1,2	Band-pass filters (Newport FSR-UG11), transmission peak at ~340 nm
BMS	Beam stop
BSP1	Optical flat beam splitter, reflects approximately 10%
BSP2	Thin glass plate (coverslip) beam splitter, reflects approximately 10%
C	Confocal microscopes: Zeiss Axiovert/LSM410; Zeiss Axioplan or Axioscope with PerkinElmer/Yokogawa spinning disk confocal
E	Motorized actuator (Newport CMA-12PP) for beam steering
G	Detector (Ophir Optronics, Model PD10) for power measurement
I	Polarizer (Newport 10GL08)
Ir1–8	Iris diaphragms
J	Polarizer stage (Newport RSP-1T) for holding and rotating the polarizer
K	Power meter (Ophir Optronics, NOVA)
L1–3	Q-switched UV laser (Continuum Quantel or MiniLite II)
M1–8	Mirrors (Newport 10D10AL.2) aluminum coated
M9,11	Mirrors (CVI PAUV-PM-2037-C) aluminum coated
O1–3	Shutters (Uniblitz VS25S2ZM0)
P	Shutter controller (Uniblitz D122)
PH	Pinhole for spatial filter
R1,2	UV-fused silica lens for spatial filter (CVI PLCX-25.4-360.6-UV, f = 700.0 mm)
R3,4	UV-fused silica lens for beam expander (Newport SPX019, f = 75.6 mm and SPX028, f = 200 mm)
R5,6	UV-fused silica lenses for telescope (CVI PLCX-50.8-180.3-UV-3555-532, f = 378 mm)

at 340 or 355 nm) is positioned at the exit of the laser and transmits only the third harmonic (355 nm) while blocking the fundamental and second harmonic. To control sample exposure to the microbeam, a shutter (O1-3) and a calcite polarizer (I) mounted on a rotary stage (J) are situated after the UV band-pass filter. The shutter is operated by a shutter controller (P) connected to the same computer that steers the beam (see later) via an RS-232 interface. Note that this computer is distinct from the imaging PC required for either laser scanning or spinning disk confocal imaging of the samples. Control of the shutter is achieved through custom plug-ins written for ImageJ, a free software package available from the Web site of the National Institutes of Health (NIH), http://rsb.info.nih.gov/ij/. The custom plug-ins that we have written are available on our Web site: http://www.biology.duke.edu/kiehartlab/biopdc/.

Continuous attenuation of the filtered UV laser beam, which is polarized linearly, is achieved by rotating the polarizer. To measure the intensity of the beam, a small fraction of the ablating beam is diverted to a detector by positioning a partially reflecting glass surface (BSP2)—in our case a glass coverslip—in the optical train of the ablating beam. The transmitted beam is for dissection and the reflected beam is for monitoring the power. Calibrating the energy ratio between the two beams (ratio ~0.1), we can unambiguously determine the energy per pulse incident on the specimen.

VII. FINE-TUNING THE OPTICAL TRAIN TO OPTIMIZE THE MICROBEAM

Minimization of the microbeam spot size at the imaging focal plane is achieved by optimizing two beam parameters: beam diameter and divergence. Our first problem is that the diameter of the emitted laser beam (<3 mm) is considerably smaller than the back aperture (~10 mm) of the objective lenses typically used for imaging and surgery. A second complication arises because the index of refraction of the lenses in the objective is wavelength dependent. Although the objectives used are neofluars (fluorite lenses sometimes called semiapochromats; Inoue and Spring, 1997; Murphy, 2001) or apochromats in the visible spectral region, the index of refraction varies with wavelength in the UV. The resulting longitudinal chromatic aberration causes a discrepancy in the position along the optical axis between the focal points of the visible light and the UV light.

To expand the beam, to permit correction of this chromatic aberration, and to deliver a near diffraction-limited spot, two fused silica lenses (R3, R4, Fig. 6) that transmit UV are introduced. We fix the position of the second lens and adjust the distance between these two lenses by moving the first lens. The focal lengths of these lenses were chosen so that the diameter of the laser beam is expanded by three times, thus nearly filling the back aperture of the objective with plane parallel light. However, as explained earlier, this plane parallel beam will not be focused in the same plane as the visible, imaging laser. To correct for chromatic aberration of the objective for the UV light, we increase the length between the two lenses of the beam expander. This introduces a slight convergence to the UV beam and alters the focal plane of the ablating laser. Due to this convergence, the expanded beam did not completely fill the back aperture of the objective. Because the Nd:YAG laser is not power limited, alternate lenses could be used to expand the beam further and overcome this limitation. Nevertheless it is important to note that we achieved our goal of providing a microbeam that was sufficiently small to ablate a single cell.

In practice, to optimize alignment of the beam expander, we made test samples constisting of a thin layer (~150 μm thick) of 1–2% agarose (in deionized water) sandwiched between a slide and a coverslip. For visible light the agarose was supplemented with 0.2% rhodamine dye, for UV light no dye was used. In each case, the focused beam cavitates the gel in a small region defined by the focus, causing a small bubble to form. Fine adjustment of the two beam expander lenses is performed by iteratively reducing the power such that it is just sufficient to cavitate the gel and then readjusting the lenses such that the focal planes of the visible, imaging light and the UV ablating light coincide. The process is repeated until minimum power is required to ablate the gel adjacent to the coverslip. Near diffraction-limited spot size is confirmed by using the laser to ablate holes in a thin film of aluminum evaporated onto glass, which forms an ideal and stable test specimen (Fig. 7A).

The ablating UV laser is pulsed and the dose of UV light delivered to the specimen can be adjusted with the computer-controlled shuttering system. By adjusting the duration for which the shutter is open, a specimen is exposed to the desired number of pulses, N. However, for small values of N, there is potentially some ambiguity in the number of UV pulses to which the specimen is exposed because the laser pulses are not synchronized to the shuttering system. In practice, the repetition rate of the laser pulses is 10 Hz, so we set the shutter-open duration to 0.1 N–0.005 s,

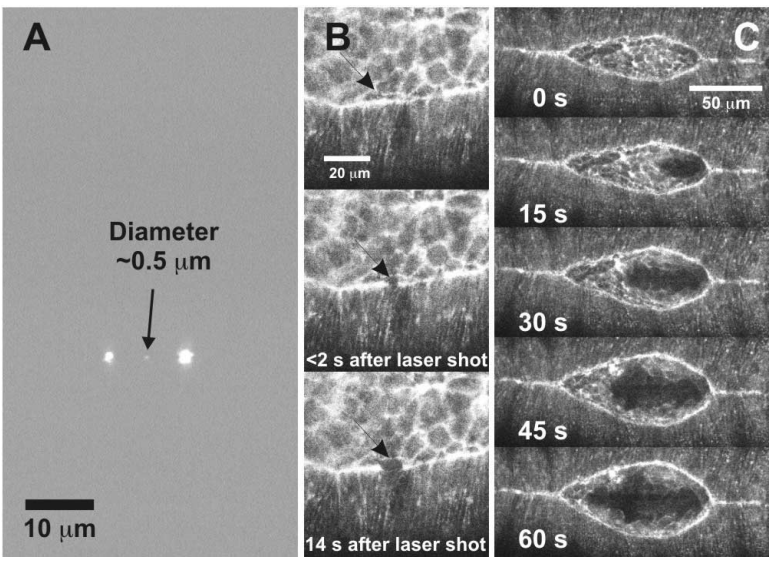

FIGURE 7 Performance of the UV microbeam. (A) Demonstration of the near diffraction-limited spot size as measured on a thin film of aluminum. The smallest spot was made by a single pulse of ~50 nJ on the film. The left and the right incisions received single pulses of ~100 and ~200 nJ, respectively. (B) Application of the near diffraction-limited microbeam to surgery on the leading edge of the lateral epidermis. The microbeam was aimed at the center of the field, a specimen was brought into position, and the supracellular purse string at the leading edge was nicked by a single pulse of ~200 nJ. (C) Demonstration of beam steering: the microbeam is steered from canthus to canthus to make a linear incision. Elapsed time is shown in seconds and starts at first lasing. Reproduced from Edwards *et al*. (2003).

i.e., slightly smaller than the period times the number of pulses. This eliminates the possibility of $N + 1$ pulses passing the shutter, but with low probability (~5%), only $N - 1$ pulses may pass. Here, the pulse duration is only 10 ns and 3 ms is needed for completion of opening or closing the shutter. Typically, more than ten pulses are used to perturb the embryo so the expected dose was constant (except for the rare occasion when it was 5–10% less than the expected value).

VIII. BEAM STEERING

By introducing two computer-controlled linear actuators (E's in Fig. 6) to angularly position one of the mirrors in the optical path, the beam can be steered systematically in two dimensions, thus converting a spot ablation tool into a precise UV-scalpel for tissue surgery (see results: Figs. 2 and 7). The actuators replace adjustment screws of a kinematic optical mount. The two motorized actuators are positioned by a two-axis motion controller (A in Fig. 6), which offers a step size of 0.1 μm. With this step size, the resolution of the laser trajectory is not limiting and is instead determined by the coarseness of the image, i.e., the number of pixels in a frame (512 × 512). With the 40× objective that we typically use, we achieve subcellular resolution in the specimen. The controller communicates via an RS-232 interface with the microbeam computer running ImageJ with custom Java plug-ins. The plug-ins allow PC-controlled steering of the microbeam at a constant velocity along any defined trajectory in the specimen plane.

When it is steered off axis, the UV laser beam may be cropped by the back aperture of the objective, thereby restricting the region in the specimen plane that is accessible to surgery (Fig. 8B). Initially, to achieve a large area for incisions, we set the final mirror (M6, M9 in Fig. 6) mounted on linear actuators (E's) as close to the back aperture of the objective as possible. In our system, this length is ~20 cm. Using the 40X objective (1.3 NA oil immersion objective), a roughly circular region with a radius of ~70 μm can be targeted for ablation. To overcome this limitation, to improve flexibility in the overall design of the optical train, and to increase the area of the specimen that is accessible to the UV microbeam, we inserted a telescope into the optical train designed to project the expanded beam onto the back aperture of the objective (Figs. 6 and 8A). The telescope is composed of one mirror (M10) and two plano-convex fused silica lenses, $f = 350$ mm (R5, R6 shown in Fig. 6). To accommodate

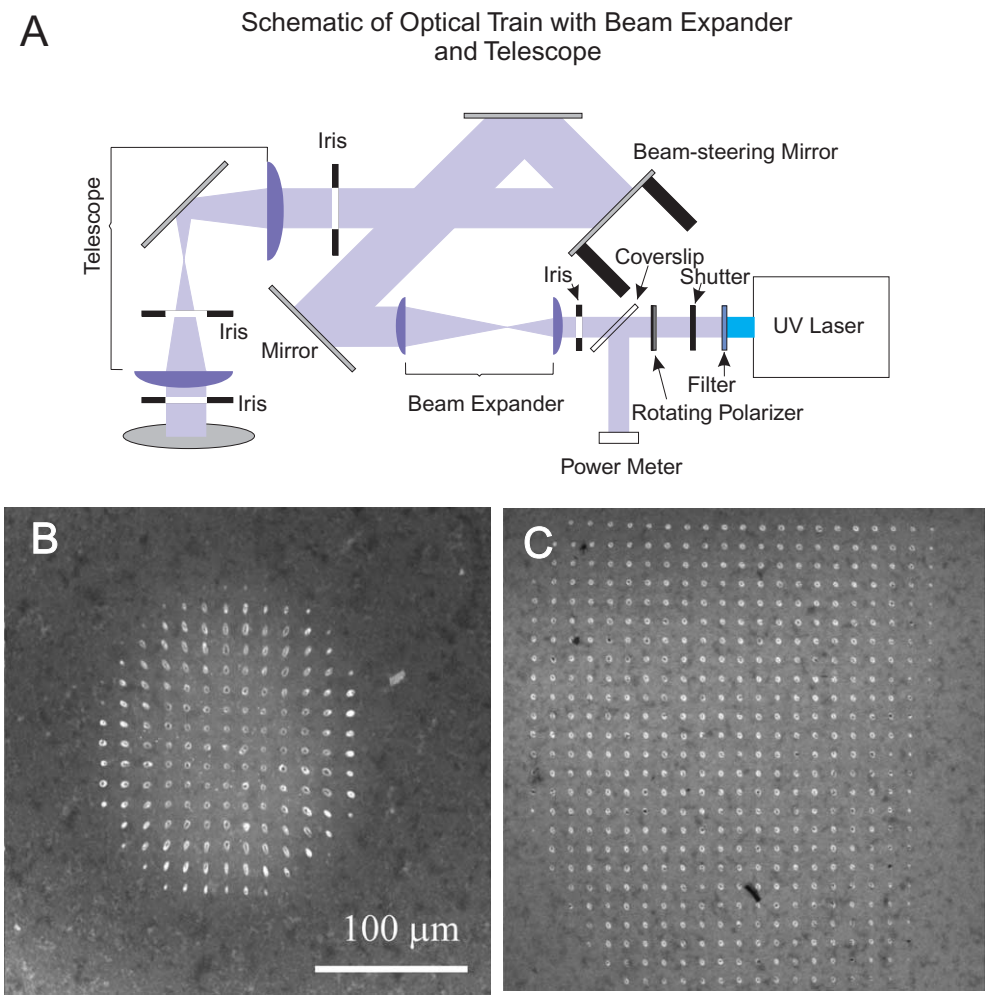

FIGURE 8 An optical telescope improves the effective area of laser ablation. (A) UV optical train using a telescope to avoid vignetting at the back aperture of the objective (see text). (B) Effective area of laser ablation without the telescope is limited due to clipping of the UV microbeam using the UV optical train shown in Fig. 5. Only the region within the circle of radius ~70 µm about the optical axis can be ablated on a target specimen (rhodamine dye in agarose gel). (C) Effective area of UV laser ablation after installation of the telescope. Note that the area is expanded significantly, covering the major part of the image plane, and that the lesions maintain a round morphology farther from the optical axis. Scale bar is for both B and C.

the travel range of the steered beam, the diameter of these optical components (2 in.) is two times larger than that of other lenses in the optical train. With this telescope, the incident laser beam can be steered off axis and yet remain centered on the back aperture of the objective, thereby increasing the area accessible to the ablating beam at the specimen plane. Moreover, the mirror that is used for beam steering no longer needs to be as close to the back aperture of the objective as possible.

The protocol for executing a laser incision is as follows. An image of the embryo from the laser scanning confocal microscope is captured by the imaging software, transferred, and displayed on the screen of the PC that controls the ablating microbeam. The pattern of a user-defined incision is drawn on this image with the PC's mouse or cursor. The desired laser incision is then executed by running custom Java plug-ins for ImageJ that coordinate opening and closing of the upstream shutter with the two motorized actuators that position the beam steering mirror. Trial and error is used to determine an appropriate rate of movement for the mirror. Typically, scan rates correspond to about 10 µm per second on the surface of the embryo. The longest incisions typically required 10 s of 10-Hz pulsed UV laser exposure.

IX. AUTOMATED ACQUISITION OF GEOMETRIC PARAMETERS

High-resolution time-lapsed analysis of morphogenesis can rapidly generate vast quantities of images that can quickly overwhelm the researcher's ability to store and interpret data. In particular, data analysis that requires manual intervention becomes a critical rate-limiting step. As a consequence, we apply automated methods designed to extract a small number of key geometric parameters from stacks of several hundred images, each 2–4 Mbytes in size. First, confocal images of dorsal closure are saved as TIFF files directly or are exported from proprietary software into TIFF or AVI format. Such images are then loaded into the ImageJ image processing software. Several basic processing functions, such as measurement of the length or the area of a designated region, are built into the software, but additional customized routines have been implemented as custom Java plug-ins.

Thus far, we have been most successful with automated methods designed to recover the shape of the exposed amnioserosa, as outlined by the bright, actin-rich, supracellular purse string that forms at the leading edge of the lateral epidermis (Figs. 1, 7, and 9).

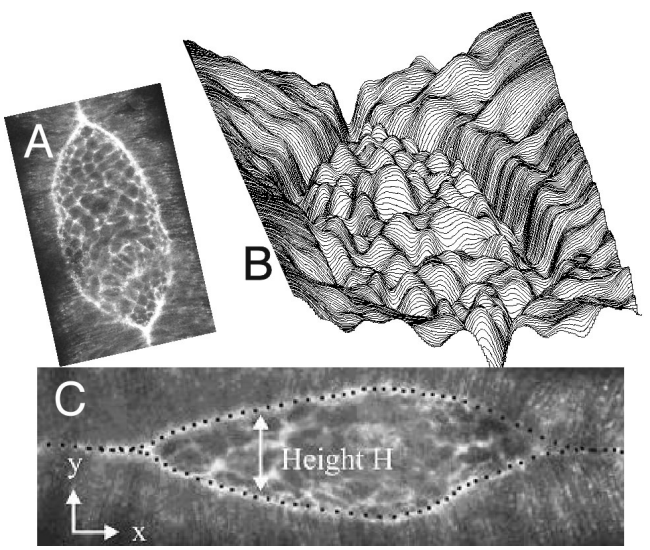

FIGURE 9 The leading edge of the lateral epidermis, the inverse intensity landscape, and the application of the snakes algorithm for the automated identification of the leading edge of the lateral epidermis. (A) Fluorescent image of the dorsal opening about two-thirds of the way through closure. (B) An inverse intensity landscape for a comparably staged embryo (see text). (C) Snakes fit to the two leading edges of the dorsal opening for an embryo at a later stage. The 50 fitting points on each edge are apparent.

To quantify how the tissue geometry changes with time in native embryos or in those cut with the UV laser microbeam, we extract the contour of the leading edge in each image as digitized information as follows: in our system, the original size of an image is typically 512 × 512 pixels, but can be as large as 2048 × 2048 pixels. To optimize handling of the large data sets, the first image is cropped to reduce its size so that it contains only the region of interest (typically the entire embryo). By treating the set of TIFF images as a stack, all of the following images are automatically cropped using the same frame. To capture the contour of the leading edge, which is represented as bright pixels forming a closed geometry, we employ the technique of active contour models, also known as "snakes" (Kass *et al.*, 1987). This method is generally used for recognizing the boundary of an object in an image and, in our images, readily identifies the supracellular purse string or actin-rich cable at the leading edge as the bright pixels due to GFPmoe fluorescence (Fig. 9). In practice, each stack of images is processed with a custom Java plug-in that executes the snakes analysis.

The snake method can be understood in terms of an "energy" landscape as follows. This landscape corresponds to the inverse image intensity, i.e., the brightest regions correspond to minimum energies (Fig. 9B). In an original image, the brightness of each pixel is stored as 8 or 12 bit intensity information (depending on the imaging system), where the dimmest pixels approach 0 and the brightest pixels approach either 255 or 4095, respectively. For the inverse intensity plot, the brightest pixels approach 0 and the dimmest, 255 or 4095, respectively. Consequently, fitting the snake corresponds to minimizing a multiterm energy equation associated with the contour in the inverse intensity landscape. The energy of a snake is determined by its length, curvature, and the brightness along a contour described by 100 discrete points. This number of points is chosen to balance accuracy with computational demands. The energy E_{total} of the snake is given by the following algorithm, implemented as a plug-in to ImageJ:

$$E_{\text{total}} = E_{\text{internal}} + E_{\text{image}} + E_{\text{constraint}} \quad (1)$$

where E_{internal} and E_{image} are integrals of $(a\,|\,d\mathbf{v}/ds\,|^2 + b\,|\,d^2\mathbf{v}/ds^2\,|)$ and $c\ \mathrm{I}(s)$, respectively. The parameter s runs from 0 to 1 and $\mathbf{v}$ is a vector in the x, y plane as shown in Fig. 9. The parameters a, b, and c weight the contributions from the terms to achieve acceptable curve fitting and are chosen by user intervention. The first term of E_{internal}, $a\,|\,d\mathbf{v}/ds\,|^2$, is analogous to the energy due to stretching of an elastic rod. Note that the 100 points are approximately distributed uniformly along the leading edge, as if "springs" that connect

these points are of nearly uniform, minimal length (Fig. 9). The second term of $E_{internal}$, $b|d^2\mathbf{v}/ds^2|$, is analogous to the bending energy of a rod and here is minimized as well: as a consequence, steep bends are energetically expensive and selected against in the energy minimization process. The image energy E_{image} is the value of the experimentally determined inverse intensity, described previously. The final energy term, $E_{constraint}$, addresses the complications of fitting the leading edges where they converge near the canthi and beyond where they are already sutured into seams. In our implementation, these constraints mimic the connection of two additional springs. One spring connects the 1st snake point to the right edge of the image; the second connects the middle (50th) snake point to the left edge. Mathematically, $E_{constraint}$ is given by $k(x_1 - w)^2 + kx_{50}^2$, where w is the width of the cropped image. Similar to a, b, and c, the parameter k is chosen by user intervention to achieve acceptable curve fitting.

Energy minimization is optimized by allowing the snake, *i.e.*, a mathematical contour, to computationally wiggle about the inverse intensity landscape using the methods of gradient descent (Kass *et al.*, 1987). There is a competition between the various terms in the energy equation. In isolation, the contribution from rods and springs favors being unstretched, the contribution from rods also favors being straight, and the contribution of E_{image} seeks out the twists and turns of the deeper valleys of the inverse intensity landscape. The computational refinement of the overall positioning of the snake is an iterative process that strikes a balance of the energy terms via the choice of parameters a, b, c, and k. Essential to the method of gradient descent is determining the derivative of change in each of the energy terms for each repositioning (wiggle) of the snake to identify the term(s) that should dominate the next choice of position in this refinement process. Consequently, successive iterations ideally optimize positioning the snake in the valley of the inverse intensity landscape that corresponds to the two leading edges. This computational approach proved quite satisfactory in practice, provided sufficient brightness and contrast are available in the individual images. Under these conditions, it takes several minutes to analyze a stack of 500 sequential images when using a Pentium IV desktop computer with a 2.4-GHz processor. The positions of points fit to the upper and lower leading edges are stored in a text file as a digitized data set that can be imported into other programs for further analysis.

We are currently developing additional strategies designed to rapidly and automatically identify other structural features (e.g., the shape and position of individual cells, the number and distribution of filopodia). Our goal is to devise methods that parallel those developed for the acquisition and mathematical description of the supracellular purse string using the snakes strategy described earlier. Thus, parameters are to be analyzed automatically as a function of time (i.e., measured on sequential images in the time-lapsed image stack), tabulated into a spreadsheet program, and analyzed and evaluated quantitatively for statistical reliability. Extracted data are reviewed on a frame-by-frame basis to verify that the imaging software accurately identified relevant structures. Together, QuickTime videos constructed from image stacks and the extracted geometric parameters constitute analysis of the experimental data sets. The reproducibility of our observations is confirmed by comparing the results from a set of at least six individual embryos that were manipulated genetically and/or surgically in an identical fashion.

X. PUTTING IT ALL TOGETHER: EMBRYO MICROSURGERY

Preparation of the Embryos for Observation

Small population cages containing 30–300 adult flies of the appropriate genotype are used to collect embryos on grape juice agar plates by standard methods (Roberts, 1998). To improve the optical qualities of the embryo, the chorion is removed mechanically by rolling an embryo on double-sided adhesive tape or is removed chemically by immersing the embryo in 50% bleach using standard methods (Roberts, 1998). This leaves behind a transparent protective layer, the vitelline envelope. With the aid of a dissecting microscope, the dechorionated embryos are oriented dorsal side up in an orthogonal array (e.g., three rows of 10 embryos each) on a pad of 1% agar. The embryos are spaced so that they are at least 1–2 embryo diameters apart. The array is then picked up on a #1.5 22 × 22-mm glass coverslip coated with a thin layer of "embryo glue" (Roberts, 1998). We find that arranging the embryos on the agar pad allows more flexibility in getting their orientation just right and dramatically reduces the number of embryos that are damaged when compared to protocols that call for aligning the embryos directly on the glue-coated coverslip. The coverslips are made in advance by putting a few drops of adhesive, solubilized from double-stick tape (type 415, 3M Company, St. Paul, MN; Whiteley and Kassis 1993) with hexane and allowing the glue to air dry for at least 5–10 minutes (we typically store the coated coverslips in a closed box to avoid accumula-

tion of dust and use them within 1–2 days of coating them). To prevent desiccation, the embryos are covered immediately with a few drops of halocarbon oil (#27 or #700, or a mixture of the two, Sigma, St. Louis, MO), which is chemically inert and allows ready access to O_2. An observation slide is prepared in advance as follows: Stretch a sheet of optically transparent oxygen-permeable Teflon membrane (Fisher Scientific, Cat. No. 13-298-82) across the opening in a machined metal slide (see later and Fig. 3) fixed into place with an O ring and then extrude, from a number 18 hypodermic needle, two low (0.1–0.5 mm) parallel ridges of high-vacuum silicone grease (Dow Corning, Midland, MI) on either side of the opening. The coverslip with its embryo array and oil is rapidly inverted onto and is then compressed gently against the ridges of vacuum grease. The vacuum grease helps hold the coverslip in place and functions as a spacer that prevents overflattening of the embryos. Together with the halocarbon oil, the silicone grease also prevents desiccation of the sample. By positioning the array of embryos over a hole in the metal slide, the embryos can be observed by transmitted light microscopy. The Teflon membrane used is extremely birefringent, such that it interferes with phase contrast and differential interference imaging systems. The thickness of the slide further precludes achieving Köhler illumination with a high NA condenser. Nevertheless, because the embryos are flattened gently against the coverslip, excellent high-resolution confocal epifluorescence images can be collected. Moreover, wild-type embryos that are unperturbed will hatch into larvae, and if such larvae are removed from the oil and treated appropriately, these will readily develop into adult flies.

XI. LASER SAFETY

Note that it is important to wear appropriate protective eyewear when working with the pulsed UV laser beam. Although we typically use the UV laser in its low-energy mode, the pulses still contain significant intensity, especially before they reach the calcite polarizer. Keep in mind that this polarizer attenuates the beam via reflection. To eliminate a potentially dangerous reflection, we cover the reflection ports of the polarizer housing with opaque electrical tape. The Continuum Minilite II is a class IV laser and special precautions and training are appropriate for personnel involved in setting up the microbeam system (Marshall and Sliney, 2000; Sliney, 2000). In practice, the UV ablating beam is attenuated by glass elements throughout the optical path of the microscope system; nevertheless, we never observe the specimen through the microscope eyepieces while it is being illuminated by the UV laser. A visible microbeam would be a significant eye hazard and safety interlocks are required.

XII. MICROBEAM OPTIMIZATION

A. Daily Protocol

To optimize the system and dissect the surface of an embryo effectively, we describe general procedures that should typically be performed daily before laser surgery on embryos is attempted. However, if the laser exhibits a Gaussian spatial profile and is stable, several steps (2, 3, 4, and 10) can be skipped. Note that the third harmonic generated by the laser is polarized horizontally and rotating the polarizer set in the optical train attenuates the power as a function of the angle ψ between the beam's polarization and the crystal polarization ($\sim\cos^2\psi$).

B. Startup and Calibration of Beam Intensity

1. Turn on the microscope, the imaging system including the imaging laser, and the computer. Turn on the ablating laser and its computer. Verify that the ablating shutter is in the closed position and that the ablating laser is in the low-energy mode. Allow all systems to warm up for several minutes.

2. To estimate the intensity of the laser and evaluate the dose delivered to the specimen plane, deflect a small fraction of the energy to a power meter (Model PD10, Ophir Optronics, Wilmington, MA) with a partially reflecting surface (a coverslip) placed in the optical train (BSP2 in Fig. 6). The steps that follow calibrate the optical train by comparing the power of the deflected light to the power measured at the specimen plane. If two calibrated detectors are available, measurements can be taken simultaneously: one detector is positioned to measure the deflected light and the other is positioned on the microscope stage (it replaces the specimen) at or near the focal point of the objective. If only one detector is available, power at the two positions is measured sequentially (we find that in practice the output from the Continuum Minilite II is very stable and that this approach is quite satisfactory).

3. Open the UV laser shutter and read the energy per pulse at each detector. Because the amount of energy deflected to the power meter by reflection from the coverslip is a function of the angle of incidence and the azimuth angle of the polarized 355-nm ablating light, the ratio of these readings shows slight depend-

ence on the angle of the calcite polarizer. Check and record the ratios for several angles. Later, during embryo surgery, observe the angle of the polarizer and use the appropriate ratio to estimate the energy incident on the sample.

4. Close the UV laser shutter.

C. Ablation on a Test Sample to Optimize the Beam

5. Remove the detector at the specimen plane and place a slide of an agarose gel made by sandwiching a drop of molten agarose or agar (1–2% in deionized H_2O containing 0.02% NaN_3 as a preservative and, for use in fluorescent mode, 0.02% rhodamine B or fluorescein) between a slide and a coverslip and sealing the coverslip (nail polish is convenient—this preparation lasts indefinitely). To aid in determining the plane of focus during subsequent steps, we first make fine scratches on the inside surface of the coverslip with a diamond-tipped marker prior to assembling the agar sandwich. We adjust the thickness of the agarose so that it is approximately 150 µm, thereby simulating the optical properties of an embryo sample chamber. For our applications, laser surgery typically occurs close to the surface of the embryo, <15 µm deep.

6. Block the UV laser beam from entering the microscope with a beam stop (not shown in Fig. 6) positioned somewhere after the coverslip beam splitter (BSP2 in Fig. 6) and then open the UV laser shutter. A small fraction of the beam will be reflected by the coverslip beam splitter (BSP2) to illuminate the detector G. Rotate the polarizer until the estimated value of the energy per pulse that would reach the sample when the beam stop is removed reaches the threshold required to cavitate the gel—for our system, this threshold, using either a 40×, 1.3 NA oil immersion lens or a 40×, 1.2 NA water immersion lens, is ~200 nJ/pulse. The angle of the polarizer and the ratio of intensities at detector G and at the specimen position for this particular angle, previously measured in step 3, are used to estimate the energy at the sample.

7. Close the UV laser shutter and remove the beam stop.

8. While monitoring the surface of the gel on the monitor screen of the confocal system using transmitted light mode, use the shutter to let a single laser pulse illuminate the gel. This procedure is repeated in steps 9 and 10.

9. Adjust the orientation of the mirror using the two-axis motion controller so that the ablation beam hits the center of the gel on the screen. Specifically, record the x, y position of the ablated spot, execute the "Center_Microbeam" custom ImageJ plug-in to recalibrate the beam steering computer's coordinate system, and set the position of the spot to the origin at the center of the imaging field.

10. Optimize the position of the two lenses in the beam expander by adjusting them so that diameter of the ablated spot is minimal. Two factors—the distance between the two lenses and between the objective and the second lens—determine the size of the lesion produced by the laser beam. For the objectives we have used, the smallest possible lesion is achieved with a slightly converging beam. Initially, align the beam expander to transmit plane parallel light and set the laser power so that a single pulse is more than sufficient to ablate a spot in the gel at the focal plane. Next, carry out an iterative process whereby the distance between the two lenses of the beam expander is increased, typically in several millimeter steps, to introduce a convergence to the transmitted light. In practice, the lens closest to the back aperture of the objective remained fixed and we moved the first lens to increase the distance between the lenses, a few millimeters at a time. This initially reduces and then expands the UV spot size in the focal plane. As a consequence, the adjustment moves the lenses through the optimal convergence—once that occurs, reduce the increment and step back to the point that gives the apparent minimum spot size. Reduce the energy per pulse and then repeat the protocol just described to fine-tune the beam expander. Typically three to five iterations are sufficient to minimize the spot size. Measured on the agarose gel, the lesion diameter is typically 1–3 µm.

11. Once the microbeam alignment has been completed, the near diffraction-limited spot size is confirmed by replacing the gel sample with a thin aluminum film. By rotating the polarizer to attain the minimum exposure that ablates with a single shot, the lesion radius approaches the diffraction limit.

D. Dissection and Imaging of the Embryo

12. Replace the aluminum film with an observation slide of appropriately staged *Drosophila* embryos. Set the laser power to below that which is expected to be a threshold dose for creating a lesion (e.g., 200 nJ per pulse) and use a target embryo to empirically define the power required to generate a lesion of desired magnitude by gradually increasing the dose until the appropriate response is seen in the confocal image of the embryo. Once a desired dose has been defined, verify this on a different region of the same target embryo or on a new embryo. Then, select a new specimen, record an image, and transfer the image from the

imaging computer to the beam steering computer. Using the beam steering computer, specify the pattern you wish to cut on the embryo.

13. On the imaging computer, initiate a time-lapsed series. Verify that the intensity in the image does not exceed the dynamic range of the digital acquisition system. With collection of the confocal time-lapse series underway, use the beam steering computer to initiate the laser surgical cut(s). Process and analyze images later.

XIII. TIPS AND PITFALLS

When choosing mirrors, one should consider their damage threshold and the reflection coefficient at the appropriate laser wavelength. Broadband aluminum-coated mirrors have been selected for all mirrors in the optical train.

For UV-transmitting lenses, those made of UV-fused silica have excellent transmission from 180 nm up to 2100 nm at moderate cost. To allow flexibility in choosing the wavelength of the beam, lenses without optical coating may be preferable.

Generally, the transmission of standard microscope objectives shows a steep drop off in the UV. If UV lasers with shorter wavelengths are selected, make sure that the objective is designed for this range and that the energy of the beam after transmission through the objective lens is sufficient for incisions. In particular, avoid laser damage to the objective itself due to UV absorption.

XIV. CLOSING REMARKS

Laser microbeams have become an essential tool to investigate dynamics in cell biology. We have presented details of our specific application to microsurgery using computer steering of near diffraction-limited UV beams. We have applied this approach, together with mathematical modeling and biophysical reasoning, to probe the forces responsible for morphogenesis in *Drosophila*, where the wide array of mutations that affect such processes allow us to investigate the molecular bases for such forces (Hutson *et al*., 2003; unpublished observations). We are extending our studies to other morphogenetic movements in *Drosophila* (e.g., thoracic closure) and are exploring the use of these approaches in other model species—*Caenorhabditis elegans* (nematode), *Danio rerio* (zebrafish), and *Mus musculus* (mouse). As described in the introduction, microbeams, particularly computer-steered microbeams, might also be applied to other approaches that use optical methods to probe molecular function, e.g., fluorescent resonance energy transfer, fluorescence recovery after photobleaching, or chromophore-assisted laser inactivation.

Fluorescent Microscopy of Living Cells

CHAPTER

10

Introduction to Fluorescence Imaging of Live Cells: An Annotated Checklist

Yu-li Wang

It is becoming clear that most biological molecules in living cells are in a highly dynamic state, changing their interactions and spatial organizations in response to signals. With recent advances in optics, probe design, and photon detection, there are few approaches as suitable as fluorescence imaging for investigating dynamic events in living cells. However, successful execution of fluorescence imaging relies heavily on proper setup of facilities. The purpose of this article is to provide a comprehensive list of the equipment, with associated notes, for those setting up new imaging facilities.

There are many options in setting up a fluorescence imaging facility, each with its advantages and disadvantages. The decision is usually dictated by a combination of experimental goals and personal preferences. While this article attempts to provide some useful guidelines, it is important not to equip much beyond what is necessary, as excess equipment wastes money, creates confusion, and often becomes obsolete when one finally finds the opportunity to use it.

Microscope Stand

An inverted microscope generally allows more flexibility and workspace for the culture (see later) and manipulation of live cells than an upright microscope. In addition, while inverted stands by major manufacturers give comparable performances, it is important to take into consideration the feasibility, accessibility, and convenience for special third-party accessories, such as the culture chamber, micromanipulator, filter wheels, and confocal optics to be used. Therefore, choice of the stand should not be made until the design of the rest of the system becomes largely clear.

One aspect particularly relevant to living cell imaging is the stability of the microscope stand. Some old microscopes are prone to stage drift, particularly at an elevated temperature. They require either extensive manual input or an autofocusing mechanism for time-lapse imaging. However, it is often difficult to obtain reliable information on the stability through manufacturers or on-site demonstration, and experience of colleagues is often the most reliable source.

Several current microscope designs incorporate useful automatic features, such as lamp shutters (see later) and motorized magnification and stage controls, which may alleviate the need to incorporate third-party components and facilitate automated multimode time-lapse imaging.

Objective Lenses and Contrasting Method

A basic set of objectives consists of 10×, 40× dry, 40× immersion, 100× immersion lenses and possibly a 60 or 63× immersion lens. Dry lenses are used primarily for scanning the samples and do not have to be expensive. However, immersion lenses should have as high a numerical aperture and light transmission efficiency as possible. Because images are typically collected near the center of the field, lenses highly corrected for flat field usually provide no detectable benefit and are more costly and less light efficient than simpler lenses such as Fluar lenses. All lenses for fluorescence imaging should be checked upon delivery for the quality of point-spread function, using fluorescent beads as the sample (see later).

For most applications, phase-contrast optics should suffice for scanning the sample and for collecting paired fluorescence and transmission images. The presence of quarter-wave plate in the phase lens does cause some (~<5%) light loss, although it is usually not serious enough to defeat the use of phase-contrast optics. The alternative is DIC optics, which requires

All rights reserved.

the repeated insertion and removal of an analyzer in the optical path when one shifts between DIC and fluorescence optics. This, and the higher cost, makes DIC optics less desirable in most cases.

Condenser

Unless the experiment involves high-resolution transmission optics or dark-field optics, a condenser with a long working distance should be used in conjunction with an inverted stand.

Control of Projection Magnification

It is critical to choose an optimal magnification for live cell imaging, balancing between signal intensity (favored by low magnification) and resolution (favored by high magnification). It is particularly important to match the final magnification with the pixel size of the detector (see later). Projection magnification may be controlled conveniently in some microscopes by switching the tube lens or by adding additional lenses (referred to as Optovar for Zeiss microscopes). New stands allow changes of magnification to be controlled automatically in time-lapse imaging.

Epi-illuminator and Fluorescence Filter Sets

Some new epi-illumination systems provide a light trap, which reduces the background stray light, and standard Kohler illumination with both field and aperture diaphragms. The aperture diaphragm may be used to control the lamp intensity as well as the angular span and depth of illumination. The light trap is useful for single molecular imaging, which is typically limited by the background.

There are several commercial sources of high-quality fluorescence filter sets. A handbook on the selection of filter sets may be found at the Web site of Chroma Optics. The main consideration is to balance signal strength (favored by cuton/cutoff filters or wide band-pass filters) against the reduction of signal crossover from probes of different colors (favored by narrow band-pass filters). The latter consideration is particularly important when an intense, long wavelength probe is used in conjunction with a weak, short wavelength probe. In addition to standard filter sets, multiband filters are now readily available that allow simultaneous illumination and/or detection of multiple fluorophores.

Heater Filter or Heat Mirror

When imaging living cells it is critical to remove the infrared component from the light source, as the fluorescence filter set may not be able to block infrared light. Failure to do so may cause not only heat damage to the cell, but also high background with some infrared-sensitive cameras. The filter (e.g., BG38) or heat-reflecting mirror may be placed either in front of the lamp or in the epi-illuminator. Attention should be paid to the UV transmission of these filters if UV excitation is to be used for imaging.

Lamps and Lamp Power Supplies

The system should include both a mercury arc lamp and a 100-W quartz-halogen lamp for epi-illumination, coupled through a selection mirror to the microscope. Contrary to common practice, the most suitable lamp for fluorescence imaging of live cells is often a 100-W quartz-halogen lamp. Unless the experiment involves single molecule or speckle imaging, quartz-halogen lamps are much more cost effective and are sufficiently intense for imaging most cellular structures while minimizing radiation damage. They also allow easy adjustment of the light intensity, using a variable, stabilized DC power supply.

The mercury arc lamp should consist of a well-shielded housing, power supply, and power supply cable to minimize the potentially damaging electromagnetic wave during ignition. Although some power supplies allow adjustment of the light intensity, the range of adjustment is limited. Therefore, it is often necessary to attenuate the light from mercury arc lamps using a set of neutral density filters to avoid radiation damage. Alternatively, the intensity may be controlled using the aperture diaphragm in the epi-illuminator as mentioned earlier.

Shutters

Electronic shutters should be used to control fluorescence excitation. These shutters should be used as much as possible to minimize the duration of illumination and should have the interface for computer control during automated time-lapse recording.

Cameras

Cooled CCD cameras are used for most fluorescent imaging applications. In choosing a camera, important parameters include quantum efficiency, noise level, pixel size and full-well capacity, and scanning frequency. In order to minimize the excitation light for imaging live cells, the camera should be as "sensitive" as possible, which generally means a high quantum efficiency, low noise, large pixel size, and slow scan rate. The sensitivity requirement must therefore be balanced against the required resolution (favored by a larger number of small pixels) and imaging rate (favored by a higher scanning frequency).

Slow-scan CCD cameras are generally limited in their frame rate. In addition, unless the sample is very intense, the signal-to-noise ratio is poor under short

exposures. This limits both their use for high-speed imaging and the ease in focusing the images. Focusing is facilitated with cameras using the shutterless, frame-transfer or interline CCDs, which are able to provide a continuous stream of images at video rate in addition to slow-scan digital signals.

Intensified CCD cameras are generally more suitable for high-speed imaging, although usually with a compromised quantum efficiency. Of particular interest are cameras that use CCD chips with the new electron amplification technology (e.g., photometric Cascade and Andor Ixon cameras), which allow both long-exposure and high-speed imaging at a high quantum efficiency.

Optical Coupling of Cameras

Coupling with the detector should be achieved with as few lens elements as possible. It is recommended to have several couplers with different magnification factors. In conjunction with different objective lenses and projection magnifications mentioned earlier, they allow a wide range of magnifications for both light-limiting and high-resolution applications. The Nyquist resolution criterion should be considered when choosing the magnification: each pixel should correspond to no more than half the required resolution limit on the sample. Due to the diffraction limit of the microscope, this distance needs not be smaller than 50 nm for most applications. The actual area imaged onto each pixel may be determined easily by taking an image of a scale standard (see later).

Vibration Isolation Table

A full-fledged vibration isolation table is necessary in adverse environment, e.g., in areas of heavy traffic or in high-rise buildings, or for demanding experiments of micromanipulations or single molecular imaging. Simple isolation measures may suffice otherwise. These include inner tires under the table or rubber isolation pads (Edmond Scientific) or tennis balls under a slab tabletop.

Motorized Stage and Focusing Control

A motorized XY stage is optional. It allows one to monitor multiple cells in separate regions and may increase the output greatly in time-lapse experiments. A motorized focusing control is required for optical sectioning, three-dimensional imaging, and automatic focusing. However, many simple imaging experiments may be better served without the complications of motorized stage controls.

Computer Hardware and Software

A high-end personal computer is required not only for image acquisition, but also for device control and data analysis. The system should have a high-capacity hard disk, a recordable CD/DVD drive for archiving and porting data, and double monitors to accommodate all the images and control windows. Before making a decision on the software package, it is advisable to prepare a list of application requirements, as many features seen in software demonstrations are visually dazzling but practically useless. The efficiency of a package should be judged by counting the number of mouse clicks or key strokes for setting up and triggering the most frequently used functions.

As a minimum for live cell imaging, the program should be able to control the camera, shutters, and motorized devices, to perform time-lapse recording, and to allow changes of recording parameters without stopping the recording. In addition, the user should be able to review dynamic processes as movies even during the recording. The program should also be able to perform automatic contrast enhancement (without losing the original intensity values) and to save images in a nonlossy file format with automatically generated or manually entered file names.

Microscope Incubators

There are a number of options available through microscope manufacturers and independent companies such as Bioptechs. Discussions of cell culture on microscopes may be found at the Web site of Bioptechs and in McKenna and Wang (1989).

There is no "ideal" culture device for all the applications. The range of possible devices varies from a heated stage, a heating collar for the objective lens, a small heated culture chamber, to a large enclosure that fits over the entire microscope. A heated stage is the most convenient but the least functional, as the point of observation is over an open area far away from the heat source. A heating collar for the objective lens applies heat much closer to the sample. However, it works only in conjunction with immersion lenses and has a limited area of heating. It is usually used in conjunction with an additional chamber or enclosure. Large microscope enclosures provide the most stable temperature; however, it must be designed carefully to provide convenient access. There are also a number of perfusion and heated culture chambers for microscopy. These chambers generally provide excellent optical and culture conditions; however, the associated wires and tubing may add to the inconvenience, and the sealed environment may not be compatible with micromanipulation experiments.

It is important to maintain the temperature stability to within a fraction of a degree, as even minor drifts in temperature can cause severe drifts in focusing and

sample positioning. In addition to heating, it is important to maintain the pH and osmolarity of the culture medium. While this should not be a problem with sealed chambers or perfusion chambers, open chambers should be used in conjunction with either a CO_2-independent medium (e.g., L-15) or injection of CO_2 into the incubator. It should be noted that HEPES-buffered media only slow down pH drift and are not suitable for long-term cultures by themselves. Osmolarity may also be a serious problem with open dishes in a heated environment. It may be controlled by replacing the medium periodically or by covering the medium with a layer of mineral oil (Sigma).

Testing Samples

Several testing samples should be prepared for characterizing the imaging system. First, a micrometern scale is essential for all microscopy laboratories for determining the final magnification. Second, a "flat field" sample is prepared by spreading a drop of appropriate fluorophores in 50% glycerol under a coverslip. It is useful for checking the uniformity of epi-fluorescence illumination and for setting the field diaphragm. Also essential is a sample of fluorescent beads. It is prepared by diluting 0.1-μm-diameter fluorescent latex beads (Molecular Probes) by ~10^5 into melt 1% agarose, and mounting a small volume (~20–50 μl) of the suspension on a heated glass slide under a coverslip, before letting the sample cool down. The bead sample is used for checking the combined optical quality of the imaging system. Defects not readily visible with cell samples are often recognized easily when one examines the images of single beads. Defocused beads should appear as radially symmetric disks or concentric rings.

Additional Equipment

Additional equipment may be required for special purposes. Multiwavelength imaging is often achieved with filter wheels at the illumination and/or detection optical path. In addition, devices such as Dual-View and Quad-View from Optical Insights generate composite images at different wavelengths. Spinning disk confocal heads have been used extensively for imaging fine structures in single cells. Its balance between light efficiency and resolution proves particularly suitable for cultured cells. Finally, total internal reflection fluorescence optics is being used extensively for imaging structures near the cell–glass interface, such as focal adhesions. Details of these approaches and devices are beyond the scope of this article; however, their potential use should be considered when designing the imaging system.

Cytoskeleton Proteins

Klemens Rottner, Irina N. Kaverina, and Theresia E. B. Stradal

I. INTRODUCTION

The visualisation of cytoskeletal proteins and their dynamics in live cells has led to invaluable insights into cytoskeleton-driven processes as various as cell migration, chromosome segregation during division, cytokinesis, and phagocytosis, as well as the establishment of cell–substrate or cell–cell adhesion. The cytoskeleton of eukaryotic cells can be grossly divided into three filamentous systems: actin filaments, microtubules, and intermediate filaments.

This article focuses on revealing the dynamics of the actin cytoskeleton and the microtubule system, as well as some proteins associating with them in interphase cells. It compares classical approaches with more recent advancements in this enormously growing field.

More specifically, this article discusses visualisation of the cytoskeleton using purified components chemically modified with fluorescent dyes and compares this method with ectopic expression of cytoskeletal genes fused to fluorescent protein tags such as green fluorescent protein (GFP). While the efficient introduction of fluorescently labelled cytoskeletal proteins is usually achieved by microinjection, which requires additional equipment and experimental effort, the expression of genes tagged to fluorescent proteins is obtained by transfection of the respective fusion constructs. We will show that both methods can lead to equally satisfying results, but as the transfection of nucleic acids seems to be continuously improved and developed further, the latter method may be used more frequently for most common tissue culture cells. However, because studies on cytoskeleton dynamics are sometimes performed on cell types that have so far not been reported to mediate the expression of ectopic genes, such as epidermal fish keratocytes, protein microinjection and subsequent analysis are still performed. In addition, we briefly mention the microinjection of specific antibodies to monitor the dynamics of cytoskeletal components.

Finally, this article gives examples of how to approach the visualisation of two distinct cytoskeletal components in the same living cell using two-colour fluorescence video microscopy.

II. MATERIALS AND INSTRUMENTATION

A. Equipment

1. Microscope

Inverted microscope (e.g., Axiovert 135TV, Carl Zeiss Jena GmbH) equipped for epifluorescence and phase-contrast microscopy with 40×/1.3NA and 100×/1.4NA oil immersion objectives, 1.6 and 2.5 optovar intermediate magnification, electronic shutters (e.g., Uniblitz Electronic 35-mm shutter including driver Model VMMD-1, BFI Optilas) to allow for computer-controlled opening of the light paths, filter wheel (e.g., LUDL Electronic Products LTD, SN: 102691 and driver SN: 1029595) to enable two-colour epifluorescence in combination with appropriate dichroic beam splitters and emission filters (Omega Optical Inc. or Chroma Technology Corp.), and tungsten lamps (Osram, HLX64625, FCR 12V, 100W) for both phase contrast and fluorescence light paths. Tungsten lamps are not as bright as mercury lamps, but the latter cause photodamage and bleaching with higher probability.

Copyright 2006, Elsevier Science (USA).
All rights reserved.

2. Data Acquisition

Preferably by a back-illuminated, cooled charge-coupled-device camera (e.g., Princeton Research Instruments TKB 1000 × 800, SN:J019820; Controller SN:J0198609) driven, for instance, by IPLab (Scanalytics Inc.) or Metamorph software (Universal Imaging Corporation). Dependent on cell types and/or processes studied, this "epifluorescence setting" can be extended to the various options of confocal microscopy (see contributions on confocal imaging within this volume).

3. Microinjection

Commercial microinjection capillaries (Femtotips I; Cat. No.: 5242952.008, Eppendorf AG) or, alternatively, self-made needles requiring a "needle puller" (e.g., Model PN-30, Narishige International LTD), mechanical (Cat. No.: 520137, Leica Microsystems), oil-pressure-driven (e.g., Model M0188NE, SN:99069, Narishige International LTD), or electronic (e.g., Model 5171, Eppendorf AG) micromanipulators used in combination with an air pressure device (e.g., Transjector 5246, Eppendorf AG); flexible microloaders for loading microinjection capillaries (Cat. No.: 5242956.003, Eppendorf AG).

4. Centrifuges

Cooled high-speed benchtop centrifuges (e.g., Biofuge *fresco*, Heraeus) to pellet protein aggregates prior to injection.

5. Heating

Open (e.g., Series 20 chamber platform, Model PH4, Warner Instruments used with heater controller model TC-324B, SN:1176) or, alternatively, closed heating chambers (e.g., Model FCS2, Bioptechs Inc.).

Cells growing at room temperature are observed on coverslips mounted to the bottom of plastic dishes harbouring a central hole or in comparable commercial devices.

6. Coverslips

Round glass coverslips, 15 or 40 mm in diameter, cleaned in 6/4 ethanol/HCl (37%), washed extensively with H_2O, dried, and sterilised by exposure to ultraviolet light or in a dry heat sterilizer at 220°C (ethanol: Sigma, Cat. No.: E-7023; HCl: Sigma, Cat. No.: H-7020).

7. Basics

General equipment and plastic-ware (e.g., from Becton Dickinson Biosciences or Greiner Bio-One GmbH) for molecular biology techniques and tissue culture.

B. Cells and Media

1. Cells

Mouse melanoma cells B16-F1 (American Type Culture Collection: CRL-6323) and goldfish fin fibroblasts (CAR, American Type Culture Collection: CCL-71).

2. Growth

All reagents are from Invitrogen Corp. unless stated otherwise. For B16-F1: Dulbecco's modified Eagle's medium (Cat. No.: 41965-039) supplemented with 10% fetal calf serum (FCS, PAA Laboratories, Clone, Cat. No.: A11-041), 2 m*M* glutamine (Cat. No.: 25030-024), 1% antibiotics (Cat. No.: 15070-063). For CAR: basal Eagle's medium with Hank's balanced salt solution (Cat. No.: 21370-028), 15% serum (Hyclone, Cat. No.: SH30070.03), 1 m*M* glutamine, 1 m*M* nonessential amino acids (Cat. No.: 11140-035), and 1% antibiotics. Upon confluence, cells are detached using trypsin (Cat. No.: 25300-054) and seeded according to standard protocols.

3. B16 Medium for Microscope

Ham's F12 HEPES-buffered medium (Sigma, Cat. No.: N8641) including complete supplements of the regular growth medium (see point **2**).

4. Substrates

Laminin (Sigma, Cat. No.: L2020) or fibronectin (Roche, Cat. No.: 1051407).

5. Lipofection

With Superfect transfection reagent (Qiagen GmbH, Cat. No.: 301305) or FuGENE6 (Roche, Cat. No.: 1 814 443).

C. Proteins and Constructs

1. *TAMRA-vinculin*: From turkey gizzard, coupled to carboxytetramethylrhodamine (5'-TAMRA) succinimidyl ester (Molecular Probes, Cat. No.: C-2211) as described (Rottner *et al.*, 1999) and upon addition of 2 mg sucrose/mg protein stored in 30-µl aliquots at 1 mg/ml at –70°C
2. *TAMRA-α-actinin*: From turkey gizzard, kindly provided by M. Gimona (Salzburg) and fluorescently modified and stored as described for vinculin
3. *Cy3-tubulin*: As described (Hyman, 1991); for a protocol of tubulin labelling (by John Peloquin) we recommend http://www.borisylab.nwu.edu/pages/protocols/cy3tub.html
4. *EGFP-tubulin*: Kindly provided by M. Geese (Braunschweig), comprises murine β3-tubulin fused into EGFP-C2 (Clontech, Cat. No.: 6083-1)

5. *EGFP-EB1*: As described (Stepanova *et al*., 2003)
6. *EGFP-p16-B*: p16B-cDNA, also known as ARPC5B (Millard *et al*., 2003), was amplified from a human EST clone (Acc. No.: 12652556, RZPD cloneID IRALp962P167) and subcloned into EGFP-C1 (Clontech; Cat. No.: 6084-1)
7. *Zyxin-EGFP*: As described (Rottner *et al*., 2001)
8. *Zyxin-dsRED*: As described (Bhatt *et al*., 2002)

III. PROCEDURES

Solutions

All chemicals are from Sigma-Aldrich.

1. *Phosphate-buffered saline (PBS) working solution*: 140 m*M* NaCl (Cat. No.: S-7653), 2.7 m*M* KCl (Cat. No.: P-1338), 10 m*M* Na_2HPO_4 (Cat. No.: S-7907), 1.8 m*M* KH_2PO_4 (Cat. No.: P-0662), pH 7.4
2. *Urea*: 2 *M* in H_2O (Cat. No.: U-0631)
3. *Laminin coating buffer*: 50 m*M* Tris (Cat. No.: T-1503) adjusted with HCl to pH 7.5, 150 m*M* NaCl
4. *Microinjection buffer (for vinculin and α-actinin)*: 2 m*M* Tris–acetate (acetic acid: Cat. No.: A-0808), 50 m*M* KCl (Cat. No.: P-1338), 0.1 m*M* dithioerythritol (DTE, Cat. No.: D-8255), pH 7.0. Note that microinjection buffers vary significantly depending on the cytoskeletal protein injected [e.g., buffers for microinjecting actin generally lack KCl (Wang, 1984), whereas buffers for injecting myosin II require KCl (up to 450 m*M*) in order to avoid polymerisation of the respective component in the needle (Verkhovsky and Borisy, 1993)].
5. *Microinjection buffer (for tubulin)*: 80 m*M* PIPES (Cat. No.: P-6757) adjusted with KOH (Cat. No.: P-6310) to pH 6.8, 1 m*M* $MgCl_2$ (Cat. No.: M-2670), 1 m*M* EGTA (Cat. No.: E-1644) (Fig. 1).

A. Visualisation Using a Fluorescently Conjugated Protein

Steps

1. Various different fibroblast cell lines survive microinjections better when grown on fibronectin. For coating of coverslips, dissolve fibronectin at a concentration of 1 mg/ml in 2 *M* urea and store at 4°C.
2. Dilute fibronectin stock 1:20 to 50 µg/ml with PBS and coat sterile coverslips for 1 h at room temperature (150 µl for 15-mm-diameter coverslips). Before seeding the cells, wash thoroughly with PBS to remove urea (two to three times).
3. Upon washing, seed the cells onto coverslips in a petri dish and let them attach and spread for 12–72 h in an incubator.
4. Thaw an aliquot of fluorescently coupled protein. If not in appropriate buffer, dialyse the sample into microinjection buffer using Slide-A-Lyzer (e.g., Pierce, 10 kDa cutoff Cat. No.: 66415) or a similar device for the dialysis of small volumes and concentrate using microcon concentrators (Amicon, YM-10, Cat. No.: 42407) (for proteins such as vinculin or α-actinin, concentrations of 0.5–1 mg/ml are ideal for injections).
5. Spin the probe for microinjection in a cooled centrifuge at maximum speed (approximately 10,000 *g*) for at least 30 min before loading the needle in order to remove protein aggregates that may clog up the needle tip.
6. Mount cells onto the microscope in a chamber freely accessible to the microinjection needle.
7. Upon loading of the needle from the back using a flexible pipette tip, carefully inspect the needle tip for the absence of air bubbles. If required, remove them by gently hitting the needle shaft, but proceed rapidly in order to avoid drying of the tip.
8. Apply pressure (20–100 hPa) to the needle holder, attach needle, and rapidly move needle into the medium. (The "background pressure" applied before entering the medium is required to avoid sucking up of the medium due to capillary force of the needle tip.)
9. Bring the needle close to the cells.
10. Before injections, check the needle flow by fluorescence.
11. In case of flow, gently inject the cells, manually or using a so-called half-automatic system (Eppendorf AG, see earlier discussion). For manual injections, carefully approach the membrane and remove immediately upon needle flow into the cell.
12. Upon injection of a sufficient number of cells, allow the cells to recover and the cytoskeletal proteins to incorporate (e.g., 30–60 min). For actin, full incorporation into the cytoskeleton may take up to 2 h. In contrast, vinculin targets to focal adhesions within minutes.
13. After incorporation of the injected protein, darken the room and search for interesting cells using epifluorescence and preferably a 40× oil immersion lens. In case no fluorescent cells can be found by eye, it will be difficult to pick up a satisfying signal using a back-illuminated CCD camera.
14. After selection of an interesting cell, switch to higher magnification (100×) with or without optovar intermediate magnification and test for the minimal exposure time required to get a good signal/noise ratio. (For important details on fluorescence imaging and image processing, see articles by Anderson and by Wang.)
15. In order to record a stack of fluorescent images, set the appropriate number of images to be taken and

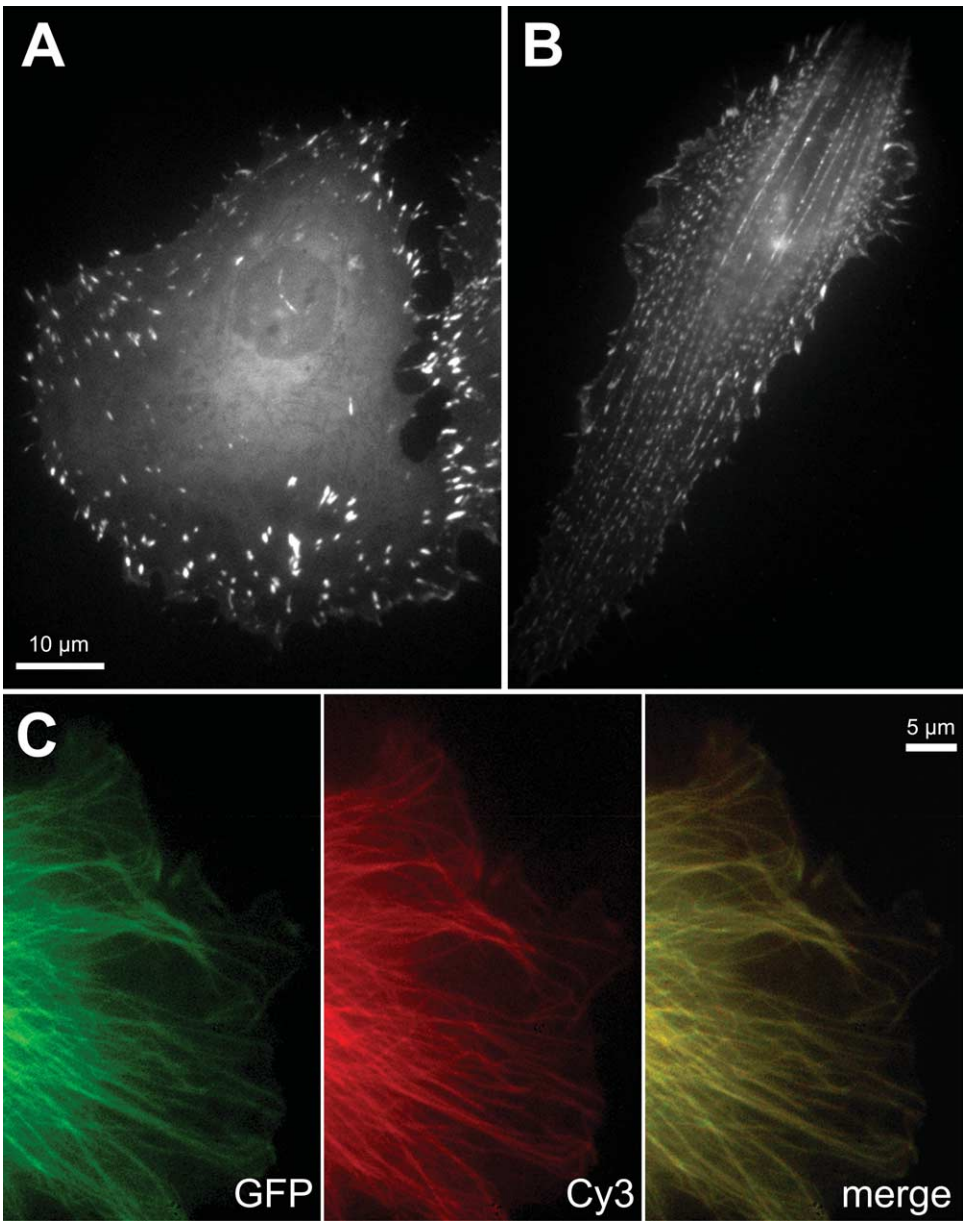

FIGURE 1 Examples for specific incorporation of fluorescently tagged, microinjected proteins: CAR fish fibroblasts microinjected with TAMRA-vinculin (**A**) or TAMRA-α-actinin (**B**). Note the specific recruitment of both probes to focal adhesions and the additional periodic incorporation of α-actinin into stress fibres. (**C**) EGFP-β-tubulin (kind gift of M. Geese, Braunschweig) expression (green) in a CAR cell additionally microinjected with Cy3-tubulin (kind gift of F. Severin, Dresden; red). Note that both probes reveal an identical microtubule pattern (merge) and can therefore be used equally to study microtubule dynamics.

the time period in between individual frames (dependent on experiment). In order to avoid photodamage, illuminate cells with strong fluorescent light as rarely as possible. Avoid focusing in between frames using epifluorescence; focus using transmitted light, for example, in phase contrast, because for transmitted optics, much lower lamp intensities are required.

B. Visualisation Using a GFP-Tagged Protein (upon Transient Expression)

Steps

1. Purify the expression vector for your GFP-tagged open reading frame of interest using standard DNA purification columns (e.g., Qiagen-tip 500); dilute the

construct in H_2O in concentrations of not less than 0.5 µg/µl.

2. Seed the cells into 3.5-cm-diameter dishes (Falcon, Cat. No.: 35.3001) and allow them to attach and spread for 12–24 h.

3. Transfect cells in 3.5-cm dishes 12–24 h according to standard protocols, e.g., using FuGENE (Roche; 3 µl FuGENE/µg DNA) or Superfect transfection reagent (Qiagen; 6 µl Superfect/µg DNA). In our hands, 1–2 µg of DNA is sufficient per 3.5-cm-diameter dish.

4. Detach transfected cells using trypsin and seed onto coverslips. For studying the dynamics of GFP-tagged proteins during the actin-based motility of B16-F1 melanoma cells, we coat coverslips with 25 µg/ml laminin in laminin-coating buffer (1 h at room temperature); laminin stock (1 mg/ml) is stored in small aliquots at –20°C.

5. Upon spreading (for B16-F1 cells, wait 3–5 h), mount coverslips on the microscope using an appropriate open or closed chamber system, including a heating device if required. Compensate for lack of CO_2 by using HEPES-buffered growth media if needed. Changing to HEPES-buffered media may require some adaption time (dependent on cell type).

6. Darken the room and search for transfected cells with your eyes with epifluorescence preferably using a 40×/1.3NA oil immersion lens.

7. Upon identification of an interesting cell, proceed as in steps **13** and **14** in Section III,A.

IV. GENERAL COMMENTS ON FLUORESCENT TAGGING

In order to obtain reliable data on the dynamics of any given cytoskeletal protein, it is important to consider potential interference of the fluorescent tag with proper subcellular targeting of the protein or with general protein function. It is therefore essential to make sure that the fluorescent analogue of a given protein incorporates identically to the endogenous protein, which can be tested for by cross-staining with appropriate antibodies. Chemical coupling of a purified protein to a conventional fluorescent tag such as fluoresceine or rhodamine can be advantageous over a fluorescent protein tag (such as GFP) due to the much lower molecular size of the former. However, certain coupling buffers (dependent on coupling chemistry) may affect proper protein folding and therefore lead to irreversible damage to a given protein avoiding its proper incorporation into the cytoskeleton. In general, monovalent dyes are advantageous over bi- or tetravalent dyes because the latter can cause irreversible protein multimerisation due to the coupling reaction (which can be tested for by SDS–PAGE).

For the fusion of cDNAs to fluorescent protein tags, the most common of which currently is the enhanced green fluorescent protein (EGFP, Clontech), also known as GFPmut1 (Cormack *et al*., 1996), we recommend always comparing the fusion of the given cDNA to both the N and the C terminus of the tag because it is difficult to predict whether the fusion to the protein tag on either side may interfere with protein function. For instance, in order to generate reliable fusion proteins for the visualisation of the actin nucleating complex Arp2/3 (Higgs and Pollard, 2001), we have so far generated N- and C-terminal fusions to each of the seven components and tested their incorporation in cells, with varying results. Some of the constructs showed poor incorporation or even interfered with lamellipodia protrusion (p34-EGFP). Good results were obtained with small molecular weight components of the complex (p16 and p21), although both N- and C-terminally tagged Arp3 also proved useful (Stradal *et al*., 2001). Figure 2 shows the dynamics of p16B (ARPC5B), a novel isoform of p16 (Millard *et al*., 2003) fused to the C terminus of EGFP in B16-F1 cells. In addition, spacers between EGFP and the gene of interest can be crucial for incorporation of the fusion constructs (Geese *et al*., 2000).

As an alternative possibility to follow the dynamics of cytoskeletal proteins, it is worth mentioning purification, fluorescent coupling, and microinjection of monoclonal antibodies directed against a cytoskeletal protein, which has been used in the past for zyxin (Rottner *et al*., 2001). This requires that the epitopes are freely accessible in the native protein and that injected antibodies do not interfere with proper protein positioning and function, prerequisites that can again only be evaluated experimentally.

V. CHOICE OF COMBINATIONS FOR DUAL LABELING

As with conventional fluorescent dyes, fluorescent protein tags today also come in different colours. As opposed to multiple labellings of fixed samples (see article by Prast *et al*.), for live cell imaging as described here, only dual-labelling experiments have proven practical so far, probably due to the lack of sufficiently bright dyes excitable by UV excitation. We provide examples here for imaging EGFP-tagged proteins together with injected proteins tagged to rhodamine derivatives or to Cy3 (see Fig. 3). An important

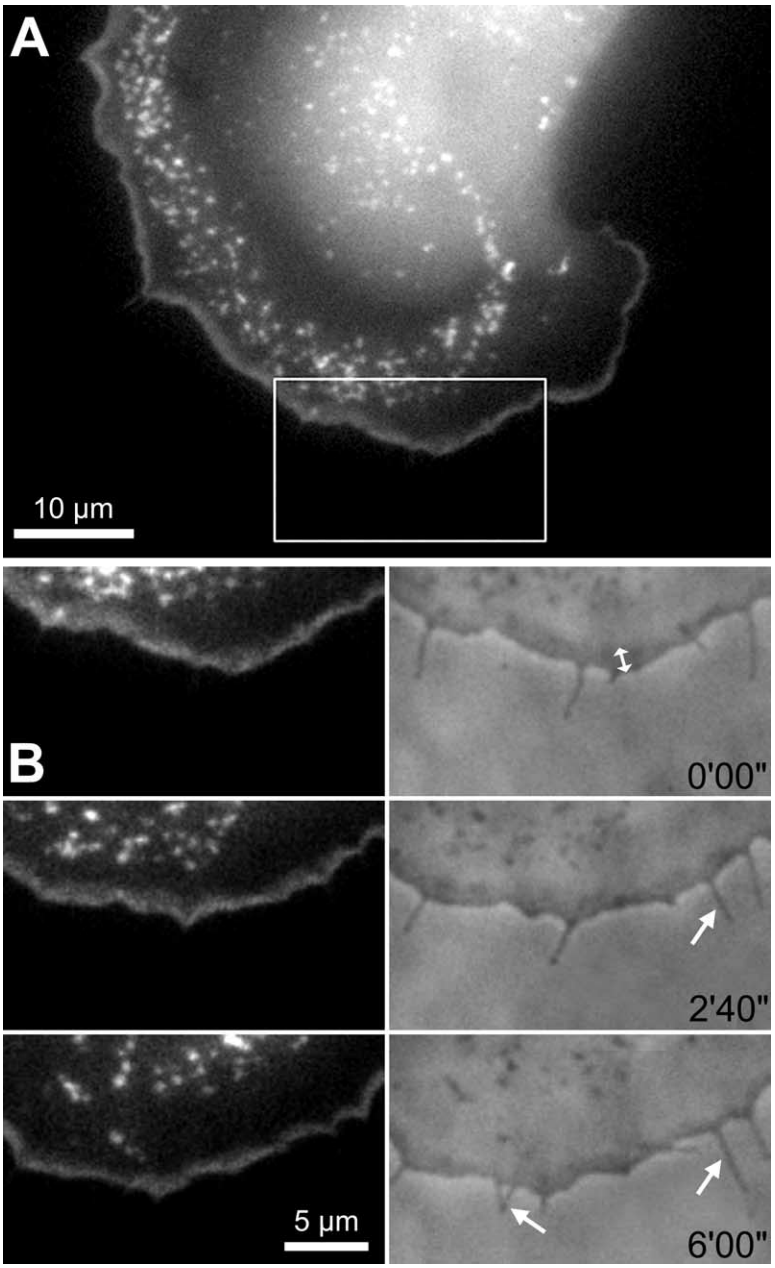

FIGURE 2 Arp2/3 dynamics in motile B16-F1 melanoma cell as revealed by transient expression of the GFP-tagged novel isoform p16B (ARPC5B). (**A**) Note that EGFP-p16B incorporated into the lamellipodial actin meshwork at the cell periphery and into highly dynamic surface ruffles, also known as actin flowers or clouds, as expected. (**B**) The time-lapse sequence from the region boxed in **A** (right panel: phase contrast) reveals reorganisation of the Arp2/3 complex during advancement of the cell periphery. Time is in minutes and seconds. Note the relatively constant lamellipodium width (double-headed arrow in **B**) during forward movement and the virtual exclusion of this Arp subunit from protruding filopodia (arrows).

alternative is the use of the red fluorescent protein from *Discosoma* sp. (dsRED), exemplified here by a dsRED-zyxin probe combined with EGFP-tubulin (Fig. 4). However, in contrast to EGFP, dsRED and even the improved variant termed dsRED2 (Clontech) are known to form a tetramer when fluorescent (Baird *et al*., 2000). Unfortunately, this feature can interfere with the function of certain cytoskeletal proteins. For instance, expression of a dsRED-calmodulin fusion protein was reported to cause severe aggregation and

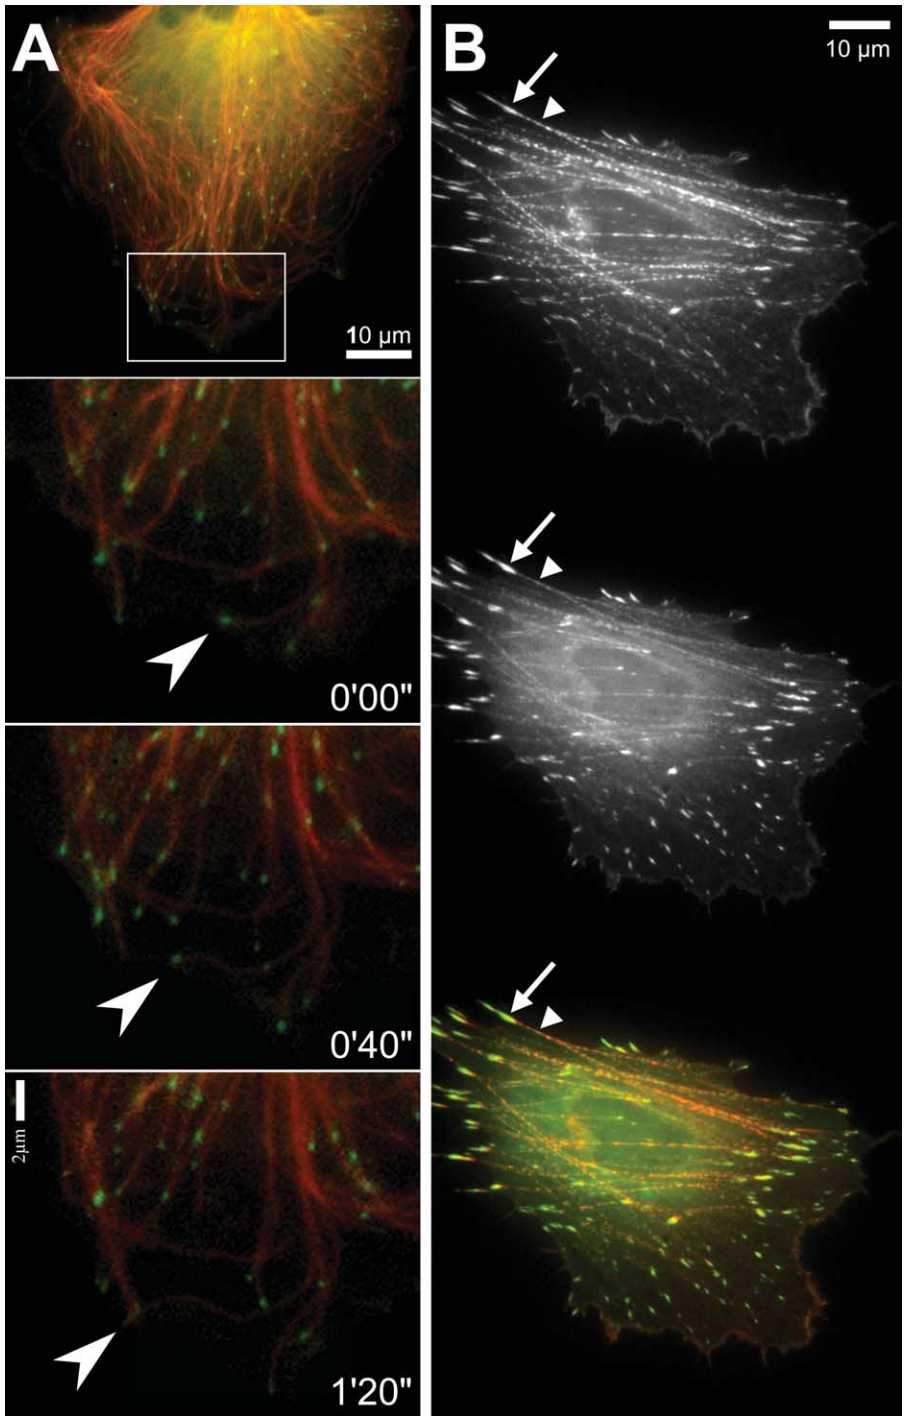

FIGURE 3 Examples of simultaneous visualisation of two distinct cytoskeletal components in the same cell. (**A**) Dynamics of microtubule plus ends in fish fibroblast CAR. Microinjected Cy3-tubulin (red) combined with ectopically expressed EGFP-EB1 (kind gift of A. S. Akhmanova, Rotterdam; green). Top image, overview. Bottom images, zoom into the boxed region in the overview, subsequent frames, time shown in minutes and seconds. Note that EB1 localises to the tips of growing microtubules (e.g., arrowheads in frames 0′00″ and 0′40″), but is absent from pausing or shrinking microtubule ends (e.g., arrowhead in frame 1′20″). (**B**) EGFP-zyxin expressing CAR cell microinjected with TAMRA-α-actinin: As shown in Fig. 2B, the α-actinin probe (top panel and red in the merged image at the bottom) mainly incorporates along stress fibers (arrowheads) and in focal adhesions (arrows). Zyxin (middle panel and green at the bottom), thought to be recruited to the cytoskeleton via α-actinin binding (Reinhard *et al.*, 1999), shows a similar, although not identical distribution. The merged image (bottom) reveals that zyxin (green) is enriched in focal adhesions, whereas α-actinin (red) targets more prominently to stress fibres, indicating that the subcellular positioning of zyxin is more complex than simple α-actinin-mediated recruitment.

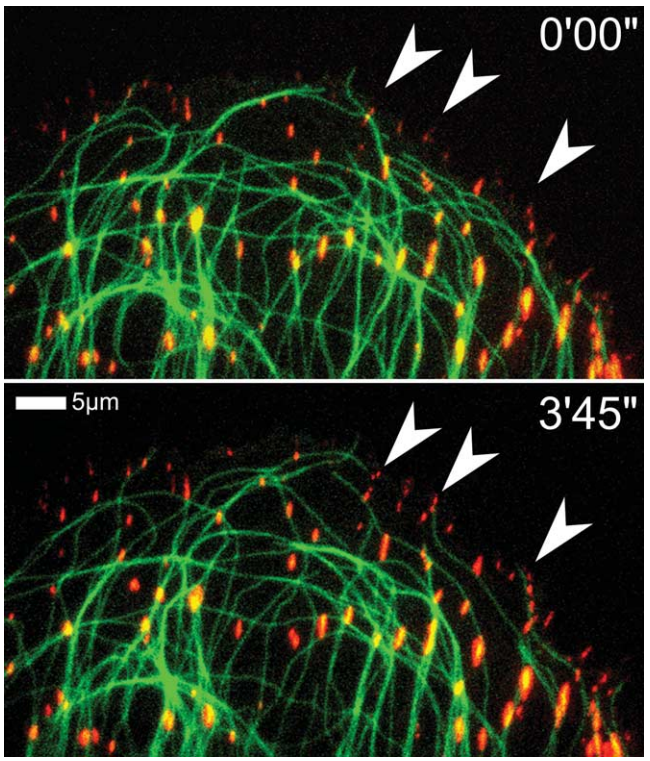

FIGURE 4 Simultaneous visualisation of two cytoskeletal components using two distinct fluorescent protein tags. Combination of EGFP-β-tubulin (pseudocoloured red) and dsRED-zyxin (kind gift of A. Huttenlocher, Madison; green) expressed ectopically in a CAR fish fibroblast. The combination reveals the formation and microtubule targeting of focal adhesions on this slowly protruding cell edge. Subsequent frames, time shown in minutes and seconds. Note newly formed adhesions (frame 3'45") and microtubules associated with them (arrowheads).

therefore mislocalisation of the tagged protein (Mizuno *et al.*, 2001).

As an alternative, mutations in EGFP have led to spectrally separable variants, ECFP (cyan) (Heim and Tsien, 1996) and EYFP (yellow) (both Clontech), which were used successfully for dual-labelling experiments of cytoskeletal proteins in the past (Geese *et al.*, 2002). However, the excitation and emission maxima of both dyes are relatively close, making it more difficult to separate them clearly. In addition, ECFP is significantly dimmer than EYFP, hence the simultaneous imaging of complex cytoskeletal structures may prove more difficult using these variants as compared to the red/green combinations given earlier.

Exciting more recent developments include far red fluorescent proteins, which appear separable not only from EGFP, but also from ECFP and EYFP. One was obtained from mutating a nonfluorescent chromoprotein from *Heteractis crispa*, termed HcRED-2A in (Gurskaya *et al.*, 2001), and is available as HcRED-1 (Clontech). The protein is a dimer and can now also be obtained as a "monomeric" tandem variant (evrogen.com).

In addition, Tsien and colleagues have developed a true monomeric red fluorescent protein (termed mRFP1) with excitation and emission peaks at 584 and 607, respectively, by introducing multiple mutations into dsRED (Campbell *et al.*, 2002). Comparisons of HcRED-1, its tandem variant, and mRFP1 as fusion proteins with actin and other cytoskeletal components revealed that mRFP1—at least in fusion with the components tested—was superior to the former red variants, mainly due to the lack of aggregation (not shown). Hence, although about 25% of the brightness of the original dsRED, the mRFP1 probe in combination with EGFP is expected to prove very useful for live cell dual imaging.

Acknowledgments

We thank Drs. Mario Gimona and Fedor Severin for kindly providing purified smooth muscle proteins and Cy3-tagged tubulin, respectively, Dr. R. Y. Tsien for mRFP1 cDNA, Drs. Anna S. Akhmanova, Marcus Geese, and Anna Huttenlocher for expression constructs, and Petra Hagendorff for excellent technical assistance.

CHAPTER

12

Systematic Subcellular Localization of Novel Proteins

Jeremy C. Simpson and Rainer Pepperkok

I. INTRODUCTION

The completion of several genome sequencing projects now reveals many thousand open reading frames (ORFs) encoding novel proteins of unknown function. One of the major challenges in the next years will be to allocate functional data to each of these new proteins and to determine how they interact with each other to form the complex regulatory networks underlying fundamental processes of life and disease. Determining the subcellular localisation of these novel ORFs is one important step to be taken in order to bridge the gap between known sequence and unknown function. One way to achieve this may be to systematically raise protein specific antibodies and use them subsequently to determine localisation by immunofluorescence microscopy. However, raising antibodies on such a scale is laborious and expensive. A good alternative to subcellular localisation by immunofluorescence using antibodies is the tagging of the novel ORFs with the green fluorescent protein (GFP) or its spectral variants (Tsien, 1998, 1998, 2002; Zhang *et al*., 2002) followed by subcellular localisation of the GFP-tagged fusion proteins in living cells or multicellular organisms (Ding *et al*., 2000; Simpson *et al*., 2000). This approach has now become much simpler and faster by advances in restriction enzyme-free cloning methods, such as the Gateway system from Invitrogen (Walhout *et al*., 2000), which enable hundreds of defined ORFs to be transferred into GFP vectors in a matter of days. GFP tagging is not only less expensive and perhaps faster, but has the critical advantage compared to immunofluorescence that the expressed GFP fusion proteins can be localised in living samples, which reduces the risk of artefacts caused by fixation and subsequent permeabilisation as is necessary for immunofluorescence. The GFP tag further enables determination of the dynamics of the fluorescent protein, e.g., by time-lapse fluorescence microscopy or fluorescence recovery after photobleaching (FRAP; Bastiaens and Peppperkok, 2000), and thus permits a further level of functional characterisation. This article describes the basic methodology used to systematically determine the subcellular localisation of novel human proteins as they have been derived by past and current cDNA sequencing projects worldwide.

II. EXPERIMENTAL STRATEGY

Our experimental strategy to systematically localise novel proteins is summarised schematically in Fig. 1. It is based on tagging of the respective cDNAs with the GFP and subsequent expression and localisation of the GFP fusion proteins in living and fixed cells. We start the subcellular localisation procedure with bioinformatic analyses of the sequences under study in order to identify organelle-specific targeting sequences or related proteins of which the localisation has already been determined. These data are always considered alongside the final experimental results obtained.

Because localisation is wholly dependent upon targeting sequences within the protein of interest, tagging of a protein with GFP always carries the risk that these targeting sequences become masked, which will finally lead to a mislocalisation of the tagged protein. We address this problem by tagging the proteins separately at their N and C termini and determining the localisation of both fusion proteins. If N- and C-

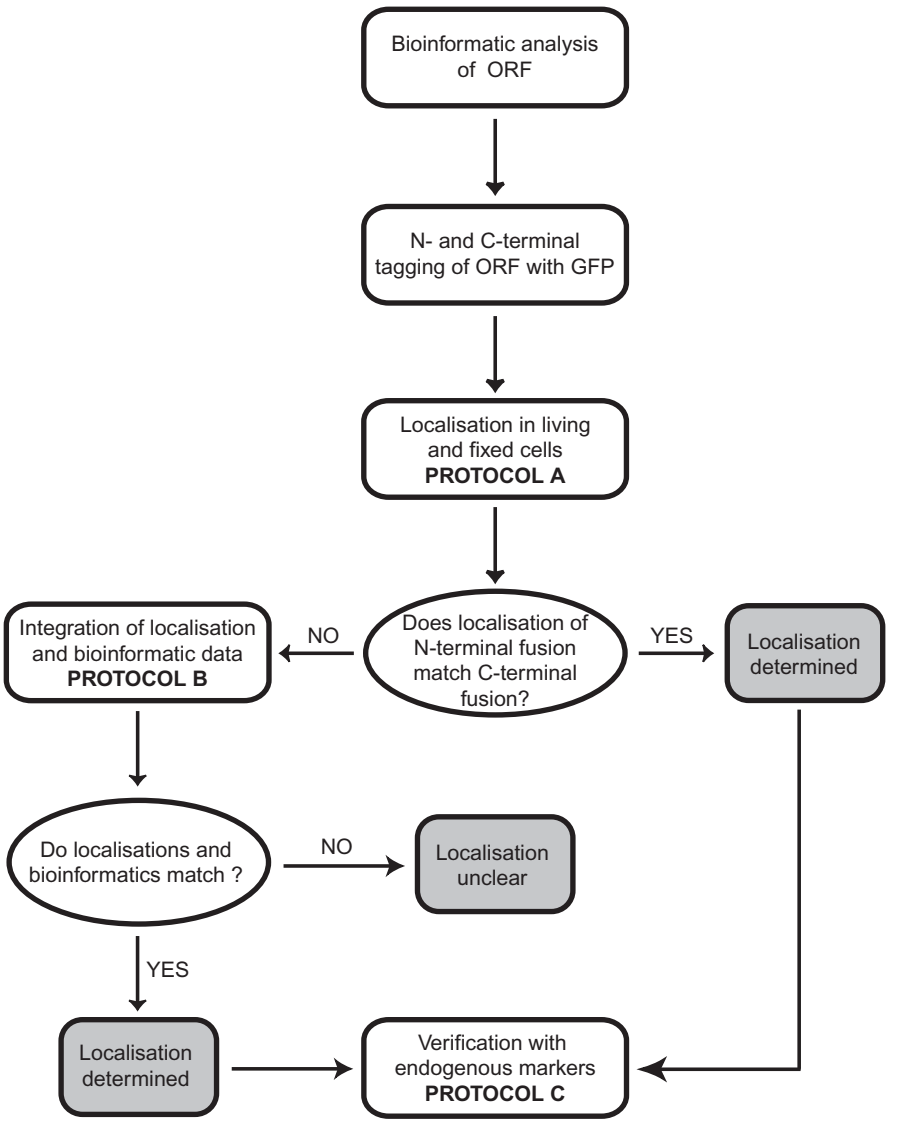

FIGURE 1 Experimental strategy to systematically localise novel proteins in cells. For details, see text.

terminal fusions show identical localisation patterns, one can be confident that the subcellular localisation determined is correct. If the N- and C-terminal fusions give different results, data are considered with respect to the bioinformatic predictions. The localisation that best matches the bioinformatic data is then considered as the correct one. Finally, data are verified by colocalisation of the GFP fusion proteins with established endogenous organelle-specific markers.

Localisation studies can be performed in a variety of cultured cell lines, the choice of which should preferably match the source of the ORFs. However, we prefer to use the monkey kidney fibroblast cell line, Vero (ATCC CCL-81), as these cells have the advantages that they are large in diameter (about 60 µm), display a very clear subcellular morphology (see examples shown in Fig. 2), and are particularly flat, which makes them ideal for imaging using wide-field fluorescence microscopy. Furthermore, we have so far observed no discrepancies of protein localisations in these cells compared to HeLa (ATCC CCL-2) cells, which are of human origin. In cases where a clear localisation of the GFP-tagged fusion protein to a cellular compartment or structure is difficult to achieve in Vero or HeLa cells, we use more specialised cell types for the localisation experiments, such as rat primary hippocampal neurons or SH-SY5Y human neuroblastoma cells (ATCC CRL-2266), when the protein under investigation is, for example, derived from a brain-specific cDNA library.

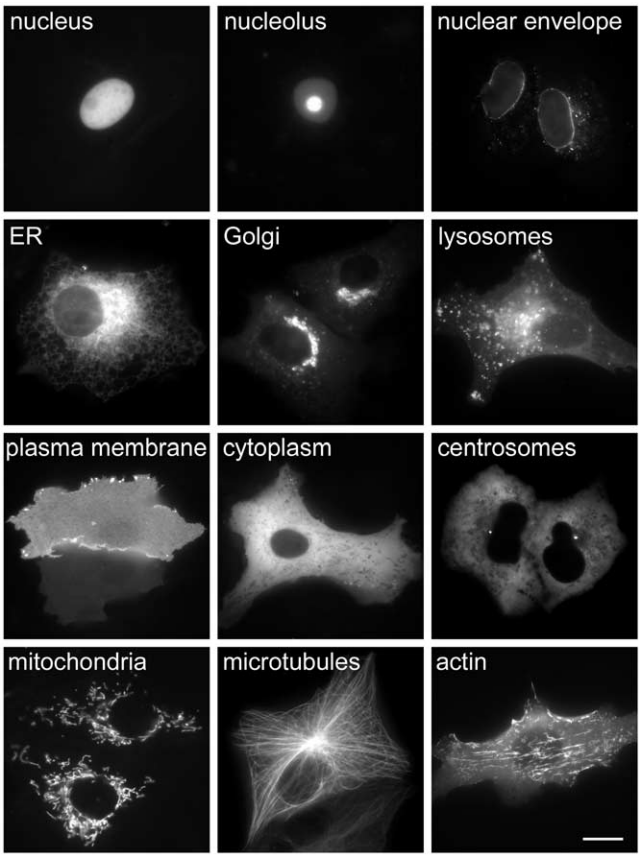

FIGURE 2 Examples of subcellular localise observed in live Vero cells. Vero cells expressing a variety of GFP-tagged proteins localise to different sub-cellular compartments. More examples of localisations can be seen at http://gfp-cdna.embl.de. Bar: 10 µm.

III. MATERIALS AND INSTRUMENTATION

Vero cells (ATCC CCL-81) are grown in minimal essential medium (MEM) containing Earle's salts (Cat. No. 21090-022) with the addition of 2 m*M* L-glutamine (Cat. No. 25030-024) and 100 U/ml penicillin/100 µg/ml streptomycin (Cat. No. 15140-122) all from Invitrogen and 10% foetal calf serum (FCS) (Cat. No. A15-043) from PAA Laboratories. Trypsin–EDTA (Cat. No. 25300-054) is from Invitrogen. Live cell imaging is performed in "Imaging Medium," consisting of MEM containing Earle's salts but lacking phenol red, FCS, and antibiotics (Cat. No. M3024) from Sigma. For transfections, OptiMEM with Glutamax (Cat. No. 51985-026) is from Invitrogen and the FuGENE6 transfection reagent (Cat. No. 1814443) is from Roche. High-purity cycloheximide powder (Cat. No. 239764) is from Calbiochem. Methanol (Cat. No. 106009) and glycine (Cat. No. 104201) are from Merck. Paraformaldehyde (PFA) (Cat. No. P6148) and Triton X-100 (Cat. No. T9284) are from Sigma. Cy5-conjugated secondary antibodies (antimouse, Cat. No. PA45002, and antirabbit, Cat. No. PA45004) are from Amersham Biosciences. Alexa Fluor647-conjugated secondary antibodies (antisheep, Cat. No. A-21448, and antigoat, Cat. No. A-21447) are from Molecular Probes. Standard cell culture plasticware is from Falcon / BD Biosciences. Glass-bottomed live cell imaging dishes (35 mm, with 10 mm number 1.5 coverglass) (Cat. No. P35G-1.5-10-C) are available from MatTek, and Lab-Tek 8-well chambered cover glass dishes (Cat. No. 155411) are from Nalge Nunc. Cells are imaged on a Zeiss Cell Observer System consisting of a Zeiss Axiovert 200 inverted microscope equipped with a Zeiss Plan-apochromat 63×/1.4 NA objective and standard CFP (Cat. No. 1196-682), GFP (Cat. No. 1114-459), YFP (Cat. No. 1196-681), and Cy5/Alexa647 (Cat. No. 488026) filter sets. Images are captured with a CCD camera (Zeiss Axiocam) using Zeiss Axiovision 3.1 software. Images are contrast adjusted and merged using Photoshop 6.0 from Adobe.

IV. PROCEDURES

A. Localisation of GFP-Fusion Proteins in Living and Fixed Cells

Solutions

1. Prepare imaging medium by dissolving 9.4 g of the powder in 900 ml water. Add 0.5 g of $NaHCO_3$, HEPES pH 7.4 to 25 m*M*, and L-glutamine to 2 m*M* final concentration. Adjust the pH to 7.0 with 1 *N* NaOH, make up volume to 1 litre, and then sterilise by filtration through a 0.22-µm filter. Store in 50-ml aliquots at 4°C for up to 3 months.
2. Prepare a 3% solution of PFA by dissolving 15 g of PFA powder in 400 ml of phosphate buffered saline (PBS) and heating the solution to 65°C whilst stirring. When dissolved, add 50 µl of 1 *M* $CaCl_2$ and 50 µl of 1 *M* $MgCl_2$. Adjust pH to 7.4 with 1 *N* NaOH, make up volume to 500 ml, filter through Whatman filter paper (No. 1), and store in 10-ml aliquots at –20°C. Aliquots should not be refrozen after use.

1. Plating Cells on Live Cell Imaging Dishes

Steps

1. The day prior to transfection, take a 90% confluent 10-cm dish of Vero cells and harvest the cells with 3 ml of trypsin–EDTA solution.

2. Resuspend the cells in a total volume of 20 ml of complete MEM growth medium.
3. Use this cell suspension to prepare either individual 35-mm live cell dishes or 8-well chambered cover glass dishes.
4. For the individual live cell dishes, mix 0.5 ml of the cell suspension with 1.5 ml of complete MEM for each dish. For 8-well dishes, mix 0.05 ml of the cell suspension with 0.25 ml of complete MEM for each well.
5. Incubate dishes in a humidified CO_2 incubator at 37°C overnight.

2. *Transfection of Cells*

Steps

1. On the day of transfection prepare the DNA and transfection reagent. Aliquot each DNA to be tested into a fresh tube, using 1 µg for the individual dishes and 0.1 µg for each well of the 8-well dishes.
2. Into fresh tubes aliquot OptiMEM (100 µl) followed by 3 µl of the FuGENE6 reagent (35-mm dishes) or OptiMEM (50 µl) followed by 0.3 µl of FuGENE6 (8-well dishes). Ensure that the transfection reagent does not come into contact with the side of the tube.
3. Mix briefly by pipetting only and then incubate at room temperature for 5 min.
4. Transfer the FuGENE6-OptiMEM mixture into the DNA, mix by pipetting, and incubate at room temperature for 30 min.
5. Add the complete transfection mixture dropwise to the cells and then mix by swirling the dishes.
6. Incubate in a humidified CO_2 incubator at 37°C.

3. *Imaging of Living Cells*

Localisations of GFP-tagged proteins may change due to the expression levels and therefore we use cells expressing low and moderate levels of the protein under investigation for our localisation experiments.

Therefore, cells are imaged at various times, typically 14, 20, and 40 h after transfection. This results in cells expressing low, moderate, and high amounts of the GFP-tagged proteins and gives further information how the expression level might influence localisation.

Steps

1. Replace the transfection medium with an equal volume of imaging medium.
2. Observe the cells on an inverted microscope using a 63× objective, taking multiple images for each plasmid transfected.
3. Replace the imaging medium with the MEM growth medium and continue incubating cells in a humidified CO_2 incubator at 37°C.
4. Repeat steps 1 to 3 at various time points after transfection.

4. *Imaging of Fixed Cells*

In parallel cultures or following image acquisition from live cells it is important to fix the cells and remove any soluble GFP signal that may be obscuring more subtle localisation patterns. The choice of fixation reagent is largely determined by the localisation pattern observed in the live cells. Paraformaldehyde, for example, allows for better fixation of small membrane structures such as endosomes. However, when appropriate, we prefer methanol as the fixative, as this is rapid and effectively removes soluble cytoplasmic GFP-tagged proteins, but leaves structures largely intact.

Steps

Methanol Fixation

1. Remove the entire growth medium from the dishes.
2. Plunge the entire culture dish into a glass trough containing methanol at –20°C.
3. Incubate at –20°C for 4 min.
4. Remove dishes from the methanol and wash cells twice, 3 min each time, with room temperature PBS.
5. Observe the cells still covered in PBS on an inverted microscope using a 63× objective, taking multiple images for each plasmid transfected.

Paraformaldehyde Fixation

1. Replace the growth medium with a similar volume of freshly thawed PFA at room temperature.
2. Incubate for 20 min.
3. Quench the reaction by replacing the PFA with PBS containing 30 m*M* glycine in order to remove cell autofluorescence due to PFA fixation.
4. After a 5-min incubation, wash the cells twice with PBS.
5. Observe the cells on an inverted microscope using a 63× objective, taking multiple images for each plasmid transfected.

5. *Classification of Localisations*

Images obtained from living and fixed cells are then inspected manually and compared to images obtained in living and fixed cells with already established GFP-tagged organelle-specific markers (see examples in Fig. 2; more examples for organelle-specific localisations can be seen at http://gfp-cdna.embl.de.

B. Integration of Localisations with Bioinformatic Predictions

Having classified localisation of the GFP-tagged protein in live and fixed cells (Section IV,A), and if the N- and C-terminal fusions give the same localisation pattern, one can be relatively confident that this represents the localisation of this protein and therefore one can proceed with confirmation of the results by colocalisation of the GFP-tagged proteins with endogenous organelle-specific markers (Section IV,C). When the N- and C-terminal localisation patterns differ, bioinformatic data about the protein of interest should be consulted. In our experience, for over two-thirds of the proteins we have screened, combination of bioinformatic predictions with experimental cell localisations allows a final localisation to be concluded.

Steps

1. Compare the protein sequence under investigation with all known sequences in worldwide databases. Such BLAST searches, for example, available from the NCBI (http://www.ncbi.nlm.nih.gov/BLAST), may reveal similar proteins from other organisms for which the localisation may have already been characterised.

2. Analyse the sequence for potential N-terminal targeting peptides known to direct proteins into either the secretory pathway or the mitochondria. The PSORT programme (http://psort.nibb.ac.jp) is very useful in this respect.

3. Scan for any known domains within the protein of interest. The SMART programme (http://smart.embl-heidelberg.de) provides a graphical interface whereby all known proteins containing any detected domains and likely transmembrane sequences can be visualised. The links provided from these results allow the unknown protein to be put into context of other proteins of potentially similar function.

4. Analyse the protein sequence for any other possible posttranslational targeting motifs such as myristoylation or prenylation consensus sites, which may also be used to target the protein to defined subcellular structures. The PROSITE programme is useful in this respect (http://www.expasy.org/prosite).

5. Determine the final localisation by considering for which of the GFP fusion protein orientations (N- or C-terminal fusions) most of the bioinformatic predictions are consistent with the experimental localisation data. For example, if proteinX-GFP was seen to localise in the mitochondria, whereas GFP-proteinX displays a diffuse localisation and a mitochondrial targeting sequence is predicted, the localisation is concluded to be mitochondrial.

C. Verification of Results by Colocalisation with Endogenous Organelle-Specific Markers

1. Immunostaining of Cells

Before staining, cells are fixed with methanol or paraformaldehyde as described in Section IV,A. For verification of the localisations, we use commercially available primary antibodies recognising organelle-specific marker proteins. The suppliers of these antibodies, the host animals in which they have been raised, the preferred cell fixation method giving best results, and the required antibody dilutions are summarised in Table I. The secondary antibodies we use are conjugated with Cy5 or Alexa647, which can be separated easily from YFP or CFP fluorescence using standard filter sets.

Steps

1. Prior to immunostaining, those cells fixed with PFA must be permeabilised. For this, incubate the cells with PBS containing 0.1% Triton X-100 at room temperature for 5 min and then wash twice with PBS.
2. Prepare the organelle-specific primary antibodies in PBS at the appropriate dilution (see Table I).
3. Overlay the cells with 50 µl (35-mm dishes) or 75 µl (8-well dishes) of these dilutions and incubate at room temperature for 30 min.
4. Remove the antibodies and wash the cells twice with PBS.
5. Dilute the appropriate secondary antibodies in PBS.
6. Overlay the cells with secondary antibodies as described in step 3.
7. Incubate for 20 min. Finally, wash cells twice with PBS, leaving them covered in PBS for imaging.

2. Analysing Colocalisation

For colocalisation of the double-labelled samples we use a Zeiss Cell Observer System for image acquisition. It is equipped with filter sets for CFP, GFP, YFP, and Cy5/Alexa647. Imaging of the two colour channels (GFP-tagged protein and Cy5/Alexa647-stained organelle marker) is performed sequentially, which has the advantage of minimising bleed through of the channels. We analyse colocalisation by merging the images acquired for the GFP-tagged protein (green) and the organelle marker (red). This is usually sufficient to accurately determine whether the suspected localisation of the GFP-tagged protein matches the one of the reference marker. However, for reasons of reliability, it is important that during image acquisition the exposure time is set such that the camera is not saturated and that the range of grey levels of the captured images covers the entire dynamic range of the imaging system (e.g., 256 on an 8-bit camera). Some image

TABLE I Commercially Available Antibodies and Stains as Organelle-Specific Markers Used for Colocalisation Experiments

Organelle	Host[a]/antigen	Supplier/Cat. No.	Fixation,[b] dilution
Endoplasmic reticulum	rb-calnexin	Santa Cruz Biotech sc11397	M/P, 1:300
Golgi complex	mo-golgin97	Molecular Probes A-21270	M/P, 1:200
trans-Golgi network	sh-TGN46	Serotec AHP500	M/P, 1:1000
Early endosomes	mo-EEA1	BD Biosciences 610456	P, 1:100
Late endosomes	mo-CI M6PR	Affinity Bioreagents MA1-066	P, 1:50
Lysosomes	mo-LAMP1	BD Biosciences 611042	P, 1:50
Peroxisomes	rb-PMP70	Zymed 71-8300	P, 1:500

Actin[c]	Alexa-647 phalloidin	Molecular Probes A-22287	P, 1:40
Nucleus[d]	Hoechst 33342	Sigma B2261	M/P, 1:1000

[a] go, goat; mo, mouse; rb, rabbit; sh, sheep.
[b] M, methanol; P, paraformaldehyde.
[c] Phalloidin stains the actin cytoskeleton directly without the need for secondary antibodies. Phalloidin conjugated to other dyes is also available; however, the Alexa 647 dye can be used with CFP-, GFP-, or YFP-tagged proteins.
[d] Stock solutions of Hoechst can be prepared in water at 1 mg/ml and stored at –20°C. It can be included in the final PBS wash step after fixation of cells. Following a 5-min incubation, cells should be washed a further time with PBS. Dilutions of Hoechst to 1:5000 may be required to avoid bleed through between this colour and CFP.

acquisition software (e.g., Axiovision) contains an autoexposure feature to ensure that this occurs.

Steps

1. Position the GFP-positive cells to be imaged within the field of view and focus on the structure(s) of interest.
2. Acquire an image using the autoexposure procedure.
3. Change to the Cy5/Alexa647 filter position.
4. Acquire an image using the autoexposure procedure. It is important not to change the focus position in steps 3 and 4.
5. Overlay the two images using the Axiovision software with the GFP image as the green channel and the Cy5/Alexa647 image as the red channel.
6. Inspect the overlay image visually. Colocalising structures appear yellow.

V. COMMENTS

1. High-quality glass-bottomed 96-well plates are now becoming more widespread and although they are still relatively expensive, they offer the clear advantage that many more DNA-GFP constructs can be screened consecutively using less material. In our experience, however, some cell types find these plates toxic for growth, and transfection efficiencies are often significantly lower than in other dish formats, presumably due to liquid mixing problems in this shape of well.

2. A wide variety of transfection reagents are available from different suppliers, with the choice of which reagent to use being largely governed by the cell line. Generally we have found that when screening large numbers of DNA molecules, it is best to choose a reagent with a simple protocol that works efficiently in the presence of serum.

3. Novel proteins of the secretory pathway often display heterogeneity of localisations (endoplasmic reticulum, Golgi complex, endosomal / lysosomal system, plasma membrane) when examined. In such cases it is important to perform a cycloheximide chase of the newly synthesised GFP-tagged proteins to try to determine their final compartment of residence. This is achieved by the addition of 100 μg/ml cycloheximide to the growth medium (stock solutions are prepared at 100 mg/ml in methanol or ethanol and stored at –20°C) followed by imaging the cells at regular intervals (every 2 h) up to 8 h after drug treatment. This

chase time is usually sufficient to ensure that even large cell surface proteins have time to fold and are able to transit the entire secretory pathway, reaching their final destination.

CHAPTER

13

Single Molecule Imaging in Living Cells by Total Internal Reflection Fluorescence Microscopy

Adam Douglass and Ronald Vale

I. INTRODUCTION

Traditional approaches to molecular and cell biology rely on techniques that infer the behavior of biomolecules based on the properties of a large ensemble. While using such methods to derive the average behavior of a system clearly has been valuable in developing our understanding of biology, bulk measurements often fail to provide information on heterogeneity within the population. The development of methods to measure the electrical activity of single ion channels (Neher *et al*., 1978) first illustrated this point quite clearly, and the ensuing years have seen an explosion of interest in expanding our ability to study biological materials on a single molecule level, especially using optical techniques. Early studies in the field focused primarily on *in vitro* systems containing a limited number of purified components (Funatsu *et al*., 1995; Dickson *et al*., 1997; Pierce *et al*., 1997) and greatly advanced our ability to detect variations not only within a population of molecules, but within the behavior of individual molecules over time. More recently, several groups have demonstrated the possibility of adapting single molecule techniques to living cells (Sako *et al*., 2000; Ueda *et al*., 2001).

These new abilities have been facilitated by several factors, including (1) the advent of green fluorescent protein (GFP) as a fluorescent tag for proteins in their natural environment, (2) the improved sensitivity of intensified charge-coupled devices (ICCDs) and other detectors, and (3) the development and refinement of total internal reflection fluorescence (TIRF) microscopy (Axelrod, 2003). While other techniques, such as near-field scanning optical microscopy (NSOM) and more traditional wide-field approaches, have been used for single molecule imaging in cells (Schutz *et al*., 1997; de Lange *et al*., 2001), TIRF is by far the most commonly used. In TIRF illumination, the excitation light is directed at the sample at a sufficiently large angle that it is totally internally reflected when it strikes the interface between the aqueous buffer and the glass substrate upon which it lies. This creates an exponentially decaying evanescent wave that penetrates into the sample to a depth of only 100–200 nm, the exact distance depending on the refractive indices of the two materials. As a result, only fluorophores lying near the interface are excited efficiently. This greatly decreases the background signal contributed by out-of-focus fluorescence and helps increase the signal-to-noise ratio in the output image to the level required for single molecule detection. Ready-built TIRF systems are available from several microscope vendors (Olympus, Nikon); however, it is relatively simple to add TIRF optics to an ordinary, inverted microscope, which is often preferable to commercial options due to the greater flexibility such an approach provides for later modifications to the system. This chapter provides an overview of how to construct, align, and use a TIRF system for single molecule imaging in live cells.

II. MATERIALS AND INSTRUMENTATION

Several commercial sources exist for optical devices and accessories. Some that are used commonly in our laboratory include the following.

In addition, some manufacturers provide prebuilt TIRF systems:

Olympus: www.olympusamerica.com
Nikon: www.nikonusa.com

III. PROCEDURES

A. Illumination Strategies

TIRF can be achieved using one of a number of illumination schemes, but most researchers use either prism- or objective-type configurations. In prism-type TIRF, the excitation laser does not enter the internal optical path of the microscope, but rather is directed at the sample from above, through a prism that is optically coupled to the glass slide via a layer of glycerol. Total internal reflection occurs at the interface between the slide and the sample medium, and the excitation beam is completely reflected away from the sample volume. In order to be visible, samples must be firmly attached to the glass slide, which is then affixed with a coverslip and inverted. This results in the major limitation of prism-type illumination, which is that the sample becomes completely enclosed between the two glass surfaces. Since the plane of illumination lies a distance equal to the thickness of the coverslip plus that of the sample away from the objective, one must use a very small sample volume in order to obtain images with high numerical aperture (NA), short working distance objectives. These considerations make it a poor choice for live cell applications in which cell health might be compromised by extended isolation in a confined, oxygen-poor environment. It is primarily for this reason that we perform the majority of our live cell, single molecule imaging using an objective-type microscope.

In objective-type TIRF, the excitation beam enters the microscope through one of its illumination ports and is directed at the sample through the microscope objective, as in epifluorescence illumination. To achieve TIR, the beam is brought into focus at the back focal plane of the objective, but is aligned at the peripheral edge of the objective rather than at the center, as in epifluorescence microscopy. This offset changes the illumination angle as the beam approaches the sample. The maximum angle of illumination depends on the numerical aperture of the objective, and for 1.4 NA objectives is 67°. Since the critical angle for TIR at the cell–glass interface is roughly 65°, this makes it difficult to position the beam so that it will be totally internally reflected. Several microscope manufacturers have begun to produce larger NA objectives that increase the ease of aligning the beam in an objective-type system. In our microscope, we use a 1.45 NA objective (Zeiss), which has a maximum cone angle of approximately 71°. Olympus sells a 1.65 NA objective that offers great flexibility in aligning TIRF systems, but carries the liability of requiring specially designed coverslips and immersion oils of a high refractive index. The major disadvantage to using objective-type configurations is that they are more prone to background signals arising from the excitation beam, as it is reflected toward the detector, and can also generate spurious reflections or fluorescence within the objective itself. However, these tradeoffs are minor in comparison to the gain in cell health offered by objective-type illumination.

B. Choice of Detector

Due to their extreme sensitivity and high readout speed, intensified charge-coupled device-based cameras are excellent for single molecule imaging. High-end ICCDs have single photon sensitivity under ideal conditions and can acquire 640 × 480 images directly to digital storage media at rates of over 100 frames per second. At these speeds, the rate of photon emission by a single fluorophore becomes a limiting factor in obtaining a reasonable signal-to-noise ratio. There are, however, several disadvantages to ICCDs. The intensification process can result in noise due to ion feedback events and dark current in the intensifier, as well as the emergence of low-intensity "valleys" at boundary points in the image, such as those surrounding single fluorophores. The intensifier also introduces nonlinearity in the response of the detector to light, and so care must be taken to ensure that one is working within the linear range of the camera if

quantitative measurements of fluorescence intensity are to be made. Advances in camera technology are changing these limitations, however. For instance, Stanford Photonics now produces a dual-intensifier camera that is cooled by a water jacket, which shows great promise for single molecule imaging due to its extremely low noise levels.

Traditional, cooled CCDs are a feasible alternative in some applications and are desirable for their high image quality and the strong linearity of their response. Unfortunately, they also have slow readout speeds, a problem that some researchers have overcome by reading from only a small region of the detector. This is of course not an option if one wishes to image a relatively large area such as an entire cell surface, and even under ideal conditions the temporal resolution provided by cooled CCDs might not be great enough to observe more rapid phenomena, such as the lateral diffusion of certain membrane proteins or lipids. Still, cooled CCDs have been extremely useful in some cases. For example, Yildiz *et al*. (2003) used this approach to track single myosin motors walking along actin filaments to a precision of 1.5 nm.

C. Microscope Layout

The configuration of our objective-type TIRF microscope is shown in Fig. 1. In this geometry, excitation light from the HeNe and argon-ion lasers is combined at the first dichroic mirror and is coaligned through the remaining optical elements. The filter wheel placed outside the argon laser allows rapid selection of the excitation wavelength from the multiwavelength source. To avoid selective excitation of fluorophores with a given orientation, the illumination light is depolarized by a quarter-wave plate placed in each beam path. Lateral positioning of the excitation beams within the objective is controlled through the movements of TM1, which regulates the incidence angle at the sample. Rotation of mirror M3 180° allows the user to switch between TIRF and epifluorescence illumination. Optics shown inside the microscope housing are all fixed components, supplied by the manufacturer.

D. Laser Alignment

1. Bring the two beams (Argon and HeNe) into alignment with one another. Irises fixed at the desired height and placed at various points in the optical path can be enormously useful in this step. Using the beam riser mirrors, align both beams to the horizontal axis at the same height, as measured at at least two points before DM1 along each path. Ensure that the beam spots at DM1 and M1 overlap completely with one another. In all alignment steps, make efforts to align the beams as close to the center of each optical element as possible.

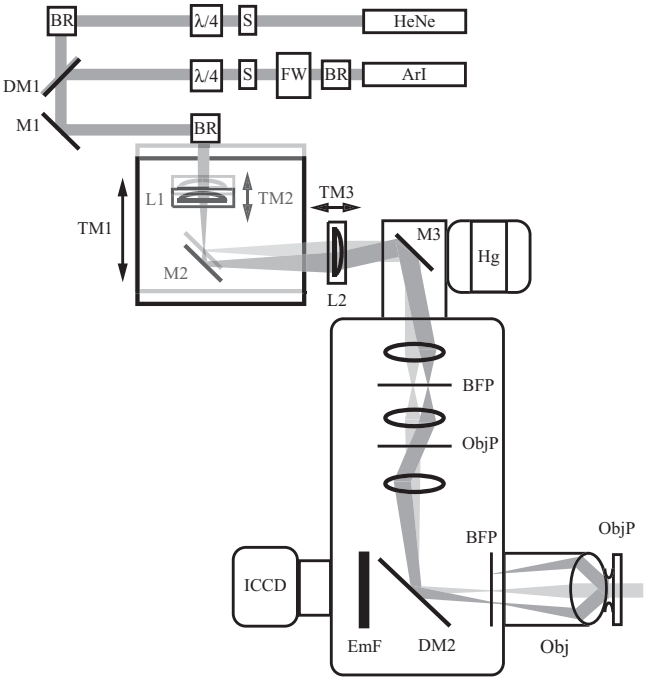

FIGURE 1 Optical configuration of the objective-type TIRF microscope used in our laboratory. The excitation light paths are indicated for both lasers in one of two configurations. In one (light gray), beams are aligned with the optical axis of the excitation port of the microscope and travel up the center of the objective, generating transmitted fluorescence illumination of the sample. In the second, beams enter the illumination port off axis, traveling up the edge of the objective, and are totally internally reflected at the sample. Switching between the two types of illumination can be accomplished by moving the translation mount TM1. Beam size, and thus the size of the TIRF illumination spot, is determined by the relative positions of lenses L1 and L2. HeNe, helium–neon laser; ArI, mixed wavelength argon–ion laser; S, shutter; BR, beam riser; FW, filter wheel; λ/4, quarter-wave plate; DM1–2, dichroic mirrors; M1–3, mirrors; L1–3, lenses; TM1–3, translation mounts; Hg, mercury arc lamp; BFP, back focal plane of the objective; ObjP, object plane; Obj, objective; EmF, emission filter; ICCD, intensified charge-coupled device-based camera.

2. Center the combined beams at L1, M2, L2, and M3.

3. Remove L1, L2, and the objective from their positions and center the beam in the microscope cavity by watching the projected illumination spot above the microscope housing. A piece of white paper placed above the microscope can be useful in this step. To achieve the best possible alignment, make sure that the beam profile is not clipped when the microscope's field and aperture diaphragms are closed.

4. Replace L2 and adjust its position to minimize the size of the projected beam spot.

5. Replace L1 and the objective, and mount a fluorescently labeled sample (preferably cells or fluorescent beads). Bring the ventral surface of the sample into focus as viewed through the eyepieces. (See Section IVD).

6. Remove the sample and clean the immersion oil from the objective. Adjust L1 to minimize the size of the projected beam spot. Ensure that the beam is collimated as it emerges from the objective.

7. Apply immersion oil to the objective and place a glass coverslip on top of it. Optically couple a plano-convex lens to the coverslip with more immersion oil. This will frustrate total internal reflection at the glass–air interface and allow one to follow the projected beam position over a wide range of incidence angles. Move TM1 to deflect the beam until it begins to be clipped by the back focal plane of the objective. This indicates that the largest possible incidence angle has been reached. Readjust TM1 to barely eliminate clipping and remove the coverslip and lens.

8. Place a fluorescent sample (in our experience, either 200-nm fluorescent beads or an aqueous solution of a fluorophore at high concentration are best) on the microscope and observe through the eyepieces to ensure that TIRF has been attained. The success of the alignment can be assessed by the presence of a very shallow focal plane and low fluorescent background from nonsurface-adsorbed fluorophores. It might be necessary at this point to center the illumination spot by moving M1 or M2.

E. Imaging Single GFPs

The greatest difficulty with imaging single fluorescent proteins lies in titrating their expression. At high levels of GFP expression, the density of tagged protein can result in multiple fluorophores being closer to one another than the diffraction limit of light, which prevents the identification of single molecules. Because most vectors are designed to drive high levels of protein expression, obtaining a suitable density of GFP can be difficult. As a long-term solution, it is desirable to create a cell line that stably expresses very low levels of GFP (Fig. 2). This is usually possible, but requires the labor-intensive screening of clonally derived cell lines (most of which will express too much of the transgene) by TIRF. Alternatively, cells can be imaged either very early (several hours) or very late (over a week) after transfection, which will enrich the number of low-expressing cells, although cells will be extremely variable in their fluorescence levels. Another approach is to sort the transfectants by FACS and collect only the lowest expression group for imaging. It is also possible to place the transgene under the control of an inducible promoter element and titrate the level of inducer to optimize expression levels. In many cases, basal levels of expression from the uninduced promoter suffice for single molecule imaging. We have found this to be true for uninduced metallothionine promoters in a Drosophila cell culture system.

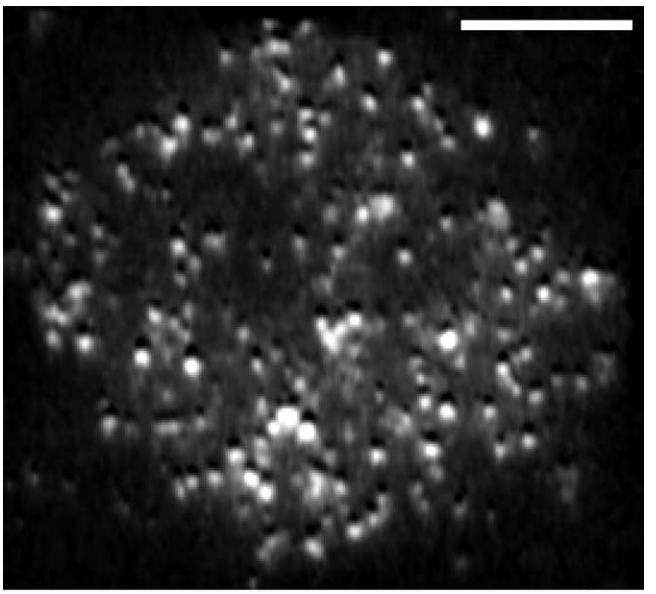

FIGURE 2 Single molecules of Lck-GFP in a T-cell membrane. Objective-type TIRF was used to image Jurkat T cells that were stably transfected with a GFP fusion of the membrane-associated, tyrosine kinase, Lck, and selected for low expression levels. Scale bar: 10 μm. The bright punctae in the image correspond to single molecules. This image was taken from a single frame of a sequence acquired at video rate (30 fps).

As the first single molecule studies of GFP demonstrated (Dickson *et al.*, 1997; Pierce *et al.*, 1997), emission from fluorescent proteins is often unstable, a property that is not usually shared by their small organic counterparts. This can result in the molecule disappearing for short intervals, thereby complicating single molecule tracking. In most situations, however, the dark states of GFP are short-lived, typically lasting only a frame or two at video rate, and are infrequent enough that they do not pose an insurmountable problem to obtaining useful data.

F. Sample Preparation

There are several options for systems in which to mount cells for single molecule imaging. A luxury afforded by objective-type TIRF is the ability to use glass-bottom tissue culture dishes, which allow one to grow cells on a surface that is suitable for microscopy. Alternatively, cells can be adhered to glass coverslips and imaged in a perfusion chamber, such as the closed

configuration system available from Bioptechs. When used in conjunction with objective and sample heating elements, the latter solution allows for the greatest degree of control over environmental parameters that affect cell health and makes it possible to change buffer conditions rapidly (e.g., by perfusing pharmacological agents, antibodies, or chemoattractants). Heating the sample with an external heat source (such as a hot air blower pointed at the stage assembly) is possible, but resulting oscillations in stage position can make in quite difficult to maintain the tight control over the focal plane that is needed for single particle tracking.

In all cases, it is advisable to clean the glass substrate before use in order to remove fluorescent impurities that would complicate imaging and to impart an electrical charge to the glass to facilitate cell adhesion or surface functionalization. This can be accomplished in a number of ways. We immerse the glass overnight in an aqueous solution of 70% sulfuric acid and 9% hydrogen peroxide. The mixture will evolve a good deal of heat when prepared and should be applied to the glass while still hot. This combination of reagents is predictably quite volatile and should only be used in a fume hood by persons wearing appropriate protective attire.

It is often useful to coat the glass with various substances prior to use. Such treatments do not appear to adversely affect the quality of single molecule images obtained by TIRF. In our experiments, we have successfully imaged various cell types adhering to a variety of materials on the coverslip surface, including antibodies, concanavalin A, and polylysine. Good cell adhesion is a prerequisite for TIRF, as the cell membrane must lie within the evanescent wave to be visible. However, in our experience with many cell types, polylysine coating is not necessary for adhesion if the glass has been cleaned thoroughly first.

Finally, the choice of imaging buffer can be tremendously important for obtaining high-quality, single molecule images. Buffers should be free of substances with appreciable fluorescence in the desired wavelength range, which eliminates the use of most tissue culture media (especially those containing serum or colorimetric pH indicators) during the imaging process. For the majority of our experiments, we have used a modified HEPES-buffered saline solution (20 m*M* HEPES, 135 m*M* NaCl, 4 m*M* KCl, 1 m*M* Na_2HPO_4, 10 m*M* glucose, 1 m*M* $CaCl_2$, 0.5 m*M* $MgCl_2$, pH 7.4). All cell types should be washed with imaging buffer one or two times before beginning the experiment. Adherent cultures should be washed especially thoroughly if they have been grown on the imaging surface, as they tend to produce debris that can complicate single molecule imaging.

G. Simultaneous Imaging of Multiple Fluorophores

The discovery and development of fluorescent proteins with a wide variety of excitation and emission properties have provided researchers with the ability to simultaneously observe the behavior of two or more types of protein in living cells. The combination of GFP and DsRed is of particular interest for single molecule imaging. Both proteins can be excited by the 488-nm line of an argon-ion laser quite efficiently, and yet emit light of widely disparate wavelengths that can be separated using conventional dichroic mirrors and filtersets. For real time, simultaneous imaging of both proteins at video rate, a beam splitter module is available from Optical Insights that projects the two emission wavelengths onto different halves of the detector, eliminating the need for multiple cameras and emission paths. This allows one to acquire both color components of the image without switching excitation sources, which is often essential due to the rapid timescale on which changes can occur at the single molecule level (Campbell *et al.*, 2002). For dual-color imaging with GFP, the most suitable version of DsRed is a dimeric variant, termed the "tandem dimer," in which two identical copies of the modified DsRed transcript are connected to one another by a short linker region. The high effective concentration of the linked fluorophores in the translated protein is thought to favor the formation of intra- rather than intermolecular contacts and prevents aggregation effects from interfering with the function of the protein to which the tag is attached. The tandem dimer is preferable to the monomeric version of the protein in that it retains the ability to be excited at 488 nm, while the monomer does not. We have imaged single molecules of GFP and the tandem dimer in the same sample using 488-nm excitation and have found the two fluorophores to be quite spectrally separable from one another. It remains to be seen how generally valuable DsRed will be for live cell, single molecule imaging, as it is significantly dimmer than GFP at 488-nm excitation and might not provide a high enough signal for the detection of rapidly moving proteins. At the very least, the tandem dimer should provide a useful counterstain to mark one component at the population level while imaging single molecules of a GFP-tagged protein.

Dual-color imaging of small organic fluorophores is also possible, but the majority of such combinations require the simultaneous use of two excitation sources. This is made relatively easy by excitation filter sets that are designed to deal with two wavelengths, but it demands that careful attention be paid to the

coalignment of the two sources with one another. We, for example, have obtained dual-color images of Cy3- and Cy5-labeled proteins diffusing in artificial lipid bilayers and interacting with Jurkat T cells. Experiments done *in vitro* have also shown this fluorophore combination to be useful for single molecule FRET, a technique that several groups have applied to living cells (Sako *et al*., 2000). Finally, although it is a nascent technology, the application of semiconductor quantum dots as single molecule tags (Dahan *et al*., 2003) promises to simplify illumination schemes greatly for multicolor, single molecule experiments.

H. Image Analysis

The precise method of analysis to choose will of course depend on the information that is desired, but there are a few analytical issues that apply to most single molecule experiments. Most prominent among these is the systematic, automated identification of single fluorophores. The relatively low signal-to-noise level achieved in single molecule images poses a problem in this regard, as it is sometimes impossible to distinguish between a fluorophore and a region of high background fluorescence based solely on a static intensity threshold. Furthermore, if the molecules of interest are moving rapidly in the *X-Y* plane, as they often are in studies of membrane proteins, it can be quite difficult to follow single molecules through consecutive frames. Several groups have developed tracking algorithms to overcome these problems, and most of these utilize some measure of the molecule's shape or *X-Y* intensity distribution to identify relevant spots in an image (Gelles *et al*., 1988; Cheezum *et al*., 2001). In our laboratory, we have developed a tracking routine that uses cross-correlation between an idealized molecule and the TIRF image to find spots (Klopfenstein *et al*., 2002). Continuity of molecular trajectories between frames is obtained by ensuring that the fluorophores are at a very low density in the cell surface (to prevent confusion between neighboring molecules) and by including a search radius as a tracking parameter. The latter point restricts the search to a small area around the initial location of the molecule, under the assumption that it is moving with a fairly predictable speed. We have implemented this routine using the commercially available MATLAB software, but similar procedures could easily be developed in other programming environments.

While cross-correlation is a great improvement over manual tracking, it is computationally inefficient, requiring a relatively large amount of CPU time to track a single spot. This makes it impractical for the automated detection and tracking of every molecule in an image, and in our analyses we manually indicate which spot to follow by providing its initial Cartesian coordinates to the tracking algorithm. Complete automation of the procedure for all spots in an image sequence might be achievable by more efficient algorithms, such as fitting to a theoretical function (e.g., a Gaussian distribution), line-based routines, or segmentation analysis. We have applied a set of particle tracking routines maintained by Dr. Eric Weeks (available at www.physics.emory.edu/~weeks/idl) to this task, with extremely promising results.

Positional information is not the only parameter that can be obtained from single molecule images. The quantized nature of single molecule fluorescence makes the technique suitable for obtaining estimates of oligomerization state based on spot intensity and has been used to this end in studies of GFP-tagged E-cadherin in living fibroblasts (Iino *et al*., 2001). The addition of polarization optics to a TIRF microscope enables measurements of molecular orientation at the single molecule level and can provide striking information about dynamic changes in parameters such as protein conformation and binding events (Khan *et al*., 2000). Single molecule FRET is also just beginning to be explored and holds great promise for measuring protein–protein interactions in living cells.

IV. PITFALLS

A. Visualization of Internal Structures

While the evanescent wave created in TIRF microscopy penetrates to a shallow depth, it is still possible to visualize structures that are inside the cell, rather than at its surface. Several studies have exploited this to monitor the dynamics of vesicle fusion with the plasma membrane (Toomre *et al*., 2000), but it can be a source of complication in single molecule experiments. This is particularly problematic with proteins that partition into both plasma membrane and vesicular pools and can lead to spurious conclusions about protein behavior. Due to the low intensity of the excitation light at the cell interior, however, it is very unlikely that single molecules on vesicle surfaces will be visible. It is more probable that signals from the cell interior will represent clusters of several fluorophores, although internal structures might show fluorescence intensities similar to those of single molecules. To avoid confusion between surface and internal components then it is important to only

analyze spots that can be attributed to single molecules, i.e., that photobleach in a single step. Alternatives might include performing TIRF with a system in which the illumination depth is reduced—for instance, by the use of substrates with higher refractive indices or by the imposition of an intermediate layer, acting as a spacer, between the glass and the sample. However, these require a significant investment of time and effort to implement.

B. Objective Fluorescence

Materials used in construction of the high NA objectives used in objective-type TIRF fluoresce at certain excitation wavelengths, an effect that was ignored in their development because the fluorescence is small compared to the signal generated by traditional epifluorescence and confocal microscopies. Unfortunately, this background fluorescence is detectable in systems with single molecule sensitivity, and while it does not prevent the detection of single molecules, it does reduce the signal-to-noise ratio. We have noticed this effect with a number of different objectives from several manufacturers. There is at present no solution to this problem, but in our hands the effect is only noticeable when simultaneously imaging dyes with wavelengths similar to Cy3 and Cy5. Excitation with the 514-nm line used for Cy3 causes the objective to fluoresce in the far red end of the spectrum, where Cy5 emits, and this contributes to the background in the Cy5 channel.

C. Inhomogeneous Illumination

A problem with coherent light such as that emitted by lasers is its tendency to generate interference patterns. The problem is compounded by imperfections in the optical elements used to route the laser to its destination, and in TIRF systems this can result in local intensity minima and maxima within the illumination spot. A number of methods can be employed to homogenize the spot profile. Holographic beam diffusers and ground glass elements accomplish this quite completely, but the resulting beam divergence is typically too severe to allow proper TIR alignment, even when a downbeam lens is used to attempt to regain collimation. A more suitable approach is to route the excitation light through a multimode optical fiber that has been bent at a narrow angle. Alignment of the beam into and out of the fiber can be laborious, but once achieved it results in a homogeneous and well-collimated beam.

D. Changes in Incidence Angle while Focusing

If the microscope utilizes a translatable objective mount to adjust the image focus, another problem will arise when implementing TIRF. As the objective is moved vertically, the position of its back focal plane will change, resulting in a loss of collimation in the beam as it passes through the objective. This is not normally a problem if the beam has been aligned such that it propagates into the edge of the objective lens, as the incidence angle will already be well beyond the critical angle required for total internal reflection, and changes in collimation will be small. It must be emphasized, however, that the objective should be as close to its in-focus location as possible before aligning the laser to achieve TIRF. Otherwise, subsequent focusing on the bottom surface of the sample can greatly disrupt the incidence angle of the laser, leading to transmission of a substantial portion of the light through the objective and into the cell. The ideal method of avoiding this is to control image focus by moving the microscope stage, rather than the objective, but it is not completely necessary.

Acknowledgments

Live-Cell Fluorescent Speckle Microscopy of Actin Cytoskeletal Dynamics and Their Perturbation by Drug Perfusion

Stephanie L. Gupton and Clare M. Waterman-Storer

I. INTRODUCTION

Fluorescent speckle microscopy (FSM) is a method used to analyze the movement, assembly, and disassembly dynamics of macromolecular structures *in vivo* and *in vitro* (Waterman-Storer *et al*., 1998). FSM capitalizes on the well-established method of fluorescent analog cytochemistry, in which purified protein is covalently linked to a fluorophore and microinjected or expressed as a green fluorescent protein (GFP) fusion in living cells, incorporated into cellular structures, and whose dynamics are visualized by time-lapse or video wide-field epifluorescence microscopy (Wang *et al*., 1982; Prasher, 1995). This approach has been limited in its ability to report protein dynamics because of inherently high background fluorescence from unincorporated and out-of-focus incorporated fluorescent subunits and the difficulty in detecting movement or turnover of subunits because of their uniform labeling of fluorescent structures. In contrast, FSM offers the capability to measure variations in molecular dynamics in living cells at high spatial and temporal resolution. In addition, FSM reduces out-of-focus fluorescence and improves the visibility of fluorescently labeled structures and their dynamics in three-dimensional polymer arrays such as the mitotic spindle (Waterman-Storer and Salmon, 1999; Maddox *et al*., 2002, 2003).

This article describes how to use FSM for measuring actin cytoskeletal dynamics in living cells using microinjected fluorescently labeled skeletal muscle actin and the manipulation of actin dynamics during high-resolution FSM imaging by drug perfusion. This allows measurement of the kinetic evolution of the response of the actin cytoskeleton to the effects of drugs with unknown or known molecular targets, including actin and its associated proteins. We have used this technique to study changes in actin dynamics in response to perfusion of cytochalasin D (an actin filament capping drug) (see Fig. 5), latrunculin A [an actin monomer sequestering drug (Ponti *et al*., 2002)], and ML-7 and calyculin-A [myosin II inhibitors and activators, respectively (Gupton *et al*., 2002)]. These experiments have provided insight into how the actin cytoskeleton is organized into functionally distinct zones in migrating cells, with an exploratory lamellipodium at the leading edge whose actin dynamics are sensitive to filament capping, and a lamellum where traction forces are generated by myosin II-mediated actin dynamics. Using FSM analysis during perfusion of drugs that specifically affect signaling molecules or other structural components of the actin cytoskeleton will be a valuable approach for understanding the molecular regulation of the cytoskeleton during cell morphogenesis.

Principles of FSM Imaging

In its initial development in 1998, FSM utilized conventional wide-field epifluorescence light microscopy and digital imaging with a sensitive, low-noise cooled

Copyright 2006, Elsevier Science (USA).

charge-coupled device (CCD) camera and was applied to study the assembly dynamics and movement of microtubule polymers (Waterman-Storer and Salmon, 1997). Since then, FSM has seen new applications in answering various questions about actin and microtubule cytoskeletal function *in vivo* during cell motility, neuronal pathfinding, and mitosis, as well as given insight into cytoskeletal dynamics *in vitro*. It also has been transferred from widefield epifluorescent microscopes to confocal and total internal reflection fluorescence (TIRF) microscopes, which reduce the out-of-focus contribution further and thus increase the speckle contrast (Grego *et al.*, 2001; Maddox *et al.*, 2002; Adams *et al.*, 2002; Adams *et al.*, 2004). Computer-based analysis of FSM image series has begun to be developed so that the use of dynamic speckles as quantitative reporters of polymer trajectory, velocity, assembly rate, lifetime, and disassembly rate can be realized (Ponti *et al.*, 2003).

FSM was initially discovered by accident when it was noticed in high-resolution images of cells injected with X-rhodamine-labeled tubulin that some microtubules exhibited variations in fluorescence intensity along their lattices, i.e., they looked speckled (Waterman-Storer and Salmon, 1997). These speckles were used as marks of the microtubule lattice to allow differentiation between mechanisms of microtubule movement in living cells.

To understand the origin of speckles on microtubules as an example, one must consider how the images of fluorescent microtubules are formed by the optics of the microscope. Microtubules assemble from tubulin dimers into polymers with 1625 dimers per micrometer of microtubule (Desai and Mitchison, 1997). In an image made by a microscope, a fluorescent microtubule appears as wide as the smallest region that the microscope is capable of resolving, defined by geometrical optics of light as $r = 0.61\lambda/\mathrm{NA}_{\mathrm{obj}}$ (Inoué and Spring, 1997), where λ is the emission wavelength of the fluorophore and $\mathrm{NA}_{\mathrm{obj}}$ is the numerical aperture of the microscope objective lens. For example, for X-rhodamine (602 nm emission)-labeled microtubules imaged with the best available 1.4 NA optics, the smallest resolvable region of a microtubule is 270 nm, which contains 440 tubulin dimers. A low fraction of fluorescent dimers, $f = 1\%$, will produce a mean number n of 4 fluorescent dimers ($n = 440 \times f$) per resolvable image region. In FSM images, the speckle pattern along the microtubule is produced by variations in the number of fluorescent dimers per resolvable image region relative to this mean. Thus, the "contrast" of the speckle pattern can be expressed as the ratio between the standard deviation and the mean of a binomial distribution with n elements: $c = \sqrt{n \cdot f \cdot (1-f)}/(n \cdot f)$. This formula indicates (i) that the contrast c increases with lowering f and (ii) that it decreases with growing n, indicating the requirement for optics with the highest NA possible.

For example, during assembly of a microtubule with 1% fluorescent-labeled tubulin and 99% unlabeled tubulin in an image taken with 1.4 NA optics, one 270-nm segment of the microtubule may contain 1 fluorescent dimer and 339 nonfluorescent dimers, while the adjacent resolvable segment of the microtubule could contain 7 fluorescent dimers, producing a 7× difference in image brightness between adjacent resolvable regions, and thus high speckle contrast. By comparison, at $f = 50\%$, adjacent minimally resolvable image regions may contain 212 and 234 fluorescent dimers, a 1.1× difference in image brightness and thus very low speckle contrast.

Thus, time-lapse FSM requires the ability to visualize high-resolution image regions (~0.25 µm) containing few (1–10) fluorophores and the capacity to inhibit fluorescence photobleaching. This requires a very sensitive imaging system with little extraneous background fluorescence, very efficient photon collection, a camera with low noise, high quantum efficiency, high dynamic range, high resolution, and suppression of fluorescence photobleaching and photodamage in the specimen with illumination shutters and/or oxygen scavengers (Waterman-Storer *et al.*, 1993, 1998; Mikhailov and Gundersen, 1995).

Since the original analysis of microtubules, the "speckle" method has been applied to other cytoskeletal systems. When injected with low levels of fluorescently labeled actin, actin-rich structures such as the lamellipodium of migrating cells appear speckled in high-resolution fluorescence images (see Fig. 1) (Waterman-Storer *et al.*, 1998, 2000; Verkhovsky *et al.*, 1999; Watanabe and Mitchison, 2002). Also, a GFP fusion of a microtubule-binding protein, ensconsin, when expressed in cells at very low levels, gave a speckled distribution along microtubules (Bulinski *et al.*, 2001). These actin and ensconsin speckles formed in different ways from those in a single microtubule polymer. For actin, the lamellipodium is filled with a cross-linked and dense three-dimensional meshwork of actin filaments (see Fig. 1), and each filament is made up of a paired helix of 360 actin monomers per micrometer (Pollard *et al.*, 2000; Small 1981; Svitkina *et al.*, 1997). Here, a fluorescent speckle may arise from fluorescently labeled actin monomers within multiple different actin filaments of the meshwork falling into the same minimally resolvable image region (Fig. 2a); however, none of the filaments are detected individually. Thus, the entire meshwork appears as a relatively even distribution of fluorescent speckles in images. For ensconsin, binding of few diffusible GFP–ensconsin

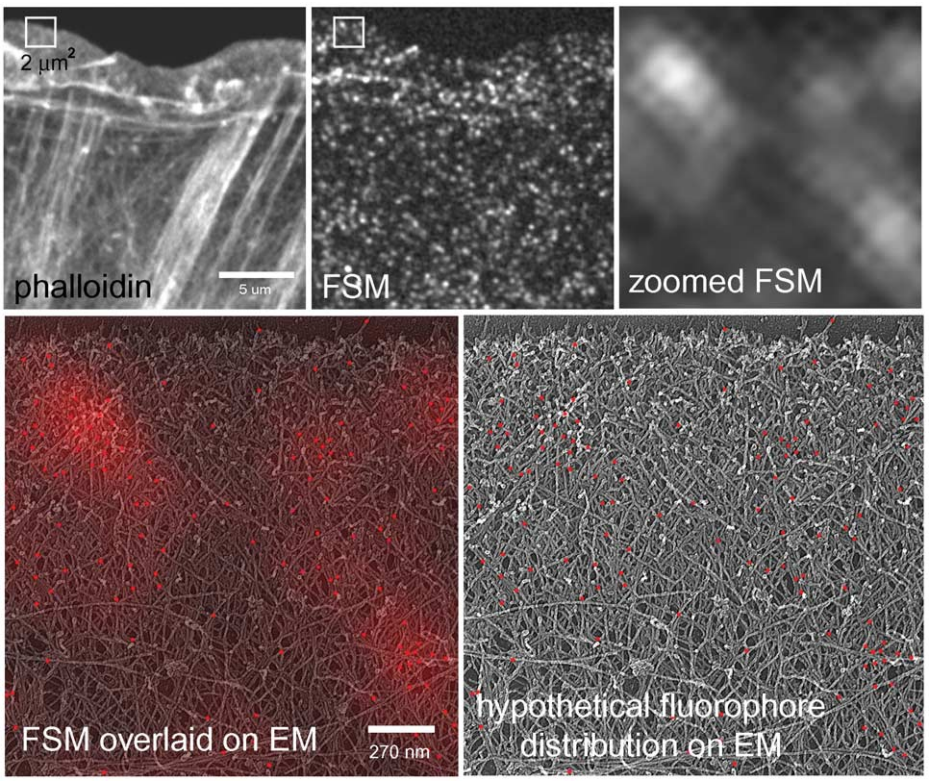

FIGURE 1 FSM of the actin cytoskeleton. (Top) A newt lung epithelial cell was microinjected with a low level of X-rhodamine-labeled actin, fixed, and stained with Alexa-488 phalloidin. In the phalloidin image, all actin filaments are labeled and can be visualized, giving much information about the higher order structural organization, including the location of filament meshworks in the lamellipodium and filament bundles in the cell body. In the single FSM image, much of the structural information is lost, but in time-lapse FSM series, dynamic information is gained that cannot be obtained with higher level labeling of the cytoskeleton. The 2 × 2-μm box in the middle panel is zoomed up in the right-hand panel, and in the bottom right it is colorized red and overlaid onto a quick-freeze deep-etch image of the same-sized region of the actin cytoskeleton in the leading edge of a fibroblast (kindly provided by Tatiana Svitkina, Northwestern University). This gives a sense of the scale of FSM compared to EM so that you can see how many filaments actually fit within the 270-nm resolution-limited image region. In the bottom right panel, a hypothetical fluorophore distribution that could give rise to the speckle pattern is shown, demonstrating the very small proportion of the total actin that is utilized for gaining information in FSM images.

molecules to the microtubule lattice, together with many unlabeled ensconsin molecules, results in GFP–ensconsin speckles along microtubules.

Thus, a "speckle" in general terms is defined as a minimally resolvable image region that is significantly higher in fluorophore concentration (i.e., fluorescence intensity) than its immediately neighboring minimally resolvable image region. In addition, for a speckle to be detected, the fluorescent molecules must be immobilized for the time required for image acquisition. The rapid motion of a small number of mobile (diffusible) fluorescent molecules results in a low level of evenly distributed background signal in the many pixels the molecules visit during the 0.5- to 3-s exposure time required by the camera to acquire an image of the dim FSM specimen (e.g., for our imaging system, actin monomers move at 63 pixels/s in the image space). This concept was demonstrated nicely by Watanabe and Mitchison (2002), who showed that diffusible GFP expressed at very low levels in cells produced an even distribution of fluorescence in high-resolution images, while a similar expression level of GFP–actin produced a speckled fluorescence image.

Speckle patterns in macromolecular assemblies act as a "bar code" pattern on structures that only change with assembly or disassembly of the structure over time (Waterman-Storer and Salmon, 1998). The pattern also serves as fiducial marks on macromolecular assemblies, which in time-lapse movies can be tracked and measured, with translation of the speckle pattern

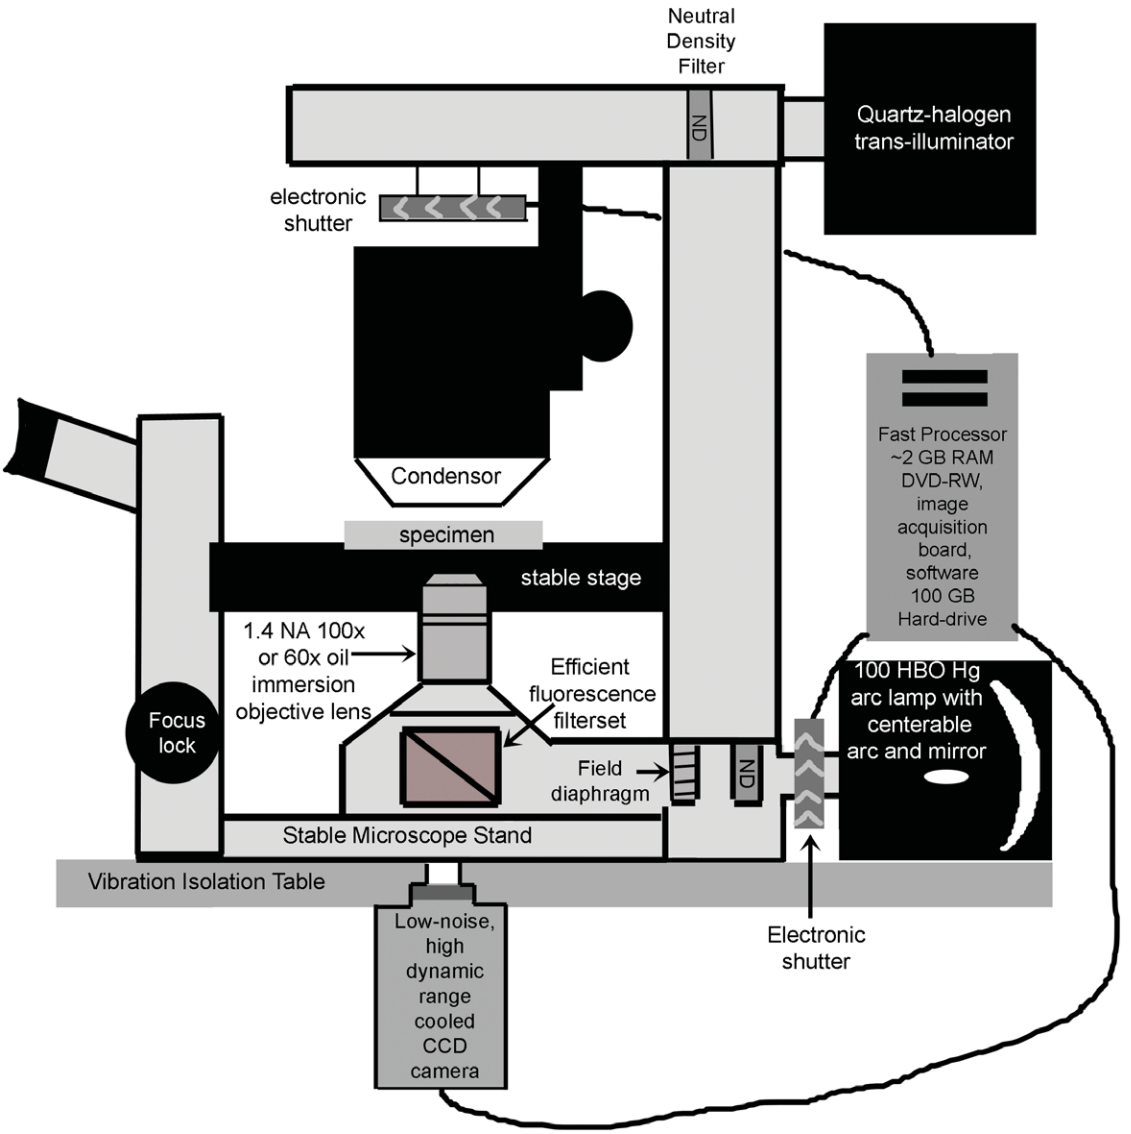

FIGURE 2 Schematic diagram of the important components of an inverted microscope optimized for FSM.

encoding trajectory and velocity and appearance/disappearance of speckles relating to assembly/disassembly dynamics. FSM therefore provides an exceptional tool for studying the actin cytoskeleton during processes such as cell migration, division, morphogenesis, and neuronal pathfinding. Furthermore, FSM can serve as the quantitative readout to link pharmacological, molecular, or genetic interventions to changes in cytoskeleton dynamics to permit a systematic deciphering of molecular regulation of the actin cytoskeleton.

This chapter article gives guidelines for designing a microscope imaging system for performing time-lapse FSM and protocols for achieving time-lapse FSM imaging of the actin cytoskeleton in living tissue cells cultured on glass coverslips. Finally, it also describes a perfusion system for temporally controlled application of drugs during time-lapse FSM of actin to observe the kinetic evolution of their effects on the dynamics and organization of the actin cytoskeleton.

II. MICROSCOPY INSTRUMENTATION

As opposed to a step-by-step protocol, this section discusses the basic components needed to set up an FSM system, giving the recommendations for critical requirements in each type of component (see Fig. 2).

The following *materials* are needed: upright or inverted epifluorescent microscope and optics, including epi-illuminator, objective lens, excitation filter, emission filter, and dichromatic mirror; electronically controlled shutter; cooled CCD camera; and computer, digital image acquisition board, and software for control of shutter and image acquisition.

A. Upright or Inverted Epifluorescent Microscope and Optics

1. The microscope stand should be of biological research quality, with a substantial mass that resists vibration. If possible, the microscope should be mounted on a vibration isolation table (available from Newport or TMC). Either upright or inverted configurations can be used, although inverted microscopes offer more flexibility in choosing imaging chambers for living cells and accommodating open petri dishes. The focusing system should be lockable during long-term time-lapse imaging, as slight shifts in focus result in changes in speckle intensity that can be interpreted artifactually as actin dynamics. Acceptable recent-model uprights include Nikon Eclipse E400, 600, 800, or 1000; Olympus BX series; or Zeiss Axioplan 2. Inverteds include Nikon Eclipse TE-2000 series, Olympus IX series, Zeiss Axiovert 200, or Leica DM IRB.

2. The microscope should be equipped with a high-quality epi-illuminator. The lamp should be a 100HBO mercury arc, and the lamp housing should include a parabolic mirror and should allow manual control of bulb and mirror centration for proper alignment of Koehler epi-illumination. It is very helpful, although not necessary, to have manual control of centration and size of the field diaphragm of the epi-illuminator. Closing down the field diaphragm to just the area of the specimen being imaged reduces photodamage to the whole specimen and reduces out-of-focus fluorescent flare in the image. Similarly, it is helpful if the epi-illuminator is equipped with slots in which to insert neutral density filters to control specimen illumination and an infrared blocking filter to minimize exposure of the specimen to damaging heat.

3. The objective lens (which also acts as the condenser in epi-illumination) should be of the highest numerical aperture available, i.e., 1.4 NA oil immersion. Magnification should be either 60, 63, or 100×, the choice being dependent on the spatial resolution of your camera detector (see Section II,6). Keep in mind that 60 or 63× lenses are often more efficient at transmitting light than 100× lenses. However, you should ***never*** sacrifice system resolution for this small gain in light detection. The lens should not contain contrast-forming elements such as phase rings that block transmission of photons. The lens should be corrected for chromatic aberration (apochromatic) and flat-field corrected (Plan). We have had good luck using DIC plan apochromat objectives.

4. The excitation and emission filters and dichromatic mirror should be as efficient as possible at exciting the fluorophore, separating the excitation from emission, and collecting the emission of the fluorophore of your choice. The use of long-pass instead of band-pass filters may maximize this efficiency. High-quality filter/mirror sets for commonly used fluorophores are available from Chroma Technologies or Omega.

5. The path from the objective lens to the detector should be simple and contain as few intervening components as possible to allow maximum photon collection. Removal of analyzers, wave plates, and Wollaston prisms that are used for various modes of polarization microscopy is required. Optovars or magnification changers should optimally be removed; however, if they are needed to match the microscope resolution to the detector resolution (see later), this is a source of light loss that will have to be lived with. The camera port should utilize the most direct path from the specimen. For an upright microscope, this would be directly over the objective, and for an inverted configuration, a bottom port underneath the microscope is the best bet. The bottom port requires a hole in the table upon which the microscope is seated in order to accommodate the camera. If this is impractical, a side camera port, which requires one mirror to direct the image to the camera, is better than a front port that requires at least two mirrors. Finally, prisms that split the image between the ocular and camera port should be removed from the light path.

B. Electronically Controlled Shutter

1. The electronically controlled shutter should be mounted with proper adapters in the light path between the lamp house and the epi-illuminator.

2. The shutter should be mirrored on the surface facing the lamp to reflect heat away from the specimen.

3. The shutter should operate quietly, quickly, reliably, and without excessive vibration. Shutters can be obtained from Vincent Instruments that are actuated from a software-triggered pulse via the serial or parallel port of the computer.

C. Cooled CCD Camera

Choice of the camera is one of the critical, make-or-break decisions in the design of an FSM imaging system. For imaging the low fluorescence of dim FSM

specimens, the camera demands are steep: it should be highly sensitive, extremely low noise (remember that speckles look a lot like noise!), high spatial resolution, high dynamic range, and, depending on your biological application, it may need high speed as well. The camera should be a scientific grade slow-scan cooled charge-coupled device camera. To date, most intensified cooled CCD we have tested (both microchannel plate type or on-chip type) have had noise characteristics that obfuscate speckle detection, although on-nip electron multiplication LCDs appear promising. Cameras are available from several manufacturers (Hamamatsu Photonics, Roper Scientific, Cohu, Andor) at prices ranging from ~$9000 to $30,000 USD. We give an example of the specifications of the camera of choice in our laboratory, the Hamamatsu Orca II ER, as a benchmark.

D. The CCD Chip

1. Spatial Resolution

Spatial resolution is determined by the physical size of the silicon photodiodes ("pixels") that convert photons to charge on the CCD chip. These currently range in size from about 6×6 to $30 \times 30\,\mu m$. The larger the pixel size, the more magnification from the microscope will be needed to ensure resolution-limited images. Thus, smaller pixel size is better for FSM, as it will not require photon-robbing magnification changers or optovars in the light path. The total number of pixels making up the CCD and the pixel size will determine the imaging area. For example, our Orca II ER has a 1344×1024 array of $6.4 \times 6.4 = 41\,\mu m^2$ pixels, resulting in a 8.67×6.60-mm CCD capable of imaging an 87×66-μm area of the specimen at 100× magnification.

2. Pixel Well Capacity

Based on the physical composition of the silicon photodiodes, pixels will have a maximal number of photoelectrons that it can "hold" before it is saturated with charge, which will correspond to white saturation in the image. The greater this "full well capacity," the greater the potential for a high dynamic range, after taking noise into consideration (see later). The full well capacity is also a function of the pixel size, so for FSM imaging one should consider the best full well capacity per micrometer of pixel area. The Orca II ER has a full well capacity of 18,500 electrons/$41\,\mu m^2$ = 45 electrons per μm^2.

3. Illumination Geometry

CCDs can be illuminated from their front or back sides. Front-side illumination requires that the light pass through substrate materials to reach the photosensitive area, reducing quantum efficiency (QE). This is the configuration of our Orca II ER. Back-illuminated CCDs are physically thinned (also called "back-thinned") to allow illumination directly on the photosensitive surface, making them much more sensitive (and much more fragile and expensive!). However, because of the thinning process, there are limits to the size of the pixels, with the smallest currently available at $13 \times 13\,\mu m$. Thus, one has to weigh whether the increased sensitivity is worth the photon loss in having an optavar in the image path, as well as whether one can afford the expense. For FSM applications, sensitive front illuminated CCDs, such as the Orca II ER, work quite well.

4. Spectral Sensitivity

Different types of CCDs have specific probabilities at any given wavelength of converting a photon striking the pixel to an electron that is counted as signal by the camera (quantum efficiency). Manufacturers supply graphs of the wavelength vs QE for their available CCDs. A CCD should be chosen that has a high (>50%) QE in the wavelength range of your fluorophore of choice. The Orca II ER has ~70% QE between 450 nm (blue-green) and 600 nm (orange-red). Some back-illuminated cameras achieve ~90% QE throughout the visible spectrum, but have excessively large pixels and terribly slow readout (see later).

5. Readout Geometry

Once photons are converted to charge in the array of pixels, the charges must be read out to an image acquisition board so that the image can be reconstructed in the computer by assigning a gray value to the relative charge at each pixel position. Charges are transferred out of the CCD in three basic ways. Full-frame readout occurs as each row of pixel charges is transferred serially out of the CCD one row after another. This type is the slowest and introduces the most noise (nonphoton-associated charge) into the image, although can still acceptable for FSM if other camera electronics do not introduce sources of noise. In contrast, in frame transfer and interline transfer CCDs, either the entire pixel charge array or whole rows of pixels are transferred simultaneously to an array of pixels that are masked from light. The charges are then read out from the masked area while the imaging area is being exposed to light again. These types are much faster and less noisy than the full-frame readout type. All three geometries are acceptable for FSM, although attention should be given to the manufacturer's specifications for the noise introduced during readout ("readout noise") as this will deter-

mine the dynamic range of the camera (see later). Our Orca II ER is the interline transfer type, giving a good balance of higher speed and low readout noise (three to five electrons).

E. Camera Electronics

1. Cooling

Heat on the CCD can cause nonphoton-associated charge to build up in pixels, thus contributing to image noise. The coldest camera possible within a reasonable budget should be chosen. Manufacturers will house the same CCD in cameras with different degrees of cooling, ranging from 20°C below ambient temperature to –50 or –60°C. Do not try to go the inexpensive route here because heat is an avoidable source for noise that can easily mask your very faint FSM signal. The Orca II ER is cooled to –60°C, contributing to its exceptionally low readout noise (see earlier discussion).

2. Readout Speed

In general, the faster the readout speed, the more error is introduced during charge transfer, which translates to noise in your image. Speeds in modern cameras range from 100 kHz/pixel in some low-noise back-illuminated cameras to 14–15 MHz/pixel in interline and frame transfer cameras. For quantitative FSM imaging of cytoskeletal dynamics, image acquisition rates of 1–2 images/s may be required, which cannot be accomplished by the slower cameras. Here, a reasonable compromise of speed and low noise must be sought, but it is recommended not to buy a camera much slower than 1 MHz. The Orca II ER has a choice of readout speeds, a higher noise, fast readout at 10 mHz/pixel or a slower low-noise (quoted earlier) 1.25-mHz/pixel readout rate.

3. Dynamic Range

For FSM imaging of very dim specimens, it is important to have the biggest dynamic range possible (again, within a reasonable budget). Although pixel full-well capacity is set for a given CCD, the number of gray levels this amount of charge is divided up into is not fixed. It can be encoded by 8, 10, 12, 14, or 16 bits of information per pixel, corresponding to 256, 1024, 4096, 16,384, or 65,536 (2^8, 2^{10}, 2^{12}, 2^{14}, 2^{16}) gray levels. However, statistically, it is not possible to distinguish between two gray levels that differ by less than the noise level. Thus the actual dynamic range is determined by the pixel full-well capacity divided by the readout noise. For example, our Orca II ER camera advertises 14 bit dynamic range (16,384 gray levels) and has a full-well capacity of 18,500 photoelectrons. Thus, it must have a noise level of 18,500/16,384 = 1.1 electrons per pixel or less to make use of the full 14 bit range. Because the Orca II ER has a minimum of three electrons noise, the actual dynamic range is 18,500/3 = 6166 discernible gray levels. For FSM imaging, a bigger dynamic range (at least 12 bit) is required so that differences between the intensity of two or three fluorophores can be detected quantitatively.

4. Subarraying and Binning

Being able to read out only a specified portion of the CCD (subarraying) can increase image acquisition speed for imaging small areas of a cell, but it is not necessary. Binning, in which the charges in a group of pixels are combined and read out as a single pixel to increase sensitivity, should not be done in FSM, as this effectively increases pixel size and decreases CCD resolution.

F. Computer, Digital Image Acquisition Board, and Software for Control of Shutter and Image Acquisition

1. Computer

A computer with the fastest processor and most random access memory (RAM) affordable should be used. Currently, computers with ~2-GHz processors and 2-GB RAM can be had for ~$3000 USD. Time-lapse FSM image series are large files often on the order of 500 MB or more and computer "horsepower" is necessary to view and manipulate these. A large hard drive (100 GB) is useful for temporary file storage.

2. File Storage

A DVD R/W device is the most economical choice recommended to archive the large files generated by time-lapse FSM. The fastest write speed available within budget should be chosen. A portable USB-based hard drives allow rapid transfer between computers. However, in the best case, a large networked file server is preferred.

3. Image Acquisition Board

Use the board recommended by your camera and software manufacturer, making sure that the board can handle the bit depth of the camera. Many cameras come with their own boards.

4. Software

Software should be capable of time-lapse digital image acquisition and triggering the shutter during camera exposure. The software should allow easy

viewing of time-lapse series as movies, with control of play-back rate and adjustment of brightness and contrast in the entire image series. Basic image processing, including the ability to perform low-pass filtering and image arithmetic (subtraction, multiplication, etc.), is required. The software should provide the ability to perform quantitative analysis of intensity, position, and distance. We have used Metamorph (Universal Imaging) with outstanding success. However, NIH-Image freeware (available at http://rsb.info.nih.gov/nih-image/) is also very versatile and many free macros are available.

G. Matching Microscope and Detector Resolution

A critical key to obtaining resolution-limited images of fluorescent speckles is matching microscope and camera resolution. The resolution-limited image region has to be magnified to an area on the CCD large enough to achieve a sampling frequency that is high enough to be able to digitally resolve structures at the resolution limit (Stelzer, 1998). As a rule of thumb, magnifying the resolution limited image region to the size of 3×3 pixels on the CCD is sufficient so that the CCD does not limit imaging system resolution or produce aliasing between pixel rows. This is referred to as the Nyquist sampling criterion. Any magnification over this value does not contain significantly more information and simply reduces the area of the specimen that is imaged. The magnification (M) required to achieve this is given by

$$M = 3 P_{width}/r$$

where P_{width} is the width of a pixel and r is the size of the resolution-limited image region. Thus, for red fluorescence with a resolution limit of 0.27 µm and a camera with 6.7 µm pixels and a 1.4 NA objective lens, the magnification required to satisfy the Nyquist criterion is 75×. Thus either a 100× objective or a 60× with 1.25× intermediate magnification should be used, whichever transmits more light.

III. MATERIALS AND INSTRUMENTATION FOR CELL PREPARATION, DRUG PERFUSION, AND FSM IMAGING

Successful time-lapse FSM imaging of actin dynamics is highly dependent on the choice of cell type. Cells should grow in tissue culture well adhered to glass coverslips and should be relatively large (>50 µm diameter), well spread, flat, and thin (<1.0 µm). We routinely use PtK_1 cells, an epithelial line from rat-kangaroo kidney (American Type Culture Collection, Manassas, VA, ccl-35). These cells are optimal as they are large, thin cells and are relatively easy to microinject. PtK_1 cells are maintained in F-12 Hams media (Sigma, St. Louis, MO, Cat. No. N-4388) and plated on 22× 22-mm #1.5 cover glasses (Corning, Kennebunk, ME, Cat. No. 2870-22) in 35-mm tissue culture dishes and maintained in a humidified incubator at 37°C supplemented with 5% CO_2. Use of this type of coverslips is critical, as high-resolution optics are specifically corrected for this thickness (#1.5 = 0.17 mm. thick), and our custom-made perfusion chamber described in Fig. 2 is specifically designed for them. Prior to plating cells, the coverslips are cleaned by sequential washes and sonications in detergent, water, and ethanol, as described in detail in Waterman-Storer (1998). This level of coverslip cleanliness is of paramount importance, as coverslip dirt results in background fluorescence that degrades speckle contrast.

Fluorescently labeled skeletal muscle actin can be bought (Cytoskeleton, Denver, CO, Cat. No. APHR-A) or made using the detailed protocol published elsewhere (Waterman-Storer, 2001). A labeling ratio of 0.3–1.0 fluorescent dye molecules per protein molecule is acceptable. We recommend using longer wavelength fluorophores, such as Texas red (ex 596 nm, em 615 nm), X-rhodamine (ex 575 nm, em 602 nm), Alexa 568 (ex 578 nm, em 603 nm), or tetramethyl rhodamine (ex 541 nm, em 572 nm), as cellular autofluorescence that degrades speckle contrast tends to be at shorter emission wavelengths (~500–550 nm). Very short wavelength excitation fluorophores (i.e., <400 nm) should not be used, as the UV light required for their excitation is very damaging to living cells. In addition, we have found no qualitative difference in FSM of actin dynamics using actin coupled to fluorescent dyes via either lysine residues (i.e., succimidyl ester fluorophore derivates) or cysteine residues (malemide derivates).

Labeled actin should be stored long term (up to 2 years) in flash-frozen aliquots at higher protein concentrations (5–10 mg/ml) at –70°C and can be diluted to the working concentration of 1 mg/ml in G buffer (2 m*M* Tris–Cl, pH 8.0, and 0.2 m*M* $CaCl_2$; just before use add 0.2 m*M* ATP and 0.5 m*M* 2-mercaptoethanol; store up to 1 day at 4°C), refrozen in 5-µl aliquots, and stored for several months before use. To prevent problems of clogged microinjection needles, prior to microinjection into cells, fluorescent actin must be clarified by centrifugation in a swinging bucket rotor (Sorvall, Newtown, CT, Cat. No. S55-S or Beckman Cat. No. TLS-55) in a microultracentrifuge (Sorval, Cat.

No. RCM120 or Beckman Cat. No. TL-100). If possible, keep the rotor stored at 4°C for convenience. Microinjection needles can be bought from Eppendorf (Femtotip II, Brinkman, Westbury, NY, Cat. No. 930000043), although we pull our own from thin wall borosilicate glass capillaries with an outer diameter of 1.00 mm, an inner diameter of 0.78 mm, and a length of 10 cm (Sutter, Novato, CA, Cat. No. BF100-78-10) using a Sutter Instruments P-87 needle puller with a 2.5 × 4.5-mm box filament (Sutter, Cat. No. FB245B). Needles are treated further with hexamethyldisilazane (HMDS, Pierce, Rockford, IL, Cat. No. 999-97-3) to prevent clogging caused by protein adhering to the insides of the needle. A 10-µl Hamilton syringe (Hamilton, Reno, NV, Cat. No. 80008) is used to back load needles with fluorescent actin.

Coverslips of cells are injected in 35-mm tissue culture dishes using an Eppendorf Injectman (Cat. No. 5179 000.018), microneedle holder and grip heads (Cat. No. 5176 190.002, Cat. No. 5176 210.003), and transinjector (Cat. No. 5246 000.010) (Brinkman, Westbury, NY) system mounted stably on a microscope. Although many fine-control microinjectors are acceptable, be sure that they are designed for mammalian cell injection, as those designed for *in vitro* fertilization of larger eggs may not have fine enough positional control. For back pressure in the needle, systems capable of repeatable femtoliter injection volumes are needed; other systems including those made by Picospritzer are acceptable. The microscope on which the microinjector is mounted must be a stable platform-inverted configuration. Although we use a Nikon TE-2000-S, all those mentioned previously are suitable, as well as less expensive "clinical" models. The microscope must be equipped with a quartz-halogen transilluminator and a long working distance phase-contrast condenser lens system that allows room for an open tissue culture dish on the stage (we use a Nikon 0.35 NA extra-long working distance condenser lens). A long working distance dry (nonimmersed) 40× phase contrast objective lens is required to image cells through the thickness of the plastic dish and coverslip during microinjection (we use a Nikon 40× 0.55 NA objective with a 2.1-mm working distance).

In order to keep cells happy and healthy during FSM imaging over time, it is necessary to keep the cells in an optimum environment on the microscope stage. This includes proper temperature and pH regulation and minimizing photodamage and photobleaching caused by exposure to excitation light. Because suppression of fluorescence photobleaching is one of the most critical aspects of successful FSM imaging, when filming PtK_1 cells, we supplement their F-12 Hams media with Oxyrase (Oxyrase Inc., Mansfield, OH, Cat. No. ES-50), an oxygen-scavenging enzyme purified from *Escherichia coli*, which decreases photobleaching and photodamage to the cell. To make this reagent effective, cells and their surrounding media must be sealed from exposure to air. In order to minimize deleterious effects of pH, one might consider adding 5 m*M* HEPES buffer (pH 7.0) to the medium. However, because we use F-12 Ham's media for PtK_1 cells, which is already buffered, this does not require extra HEPES. For temperature control, we find that an airstream stage incubator, such as those produced by Nevtek instruments (ASI-400), is the best bet. One should experiment ahead of time to determine the setting on the thermostat that gives a sample temperature ***(with the objective lens coupled by immersion oil!)*** of 37°C and keeps cells viable over several hours.

For drug treatment studies we have custom designed a live-cell perfusion chamber that allows use of high-resolution oil-immersion objective and condenser lenses and gives near laminar flow for complete exchange of media in a minimal volume while remaining sealed from the environment (Fig. 3). The chamber portion comes in direct contact with media that washes over cells, and thus must be made of inert stainless steel. The chamber top that holds down the coverslip of cells on the chamber has no contact with media, and thus can be made of less inert aluminum, while the coverslip gasket is made of 0.005-in. thick Teflon sheet, for flexibility. A 24 × 60-mm coverslip (Corning, Cat. No. 2940-246) must be sealed to the bottom of the chamber with hot VALAP (a 1:1:1 mixture of Vaseline, paraffin, and lanolin prepared in the laboratory) to complete the condenser lens-facing side of the imaging chamber. Any good machine shop should be capable of reproducing this chamber based on the diagram in Fig. 3.

IV. PROCEDURES

A. Microinjection of Fluorescent Actin

Microinjection of 1 mg/ml fluorescently labeled actin allows later visualization of protein dynamics by time-lapse FSM.

1. Plate cells onto cleaned coverslips (Waterman-Storer, 1998) at least 24 h before microinjection.

2. Pull microinjection needles from borosilicate glass capillaries (1.0 mm outer and 0.78 mm inner diameter). Proteins that polymerize, such as actin, are notoriously difficult to microinject, as the large polymers will clog the needle tips. We have ascertained that

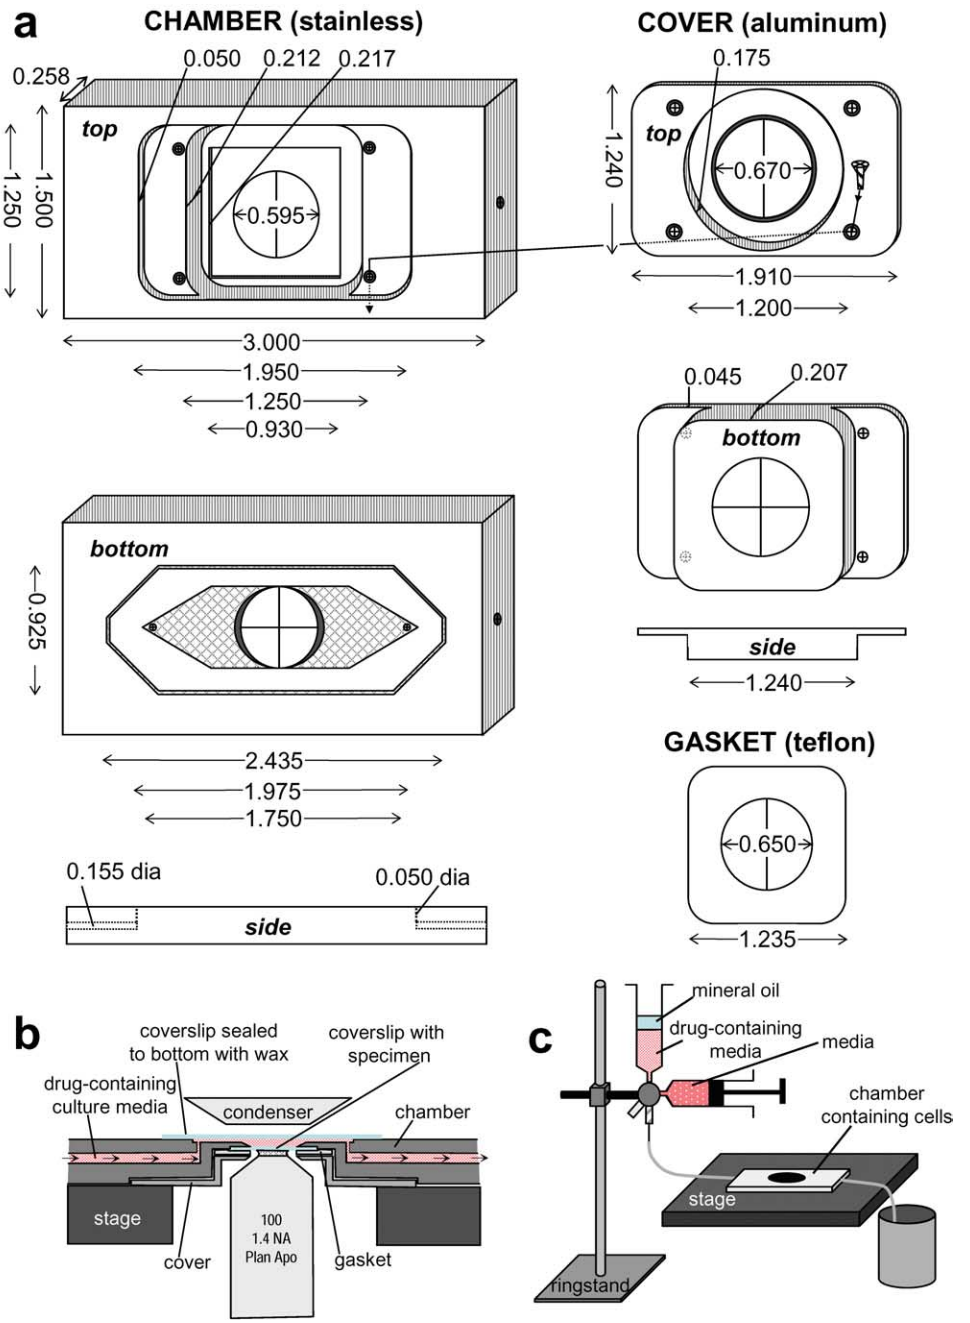

FIGURE 3 A custom-designed perfusion system for drug application during high-resolution FSM imaging. (a) Specifications for chamber design. The chamber is made of stainless steel, the top of aluminum, and the gasket of a 0.005-in. Teflon sheet. Forty-five degree beveled areas are shown in dark gray, holes have crosses across them, and on the bottom of the chamber, the hatched areas are machined-in 0.007 in. to create the imaging chamber. (b) Cutaway side view of the chamber in operation on the microscope stage (not to scale). (c) Schematic of the setup used for drug perfusion.

needles efficient for injecting actin and other polymerizing protein such as tubulin consist of an inner tip diameter of less than 1 µm, and a short, relatively blunt taper to prevent clogging, breaking, or overflexible needles. By experimenting with the parameters of the needle puller, one can adjust the shape of the needle. The following four-step program may serve as a starting point for achieving good needles on the Sutter needle puller, but depending on the age and capabilities of the glass-heating filament in the needle puller,

the needle-pulling program will necessitate some variation according to the guidelines in the owner's manual.

Heat	Pull	Velocity	Time	Pressure
Ramp + 10	100	10	250	500
Ramp	100	10	250	500
Ramp	100	10	250	500
Ramp + 10	100	15	250	500

Commercially available microinjection needles such as Eppendorf Femtotips II work well for actin microinjection and thus are an alternative to pulling your own needles; however, they are expensive and can only be used with Eppendorf injection systems.

3. In a closed petri dish, rest freshly pulled (or freshly opened commercial) needles on a small cylinder of modeling clay to immobilize them and prevent breaking of the tip. In a chemical fume hood, add a few drops of HMDS to the bottom of the petri dish and close the dish immediately. This silanization vapor on the glass will prevent absorption of protein, therefore reducing needle clogging. Allow at least 2 h incubation of needles in the hood with HMDS before use.

4. Just prior to microinjection, chill the microultracentrifuge to 4°C. Thaw an aliquot of labeled actin at body temperature and transfer it to ice immediately. Centrifuge for 20 min at 30,000 *g* in a swinging bucket rotor to remove aggregates that may clog the needle.

5. Following centrifugation, transfer the tube of labeled actin to ice. Using a Hamilton syringe, back load approximately 1 µl of clarified fluorescent actin (being careful not to touch the syringe needle to the pellet!) into a microinjection needle inserted as close as possible to the microneedle tip. Insert the microneedle into the needle holder of the microinjection device. The needle holder should be at an angle of approximately 45° relative to the microscope stage. The back pressure should be set to ~0.8 psi. To rid the needle of air bubbles, use the clean button (which transiently increases the back pressure to a maximum of 65 psi) to push solution through the needle tip.

6. Center the needle over the objective lens as well as possible by eye and lower the needle into the medium in the 35-mm tissue culture dish, stopping immediately when the needle comes in contact with the medium. Close the condensor diaphragm down and move the needle in the *x*–*y* plane so that the very tip of the needle is in the centered cone of light. The needle should be well above the cells, so open the condensor diaphragm and look through the microscope, moving the needle slowly in the *xy* direction and looking for the out-of-focus shadow of the needle in the image field of view. Once the shadow of the needle is in the field, focus up until the needle is in focus. Now slowly alternate between moving the focus down and then the needle down until the needle is in focus just above the cells. Alternatively, using a Bertrand lens, view the objective lens back aperture, where the tip of the needle will be in focus when the needle has just entered the medium. Center the needle tip in the image of the phase ring, then view the image, and lower the needle until it is in focus. Quickly getting needles in focus at the plane of the specimen without breaking their tips will likely take some practice.

7. We find it most simple to keep constant slow flow of labeled actin from the needle tip to help prevent clogging. Bring the flowing needle tip over the cell that you want to inject and lower the needle until it touches the cell just adjacent to the nucleus. As the solution flows into the cell, you will see a change in the contrast of the cell around the nucleus. Rapidly remove the needle from the cell before it blows up.

8. After microinjecting approximately 40 cells in a dish successfully, replace the medium with fresh medium, and place the dish back into the incubator for at least 2 h to allow the cells to recover from injection and to incorporate fluorescently labeled actin into the cytoskeleton.

B. Live-Cell Imaging and Drug Perfusion

1. After microinjection of cells, begin preparing for live-cell imaging and drug perfusion. Turn on the heater to preequilibrate stage and objective lens temperatures several hours before you plan on imaging the cells. This will minimize focus drift caused by temperature shifts that expand/contract the metal in the microscope body. Prepare 20 ml of media (buffered with 10 m*M* HEPES if necessary) containing 30 µl of Oxyrase/ml of media.

2. Right before mounting cells in the perfusion chamber, prepare the perfusion setup (see Fig. 3c). Our custom-designed perfusion setup uses two 10-ml syringes mounted into a two-way luer-lock syringe stopcock (available from medical supply houses) with a 25-gauge needle at the bottom, feeding into a tube that connects to the perfusion chamber (Fig. 3). One syringe should be filled with 10 ml of drug-free media containing 30 µl of Oxyrase/ml of media. Be sure to tap out all bubbles from the syringe to maintain Oxyrase activity. This syringe should be mounted on the stopcock valve parallel to the tabletop. The second syringe will be used for drug-containing media. Remove the plunger from this syringe and place into the stopcock valve perpendicular to the first syringe (perpendicular to the tabletop). Fill it with 8 ml of drug-treated media

supplemented with oxyrase and then cover with mineral oil to protect the oxyrase from the air. The drug perfusion will be done by gravity, as opposed to pushing a syringe.

3. To prepare the perfusion chamber, melt VALAP and heat the perfusion chamber on a heating block for a few minutes. Using a cotton-tipped applicator swab, place a thin layer of VALAP around the outer ring on the bottom of the perfusion chamber and adhere a 24 × 60-mm coverslip onto this. Allow the valap to solidify under the cover glass and place on a cool surface to return the perfusion chamber to room temperature.

4. Once the perfusion chamber is at room temperature, place vacuum grease around the perimeter of the coverslip-mounting surface of the top side of the chamber. Place the chamber on the microscope stage to allow it to heat to 37°C. Once the perfusion chamber is warm, place the coverslip with injected cells face down onto the chamber. Put the gasket on top of the coverslip, making sure it seals the chamber; an additional layer of vacuum grease may aid in this. Then place the aluminum chamber cover over the gasket and attach it to the chamber by screwing down opposite corners in turns, being careful not to crack the coverslip.

5. Once the perfusion chamber is set up, insert the drug-free media inlet tube into one end of the perfusion chamber and hold the chamber so the inlet end is facing down so that when the chamber is filled with media, all air bubbles will be pushed up through the upper outlet. Slowly push the drug-free media through the perfusion chamber. Avoid trapping bubbles by lightly tapping the chamber on a hard surface as you fill it.

6. Insert another tube into the outlet end of the perfusion chamber for discarded media to flow into a waste beaker.

7. Back the microscope focus all the way down and then place a small drop of the appropriate immersion oil on the 100× 1.4 NA objective lens front element. Place the filled perfusion chamber cell side down on the microscope stage and bring the focus up until the oil on the objective is in contact with the coverslip.

8. Bring the cells into focus using phase-contrast or DIC optics, being careful not to smash the objective lens into the coverslip. If using DIC, remember to remove the Wollaston prism and analyzer from the imaging path after finding the cells! Search the coverslip using epifluorescence for the injected cells and verify their viability by seeing if fluorescent actin is excluded from the nucleus. Be careful to keep your cell-gazing time to the absolute minimum, as you will be photobleaching the fluorescent actin. Choose a cell to image that is very dimly fluorescent. Getting the cells in focus with a high-magnification oil-immersed lens and finding the injected cells will take practice and patience.

9. Begin FSM image acquisition. Using the microscope system described in Section II with a mercury arc bulb with <200 h of use on it, exposure times for FSM images taken with unattenuated (neutral density filters removed) light of 500–1000 ms should provide a signal of around 0.3–0.6% of the total gray scale. This translates to a signal of 50–100 gray levels above background for a 14 bit camera or 10–20 for a 12 bit camera. We find that maximizing the gain setting of the camera (if available) is very helpful when taking images of actin speckles. For imaging processes such as actin flow in a PtK_1 cell, an acquisition rate of one image every 5–10 s will allow accurate actin flow velocity analysis. Microscope control software such as Metamorph can be set up easily to acquire images with specific camera parameters and light exposure times at regular intervals for a prescribed total length of time. Plan on taking predrug images for 5–10 min and postdrug images for several tens of minutes.

10. After an appropriate accumulation of images of actin dynamics in the untreated cell, switch the stopcock position to allow drug-containing media to flow through the chamber at a rate of ~2–4 ml/min. Drug perfusion should take approximately 30 s. Continue to acquire images before, during, and after drug perfusion.

11. Continue imaging until the process of interest has terminated or the fluorescent actin is photobleached.

C. Interpreting Speckle Dynamics

Interpretation of actin speckle dynamics provides information about actin turnover and actin flow in a cell and how this relates to cell behavior. Using image analysis software such as Metamorph, images can be processed and analyzed.

1. After acquiring a time series of actin FSM images for at least 5 to 10 min, observe the actin movement by simply watching the time series as a movie. This can be done using Metamorph, Quicktime (Apple, Cupertino, CA), or NIH Image. Pay careful attention to the trajectories of actin movement, convergence of actin in different regions of the cell, and speeds of actin movement in different regions of the cell.

2. Use kymograph analysis to obtain information about the rate of actin retrograde flow and/or the activity of the leading edge. Kymographs are time–distance plots created by extracting the same row of pixels from each image in a time series and laying them side by side in a montage (see Figs. 4 & 5). For measuring

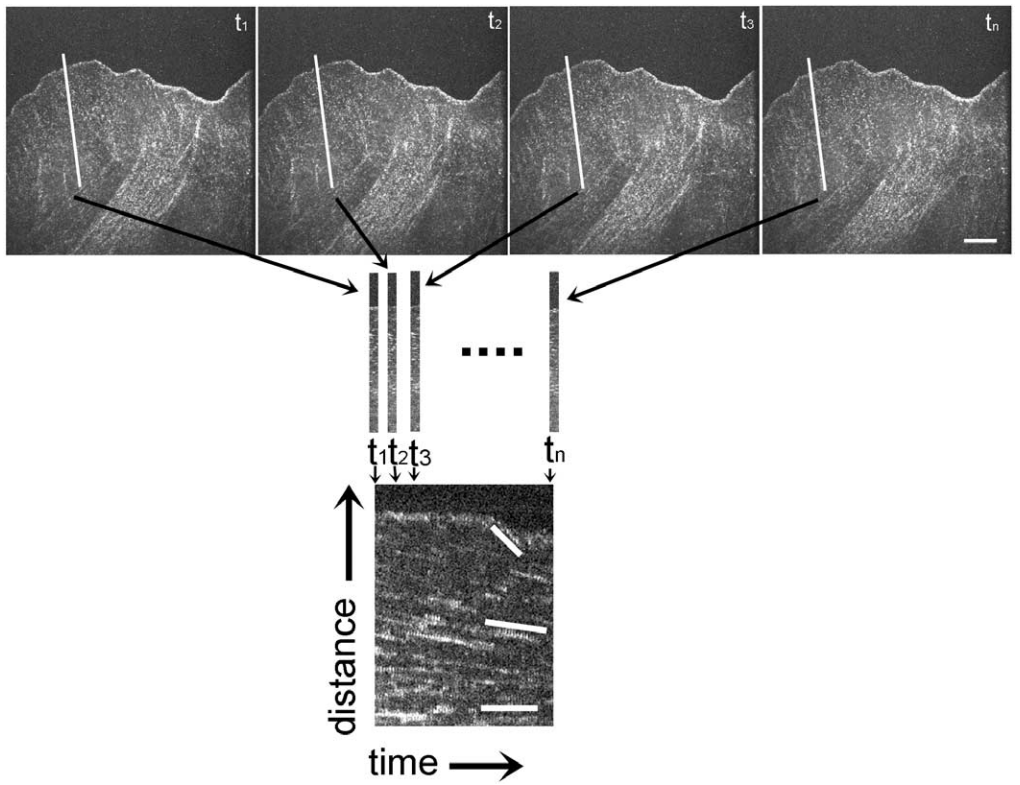

FIGURE 4 Kymograph construction from an FSM time series. The first row of images is taken from a FSM time series. The white line in each image depicts the row of pixels along the trajectory of actin movement (as determined from watching the series as a movie) extracted to construct the kymograph to show actin dynamics, seen below the images. Rows of pixels are laid side by side in a montage to create a time vs distance plot, seen on the bottom of the figure. This kymograph allows analysis of the rates of actin movement within different regions of the cell. Lines in the kymograph on the bottom highlight discreet rates of actin flow in which the magnitude of the slope of the lines relates to the velocity of actin movement. Bar: 10 μm.

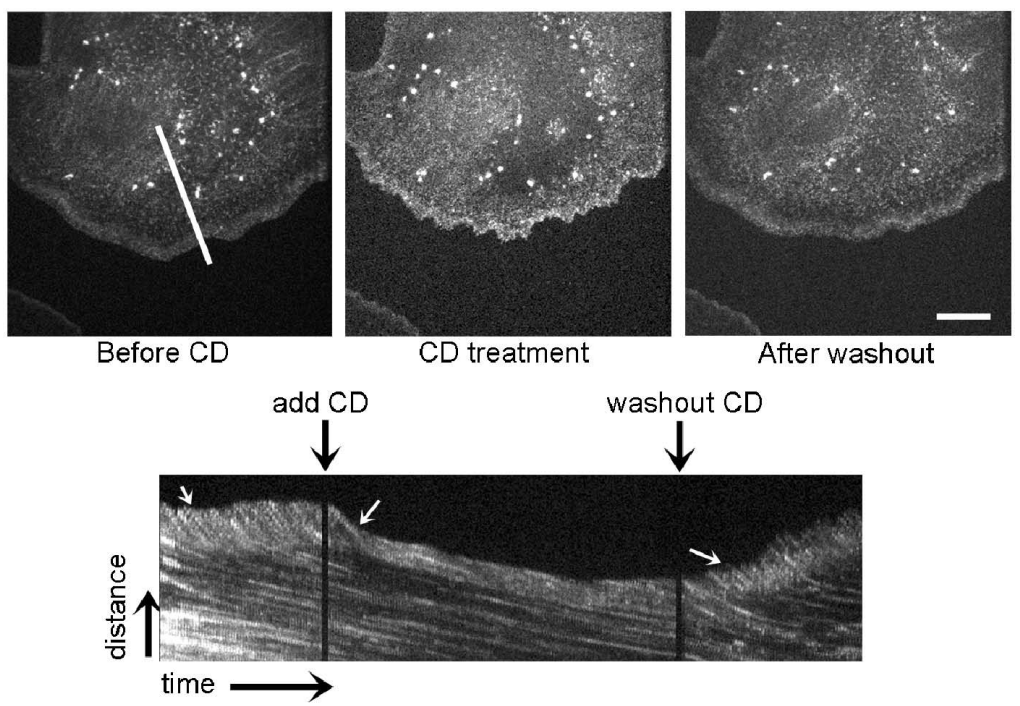

FIGURE 5 FSM reveals that cytochalasin D (CD) halts actin polymerization and fast retrograde flow in the lamellipodium. Images are taken from a time series before CD treatment, during CD treatment, and after washing out CD. (Bottom) A kymograph taken from the time series along the white line indicated in the first image. Perfusion and washing out of CD are marked by black arrows over the kymograph. White arrows on the kymograph indicate the region of rapid retrograde flow inhibited by CD treatment and relieved after CD washout. Bar: 15 μm.

actin dynamics, choose a row of pixels along the trajectory of actin movement as determined from watching the movie. For measuring leading edge activity, choose a row of pixels perpendicular to the leading edge.

V. PITFALLS

Successful FSM imaging of live cells requires several critical components, such as proper fluorescent protein concentration, successful suppression of photobleaching, and high-quality, well-labeled, fully functional fluorescent protein. Fluorescent actin speckles cannot be detected if the concentration of fluorescent protein in the cell is too high, which can occur if the microneedle concentration is >1 mg/ml. Even at proper needle concentrations, too much fluorescent actin can get into the cell if the microinjection technique is not optimized. Conversely, if there is not enough fluorescent protein injected into cells, the camera exposures required to acquire a decent image will be excessively long and may result in motion artifacts within the image. Photobleaching is also a major pitfall in FSM imaging. This can occur if the imaging chamber is not fully sealed, if there are air bubbles present in the chamber, or if the Oxyrase has begun to lose its potency. Ensuring an airtight chamber with fresh Oxyrase will reduce photobleaching greatly. Finally, ensuring that the actin remains functional during the labeling process is an extremely important consideration for quality FSM imaging. If you are making your own fluorescent actin, be sure to use high-quality acetone powder that is finely powdered or "fluffy" and that the dye is fresh and has been stored in dessicant at –20°C. Old dye will render actin nonpolymerizable, so avoid using dye that is not fresh.

Imaging Fluorescence Resonance Energy Transfer between Green Fluorescent Protein Variants in Live Cells

Peter J. Verveer, Martin Offterdinger, and Philippe I. H. Bastiaens

I. INTRODUCTION

In recent years, the measurement of fluorescence resonance energy transfer (FRET) between variants of fluorescent proteins has emerged as a powerful tool for intracellular measurements of protein reactions (Heim and Tsien, 1996; Matz *et al*., 1999; Tsien, 1998; Wouters *et al*., 2001). For FRET assays in living cells, the green fluorescent protein (GFP), cyan fluorescent protein (CFP), and yellow fluorescent protein (YFP) variants are used most frequently. These GFP variants are intrinsically fluorescent and do not require any exogenous cofactors or substrates, rendering them particularly useful as genetically encoded fluorescent tags to participate as a donor or acceptor fluorophore in a FRET pair. FRET is a photophysical effect where energy is transferred from an excited donor to an acceptor fluorophore; it is a process that is mediated by a direct electromagnetic interaction and does not involve the emission and subsequent absorption of a photon (Clegg, 1996). The efficiency of the transfer depends on the spectral properties of the donor and acceptor and on their relative orientation and distance. Most importantly, the energy transfer efficiency has an inverse sixth order dependency on the distance between the two fluorophores, and therefore FRET only occurs at distances that are typically less than 10 nm. As a result, FRET can be used to specifically image molecular interactions or conformational changes as these events may bring donor and acceptor fluorophores within this distance range, providing they are attached to the same macromolecule or to the interacting molecules.

FRET cannot be measured directly, but its occurrence is reflected by changes in the fluorescence kinetics of both the donor and the acceptor molecules that can be measured by optical means. Due to the direct transfer of energy from the donor to the acceptor, the rate at which the donor returns to its ground state after excitation increases and therefore its fluorescence lifetime decreases. Since the quantum yield of a fluorophore is proportional to its lifetime, the steady-state intensity of the donor molecule also decreases if FRET occurs. However, the steady-state fluorescence of the acceptor increases due to the sensitized emission induced by the energy transfer. Here we outline two methods to detect FRET that are based on the measurement of these effects: (1) fluorescent lifetime imaging microscopy (FLIM) and (2) sensitized emission measurements.

The fluorescent lifetime of a fluorophore is a measure of the time that the fluorophore spends in the excited state and is independent of probe concentration and light path length (Bastiaens and Squire, 1999). FRET reduces the fluorescence lifetime of the donor molecule since it depopulates its excited state. Thus, the measurement of the fluorescence lifetime of the donor can be used as an indicator for FRET. In such an assay, the donor–acceptor pair is chosen such that the donor fluorescence can be detected specifically without detecting any acceptor fluorescence. Therefore absolute specificity of the acceptor probe is not required, and experiments can be carried out with an

excess of acceptor. The reduction of the fluorescence lifetime due to FRET should be judged in comparison to the fluorescence lifetime of the donor in the absence of FRET. This can be achieved using an internal control where at the end of the experiment the acceptor is photobleached (Bastiaens and Jovin, 1998). This may require illumination of the acceptor for an extended period during which relocation of the proteins may occur. However, because the fluorescence lifetime of the donor is independent of probe concentration, this poses no problem because only the average value of the lifetime after photobleaching is required. FLIM can be implemented in two conceptually different ways (Bastiaens and Squire, 1999). In the first approach, the sample is illuminated with a short laser pulse, and the resulting fluorescence decay is sampled using a fast, gated detector. The measured curve is a direct reflection of the fluorescence decay from which the fluorescent lifetime can be derived. The second approach uses sinusoidally modulated laser light to illuminate the sample at a high frequency (typically ~80 MHz). The resulting fluorescence is also sinusoidally modulated but phase shifted and demodulated compared to the excitation. This phase shift and demodulation depend on the fluorescent lifetime, which can therefore be derived if these quantities can be measured. This can be achieved with a sinusoidally modulated detector whose phase is shifted systematically with respect to the phase of the illumination. The result is a sinusoidally shaped curve from which the phase shift and demodulation, and thus the lifetime, can be derived. Although this approach appears more complex, it requires a less expensive and complicated laser setup and has proven to be a reliable approach in biological applications.

Sensitized emission measurements can be achieved using standard wide-field or confocal microscopes if the appropriate excitation sources are available and the fluorescence emissions of the donor and acceptor can be detected. Generally it is not possible to image the sensitized emission directly, as excitation of the donor cannot be achieved without also directly exciting the acceptor. In addition, bleed through from the donor fluorescence also contributes to the signal that is detected in the acceptor channel upon excitation of the donor. Thus, the signal that is measured upon excitation of the donor consists of three components: bleed through from donor emission, acceptor emission due to direct excitation of the acceptor, and sensitized emission from the acceptor due to energy transfer. Thus the measurement must be corrected for bleed through and direct excitation, which can be achieved using an additional specific measurement of the donor fluorescence upon donor excitation and a measurement of the acceptor fluorescence upon specific excitation of the acceptor. These corrections require scalar calibration factors that can be found using two reference samples that contain either donor or acceptor molecules alone.

The use of green fluorescent protein variants as partners in a FRET pair requires consideration of the relative expression levels of the two protein–GFP fusions in the light of the measurement method that is being used. Using FLIM implies that only the donor fluorophore is being used to measure FRET, which makes this method eminently useful in the case that the acceptor is expressed in a saturating excess over the donor. This is an advantage if the acceptor-tagged protein is used as a sensor to report on the activity or covalent state of the donor-tagged protein, as it is then ensured that any donor-tagged protein can bind to at least one sensor molecule. In sensitized emission measurements the use of excess amounts of acceptor may lead to problems, as the contribution of sensitized emission may then be low compared to the direct excitation of the acceptor. Thus, care should then be taken that the expression levels of acceptor and donor are comparable.

This article uses an example of an assay for the detection of the phosphorylation state of the epidermal growth factor receptor (EGFR). YFP was fused to a phosphotyrosine-binding domain (PTB-YFP) from Shc, which recognizes three high-affinity binding sites on the intracellular part of the EGFR upon phosphorylation (Zhou *et al.*, 1996). We used the citrine variant of YFP that, compared to previous variants, has a reduced sensitivity to pH due to a much lower p*K*a (5.7), has twice the photostability, and exhibits much better expression at 37°C (Griesbeck *et al.*, 2001). CFP was fused to EGFR (EGFR-CFP) and FRET between CFP and YFP was used to detect the binding of PTB to EGFR and thereby the phosphorylation of EGFR.

II. MATERIALS AND INSTRUMENTATION

A. Materials

Dulbecco's modified Eagle's medium

CO_2-independent imaging medium, containing no components that are autofluorescent. Available commercially from Life Technologies or prepared using the standard formulation of Dulbecco's modified Eagle's medium by omitting pH indicator phenol red, penicillin, streptomycin, folic acid, and riboflavin.

Glass-bottomed tissue culture dishes (35-mm, MatTek Corporation)

Transfection reagent, e.g., Superfect, Qiagen; Lipofectamine, Invitrogen; FuGENE-4, Roche
Plasmids encoding the CFP- and YFP-tagged proteins of interest

B. Instrumentation

Fluorescence lifetime imaging microscope suitable for measuring the lifetime of CFP and equipped with a filter set suitable for specifically exciting and imaging YFP. For the experiments described here, we used a home-built wide-field system (Squire and Bastiaens, 1999). CFP excitation: Ar laser at 457.9 nm, CFP filter set (dichroic beam splitter 467; DELTA, Lyngby, Denmark, emission filter HQ480/20; Chroma). YFP excitation: 100-W mercury lamp, YFP filter set (dichroic filter 530 long pass, excitation 510/25, emission filter HQ560/50).
Leica SP2 confocal microscope, equipped with Ar laser with 457.9-nm laser line for CFP excitation and a 514-nm line for YFP excitation
Wide-field fluorescence microscope with appropiate filter sets. For example (from Sorkin *et al.*, 2000): YFP filter set (excitation 500/20 nm, emission 535/30 nm), CFP filter set (excitation 436/10 nm, emission 470/30 nm), FRET filter set (excitation 436/10 nm, emission 535/30 nm).
Computer with image processing software, such as IPLab (Scanalytics)

III. PROCEDURES

A. Cell Preparation

To prepare cells for FRET experiments with either FLIM or sensitized emission, the donor and acceptor plasmid DNA must be introduced into the cells. This is accomplished using standard transfection methods or, alternatively, using nuclear microinjection. The following steps are used to prepare adherent cells for imaging using transient transfection:

1. Day 1: Seed the cells onto glass-bottomed dishes.
2. Day 2: Cell transfection.
   a. Transfect a number of dishes with both plasmids encoding CFP- and YFP-tagged protein, according to the protocol provide by the supplier of the transfection agent.
   b. For sensitized emission measurements only: transfect a number of dishes with plasmids encoding the CFP-tagged protein.
   c. For sensitized emission measurements only: transfect a number of dishes with plasmids encoding the YFP-tagged protein.
3. Incubate the transfected cells under the appropriate conditions for 15–24 h (e.g., 37°C, 5% CO_2) to allow the cells to express the proteins.
4. Day 3: Before imaging, proceed optionally with any necessary cell-handling protocols such as starvation in medium without growth factors.
5. Immediately before imaging replace the culture medium with CO_2-independent imaging medium.

B. Fluorescence Lifetime Microscopy

Fluorescence lifetime microscopy is well suited for FRET experiments where the acceptor is present in excess, as only the fluorescence of the donor needs to be measured. Figure 1 shows an example where FRET between EGFR-CFP and PTB-YFP was measured with FLIM before and after stimulation with epidermal growth factor (EGF). An experiment on living cells requires following the response of the cells to a stimulus in time. At selected time points, a FLIM data set is acquired that contains fluorescence intensity and lifetime information of the donor. Additionally, a fluorescence intensity image of the distribution of the acceptor is acquired. Finally, a control measurement is performed to obtain the lifetime of the donor in the absence of FRET. A detailed description of the FLIM data acquisition itself falls outside the scope of this article. Acquisition of a single data set that captures the spatially resolved lifetimes at a given time is therefore assumed to be a single step in our protocol. More details can be found in the relevant literature (Clegg and Schneider, 1996; Gadella *et al.*, 1993; Squire and Bastiaens, 1999). An experiment involves the following steps.

1. Acquire a FLIM data set using the 457.9-nm line to excite the CFP donor.
2. Acquire an image of the YFP fluorescence using the 100-W mercury lamp and the YFP filter set.
3. Optionally, repeat steps 1 and 2 for several time points to require a time-lapse series.
4. Illuminate the acceptor extensively with the YFP filter set until the fluorescence from YFP is abolished completely.
5. Acquire a final FLIM data set to find the lifetime of the donor in the absence of acceptor.

C. Fluorescence Lifetime Imaging Microscopy Data Analysis

Analysis of fluorescence lifetime imaging microscopy data is an extended subject that is described

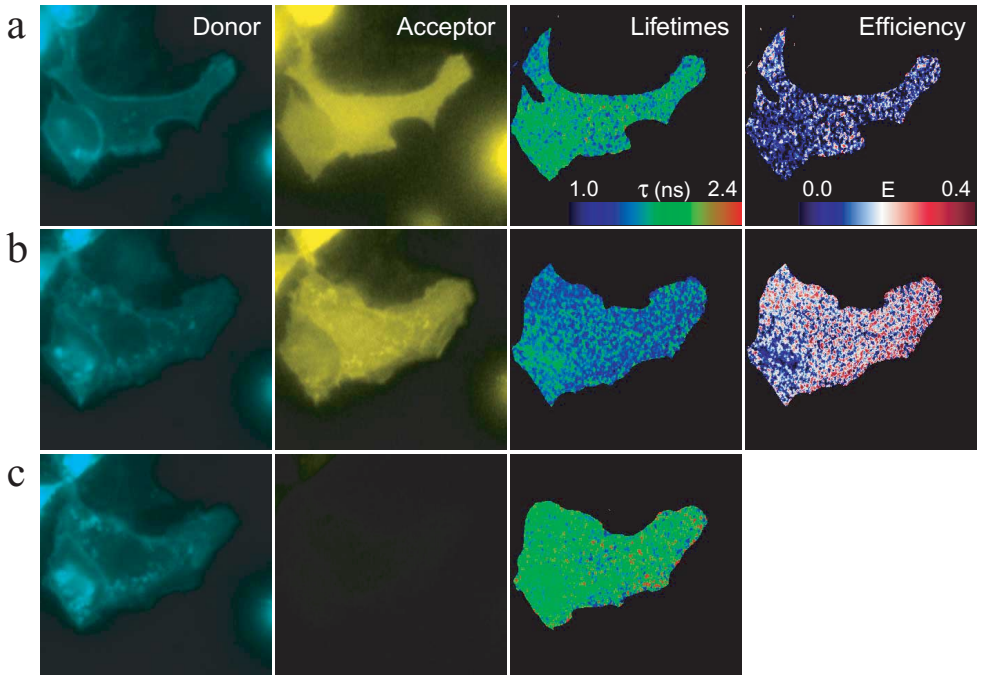

FIGURE 1 Fluorescence lifetime imaging microscopy of CFP-tagged epidermal growth factor receptor (EGFR-CFP) cotransfected with YFP-tagged phosphotyrosine-binding domain (PTB-YFP) stimulated with epidermal growth factor (EGF). Measurements are made before and after stimulation, and finally after photobleaching of the acceptor. The lifetime of the donor in the absence of FRET is calculated from the average lifetime after photobleaching and is used to calculate the energy transfer efficiencies for the other measurements as described in the text. From left to right: CFP fluorescence (donor), YFP fluorescence (acceptor), fluorescence lifetime, and apparent energy transfer efficiency. (a) Results before stimulation with EGF. (b) Results after stimulation with EGF for 18 min. (c) Results after destruction of the acceptor fluorophores by photobleaching. The average apparent lifetime of the donor after photobleaching of the acceptor was 1.9 ns.

elsewhere (Gadella *et al.*, 1994; Verveer *et al.*, 2001). We will therefore assume that the FLIM data analysis software is provided as a part of the instrumental setup and calculates a lifetime value at each pixel position from the measured FLIM data. The result found at a given pixel location is a weighted summation of the fluorescence lifetimes of the individual molecular components present, and if a significant proportion of those components have a short lifetime due to FRET, this is reflected in a decrease in the measured lifetime. This measured value should be compared to the lifetime of the donor fluorophore in the absence of FRET, which can be found from the sample itself by photobleaching the acceptor. Given the measured lifetime at each pixel $\tau_{DA}(i)$, and the donor lifetime τ_D, an apparent energy transfer efficiency can be calculated in each pixel:

$$E(i) = 1 - \frac{\tau_{DA}(i)}{\tau_D}.$$

The analysis consist of the following steps.

1. Calculated the fluorescence lifetime image for the FLIM data set that was obtained after acceptor photobleaching. Calculate the average value to obtain the lifetime of the donor τ_D in the absence of acceptor.
2. Calculate the fluorescent lifetime images for all the other measured FLIM data sets.
3. Divide each pixel of the fluorescent lifetime images by τ_D.
4. Multiply the resulting pixel values by –1 and add 1 to obtain $E(i)$.

D. Sensitized Emission Measurements

Sensitized emission measurements are well suited for cases where donor and acceptor are expressed at similar levels. Detecting FRET by sensitized emission requires correction for fluorescence bleed through and unmixing of direct and sensitized acceptor emission (Gordon *et al.*, 1998; Nagy *et al.*, 1998). For illustration purposes we will assume the use of a Leica SP2 micro-

scope, but the discussion generalizes to any microscope equipped with the proper excitation and emission filters. Figure 2 shows an example where FRET between EGFR-CFP and PTB-YFP was measured using sensitized emission before and after stimulation with EGF. This article limits itself to donor and acceptor pairs with the following spectral properties: (1) upon donor excitation the donor fluorescence can be detected specifically; and (2) the acceptor can be excited specifically (i.e., no donor fluorescence upon acceptor excitation). The CFP-YFP FRET pair that we use in this article meets these requirements. The CFP was excited at 457.9 nm, which yields also significant direct excitation of YFP, and the YFP was excited specifically at 514 nm. The Leica SP2 microscope allows flexible settings for measurements of the emission with up to four detectors simultaneously. We simultaneously detected fluorescence at 460–495 nm (CFP channel) and at 520–570 nm (YFP channel). In the CFP channel, no significant YFP emission is detected, but in the YFP channel, a significant contribution of CFP fluorescence is present upon excitation of CFP. Measurement of the CFP channel upon CFP excitation allows for estimation of the amount of bleed through if it is known how much CFP emission is detected in the YFP channel. This can be calibrated by excitation of CFP in a reference sample transfected with CFP-tagged protein only. Dividing the total signal in the YFP channel by the total signal in the CFP channel gives the scalar bleed-through correction factor. To calculate the bleed-through image in a sample with both CFP and YFP, each pixel in the image from the CFP channel is multiplied with the scalar bleed-through correction factor obtained from a reference sample. In a similar fashion, the amount of direct excitation is calibrated from a reference sample that expresses only the YFP-tagged protein. The total signal detected in the YFP signal upon CFP excitation is divided by the total

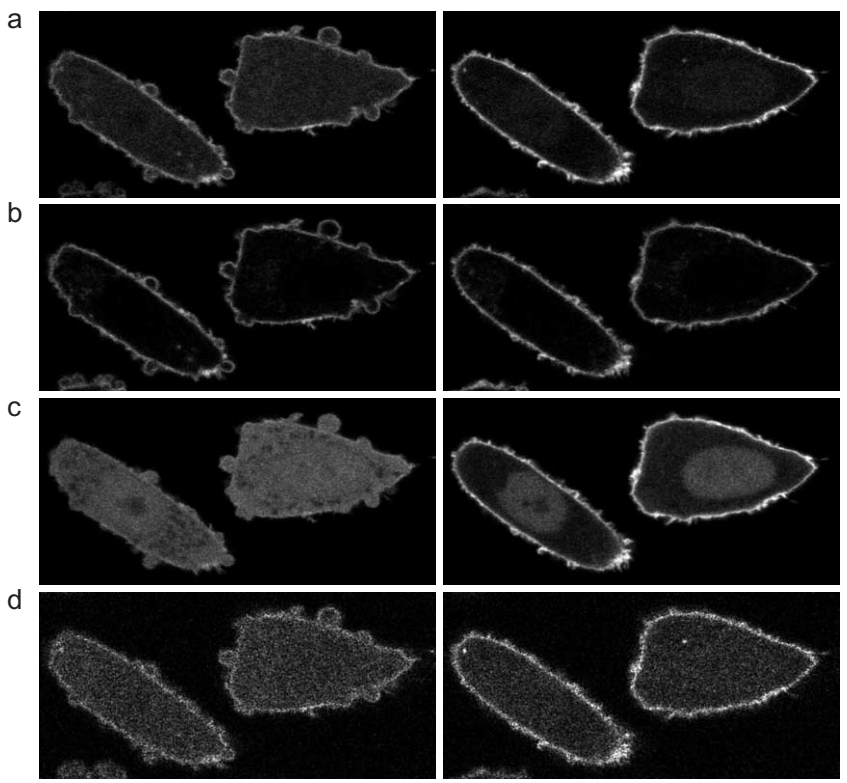

FIGURE 2 Sensitized emission measurement of FRET between CFP-tagged epidermal growth factor receptor (EGFR-CFP) cotransfected with YFP-tagged phosphotyrosine-binding domain (PTB-YFP) stimulated with epidermal growth factor (EGF). Measurements were made before stimulation and after 90 s of stimulation with EGF. Different images and the calculated result before (left) after (right) stimulation. (a) Images measured in the acceptor channel upon excitation of the donor. (b) Images measured in the donor channel upon donor excitation. (c) Images measured in the acceptor channel upon acceptor excitation. (d) Sensitized emission calculated by subtracting the images in b and c from the images in a after scaling with the appropriate scalar correction factors for bleed through and direct excitation.

signal upon YFP excitation to obtain the scalar direct excitation correction factor. To calculate the direct excitation image in a sample with both CFP and YFP, each pixel in the image measured in the YFP channel upon specific YFP excitation is multiplied with the scalar direct excitation correction factor. An image of the sensitized emission is then calculated by pixel-wise subtraction of the bleed-through and direct excitation images from the image that is measured in the YFP channel upon excitation of CFP.

The reference measurements should be taken at the same instrumental settings (detector gains and offsets, illumination power) as used for the sensitized emission measurements itself. Results of the reference measurements for a given setting should be reproducible and it is advisable to check this by repeating the reference measurement procedure a few times. Reference measurements are done using the following steps.

1. A sample with only donor molecules is used to calibrate the contribution of bleed through.
   a. Excite the donor and acquire an image of the donor channel, yielding image $D_{DD}(i)$, where i is the pixel index.
   b. Excite the donor and acquire an image of the acceptor channel, yielding image $D_{DA}(i)$.

Care should be taken that the sample is not moved between acquisitions. In live cells the images should be taken in quick succession to avoid artifacts due to relocation of the donor-tagged protein or movement or deformation of the cell. In some instruments (e.g., the Leica SP2 used by us) it is possible to acquire the two images simultaneously, which is preferable.

2. The contributions of direct excitation are calibrated using a sample that has only acceptor molecules.
   a. Excite the donor and acquire an image of the acceptor channel, yielding image $A_{DA}(i)$.
   b. Excite the acceptor and acquire an image of the acceptor channel, yielding image $A_{AA}(i)$.

These images must be taken separately, but the same concerns about sample movement, as described in point 1, are valid. The Leica SP2 microscope allows switching between donor and acceptor excitation sources on a line-by-line basis or on a frame-by-frame basis. The former is preferable, as less movement will occur between acquisitions of successive lines than between acquisitions of successive images.

For sensitized emission measurements with samples that have both donor and acceptor molecules, the following steps are taken.

1. Excite the donor and acquire an image of the donor, yielding image $F_{DD}(i)$.
2. Excite the donor and acquire an image of the acceptor, yielding image $F_{DA}(i)$.
3. Excite the acceptor and acquire an image of the acceptor channel, yielding image $F_{AA}(i)$.

Again, care should be taken that the sample is not moved between image acquisition or that significant relocation of the proteins of interest or the cell as a whole takes place. Using a Leica SP2 microscope, steps 1 and 2 can be done simultaneously and switching between illumination sources should be done on a line-by-line basis.

When possible, the detector used should have a high dynamic range for all measurements. For instance, modern confocal microscopes allow recording data with 12-bit precision.

E. Sensitized Emission Data Analysis

The data analysis steps for sensitized emission measurements are fairly simple and can be performed with many commercially available image processing packages. The following steps are used for calculating the sensitized emission image from the measured images.

1. Background correction, applied to all images:
   a. Select a small region of interest in the background of the image.
   b. Calculate the mean intensity with the region of interest to obtain the background value.
   c. Subtract the background value from each pixel the image.
2. Calculate the correction factor for the bleed through from the reference measurements by taking the ratio between the signal in the acceptor channel to the donor channel.
   a. Create a mask from the pixels with high signal within image $D_{DD}(i)$, by thresholding, or interactive selection. It is important to exclude saturated pixels from the mask, as the calculated result from such pixels will be incorrect.
   b. Calculate the sum of the pixel intensities in image $D_{DD}(i)$, within the mask:

$$sum(D_{DD}) = \sum_{i \in mask} D_{DD}(i).$$

   c. Calculate the sum of the pixel intensities in image $D_{DA}(i)$, within the mask:

$$sum(D_{DA}) = \sum_{i \in mask} D_{Da}(i).$$

   d. Calculate the scalar bleed-through correction factor

$$C_{\text{bleed-through}} = \frac{sum(D_{DA})}{sum(D_{DD})}.$$

3. Calculate the correction factor for direct excitation from the reference measurements by taking the ratio of the signals in the acceptor channel upon excitation of the donor and acceptor, respectively.

a. Create a mask from the pixels with high signal within image $A_{AA}(i)$ by thresholding or interactive selection. Exclude saturated pixels.

b. Calculate the sum of the pixel intensities in image $A_{DA}(i)$, within the mask:

$$sum(A_{DA}) = \sum_{i \in mask} A_{DA}(i).$$

c. Calculate the sum of the pixel intensities in image $A_{AA}(i)$ within the mask:

$$sum(A_{AA}) = \sum_{i \in mask} A_{AA}(i).$$

d. Calculate the scalar direct excitation correction factor:

$$C_{\text{direct-excitation}} = \frac{sum(A_{DA})}{sum(A_{AA})}.$$

4. Calculate the bleed-through correction in each pixel by multiplying the image in the donor channel upon donor excitation with the correction factor obtained in step 2:

$$BT(i) = C_{\text{bleed-through}} \cdot F_{DD}(i)$$

5. Calculate the correction for direct excitation of the acceptor in each pixel by multiplying the image in the acceptor channel upon acceptor excitation with the correction factor obtained in step 3:

$$DE(i) = C_{\text{direct-excitation}} \cdot F_{AA}(i)$$

6. Calculate the sensitized emission image by subtracting the corrections for bleed-through and direct excitation calculated in steps 4 and 5 from the image that was measured in the acceptor channel upon donor excitation:

$$S(i) = F_{DA}(i) - BT(i) - DE(i).$$

This image represents the fluorescent light due to energy transfer that is directly proportional to the concentration of donor–acceptor complexes.

7. *Optional*: Calculate an apparent energy transfer efficiency using

$$E_A = \frac{S(i)}{F_{AA}(i)}.$$

This equation normalize the sensitized emission with the emission of the acceptor only, and therefore the result is proportional to the fraction of interacting molecules with respect to the total amount of acceptor-tagged molecules (Wouters *et al.*, 2001). It is also possible to normalize the sensitized emission with the donor fluorescence; however, because the donor emission is quenched by FRET, this is *not* proportional to the relative fraction of donor-tagged molecules that is in an interacting pair.

Measurements of Endosomal pH in Live Cells by Dual-Excitation Fluorescence Imaging

Nicolas Demaurex and Sergio Grinstein

I. INTRODUCTION

The pH of endosomes can be measured with minimal interference to cellular function using internalized ligands or antibodies labeled with pH-sensitive fluorescent probes. Following internalization of receptor-bound or fluid phase probes, a rapid acidification can be detected along the endosomal pathway, with the pH decreasing within minutes by nearly one pH unit (Fig. 1). Cargo can then recycle back to the plasma membrane, reach the Trans-Golgi-Network (TGN) (pH~6.0), or be targeted for degradation through late endosomes (pH < 6.0) and lysosomes (pH < 5.5). Determination of the vesicular pH thus allows one to establish whether, at a specific time point, the cargo resides within a sorting, recycling, or degradation compartment (Demaurex, 2002). Repeating such pH measurements at different times during the internalization provides a functional readout of the pathway followed by internalized compounds.

The most convenient indicator for such measurements is Fluorescein Isothiocyanate (FITC), and numerous specific antibodies and ligands labeled with FITC are readily available. Covalent labeling of specific proteins or antibodies with FITC is relatively easy to perform, at low cost (Grinstein and Furuya, 1988). From a measurement standpoint, the most important feature is that the bright fluorescence of FITC is strongly pH dependent at its peak excitation wavelength of λ_{ex} = 490 nm, but is almost completely pH insensitive at λ_{ex} = 440 nm, thus allowing dual-excitation ratio fluorescence imaging. The ratio λ_{ex} = 490/λ_{ex} = 440 normalizes the measurements for the amount of fluorophore, as well as for differences in refractive index and changes in focus, and truly represents pH. The fluorescence ratio can be calibrated *in situ* by equilibrating the pH of the vesicle with the extracellular pH using nigericin, a K^+/H^+ ionophore, and monensin, a Na^+/H^+ ionophore (for details, see Thomas *et al*. (1979)). Using a standard fluorescence microscopy apparatus, such as the one described in Fig. 2 and the protocol and image analysis techniques described here, the pH of endocytic compartments can be measured simply by incubating cells with FITC-labeled ligands or antibodies (Demaurex *et al*., 1998; Gagescu *et al*., 2000; Piguet *et al*., 1999, 2000).

II. MATERIALS AND INSTRUMENTATION

MES, HEPES, and RPMI 1640 medium (bicarbonate free) are obtained from Sigma. Ionophores (sodium salts) are from Fluka (nigericin, Cat. No. 72445; monensin Cat. No. 69864).

The open perfusion microincubator, Leiden coverslip holder, and temperature controller are from Harvard Apparatus (refs. PDMI-2 and TC-202A). Glass coverslips are "Assistent" circular cover glasses No. 1001, Ø 25 mm, thickness 0.16 mm from Karl Hecht Glaswarenfabrik, D-97647 Sondheim/Rhön, Germany.

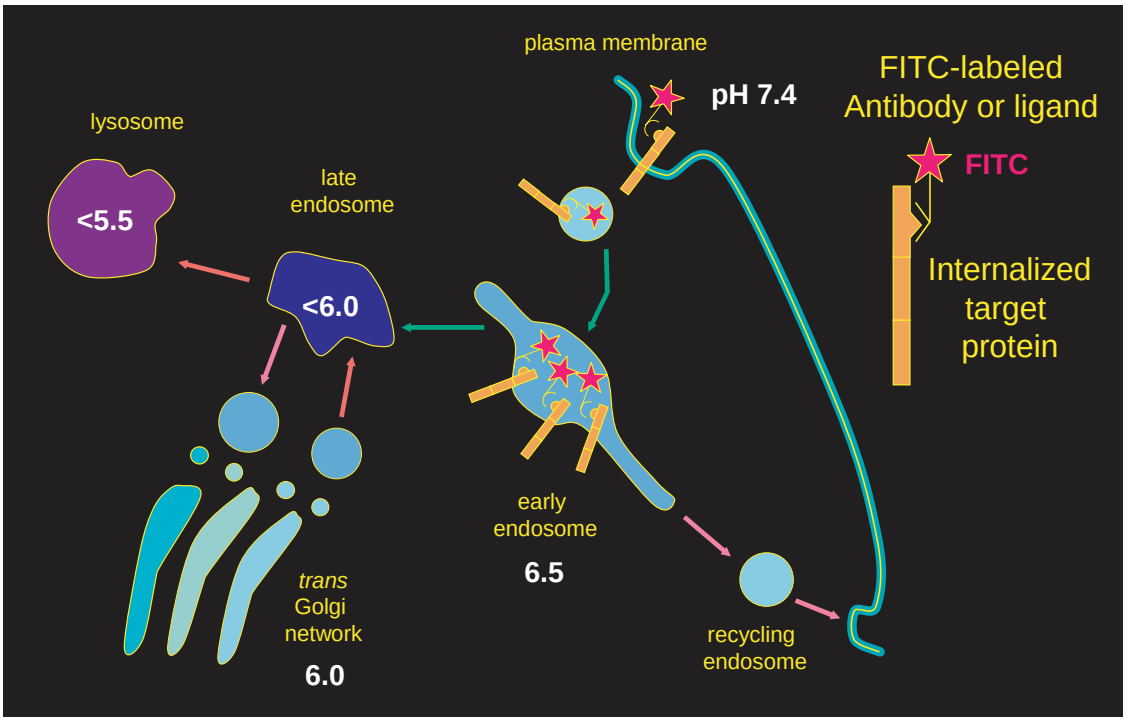

FIGURE 1 **Measuring the pH of endocytic organelles with internalized FITC.** Organelles acidify rapidly as they progress along the endocytic pathway. The pH of endocytic compartments can be measured simply by allowing cells to internalize FITC-labeled antibodies or ligands (red stars). The fluorescence of the FITC-labeled compartments is then imaged at the pH-dependent (λ_{ex} = 490 nm) and pH-independent (λ_{ex} = 440 nm) FITC excitation wavelength to determine the pH of the organelle.

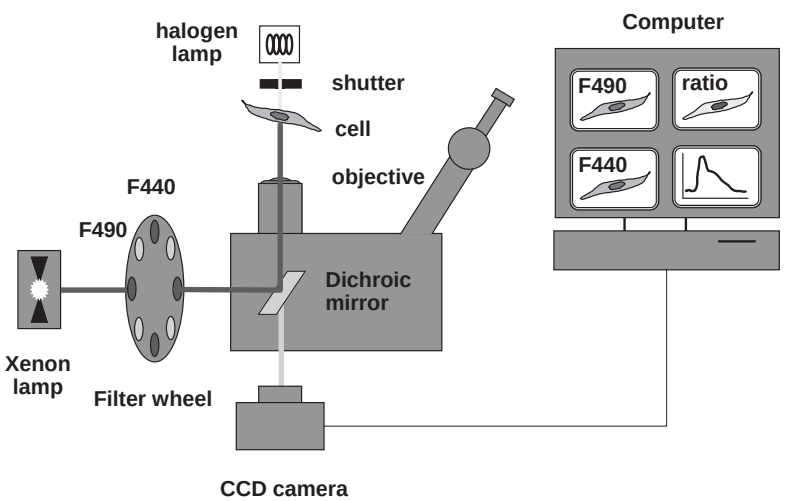

FIGURE 2 **Optical and hardware components used for endosomal pH measurements.** The key components are (1) an objective with high (1.4) numerical aperture (2) high-quality filters and dichroic mirrors, and (3) a fast, low-noise, highly sensitive CCD camera. The camera is attached at the bottom port of the microscope to maximize light collection. High-quality optics and a sensitive camera are required to capture the faint fluorescence of small moving endosomes with sufficient signal to noise.

The setup for ratio fluorescence imaging is illustrated in Fig. 1. We use a Axiovert S100TV microscope and a 100X, 1.3 NA oil-immersion objective (Carl Zeiss AG, Feldbach, Switzerland). Alternate excitation at 440 ± 10 and 490 ± 10 nm is achieved using a fast monochromator (Deltaram, Photon Technology International Inc., Monmouth Junction, NJ) or a filter wheel equipped with excitation filters 440DF20 (Cat. No. XF1010) and 490DF20 (Cat. No. XF1011, both from Omega Optical, Brattleboro, VT). The light path comprises a 515DRLPXR dichroic mirror (Cat. No. XF 2058) and 535DF25 emission filter (Cat. No. XF3001) inserted into the microscope filter slider. Images are captured with a back-illuminated CCD frame transfer camera (MicroMax 512 BFT; Roper Scientific; Trenton, NJ) attached to the bottom port of the microscope.

III. PROCEDURES

A. Preparation

Solutions

1. *Recording solution:* 140 m*M* NaCl, 5 m*M* KCl, 1 m*M* $MgCl_2$, 1 m*M* $CaCl_2$, 10 m*M* glucose, 20 m*M* HEPES, pH 7.4, with NaOH. To make 100 ml, add 14 ml NaCl 1 *M*, 0.5 ml KCl 1 *M*, 0.1 ml $MgCl_2$ 1 *M*, 0.1 ml $CaCl_2$ 1 *M*, 0.5 ml 40% glucose, 2 ml HEPES 1 *M*, and complete to 100 ml with distilled water.

2. *Calibration solution:* 140 m*M* KCl, 1 m*M* $MgCl_2$, 0.2 m*M* EGTA, 20 m*M* HEPES (pH 7.0–8.0) or MES (pH 5.5–6.5), 5 µg/ml nigericin, 5 µ*M* monensin. To make 50 ml of each, add 28 ml KCl 1 *M*, 4 ml MES 1 *M*, 200 µl $MgCl_2$ 1 *M*, 200 µl EGTA 0.4 *M*, and complete to 200 ml with distilled water. Divide in 50-ml aliquots labeled "5.5," "6.0," and "6.5." Repeat the same procedure using HEPES instead of MES as buffer and divide in 50-ml aliquots labeled "7.0," "7.5," and "8.0." Adjust the pH to 5.5, 6.0, 6.5, 7.0, 7.5, and 8.0 with KOH or HCl using a pH electrode precalibrated at 37°C under continuous magnetic stirring. These solutions can be kept at 4°C for 1–2 weeks. On the day of the experiment, take 10 ml of each calibration solution and add 10 µl nigericin (stock 5 mg/ml) and 1 µl monensin (stock 50 m*M*) to each vial. Measure the pH precisely with the pH electrode (at 37°C) and write down the pH value to two decimals (e.g., pH 5.54; 5.92; 6.02; 6.54; 7.04). These solutions must be used the same day.

3. *Nigericin stock:* Add 1 ml ethanol 100% to 5 mg nigericin and store at –20°C for no more than 3 months.

4. *Monensin stock:* Add 1.44 ml ethanol 100% to 50 mg monensin and store at –20°C for no more than 3 months.

Steps

1. In a hood, wash the coverslips separately with ethanol and rinse with distilled water. Place coverslips into a tank filled with distilled water. Autoclave. Clean coverslips can be stored in sterile water for 1–2 months.

2. If necessary, coat the coverslips with an agent that promotes attachment of weakly adherent cells. Poly-L-lysine and Cell Tak (collaborative Research Inc) have been used extensively. Wash excess adhesive agent.

3. Place each coverslip into a 35-mm petri culture dish (single or multiwell). Close the lid and leave for 20 min under UV illumination. The culture dishes "loaded" with clean coverslips can be used for 1–2 weeks.

4. Two to 3 days prior to the measurements, plate cells on the glass coverslip at low density (~10^4 cells). Fill the petri dish with 3 ml of culture medium.

5. *Optional*: One to 2 days before measurements, transfect cells with the receptor or recombinant protein bearing the cognate epitope for the FITC-labeled ligand or antibody.

B. Loading Cells with the FITC-Labeled Ligand or Antibody

The example given here is for endosomal pH measurements with internalized FITC-transferrin. Optimal concentrations, requirement for serum depletion, and incubation times have to be determined for each particular ligand or antibody.

Steps

1. Incubate cells in their appropriate culture medium with 25 µg/ml of FITC-labeled ligand for 20 min at 37°C.

2. Wash the cells twice with phosphate-buffered saline (PBS) to remove extracellular FITC. Maintain cells in recording medium until use. Measurements should be performed within 30 min of loading.

3. If necessary, wash the cells twice with acidic solution (pH 4.0) at 4°C to remove FITC bound to the plasma membrane.

4. Using fine tweezers, place the coverslip into the Leiden chamber, orienting the coverslip so that cells face upward. Ensure that a good seal exists between the coverslip and the O ring by wiping away excess medium from the underside of the coverslip and

checking for leaks. The underside should remain dry and clean to allow oil-immersion microscopy.

5. Add 2 ml of recording solution to the dish and proceed to the experiment.

C. Measurements of FITC Fluorescence Ratio

1. Place a drop of oil on the immersion objective and position the loaded Leiden dish in an open perfusion microincubator over the objective.

2. Turn off room lights or use a dark curtain around the microscope to eliminate stray light from entering the optical system. Red light can be used for dim illumination of the room if a red-blocking filter (550CFSP-Omega Optical) is mounted in front of the camera.

3. Turn on the lamp power supply and then start the arc lamp. It is important to start the lamp before turning the computer on to eliminate possible damage due to power surges.

4. Turn on the computer and other external hardware devices. Verify that the temperature controller of the microincubator is set to the appropriate value (e.g., 37°C).

5. Launch the software designed for time-lapse ratio fluorescence measurements and initiate a new experiment. We use Metafluor 5.0 from Universal Imaging Corp. Using the illumination control panel, install the correct hardware drivers for the external devices, and configure them with the appropriate settings. Through the use of "Metadevices," Metafluor allows the user to create a variety of hardware configurations with different names.

6. In the "configure acquisition" window set the experiment-specific parameters such as exposure time, pixel binning, and Metadevice selection for each wavelength. Typical exposure times range from 0.5 to 1 s and should not exceed 2 s (see Section V). Keep in mind that wavelength 1 is always the numerator of ratio 1. After configuring these settings, save them as a protocol file that can be retrieved for subsequent use.

7. In the "configure experiment" menu, choose the wavelengths to acquire (W1 and W2) and ratio to be calculated (W1 over W2). Make sure that the acquired images and calculated ratio are displayed and updated continuously.

8. Observe the sample using transmission light to bring the cells in focus and then switch to fluorescence illumination to select cells that express the internalized probe correctly. Open the camera port and acquire a set of images. If necessary, reset the "configure acquisition" parameters to optimize the exposure times.

9. In the "reference image" menu, acquire a set of images with the illumination shutter closed to subtract the background noise of the camera. Then reopen the shutter and acquire updated images with background subtraction.

10. Use the "region" tool to define regions of interest around individual cells. For each region, spatially averaged fluorescence and ratio data will be graphed only for pixels with absolute values higher than the preset threshold. Once the regions are defined, return to the image windows and set the threshold levels to separate the labeled structures from the background fluorescence.

11. From the "experiment control panel," select "save image" to save the fluorescence images. Always save the original fluorescence images during acquisition, not the calculated ratios.

12. Open the "event mark" window to define and reuse markers associated with a specific experiment. Markers applied during drug addition and calibration facilitate the analysis of the experiment during playback.

13. Acquire a series of fluorescence images from several individual cells (~50) to obtain the steady-state ratio value of the labeled organelle. Do not perform more than two to three image acquisitions per field to avoid bleaching of FITC. Check on the ratio graph that the spatially averaged ratio values are homogeneous between cells.

D. Calibration of pH vs Fluorescence

1. At the end of the acquisition period, select one representative field and perfuse the dish sequentially with the calibration solutions. Monitor the fluorescence to ensure establishment of a stable ratio, indicating equilibration of the vesicular pH with the external pH.

2. Once a steady-state ratio has been collected, change to the next solution and repeat step 1. Continue until fluorescence ratios have been recorded for all the calibration solutions.

3. Using the Metamorph software, create a titration calibration table to convert fluorescence ratio values to pH. The calibration table can be used to plot real-time pH change and to create a pH "map" of the labeled structures.

E. Image Analysis: Determining the pH of Individual Endosomes

Preparation

Using Metamorph, create the following analysis "Journals," "table," and "state file":

1. Journal "Initialize Ratio.jnl"

Line	Function	Value	Description
1	Load gray calibration table	File: 256.GRY	Load predefined calibration table
2	Apply gray calibration table		Rescale the 8-bit ratio image from 256 digits into ratio units
3	Threshold image	Image: current at start Threshold: 1; 255; inclusive	Select labeled structures on the ratio image
4	Integrated morphometry-load state	File: Ratio.IMA	Load predefined object selection and measurement criteria

2. Calibration Table "256.GRY"

Image depth: 8 bit; gray vs calibration values: 0 → 0.5; 256 → 3.5; interpolation: linear

3. State file "Ratio.IMA"

Setup parameters for classifying: *Enable*: pixel area: 10 <= N <= 500; hole area: 0 <= N <= 0

Setup parameters for measuring: *Enable*: area; average gray value; format: #.###

Configure log: *Enable*: image name; image plane; object #; average gray value; area

Preferences: Measure objects: *Disable*: "warn user when measurements data will be erased"

4. Journal "Measure ratio.Jnl"

Line	Function	Value	Description
1	Integrated morphometry-measure	Image: current at start Plane: current	Measure all thresholded objects meeting criteria on current plane
2	Integrated morphometry-log data	Image: current at start	Log measurement data to spreadsheet

Steps

1. Using the MetaFluor program, open a previous experiment and create a series of ratio images. In the "Image display controls," check that the minimal and maximal ratio values are set to 0.5 and 3.5, respectively. Adjust the threshold on the 440-nm image (W2) to separate the fluorescent vesicles from the background. If possible, the same threshold should be used for all images. From the "experiment control panel," select "save ratios" to save the ratio images as 8-bit TIF images. Make sure to save only one ratio image for each field acquired during the steady-state measurement period.

2. Launch the MetaMorph program. In the "File" menu, use the function "Build stack: numbered name" to load a stack of ratio image from the desired experiment. Use the "Stack: Montage" function to create and print an image gallery. Check for duplicates.

3. In the "Journal" menu, use the function "Run" with journal "Initialize Ratio.jnl" to rescale the 8-bit ratio image and load the object selection and measurement criteria. *Tip*: Journal playback can be simplified by defining journals as button on the "Journal Taskbar."

4. In the "Log" menu, use the function "Open object log" to create the connection with the spreadsheet program (e.g., Microsoft Excel).

5. In the "Journal" menu, use the function "Loop for all planes," with journal "Measure ratio.Jnl." This will extract the average ratio value of all objects that meet the criteria (area size between 10 and 500 pixels, devoid of holes) in every image from the ratio stack. Check the quality of the segmentation by comparing the measurement images with the original fluorescence images. Most individual vesicles should be included as well as aggregates of <10 vesicles. Spots and very large compound structures should not be included (Fig. 3).

6. Switch to the spreadsheet program. Check the quality of the measurements by displaying ratio data as a histogram. The distribution should be gaussian if the population of vesicles has a homogeneous pH.

7. Using the spreadsheet program, create a calibration curve for the experiment. Enter the ratio values measured during the calibration procedure as X column and the pH values of the calibration solutions (measured at two decimals) as Y column. Display the resulting points on a dot graph. Fit a linear equation to the points and copy the parameters. Use these values to apply a calibration equation to ratio data. A pH histogram can now be generated and the average pH values of the population of vesicles determined.

IV. COMMENTS

Even for experienced users, a few minutes are required to collect enough images of FITC-labeled cells to construct a pH histogram. Within the acquisition period, the pH of endosomes can change significantly, particularly during the early phases of endocytosis. For this reason, it is important to check that the pH is at steady state by graphing the ratio values during the

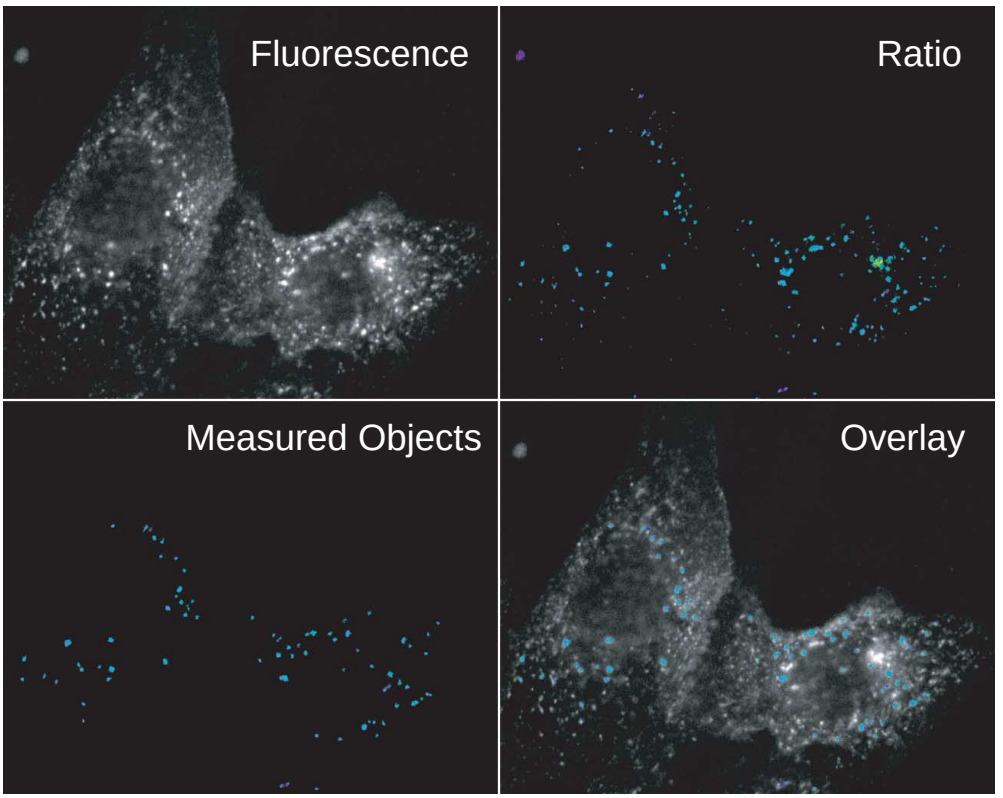

FIGURE 3 Fluorescence and ratio images of early endosomes in MDCK cells. MCDK cells were allowed to internalize FITC-labeled transferrin for 5 min at 37°C. (Top left) A 490-nm fluorescence image, exposure time 1 s. (Top right) A 490/440-nm ratio image. A low-intensity threshold of 30/4095 was used to separate fluorescent vesicles from background. (Bottom left) Vesicles recognized as individual endosomes by the image analysis routine. Seventy-three individual objects met selection criteria (pixel area 10–500, no holes). (Bottom right) Composite image of the vesicles selected by the image analysis routine and the original fluorescence image.

acquisition period. In any case, the acquisition period should be kept as short as possible and should not exceed 20 min.

When counting individual vesicles, small and large structures have the same "weight" in the pH histogram. This biases the readout toward the pH value of the smallest, most numerous vesicles. If the vesicles are highly heterogeneous in size, the pH values should be normalized to the vesicle area.

Failure to wash carefully extracellular FITC might result in a large contribution of the plasma membrane to the ratio images. These structures are normally excluded by the size criteria, but will otherwise appear as a second peak around pH 7.4 on the histogram.

V. PITFALLS

1. Do not use exposure times longer than 2 s to avoid distortions caused by the movement of endosomes. The division of two fluorescence images acquired sequentially will invariably produce "hot" or "cool" pixels on the ratio images, mainly at the organelle edges. Most irrelevant pixels are removed by the intensity threshold, but this procedure discards many small moving vesicles, resulting in a significant loss of information. Using short exposures is the best way to capture the rapidly moving endosomes and to avoid such distortions. The gain in resolution allows to better quantify the ratio images so that a fast, sensitive camera is highly desirable to obtain accurate pH data.

2. Use minimal illumination to prevent photobleaching and cellular damage. Do not make repeated measurements of the same field, but instead perform separate measurements on different fields. The best procedure is to select the cells at random, using bright-field illumination. If only a few cells are labeled with the FITC ligand, the labeled cells should be selected using 440-nm illumination to avoid selection bias induced by the pH dependency of FITC—a bright 490-

nm fluorescence reflecting not only a successful labeling, but also an elevated pH.

Genome-Wide Screening of Intracellular Protein Localization in Fission Yeast

Da-Qiao Ding and Yasushi Hiraoka

I. INTRODUCTION

Intracellular localization is an important part of the characterization of a gene product. In order to search for genes based on the intracellular localization of their products, we constructed a green fluorescent protein (GFP)–fusion genomic DNA library of the fission yeast *Schizosaccharomyces pombe* (Ding *et al*., 2000). This was accomplished by fusing random fragments of genomic DNA to the 5′ end of the GFP gene in such a way that the expression of potential GFP–fusion proteins would be under the control of the endogenous promoters contained in the genomic DNA fragments. The intracellular localization of the fusion proteins was determined by microscopic observation of individual transformants. As genes fused to GFP are expressed under their native promoters, the intracellular localization of gene products can be examined under physiological conditions in both mitotic and meiotic cells. This library provided the foundation for a survey of the intracellular localization of *S. pombe* proteins. Now that the *S. pombe* genome project is completed, genes can be searched from the intracellular locations of their protein products using our image database. Our library of GFP–fusion constructs also provides useful fluorescent markers, which can be used readily for microscopic observation in living cells and for various intracellular structures and cellular activities.

II. MATERIALS AND INSTRUMENTATION

Polypeptone is from Nihon Pharmaceutical (Cat. No. 394-00115), yeast extract is from Difco (Cat. No. 212750), agar is from Wako (Cat. No. 010-15815), ampicillin is from Wako (Cat. No. 016-10373/TWK6416), glucose is from Wako (Cat. No. 041-00595), Zymolyase-100T is from Seikagaku (Cat. No. 120493/109406), novozym 234 is from Novo Nordisk (Cat. No. 2880/PPM4356), proteinase K is from Merck (Cat. No. 24658-0100/V354968 92), and T4 DNA ligase is from TaKaRa (Cat. No. 2011A/1511). Water used for the preparation of the culture medium and all of the solutions is first treated using the Elix 5 water purification system (Millipore) and then the MilliQ ultrapure water purification system (Millipore).

Ten-well 25 × 75-mm glass slides are from Polyscience (Cat. No. 18357), and glass-bottom culture dishes are from MatTek (Cat. No. P35G-1.5-10-C). The DNA sequencer used is the ABI377 from Perkin-Elmer. A computer-controlled, fluorescence microscope system (DeltaVision, Applied Precision; Haraguchi *et al*., 1999) is used for visual screening of the GFP library. This microscope system is based on an inverted fluorescence microscope (IX70, Olympus Optical) equipped with a Peltier-cooled, charge-coupled device (CCD) (CH250 or CH350, Photometrics Ltd., Tucson,

Copyright 2006, Elsevier Science (USA).

AZ). The objective lens used is an Olympus oil immersion lens (SPlan Apo 60/NA 1.4).

III. PROCEDURES

A. Construction of the GFP–Fusion Genomic DNA Library

Figure 1 summarizes our strategy for the construction and screening of a gene library in which *S. pombe* genomic DNA fragments from a wild-type strain were fused to the 5′ end of the GFP–S65T gene.

1. Construction of Plasmid Vectors for the Library

The construction of one such library is described in detail in Ding *et al*. (2000). The multicopy plasmid used as a vector for our library was created by modification of a popular vector for fission yeast, pREP1 (Maundrell, 1993). In order to express GFP–fusion genes under the control of endogenous yeast promoters, the nmt1 promoter region in pREP1 was deleted; therefore, only genes in DNA fragments that also contained the genes' endogenous promoters would be expressed. Next, the coding sequence of GFP–S65T (Heim and Tsien, 1996) was amplified by polymerase chain reaction (PCR), and inserted upstream of the nmt1 terminator. Linker oligonucleotides were then designed such that all three reading frames of the restriction DNA fragments were fused to the GFP-coding sequence. Each of the resultant plasmids contained the *S. pombe* ars1 as a replication origin and the *S. cerevisiae* LEU2 gene as a selection marker, both of which were derived from the pREP1 plasmid (Fig. 1).

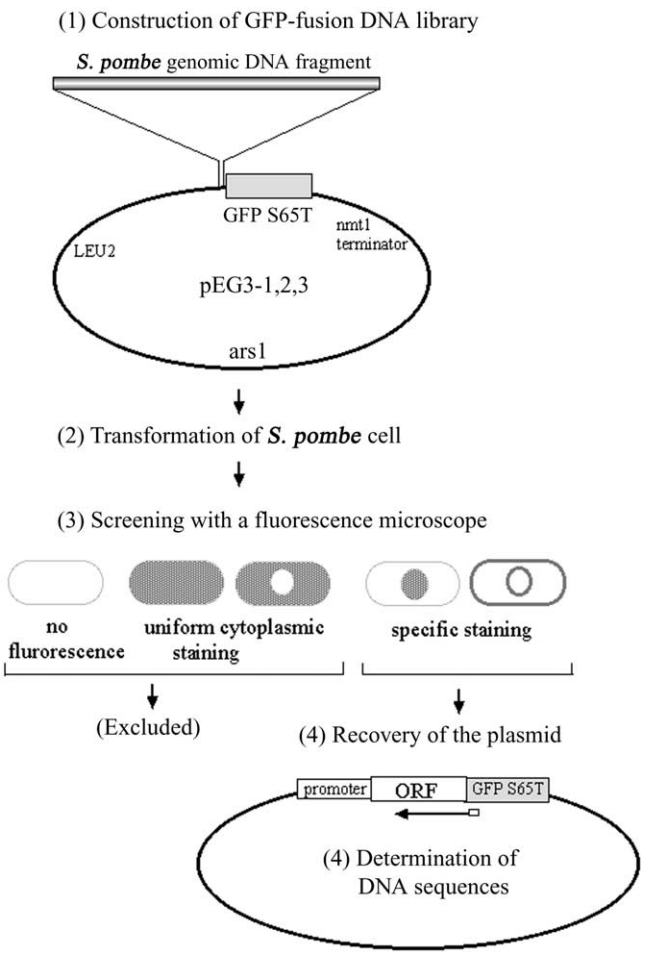

FIGURE 1 Strategy for construction and screening of the GFP–fusion genomic DNA library. Modified from Ding *et al*. (2000).

Insertion of the GFP PCR product into the nmt1 promoter deleted pREP1, resulting in pEG3-1. This plasmid has a *Bam*HI site immediately 5′ to GFP and was used as the first frame library plasmid. The second frame plasmid, pEG3-2, was constructed by inserting a 12 base (CCCAGATCTGGG) *Bgl*II linker into pEG3-1 that had been digested with *Bam*HI and blunt-ended. The third frame plasmid, pEG3-3, was constructed by inserting a 10 base (CCAGATCTGG) *Bgl*II linker into *Bam*HI digested, blunt-ended pEG3-1. Importantly, restriction enzyme sites that can be used for recloning of the yeast gene into other GFP–fusion vectors must be present. In our library, DNA restriction fragments were cloned into the *Bam*HI site of pEG3-1. In pEG3-2 and pEG3-3, however, the *Bam*HI site was absent, as the *Bgl*II linkers were blunt ended into this site. Therefore, the *Bam*HI site present in pEG3-1 was used to reclone genes from this plasmid, while *Bgl*II restriction sites were used to reclone genes present in pEG3-2 and pEG3-3.

Insertion of the library of DNA restriction fragments into each of the three plasmids, pEG3-1, pEG3-2, and pEG3-3, resulted in a library of random fragments of genomic DNA fused to the GFP-coding sequence. Microscopic observation was used to eliminate transformants that did not express GFP–fusion proteins (Fig. 1). These included transformants that did not express a GFP–fusion protein due to the absence of an endogenous promoter to drive the expression of the fusion gene or because the GFP-coding sequence was not in-frame with the fission yeast protein-coding sequence. Thus, after visual screening, a significant proportion of the library consisted of fission yeast genes fused in-frame with GFP and driven by their natural biological promoters.

An important point that needs to be taken into consideration in this type of library is that the linker oligonucleotides used to generate alternative GFP

reading frames introduce a spacer between GFP and the yeast gene, and this spacer may affect the localization of the GFP–fusion protein (see Section IV).

2. Preparation of Genomic DNA

The *S. pombe* strain 968 h^{90} was used to prepare genomic DNA. Genomic DNA was isolated according to Matsumoto *et al*. (1987), which involves two centrifugation steps for the isolation of nuclei to reduce mitochondrial DNA contamination.

Solutions

1. *YEade culture medium*: 0.5% yeast extract, 3% glucose, 75 µg/ml adenine sulfate dihydrate
2. *CPS buffer*: 50 m*M* citrate/phosphate, pH 5.6, 40 m*M* EDTA, 1 *M* sorbitol
3. *10 mM TE buffer*: 10 m*M* Tris–HCl, pH 7.5, 1 m*M* EDTA
4. *50 mM TE buffer*: 50 m*M* Tris–HCl, pH 7.5, 50 m*M* EDTA

Steps

1. Prepare a 200-ml liquid culture of *S. pombe* cells in a rich medium (YEade) and grow to midlog phase (1×10^7 cells/ml) with shaking at 33°C.
2. Harvest by centrifugation at 2500 rpm for 5 min.
3. Wash cells in 10 ml of 10 m*M* TE buffer. Centrifuge at 2500 rpm for 5 min.
4. Resuspend cells in CPS buffer at 3.4×10^8 cells/ml, add Zymolase-100T and Novozym to a final concentration of 0.2 mg/ml, and incubate at 36°C with gentle shaking for 30 min to digest the yeast cell walls.
5. Check digestion of cell walls using a phase-contrast microscope. Continue the digestion until 80% of the cells become round-shaped protoplasts.
6. Spin down at 2000 rpm for 5 min.
7. Wash with 5 ml CPS buffer and resuspend in 5 ml ice-cold 10 m*M* TE buffer containing 1% Triton X-100.
8. Spin down at 2000 rpm for 5 min at 0°C. Transfer the supernatant to a new tube and centrifuge at 10,000 rpm for 30 min at 4°C. Discard the supernatant and dry the pellet.
9. Resuspend the pellet in 5 ml of 50 m*M* TE buffer. Add 0.5 ml 10% SDS, 0.375 ml 4 *M* sodium chloride, and 0.5 mg protease K and incubate overnight at 50°C.
10. Add 5 ml of phenol/chloroform (1:1) and mix well. Spin down at 10,000 rpm for 10 min.
11. Transfer the upper aqueous phase to a new tube and repeat step 10.
12. Transfer the upper aqueous phase to a new tube and precipitate DNA with 2 volumes of ethanol. Wash the pellet with ice-cold 70% ethanol and dry under vacuum.
13. Finally, resuspend DNA in 0.1 ml of 10 mM TE buffer containing 100 µg/ml RNase A. The DNA can be quantified by running an aliquot on an agarose gel alongside a calibrated DNA sample. Typical yields are about 5–15 µg per a starting culture of 200 ml at midlog phase.

3. Partial Digestion of Genomic DNA

Genomic DNA is partially digested with a four-base cutter restriction enzyme, e.g., *Sau*3AI (Ding *et al*., 2000). A combination of several four- or six-base cutter restriction enzymes is also applicable (Sawin and Nurse, 1996). Considering the average size of fission yeast genes, including their promoters, 3- to 6-kb DNA fragments are appropriate. A suitable digestion time should be determined empirically in a small-scale pilot experiment. Centrifuge the partially digested DNA through a sucrose gradient (10–40%) at 50,000 rpm for 15 min using a RP-50T2 rotor in a Hitachi ultracentrifuge (Himac CP70G). Collect fractions and run aliquots out on an agarose gel. Pool the fractions that contain DNA fragments with the preferred length. Recover the DNA by ethanol precipitation.

4. Construction of Plasmid Libraries in Escherichia Coli

Digest each plasmid vector—when constructing our library, these were pEG3-1, pEG3-2, and pEG3-3—with an appropriate restriction enzyme and treat with alkaline phosphatase to inhibit self-ligation of the plasmid. Run small-scale pilot ligation experiments to find ligation conditions that minimize background transformants derived from self-ligation. In our large-scale experiments, 30 ng of the alkaline phosphatase-treated vector and 150 ng of DNA fragments were incubated with 350 units of T4 ligase in a total volume of 30 µl overnight at 16°C. Competent *E. coli* (DH5α) were transformed with 30 µl of each of the three plasmid DNA libraries and were plated on LB plates containing 50 µg/ml ampicillin at a dilution suitable for the appearance of isolated single colonies. This procedure yielded approximately 12,000 *E. coli* transformants for each library. Ampicillin-resistant colonies were scraped from plates with LB medium. A portion of this pool of cells (1/10 volume) was saved in small aliquots at –80°C as a frozen stock. DNA was prepared from the remaining cells. Small-scale preparations of DNA from 30 individual transformants showed that 76–85% of the plasmids had insert DNAs with an average length of 5 kbp.

B. Transformation of *S. pombe* Cells with the Library

Three sets of transformation were carried out using the libraries based on the three plasmid vectors, pEG3-1, pEG3-2, and pEG3-3. Homothalic *S. pombe* strains CRL126 (h^{90} leu1-32 ura4 his2) and CRL152 (h^{90} leu1-32 ura4 lys1) were used for transformation with the GFP–fusion genomic DNA libraries. Homothalic (h^{90}) strains can readily be induced to undergo meiosis and thus can be conveniently screened for mitotic and meiotic localization of fluorescently labeled proteins. A standard lithium chloride method (Moreno *et al.*, 1991) can be used for the transformation of fission yeast cells with the library DNA. Transformants were selected on plates of EMM2 (Edinburgh minimal medium; Moreno *et al.*, 1991) lacking leucine. In our experiments, 50 μg of one library transformed into 7×10^8 cells generated about 40,000 fission yeast transformants on 45 plates of EMM2 in 90-mm dishes.

C. Microscopic Screening of *S. pombe* Transformants

A total of about 50,000 transformants from the three libraries were selected for microscopic screening (Table I). Single colonies were picked with toothpicks and transferred onto new plates of EMM2. Cells were grown for 24 h at 33°C and then for 12 h at 26°C. Culture of the cells at 26°C enhances GFP fluorescence. Cells were then suspended in liquid EMM2 lacking a nitrogen source on a 10-well glass slide (Polysciences) and were observed with our CCD microscope system using an Olympus oil immersion objective lens (SPlan Apo 60/NA 1.4) and high-selectivity excitation and barrier filters for fluorescence (Chroma Technology, Brattleboro, VT). GFP signals are usually bright and easily detected by eye, but when the signal is weak it is recommended that images be taken on the CCD with relatively long exposure times (a few seconds on our system). Note that dead cells often produce strong autofluorescence at the emission wavelength of GFP and should therefore be avoided when ascertaining the intracellular localization of GFP–fusion proteins.

D. Recovery of Plasmids from Selected Transformants and Determination of Nucleotide Sequences of a DNA Insert

Out of 50,000 transformants, 728 transformants exhibited distinct patterns of GFP fluorescence (Table I). Examples of localizations of GFP–fusion proteins are shown in Fig. 2. Plasmids from these transformants were recovered using standard methods (Moreno *et al.*, 1991). Isolated plasmids were retransformed into fission yeast cells to confirm the intracellular localizations determined from the first screening. Partial nucleotide sequencing of the ORF of the inserted yeast gene was performed using a portion of the GFP gene

TABLE I Summary of GFP–Fusion Library[a]

	Frame 1	Frame 2	Frame 3	Total
Total clones screened	25,494	12,084	12,267	49,845
Clones with GFP staining	3,295	1,279	2,380	6,954
Clones with discrete GFP-staining patterns	302	130	296	728

Localization pattern	Total number	Sequenced clone	Independent gene
Nucleus (general nuclear staining)	307	236	98
Nuclear dots	31	26	10
Nucleolus	29	29	22
Nuclear rim	26	26	15
Membrane (nuclear and plasma membrane, ER)	180	115	57
SPB	6	6	3
Microtubule	22	22	5
Cell pole, septum	10	12	8
Cell periphery	26	14	11
Cytoplasmic structures	85	25	19
Spore rim	6	5	2
Total	728	516	250

[a] Reproduced from Ding *et al.* (2000).

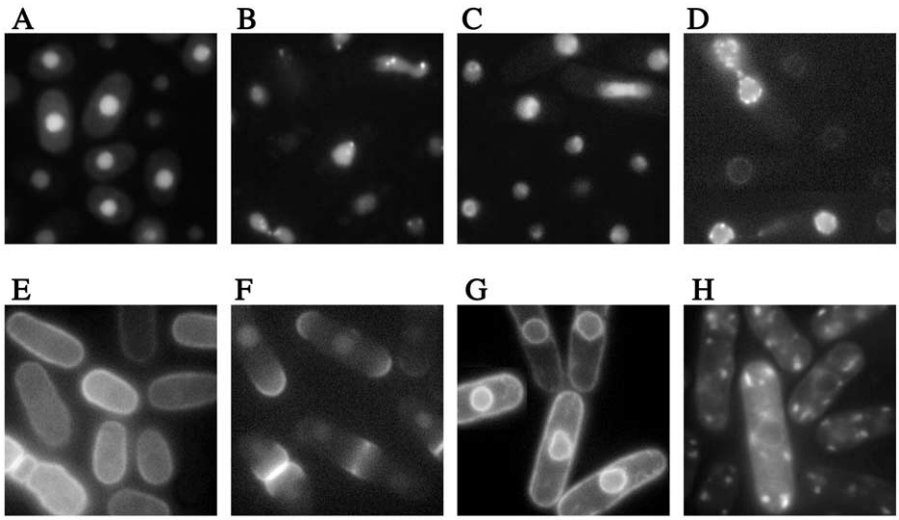

FIGURE 2 Examples of localizations of GFP–fusion proteins. (A) General nuclear staining, (B) nuclear dots, (C) nucleolus, (D) nuclear rim, (E) cell periphery, (F) cell pole and septum, (G) membrane, and (H) cytoplasmic dots. Scale bar: 10 μm.

as a sequencing primer (Fig. 1). Sequencing identified 250 independent genes (Ding *et al.*, 2000).

E. Construction of Image Database of Intracellular Localization

We constructed an image database of the intracellular localization of these 250 gene products and categorized them into 11 groups as shown in Table I (Ding *et al.*, 2000). Occasionally, a GFP–fusion protein was observed in more than one intracellular localization, as some proteins localize to several structures simultaneously or localize to various different structures during passage through the cell cycle. In these cases, we categorized the gene by the intracellular location that exhibited the most prominent staining. Secondary localizations are also listed in the database and genes can be searched for by any of their detected locations. Using this database, DNA sequences can be searched based on the localization of their products (see our Web site, http://www.karc.crl.go.jp/d332/CellMagic/index.html).

F. Time-Lapse Observation in Living Cells

Time-lapse images of GFP fluorescence in living cells were obtained on a cooled CCD using our computer-controlled fluorescence microscope system (Ding *et al.*, 1998; Haraguchi *et al.*, 1999). For time-lapse observation, living fission yeast cells expressing a GFP–fusion construct are mounted between two coverslips (Method 1) or in a 35-mm glass-bottom culture dish (MatTek Corp., Ashland, MA) coated with concanavalin A (Method 2), and observed in EMM2 medium. Sandwiching between coverslips generates clearer images, but allows observation for only about 2 h due to the limited amount of nutrition and oxygen available to the cells in such an arrangement. For longer observation, the use of glass-bottom culture dishes is recommended.

Solution

To make 1 liter of EMM2, add 20 g glucose, 5 g NH_4Cl, 2.2 g Na_2HPO_4, 3 g potassium hydrogen phthalate, 20 ml salts,[1] 0.1 ml trace elements,[2] 1 ml vitamins,[3] and 20 ml amino acids[4].

Complete EMM2 medium containing NH_4Cl as the nitrogen source generates optical turbidity after autoclaving, disturbing microscopic observation. The use of EMM2 depleted of NH_4Cl (EMM2-N) is recommended because of its optical clarity. Usually EMM2-N is used for the induction of meiosis and the observation of meiotic cells. For mitotic growth,

[1] Salts (50× stock): 52.5 g/liter $MgCl_2{\cdot}6H_2O$, 0.735 g/liter $CaCl_2{\cdot}2H_2O$, 50 g/liter KCl, and 2 g/liter Na_2SO_4.

[2] Trace elements (10,000× stock): 5 g/liter boric acid (H_3BO_3), 4 g/liter $MnSO_4$, 4 g/liter $ZnSO_4{\cdot}7H_2O$, 2 g/liter $FeCl_2{\cdot}6H_2O$, 0.4 g/liter molybdic acid (H_2MoO_4), 1 g/liter KI, 0.4 g/liter $CuSO_4{\cdot}5H_2O$, and 10 g/liter citric acid.

[3] Vitamins (1000× stock): 1 g/liter pantothenic acid, 10 g/liter nicotinic acid, 10 g/liter *myo*-inositol, and 10 mg/liter biotin.

[4] Amino acids (50× stock): 10 mg/ml L-leucine, 3.75 mg/ml adenine sulfate dihydrate, 3.75 mg/ml uracil, 3.75 mg/ml L-histidine hydrochloride monohydrate, and 3.75 mg/ml L-lysine hydrochloride.

however, a nitrogen source is necessary; in this case, autoclave EMM2-N and add a filtered 50x stock solution of NH_4Cl to the autoclaved EMM2-N.

Method 1: Sandwiching between Coverslips (Fig. 3)

Steps

1. Prepare two coverslips (60 × 24 mm and 18 × 18 mm).
2. Suspend fission yeast cells in the EMM2 medium.
3. Place 2.5 µl of cells on the larger coverslip (60 × 24 mm).
4. Cover with the smaller coverslip (18 × 18 mm) carefully so as not to introduce air bubbles.
5. Seal with silicon grease to avoid evaporation during observation (Fig. 3A). Do not use organic solvent-containing sealing reagents such as nail enamel as they are toxic to living cells. If the sealing is poor, cells can move due to streaming of media caused by evaporation.
6. Observe the specimen on an inverted microscope (Fig. 3B).

Method 2: Glass-Bottom Culture Dishes (Fig. 4)

Steps

1. Coat a glass-bottom culture dish (Fig. 4A) with concanavalin A shortly before use. Spread 50 µl of 1 mg/ml concanavalin A solution on the glass bottom of the dish. Then, remove excess solution and dry.
2. Suspend fission yeast cells in EMM2 medium.
3. Place 50 µl of cells on the glass bottom in the center of the dish. The cell wall will adhere to the concanavalin A.
4. Place small drops of water, or small pieces of wet paper or cotton, at the periphery of the dish to avoid evaporation during observation. Seal the lid of the dish with parafilm.
5. Place the dish on an inverted microscope (Fig. 4B). Leave the specimen on the microscope stage for about 10 min before observation to allow the cells to settle down in the dish.

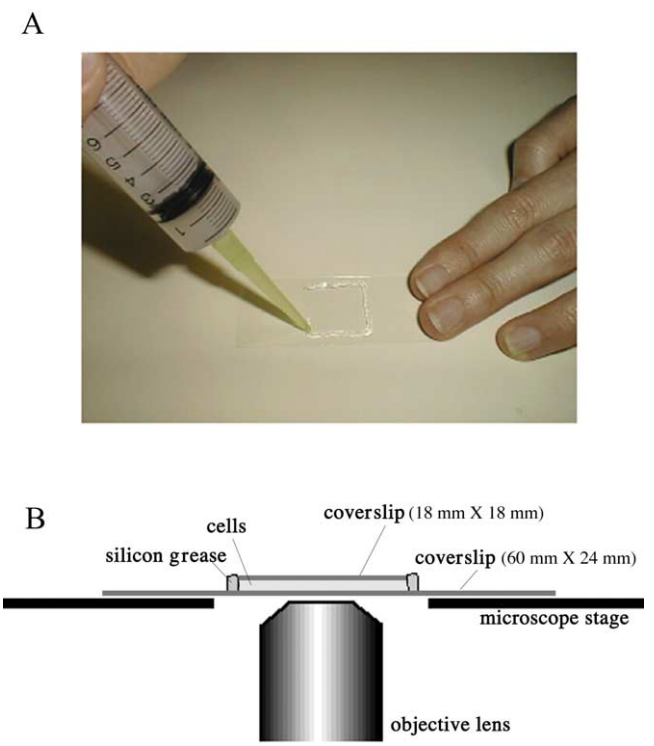

FIGURE 3 Living cells between coverslips. (A) Living fission yeast cells are mounted between coverslips and sealed with silicon grease. Silicon grease is packed in a syringe capped with a micropipette tip and applied to the edges of the smaller, upper coverslip. (B) A side view of a specimen on the microscope stage.

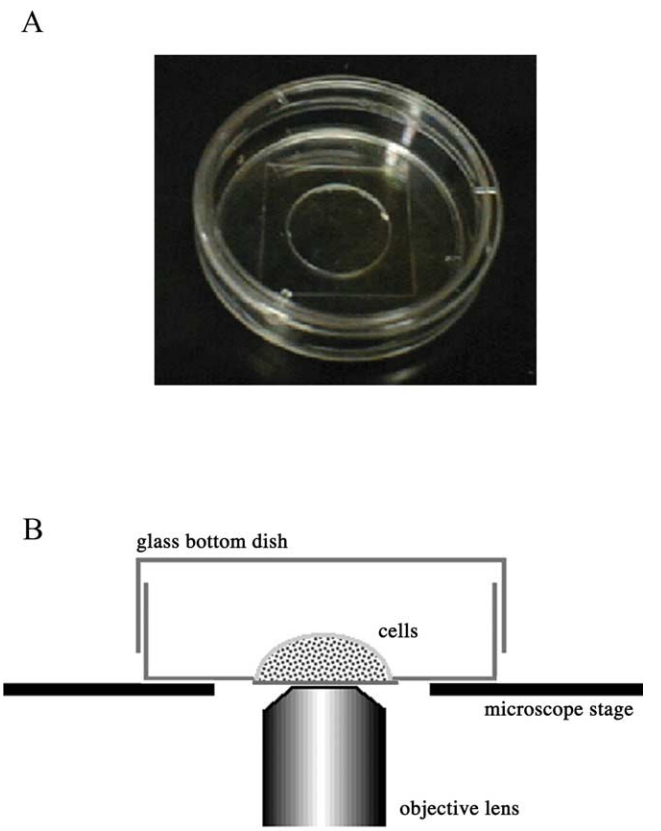

FIGURE 4 Living cells in a glass-bottom culture dish. (A) A 35-mm glass-bottom culture dish. (B) A side view of a specimen on the microscope stage.

IV. COMMENTS

A spacer between GFP and the gene may affect the localization of the GFP–fusion protein. We constructed our library using three plasmid vectors, pEG3-1, pEG3-2, and pEG3-3. In pEG3-1, there was no spacer codon between GFP and the yeast coding sequence, whereas in pEG3-2, three amino acid residues, Trp, Gly, and Ser, were inserted between GFP and the yeast coding sequence, and in pEG3-3 three amino acid residues, Leu, Gly, and Ser, were inserted. The best results were obtained when Leu, Gly, and Ser were inserted between GFP and the fission yeast coding sequence (Ding *et al*., 2000). Fusing the GFP directly to the protein backbone or with a spacer made of a heterocyclic aromatic amino acid, such as tryptophan, may affect the secondary structure of the fusion protein and, consequently, may disturb its intracellular localization.

An obvious limitation of our library is that those gene fragments that abate cell viability cannot be obtained. Another limitation of our library is occasional mislocalization of the fusion gene products. Because we fused GFP to random fragments of the genomic DNA, the C-terminal portion of the gene product was truncated to various extents and replaced by GFP. Gene products that have localization signals at their C termini could be mislocalized or excluded during screening. Also, cryptic localization signals can occasionally be contained within the amino acid sequences fused to GFP. Now that all the protein-coding genes of *S. pombe* have been identified by the completion of the *S. pombe* genome project (Wood *et al*., 2002), these limitations can be partly eliminated by constructing an ordered library in which the GFP gene is fused to full-length open reading frames. In the budding yeast *S. cerevisiae*, a collection of strains have been constructed, in which the GFP–fusion construct is integrated into the native chromosomal locus and expressed under their own promoter (Huh *et al*., 2003).

V. PITFALLS

1. For observing living fluorescently stained cells, use a high-sensitive camera to avoid damage to the cells caused by the excitation light and also minimize the excitation by the use of a shutter.

2. Occasionally an isolated plasmid will contain two different GFP–fusion genes, presumably as a result of heterodimer formation. This is seen during nucleotide sequence determination as two sequences overlapping each other. In such cases, the fusion proteins must be recloned into separate plasmids and the intracellular localization of the GFP–fusion products examined individually.

3. Because the GFP–fusion constructs are expressed on a multicopy plasmid, overexpression of the GFP–fusion protein may occur and affect its intracellular localization. To minimize this problem, it is recommended to use fresh preparations of exponentially growing cells for observation. Cells with physiological perturbations tend to fluoresce brightly or to accumulate fluorescent protein aggregates in the cell. Avoid observing such cells that give atypically bright fluorescence. In principle, localization patterns representative of the major population of cells in a microscope field are reliable.

Large-Scale Protein Localization in Yeast

Anuj Kumar and Michael Snyder

I. INTRODUCTION

Proteomics has contributed significantly to our knowledge of eukaryotic cell biology through large-scale studies describing protein–protein interactions, protein complex composition, and relative protein abundance. Recent work in the budding yeast *Saccharomyces cerevisiae* (Kumar *et al*., 2002) has extended the scope of proteomics to encompass the genome-wide analysis of protein localization—the large-scale and systematic identification of the subcellular compartment or organelle to which a protein localizes. The subcellular localization of a protein can be of fundamental importance in characterizing the function and regulation of that protein. For example, an uncharacterized protein that localizes to the mitochondria may be inferred to function directly or indirectly in cellular respiration. Many transcription factors are regulated through subcellular compartmentalization: nuclear export of the transcription factor Pho4p is tightly regulated such that it is only localized within the nucleus (and therefore capable of activating transcription) in response to phosphate starvation (O'Neill *et al*., 1996). Protein function can also be addressed on a global scale by integrating protein localization data with a variety of other proteomic data sets. In particular, protein localization data are a strong complement to large-scale protein–protein interaction studies, corroborating many putative interactions while also highlighting potential false-positive results (Gerstein *et al*., 2002). Ultimately, genome-wide protein localization data will be helpful in identifying the constituent proteins of each cellular organelle and, potentially, mechanisms by which some of these proteins are regulated.

Yeast proteins may be localized through any of several approaches. By one common strategy, antibodies against a target protein can be used to immunolocalize that protein within a fixed cell. Antibodies against native proteins may be prepared by standard immunology; however, the feasibility of applying this approach on a proteome-wide scale has yet to be demonstrated. Alternatively, yeast proteins may be epitope tagged for subsequent immunolocalization. Tagged proteins can be localized by indirect immunofluorescence using monoclonal antibodies directed against the epitope tag. Epitope tags may be introduced into a protein-coding sequence by several methods. Many yeast vectors are available by which epitope tags may be fused to the amino (N) terminus or carboxy (C) terminus of a cloned gene (Longtine *et al*., 1998). In addition, epitope tags may be introduced at random within a protein-coding sequence by insertional mutagenesis using a modified epitope-bearing transposon (Hoekstra *et al*., 1991; Ross-Macdonald *et al*., 1997, 1999). A combination of random and directed tagging methods has been used successfully in *Saccharomyces* to epitope tag approximately 3600 yeast genes; subsequent immunolocalization of this protein set has defined the subcellular localization of nearly 2800 yeast proteins (Kumar *et al*., 2002).

As an alternative to immunolocalization, proteins may be localized by fluorescence microscopy using yeast open reading frame (ORF)–fluorescent protein chimeras. Coding sequence for a fluorescent protein [e.g., green fluorescent protein (GFP)] can be fused to a protein of interest using any number of appropriate tagging vectors (e.g., GFP-tagging vectors of the pFA6a series) (Longtine *et al*., 1998). Yeast ORF–GFP fusions may be constructed as integrated chromosomal alleles using these vectors in conjunction with standard

polymerase chain reaction (PCR)-based methods. GFP tagging has been used extensively in *S. cerevisiae* for the localization of individual target proteins; ongoing efforts to tag all annotated yeast ORFs with GFP should enable large-scale analysis of protein localization by fluorescence microscopy in living yeast cells.

This article presents detailed protocols by which yeast ORFs may be epitope tagged and yeast strains containing tagged proteins prepared for immunofluorescence analysis in a 96-well format. The protocols presented here utilize the PCR-based tagging method of Longtine *et al.* (1997) to generate C-terminal chromosomal gene fusions with a sequence encoding three copies of the hemagglutinin (HA) epitope. The resulting HA-tagged yeast proteins can be immunolocalized by indirect immunofluorescence as described; the immunofluorescence protocol is adapted for performance in a 96-well format, facilitating proteome-scale analysis of protein localization.

II. MATERIALS AND INSTRUMENTATION

G418 sulfate (geneticin) may be purchased from Invitrogen Corp. (Cat. No. 11811023). Glusulase is a trademarked preparation of β-glucuronidase / sulfatase, each available from Sigma (Cat. Nos. G0258 and S8504). Zymolyase-100T is from Seikagaku America; Lyticase from Sigma may be substituted (Cat. No. L4025). The mouse anti-HA monoclonal antibody 16B12 is from Covance (Cat. No. MMS-101R-1000). Cy3-conjugated affinity-purified goat antimouse IgG is from the Jackson Laboratories (Cat. No. 115-165-146). 4,6-Diamidino-2-phenylindole (DAPI) is available from Sigma (Catalog No. D-9542). Poly-L-lysine is from Sigma (Cat. No. P1524). Microscope slides are from Carlson Scientific (Cat. No. 101805).

III. PROCEDURES

A. Epitope-Tagging Yeast Genes

Yeast genes may be epitope tagged through a variety of methods: the protocol described here is essentially that of Longtine *et al.* (1997) in which PCR is used to amplify a cassette from the vector pFA6a-3HA-kanMX6 suitable for generating an integrated C-terminal HA-tagged allele of any nonrepeated yeast gene. The HA-tagging cassette (Fig. 1A) consists of a sequence encoding three copies of the HA epitope, the *S. cerevisiae ADH1* terminator, and the *kanMX6* module encoding resistance to G418. Tagging cassettes are amplified using primers with 5′ ends corresponding to the target gene and 3′ ends corresponding to the

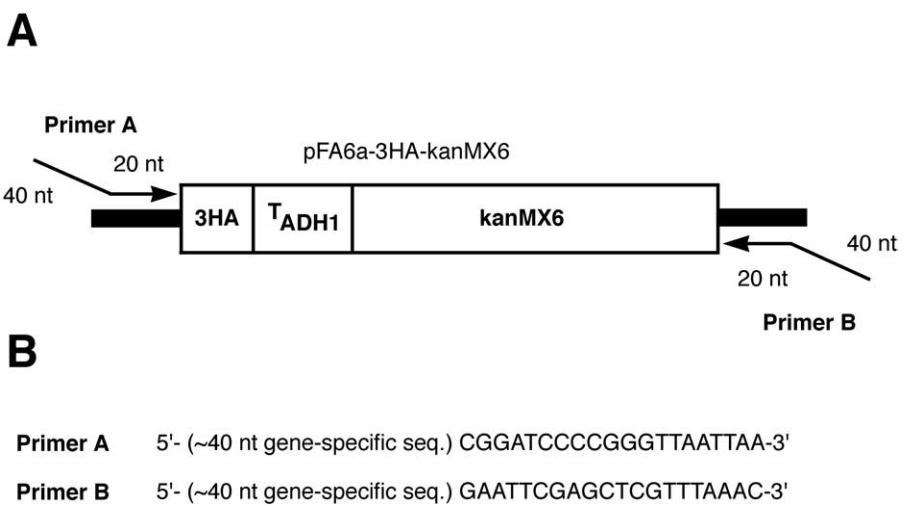

Figure 1 (A) HA-tagging cassette amplified from the yeast vector pFA6a-3HA-kanMX6. The tagging cassette contains a sequence encoding three copies of the influenza virus hemagglutinin epitope (3HA), the *S. cerevisiae ADH1* terminator, and the sequence encoding the kanMX6 cassette (encoding resistance to G418 sulfate). PCR primers for amplification of this cassette are designed such that the 5′ end of each primer consists of approximately 40 nucleotides of a gene-specific sequence, whereas the 3′ end consists of approximately 20 nucleotides of sequence from the polylinker immediately flanking the tagging cassette. (B) Example of PCR primers suitable for C-terminal HA tagging of target genes.

cassette; primer design is discussed later. Amplified cassettes are subsequently introduced into yeast by standard methods of DNA transformation (Gietz *et al*., 1992). By homologous recombination, the tagging cassette integrates at its intended genomic locus; transformants containing this cassette are selected on medium supplemented with G418. By this PCR-based approach, yeast genes may be systematically epitope tagged for subsequent large-scale immunolocalization.

Solutions

1. *YPD medium:* 1% Bacto-yeast extract, 2% Bacto-peptone, 2% glucose, 2% Bacto-agar, distilled water. Autoclave at 121°C and 15 lb/inz. in of pressure for 15 min; cool to ~55°C and pour plates. Omit agar for liquid media.

2. *YPD-G418 plates:* Prepare YPD medium. After cooling, supplement YPD with 150 mg/liter G418. To prepare a stock solution of G418 (geneticin), dissolve in water at a concentration of 80 mg dry weight per milliliter and filter sterilize.

Steps

1. Design primers enabling targeted integration of the amplified tagging cassette at its intended genomic locus. Example primers are shown in Fig. 1B. Design the 5′ end of each primer such that it consists of 40–50 nucleotides of sequence from the target gene. Choose the gene-specific sequence of the forward primer (A) such that it ends just upstream of the stop codon; choose the gene-specific sequence of the reverse primer (B) such that it ends just downstream of the stop codon.

2. Amplify the HA-tagging cassette from plasmid pFA6a-3HA-kanMX6 using PCR primers A and B. Use standard cycling conditions; vary conditions and primer/template concentrations as needed. Repeat PCR reaction four or more times. Pool reactions, extract once with phenol:chloroform:isoamyl alcohol (25:24:1), precipitate, and resuspend in a small volume of water (~10 µl).

3. Introduce concentrated PCR product into *S. cerevisiae* by any standard DNA transformation protocol (e.g., the lithium acetate protocol of Gietz *et al*., 1992). This process may be performed in 96-well format as described previously (Kumar *et al*., 2000).

4. Select transformants on YPD medium supplemented with G418. Wash cells in water (~1 ml), and resuspend in 200 µl of water. Spread onto YPD plates; incubate overnight at 30°C and replicate onto YPD-G418 plates. Pick individual G418-resistant colonies. Alternatively, G418 selection may be performed in large scale. Wash, precipitate, and resuspend transformants in 400 µl YPD in 96-well plates. Incubate at 30°C for 4–6 h with shaking. Streak transformant mixtures onto rectangular 86 × 128-mm YPD plates supplemented with G418. Use an eight-pronged replicator, such that 24 streaks (correponding to 24 transformant cultures) may be produced per plate. Pick G418-resistant colonies as described previously.

5. Using PCR, confirm that the HA-tagging cassette has integrated by homologous recombination with the target gene. Choose one primer such that it anneals within the HA-tagging cassette and another primer that anneals to the target gene locus outside of the insertion region. Identify a PCR product of the expected size as evidence of homologous integration.

B. Large-Scale Immunolocalization of Epitope-Tagged Proteins

Strains containing HA-tagged proteins may be immunolocalized by indirect immunofluorescence using monoclonal antibodies directed against the HA epitope (primary antibody) and the Cy3-conjugated secondary antibody. Immunolocalization in yeast necessitates permeabilization of the cell wall; here, yeast cells are spheroplasted using the trademarked enzyme preparations glusulase and Zymolyase-100T. The provided immunolocalization protocol is tailored for implementation in a 96-well format. Using this procedure, a single researcher can easily prepare 192 samples (two 96-well microtiter plates) for immunofluorescence in a period of 3 days (Kumar *et al*., 2000). Sample immunofluorescence patterns in cells containing HA-tagged proteins are presented in Fig. 2.

Solutions

1. *Solution A:* 1.2 *M* sorbitol, 50 m*M* KPO_4, pH 7. Prepare sorbitol as a 2 *M* stock solution in water. Store solution A up to 1 week at 4°C.

2. *Solution A / glusulase / Zymolyase:* Supplement solution A with 1 µl/ml 2-mercaptoethanol, 1 µl/ml glusulase, 1 µl/ml Zymolyase (at a concentration of 10 mg/ml). Prepare a stock solution of 10 mg/ml Zymolyase in 5% glucose in 20 m*M* phosphate buffer, pH 7.4. Store stock solution of Zymolyase at –20°C. Add 2-mercaptoethanol under a chemical fume hood. Prepare this mixture immediately before use.

3. *Phosphote-buffened Saline (PBS) buffer:* 20× PBS buffer per liter, 160 g NaCl, 4 g KCl, 28.8 g Na_2HPO_4, 4.8 g KH_2PO_4, 800 ml water. Adjust pH to 7.4; adjust volume to 1 liter. Autoclave and store at room temperature. Dilute 20-fold prior to use. PBS buffers supplemented with BSA may be stored for approximately 1 week at 4°C.

4. *Antibody solutions:* Primary and secondary antibodies should be added to PBS buffer immediately

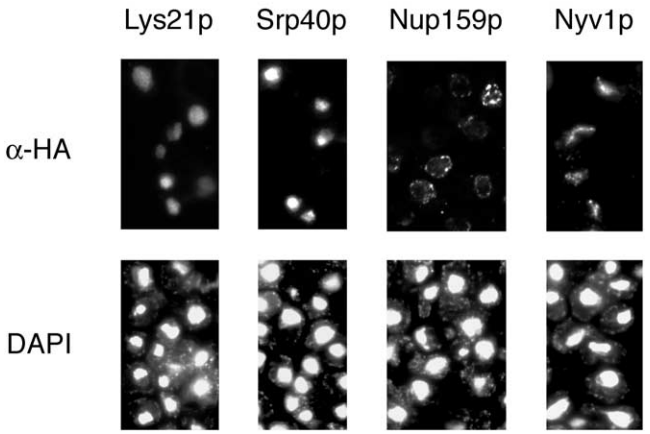

Figure 2 Examples of immunofluorescence patterns from large-scale protein localization studies in *S. cerevisiae*. (Top) Immunofluorescence patterns in vegetative yeast cells stained with monoclonal antibodies directed against HA. (Bottom) The same cells stained with the DNA-binding dye 4,6-diamidino-2-phenylindole (DAPI). Staining of the nucleus is evident in cells carrying a tagged allele of the homocitrate synthase Lys21p, while nucleolar staining can be seen in cells HA tagged for the chaperone Srp40p. HA-tagged Nup159p localizes to the nuclear rim, while staining of the vacuole may be observed in cells containing a tagged form of the v-SNARE Nyv1p.

prior to use. Centrifuge antibodies at 4°C for 10 min at maximum speed in a variable-speed microcentrifuge (e.g., Eppendorf Model 5415C centrifuge). Store the Cy3-conjugated secondary antibody in the dark at –20°C.

5. *Poly-L-lysine solution:* 0.5 mg/ml poly-L-lysine. Dissolve 50 mg poly-L-lysine powder in 10 ml H_2O; dilute 10-fold in H_2O. Filter sterilize if desired and aliquot into 1.5-ml tubes. Store at –20°C. Centrifuge poly-L-lysine solution for 10 min prior to use.

6. *DAPI stock solution:* Dissolve DAPI at a concentration of 1 mg/ml in sterile H_2O. Wear gloves and safety glasses when working with DAPI, as it is a possible carcinogen. Store at –20°C.

7. *Mount medium with DAPI:* 1 mg/ml *p*-phenylenediamine in PBS supplemented with DAPI (final concentration of 1 µg/ml). Dissolve 100 mg *p*-phenylenediamine in 10 ml PBS buffer; prepare solution in a small beaker covered with aluminum foil. Add 90 ml glycerol and continue stirring. Aliquot into 1.5-ml tubes and store at –70°C. Before use, add 1 µl DAPI stock / ml mount medium. Mount medium with DAPI may be stored for up to 2 weeks.

Steps

1. Inoculate strains containing HA-tagged proteins in 96-well microtiter plates containing 75 µl YPD media per well. Grow cultures overnight (approximately 12 h) at 30°C with gentle shaking on an orbital platform shaker (240 rpm). Alternatively, incubate plates on a vortex shaker set to its lowest speed. After overnight growth, add 45 µl YPD; grow for an additional 90 min to an OD_{600} of 0.75–1.

2. Fix cells in formaldehyde at a final concentration of 3.75% (v/v). Agitate cells gently for 30 min using a vortex shaker set to its lowest speed. Collect cells by centrifugation at 2000 rpm for 4 min in a Sorvall H-1000B rotor. Wash pelleted cells three times in 100 µl solution A. Resuspend cells in 100 µl of solution A supplemented with 0.1% (v/v) 2-mercaptoethanol, 0.02% (w/v) glusulase, and Zymolyase-100T (5 µg/ml).

3. Spheroplast cells in this mixture at 37°C with gentle shaking for 13–20 min (optimal incubation times must be determined empirically). Check cells periodically during this incubation; once translucent, recover cells and wash in 100 µl solution A. Resuspend pelleted cells in 100 µl PBS buffer supplemented with 0.1% (v/v) Nonidet P-40 and 0.1% (w/v) bovine serum albumin (BSA). Incubate samples at room temperature without shaking for 15 min. Pellet cells by centrifugation as before. Remove excess liquid by aspiration, and resuspend pellets in 100 µl PBS supplemented with 3% (w/v) BSA. Gently shake cells at room temperature for 30 min to 1 h.

4. Add 40 µl of mouse anti-HA monoclonal antibody 16B12 at a final dilution of 1:1000 in PBS supplemented with 3% (w/v) BSA. Incubate overnight at 4°C with gentle shaking.

5. Wash cells as follows: once in 150 µl PBS supplemented with 0.1% (w/v) BSA, once with 100 µl PBS supplemented with 0.1% (w/v) BSA and 0.1% (v/v) Nonidet P-40, and once in 100 µl PBS supplemented with 0.1% (w/v) BSA. During this final wash, gently shake cells for 5 min at room temperature prior to centrifugation.

6. Treat pelleted cells with Cy3-conjugated affinity-purified goat antimouse IgG (secondary antibody) at a final dilution of 1:200 in 40 µl of PBS supplemented with 3% (w/v) BSA. Shake cells gently at room temperature for 2 h in the dark (to minimize Cy3 exposure to light).

7. Prepare poly-L-lysine-coated slides for use in step 9. To prepare two slides, add a total volume of 40 µl poly-L-lysine solution (0.5 mg/ml in H_2O) to one slide; distribute the poly-L-lysine in five or six wells spaced evenly over the surface of the slide. Place the other slide (with no added polylysine) onto the poly-L-lysine-treated slide such that the two faces of the slides are sandwiched together. Wait 15 min. Separate slides and rinse in H_2O; allow slides to air dry before use in step 9.

8. Wash cells (from step 6) as follows: once in 150 µl PBS plus 0.1% (w/v) BSA, once in 100 µl PBS plus 0.1%

(w/v) BSA with gentle shaking for 5 min, twice in 100 µl PBS plus 0.1% (w/v) BSA and 0.1% (v/v) Nonidet P-40, and once in 100 µl PBS plus 0.1% (w/v) BSA.

9. Resuspend cells in 75 µl PBS. Using a multichannel pipetter, transfer 15 µl of this cell suspension into 12 individual wells on a poly-L-lysine-treated slide. Allow cells to sit for a minimum of 15 min before removing excess solution by aspiration. Add mounting medium supplemented with DAPI such that a total volume of 40 µl is spotted at five or six locations in between the wells. Place a coverslip on the slide; avoid air bubbles and ensure that mounting medium is spread over all wells. Seal slides with nail polish and store in the dark at –20°C; do not store slides longer than 1 month prior to examination.

PITFALLS

In designing protein localization studies, consideration should be paid to the placement of reporter/epitope tags relative to each target open reading frame. Typically, reporters and epitope tags are fused to either N or C termini of target genes; however, each tagging strategy possesses associated advantages and drawbacks. Organelle-specific targeting signals (e.g., mitochondrial targeting peptides and nuclear localization signals) are often located at the N terminus (Silver, 1991). N-terminal reporter fusions may disrupt these sequences, resulting in aberrant protein localizations. In other cases, C-terminal sequences may be important for proper function and regulation. For example, isoprenylation motifs are typically C-terminal, and sequences important for plasma membrane localization may be found throughout the gene-coding sequence (Nakai and Horton, 1999). While no single tagging strategy can be all-encompassing, a greater proportion of the yeast proteome should remain functional as C-terminal fusions: several studies have generated genome-wide C-terminal fusions for large-scale protein localization (Ding *et al*., 2000; Kumar *et al*., 2002).

Gene copy number may also impact upon the accuracy with which a tagged protein is localized. Overexpressed protein products can saturate intracellular transport mechanisms, potentially resulting in anomalous protein localization. However, weakly expressed single copy genes may yield insufficient protein levels for analysis, although the protocol presented here—in which tagged proteins are expressed endogenously under control of their native promoters—has been used successfully to localize nonabundant proteins (Kumar *et al*., 2002).

The immunofluorescence protocol presented here is reliable, but care should be taken to empirically determine optimal incubation times for spheroplasting (Zymolyase/glusulase treatment). The efficiency of spheroplasting may be monitored by phase-contrast microscopy. Ideally, cells should be a dark, translucent gray. Bright cells may have been insufficiently digested, whereas pale gray cells with little internal structure have likely been overdigested (Adams *et al*., 1998). In our hands, cells spheroplasted for 13–20 min yield good staining patterns upon subsequent antibody treatment.

Lifting the Fog: Image Restoration by Deconvolution

Richard M. Parton and Ilan Davis

I. INTRODUCTION

Deconvolution is a data processing technique that is very widely used in science and engineering. Biologists first applied this method to fluorescence microscopy in the early 1980s (Agard, 1984), but it was already in common use by astronomers for sharpening images acquired using telescopes. The term deconvolution is derived from the fact that it reverses the distortion (convolution) of data introduced by a recording system, such as a microscope when it forms an image of the specimen. Any microscope image of a fluorescent specimen can, in principle, be deconvolved after acquisition in order to improve contrast and resolution. The most common application in biology is for deblurring images acquired as three-dimensional (3D) image stacks using a wide-field fluorescence microscope, where each image includes considerable out-of-focus light or blur originating from regions of the specimen above and below the plane of focus. In essence, deconvolution techniques use information describing how the microscope produces a blurred image in the first place as the basis for a mathematical transformation that refocuses or sharpens the image. Deconvolution of wide-field data can provide results resembling the blur-free "optical sectioning" achieved with confocal microscopes, which remove the out-of-focus light optically before image acquisition by placing a pinhole in the appropriate position in the light path. Deconvolution is also applicable to confocal or multiphoton images as they too involve a convolution of data and, in practice, rarely exclude all out-of-focus information. The best deconvolution techniques attempt to correctly reassign each photon of the out-of-focus light from the blurred optical sections being processed to their points of origin within the image state. When successful, this gives wide-field microscopy an advantage over confocal optics, particularly with live-cell work, as all the available emitted fluorescent light, including that coming from out of focus regions, is collected in parallel and is then reassigned to its correct location in the 3D image. This affords the wide-field microscope its faster imaging speeds and flexibility. In contrast, the out-of-focus fluorescence blur removed optically by confocal microscopy can never be recovered, resulting in lower light capture efficiency. However, deconvolution requires powerful computers, thus introducing additional cost and delay before the sharpened image can be viewed. Nevertheless, if one is required to resolve and analyse fine structural details and carry out true volume analysis, deconvolution is an option that should be seriously considered.

This technical guide is intended both for those researchers who are completely new to the method and for those who use deconvolution, but would like a better appreciation of how the method works and the present state of the art. We will first briefly explain the principles of deconvolution and then describe the different types of deconvolution methods currently available. Next we discuss practical considerations and limitations in applying the techniques. Finally, we describe improved deconvolution algorithms, which are currently being developed.

II. CONVOLUTION AND DECONVOLUTION

The magnified image of a specimen observed by eye or a digital camera mounted on a microscope is not a

Copyright 2006, Elsevier Science (USA).

perfect representation of the specimen. The image is blurred or **convolved** by the microscope optics and some information is lost (Fig. 1A). This is an inevitable consequence of how objective lenses work and there are no simple ways round the problem (Hecht, 2002). The nature of image convolution in fluorescence microscopy is appreciated most easily by viewing small spherical fluorescent beads (with diameters in the order of hundreds of nanometers; Figs. 1B–1D). When the beads used are smaller than the smallest detail that the optics can resolve (i.e., **subresolution**, 50 to 200 nm), they form effective single point sources of light and the image resulting from a single bead is known as the **point spread function (PSF)**, being a record of how much the microscope has spread or blurred a single point while imaging it (Jonkman *et al*., 2003; Figs. 1B–1D). Such images consist of a series of concentric rings in three dimensions (so-called **airy rings**) of out-of-focus light around points of light (Figs. 1B and 2A). The PSF is a three-dimensional function, describing how the image of a subresolution point is blurred in the z dimension as well as in x and y, and it varies between different objectives, those with higher numerical apertures giving less blurring (Figs. 1B–1D). Wide-field, confocal, and multiphoton imaging configurations all have their own characteristic PSFs. A biological specimen may be thought of as a collection of subresolution points, each of which is convolved by the objective's PSF independently. Mathematically, convolution involves replacing each point in the specimen by a point spread function during the process of image formation. It is the combination of out-of-focus

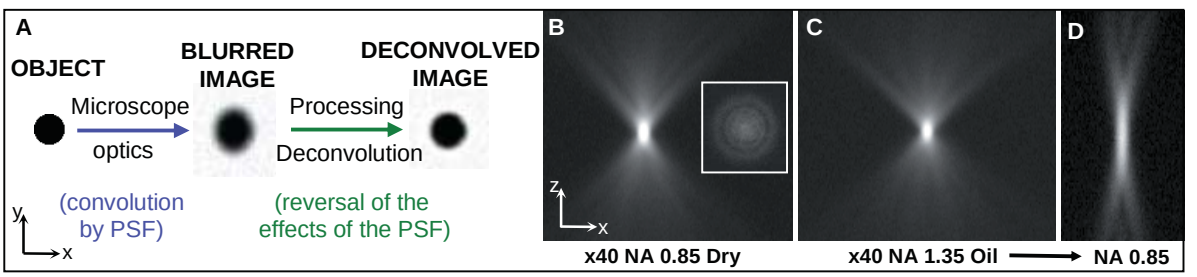

FIGURE 1 Convolution, deconvolution, and the point spread function (PSF). (A) Interpretive diagram of the principles of convolution and deconvolution based upon a simple spherical object. (B–D) Wide-field fluorescence PSFs obtained by imaging 100-nm fluorescent beads (excitation 520 nm; emission 617 nm) with a ×40/NA 0.85 dry objective and with a ×40/NA 1.35 oil immersion with adjustable collar set at NA 1.35 and NA 0.85. Images shown are single median x, z planes from 3D data sets, step size 0.1 µm. (Inset) An x, y view 20 µm from the centre. Deterioration of the PSF from C to D is a consequence of mismatch of the immersion oil refractive index with the reduced numerical aperture set. Resolution in z depends upon both RI and NA.

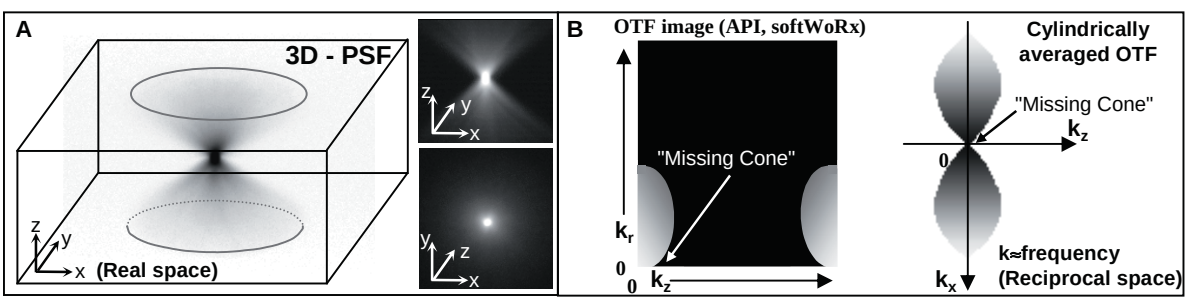

FIGURE 2 (A) Three-dimensional (x, y, z) view of a wide-field fluorescence point spread function. For clarity, the volume representation is shown as a negative image. (B) Two different representations of the Fourier transform of a PSF—an optical transfer function (OTF). In the OTF, frequency information is plotted in "k space" or reciprocal space (where k_z is reciprocally related to z and k_r to x and y in real space, see Technical Summary 2). OTFs are often averaged radially over x, y, hence the axis k_r. The area covered by the OTF corresponds to the frequency information collected by the optics. The "missing cone" region (arrows) corresponds to lost frequencies due to the limited size of the objective pupil, a consequence of this being the far greater blurring of an object along the z axis than in x and y.

light from these overlapping PSFs in and beyond the plane of focus that leads to the familiar blur in wide-field fluorescence images (Figs. 3A and 4A).

Image **deconvolution** refers to a mathematical process by which the effects of image convolution by the microscope are reduced or reversed to allow one to reproduce more closely the detail present in the original specimen (Agard, 1984; Hiraoka *et al*., 1990; Figs. 3B and 4B–4H). The more advanced deconvolution methods attempt to reassign this out-of-focus light to its point of origin (i.e., converting airy rings back into single point sources of light); the resulting image

(C) Deconvolution as in B using a second 60 image 3D data set of the same tissue collected at an *x*, *y* pixel size of 0.106 µm—higher sampling rate. (D) Two-dimensional iterative constrained deconvolution of the first image data set (*softWoRx*, API: empirical PSF). Each *z* plane is deconvolved independently as if it were part of a time-series data set. (E) Deconvolution as in B but using a different PSF (OTF) and more severe smoothing. (F) Using the "nearest neighbours" deconvolution algorithm (*softWoRx*, API). (G) Using the 3D iterative, "adaptive blind" deconvolution algorithm (*Autodeblur*, Autoquant—10 iterations; low noise; no spherical aberration; recommended expert settings). (H) Using the 2D iterative, adaptive blind deconvolution algorithm (*Autodeblur*, Autoquant—15 iterations; low noise; no spherical aberration; recommended expert settings). Scale as for Fig. 3D. Raw data were 12 bit saved as 16 bit; the images shown are 8 bit; with contrast stretched to fill the full dynamic range.

should be sharper with increased contrast and, under certain circumstances, increased *Z* resolution (Figs. 3B, 4B, 4C, 4E, and 4G; Agard, 1984; Agard *et al*., 1989).

III. DECONVOLUTION, DEBLURRING, AND IMAGE RESTORATION

Given the raw image and the PSF for the imaging system it should, in principle, be possible to reverse the convolution of an object by the microscope mathematically, according to a simple relationship—the so-called "linear inverse filter" (Technical Summary 1). However, in practice, simple reversal of convolution is not possible, primarily because of the confounding effect of noise in image data, which becomes amplified during this process (Technical Summary 1). Several fundamentally different deconvolution approaches of varying complexity have been developed to overcome this problem (see Table I; Agard, 1984; Agard *et al*., 1989; Holmes *et al*., 1995; van Kempen *et al*., 1997).

For the biologist, it is important to be able to recognise the different algorithms and appreciate the consequences of those differences to processed data (noted in Table I). The differences are significant: from simple rapid contrast enhancement by deblurring algorithms such as "nearest neighbours" to the much slower restoration procedures such as the constrained iterative algorithms, which can, under ideal conditions, "recover" information lost through convolution by the microscope optics (see later).

Technical Summary 1: Convolution Theory and Fourier Space

Convolution refers to the effect that the microscope optics has in forming the image of an object viewed through the microscope. The microscope image is the result of the convolution (symbolised by ⊗) of the object by the PSF of the microscope (Fig. 1). Mathematically, convolution involves applying the function that relates object to image to each point of the function defining the image (Hecht, 2002). The PSF empirically defines the function relating an object to its image:

$$\text{Microscope image} = \text{object} \otimes \text{PSF}$$

In theory, determing what the object should look like, given the microscope image and the PSF, simply requires reversal of this convolution. Performing this calculation using image data directly (known as calculating in "**real space**") is computationally very time-consuming. This limitation may be overcome by carrying out calculations in "**Fourier space"** by computing the Fourier transform (FT) of both image data and the PSF (see Technical Summary 2). The Fourier-transformed PSF is also known as an optical transfer function (**OTF**). In Fourier space, the convolution relationship described earlier becomes a simple multiplication:

$$\text{FT (microscope image)} = \text{FT (object)} \times \text{FT (PSF)}, \text{ or equivalently}$$

$$\text{FT (microscope image)} = \text{FT (object)} \times \text{OTF (Van der Voort and Hell)}$$

Deconvolution on the basis of the aforementioned equation is known as a simple linear inverse filter (Table I). However, the simple linear inverse filter is of very little practical use, as the relationship between image and object is invalidated by **noise** in the collected image. The simple linear inverse filter does, however, provide the theoretical basis for more complex deconvolution algorithms that take account of real imaging situations (Hiraoka *et al*., 1990).

A. Classification of Algorithms

There is considerable confusion caused by the existence of different names for deconvolution algorithms due to the history of development of this method (Agard, 1989; van Kempen *et al*., 1997). Currently, only a few algorithms are routinely employed in biological image processing (Table I). In an article by Wallace *et al*. (2001), algorithms are classified into (1) "**deblurring**" methods (Table I), which are said to act two-dimensionally, on one *z* plane at a time, and (2) "**image restoration**" or "true deconvolution" methods, which act in a truly three-dimensional way on all planes simultaneously. In general, deblurring methods may be useful for a rapid qualitative improvement in image contrast, e.g., to aid data screening (Fig. 3F, nearest neighbour deconvolution). However, the most powerful algorithms are the constrained iterative procedures of the second class: considered as the method of choice for quality 3D data processing, these will be the focus of the remainder of this article. Within the family of constrained iterative approaches, different algorithms vary in the way noise is modelled and how PSF information is dealt with (Table I; Agard *et al*., 1989; Holmes *et al*., 1995; van Kempen *et al*., 1997).

B. Constrained Iterative Deconvolution

The constrained iterative deconvolution approach (Agard, 1984; Agard *et al*., 1989) is truly restorative, in

TABLE I Deconvolution Algorithms Used in Biological Fluorescence Image Processing[a]

	Algorithm/product name[b]	Features
Deblurring class		
Subtractive	Widely available in image processing software as "nearest neighbours" or "no neighbours" processing. (e.g., *Metamorph*, Universal Imaging; *Autodeblur*, Autoquant)	Works on the basis that most of the out-of-focus blur originates in the neighbouring planes in *z* (when sampling at approximately the *z* resolution). The nearest *z* sections above and below the section being corrected are blurred with a filter and these blurred images are then subtracted from the plane of interest to give the deblurred section. "No neighbours" extrapolates only from a single plane. • Computationally inexpensive and therefore useful for quick results • Prone to creating artefacts • Signal is reduced by the subtractions and noise is propagated • Affects quantification: should be used only for qualitative contrast enhancement
Image restoration class		
Linear inverse filter	For example, the Tikhonov-Miller filter used in *analySIS*	The simplistic approach of reversing convolution by the optics. Does not take account of the effects of noise. Often used as the "first guess" for iterative deconvolution. Still a true 3D method requiring a PSF, which attempts to reassign out of focus information to its point of origin. • Computationally inexpensive and therefore useful for quick results • Prone to creating artefacts • Noise is propagated, thus tends to be used only as a qualitative method • Not capable of super resolution but can restore information supported by the OTF coverage.
Regularised inverse filter	For example, the regularised Wiener filter. Found in several applications, e.g., *DeconvolveJ*, NIH image,[c] *Autodeblur-inverse filter* from Autoquant and *AxioVision 3D-Deconvolution* from Carl Zeiss	A refinement of the above employing regularisation so that the deconvolution solutions are physically realistic and artifacts are suppressed. **Regularisation** involves limiting the possible solutions that are accepted in accordance with certain assumptions made *a priori* about the object, such as the degree of smoothness, essential when dealing with real, noisy data. Limiting the contribution of noise by regularisation comes at the expense of resolution, and to optimise this trade-off between image sharpness and noise amplification, different values of the **regularisation parameter** must be assessed.
Constrained Iterative Additive (Gaussian) noise model	For example, the modified Jansson van Cittert algorithm (Agard *et al*., 1989) implemented in modified form in *softWoRx* from API	A further refinement on the aforementioned; an additional positivity constraint is applied that restricts output image intensities to be positive (see main text). • Computationally expensive and therefore slow • Less prone to artifacts • Signal is reassigned, increasing the brightness of features and the signal-to-noise level • Works very well when the OTF is matched to data, suffers when data is affected by spherical aberration • Quantitative and capable of superresolution in *z* (beyond the *z* optical resolution limit of the microscope)
Constrained Iterative Maximum Likelihood estimation (Poisson noise model)	For example, the Richardson–Lucy algorithm implemented in *Huygens Essential* from Scientific Volume Imaging. Also *AxioVision 3D-Deconvolution* from Carl Zeiss	A variant of the constrained, iterative algorithms that assumes a Poisson model to quantify the noise present during imaging. Huygens essential uses the classical maximum likelihood estimation method and either optimised empirical or theoretical PSFs. • Computationally even more expensive, requiring more iterations and therefore slower • More recent than the Agard/Sedat-modified Jansson van Cittert algorithm • Quantitative (but see main text) and capable of superresolution in *Z* • Useful for noisy, photon-limited confocal imaging data (e.g., van Kempen *et al*., 1997)
Constrained Iterative Adaptive Blind deconvolution	Includes the EM-MLE (expectation minimisation algorithm) of Autoquant's *Autodeblur-2D* and *3D blind* deconvolution options	Blind deconvolution is also iterative and constrained but it determines an estimate of both the object and the PSF of the imaging system based upon raw image data and certain *a priori* assumptions about the PSF. These algorithms also assume a Poisson model of noise in the image. • Determining two unknowns is computationally more expensive and therefore even slower • Does not require an empirical PSF and is more tolerant of spherical aberration and asymmetry • Can generate a derived calculated PSF that can be used to speed up subsequent processing • May not be able to restore to as high resolution as when using an optimised empirical PSF • Better at dealing with signal-limited noisy data (such as confocal images) • May affect image data such that it is no longer absolutely quantitative

[a] Represents a summary of commonly used algorithms and is not intended to be exhaustive.

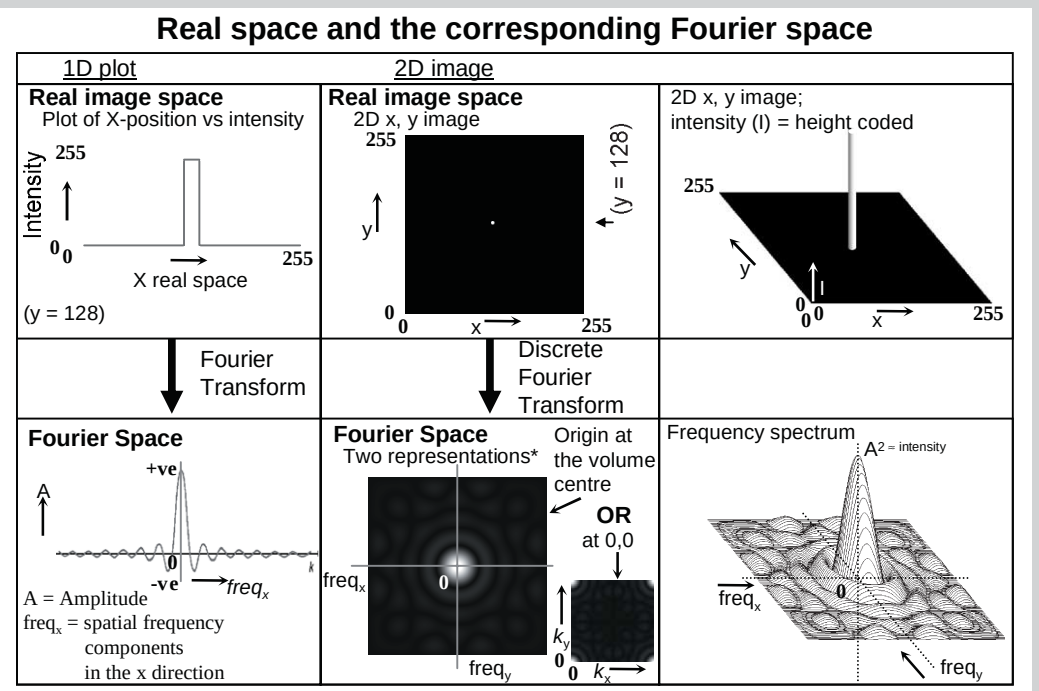
that it attempts to reassign (put back) the out-of-focus light to its expected point of origin rather than simply subtract it from the image as with the deblurring methods (Table I; Figs. 3 and 4). This not only increases the brightness of features in the object, thus improving signal-to-noise levels, but also improves contrast and apparent resolution. Furthermore, these algorithms are capable, under ideal circumstances, of deconvolution solutions with so-called **superresolution** along the *Z* axis—the recovery of detail lost from the image by the convolution of the optics (i.e., beyond diffraction-limited resolution). This phenomenon is usually explained in terms of "the recovery of lost spatial frequencies" or the "**missing cone**" of *z* information (Hiraoka *et al*., 1990; Goodman, 1996), a reference to the shape of the PSF in **Fourier space** (Fig. 2B; Technical Summary 2).

Technical Summary 2: Fourier Transformation and Fourier Space

Fourier transformation represents an image in terms of the spatial frequency information it contains. Sharp edges or fine details correspond to high spatial frequencies; large areas of slowly changing intensity have low spatial frequencies. The entire image can be considered to be the result of the combination of a set of complex "waves." The summation of these waves to create the image is described mathematically as the three-dimensional integral of many simple sinusoidal wave functions, each having specific frequencies, phases, and amplitudes. The Fourier transform of the image (a "discrete Fourier transform" in the case of image data) is a plot of the frequency information present in the real space image, each point representing a particular spatial frequency (see figure below; Hecht, 2002).

1. Fourier transformation is used in deconvolution processing simply because the convolution calculation is much faster in Fourier space (*Frequency*$_x$, *Frequency*$_y$, *Frequency*$_z$) than in real space *x*, *y*, *z* (Van der Voort and Hell, 1997).

2. In Fourier space, the dimensions along the axes are spatial frequency. These reciprocal space coordinates do not map directly to *x*, *y*, *z* positions in real space, but are related to them reciprocally, i.e., things that are closer together in real space (fine details) give high spatial frequency components that are further from the mathematical origin of the Fourier transform in Fourier space and *vice versa*. For this reason, Fourier space is often referred to as "reciprocal space." Amplitudes in a real space image result from the summed amplitudes of each spatial frequency component (effectively how often a particular frequency occurs).



* Note the two different ways that the Fourier space image can be represented depending upon where the origin is located (see also Fig. 2B). The lack of complete radial symmetry in the discrete Fourier transform of the 2D image is an artefact of the discrete Fourier transform algorithm used (Image-J, FFT; NIH).

The name used for the "constrained iterative" class of deconvolution refers to the two critical features that define it: "constrained" and "iterative." The term "**constrained**" refers to the use of the "**positivity constraint**." "**Iterative**" refers to the way in which these algorithms are implemented by repeated cycles of comparison and revision.

The positivity constraint is simply a mathematical term in the algorithm that rejects solutions for the image intensity at any point that give negative values. This limits possible solutions to more realistic outcomes—photons are there or not there, but are never negative. The positivity constraint means that there is no longer a simple linear relationship between the collected image and the deconvolved result, as with the inverse linear filter. Such algorithms are, therefore, also known as **nonlinear methods**. [The positivity constraint is similar in concept to **regularisation** (Table I), which also imposes constraints on possible solutions, but should not be confused with it.] A consequence of the positivity constraint is that it confers the superresolution capabilities of these algorithms by allowing meaningful extrapolation to "recover" some of the z information missing from raw data due to the convolution by the PSF of the microscope (Hiraoka *et al*., 1990; Goodman, 1996).

The iterative process of these deconvolution algorithms may be described in simplified empirical terms as follows. An "**initial guess"** at the deconvolved solution (i.e., the true object) is generated from raw image data. This **initial guess** can be different depending upon the actual algorithm used and may be raw image data transformed with a fast, simple, linear inverse filter step (see Table I) or simply raw image data itself after smoothing. The next step assesses the success of the initial guess as an estimate of the true object by comparing the guess convolved with the PSF of the microscope with the raw original image data. If the guess is correct, then convolving it according to the expected relationship between the true image and collected image (on the basis of the appropriate PSF, see Technical Summary 1) should yield values equivalent to raw image data, i.e., the difference between the two should be minimal. Iterative processing then begins: repeated cycles of calculating a revised convolved guess and comparing with original data operate to incrementally minimise the difference between the two. The positivity constraint is imposed at each revision of the guess. In practice, the number of iterations is predetermined either as a definite number of cycles (which can be from tens to hundreds depending upon data and algorithm, Table I) or when a predefined limit is reached in terms of the difference found upon comparison. Generally, excessive numbers of cycles are nonproductive and an optimum can be found for one's particular data type, this is commonly between 10 and 40. The final guess is taken to be the optimally deconvolved image.

A consequence of all this processing is that implementation is very computationally demanding and so potentially slow. However, modern computers have become so fast and relatively inexpensive that a large deconvolution task, such as a stack of 64 z sections, each of 512 × 512 pixels, can be completed in a few minutes.

C. Using Deconvolution

To achieve the best image quality from a wide field imaging system (i.e., resulting in features sharply defined by high contrast and with a resolution approaching the diffraction limit), deconvolution is almost indispensable.

Wide-field deconvolution is appropriate to many imaging applications. However, it works best for 3D image sets obtained from thin (>50 μm) culture cells or optically very transparent material with low background fluorescence. These criteria are most usually met with fixed material. Live cell imaging is far more challenging for deconvolution, as it introduces problems such as motion blur and increased scattering, bleaching, and **spherical aberration** (SA) made worse by the constraints on excitation exposure due to phototoxicity. Deconvolution can be used to assist visualization of fine structures (Figs. 3 and 4), for calculating z projections (extended focus images), for 3D rendering and quantitative volume analysis, for colocalisation studies (Landmann, 2002), and for fast quantitative tracking of dynamic structures (MacDougall *et al*., 2003).

Wide-field deconvolution can provide a similar degree of reduction in out-of-focus blur as does confocal microscopy, but without the elimination and loss of signal associated with passing the emitted light through a confocal pinhole (Swedlow *et al*., 2002; Pawley and Czymmek, 1997). Aided by the high quantum efficiency (QE) charge-coupled device (CCD) detectors used (Amos, 2000), wide field is both fast and sensitive compared to point scanning confocal imaging, making it especially useful for rapid imaging of labile, dynamic processes in live material (Periasamy *et al*., 1999; Wallace *et al*., 2001; Swedlow *et al*., 2002).

Confocal microscopes, however (particularly in the special case of multiphoton imaging), are better at imaging thick, opaque, and scattering specimens with higher background fluorescence (Periasamy *et al*., 1999; Diaspro, 2001; Swedlow *et al*., 2002).

Confocal systems also tend to have simultaneous multichannel imaging, which is not common for wide field. On the down side, confocals are usually photon limited and so can only be used effectively with samples that are bright enough to see clearly by eye and that have a narrow dynamic range of signal strength, as dim samples require intense illumination (which promotes bleaching) and high photomultiplier (PMT) gain settings (which increase noise). Point scanning confocals also tend to be slow, which means that they suffer from motion blur artefacts when imaging dynamic processes in living cells.

Deconvolution and confocal imaging are by no means mutually exclusive: confocal imaging can nearly always benefit from the improvements in contrast, signal-to-noise ratio, and resolution afforded by restorative deconvolution methods (Wiegand *et al*., 2003). Furthermore, while excluded photons cannot be restored, the application of deconvolution to confocal images does allow the confocal pinhole to be opened slightly during imaging, sacrificing confocality but increasing signal and reducing spherical aberration effects (Pawley, 1995). The brighter but more blurry images are then restored by deconvolution. This is particularly helpful where SA precludes the use of small pinhole settings, e.g., when imaging deep within a specimen (>10 μm). However, one of the biggest limitations when deconvolving confocal images is that they tend to be very noisy because of the low signal available due to the low light throughput and low quantum efficiency of photon multipliers used as detectors in confocal imaging. This problem can best be dealt with either by averaging frames or decreasing scan rate, both at the expense of speed, rather than by increasing the gain on the PMT (which merely introduces more noise). The *Huygens Professional* software from scientific volume imaging (SVI) addresses the noise content of raw data and makes use of this information during restoration. Another potential problem with deconvolution of laser scanning confocal images is that the pinhole size affects the point spread function. SVI's *Huygens* deconvolution software or Autoquant's *Autodeblur* program both offer solutions to this problem in that they have options to take account of the effect of the confocal pinhole on the PSF.

The issues of limited signal to noise and slow scan speed of point scanning confocals means that the generation of image data of sufficient quality to fully benefit from deconvolution is not well suited to fast live-cell imaging. A spinning disc (or "multifocal") confocal microscope, however, uses multiple pinholes for high-speed scanning and captures images on a highly sensitive CCD camera, which is inherently much less noisy than a PMT, combining the advantages of increased contrast of confocal imaging with the efficiency of the CCD detector and speed of wide field. *Huygens* (SVI) provides a deconvolution algorithm specifically tailored to the multiple scanning spots of this form of imaging.

While true deconvolution is a spatial 3D (x, y, z) phenomenon, often the need is to process tme-lapse data (x, y, and *time*). Algorithms exist that are specifically designed to deal with such data (see later for details); however, deconvolution with only spatial 2D data is necessarily not as effective as with a full 3D stack of z sections, as it lacks information to take proper account of distortion in the z dimension. It is also important to note that deconvolution cannot take account of "motion blur" during image capture so suitably short exposure times are essential.

IV. PRACTICAL IMPLEMENTATION OF DECONVOLUTION

Deconvolution, particularly the more advanced approaches, is implemented through a software package where the algorithm is generally assisted by data correction before and noise reduction steps both before and between iterations. With a given deconvolution package, the quality of results obtained will depend foremost upon the quality of raw image data and upon the accuracy of PSF data. Next in importance is the algorithm used and how well it is implemented: noise handling, background or dark signal correction, the initial guess, the regularisation parameter, and filtering and smoothing steps. As different settings, algorithms, or packages may have varying success with different data, it is invaluable to test different programs to understand how a program behaves with your own raw data (Fig. 4A–4H) and to pay close attention to software manufacturers' criteria for raw data and data collection.

A. Collection of Raw Image Data

The quality of raw data is arguably the most important determinant in obtaining good deconvolution results. Essentially, improving raw data involves improving the **useful** signal-to-noise ratio of images (Pawley, 1995). The most important factors relating to this are given in Technical Summary 3. In our experience, it is always easier to meet criteria for good imaging in fixed material than it is for living material

where compromises must be made (Davis and Parton, 2004).

In some situations, such as rapid time-lapse experiments with live material, it is desirable to collect 2D x, y images rather than full 3D x, y, z data sets at each time point. Some 3D iterative algorithms will permit limited processing of 2D data sets by effectively ignoring the z dimension (e.g., Applied Precision's *softWoRx*; Figs. 4D and 4H). In such cases, "displaced" out-of-focus light in the plane of imaging is effectively reassigned to its point of origin within the same plane, but out-of-focus light originating from other planes of focus is ignored. Accordingly, this works best when the out-of-focus blurring effect in z is least detrimental, i.e., with low numerical aperture, low magnification objectives, or thin, optically transparent specimens. Autoquant's *Autodeblur* program suite offers an iterative blind algorithm for use with 2D images that similarly tackles x, y data on the assumption that everything is in one plane of focus, which is acceptable for thin specimens. This should not be confused with the no-neighbours algorithm (Table I), a simple deblurring method for 2D data, which is essentially a contrast enhancement algorithm.

Technical Summary 3: Data Collection Procedures

1. Use a correctly set up and aligned microscope with high-quality objective lenses, accurate z control (by Piezo focusing or motorised stage, Fig. 5), and low noise detectors of good dynamic range and high QE (proportion of photons arriving at the detector that go to produce an output signal).

The quality of deconvolution is dependent upon correct positional information. Pixel sizes should be determined by accurate calibration of the image in x and y, and the z drive should be as precise and reproducible as possible. [For example, the nanomovers offered by Applied Precision Inc. (API) for their *Deltavision* system have 4 nm precision and 30 nm repeatability. Pifoc drives supplied by Precision Instruments are more accurate and reproducible, depending on the speed of movement and the time allowed to settle (Fig. 5), but alter the point spread function and can only be mounted on objection at a time.]

In general, current deconvolution methods are poor at taking account of aberrations in the imaging optics or distortions produced by imaging in thick specimens (primarily SA) or by motion blur. Sample preparation using appropriate mounting media to match the refractive index (RI) of the specimen and the use of correct immersion medium for the objective used (dry, oil, water, or glycerol) can reduce spherical aberration. It is also important to use the correct coverslip thickness or correction collar setting for the objective (default 0.17 mm; #1.5) and to ensure that as far as possible the specimen is immediately adjacent to the coverslip. Imaging deep into specimens (>10 µm) increases SA, which can be partly corrected using objectives with correction collars or by using immersion oils of higher than normal RI (Fig. 6; Davis, 2000).

2. To realise the optical resolution of your imaging system, it is important to follow the **Nyquist** sampling rule by using a pixel size in the electronic imaging device at least two times smaller (ideally, a minimum 2.3 times) than the expected optical resolution in x, y, and z (Pawley, 1995; Jonkman *et al*., 2003). It is possible to determine the theoretical optical resolution based upon the numerical aperture of the objective and emission wavelength using the equation below. The values obtained should be used as an estimate on which to base the digital sampling size. However, in reality it may benefit the final result to make a small

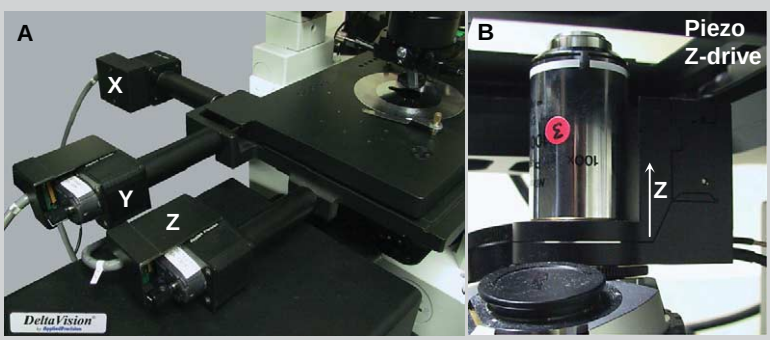


FIGURE 5 Different approaches to z movement control. (A) An x, y, z motorised stage from the API *Deltavison* system. (B) A piezo z-drive nosepiece from Precision Instruments. Note that use of a nosepiece under an objective may alter its PSF.

RI	1.502	1.506	1.510	1.514	1.532

	RI		RI
Air	1.00	Cargille Oils	1.33–1.53
Water	1.33	Vectashield	1.46
Glycerol	1.47	Cytoplasm	1.35–1.45
Glass	1.515	Membrane	1.46–1.6

FIGURE 6 Cargille immersion oils of varying refractive index (RI) and several useful RI values. Note that dilutions of glycerol (80 to 40%) give RI of 1.446 to 1.391.

sacrifice in the sampling rate by binning pixels on a CCD readout to boost signal-to-noise ratio, increase imaging speed, or avoid fluorochome photobleaching. Figure 4C shows deconvolution result improvement with better x, y spatial sampling (0.106 µm pixel) compared to Fig. 4B (0.212 µm), despite the lower fluorescence signal.

Calculation to determine theoretical resolution limits:

$$\text{Lateral } (XY) \text{ resolution} = 0.61 * \text{wavelength}_{\text{emision}} / \text{numerical aperture}_{\text{objective}}$$

$$\text{Axial } (Z) \text{ resolution} = 2 * \text{wavelength}_{\text{em}} * \text{refractive index} / (\text{numerical aperture}_{\text{obj}})^2$$

(refractive index in this case refers to the **specimen immersion medium** RI)

3. In general, it is not advisable to collect Z planes so far below or above the best focus that only blur is seen, as you only end up bleaching the sample.

4. Noise is a significant problem for deconvolution and should be reduced during collection as much as possible. Noise is generally given as the signal-to-noise ratio (S/N; Sheppard, 1995). Poisson distributed Shot noise ($S/N = n/\sqrt{n}$ or simply $\sqrt{n}$, where n may be approximated as the image signal) is the fundamental limitation in S/N. As the number of photons detected increases, the signal-to-noise ratio improves according to the Poisson statistics of photon detection. The signal should not, of course, be so high as to saturate the detector. Both the *Huygens* (SVI) and *Autodeblur* (Autoquant) programs make use of "roughness penalty factors," which, unlike smoothing filters, can be set by the user to constrain their deconvolved solutions to reduce noise while preserving edge features.

The detector should have good dynamic range, high quantum efficiency (QE), low dark signal, and low readout noise (Amos, 2000). When taking short exposures with CCD detectors, readout noise tends to be the most important source of detector noise, whereas when taking long exposure, dark current predominates.

Slow-scan cooled CCD detectors with low dark current and readout noise, reading out pixel intensities as 12–16 bit images (2^{14} = 4096, 2^{16} = 65,536 intensity levels), are used most commonly in wide-field fluorescence imaging systems. They can produce images with a large dynamic range (total intensity levels/intensity levels of noise) and favourable overall S/N ratio.

Confocal systems are less light efficient, and the images they produce are generally photon limited and most commonly recorded as only 8 bit data (= 256 intensity levels). Therefore confocals are more prone to noise problems. Point scanning confocals use relatively low QE photomultipliers, whereas disc scanning systems use CCDs. Imaging only bright signals or averaging several frames to count more photons can help reduce such noise problems.

5. Generally a **dark signal** should be determined (by collecting an image without illumination). However, as different algorithms deal with this parameter differently, which can have significant effects on deconvolution, its use requires careful consideration. In certain algorithms, if too little subtraction correction is made the positivity constraint is not implemented correctly, too much and genuine signal is lost. *Huygens* Professional (SVI) permits automatic estimation or manual input of this information. Some programs correct for **background** signal from part of an image that does not include the specimen (but which can, however, include certain sources of **autofluorescence** from slide preparations and evenly distributed **non-specific staining**).

6. Intensity fluctuations due to light source flicker or bleaching during the collection of z sections or time series images have an adverse affect on deconvolution. Using stable power supplies, regularly changing **mercury arc lamps**, or measuring fluctuations and correcting collected data can help significantly (*DeltaVision* System, API). Bleaching may be reduced by the use of an antifade reagent, which are available commercially or can be home made. Some algorithms include bleaching correction based upon an expected theoretical rate of decline in fluorescence.

B. The PSF (and Its Fourier Transform the OTF)

In addition to optimising raw image quality, using the correct PSF for the image being deconvolved is fundamental to the final result, as one might expect

from the convolution relationship discussed in detail earlier (Fig. 1; Fig. 4B compared to Fig. 4E). A PSF may be empirical (i.e., measured; Hiraoka *et al*., 1990; but see Van der Voort and Strasters, 1995; Davis, 2000) or theoretical (calculated). The former is generally recorded by 3D imaging of subresolution beads using exactly the same optics as used to image the specimen, whereas the latter is generated by the software package used, after inputting the emission wavelength, objective lens details, and refractive index of the immersion medium and mounting medium (e.g., *Huygens* from SVI; *Zeiss 3D Deconvolution Module* from Zeiss; *Autodeblur* from Autoquant). Important considerations relating to PSFs are given in Technical Summary 4.

Technical Summary 4: Use of PSF (OTF)

Empirical PSFs

1. If collected correctly, these have the greatest potential for high-quality deconvolution of images taken with high numerical aperture lenses. However, a poor empirical PSF is certainly worse than a theoretical one (Hiraoka *et al*., 1990).
2. Are often collected at 488-nm excitation and 520-nm emission wavelengths. Software packages usually make adjustments when the actual imaging situation is at a different wavelength. *Huygens* (SVI) offers the possibility of multiwavelength PSF processing as an aid to chromatic aberration correction in colocalisation.
3. Experience reveals that collecting a PSF to match the true aberrated imaging situation *in vivo* (e.g., by injecting fluorescent beads into a cell or by mounting beads so that they are imaged through a particular depth of media of refractive index close to that of a cell) is less effective than using a PSF corresponding to optimal imaging conditions and aspiring to match *in vivo* imaging conditions to that situation.
4. Some software packages come with prerecorded optimised (e.g., averaged over many beads or "processed" by averaging, smoothing, or deconvolving) empirical OTF's for particular objectives, and using these is often preferable to collecting your own (e.g., API's *softWoRx* package; Fig. 2B). *Huygens* (SVI) permits optimisation of your own empirical PSF data by registering and averaging images of multiple beads and correcting for the fact that a bead is, in reality, not an infinitely small point source.
5. In the case of objective lenses with numerical aperture collars, it may be necessary to collect specific PSFs for each setting of the collar (Figs. 1C and 1D), similarly for different confocal pinhole apertures.

Theoretical PSFs

1. These work well with low NA, low magnification objectives.
2. They are usefully employed in some software packages for use with confocal (and MP) imaging, as they can be optimised for different confocal pinhole settings by calculation.

Blind Deconvolution, Estimated, or Adaptive PSF

1. "Blind deconvolution" methods (Table I; renamed "adaptive blind deconvolution," Autoquant, Autodeblur) offer an effective way to circumvent some of the issues mentioned earlier. Instead of using an empirical or calculated PSF, an estimate of the "true" PSF is generated iteratively from the image data itself at the same time as image restoration (Holmes *et al*., 1995).
2. Adaptive blind deconvolution can be useful where a representative PSF is not easy to obtain, such as with confocal imaging using variable pinhole settings, multiphoton imaging, or imaging in the presence of SA.
3. Adaptive blind deconvolution is not a perfect solution, as it is only an estimate determined on the basis of severe constraints imposed upon possible solutions.

Ultimately, it is necessary to determine by trial and error the approach that works best for any particular data type. In virtually all cases, the use of a single PSF for an entire 3D image set is a compromise, especially with live material. Generally, the optical conditions vary between parts of the same image or at different z planes (i.e., the PSF itself varies spatially). However, most current algorithms assume a spatially invariant PSF to simplify processing (Hiraoka *et al*., 1990).

C. Computer System Organisation

Advances in computer technology have had a great impact upon deconvolution, largely because of the computational demands of this approach (Holmes *et al*., 1995; Wallace *et al*., 2001). Be aware that with the requirements of deconvolution for multiple z planes and with CCD image detection now able to generate $1024 \times 1024 \times 16$ bit images many times a second, computer systems must deal with many gigabytes of information within relatively short periods of time. Implementation of deconvolution algorithms requires appropriate processor power and adequate data transfer, short-term storage, and archiving capabilities. While in the past deconvolution required special high-performance workstations, dual processor personal computers with at least 1 Gb of RAM, greater than 50-

Gb hard drives, CD, or DVD-R writers and network connection speeds of 100 Mbit/s to 1 Gbit/s are now standardly used for deconvolution. To increase the efficiency of a laboratory, it is desirable to have separate computers dedicated to image capture and image analysis. A high-quality properly set up monitor (24- or 32-bit colour; calibrated to set contrast and brightness) is necessary for viewing image data. Where many users are involved, it is desirable to have a rack-mounted cluster of many computers linked to a RAID disk (redundant array of independent discs), networked to stand-alone acquisition and processing stations for individual user access.

V. ASSESSMENT OF DECONVOLVED IMAGES

Deconvolution works best when imaging conditions are near optimal, which is possible for fixed material but rarely achieved in living specimens (Kam *et al*., 2000). If the raw images are poor, deconvolution can perform poorly or even produce artefacts that degrade the images. Visual assessment of the removal of out-of-focus blur is a useful guide of success, taking care to correctly set the brightness and contrast of the image display. Features should emerge sharpened with increased brightness after processing. However, as a general guide, you should only trust features observed in the deconvolved image when they are also present, however faintly, in the unprocessed original image. Comparison of the deconvolved results with images acquired by an independent technique, such as electron microscopy or confocal imaging, is also useful. Detailing deconvolution artefacts and their basis is beyond the scope of this article and are dealt with elsewhere (e.g., Wallace *et al*., 2001). In general, small punctate or ring-like features should be viewed with scepticism, while excessive noise suggests poor initial data or problems with the parameters used. If detail appears to be lost after processing, then initial background subtraction may have been too high or filtering and noise suppression steps too aggressive.

VI. QUANTIFICATION

As true deconvolution algorithms (but not deblurring methods) relocate signal to the point of origin within 3D features, while decreasing intensity in the background, they should conserve the sum of the fluorescence signal and permit or even improve quantitative analysis of data (van Kempen *et al*., 1997; Wiegand *et al*., 2003). However, some argue that the reassignment of distant, dim light where noise dominates (Pawley and Czymmek, 1997) and also the processing by which noise is dealt with [particularly in the case of blind deconvolution (Van der Voort and Strasters, 1995)] result in absolute conservation being compromised. If strict quantitative intensity comparison (or intensity ratio calculation) is required, undeconvolved data should always be analysed as well for comparison and independent controls sought. As with all image analysis, caution should be exercised when making direct comparisons between different images—initial imaging conditions and deconvolution processing should be comparable between data sets.

Quantitative positional and structural analysis, which is not so dependent upon absolute intensity values, including centroid determination, movement tracking, volume analysis, and colocalisation, have all been performed successfully on deconvolved data (e.g., Van Der Voort and Strasters, 1995; Wallace *et al*., 2001; Landmann, 2002; Wiegand *et al*., 2003; Macdougall *et al*., 2003). Where quantitative analysis is intended, it is essential to apply deconvolution systematically, with an understanding of possible artefacts and, if possible, with confirmation by an independent technique.

VII. FUTURE DEVELOPMENTS

Improvement in the quality of the initial imaging is the most effective way to enhance deconvolution. For example, correct sampling, noise reduction, use of photon limited (rather than noise limited) detectors, precise and rapid piezo *z* movers, and better corrected objectives all help to improve the quality of imaging and hence the deconvolution result. However, advances are also being made in the quality of processing. Faster computers are allowing the use of increasingly more complex calculations within realistic timescales. More advanced deconvolution algorithms are being developed to deal with the poor signal to noise and with the aberrations associated with imaging *in vivo* (Holmes *et al*., 1995; Kam *et al*., 2000). **Pupil functions**, which are in use in astronomy, are beginning to be used in biology (Hanser *et al*., 2003) in order to correct for asymmetries in the PSF (current deconvolution algorithms assume that the PSF is radially symmetric in *x* and *y* and bilaterally symmetric in *z*). Iterative constrained algorithms aided by **wavelet analysis** may allow us to tackle situations of poor

signal to noise and distorted PSF when imaging deep *in vivo* using confocal and multiphoton techniques (Boutet de Monvel, 2001; Gonzalez and Woods, 2002).

Acknowledgments

We thank John Sedat, Satoru Uzawa, Sebastian Haase, Lukman Winito, and Lin Shao (University of California San Francisco) and also Zvi Kam (Weizmann Institute of Science) for interesting discussions relating to deconvolution. We are also indebted to Jochen Arlt and the COSMIC imaging facility (Physics Department, University of Edinburgh) for invaluable technical advice and access to advanced imaging equipment and also to Simon Bullock, David Ish-Horowicz, Daniel Zicha, and Alastair Nicol (Cancer Research-UK, London) for allowing access to their imaging equipment and for the introduction to wavelet analysis. Thanks for technical advice must also go to the many contributors to the Confocal List (URL: http://listserv.acsu.buffalo.edu/cgi-bin/wa?S1=confocal); Carl Brown of Applied Precision Inc. (USA); Jonathan Girroir of AutoQuant Imaging (USA); and Rory R. Duncan, University of Edinburgh Medical School. We are grateful to Renald Delanoue, Veronique van De Bor, and Sabine Fischer-Parton (University of Edinburgh) for critical reading of the manuscript.

CHAPTER

20

The State of the Art in Biological Image Analysis

Federico Federici, Silvia Scaglione, and Alberto Diaspro

I. INTRODUCTION

The general chain of image acquisition and treatment can be sketched as shown in Fig. 1. Before undertaking analysis of a collected set of images, one should identify the most suitable procedure to be followed. In particular, two different approaches can be outlined:

1. An image *processing* procedure (whose output is an image) requiring the use and development of tools for image enhancement.
2. An image *analysis* procedure in which further quantitative statistics of both morphological and fluorescence intensity parameters are determined, leading to numerical data output.

II. IMAGE PROCESSING

The first steps to be performed are noise reduction, shading correction, contrast, and edge enhancement. Depending on the noise sources and the hardware devices involved, images can be processed via software or hardware. Different standard image processing routines can be run and eventually adapted according to the kind of captured and stored data input (RGB, grey scale, or binary color space, multilayered or single-layered, compressed or uncompressed).

For software data treatment, special algorithms (filters) are used or developed, either directly acting on the original numerical matrix (representative of the image) or within the frequency domain obtained by a particular mapping of the spatial data set through the Fourier transform (Diaspro *et al.*, 2002). Although automated software with a wide range of standard and optimised filters is available, the use of these tools as black boxes can cause new unexpected artefacts to be added to images. This can be particularly risky when dealing with biological samples whose degree of complexity may often prevent the user from relying on his common sense. The final goal of these procedures is that of improving the signal to noise ratio (SNR), leading to better image visualisation without any loss of intrinsic amount of information.

III. IMAGE ANALYSIS

Quantitative image analysis deals with both collecting information from fluorescence intensity signals and obtaining morphological–geometrical parameters from the sample. Different biological treatments and data acquisition procedures (using specific off-line processing) are typically required, according to the topic under study. It is worth listing some of the most commonly used procedures: *colocalization, morphological analysis [geometrical parameter estimation on three-dimensional (3D) and two-dimensional (2D) samples], image classification (fractal analysis and feature extraction), and frequency domain analysis* (Diaspro *et al.*, 1990; Castleman, 1996).

IV. COLOCALIZATION

The observations of *in vivo* cellular details and events often involve the use of single or multifluorescence labelling with a high degree of specificity with the respect of the structures under investigation. The

necessity of simultaneously imaging different functional parts of samples (such as microtubules, nuclei or mitochondria) demands the use of multiple distinct fluorescence dyes in order to reveal the parts of interest by keeping them visually distinct from one another. In this situation, image acquisition is typically carried on separately at the different excitation wavelengths and the later offline analysis may deal, among other things, with one more problem: that of extracting information about the eventual overlap (colocalization) between the different fluorescence signals expressed by the various part of the sample, which thus occupy the same physical location. This is a crucial task, especially in biological and medical studies where one is interested in studying the molecules distribution with the respect of particular functional structures such as receptors.

Provided that the probes' emission spectra are sufficiently separated and correct filter sets are used during the data acquisition, colocalization means that the emitted fluorescence signals (colors) are pictured within the same pixels. In the case of two-probe labelling (Fig. 2), data analysis can be performed by generating a scatter plot in which x-y coordinates represent, respectively, red and green intensity values, and the intensity of each point (according to a suitable color code) represents the number of pixels with that intensity value (Fig. 3).

In addition to this visualisation, a proper quantification of the degree of colocalization can be obtained by comparing each of the acquired images by means of suitable coefficients (Fig. 4), which may account either for the similarity of shapes between the two images (without considering intensities) or for the

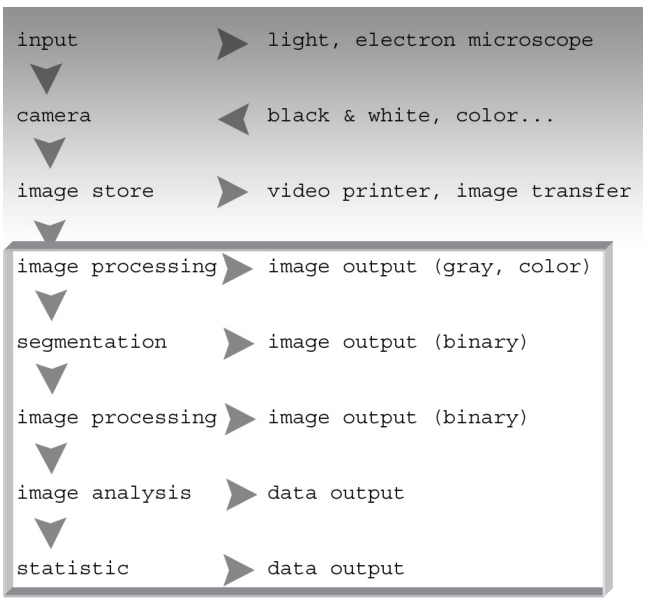

FIGURE 1 Chain of image acquisition and treatment.

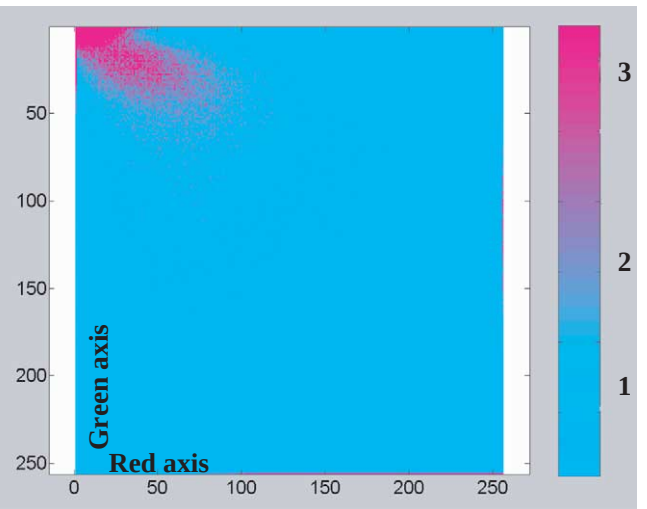

FIGURE 3 Scatter plot: purple dots represent highly colocalized red–green intensity pixels.

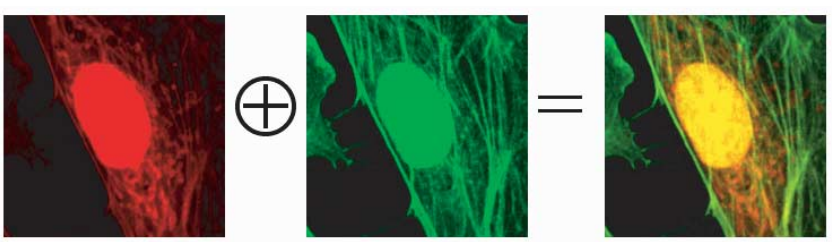

FIGURE 2 Two-photon imaging (750-nm wavelength) of an artery endothelial bovine pulmonary cell. Mitochondria (labelled with MitoTracker) are visible in the red channel, actin filaments (labelled with BODIPY) in the green one, and nuclei (labelled with DAPI) in both. The emission intensity of the nucleus is much higher than the others due to the strong concentration of DNA-bounded DAPI inside the cell with respect to the other dyes. Colocalized pixels are yellow ones in the RGB image (Diaspro, 2001).

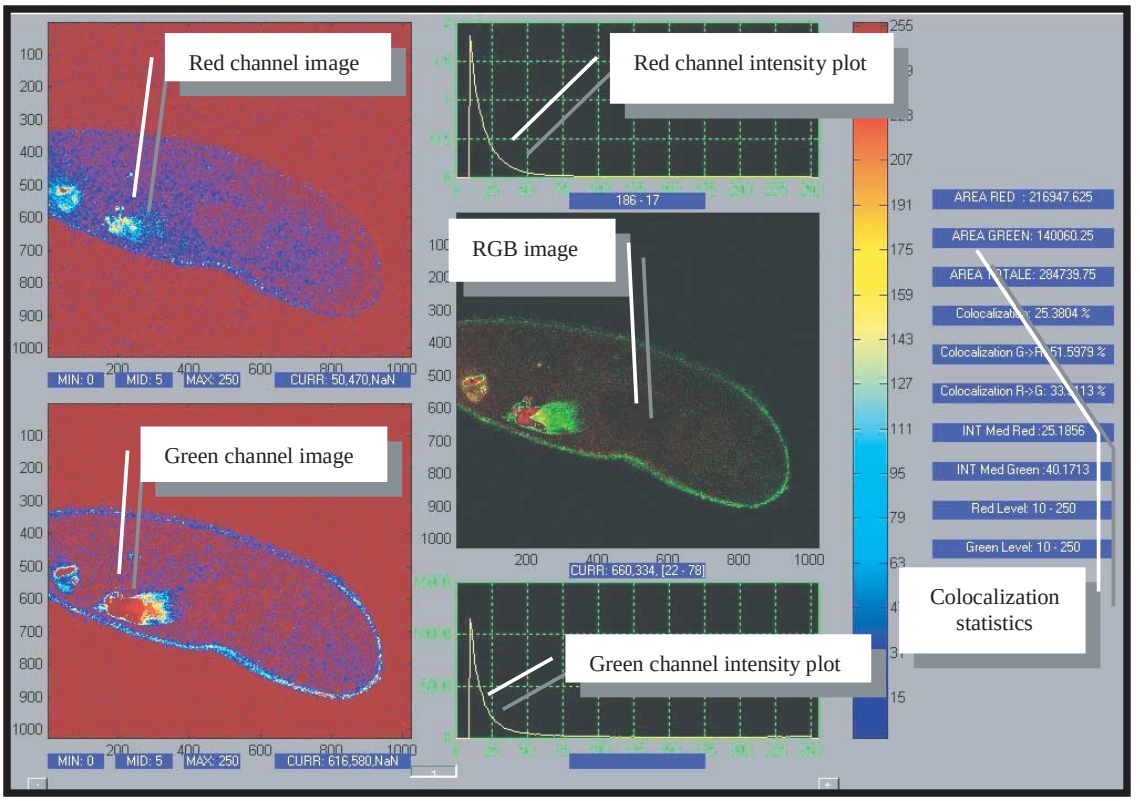

FIGURE 4 Snapshot of a typical image analysis user interface for colocalization analysis. Courtesy of Marco Raimondo and Paola Ramoino, LAMBS, http://www.lambs.it.

difference of intensity between colocalized pixels, depending on the kind of information one is interested in.

A. Morphological Analysis and Classification

Morphological investigations of images are strictly connected to the idea of topological space due to the mathematical environment wherein tools for quantitative analysis are developed. As a first step, this requires a unequivocal relationship between each image array and a set of real space coordinates to be established. For single-layered images, this goal can be accomplished by dividing the field of view (i.e., the real dimension of the region within the image) by the number of pixels, thus getting the effective size of the elementary dot in the image. This is all one typically needs for geometrical calculations in the plane. Multilayered images naturally involve a third dimension so that one more relationship needs to be established between the optical sections and their real world distance from one another. The simplest approach for solving this task consists of assigning the optical sectioning distance (eventually scaled to account for further data acquisition artefacts) to two contiguous slices. Once these correspondences are established between the images and the topological space, further and more complex computer-based processing can be performed, including 3D sample reconstruction (Fig. 5), morphometrical estimations, object counting, and localization (Bianco and Diaspro, 1989; Diaspro *et al*., 1990).

The need of morphometrical measurements is often the main prerequisite in most biological and medical comparative studies where the shape and dimension of structural components of the samples (such as tissues, cells, and organlets) are strictly related to their functions. In these cases, an effective 3D visualization may be nice looking while failing to provide accurate results in terms of accurate characterization of the structural properties of interest. It is far better to use suitable stereological methods, implemented using highly efficient software, involving single slices. These procedures can be either semi-interactive or completely automated. The main difference between these two approaches is that the latter ones are faster but require reliable automatic thresholding and segmentation routines for the recognition of the objects of interest within the images.

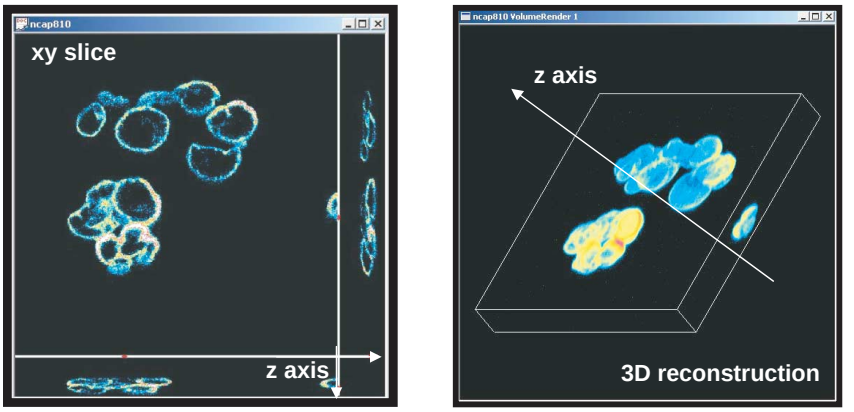

FIGURE 5 Snapshot of a 3D sample data acquisition (left) and 3D sample reconstruction (right).

Several different stereological methods have been tested and improved over the years: the optical dissector principle (Gundersen, 1986; Sterio, 1984) or the unbiased sampling brick rule (Howard *et al*., 1985) for particles counting; the nucleator (Gundersen, 1988) and the planar rotator (Jensen and Gundersen, 1993) applied to a stack of optical sections for estimating the mean particle volume; the optical rotator (Kieu and Jensen, 1993; Tandrup *et al*., 1997), spatial grid method (Sandau, 1987), and "Fakir method" (Kubinova and Janacek, 1998) for surface area estimation; and the vertical slices method (Gokhale, 1990) and global spatial sampling (Larsen *et al*., 1998) for length estimation. Moreover, volume and surface area or curve length estimation can be obtained with known precision and are considered to be free from any systematic error (bias) relating to the sample strategy. Furthermore, they can be undertaken without any previous assumptions about the shape or the structure of the objects under investigation, thus allowing the user to get a realistic average value of the parameters of interest as a result of an average obtained from repeated measurement processes. One more important parameter for many computer vision tasks, such as image classification, is texture segmentation, consisting of splitting an image into regions of similar texture. This task is usually performed in two stages: texture feature extraction (to characterize each texture) and further texture segmentation (to determine homogeneous regions), allowing a proper segmentation of the image.

The limiting factors for all these investigations are the resolution of the imaging system, determined by its point spread function (PSF), and the intrinsic reproducibility of the observed phenomenon itself, which if poor might demand an improvement in the accuracy of the data acquisition protocol (Bianco and Diaspro, 1989; Castleman, 1996).

The approaches discussed so far mainly rest on some common properties of the familiar topological space, but there exist in nature objects whose properties are not fully analysable by any possible set of standard topological parameters. When considering the morphology of samples, for instance, it is very common to take into account those geometrical parameters suggested by a suitable modelling of structures, involving elementary shapes such as lines, circles, spheres, or simple polygon. This allows one both to obtain a preliminary quantitative analysis of the geometrical properties of the samples and to cluster them according to the values of some characteristic parameters. Unfortunately, this method cannot always be applied successfully, as most of the complex biological structures cannot be modelled easily by simple shapes. One popular example is that of the branching structure of many biological structures, such as the arteries, veins, nerves, the parotid gland ducts, or the bronchial tree in the human body. The presence of a certain self-similarity and the lack of a well-defined scale suggest that a complete characterization cannot be based simply on a conventional surface/volume estimation, as such a numerical value does not convey any further information about the degree of complexity of the shape to which it is related. These empirical evidences lead to the idea that some other independent parameter might exist, something like a space-filling factor: this is the fractal dimension (*fd*), existing somewhere between the usual topological dimensions, whose value ranges between 1 and 2, respectively, depending on whether the object fills almost no space (such as in the case of a line) or fills all the available space (such as in the case of a square or a circle). A combination of fractal dimension and standard texture features has been shown to provide better discrimination than standard texture features alone. An example of this

application is that related to the study of the breaking strength of bones. Despite the fact that there is a strong dependence of breaking strength on mineral density, more refined models are required to explain variations in the strength of bones having identical densities. Consideration of the way in which mineral density is arranged within the bones, thus influencing their structural resistance, has led to the use of the fractal index as a parameter, which is both calculated easily from images and particularly efficient for their classification. Other studies employing fractal analysis have involved the characterization of mammographic patterns (Caldwell *et al*., 1990), colorectal polyps (Cross *et al*., 1994), trabecular bones (Cross *et al*., 1993a; Majumdar *et al*., 1993; Benhamou *et al*., 1994), retinal vessels (Mainster, 1990), renal arteries (Cross *et al*., 1993b), Papanicolaou-stained cervical samples (MacAulay *et al*., 1990), and epithelial lesions (Landini *et al*., 1990).

It is worth pointing out here that a variety of procedures have been proposed for estimating the *fd* of images, such as the box-counting method (BC) or the fractional Brownian motion method (FBM); the best algorithm for the job will vary according to the kind of images under study. It can be shown that the BC method is ineffective if applied to low-resolution images, whereas the FBM one reveals its limits when applied to noisy images or to systems with strong local scaling factors.

Moreover, because every *fd* calculation needs a threshold level to be set in order to discriminate different regions within the same image, this implies the existence of a fractal spectrum in which the value of *fd* depends on the threshold level. The best choice for this threshold can be made either from prior knowledge about the inner structure of the sample or through some parameters (such as the linear correlation coefficient for the BC method), intrinsic to the particular *fd* algorithm used, which may somehow account for the fractal dimension.

B. Frequency Domain

Some image analysis techniques employed in a wide range of applications, such as image filtering, reconstruction and compression, turn time domain inputs into frequency domain outputs. A representation of a given multidimensional signal in the frequency domain is often useful for identifying periodical components within signals.

The Fourier transform provides a unique and invertible mapping of original data to frequency domain data represented as complex numbers, termed structure factors, in which the frequency characteristics are displayed in terms of their magnitudes and phases. Both the magnitude and the phase functions of the structure factors are necessary for the complete reconstruction of an image from its Fourier transform. The magnitude-only image is unrecognizable and has severe dynamic range problems. The phase-only image is barely recognizable, i.e., severely degraded in quality. The advantage of using the Fourier transform lies in its invariant properties. It is easy to demonstrate, for instance, that rotating the object merely causes a phase change to occur and that the same phase change is caused to all the structure factors. The magnitude is independent of the phase and so is unaffected by rotation. (This is an example of the very important property of shift invariance.) Second, consider a change of size of the object. This does not change any of the phases and changes the magnitudes of all the structure factors by the same factor. If the magnitude of the spectrum is normalised, then it is invariant to object size as well. Finally, consider the effect of noise and quantisation errors on the boundary. This will cause local variation of high frequency components and will not change the low frequencies. Hence, if the high frequency components of the spectrum are ignored, the rest of the spectrum is unaffected by noise. Thus, for object recognition, the Fourier descriptor offers many advantages and is very useful not only in comprehensively understanding digital image analysis, but also in digital image processing. It could be a useful tool to deal with texture analysis, which is an important field in remote sensing, and it is fast to compute.

V. CONCLUSIONS

This article outlined the fundamental concepts of image processing and image analysis, addressing the main methods and giving a full list of references for deeper insights on topics of interest.

Publishing and Finding Images in the BioImage Database, an Image Database for Biologists

Chris Catton, Simon Sparks, and David M. Shotton

I. INTRODUCTION: THE NEED FOR IMAGE DATABASES

Images and videos form a vital part of the scientific record. While the significance of the various genome publications is beyond dispute, attention has now shifted to the organization and integration of information within cells, where the need for functional analysis of gene products is universally recognised. The significance of microscopy images in the process of determining the spatiotemporal expression patterns of gene products cannot be overestimated. The volume of such images is also significant. In a single day, an active cell biology lab may generate between 5 and 50 Gbytes of multidimensional confocal image data or digital video data.

We recently wrote to a colleague requesting a copy of a beautiful confocal image that he had collected some years ago while a graduate student in Heidelberg, which showed the expression sites of a particular gene in the developing mouse embryo. His reply typifies the wasteful fate of an unfortunately large proportion of biological research images, and is perhaps the best possible argument for a publicly funded image database that can provide free access to and a safe repository for such images:

> Concerning the image data you requested—this is a tough one. The image was recorded about ten years ago, and I never managed to write a paper about the work so it was never published. The original data (if they still exist) must be on some magneto-optical disk in one of many boxes in my flat—quite hopeless to find at short notice. All I can promise is that I'll look into this once I am back from my travels, but that will take a few months. Whether anyone still has hardware capable of reading the disc is quite another matter! Sorry about this.

The European Commission-funded ORIEL Project (*Online Research Information Environment for the Life Sciences*; www.oriel.org), coordinated from the European Molecular Biology Organization in Heidelberg, is developing tools and procedures to promote access to and integrated retrieval of various types of digital biological information. Within this umbrella project, the BioImage Database project (www.bioimage.org) has four purposes: to provide the scientific community with a freely accessible database and archive of high-quality multidimensional digital images of biological research relevance, with deep descriptive metadata; to make the images and their metadata available electronically via the Internet for personal study, educational, commercial, medical, and scientific research purposes; to provide tools to assist in the submission, downloading and visualization of such images, and in making comparisons between them; and to provide links between these image data and other relevant digital items of biological information (Shotton, 2003; Shotton *et al.*, 2003).

Taking its name and concept from an earlier BioImage Database prototype (Carazo *et al.*, 1999; Carazo and Stelzer, 1999; Lindek *et al.*, 1999), the BioImage

Copyright 2006, Elsevier Science (USA).
All rights reserved.

Database has been completely redesigned and rewritten within the Image Bioinformatics Laboratory of the Department of Zoology at Oxford University and it is now standards-based, using open source components throughout and employing semantic web technologies to provide a semantic reasoning layer between the users and the stored metadata. Central to these is a newly written ImageStore Ontology that defines the metadata descriptors used for the images and through which all user interactions with the database occur (Catton and Shotton, 2002; Sparks and Shotton, 2003). We are now starting to populate this publicly accessible BioImage Database with images from biological journals, individual researchers, learned societies, and research collections, with the intention that it should become for biological images what the standard bioinformatics databases are for sequences and structural data, with an emerging culture of image submission to the BioImage Database of high-quality research imagery arising from publicly funded biological research.

Our motivation in creating the BioImage Database is the belief that images are important assets created by the scientific process, but that they are only useful if they can be found by those interested in viewing or using them. Images held on unlabelled slides in desk drawers, dusty stacks of CDs, or forgotten discs in cardboard boxes are not scientific assets but liabilities. The purpose of this article is to bring the BioImage Database to your attention and to invite you both to submit your image collections for publication in the BioImage Database and to use its contents for your own research and teaching activities.

II. METADATA IN BIOIMAGE

Accurate and detailed metadata (data about data) are essential for finding images in a databse because, unlike sequences and text, images are not self-describing. While it is possible to scan through a sequence and recognise particular codons or transcription factor binding sites or to search a text document and extract key words that can be used to rank the relevance of a document to a query, the development of software that can identify the contents of an image by analysing its pixels is in its infancy. Thus without appropriate metadata, images are difficult or impossible to find, and online databases become little more than meaningless and costly data graveyards. Unfortunately, the process of manual metadata submission can be time-consuming, which is a disincentive to sharing information. Traditionally, there has been a tension between the cost of investing this effort "up front" at the time of image creation and storage and the subsequent benefits gained in terms of ease of image location and retrieval. The BioImage Database attempts to assist in the metadata submission process both by simplifying the submission of metadata by authors and by automating the harvesting of prerecorded metadata from image files, as described later.

The image metadata within the BioImage Database relate to several domains.

A. People and Institutions

With the consent of the authors, the BioImage Database holds contact information (names, postal and e-mail addresses, phone and fax numbers, etc.) about the people responsible for conducting experiments and creating the submitted images, the institutions in which they work, and the agencies that have funded their research. The data structure is flexible enough to record individuals' affiliations to several institutions, either simultaneously or sequentially, as appropriate.

B. Studies, Publications, and External Databases

Within the BioImage Database, the fundamental unit of record is the BioImage Study, roughly equivalent in scope to a peer-reviewed scientific paper. Indeed, a BioImage Study will normally be hyperlinked to one or more scientific papers based upon the image data contained within the study. From these studies, users may also make direct links to the principal taxonomic, structural, and sequence databases, permitting the BioImage Database to be used for lateral access to the wider scientific literature and other relevant factual data.

C. Experiments, Data Sets, and Images

The findings included within a BioImage Study may have been obtained from several experiments. All the images resulting from a single experiment, typically obtained from observation of similar specimens (or a single one), constitute a single BioImage image set. However, image sets do not necessarily have to be associated with particular scientific experiments. Collections of images on a related theme, e.g., historical time-lapse cine footage of mitosis in *Haemanthus*, may be grouped together into a single image set, even though they were not all obtained during a particular experiment.

D. Media Objects

An experiment may result in the creation of one or more media objects, e.g., images, videos, and models, which may be of any type or dimensionality—conventional 2D images, 3D, or 4D (*x*, *y*, *z*, and *time*) images comprising one or more fluorescence channels, videos, animations, surface reconstructions, etc. Ancillary data in the form of interpretive diagrams, graphs, tables, etc. may also be included. The BioImage data model is capable of recording all the basic details concerning these media objects. For example, for a conventional 3D confocal image, metadata would include the file format and size, the compression codec and quality settings, the *x*, *y*, and *z* pixel resolutions and pixel dimensions at the image plane, the corresponding optical resolutions at the image plane, the *x*, *y* and *z* data acquisition speeds, and the wavelength characteristics of each separate imaging channel. The provenance of the image is also recorded, showing when and by whom it was created and entered into the BioImage Database, how it may have been derived from another image, and, if so, the image processing and/or compression algorithms that have been used. Thus, for example, one might record the algorithm and point spread function parameters used to produce a blur-free deconvolved 3D image from a set of raw fluorescence optical sections showing out-of-focus blur. Similarly, if a section of video is submitted for publication, the BioImage Database can record details about the source file from which it was edited and the original tape or disc upon which that original was recorded.

E. Semantic Metadata

The metadata domains described so far cover only *who* created an image and *when*, *where*, *how*, and *why* it was made. They do not tell us *what* the image actually represents, and its *significance*, and these are arguably the most important kind of metadata (Shotton *et al.*, 2002). Many image databases fail to distinguish adequately between the content and the meaning of an image or to take into account different interpretations of the same data. Within the ImageStore ontology, we make a clear distinction between what the image represents (i.e., what is being denoted in the image—the species, cell type and preparation conditions of the specimen, and the identifiable features within the image) and the connotations attached to the image (the interpreted meaning, purpose, or significance of the image, its relevance to its creator and others, and its semantic relationship to other images) (Catton and Shotton, 2002, 2003). In addition, we use external ontologies and taxonomies to assist in the description of image content, instead of relying solely on conventional key words. Currently we are using GO ontology (http://www.geneontology.org) to describe genes and gene products and NCBI taxonomy (http://www.ncbi.nlm.nih.gov/Taxonomy/) to identify species.

III. HOW TO SUBMIT IMAGES TO THE BIOIMAGE DATABASE

Via the BioImage home page (www.bioimage.org), users may apply for a submission account to the BioImage Database. They will then be supplied with a username and password that will permit them to use the submission service. On entering the service, the user may enter or update personal details and is presented with a list of previously submitted BioImage Studies that may be edited and the option to submit more.

While at the time of writing the details have yet to be fully worked out, the BioImage Database intends to adopt two complementary approaches to submission—manual and semiautomatic. The manual submission interface is interactively customized for the type of submission to be made (e.g., entry of the accelerating voltage will be requested for submissions of electron micrographs but not of light micrographs), with the submission forms being generated dynamically as appropriate from the structures within the ImageStore ontology and any approved auxiliary ontologies. Any new submission starts at the BioImage study page and progresses to subsequent pages according to related resources required. Each page allows the user to enter appropriate values for that resource's attributes.

For example, a user may start the submission of a new study by entering its title and a brief textual description in the study page. The user may then wish to describe an experiment within that study, bringing up the experiment page within which (s)he can enter details of the technique used and specify the parameters used for image capture and subsequent digital image processing. The user effectively creates a tree of resources, each with its own defining attributes, which may be navigated, modified, pruned, and expanded before being finally committed to the database. An example is shown in Fig. 1.

Many of the metadata required to document an image may already be available in digital form, e.g., in the headers of image files generated by modern research microscopes and digital cameras. By captur-

FIGURE 1 A BioImage database submission interface.

ing this information at source, the process of managing images locally and submitting them to BioImage can be streamlined significantly, since BioImage can read the image header files, extract the relevant metadata, and use these to populate the submission forms, easing the task of manual submission.

The ultimate extension of this rationale will be the automated uploading of the entire metadata content of studies recorded in a local image asset management database using open source software provided by the Open Microscopy Environment (www.openmicroscopy.org; Swedlow *et al.*, 2003), together with any analytical results associated with such studies. To achieve this, we are working with the developers of the Open Microscopy Environment in two ways. First, BioImage will directly import and export image files and associated metadata recorded in OME-XML, a format that has been adopted as a common image exchange format by the European Light Microscopy Initiative and a number of leading microscope and software manufacturers. Second, we plan to develop a cross-mapping ontology and a BioImage plug-in for the OME system that will allow the automated uploading of selected OME studies from a researcher's local OME database direct to BioImage using Web services protocols, permitting OME users to publish the best of their images and associated analytical results to the BioImage Database without hassle, with the submitters being required to add manually only a minimum amount of additional information for each study.

It is important to note that while most original high-resolution multidimensional images will be directly available from the BioImage Database server, this does not have to be the case. Provided that URLs for these original high-resolution multidimensional images are provided and that these images themselves are made

permanently available on a stable server elsewhere, they need not reside on the BioImage Database server. However, medium-resolution "Web quality" 2D representative versions of the original images, of at least 512 by 512 pixels, must be submitted to the BioImage Database in PNG, TIFF, or JPEG format at the same time as the metadata relating to them. This permits authors to maintain copyright control over their high-resolution images if so desired (see Section VI). However, the BioImage staff will need initial access to any multidimensional high-resolution images that they will not be hosting directly in order both to check image quality and to extract metadata from the image header files.

IV. HOW TO FIND IMAGES IN THE BIOIMAGE DATABASE

Users can employ several strategies to find images described in the BioImage Database—browsing, searching, or a combination of both.

A. Browsing

After logging on to the BioImage Database, users will immediately be presented with the main browse interface (Fig. 2). This page will allow users to start their search by selecting an organism type (e.g., plant),

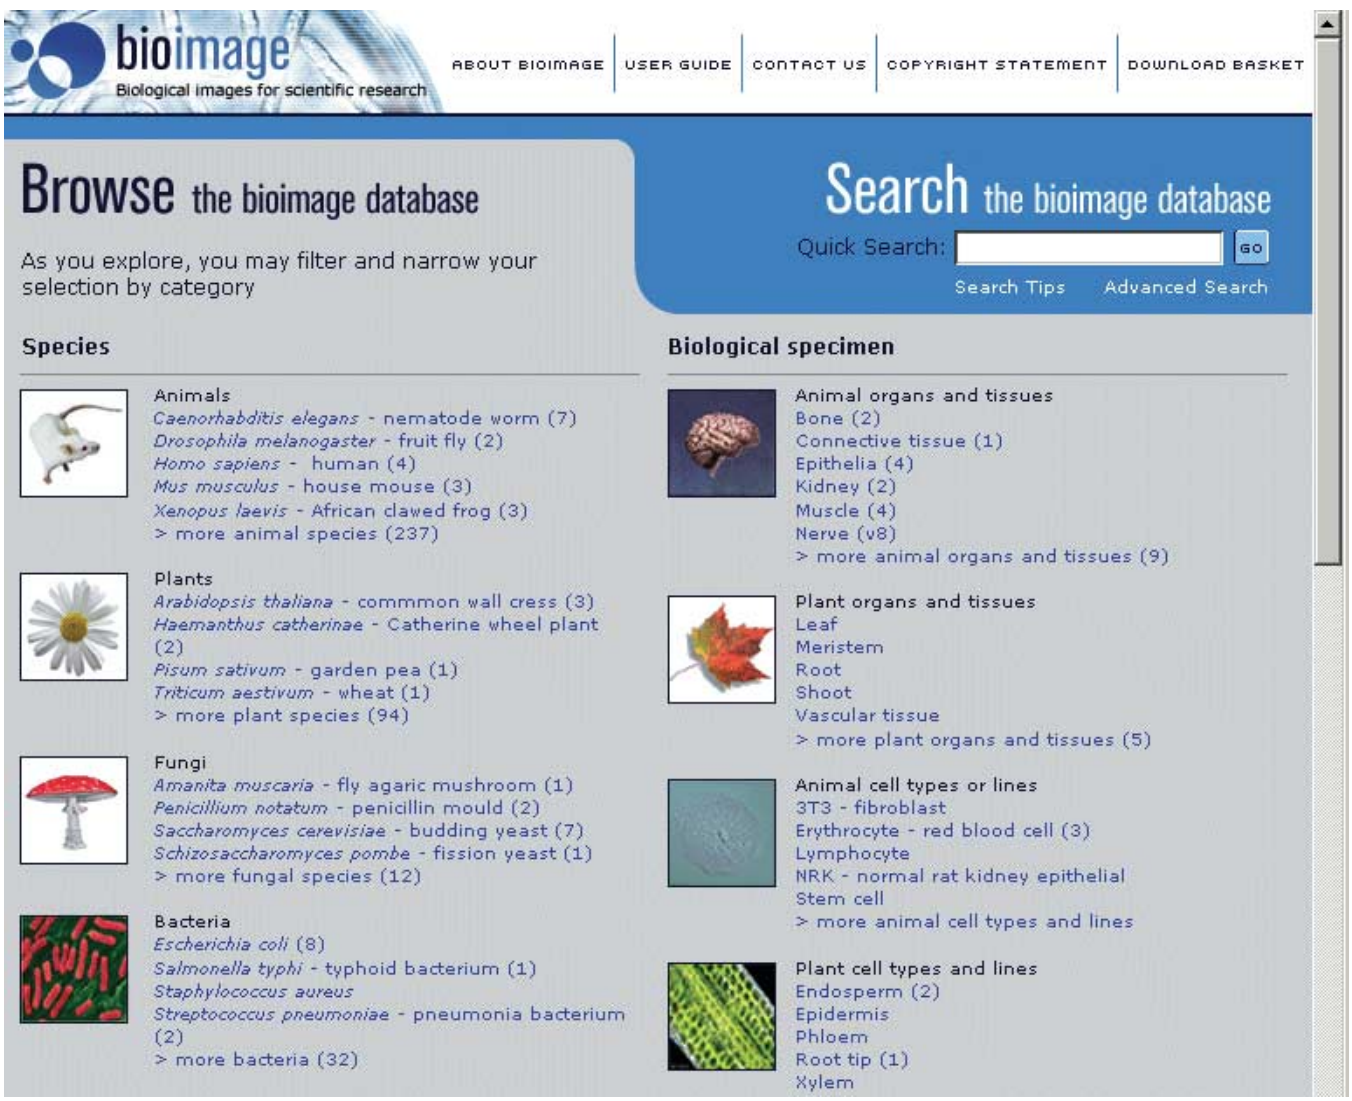

FIGURE 2 Design for the BioImage Database home page and browse interface.

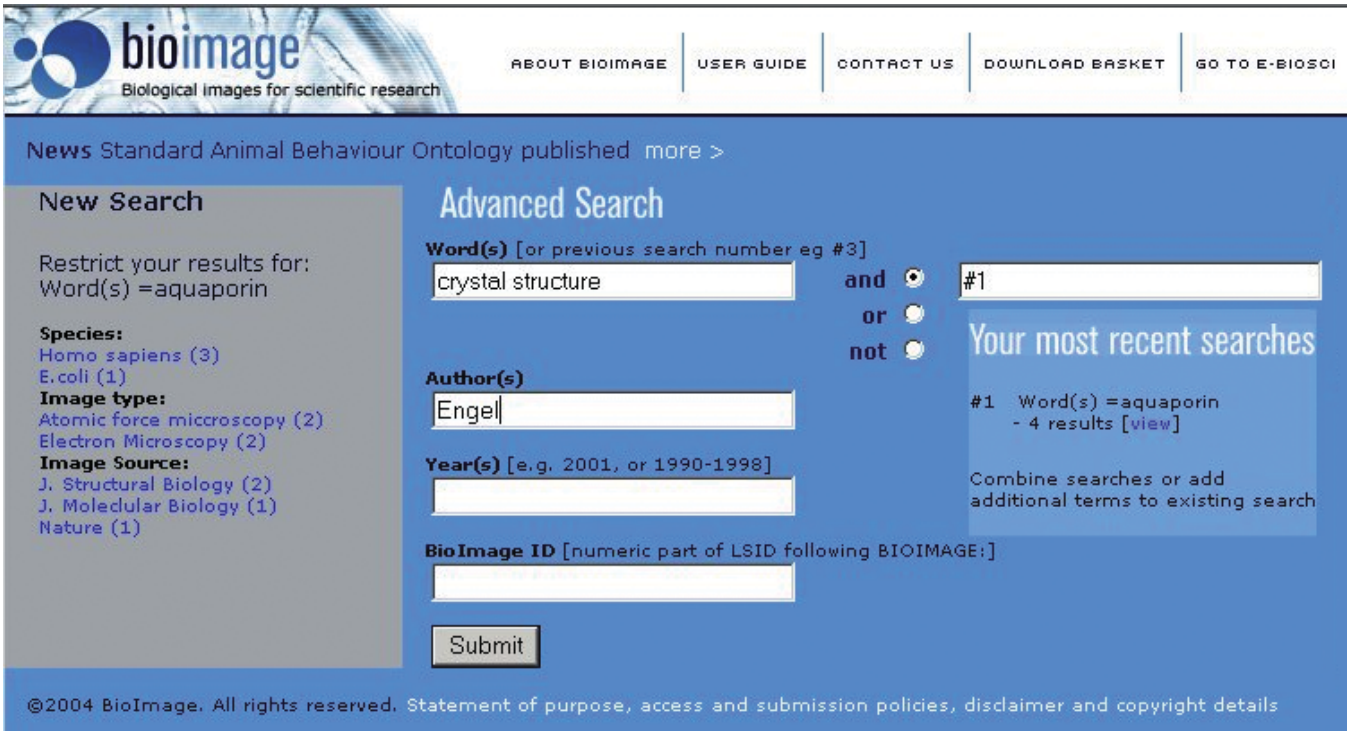

FIGURE 3 The BioImage Database advanced search interface.

a biological process (e.g., cell cycle, reproduction, or motility), a biological specimen (e.g., an organ, tissue, cell type, or organelle), an image type (e.g., electron micrograph), or an image source (e.g., *EMBO Journal* or University of Oxford). Each main section has several subheadings, and under each subheading the most commonly requested categories in the database are listed. Selecting ">other . . ." will list all the categories under that subheading. Selecting the "*Homo sapiens*—human" category, for example, will immediately list for the user all BioImage studies that contain images of humans, of human tissues, of human cells, and of organelles or macromolecules of human origin.

The results set can be refined at any stage using the grey "Refine Results" panel to the left of the screen—so that, for example, selecting Biological Specimen>Organelle>Golgi apparatus will restrict the results to those that show the human Golgi apparatus.

B. Searching

Browsing and searching within the BioImage Database are complementary and mutually supportive activities, with a search tab always available within the browse window (Fig. 2).

Users can employ two modes of searching:

1. Quick Search Interface, Available from the Browse Window

This permits simple key word or key phrase searching for matching text in all titles, descriptions, categories, and author records.

2. Advanced Search Interface

This window (Fig. 3) appears after clicking the "Advanced search" button beneath the Quick Search box. It permits the use of Boolean operators (and, or, not) between search terms applied to BioImage study titles, descriptions and categories, and enables restriction by author, date, and BioImage identifier. It further permits iterative refinement by reusing previous search results in a manner familiar to users of the bibliographic database software WinSPIRS, as all search results are saved automatically for the duration of a session.

The advanced search interface thus enables users to enter queries of the type: "Retrieve all studies containing images of Drosophila testes showing expression of the gene *always early* (*aly*)" by combining the terms "*Drosophila testis*" and "*aly*." The user can then link out from the retrieved BioImage studies both to the relevant gene sequences and to literature publications about them.

BioImage text searches should not include "wild cards," as the BioImage text search engine is a reasonably sophisticated tool that looks for matches in word stems and will automatically identify plural forms and other grammatical variants. So, for example, a search for "Kills," "Killing," or "Killed" will all return the study "Killing of mouse L929 fibroblasts by mouse HA-8 cytotoxic lymphocytes (CTL)" but not a study on killifish.

A major goal of the current BioImage Database development is to move away from conventional searching by exact key word matching and instead use ontologies to provide the ability to undertake semantically rich searches that can handle synonyms ("yeast" and "*S. cerevisiae*"), homonyms ("G protein": does it mean a GTP-binding protein or the coat glycoprotein from Semliki forest virus?), related terms ("cell division" and "mitosis"), and hierarchies ("*Mus musculus*," "rodent," and "mammal"). A search for "yeast" would thus return studies of *S. cerevisiae* even if the term "yeast" appears nowhere in the study metadata. The improved accuracy of search and browse results will become increasingly apparent to users of the BioImage Database as these improvements are introduced. Users should check the online "Development status" page for the current status of this work.

C. Viewing Browse and Search Results

Results can be displayed in one of three ways by using the tabs shown at the top of the results page.

1. *As a List of Studies*

For each study retrieved, the user is shown a representative thumbnail image, the study title, and its brief textual description, the study ID [in the form of a Life Science Identifier (LSID; http://www.i3c.org)], the authors' names, the categories into which the study falls, and the number of image sets and images within the study, as shown in Fig. 4.

2. *As a List of Image Sets*

For each image set, the user is similarly shown a representative thumbnail image, the image set title, and its brief textual description, the image set ID, the authors' names, the categories into which the image set falls, the ID and title of the study to which the image set belongs, and the number of images contained within the image set.

3. *As an Array of Images*

For each image, the user is simply shown a thumbnail image, with the image title and ID, and a list of the versions of that image that are available for download (e.g., for a 3D confocal data set: there may be a Web resolution 2D representative image, a high-resolution 2D representative image, a Web resolution 3D image stack, or the original high-resolution 3D image dataset), with check boxes against each option that allows the user to select one or more for downloading, in one or more formats. Mousing over each option will open a transient display giving details of the formats, file sizes, and so on available for each version of the image. For each type of display, clicking on a thumbnail image opens a larger version of the image, whereas clicking on a title will take the user to another page showing more complete metadata relating to the study, the image set, or the image, as appropriate.

The best way of viewing results depends to some extent on the purpose of the search. Users looking for a striking image to illustrate a particular biological topic will probably want to scan the array of images visually, matching their search criteria displayed by using the "Image" tab, whereas users more interested in the significance of the images may prefer the study or image set displays, with their richer metadata descriptors.

Users can move between these alternative display modes by clicking on the relevant tabs (Figs. 4 and 5), and the range of results displayed may be progressively refined using the "Refine Results" panel. For example, after an initial selection for all studies relevant to the "*Homo sapiens*—human" category, it may be that not all the image sets in a particular returned study involved human material. If the study involved a comparison between cellular structures in human and mouse brain, it would be quite likely to contain separate image sets for each. If mouse data were irrelevant to the user's requirements, they could be removed from the image set or image result displays by restricting the display, using the Refine Results panel, to show only "*Homo sapiens*—human" results. This area of the database functionality is currently under development, but the ultimate aim is to allow users to navigate hierarchically through each set of categories using taxonomies and ontologies provided by third parties, permitting both restriction and expansion of the scope of displayed results. Again, users should refer to the BioImage online "Development status" page for the current status of this facility.

V. DOWNLOADING IMAGES AND VIDEOS

A. Downloading Images

When viewing image search/browse results, users may mark individual images to be added to their

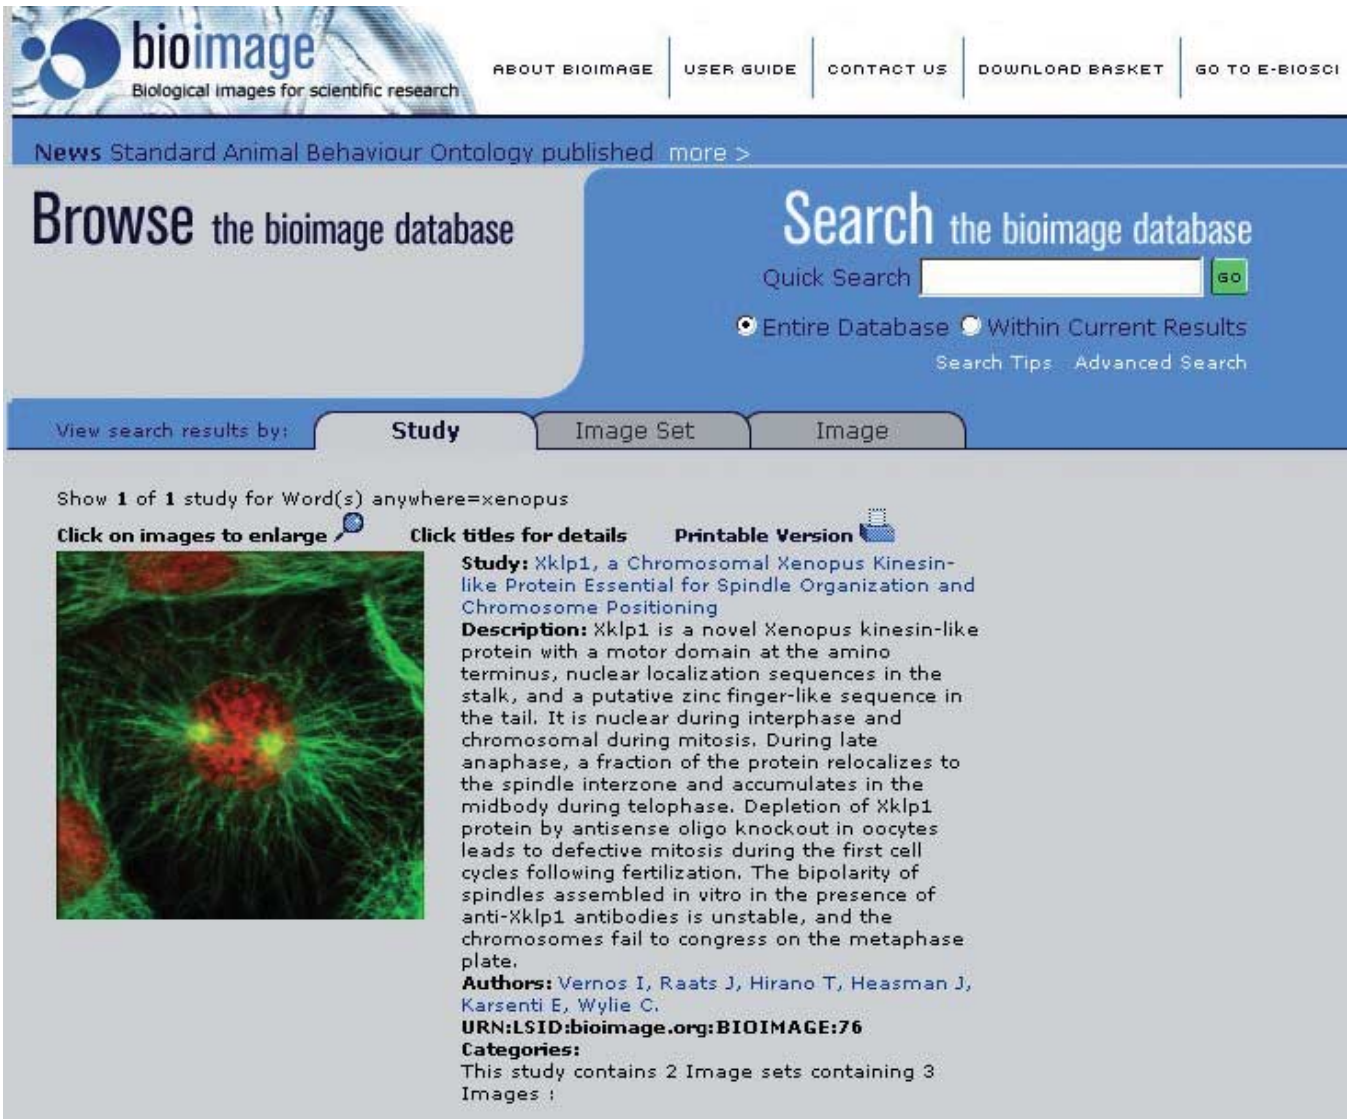

FIGURE 4 The BioImage Database results interface, showing study results.

download basket. To review the selected images and to initiate the download, users must select "Download Basket" from the main menu at the top of the browser window. Users will then be asked to confirm their agreement to the BioImage Database conditions of use before beginning the download process. Currently the download process begins immediately once these options have been specified and the download button is clicked, although it may be necessary in the future to schedule downloads to later times if current traffic is high and the requested files are large. Users may wish to check the online "System status" page to determine the current workload on the system.

Together with the downloaded images, users will be sent XML documents containing core metadata relating to the selected images, and to the image sets and studies of which they are a part, unless these are already bundled with the image as an OME-XML file.

B. Customizing Videos

For videos stored within the BioImage Database, we hope shortly to provide two possibilities for customising selected videos before downloading them, both of which depend upon a separate software service entitled VIDOS (Boudier and Shotton, 2000), which is part of a suite of on-line video services that we are developing under the umbrella title of VideoWorks (www.videoworks.ac.uk).

In interactive mode, a BioImage user, having selected a video, can choose the "Customize the video using VIDOS" button. In this case, the video will

automatically be made available to the VIDOS server, which will cause a VIDOS customization applet to open in a new browser window on the user's machine. The user can then interactively select the desired spatial and temporal editing parameters for the video and choose the required download format, codec, and compression quality. The VIDOS server then commissions a conversion job that runs on a VIDOS slave processor and finally delivers the customised video file to the user.

The alternative method of using VIDOS is more sophisticated, although less flexible, and depends upon the presence of prerecorded semantic content metadata for the video within the BioImage Database (Shotton *et al.*, 2000; Machtynger and Shotton, 2002; Rodriguez *et al.*, 2004). This permits users to search not just for entire videos, but also for clips from videos containing particular scenes, events, objects, or actors specified in the search. For example, a search might be for any clip showing apoptotic death of a fibroblast induced by a cytotoxic T lymphocyte. The images within any BioImage study returned by this search would include not only the entire video(s) containing such events, which could be downloaded directly or customised interactively as described earlier, but also those named video clips within the complete video(s) containing the specified events. Streaming previews of each such video or video clip could be viewed by clicking on the appropriate thumbnail keyframe image, while selection of a particular clip for downloading in a selected format would trigger a sequence of automated interactions between the BioImage server and the VIDOS sever using Web services protocols that would pass predetermined spatiotemporal editing and format customization parameters to the VIDOS server, commissioning an appropriate VIDOS customization job, and finally returning the requested clip to the user. For efficiency, such clips, once created, would be cached so that they would be available immediately for downloading upon a second request by a different user. While this Web services version of VIDOS has been tested and shown to work in prototype, it has yet to be fully implemented within the BioImage system, and potential users should consult the BioImage online "Development status" page for further information.

VI. COPYRIGHT ISSUES AND LICENSING AGREEMENTS

BioImage encourages users to submit their images under the Creative Commons Public Licence (http://creativecommons.org) that is also used by the Public Library of Science (www.plos.org). This licence, the terms of which are viewable at http://creativecommons.org/licenses/by/1.0/legalcode, grants to the BioImage Database and its end users "a worldwide, royalty-free, nonexclusive, perpetual (for the duration of the applicable copyright) license to exercise the rights in the Work." This effectively provides open access for BioImage Database users to view, download, and use the images, provided that copyright is acknowledged by including the name of the author and the original title of the image in any reproduction or derivative work and by insisting that any subsequent distribution of the image or derivative work is made under the same Creative Commons Public Licence. We believe this approach to be the most appropriate for images created as part of research projects undertaken using public funds and will maximise the potential usefulness of the images.

However, because some people may wish to submit images to the database that may have been created primarily for commercial purposes or may have significant commercial value that the copyright holders wish to retain, the Creative Commons Public Licence is not always appropriate. We therefore alternatively allow images to be submitted and licensed to the BioImage Database for noncommercial use only. Under this agreement, contributing authors retain full copyright to their material. However, they licence to the BioImage Database the right to make the image available to BioImage users, but only for noncommercial purposes and not for financial gain. End users must acknowledge the name of the original author and the source of the images as being the BioImage Database Web site and are legally obliged to contact the copyright holders for permission to reproduce the image outside the terms of this license.

As a further safeguard, authors may submit to the BioImage Database only thumbnail and Web resolution images, as defined earlier, while retaining the original high-resolution image files on their own Web sites, to which potential users must go for access to them, with whatever access and payment regulations that the user requires. The BioImage Database itself will take no part in such commercial transactions.

An alternative safeguard for those submitting images to the BioImage Database under either of the aforementioned licences is the ability to embargo publication of the images until some future date, e.g., until after the publication of that important *Nature* paper that is dependent upon the information contained within the images. For full details of these licenses and how they are applied, please see the BioImage Web site.

VII. VALUE AND FUTURE POTENTIAL OF THE BIOIMAGE DATABASE

The biological community is currently suffering form a surfeit of information in digital form, including journal publications, sequences and sequence-related information, three-dimensional structures, and digital image data. In 1999, an advisory committee to the U.S. National Institutes of Health estimated that some biomedical laboratories were already producing 100 terabytes of information a year. In the same year, the NCBI reported that 600,000 searches a day were being carried out on its collection of databases (Botstein and Smarr, 1999). In the time since that report, the volume of sequence data to be searched has increased by almost an order of magnitude and the volume of requests has approximately doubled every year. The EMBO DNA sequence database run by the EBI now receives over a million queries a day and is updated once a second (G. Cameron, personal communication, 2003). As David Roos (2001) has said: "We are swimming in a rapidly rising sea of data . . . how do we keep from drowning?"

With the advent of high-throughput cellular screening systems capable of generating 40,000 images a day and of functional MRI scans generating 100 Gb of data with each experiment, images are adding significantly to the scale of this data deluge. The integration of such multidimensional image data with the scientific literature and with a rapidly growing set of disparate bioinformatics resources, it is rapidly becoming one of the most demanding challenges for information science. There is an urgent need to better exploit the potential of the Internet and other communication networks to help researchers navigate through what is becoming an intricate and confusing information landscape. This need can be met in part by providing research communities with sophisticated tools to manage large complex multimedia datasets. The BioImage Database is one such tool.

We therefore invite you to use and to tell your colleagues about the BioImage Database and to submit your best images for publication within it, thereby not only maximizing exposure of your research achievements, but also ensuring that in 10 year's time *you* will know where to find your images in a format in which they can still be viewed!

Fixation and Embedding of Cells and Tissues for Transmission Electron Microscopy

Arvid B. Maunsbach

I. INTRODUCTION

Chemical fixation is the first step in most procedures for the preparation of cells and tissues for transmission electron microscopy. It is a very critical step, as the quality of fixation is of fundamental importance for results of the electron microscopical analysis. The main purposes of chemical fixation are to stop metabolic processes, to preserve cellular fine structure, and to stabilize the cells for subsequent steps in the preparatory procedure. In some studies, care must also be taken to preserve enzyme activity and/or tissue antigenicity. The choice of chemical fixation procedure requires careful consideration of three main factors:

1. Selection of the fixing agent itself, e.g., glutaraldehyde, formaldehyde, osmium tetroxide, or mixtures or sequences thereof.
2. Selection of the proper vehicle for the fixative, e.g., choice of buffer, pH, added salts, or other substances.
3. Selection of the procedure for applying the fixative to the cells or tissues.

No single standard fixation method is suitable for all types of cells and tissues. The aforementioned three factors usually have to be adjusted for each specific cell type, tissue, or experimental situation and, consequently, a very large number of fixation procedures have been described. The literature on chemical fixation for electron microscopy is extensive (see Sabatini *et al*., 1963; Maunsbach, 1966a,b; Griffith, 1993; Glauert and Lewis, 1998; Maunsbach and Afzelius, 1999). It is nevertheless possible to point at some general principles and procedures with wide applicability. This chapter describes such procedures found useful for different applications in cell biology in our laboratory.

Tissues to be analyzed in the electron microscope are usually embedded in resins for ultramicrotomy. The embedding procedures vary with respect to chemical composition of resins, protocols for dehydration, and procedures for infiltration with resins, as well as the properties of the embedded tissue with respect to sectioning quality, tissue shrinkage, and tissue contrast in the electron microscope. Epoxy resins are the most commonly used embedding media in biological electron microscopy (Luft, 1961; Glauert and Lewis, 1998). They combine good ultrastructural preservation of the tissues, ease of sectioning, reproducibility, and relative ease of handling. However, they preserve tissue antigenicity only to a very limited extent. Acrylic resins, such as the Lowicryls (Carlemalm *et al*., 1985), provide both good ultrastructural preservation and preserve, to a larger extent, tissue antigenicity. Embedding in acrylic resins is carried out at low temperature either by progressively lowering the temperature during dehydration and resin infiltration or by cryofixation followed by freeze substitution and UV polymerization at low temperature (see article by Maunsbach).

II. MATERIALS AND INSTRUMENTATION

A. Fixation

Agar (Merck 101615)
Glutaraldehyde, 25% aqueous stock solution EM grade (Merck 104239)
Sodium cacodylate ($C_2H_6AsNaO_2 \cdot 3H_2O$, Merck Art 820670)
Osmium(VIII) tetroxide ($Os0_4$, 76028 Johnson Matthey Materials Technology)
Paraformaldehyde powder (Merck 104005)
Operating table
Anesthetic
Scissors, forceps, scalpels, and clamps for surgical procedures
Small forceps with fine claws
Gauze swabs
Plastic petri dishes
Thin razor blades
5- to 10-ml vials with lids for specimens
Gloves
Short-beveled syringe needle for perfusion of rat aorta, length about 50 mm, outer diameter 1.3–1.5 mm
Blunt syringe needle for heart perfusion, length about 100 mm, outer diameter 2.0–2.4 mm
Perfusion set with drip chamber as used for intravenous blood infusions (Fig. 1)
Flask to which the perfusion set fits
10- to 15-cm-thick syringe needle to ventilate the flask
Stand to hold the fixative flask upside down about 150 cm above the operating table
Adequate ventilation

B. Dehydration and Embedding in Epoxy Resin

Epoxy resin kit (TAAB TO24) containing epoxy resin (TAAB 812), dodecenyl succinic anhydride (DDSA), methyl nadic anhydride (MNA), and 2,4,6-tri(dimethylaminomethyl)phenol (DMP-30)
Ethanol
Maleic acid ($C_4H_4O_4$, Merck 800380)
Uranyl acetate dihydrate [$(CH_3COO)_2UO_2 \cdot 2H_2O$, TAAB 1001]
Propylene oxide (C_3H_6O, Merck 112492).
5- to 10-ml glass vials with lids (Fig. 2a).
Gloves
Disposable beaker for mixing resin
Disposable Pasteur pipettes
Flat embedding molds in resistant rubber (G3690, Agar Scientific Ltd., Fig. 2b)
Fine forceps
Wooden stick

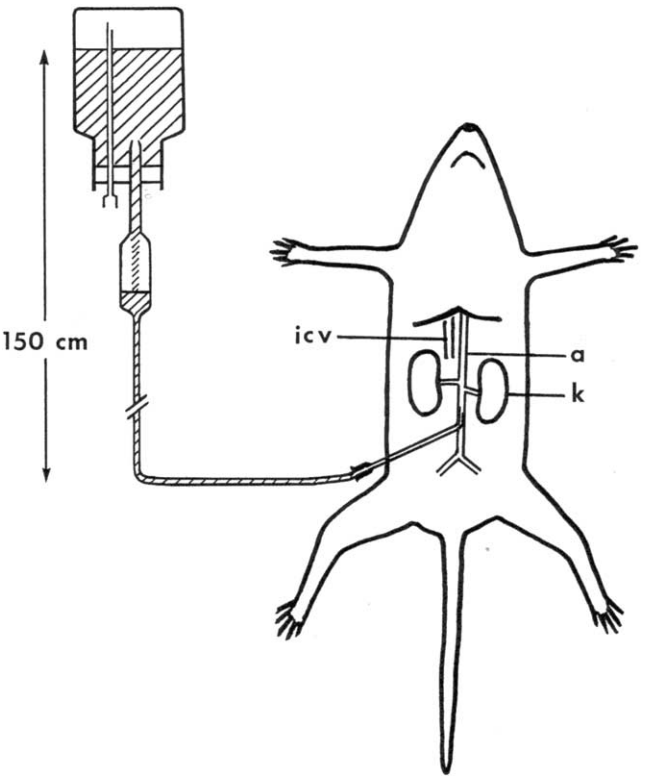

FIGURE 1 Schematic drawing of perfusion fixation of rat through the abdominal aorta. The flask with the fixative and the drip chamber is placed about 150 cm above the animal. a, aorta; icv, inferior caval vein; k, kidney.

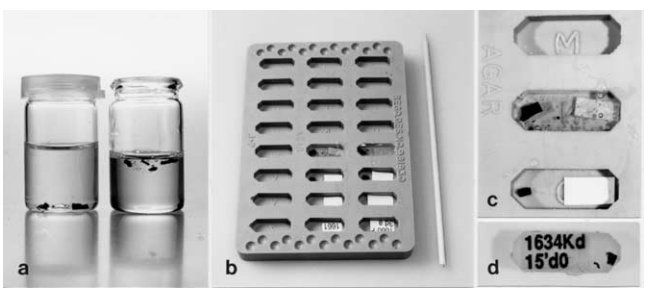

FIGURE 2 Embedding in epoxy resin. (a) Vials with specimens during ethanol dehydration (left) and infiltration in pure epoxy resin (right). At the start of infiltration the tissue blocks are placed on top of the resin and allowed to sink to the bottom. (b) Flat embedding mold used for epoxy embedding. Specimens and labels are placed in the wells. The wooden stick (right) is used to orient blocks and labels in the resin. (c) Enlargement of central wells showing specimen and label without resin (below), specimen with label and epoxy (middle), and empty well (top). (d) Polymerized epoxy block with label seen from back side.

III. PROCEDURES

For many purposes, adequate fixation is obtained by simple immersion of small tissue pieces into the fixative solution. This is the only mode of fixation possible for many tissues and for biopsies. However, a more rapid and uniform fixation is usually obtained if the fixative solution is perfused via the vascular system, either through the heart or through the abdominal aorta (Fig. 1) or, in some cases, through the venous system. Perfusion fixation (Figs. 3a and 4) should be preferred over immersion fixation (Figs. 3b and 5) whenever possible. For most tissues, 1% glutaraldehyde is sufficient for general ultrastructural studies. This concentration does not require a preceding rinse of the vascular system with a salt solution. For cytochemical or immunocytochemical studies, 4% formaldehyde plus 0.1% glutaraldehyde is preferable (Fig. 3b), but the glutaraldehyde should be omitted if the enzymes or antigens are inhibited by glutaraldehyde.

A. Perfusion Fixation of Rats through the Abdominal Aorta

The following procedure (Maunsbach, 1966a) results in efficient fixation of kidney, liver, pancreas, and small intestines. In the kidney, which is very sensitive to variations in the mode of applying the fixative, it preserves open tubules and normal relationships between tubule cells. The procedure is described for rats but can also be adapted for other animals.

Solutions

1. *0.2 M sodium cacodylate buffer*: To make 1000 ml, dissolve 42.8 g sodium cacodylate in 900 ml of distilled water. Adjust pH to 7.2 with 1 *N* HCl. Complete to 1000 ml with distilled water.
2. *0.1 M sodium cacodylate buffer*: Dilute 0.2 *M* sodium cacodylate buffer with an equal amount of distilled water.
3. *1% glutaraldehyde in 0.1 M sodium cacodylate buffer*: To make 500 ml of fixative solution, mix 250 ml 0.2 *M* sodium cacodylate buffer and 20 ml 25% aqueous glutaraldehyde and add distilled water to 480 ml. Adjust pH to 7.2 with 0.1 *N* NaOH or 0.1 *N* HCl. Complete with distilled water to 500 ml.
4. *20% stock solution of formaldehyde*: To make a 100-ml solution, mix 20 g of paraformaldehyde powder with 80 ml of distilled water in a glass flask. Heat to 60°C while gently agitating the milky solution. Add 1 *N* sodium hydroxide dropwise until the solution clears up. Complete to 100 ml with distilled water. This procedure should be carried out in a well ventilated hood and with protection for the face. The solution can be stored for a few days in the refrigerator.
5. *4% formaldehyde plus 0.1% glutaraldehyde in 0.1 M sodium cacodylate buffer for immunocytochemistry*: To make a 500-ml solution, mix 100 ml of 20% formaldehyde stock solution, 2 ml 25% glutaraldehyde, and 250 ml 0.2 *M* sodium cacodylate buffer. Add distilled water to 480 ml. Adjust pH to 7.2 with 0.1 *N* NaOH or 0.1 *N* HCl. Complete with distilled water to 500 ml. For sensitive antigens, omit the glutaraldehyde.
6. *2% osmium tetroxide stock solution*: 1 g crystalline osmium tetroxide is obtained preweighed in closed glass ampules. Wash the ampule carefully and score the vial around its perimeter with a diamond or a fine file. Break the vial cautiously and empty the crystals into 50 ml of distilled water in a glass vial with a tight lid. The crystals dissolve very slowly and the solution should be prepared at least the day before use. Shaking and/or ultrasonic treatment speeds up the process. All steps should be carried out in a well-ventilated hood. Always wear gloves when handling osmium tetroxide solutions. The solution is stable if kept in the cold and protected from strong light.
7. *1% buffered osmium tetroxide*: To make 10 ml of fixative solution, mix 5 ml of 0.2 *M* cacodylate buffer and 5 ml of 2% osmium tetroxide stock solution.

Steps

1. Place the closed flask containing the fixative upside down about 150 cm above the level of the aorta in the animal. The fixative has room temperature.
2. Connect the flask to the perfusion needle via the administration set for intravenous solutions and ventilate the flask (Fig. 1).
3. The size of the needle has a 1.3- to 1.5-mm outer diameter for a 300-g rat and is proportionally smaller for lighter animals. The needle is bent at an angle of about 45° with the beveled side out (i.e., down during perfusion).
4. Connect the perfusion needle via the infusion set to the flask containing the fixative. Check that there are no air bubbles in the tubing of the infusion set.
5. Fix the anesthesized animal onto the operating table with its back down. No artificial respiration is used.
6. Open the abdominal cavity by a long midline incision with lateral extension and move the intestines gently to the left side of the animal.
7. Carefully expose the aorta below the origin of the renal arteries and very gently free the aorta from overlaying adipose and connective tissues.

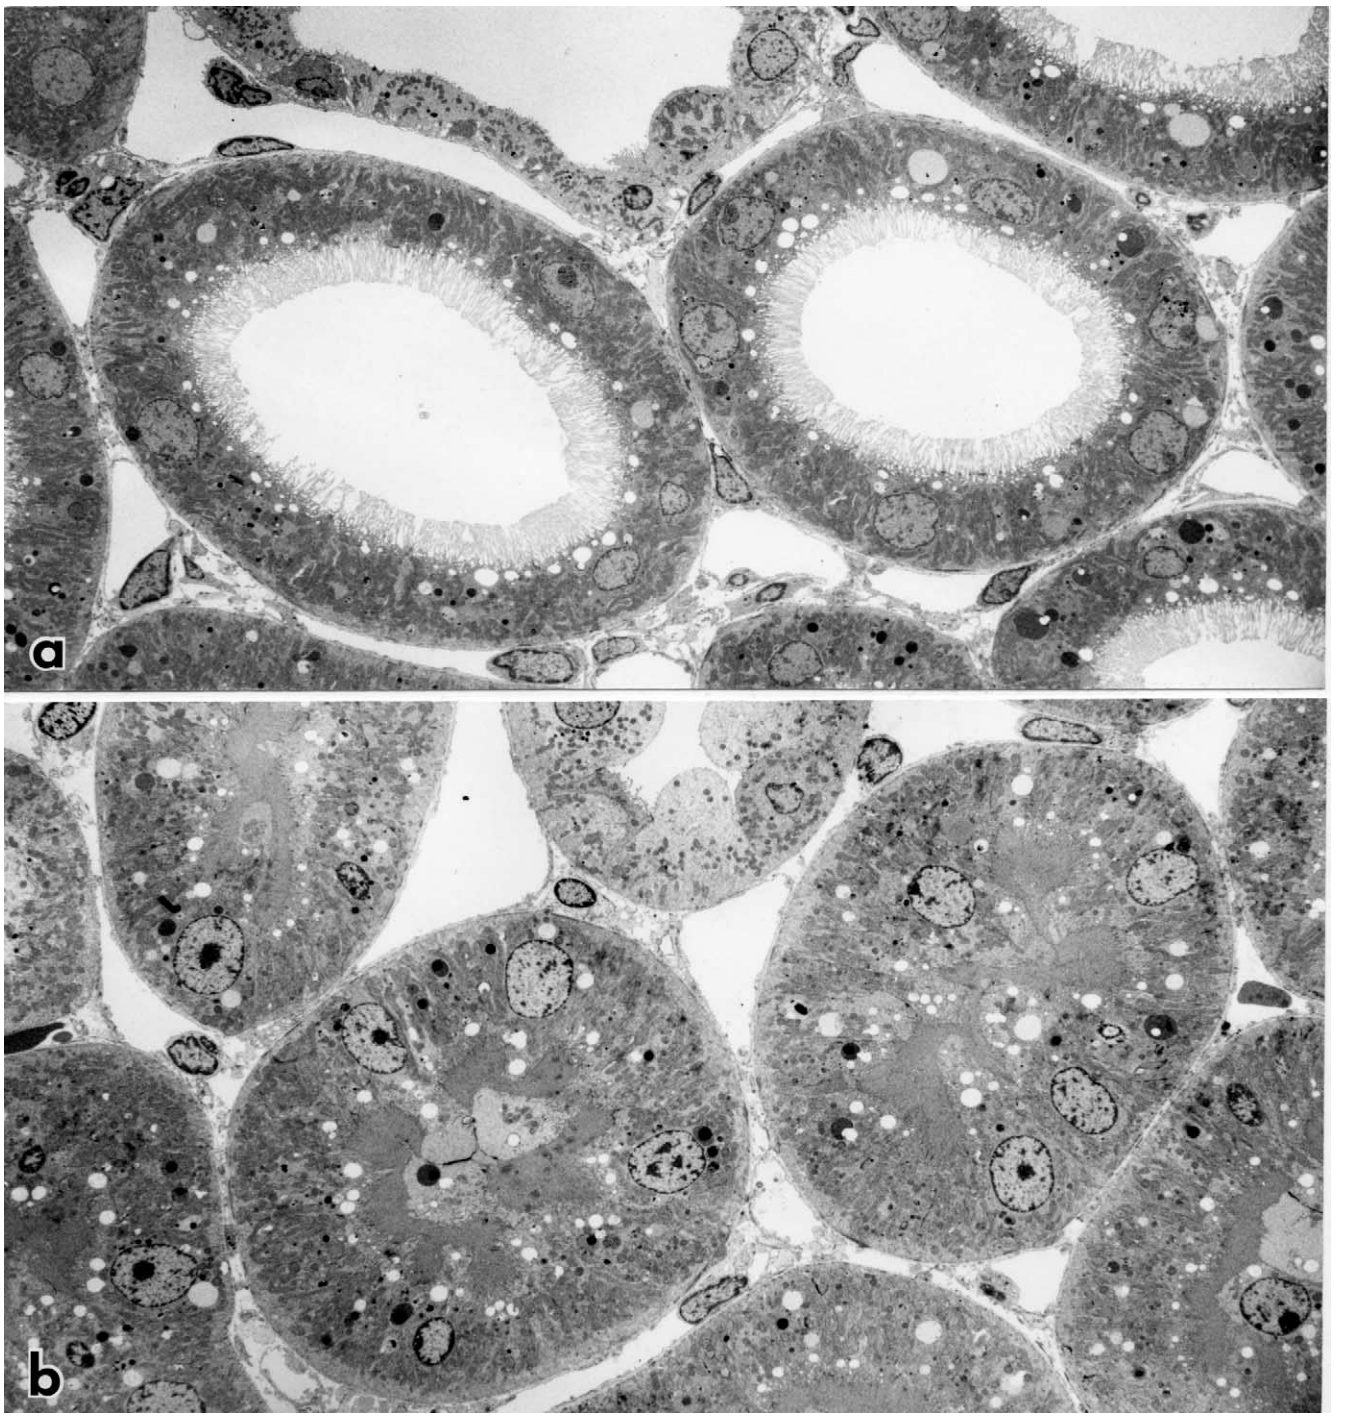

FIGURE 3 Transmission electron micrograph of rat kidney cortex perfusion fixed through the abdominal aorta with 1% glutaraldehyde (a). Tubule lumens are open and brush borders of proximal tubules are arranged uniformly. (b) Comparable area of rat kidney cortex immersion fixed with 1% glutaraldehyde. All proximal tubules are collapsed with portions of cytoplasm occupying the tubule lumen, and nuclei have moved away from the basement membrane. Both specimens were postfixed in 1% osmium tetroxide in 0.1 *M* cacodylate buffer, block stained with 1% uranyl acetate in sodium maleate buffer at pH 5.5, dehydrated in ethanol, and embedded in Epon resin, and sections were double stained with uranyl acetate and lead citrate. 1200×.

8. Hold the wall of the aorta firmly with the small forceps with fine claws about 0.5–1.0 cm from its distal bifurcation. Insert the bent needle close to the forceps toward the heart into the lumen of the aorta (with the beveled side of the tip down).

9. In very rapid succession (a) cut a hole in the inferior caval vein with fine scissors, (b) start the perfusion, and (c) clamp the aorta below the diaphragm, but above the origin of the renal arteries. When performing these manipulations, accuracy and speed are essential and the fixation procedure is preferably carried out by two persons. It is particularly important to clamp the aorta rapidly after the perfusion has been started. This is done most easily by compressing the aorta toward the posterior wall of the peritoneal cavity with a finger (wear gloves), which is then replaced by a clamp. Finally, cut the aorta above the compression.

10. The kidney surface must blanch immediately and show a uniform, pale color. The flow rate should be at least 60–100 ml/min for an adult rat. Perfuse for 3 min. Stop the perfusion and excise and trim the tissues with a razor blade. Store the tissue in vials and immersion fix in the same fixative for 2 h.

11. Rinse the tissue two times for 30 min in 0.1 *M* sodium cacodylate buffer.

12. Postfix the tissue in 1% osmium tetroxide for 1 h in the cold. Swirl the vial occasionally to secure uniform penetration of the fixative.

13. Rinse two times for 30 min in 0.1 *M* sodium cacodylate buffer. The tissue is now ready for dehydration and embedding.

B. Perfusion Fixation through the Heart

The following procedure provides fixation of most rat organs with 1% glutaraldehyde. For some organs the glutaraldehyde concentration should be increased (e.g., to 5% for the brain) and the fixative preceded by a brief rinse with a balanced salt solution such as Tyrode. For immunocytochemistry, use 4% paraformaldehyde with or without 0.1% glutaraldehyde .

Solutions

1. *1% glutaraldehyde in 0.1 M sodium cacodylate buffer*: See Section III,A.

2. *4% paraformaldehyde plus 0.1% glutaraldehyde in 0.1 M sodium cacodylate buffer*: See Section III,A.

3. *0.1 M sodium cacodylate buffer*: See Section III,A.

Steps

1. Place the closed flask containing the fixative upside down about 150 cm above the level of the aorta in the animal.

2. Connect the perfusion needle via the infusion set to the flask containing the fixative and ventilate the flask. Check that there are no air bubbles in the tubing of the infusion set.

3. Fix the anesthetized animal onto the operating table with its back down.

4. Open the thoracic cavity of the animal without giving artificial respiration.

5. Grasp the heart close to its apex with a forceps. Cut a small hole in the wall of the left ventricle close to the apex with fine scissors. Rapidly insert a blunt syringe needle (2.0–2.4 mm outer diameter for a 300-g rat and proportionally smaller for lighter animals) and move it into the ascending aorta. Place a clamp on the aorta to hold the needle.

6. Cut a hole in the right atrium of the heart and start perfusion immediately.

7. Check the flow rate in the drip chamber and flask. The flow rate should be at least 150 ml/min for an adult rat. Perfuse for 3 min. Stop the perfusion and remove pieces of tissue. Subdivide the tissue and fix it additionally for 2 h in the same fixative.

8. Proceed as described earlier for perfusion fixation through the abdominal aorta (steps 11–13).

C. Immersion Fixation

Immersion fixation of tissues for general ultrastructural studies is carried out with 1 or 2% glutaraldehyde for small tissue blocks. If the size of the tissue in one dimension is about 0.5 mm or more, the concentration should be increased to 3%, which is recommended for renal biopsies. For large specimens, an alternative solution is 2% formaldehyde plus 2.5% glutaraldehyde fixative (Fig. 4b). For immunocytochemical studies, use 4% formaldehyde with or without 0.1% glutaraldehyde fixative. If the antigen is sensitive to fixation, glutaraldehyde should be excluded.

Solutions

1. *1% glutaraldehyde in 0.1 M sodium cacodylate buffer*: See Section III,A.

2. *3% glutaraldehyde in 0.1 M sodium cacodylate buffer*: To make 100 ml of fixative solution, mix 50 ml 0.2 *M* sodium cacodylate buffer, 12 ml 25% aqueous glutaraldehyde, and add distilled water to 90 ml. Adjust pH to 7.2 with 0.1 *N* NaOH or 0.1 *N* HCl. Complete with distilled water to 100 ml.

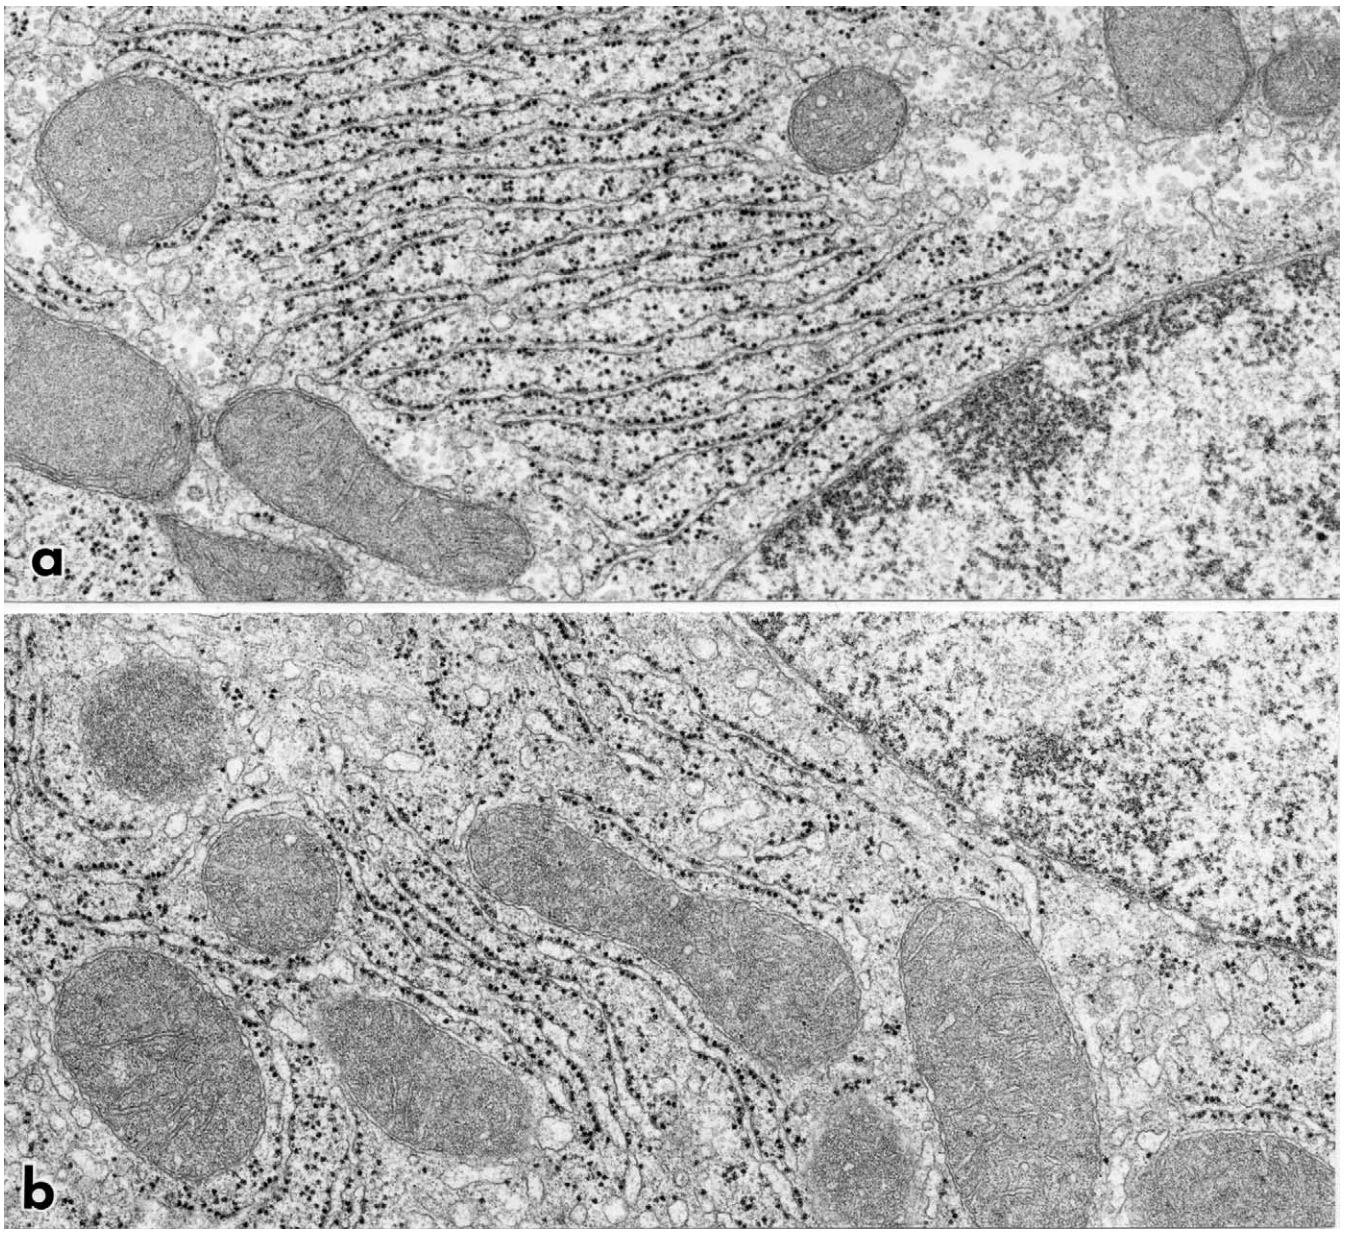

FIGURE 4 Parts of liver cells from rats perfusion fixed through the heart with 1% glutaraldehyde (a) and 4% formaldehyde plus 0.1% glutaraldehyde (b). Cell ultrastructure is similar but small focal expansions of the endoplasmic reticulum occur (b). 32,500×.

3. *4% formaldehyde plus 0.1% glutaraldehyde in 0.1 M sodium cacodylate buffer*: See Section III,A.

4. *2% formaldehyde plus 2.5% glutaraldehyde in 0.1 M sodium cacodylate buffer, often referred to as half-strength "Karnovsky's fixative" (Karnovsky, 1965)*: To make 250 ml of fixative solution, mix 25 ml 25% aqueous glutaraldehyde stock solution, 25 ml 20% formaldehyde stock solution, and 125 ml 0.2 *M* sodium cacodylate buffer; add distilled water to about 240 ml and adjust pH to 7.2 with 0.1 *N* NaOH or 0.1 *N* HCl. Complete with distilled water to 250 ml.

5. *1% osmium tetroxide in 0.1 M sodium cacodylate buffer*: See Section III,A.

6. *0.1 M sodium cacodylate buffer*: See Section III,A.

Steps

1. Cut out a piece of tissue from the organ under study and place it in a precold, empty petri dish.

2. Hold the tissue gently with a forceps and cut thin slices with a thin razor blade using sawing movements. The slices should not exceed 0.5 mm in thickness. Great care should be taken not to strain the tissue mechanically. Areas where the forceps have touched the tissue should be discarded.

3. Trim the slices to less than than $0.5 \times 5 \times 5$ mm and immerse them into the fixative solution.

4. Swirl the vial occassionally during fixation to secure uniform penetration of the fixative from all sides into the tissue. Fixation should last at least 2 h. In most cases the temperature of the fixative is not important. Initial fixation can be carried out at room temperature and followed by fixation in the cold.

5. Trim down the dimensions of the tissue slices while in the fixative solution in order to get small blocks suitable for embedding. It is absolutely essential that only tissue from the surface of the tissue is used, as the quality of fixation deteriorates with increasing distance from the surface of the immersion fixed slice (Fig. 5).

6. Proceed as described earlier for perfusion fixation through the abdominal aorta (see Section III,A, steps 11–13).

D. Fixation of Tissue Cultures

Solutions

1. *2% glutaraldehyde in 0.1 M sodium cacodylate buffer*: To make 100 ml, mix 50 ml 0.2 *M* sodium cacodylate buffer, 8 ml 25% glutaraldehyde, and 30 ml distilled water. Adjust pH to 7.2 with 0.1 *N* NaOH or 0.1 *N* HCl. Complete with distilled water to 100 ml.
2. *0.1 M sodium cacodylate buffer*: See Section III,A.

Steps

1. Gently decant the tissue culture medium.
2. Immediately add 2% glutaraldehyde in 0.1 m*M* cacodylate buffer. Very gently swirl the fixative in the culture dish.
3. Fix for 1 h.
4. Proceed as described earlier for perfusion fixation through the aorta (see Section III,A, steps 11–13).

E. Fixation of Cell Suspensions

Solutions

1. *2% glutaraldehyde in 0.1 M sodium caocdylate buffer*: See Section III,D.
2. *2% agar in 0.1 M sodium cacodylate buffer*: Dissolve during stirring 2 g agar in 100 ml 0.1 *M* sodium cacodylate buffer. Heat to close to 100°C until dissolved.

Steps

1. Mix the cell suspension rapidly with an equal volume of 2% glutaraldehyde in 0.1 *M* cacodylate buffer.
2. Fix for 1 h.
3. Sediment the cells in a centrifuge tube by centrifugation at approximately 1000 *g* for 5 min. Decant the supernatant.
4. Resuspend the cells in an excess of 0.1 *M* cacodylate buffer. Repeat step 3 after 15 min.
5. Add 1% osmium tetroxide in 0.1 *M* cacodylate buffer and resuspend the cells. Fix for 30 min. Repeat step 3.
6. Add 0.1 *M* sodium cacodylate buffer and resuspend the cells. Repeat step 3.
7. To the pellet add an equal volume of 2% agar in 0.1 *M* sodium cacodylate buffer, which has been heated to about 40°C. Mix the agar and the pellet rapidly with a fine glass rod. Allow the pellet to cool. Thereafter treat the pellet as a tissue block during dehydration and further processing. Take care not to resuspend the cells.

F. Dehydration and Embedding in Epoxy Resin

The following procedure results in embedded tissue blocks with good cutting properties from a variety of tissues. It includes *en bloc* staining with uranyl acetate, which improves contrast in subsequent section staining. If *en bloc* staining is not desired, steps 2–4 should be omitted (compare Figs. 6a and 6b).

Solutions

1. *70, 90, and 95% ethanol in water*
2. *0.05 M maleate buffer*: To make 100 ml, dissolve 0.58 g maleic acid in about 80 ml water and adjust pH to 5.2 with 1 *N* NaOH. Fill up to 100 ml with water.
3. *0.5% uranyl acetate in 0.05 M sodium maleate buffer*: To make 100 ml, dissolve 0.58 g maleic acid in 80 ml water and adjust pH to 6.0 with 1 *N* NaOH. Dissolve 0.5 g uranyl acetate dihydrate in this solution and adjust (if necessary) pH to 5.2 with NaOH. Fill up to 100 ml with water.
4. *Epoxy resin*: To make 100 g resin, mix 48 g TAAB 812, 19 g DDSA, and 33 g MNA. Stir continuously for 5 min. Add 2 g DMP-30 and stir continuously for another 5 min. The complete epoxy mixture should be used for initial infiltration within the next few hours, as it will slowly start to polymerize at room temperature. The freshly mixed complete resin can be stored in the freezer (e.g., –20°C) for months in closed vials. The vials must attain room temperature before being opened and used for embedding.

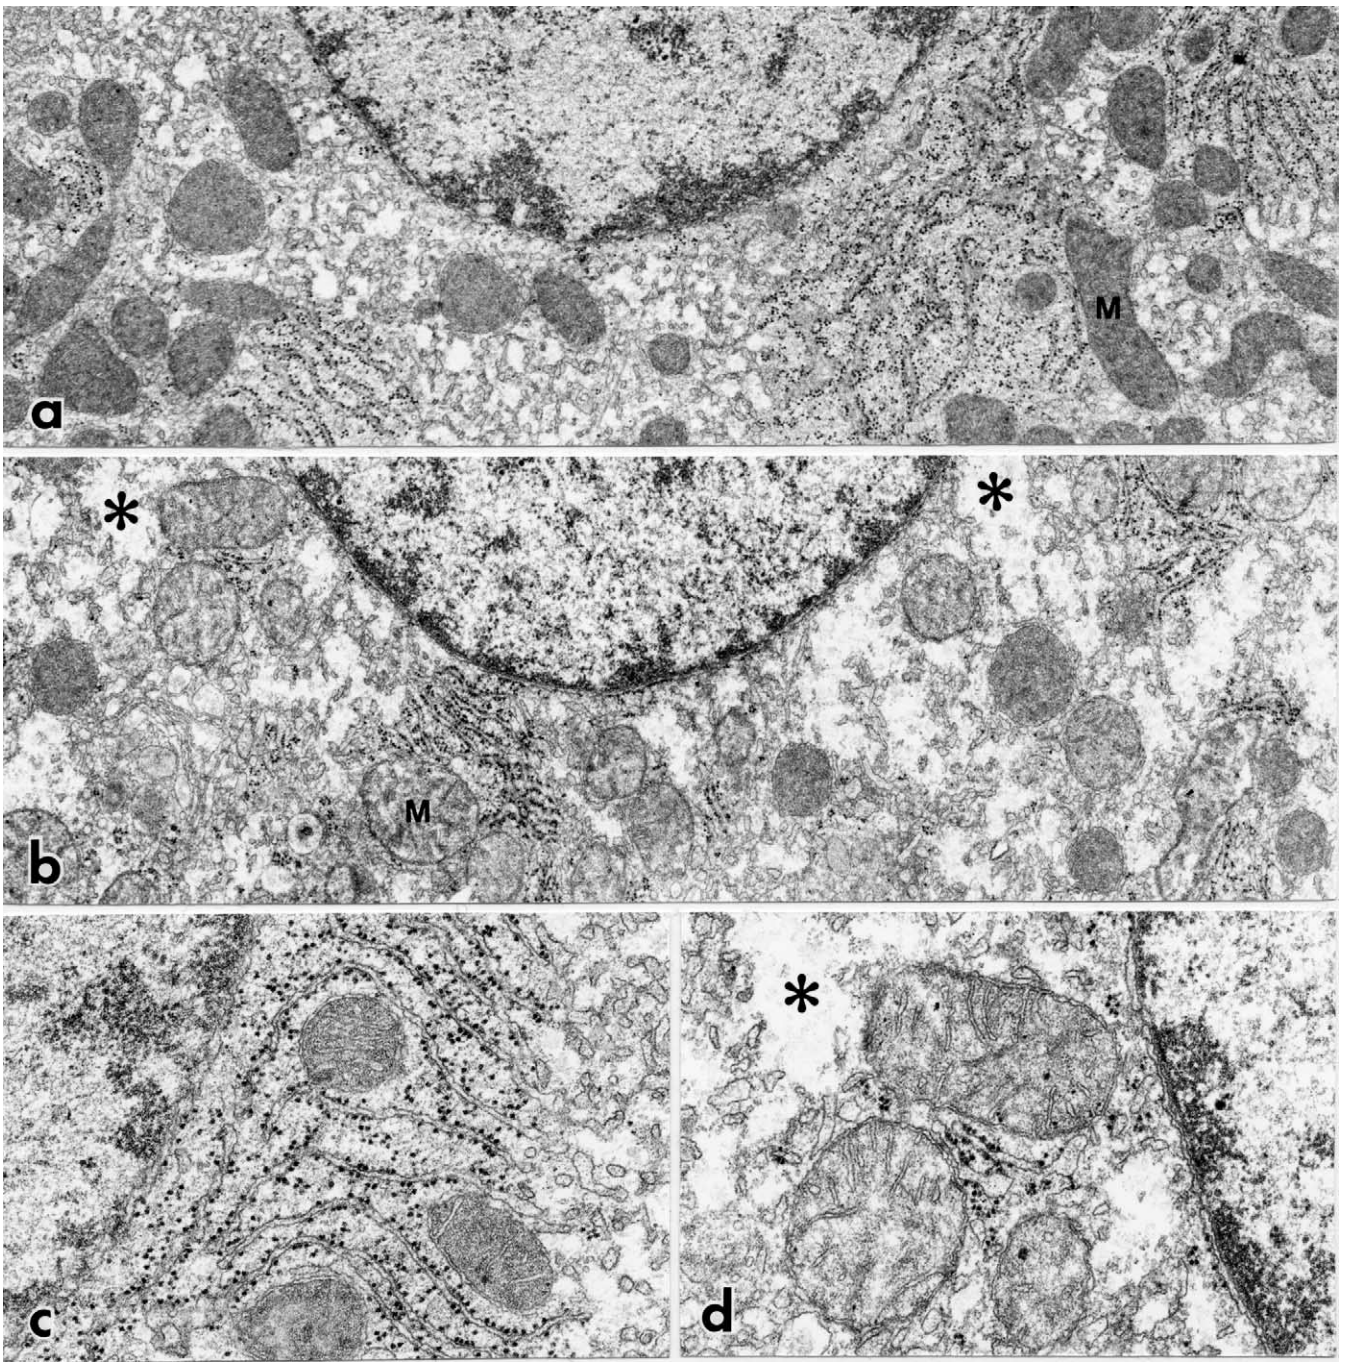

FIGURE 5 Liver cells fixed by immersion in 1% glutaraldehyde and observed in a section cut at a right angle to the liver surface. (a) The cell is located at the very surface of the liver. (b) The cell is located about 200 µm from the surface and thus fixed with some delay. The cytoplasm of the superficial cell, shown at higher magnification (c), is well preserved, but the cytoplasm of interior cells shows evidence of cell swelling with almost empty regions (*). Mitochondria (M) are well preserved (a, c), but dilated with a partly empty matrix (b and d). a and b: 15,000×; c and d: 32,500×.

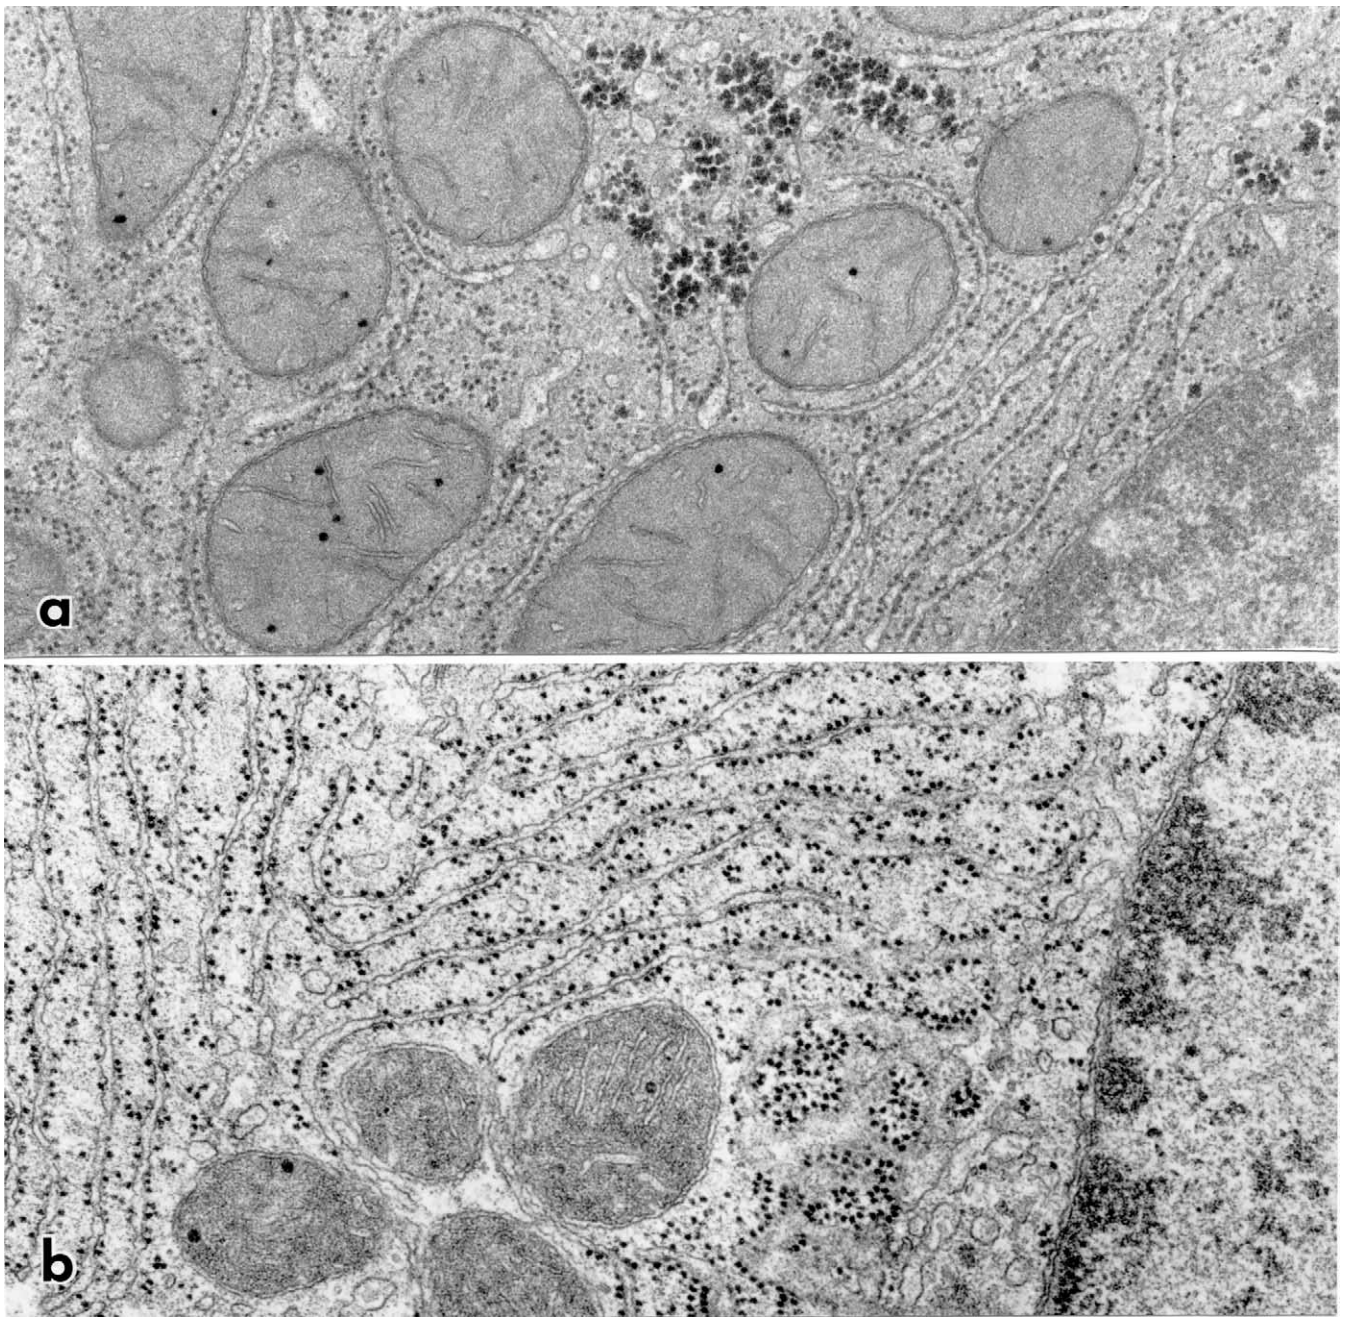

FIGURE 6 Electron micrographs of cells in liver perfusion fixed with 1% glutaraldehyde, postfixed in osmium tetroxide, and embedded in epoxy resin. (a) Embedding without *en bloc* staining but section staining with lead citrate. This preparation gives a good overall image of subcellular architecture. (b) Same fixation and embedding except that the tissue was *en bloc* stained with uranyl acetate and the section was double stained with uranyl acetate and lead citrate. The micrograph shows considerable contrast with emphasis on membranes, ribosomes, and nuclear components. 40,000×.

Steps

1. Rinse tissue fixed in aldehydes and/or osmium tetroxide for 2 × 30 min in buffer (e.g., same buffer used for fixation). Keep the tissue at 0–4°C until step 6. If *en bloc* staining is not desired, proceed to step 5.

2. For *en bloc* staining, rinse for 2 × 15 min with sodium maleate buffer. As in all the following steps up to step 10, remove fluid with a Pasteur pipette before adding new fluid. The tissue must never be allowed to dry.

3. Stain for 60 min in uranyl acetate in maleate buffer.
4. Rinse for 2 × 15 min in sodium maleate buffer.
5. Dehydrate for 2 × 15 min in 70% ethanol.
6. Dehydrate for 2 × 15 min in 90% ethanol. This and the following steps of dehydration and infiltration are carried out at room temperature.
7. Dehydrate for 2 × 15 min in 95% ethanol.
8. Dehydrate for 2 × 15 min in absolute ethanol. Repeat for large specimens.
9. Place the tissue for 2 × 15 min in propylene oxide, which acts as a transition medium. Take particular care that the tissue does not dry, as propylene oxide evaporates very rapidly. Because propylene oxide is toxic and very volatile, this and all subsequent steps should be carried out in a well-ventilated hood with gloves.
10. Infiltrate the tissue for 60 min in a mixture of 50% propylene oxide and 50% completely mixed epoxy resin.
11. Transfer the specimens to the surface of the epoxy resin in a clean vial containing 100% resin (Fig. 2a). Use a fine forceps or a wooden stick. Propylene oxide gradually diffuses out of the tissue blocks when they sink through the resin. Leave the specimens in the epoxy resin overnight at room temperature.
12. Fill the flat embedding mold with epoxy resin (Fig. 2b). Place a small piece of paper with the identification number of the specimen upside down in the resin next to the specimen (Figs. 2c and 2d). If necessary, adjust the location of the tissue block and/or the paper with a wooden stick.
13. Polymerize the specimens at 60°C for 2 days.

IV. COMMENTS

1. Chemicals used in fixation for electron microscopy, notably aldehydes, osmium tetroxide, and cacodylate, are toxic and should be handled with adequate safety precautions. Exposure to formaldehyde may lead to allergic reactions. Also, chemicals used during dehydration and embedding in epoxy or acrylic resins are toxic (mutagenic, allergenic, and, in some cases, perhaps carcinogenic) and should be handled with adequate safety precautions (Ringo *et al.*, 1982). Work in a well-ventilated hood and use gloves. Note that resins can penetrate most types of gloves within a short time.

2. For immunocytochemistry the sensitivity of the antigen to aldehydes determines the compositions of the fixative. As a rule of thumb, insensitive antigens can be fixed with 1% glutaraldehyde, sensitive antigens with 4% formaldehyde plus 0.1% glutaraldehyde, and very sensitive antigens with 4% formaldehyde only. In the latter case the formaldehyde concentration may be increased to 8%.

3. Cells tend to swell if the osmolality of the fixative vehicle (buffer) is low, whereas they shrink if the fixative solution has a high solute concentration (Maunsbach, 1966b). For this reason the osmotic composition of the fixative vehicle has to be adjusted for some tissues. In the outer renal medulla, where extracellular osmolality is high, the normal perfusion fixative (1% glutaraldehyde in 0.1 *M* cacodylate buffer) should be supplemented with 0.2 *M* sucrose, whereas for amphibian tissues, the vehicle osmolality should be decreased slightly.

4. The pH of aldehyde fixatives is normally 7.0–7.5 and fine adjustments of pH are not crucial in most ultrastructural studies. The choice of buffer in the fixative may influence the appearance of the tissue but in most tissues only to a moderate degree. Phosphate buffers are often used instead of cacodylate but in some tissues give a fine precipitate at concentrations around 0.1 *M* or more.

5. In highly vascularized organs, such as the pancreas, perfusion fixation leads to a distension of the extravascular space. Such swelling can be prevented by the addition of 2% dextran (molecular weight around 40,000) to the perfusion solution (Bohman and Maunsbach, 1970).

6. Storage of cells and tissues in glutaraldehyde fixatives has very little influence on the final appearance of the tissue in the transmission microscope. Except for immunocytochemical studies, the preparation procedure can be halted for days, sometimes even months, while the tissue is in the aldehyde fixative. Pieces of aldehyde-fixed tissue can therefore be transported easily in fixative between laboratories.

7. The protocol for ethanol dehydration in connection with epoxy resin embedding can be varied considerably without great effects on the final result. In most cases, short dehydration times seem preferable but storage of the specimens overnight at 4°C is usually without problems.

8. Acetone is often used as an alternative to ethanol for dehydration but the results are in most cases essentially the same. Both ethanol and acetone dehydration lead to extraction of tissue lipids and shrinkage of tissue dimensions. These effects vary between tissues and may be slightly different in different protocols but cannot be eliminated.

9. The chemical composition of epoxy resins from different manufacturers varies considerably (see Mollenhauer, 1993; Glauert and Lewis, 1998). Consequently, the properties of the different epoxy resins also vary with respect to viscosity and flow rate, hard-

ness after polymerization, stainability, and stability in the electron beam. However, ultrastructural observations using presently available epoxy resins are quite comparable and in fact are often indistinguishable.

10. The hardness of the polymerized epoxy blocks can be modified by changing the ratio of DDSA/MNA in the epoxy-embedding medium. Thus, an increase of DDSA gives softer blocks and an increase of MNA given harder blocks. However, adjustment of the anhydride : epoxide ratio is not necessary, although this was previously considered important for controlling the properties of the resin. While polymerization is normally carried out at 60°C, a higher curing temperature (80–100°C) can be used for very rapid polymerization, although this may lead to structural derangement of membranes.

V. PITFALLS

1. If the fixative flow is compromised during perfusion fixation, sufficient concentration of fixative is not obtained throughout the tissue and cells may undergo various abnormal alterations before they are fixed. In a successful perfusion the surfaces of the organs blanch very rapidly, the kidney surface within less than a second, and the tissues harden quickly. There is usually a good correlation among the speed of tissue blanching, fixative flow as observed in the drip chamber, absence of blood in dissected tissues, and final quality of tissue preservation as observed in the electron microscope.

2. It is very important that the tissues are not damaged mechanically when dissected and trimmed before immersion fixation or after fixation. Small pieces cut out with a razor blade should only be transferred between vessels with a fine forceps holding onto corners of the tissue blocks or with a Pasteur pipette.

3. Following immersion fixation it is necessary to secure that the tissue analyzed in the electron microscope originates from the surface layers of the tissue block, as there is a gradient in the quality of fixation from the surface to the center of the block (Fig. 4). In the center of tissue slices, where the fixative has arrived with some delay, there is swelling of cytoplasm and organelles. Thus, before cutting thin sections it is practical first to examine thick (1–3 µm) sections of the same tissue block by light microscopy to select the optimal location of tissue for electron microscope analysis.

4. Difficulties in sectioning of tissue embedded in epoxy resin are often due to soft resin blocks. This condition may originate from one or more deviations from the dehydration/infiltration protocol: (a) Wrong epoxy resin composition, (b) insufficient stirring of the components of the resin, (c) too short an infiltration time in pure resin, (d) too large a specimen (all dimensions exceeding 1 mm), (e) too short a polymerization time, (f) incomplete dehydration, or (g) incomplete removal of ethanol.

CHAPTER

23

Negative Staining

Werner Baschong and Ueli Aebi

I. INTRODUCTION

Heavy metal negative staining, a now widely used routine technique to prepare biological material for imaging in the transmission electron microscope (TEM), was introduced almost 50 years ago (Brenner and Horne, 1959; for reviews, see Oliver, 1973; Horne, 1991). Suitable specimens may either be in solution or in suspension and thus include the whole spectrum of structural organization of biomolecules, ranging from monomeric and oligomeric proteins [e.g., RNA polymerase (Fig. 1a) or glutamine synthetase (Fig. 1b, bottom)], to protein polymers [e.g., cytoskeletal filaments or the multistranded helical cables of glutamine synthetase (Fig. 1b, top)], and eventually to large multicomponent supramolecular assemblies [e.g., nuclear pore complexes or bacteriophages (Fig. 1c)]. Compared to other electron microscopic techniques, negative staining is remarkably simple and can easily provide reliable structural information as quickly as 2 min after preparing the specimen down to resolutions of 2.0 nm (reviewed by Bremer *et al*., 1992) and below (Harris, 1999).

As shown schematically in Fig. 2a, a negatively stained specimen is embedded in a microcrystalline heavy atom salt replica that portrays its molecular architecture. Because heavy metal atoms (e.g., U, V, W, Au, Mo, Pt, Pb, Os) scatter electrons much more strongly than elements constituting the biomolecules (i.e., C, H, O, N, P, S), the contrast of negatively stained specimens (Fig. 2b) is much higher than that of unstained specimens and reversed (hence "negative" staining). In addition, the heavy metal salt replica stabilizes the specimen against collapse and distortion and substitutes, at least partially, for the aqueous environment typical for biomolecules. It also serves as a radiation protectant in the sense that it is more radiation resistant than biological matter (cf. Aebi *et al*., 1984; Bremer and Aebi, 1992).

II. MATERIALS AND INSTRUMENTATION

Negative staining requires only minor investment for instrumentation and supplies. For routine applications, the following items are needed.

1. *Specimen support grids* (Fig. 3a): For example, from Pelco International (www.pelcoint.com). Typically 200–400 mesh/in. copper grids, 3.05 mm in diameter and 0.7 mm thick, coated with a specimen support film (mostly either a carbon/collodion composite film, or a thin carbon film). The specimen grids should be stored dust free, e.g., in a petri dish (Fig. 3b) that is kept at relatively low humidity.
2. *Precision forceps* (Fig. 3c): For example, from Electron Microscopy Sciences (www.emsdiasum.com). It is advisable to bend the jaws of the forceps slightly inwards to prevent surface tension from trapping buffers and solutes between the jaws. A tightly fitting rubber band or piece of plastic tubing allows the jaws to be fixed in the closed state.
3. *Glow discharge unit* (Fig. 3d). It is used to render the support film of the specimen grids hydrophilic and can be built as detailed by Aebi and Pollard (1987). The specimen grid is glow discharged on a small glass block coated with Parafilm (Fig. 3d, arrowhead).
4. A *metal* or *plastic tray* (Fig. 3e) serves as the "workbench." Drops of water and stain, typically 100 µl each, can be placed on a piece of Parafilm (Fig. 3e,

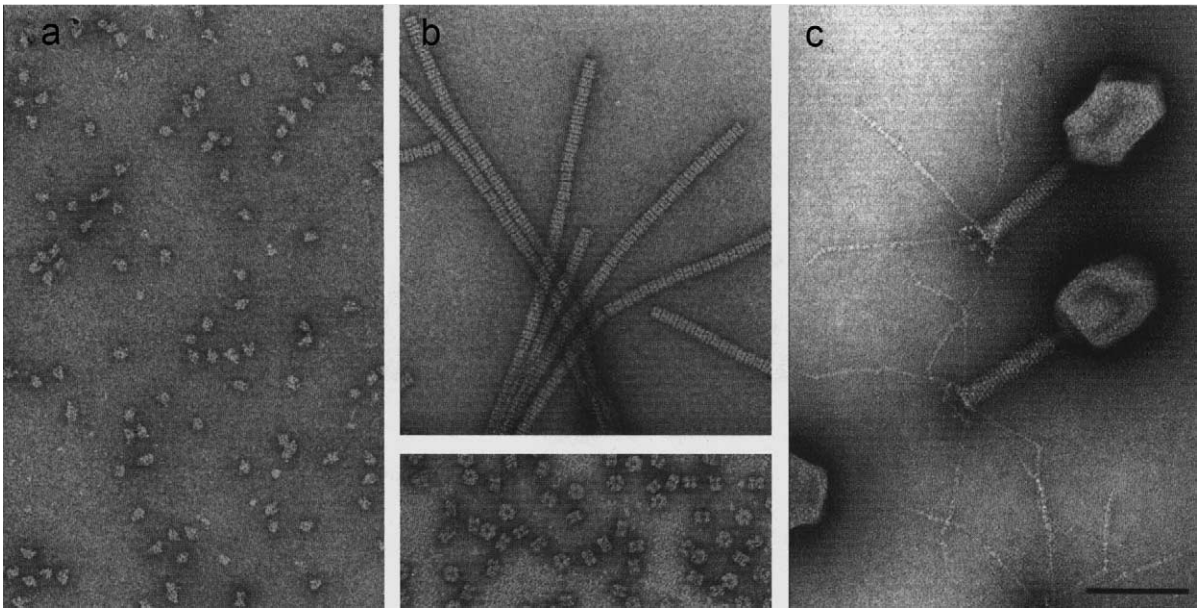

FIGURE 1 From molecules to replicating molecular machines—examples of negatively stained preparations. **(a)** Monomers of *Escherichia coli* RNA polymerase holoenzyme. **(b)** Glutamine synthetase from *E. coli.* (Top) Helical filaments are formed in the presence of millimolar amounts of Co^{2+} ions. (Bottom) The intact enzyme molecule is composed of 12 identical 50-kDa subunits that associate with 622 symmetry: i.e., end-on views display a typical blossom-like appearance with six-fold symmetry, whereas side views reveal twofold symmetry. **(c)** *E. coli* bacteriophage T4: organization into a distinct prolate icosahedral head and a contractile helical tail to which a base plate with extended fibers is attached at the bottom are evident. RNA polymerase (a) and glutamine synthetase (b) were stained with 0.75% uranyl formate; and bacteriophage T4 (c) was stained with 1% uranyl acetate. Scale bar: 100 nm.

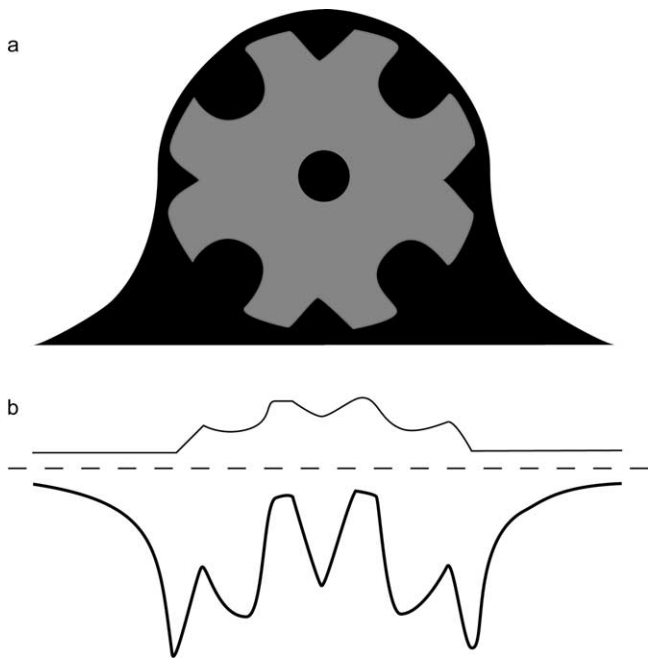

FIGURE 2 Schematic representation of a "negatively stained" model specimen. **(a)** The schematic view represents a cross section through a model specimen (light grey) that has been embedded in an ideal negative stain (dark grey). **(b)** The schematic view in a was projected by adding the pixel values along the vertical axis. The projection profile of the "negatively stained" model specimen is represented by a thick black trace, whereas the projection profile of the "unstained" model specimen is depicted by a thinner grey trace. In the case of the "negatively stained" specimen, its projection profile was inverted, i.e., multiplied by –1, to compare it directly with the corresponding profile of the "unstained" specimen.

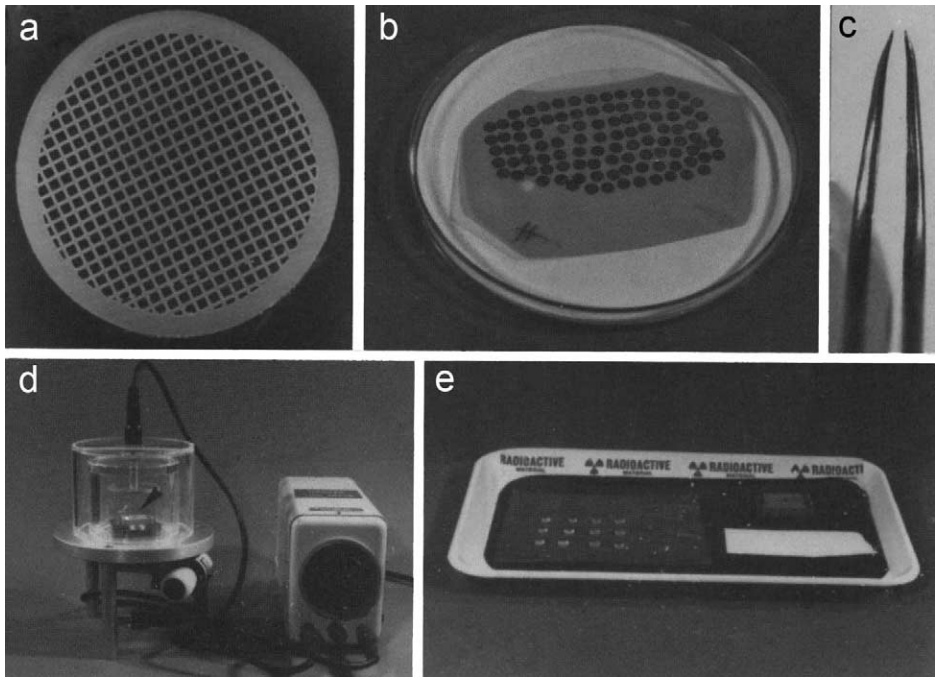

FIGURE 3 Materials and equipment required for negative staining. **(a)** Specimen support grid (e.g., 200 mesh/in. copper grid, 3.05 mm in diameter and 0.7 mm thick) coated with a collodion-carbon composite film (the support film is particularly evident at the edges). **(b)** The specimen support grids are stored on filter paper in a covered petri dish (the cover is removed for clarity). **(c)** Precision forceps with the jaws slightly bent inwards are used for all manipulations. **(d)** The specimen grids are rendered hydrophilic in a reduced atmosphere of air using a custom-built glow-discharge unit (for the design, see Aebi and Pollard, 1987). The specimen grids are glow discharged on a small glass block that is covered with Parafilm (see arrowhead). **(e)** A plastic or metal tray serves as the "workbench" for staining. The water and stain drops are placed on a piece of Parafilm on the left, the glass block with a glow discharged grid is seen on right at the back, and a piece of filter paper is depicted in the front.

left). Filter or blotting paper (Fig. 3e, right) is required for removing excess liquid from the specimen grid.

5. *Micropipettes*: 5 µl and adjustable to 20–200 µl or similar.

6. A *stopwatch* is required to control adsorption and staining times.

7. A *Pasteur pipette* drawn out into a capillary and connected to a suction device such as a water jet pump serves to remove excess stain from the specimen grid (Fig. 4f).

III. PROCEDURES

Solutions

The following solutions are required for negative staining.

1. *Specimen solution/suspension*
2. *Deionized or, even better, double-distilled water*. Water is required for washing the specimen grid after specimen adsorption.
3. *Negative stain, i.e., heavy metal solution*. For instance, uranyl acetate or sodium phosphotungstate.

A. Preparation of Negative Stain Solution

For the properties of various negative stains, along with references on their preparation, see Bremer *et al.* (1992). Here, the preparation of uranyl formate, one of the more delicate procedures, is described as an example:

(Mind, uranyl salts are radioactive, cf. p xxx)

Steps

1. Weigh out uranyl formate to obtain a final concentration of 0.75% (i.e., 7.5 mg/ml).
2. Boil an appropriate amount of water to remove CO_2 and to increase the solubility of the uranyl formate in the boiling water.
3. Pour the boiling water into a small beaker containing the weighed uranyl formate.
4. Stir slowly for 5–10 min in the dark (i.e., with the beaker wrapped into aluminum foil).

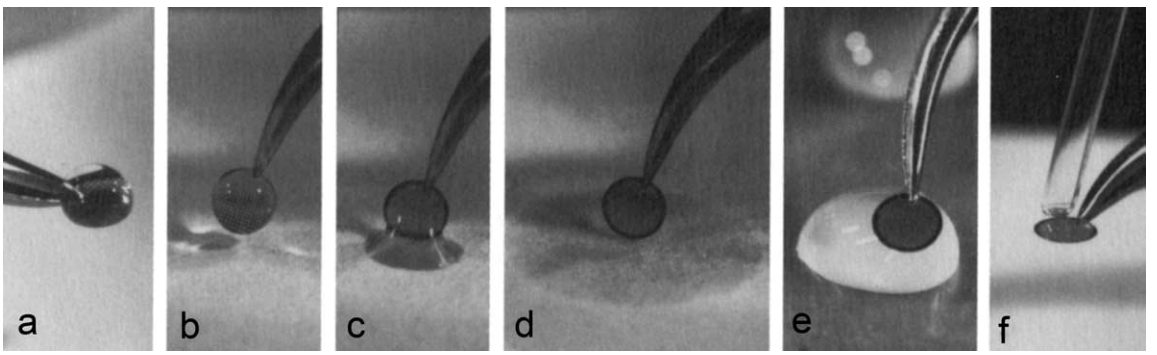

FIGURE 4 Negative staining. **(a)** A ~5-µl drop of sample solution/suspension is placed onto a glow-discharged specimen support grid that is held horizontally by a pair of forceps and allowed to adsorb for 30–60 s. **(b)** The specimen grid is then turned vertically and **(c)** allowed to gently touch the filter paper, which **(d)** removes excess liquid. **(e)** The adsorbed specimen is then washed by carefully placing it sideways onto a drop of water for 1 s, blotted as shown in b–d, and washed a second time. The actual staining is performed similarly by first washing the specimen grid on a drop of negative stain as described in **e**, blotting and repeating this step once more, this time leaving the specimen grid for 10 s on the drop of negative stain solution. **(f)** After blotting off excess stain, the residual stain is removed by gently moving a capillary (drawn-out and shaped from a Pasteur pipette) around the edge of the grid. The capillary is connected to a low-vacuum suction device (e.g., a water jet pump).

5. Filter the solution through a 0.2-µm membrane filter [e.g., a Supor 0.2-µm *Acrodisc 32* from Gelman Sciences (www.pall.com)].
6. Adjust the pH to 4.25 by adding 10 *N* NaOH (about 2 µl per 1 ml negative stain solution). The uranyl formate solution should turn into a moderately intense yellow (*Caution*: Increasing the pH toward neutral rapidly leads to precipitation of uranyl salts.)
7. Stir for another 5 min in the dark.
8. Filter a second time.
9. Readjust the volume with double-distilled water to compensate for water loss due to evaporation, filtration, etc.
10. Store stain in the dark (e.g., in a tube wrapped into aluminum foil). It will keep stable for 1–2 days.

Note: Uranyl formate may be difficult to purchase: Try, e.g., www.pfaltzandbauer.com (Pfaltz & Bauer Inc., Waterbury, CT 06708).

B. Staining

Our standard staining procedure for soluble proteins and their supramolecular assemblies is illustrated in Fig. 4. As might be appreciated, this procedure is quick, simple, and straightforward.

Steps

1. Glow discharge specimen grids in a unit such as shown in Fig. 3d, e.g., for 15 s (for details, see Aebi and Pollard, 1987).

2. To the freshly glow-discharged specimen grid, apply a 5-µl drop of the sample solution/suspension (Fig. 4a). Let it adsorb for 30–60 s, and then blot off the drop as illustrated in Figs. 4b–4d. For blotting, hold the specimen grid vertical (Fig. 4b) and allow it to touch the filter paper gently (Fig. 4c). The drop will be removed by capillary forces (Fig. 4d).

3. Next, wash the specimen grid on a drop of double-distilled water by carefully lowering it sideways onto the surface of the drop (Fig. 4e). After 1 s, carefully remove the specimen grid from the water drop, blot as shown in Figs. 4b–4d, and repeat this washing regimen once more.

4. Finally, stain the specimen for 1 s by lowering the specimen grid onto a drop of negative stain solution as described for the washing regimen (Fig. 4e) and then blot the specimen grid as described in Figs. 4b–4d. Repeat this step once; this time, however, leave the specimen grid for 10–15 s on the negative stain drop (as illustrated in Fig. 4e) before blotting.

5. After blotting off excess stain (Figs. 4b–4d), further reduce the residual stain layer to just a thin (i.e., 50–100 nm thick) liquid film prior to air drying. This should be achieved in a controlled fashion; a drawn-out and shaped into a slightly bent capillary Pasteur pipette, connected to a suction device such as a water jet pump, is moved gently around the edge of the specimen grid (Fig. 4f). The preparation is now ready for inspection in the EM.

IV. COMMENTS

The quality of a negatively stained preparation (i.e., the interpretable structural detail captured on the EM

screen, depicted on an electron micrograph, or monitored by a video or slow-scan camera attached to the EM) depends primarily on the penetration properties (e.g., size, charge, and hydrophobicity) of the heavy metal salt used for negative staining and on the physicochemical properties (e.g., solubility, charge, and hydrophobicity) of the specimen. Because some negative stains have a relatively acidic pH, whereas others are neutral or moderately basic and because they may be neutral, anionic, or cationic (for review, see Bremer *et al.*, 1992), negative staining is quite versatile and can be tailored to specific needs.

When visualizing structures comprising components of different electron densities, e.g., colloidal gold-labeled proteins, the electron density of the heavy metal may become crucial. While 2- to 3-nm Au particles associated to bacteriophage T4 polyheads, i.e., aberrant tubular assemblies constituted exclusively of the major viral head protein gp23, are barely discernible from the uranyl acetate acetate-stained protein units (Fig. 5a), 3-nm Au-labled immunoglobulin G binding to the appropriate haemaglutinin antigen (Fig. 5b) and even 1- to 2-nm Au-labeled Fab fragments binding to haemaglutine assemblies (Fig. 5c), are still well discernible when stained with $NaSiO_4WO_4$, a less electron dense and intrinsically neutral negative stain (Baschong and Wrigley, 1990). *A priori*, the optimal stain for a particular specimen has to be chosen and evaluated by trial and error.

In our laboratory, starting in a first trial with an uranyl salt [we still favour uranyl salts and formate over acetate for it is slightly more stable in the electron beam (cf. Bremer *et al.*, 1992)] or with a tungstate (e.g., NaPT, i.e., sodium phosphotungstate) proved successful with a wide variety of specimens, including cytoskeletal, membrane and soluble cytosolic proteins, and their supramolecular assemblies (for examples, see Aebi *et al.*, 1983, 1984, 1988; Bremer *et al.*, 1991, 1992, 1994; Hoenger and Aebi, 1996). Within this respect, it may be noteworthy that uranyl acetate can also act as a primary fixative: It was observed to stabilize bacteriophage T4 polyheads against dilution-induced dissassembly in an aldehyde-like manner (Baschong *et al.*, 1983; W. Baschong unpublished results) and was more recently documented to act as a primary fixative for skeleton muscle (Fassel and Graeser, 1997).

With tightening safety rules for the use of radioactive substances—uranyl salts are radioactive—ordering, handling, and disposal of uranyl salts usually have specific guidelines (check with your safety responsible). In turn, the availability of uranyl salts may become more restricted, while novel ready-made commercial methylamine–vanadate (Tracz *et al.*, 1997) and methylamine–tungstate-based stains (Shayakhmetov *et al.*, 2000) have been introduced (www.nanoprobes.com, Nanoprobes Inc., Yaphank, NY 11980-9710). As a consequence, nonradioactive metal salts such as tungstates, molybdates and vanadates may be given preference. The performance of such alternatives is best evaluated by trial and error, as illustrated in Figs. 6a–6e by staining bacteriophage T4 polyheads with uranyl formate (a) and prospective alternatives, i.e., with NH_4MoO_4 (b), NH_4VO_4 (c), Na_2WO_4 (d), and $RhCl_3$ (e), and liposomes with methylamine vanadate (f).

The negative staining protocol described earlier is suitable for most specimens and stains. With delicate proteins, an additional washing step of the grid with water or sample buffer *prior* to applying the specimen may be included to wet the specimen support film and to minimize surface tension and/or denaturation of the specimen. The optimal sample concentration, which obviously has to be determined experimentally, should yield well-dispersed and evenly distributed particles adsorbed to the specimen support film. It is determined by the size, shape, and adsorption properties of the biomolecules or supramolecular assem-

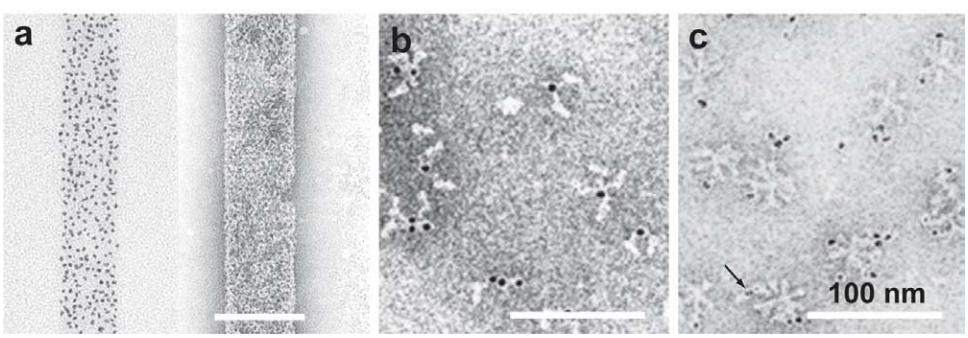

FIGURE 5 Negative staining of Fab–gold and antibody–gold complexes: (**a**) Bacteriophage T4 polyheads labeled with Fab-$Au_{2.5\,nm}$ unstained (left) and stained with 1% uranyl acetate. (**b**) Au_3-labled immunoglobulin G bound to bromelain-treated haemagglutinin. (**c**) $Au_{1–2\,nm}$-labeled Fab bound to haemagglutinin rosettes. Arrow: $Au_{1–2\,nm}$ colloid. (Adapted from Baschong & Wrigley, 1990)

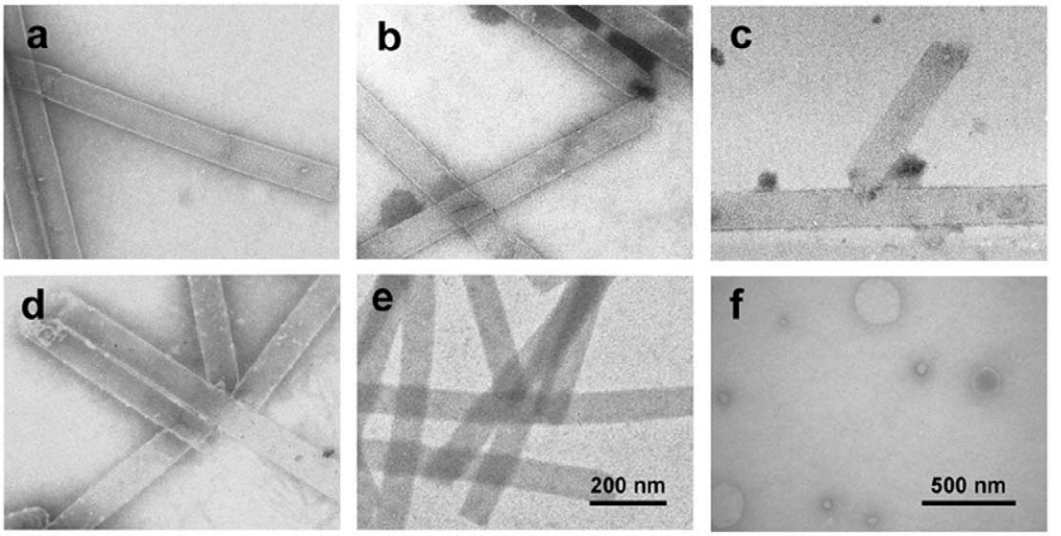

FIGURE 6 Comparative series of prospective negative stains used on bacteriophage T4 polyheads: (**a**) with 1% uranyl formate, (**b**) with 2% NH_4MoO_4, (**c**) with half-saturated NH_4VO_4, (**d**) with 1% Na2WO_4, and (**e**) with 2% $RhCl_3$. (**f**) Liposomes stained with metylamine–vanadate, courtesy of C. Prescianotto-Baschong.

blies under investigation, but also by the washing and staining regimen employed. For oligomers or polymers (e.g., such as filaments), crystalline, or paracrystalline specimens, a higher concentration than for individual biomolecules is required. As a rule of thumb, a few micrograms per milliliter for single particles (see Fig. 1a and bottom of Fig. 1b) and a few hundred micrograms per milliliter for supramolecular assemblies such as filaments (see top of Fig. 1b) or virus particles (see Fig. 1c) usually yield a reasonable particle density on the EM grid. The ionic conditions of the sample buffer and the presence of detergents, while strongly interfering with specimen adsorption, may have little effect on the quality of the negative stain replica surrounding the biomolecules, as long as a sufficient number of washing steps (usually two to six for most compounds) are employed prior to applying the negative stain solution to the specimen.

Heavy metal salts may not be inert but may interact physically or chemically with the specimen. Such sample–stain interactions may not explicitly produce "preparation artifacts" but sometimes unveil biologically significant information about the specimen going beyond purely structural aspects. For instance, human epidermal keratin filaments (cf. Aebi *et al*., 1983), after negative staining with uranyl formate (UF; pH 4.25), appear rather compact and featureless with a fairly uniform width (Fig. 7a). By contrast, when the same filaments are stained negatively with sodium phosphotungstate (NaPT; pH 7.0), they partially unravel and thereby unveil their protofibrillar substructure (Fig. 7b). This local unraveling becomes even more pronounced after washing the filaments briefly with 10 m*M* phosphate buffer (NaP_i; pH 7.0) prior to staining them negatively with UF (Fig. 7c). Most likely, the inorganic phosphate (P_i) acts as a modulator of the lateral interaction of the protofilaments and/or protofibrils constituting the filament (cf. Aebi *et al*., 1983, 1988). In fact, a similar response to different negative stains has also been observed with F-actin filaments where inorganic phosphate appears to modulate the relative strength of the intersubunit bonds *along* and *between* the two long-pitch helical strands of actin subunits defining the filament (cf. Bremer *et al*., 1991, 1994; Bremer and Aebi, 1992).

V. PITFALLS

A. Poor Specimen Adsorption

1. *Specimen support film is wrongly charged:* Highly negatively charged proteins or DNA do adsorb poorly to support films exhibiting a net negative charge as produced by glow discharge in a reduced atmosphere of air. By contrast, glow-discharging specimen grids in a reduced atosphere of pentylamine yield a *net positive charge* of the support film (cf. Aebi and Pollard, 1987).

2. *Specimen support film is not properly glow discharged:* Try longer glow discharge, and glow discharge only one grid at a time and use it immediately.

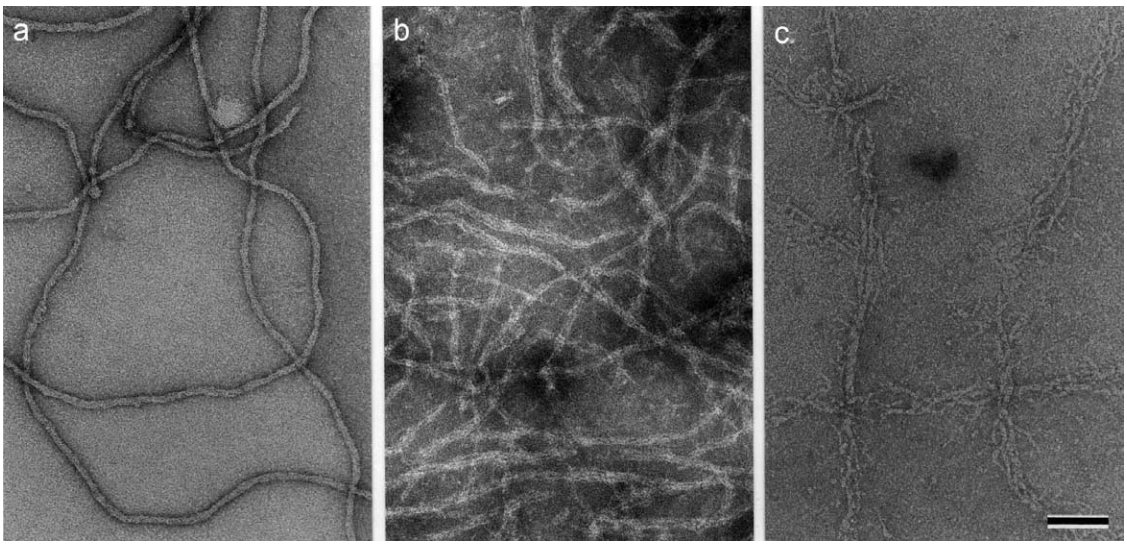

FIGURE 7 Negatively stained human epidermal keratin filaments. **(a)** Keratin filaments in 10 m*M* Tris, pH 7.5, stained negatively with 0.75% uranyl formate (UF; pH 4.25) appear relatively featureless and compact with a fairly uniform width. **(b)** In contrast, when the same keratin filaments are stained negatively with 2% sodium phosphotungstate (NaPT; pH 7.0) instead, they locally unravel and exhibit their protofibrillar substructure. **(c)** Even more dramatic unraveling into their protofibrils occurs when the adsorbed filaments are washed briefly with 10 m*M* phosphate buffer (NaP_i; pH 7.0) prior to staining them with 0.75% UF, pH 4.25. Scale bar: 100 nm.

B. Patchy, Poor, or Bad Staining

1. *Specimen concentration is too high:* A high density of particles adsorbed to the specimen support film renders quantitative and/or controlled removal of excess stain more difficult, thereby resulting in inhomogeneities in the staining even in particle-free areas. Try lower specimen concentration.

2. *Stain is not sufficiently removed:* Try removing stain more quantitatively by suction with a capillary as illustrated in Fig. 4f.

3. *Suboptimal stain for the specimen:* Try a different stain.

4. *Suboptimal wetting properties of the specimen support film:* Try longer glow discharge times or switch to a different sample buffer, assuming that this does not compromise the specimen.

5. *Incompatibilities between stain and buffers:* For instance, uranyl salts precipitate in the presence of inorganic phosphate. Hence avoid using phosphate buffers.

6. *Buffer contains high molar salt or detergent:* Try including more washing steps.

C. "Bubbling" of Stain Upon Irradiation

1. *Strong recrystallization or water content of stain is too high:* Try "prebaking" specimen at a low magnification (e.g., at 1000×) for 3–5 s before using higher magnifications.

D. Disintegration of Specimen During Preparation

1. *Specimen is instable in water* (washing steps!): Wash and preequilibrate the specimen with sample buffer instead of water. Replace the conventional buffer with a buffer that will dry off by sublimation when in the electron microscope, such as ammonia acetate. Alternatively, use such a volatile buffer at least for the washing steps. Mild cross-linking with, e.g., 0.05–0.25% glutaraldehyde for 2 min on ice (quench with 1% glycine, pH 7.0, or with 1% freshly made $NaBH_4$) may also stabilize the specimen.

E. Significant Background of Monomers and/or Small Oligomers with a Specimen Containing Supramolecular Assemblies

1. *Specimen is in steady-state equilibrium with monomers and/or oligomers:* Pellet the specimen (e.g., in a tabletop or air fuge at 100,000 *g*), discard the supernatant, resuspend the pellet in sample buffer, and immediately prepare the grid. Alternatively, fix, e.g., the protein assembly, with 4% formaldehyde while in

equilibrum and purify on a sucrose gradient (Baschong *et al*., 1991).

Glycerol Spraying/Low-Angle Rotary Metal Shadowing

Ueli Aebi and Werner Baschong

I. INTRODUCTION

Heavy-metal replication (Williams and Wyckoff, 1945) is one of the oldest and yet most effective methods to provide enhanced contrast when imaging biological specimens in a transmission electron microscope (TEM) (for review, see Fowler and Aebi, 1983; Mould *et al*., 1985; Nermut and Eason, 1989). This technique requires efficient adsorption of the sample to a specimen support so that the biomolecules or particles to be visualized become well dispersed and distributed evenly. Moreover, to minimize shadow-casting artifacts produced by corrugations of the specimen support, it should ideally be smooth at atomic dimensions. Mica fulfills both these requirements and hence emerges as an ideal specimen support. For a good replica, the contrast-enhancing metal should produce a fine grain, detach easily from the specimen support, and be stable in the electron beam. An example of a metal that favorably meets these three criteria is platinum (Pt).

The combination of mica and platinum was first proposed by Hall (1956) in his 'mica replication' technique. Hall sprayed different solutions of biomolecules (i.e., an adenosine phosphate polymer, collagen, DNA, and fibrinogen) onto a piece of freshly cleaved mica. The mica was then dried in a vacuum evaporator and subsequently metal casted at a low angle (i.e., 5–15°) with platinum. The metal layer on the mica was stabilized by backing it with a layer of each of SiO and collodion. The resulting replica was then floated off the mica onto distilled water, picked up on a specimen support grid, and imaged in a TEM (Hall, 1956). More disperse spreading and even distribution of the biomolecules on the mica surface were achieved by adding glycerol to the sample before spraying it (Tyler and Branton, 1980; Fowler and Erickson, 1983). For their modification of Hall's technique, Tyler and Branton coined the term *glycerol drying*. Specifically, they added glycerol to the sample before spraying it onto the mica and backed the metal replica with carbon only. The more accurate and appropriate term used now is *glycerol spraying/low-angle rotary metal shadowing*.

Glycerol spraying/low-angle rotary shadowing has been claimed to preserve native conformations comparably to cryotechniques (Mould *et al*., 1985; Nermut and Eason, 1989). It has been used time and again to characterize complex macromolecules at near-native conditions and especially also proteoglycans (Moergeli *et al*., 1985; Rodriguez *et al*., 1995; Scheel *et al*., 1999, Hofmann *et al*., 2000; Griffith *et al*., 2002). Indeed, a stabilization of the native confirmation by glycerol against temperature-, pH-, or organic solvent-induced changes was corroborated by electron spray mass spectrometry (Grandori *et al*., 2001).

For glycerol spraying, droplets of a glycerol-containing solution are vaporized using air pressure and sprayed against a mica surface. The droplets spread on impact and retract rapidly due to the high surface tension of the glycerol-containing solution. Molecules or particles adsorbed to the mica surface are left behind with little or no solvent surrounding them. Therefore, they dry almost instantaneously. The dried, retracted sample droplets produce the characteristic "droplet centers" (see Fig. 3a) that are observed with glycerol-sprayed preparations at low magnification. These droplet centers represent a residue that is formed by the salts in the sample buffer and by unabsorbed protein and other debris that is swept off the mica by the advancing or retracting drop (Tyler and Branton, 1980).

All rights reserved.

Specimens that are suitable for glycerol spraying/low-angle rotary metal shadowing range from single protein (e.g., myosin) and DNA molecules to relatively stable biopolymers or supramolecular assemblies such as intermediate filaments or protein/glycosaminoglycan complexes. The achievable resolution is a few nanometers and thus sufficient to reveal the overall size and shape and/or the principal domain architecture of many biomolecules.

II. MATERIALS AND INSTRUMENTATION

For routine applications of glycerol spraying/low-angle rotary metal shadowing, the following items, gadgets, and equipment are required.

1. Gilson Pipetman adjustable pipette P20, with tips (Fig. 1a), and Gilson Microman adjustable pipette M25, with tips (Fig. 1b) (http://www.gilson.com/)
2. Vortex apparatus
3. Pair of scissors (Fig. 1c).
4. Double-sided adhesive Scotch tape
5. Specimen support grids (Fig. 1d): For example, from Pelco International (http://www.pelcoint.com/) (typically, 400 mesh/in. copper grids, 3.05 mm in diameter and 0.7 mm thick)
6. Spot plate (Fig. 1e): For example, from BAL-TEC (http://www.bal-tec.com/) (Cat. No. B 8010 030 83)

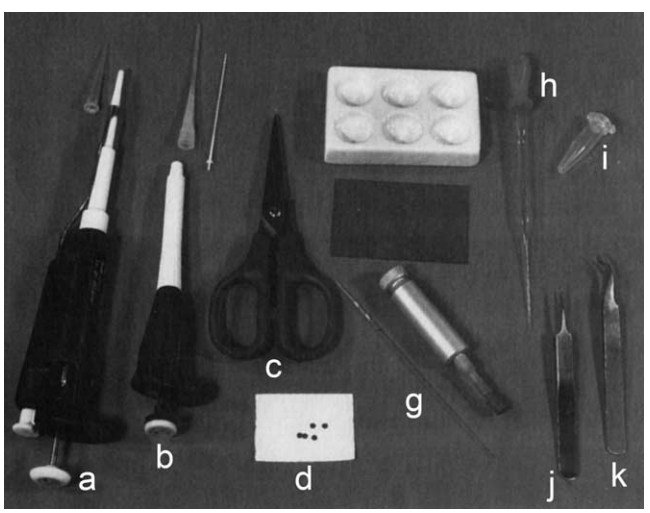

FIGURE 1 *Standard equipment for glycerol spraying/low-angle rotary metal shadowing*. Two adjustable pipettes: (**a**) Gilson Pipetman P20, and (**b**) Gilson Microman M25, together with their respective tips; (**c**) a pair of scissors; (**d**) copper specimen grids; (**e**) spot plate; (**f**) mica sheet; (**g**) 25-µl glass micropipettes with pipettor; (**h**) Pasteur pipettes; (**i**) Eppendorf tubes; and a pair each of (**j**) fine, straight forceps, and of (**k**) fine, bent forceps.

7. Mica sheets (Fig. 1f): For example, from BAL-TEC (Cat. No. BU 006 027-T)
8. 25-µl glass micropipettes with pipetter (Fig. 1g)
9. Pasteur pipettes (Fig. 1h)
10. Eppendorf tubes (Fig. 1i)
11. Precision forceps: For example from Electron Microscopy Sciences (http://www.emsdiasum.com/ems/). A pair of fine, straight forceps (Fig. 1j) and a pair of fine, bent forceps (Fig. 1k).
12. Compressed air at a pressure of 0.8 bar (80 psi)
13. Custom-built spray apparatus with air-pressure controller (Figs. 2d and 2e). The major elements or pieces to be manufactured or purchased include
    - A polyvinyl chloride (PVC) frame mounted onto an aluminum base
    - A Pasteur pipette connected to a compressed air supply via an air pressure/volume controller unit so that a set volume of a fine stream of air is produced at its nozzle by the push of the release button on the controller
    - A clamp mounted on a post to fasten a 25-µl glass micropipette containing the sample so that it points to the center of the stream of pressurized air
    - A metal sphere on a height-adjustable post so that it can be placed into the center of the fine air stream and disperse the sample drops evenly
    - A curved glass tube that traps the large sample droplets, aggregates, and other heavy particles
    - A square piece of freshly cleaved mica that is fastened with a piece of double-sided adhesive tape below the curved glass tube
14. Glow-discharge apparatus: For example, custom built as detailed by Aebi and Pollard (1987) (see also article by Baschong and Aebi) or SCD 005 (Cat. No. BU GO5 750 116-T) from BAL-TEC.
15. High-vacuum evaporation unit: For example, BAE 080-T (Cat. No. BU P03 527) from BAL-TEC specifications:
    a. High-vacuum pumping unit with rotary vane pump
    b. Vacuum measuring device for rough and high vacuum
    c. Evaporation unit with controller, high current supply, and cross-shaped vacuum chamber
16. Accessories for BAL-TEC high-vacuum evaporation unit:
    a. Cold trap for BAE 080-T (Cat. No. BB 176 942-W)
    b. Quick-release flange WF 206, including EK-030 electron gun (Cat. No. BU 007 038-T)
    c. Quick-release flange WF 211, rotary table (Cat. No. BB 192 281-T)

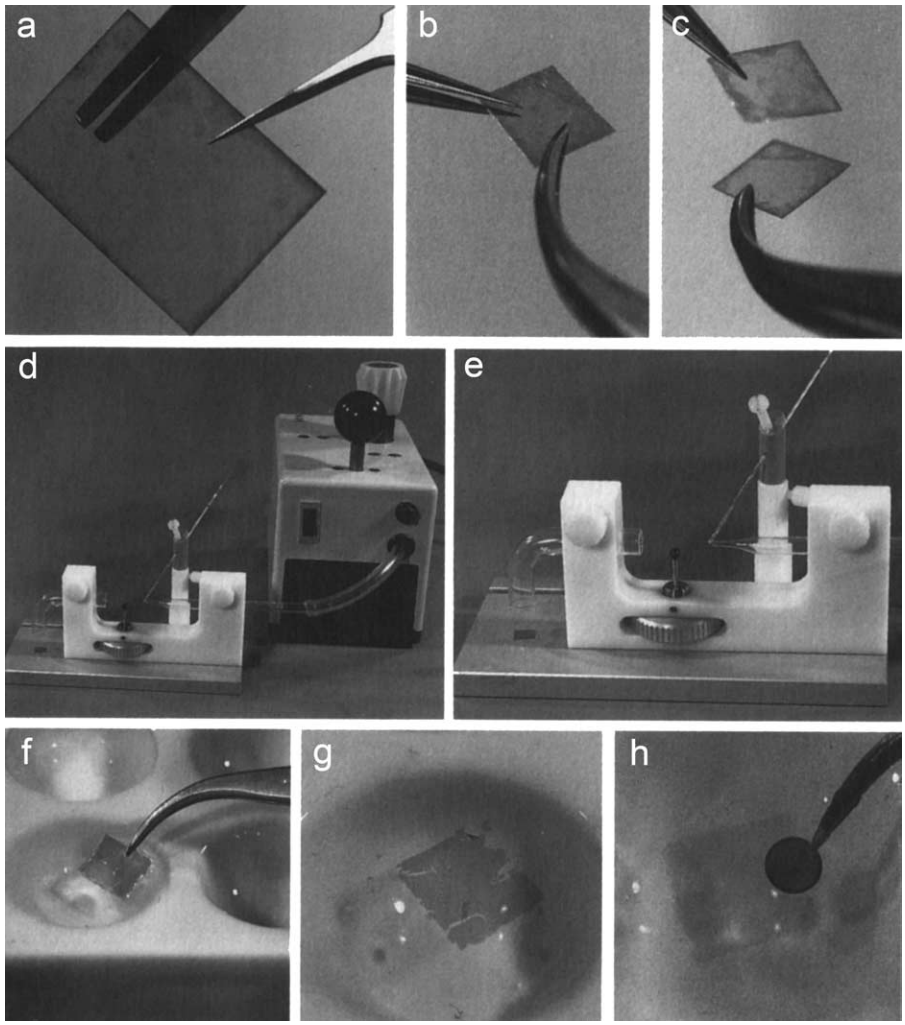

FIGURE 2 *Selected steps of the glycerol spraying/low-angle rotary metal shadowing technique.* (**a**) A piece of mica held with a pair of straight forceps is cut into square pieces with a pair of scissors. (**b and c**) Using forceps, the mica is next cleaved into two sheets. (**d and e**) The glycerol-containing solution is drawn into a 25-µl glass micropipette that is mounted on the spray apparatus such that it points to the center of the stream of pressurized air that is focused by a Pasteur pipette. (**f**) The Pt/C-shadowed and C-backed mica is slowly immersed into water, and (**g**) the mica sheet is removed once the Pt/C+C-replica is floated off. (**h**) The replica is then placed on a specimen grid with a pair of forceps.

d. Quick-release flange WF 204, C-evaporator (Cat. No. BB 192 276-T)
e. Digital quartz-crystal thickness meter QSG 060 (Cat. No. BU M01 259)
f. Electron beam evaporation device EVM 030, (Cat. No. BU S04 000)

17. Materials for BAL-TEC high-vacuum evaporation unit:
    a. Carbon rods for Pt/C evaporator (Cat. No. BU 006 101-T)
    b. Platinum inserts (Cat. No. BU 006 103-T)
    c. Carbon rods for C-evaporator (Cat. No. BU 006 115)
    d. Tungsten cathodes (Cat. No. BU 020 023-T)
18. Liquid nitrogen

III. PROCEDURES

Solutions

1. *Glycerol 100% anhydrous*: For example, from Fluka (http://www.sigmaaldrich.com/)(Cat. No. 49770)
2. *Sodium hypochlorite solution, 13–15%, technical grade*: For example, from Siegfried (http://www.siegfried.ch/) (Cat. No. 180550–01)

A. Spraying

Steps

1. Hold a piece of mica with a pair of straight forceps and cut it into square pieces (5–7 mm side length) with a pair of scissors (Fig. 2a).
2. Dilute the sample to a concentration of about 10–100 n*M* (0.1–1.0 mg/ml for most proteins) and pipette 20 µl into an Eppendorf tube.
3. Add 8.6 µl of 100% glycerol to the sample (i.e., 30% final glycerol concentration) using the Gilson Microman M25. Mix thoroughly with the pipette and vortex.
4. Draw 10 µl of the glycerol-containing solution into a 25-µl glass micropipette and mount it on the spray apparatus (Figs. 2d and 2e).
5. With two pairs of forceps, cleave the mica into two sheets (Figs. 2b and 2c).
6. With its freshly cleaved side up, place the mica below the bent glass tube of the spray apparatus. During spraying, the mica sheet should either be fixed with a piece of double-sided adhesive tape as shown in Fig. 2e or held in position with a pair of forceps.
7. Briefly (i.e., for about 1 s) press the button of the air-pressure control unit (depicted in Fig. 2d) to spray the sample suspension onto the freshly cleaved mica.

Note: The metal sphere placed in the spray path disperses the sample droplets evenly. The curved glass tube traps remaining large droplets, aggregates, and other heavy particles that will not follow the air flow when the spray path changes its direction by 90°.

8. Repeat spraying in the same way with another 10 µl of suspension onto the second piece of mica, etc.

B. Metal Evaporation

Steps

1. Switch on the thin film quartz monitor.
2. Set up the electron gun for Pt/C evaporation and the carbon evaporation unit for C-evaporation according to the instruction manual of the supplier.
3. The recommended working distance between the Pt/C tip in the electron gun and the middle of the table is 12 cm and the tilt angle of the table relative to the evaporation axis should be around 5°. For the C tips in the C evaporation unit, the recommended working distance is the same but the tilt angle should be 80–90°.
4. Mount the mica with double-sided adhesive tape onto the table. Make sure that the sprayed side of the mica is up!
5. Mount the table onto the rotating base in the vacuum chamber and start evacuating.
6. After 30 min, the vacuum meter should read better than 2×10^{-5} mbar.
7. Pour liquid nitrogen into the Meissner trap.
8. After an additional 5 min, the vacuum meter should read better than 6×10^{-6} mbar.
9. Degas Pt/C tip according to the instruction manual of the supplier.
10. Start the motor of the rotating base (set to about 120 rpm).
11. Set the thin film quartz monitor to zero.
12. Start evaporating Pt/C according to the instruction manual. Open the manual shutter.
13. Read the frequency on the thin film quartz monitor.
14. After the frequency has changed by 300 Hz, close the manual shutter and stop evaporation.
15. Evaporate C according to the instruction manual of the supplier.
16. On a white reference the carbon layer should look deep brown (cf. Figs. 2f and 2g).

Note: It is advisable to calibrate current and evaporation times of the power supply so that standard settings can be used.

17. Turn the rotating table off, break the vacuum, and remove the rotating table from the vacuum chamber.

C. Floating off the PT/C+C Replica

Steps

1. Fill the wells of the spot plate (Fig. 1e) with distilled water (Fig. 2f).
2. As illustrated in Fig. 2f, slowly immerse the mica at an angle of ~45° holding it firmly with the forceps.
3. Submerge the mica completely and remove it when the Pt/C+C-replica is floating on the water surface (Fig. 2g).
4. With a pair of forceps, submerge a freshly glow-discharged specimen grid, place it underneath the Pt/C+C-replica, and use it as a sieve to collect the replica piece by piece.
5. Dry the specimen grids by layering them with the film side up onto a piece of filter paper.
6. The specimen grids are now ready for inspection in the EM.

D. Electron Microscopy

Steps

1. Identify droplet centers as shown in Fig. 3a at a low magnification of, e.g., 5000×. *Note:* The droplet

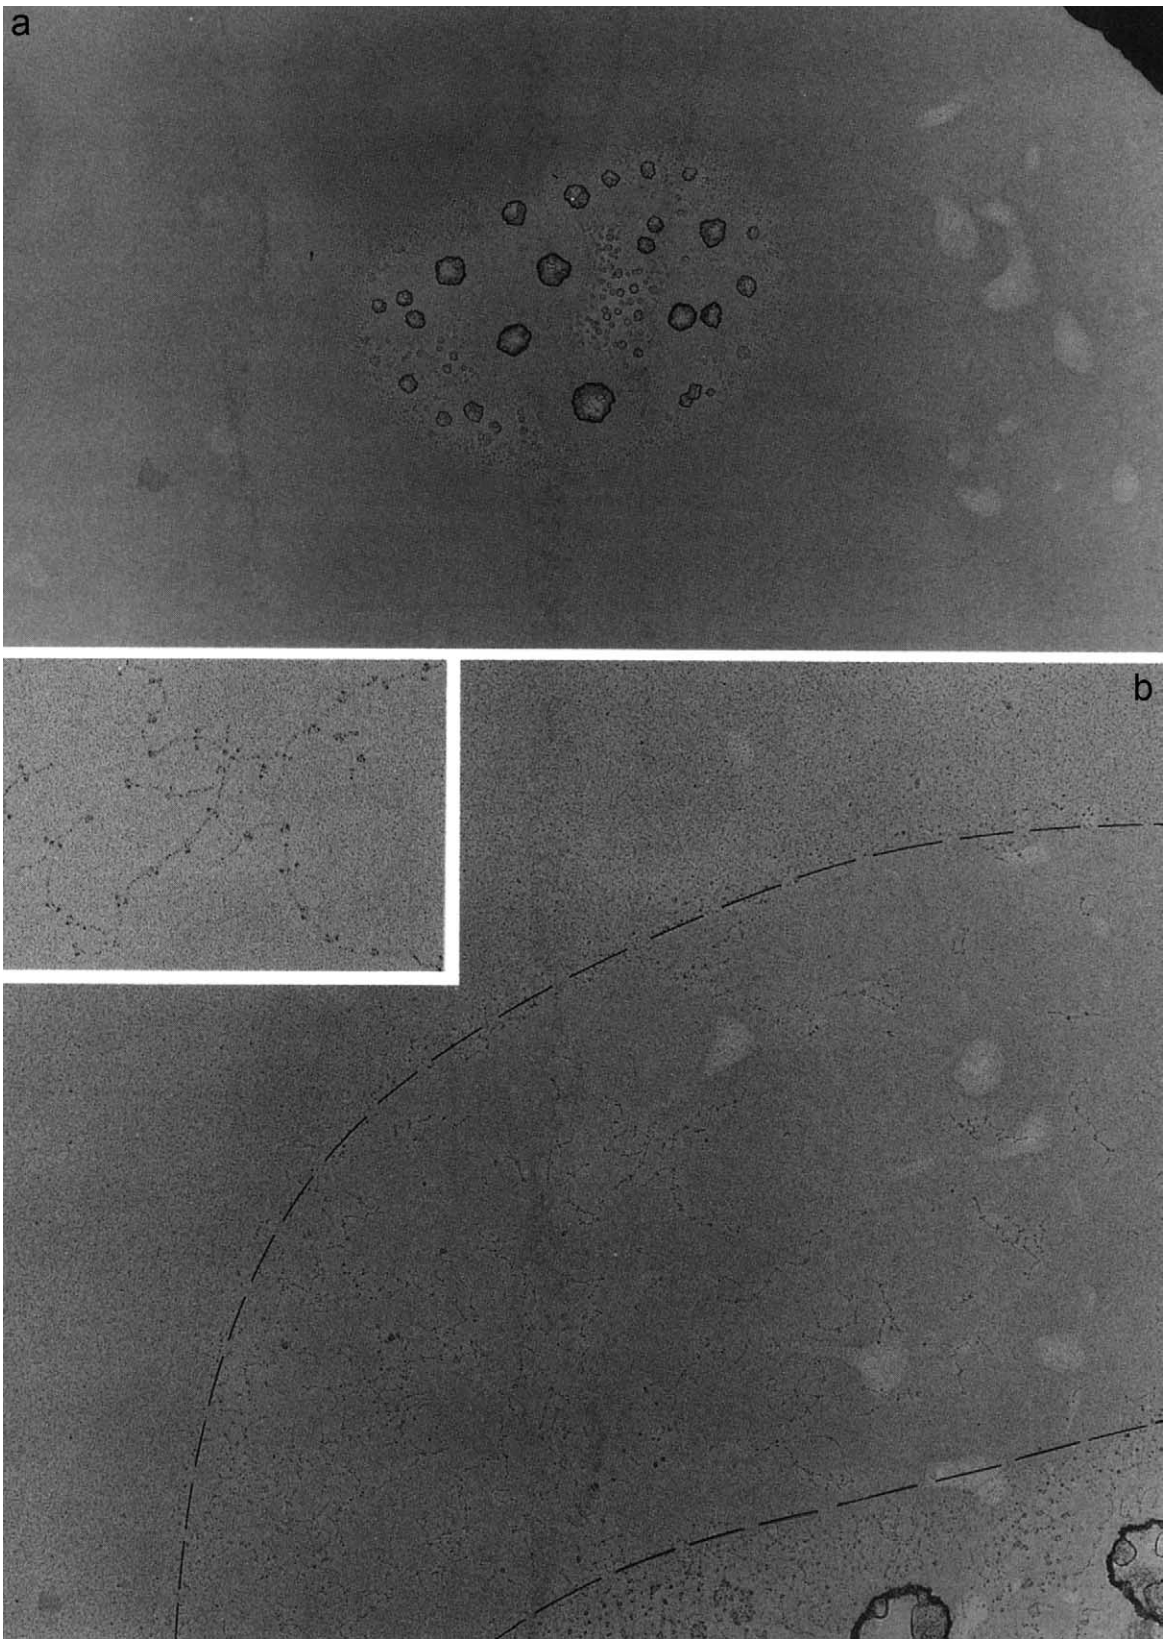

FIGURE 3 *Electron microscopy of glycerol-sprayed/low-angle rotary metal-shadowed preparations.* (**a**) At low magnification, very prominent features of glycerol-sprayed/low-angle rotary metal-shadowed preparations are the "droplet centers" formed by the salts in the buffer, unabsorbed protein, and debris that are swept off the mica by the advancing and/or retracting drop of the specimen/glycerol solution. (**b**) When moving from the center of such a droplet center outward, a transition from a coarse and irregular to a smooth and clean background is observed. Well-spread molecules are found in the zone that shows a clean background (demarcated by dashed lines). (Inset) A higher magnification view that reveals head-to-tail polymers of myosin-like lamin dimers (see Heitlinger *et al*., 1991).

centers are easy to find if your sample is kept in non-volatile buffers and/or contains salts. The droplet center size varies from 5 to 50 µm in diameter. Choose droplet centers with a size of about 5–10 µm.

2. Increase the magnification to about 20,000–50,000×. Set coarse focusing and then slowly move from the center toward the edge of the droplet.

3. Dashed lines in Fig. 3b highlight the sharp transition from salt crystals to a clean background that is typically observed over increments of the droplet center distance by 0.5–2 µm. In this "clean belt" around the droplet center well-spread and well-preserved protein particles are usually found readily (Fig. 3b, inset).

IV. PITFALLS

1. ***Replica resists detaching from the mica.*** Occasionally, the Pt/C+C replica sticks to the mica. The replica usually detaches more easily after the mica has been incubated in a moist atmosphere at 37°C for 30 min. Alternatively, the replica may also be floated off onto 6% sodium hypochlorite rather than water; however, after this treatment, the replica has to be transferred with a platinum loop to distilled water and allowed to incubate for 10 min. One reason for frequent sticking of the Pt/C+C replica to the mica may be too good a vacuum during C evaporation. Breaking the vacuum after Pt/C evaporation, reevacuation to 7×10^{-5} mbar, and subsequent C evaporation may solve this problem.

2. ***Preparation not satisfactory*:** (a) *Specimen dependent*: The specimen may not be optimal for glycerol spraying. Some specimens, including actin filaments, are relatively sensitive to shearing forces and may thus break into small pieces on spraying. (b) *Buffer dependent*: Many buffers and solutions can be used but detergents or high concentrations (i.e., ≥2 *M*) of urea or guanidine hydrochloride cause problems through eutectic effects. In this case, the buffer should be changed or diluted.

3. ***Phase separation after addition of glycerol.*** For good results, it is essential that the sample is a solution that contains glycerol. In case of phase separation, different buffers should be tried. If volatile buffers (e.g., ammonium acetate) are used, the evaporating unit should be evacuated for 2–3 h rather than for 30 min before metal evaporation (see earlier discussion).

Rapid Freezing of Biological Specimens for Freeze Fracture and Deep Etching

Nicholas J. Severs and David M. Shotton

I. PRINCIPLES OF RAPID FREEZING

Stabilization of biological structure by the physical process of freezing (cryofixation) forms the starting point for freeze fracture and deep etching (see article by Shotton) and for freeze substitution, cryoultramicrotomy, and cryoelectron microscopy (see articles by Roos *et al.*, and Resch *et al.*). To avoid ultrastructural damage to the specimen caused by the growth of large ice crystals, rapid freezing is essential. True vitrification (i.e., formation of amorphous, noncrystalline ice) can be achieved only by cooling rates of greater than 2×10^5 °C/s over the critical range of 20 to –100 °C, i.e., cooling over this range in a fraction of a millisecond. Rates of this magnitude can be attained in very thin (<3 μm) films of suspended liquid that are plunged rapidly into liquid nitrogen-cooled liquid propane or ethane, and particulate specimens (e.g., viruses) embedded in such frozen thin films may be observed directly in the vitrified state on the cold stage of a cryoelectron microscope. For freeze fracture and deep etching, however, the requirement for a larger specimen size precludes true vitrification throughout the specimen because the maximal cooling rate possible within the sample is limited by the rate of heat conduction through it. Thus, for most practical purposes, the goal when applying cryofixation for freeze fracture and deep etching is to apply cooling conditions that reduce ice crystal size sufficiently that there is no visible distortion of cellular structure. The techniques employed for such rapid freezing may be divided into three groups: conventional rapid freezing techniques, with cooling rates of between 10^3 and 10^4°C/s; ultrarapid freezing techniques, with rates in excess of 10^4°C/s; and hyperbaric freezing in which, although a relatively slow cooling rate is employed, ice crystal nucleation and growth are retarded by high pressure. This article gives a brief account of the principles and practical applications of these techniques. Comprehensive reviews of the field as a whole can be f ound in Robards and Sleytr (1985), Steinbrecht and Zierold (1987), Echlin (1992), and Severs and Shotton (1995).

Working with cryogenic liquids is potentially hazardous. Novices should ensure that they are fully conversant with appropriate safety precautions by consulting their institutional safety advisor. For further guidance articles on safety in Robards and Sleytr (1985), Ryan and Liddicoat (1987), and Steinbrecht and Zierold (1987).

II. CONVENTIONAL RAPID FREEZING FOR FREEZE FRACTURE

A. Chemical Fixation and Glycerination

Ice crystal damage can be avoided at relatively slow cooling rates if the specimen is first infiltrated with a buffered cryoprotectant. Glycerol, used at concentrations of 20–30%, is by far the most commonly used cryoprotectant. Prior fixation with aldehydes (usually glutaraldehyde) is routinely carried out with the aim of minimizing cryoprotectant-induced artifacts, although such aldehyde fixation may itself induce artifacts. A few specimens (e.g., cells of low water content such as yeast or bacteria, or concentrated membrane preparations such as erythrocyte ghosts) may be successfully frozen by conventional methods without prior chemical pretreatment.

Copyright 2006, Elsevier Science (USA).
All rights reserved.

B. Mounting of Specimens Prior to Freezing

To enable processing through the various subsequent steps of freeze fracture or deep etching, specimens are first mounted on specially designed supports (Fig. 1). Standard specimen supports are made from metals of high thermal conductivity and are as small as is compatible with ease of handling. The precise design of support used will vary according to the nature of the specimen, the type of freeze-fracture apparatus, and the manner in which fracturing is executed. Careful mounting is critical and should always be done with the aid of a binocular microscope.

For conventional knife fracture of cell suspensions (see article by Shotton), a droplet of concentrated cell suspension is placed on the central raised portion of a cleaned flat-topped specimen support (Figs. 1a and 1c). Care should be taken to avoid bubbles and to avoid getting liquid on the rim of the holder (which will prevent it fitting the specimen table after freezing). Tissue blocks for knife fracture are conventionally mounted in similar supports that have a central well (Fig. 1b). The tissue is held securely in the well with a portion protruding for subsequent fracture. Flat-type holders without wells can also be used as mounts for tissue pieces; in this case, polyvinyl alcohol (PVA) mounting medium is recommended to attach the sample firmly to the holder. PVA mounting medium consists of 20–30% PVA in phosphate-buffered saline (PBS) containing 20–33% glycerol. A simple recipe is to dissolve the PVA powder (mean molecular mass 10 kDa) to 45% in PBS by prolonged heating at below 100°C in a double boiler and then to dilute with half the volume of glycerol to give a solution containing 30% PVA and 33% glycerol. PVA is conveniently applied from a syringe or using a sharpened applicator stick and should be kept at 4°C or, for prolonged storage, at –20°C.

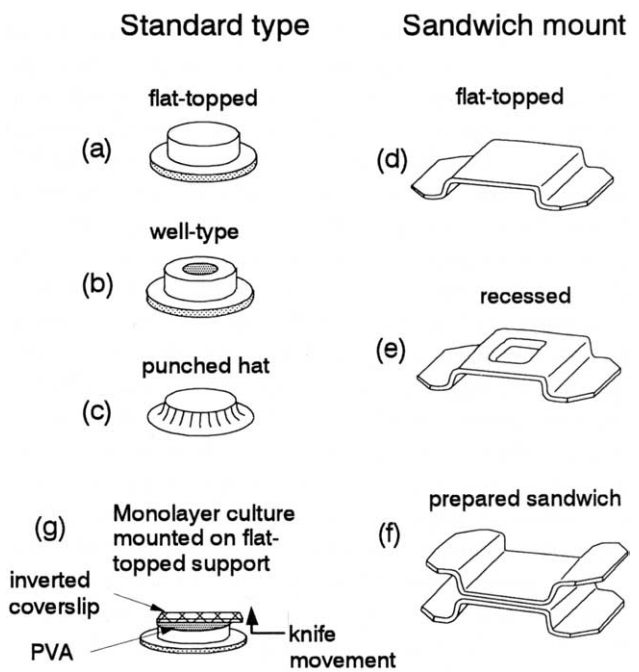

FIGURE 1 Examples of supports used for mounting specimens prior to freezing. (a and b) Standard supports for knife fracturing made either from a gold–nickel alloy (Balzers) or from copper (e.g., Reichert Cryofract, Polaron). (c) An inexpensive alternative, compatible with the same type of specimen table, punched out from a copper sheet. (d–f) Mounting systems for fracturing specimens in double-replica devices. Different designs of these mounts are used in different freeze-fracture plants. (d and e) Different types of mount used to sandwich thin specimens as shown in f. When a pair of flat-topped mounts (d) is used, a spacer may be included to prevent compression of the sample. (g) Use of a standard flat-topped support and PVA for mounting of cells cultured on a plastic coverslip. Reproduced from Severs and Shotton (1995), with permission.

As an alternative to fracturing by knife, specimens may be fractured by being broken apart in a hinged double-replica device. This dictates use of a pair of mounts between which the specimen is sandwiched (Figs. 1d–1f). The double—mount principle was originally devised for making complementary P- and E-face replicas, but is often convenient for routine preparation.

Various techniques have been developed for mounting cultured cells for freeze fracture. A particularly versatile approach, suitable for cells grown on plastic coverslips, is that of Pauli *et al*. (1977). A piece of the coverslip is mounted cell side down on a droplet of PVA placed on a standard flat-topped support, leaving a portion of the coverslip projecting horizontally by about 0.5 mm (Fig. 1g). Fracturing is done by raising the tip of the knife from below the coverslip; this flips the coverslip off the frozen PVA, directing the fracture plane through the cells.

C. Freezing

Conventionally fixed and cryoprotected specimens are normally frozen by simple immersion in a liquid cryogen. However, direct immersion of specimens into liquid nitrogen (which at atmospheric pressure is at its boiling point, –196°C) leads to formation of an insulating layer of evaporated nitrogen gas around the specimen, preventing rapid cooling (the *leidenfrost* effect). This problem is avoided by using nitrogen slush, a mixture of solid and liquid nitrogen at its freezing point (–210°C).

A simple way to make nitrogen slush is to fill a small, well-insulated styrofoam container with liquid nitrogen, place it in a desiccator, and evacuate it using

a water pump or rotary pump until, through loss of latent heat of evaporation, the nitrogen ceases to bubble and solidifies. After a further 30 s, the vacuum is released, and some of the solid nitrogen melts, giving a slush at –210°C. By repeating this process several times, the entire volume of nitrogen is brought down to the same temperature before removal for use. Slush can be made similarly using a standard vacuum evaporator unit or a commercially available slusher. Once made, the slush must be used immediately. The mounted specimen, held in fine forceps, is inserted swiftly into the nitrogen slush and is then transferred into a separate container of liquid nitrogen for storage or further processing. After a few minutes the solid nitrogen will have melted and a new batch of slush must be prepared.

The traditional alternative method for freezing specimens is to immerse them manually into a secondary cryogenic liquid cooled to near its freezing point using liquid nitrogen as the primary cryogen. Such a secondary cryogenic liquid ideally combines the properties of high thermal conductivity, a high heat capacity, a freezing point close to the boiling point of liquid nitrogen, and a large temperature difference between its freezing and boiling points. The nonflammable refrigerant gases freon 22 (chlorodifluoromethane, $CHClF_2$; melting point –160°C, boiling point –40°C) and freon 12 (CCl_2F_2; melting point –155°C, boiling point –30°C) fit these requirements and were, for many years, used as the standard secondary cryogens for the freezing of cryoprotected specimens. However, freons are no longer used due to their deleterious effects on the earth's ozone layer. The cooling rates obtainable with nitrogen slush are comparable to those achieved with the fluorocarbon cryogens and are certainly adequate for the freezing of cryoprotected specimens.

III. ULTRARAPID FREEZING

Ultrarapid freezing techniques opened a new chapter in biological ultrastructure research, permitting the examination of specimens that had been frozen directly from the living state, without prior chemical treatment. There are four principal methods for the ultrastructural preservation of biological specimens by extremely rapid freezing in the absence of cryoprotectants: plunging, spraying, jetting, and metal block-impact freezing (reviewed by Gilkey and Staehelin, 1986). With all these methods, good ultrastructural preservation is confined to a 10- to 20-µm surface layer. Further from the surface, the inherently low thermal conductivity of biological tissue limits the rate of heat loss and leads unavoidably to the growth of large ice crystals and consequent ultrastructural damage, similar to that observed if noncryprotected samples are frozen directly by standard immersion freezing.

A. Plunge Freezing

By optimizing conditions for the traditional approach of immersing specimens in a liquid nitrogen-cooled cryogen, cooling rates can be improved sufficiently to permit observation of a well-frozen structure in the absence of chemical cryoprotection. Numerous pneumatic, solenoid-operated and spring-driven devices incorporating these features have been developed; one example is illustrated in Fig. 2a. Key conditions for efficient cooling are that the specimen should have a maximal surface to volume ratio and be mounted in thin supports of low mass, and that its entry velocity into the cryogen should be high (hence the term *plunge* freezing). The stirred cryogen should fill a deep container to the brim so that the specimen does not undergo precooling before entry and completes its cooling over the critical range from 20°C to –100°C while still in motion through the liquid.

Liquid propane (C_3H_8; melting point –189°C, boiling point –42 °C) and liquid ethane (C_2H_6; melting point –172 °C, boiling point –89 °C), cooled with liquid nitrogen to close to their freezing points, are the most efficient cryogens for plunge freezing; they are, however, potentially hazardous and need special care in handling.[1] The usual mounting method is to sandwich the specimen between a pair of thin supports; not only can these mounts be adapted readily to fulfill the criteria given earlier, but, upon their separation during fracturing in a double-replica device, the fracture plane tends conveniently to follow

[1] Extreme care must always be taken to eliminate any possibility of explosion hazard when working with liquified flammable gases, as ignition of even a small volume of liquid can have devastating consequences. The flash point of liquid propane is –104°C; that of liquid ethane is –130°C. These gases create explosive mixtures in air at concentrations above 3% (ethane) or 2.2% (propane). Beware also that below –183°C oxygen will condense from the air, forming a potentially explosive mixture. All work involving liquified flammable gases must be undertaken within the confines of an extraction fume cupboard suitable for flammable vapours, and naked flames and electrical switches that might generate sparks must be totally excluded from the work area. The liquified cryogens should not be stored, but should be safely discarded after each experiment either by evaporation within the fume cupboard or, if direct access to outdoors is available, by carefully pouring the liquid onto the ground at a site distant from people, cars, buildings, and other man-made installations. Liquified gases should never be poured down a drain.

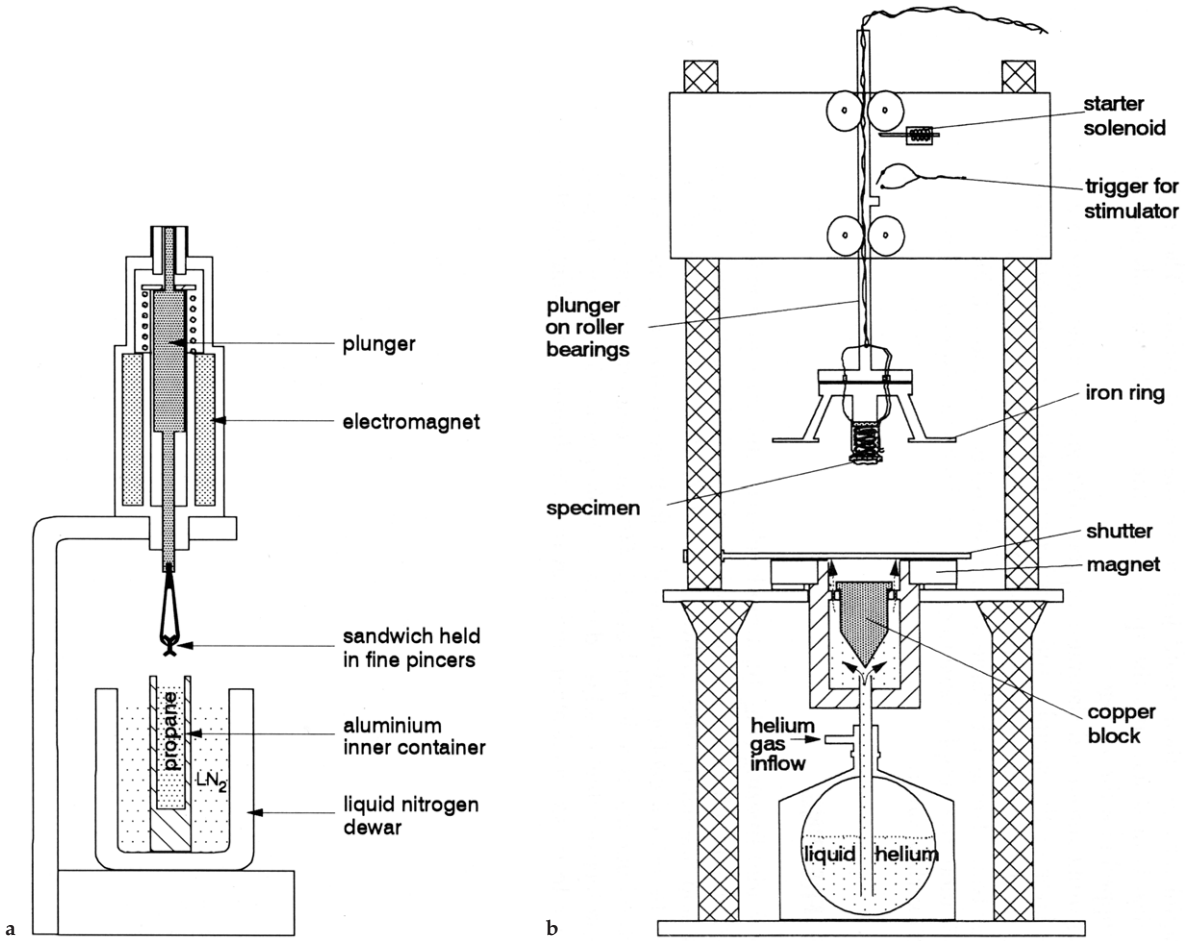

FIGURE 2 Examples of rapid freezing apparatus. (**a**) An example of a solenoid-operated plunge-freezing apparatus [adapted from Escaig (1982), with permission]. (**b**) A metal block slam-freezing device (Heuser version). The specimen is mounted on a detachable freezing head, which plugs into the plunger, the highly polished pure copper block is cooled from below with a spray of liquid helium, and the plunger is allowed to fall onto the block under gravity. The original device was set up to permit stimulation in nerve muscle preparations. From Heuser *et al.* (1979), with permission.

a superficial well-frozen layer of the specimen, adjacent to the support. If a mechanical plunge-freezing machine is not available, simple manual plunge freezing of specimens into propane under optimized conditions is always worth trying. Sandwich-mounted cell and membrane suspensions, in particular, lend themselves to this approach, and satisfactory results have been obtained in some animal and plant tissues (Severs and Green, 1983; Galway *et al.*, 1995). The entry velocity attainable by manual plunging will not be as high or as reproducible as that achieved using a mechanical device, but the method is simple, has negligible cost, and, with practice, can give satisfactory results.

B. Spray Freezing

Spray freezing is essentially a version of immersion freezing in which the specimen size is reduced to microscopic droplets and, as such, this method is only suitable for suspensions of single cells, organelles, or membranes (Bachmann and Schmitt-Fumian, 1973). The low thermal mass of the individual droplets permits satisfactory freezing in the absence of cryoprotection. Minute droplets of the suspension are sprayed into liquid nitrogen-cooled propane. The propane is then warmed to –85°C and removed using a vacuum pump. The frozen droplets are mixed with butyl benzene at –85°C and transferred to a standard flat-topped specimen support, which is finally immersed in liquid nitrogen to solidify the specimen. Although, as a freezing method for particulate specimens, spray freezing was superseded by other more straightforward methods (e.g., plunge freezing a sandwich-mounted suspension into propane), it forms an integral part of *quenched flow* devices designed to capture very rapid dynamic cellular events, on a

millisecond time scale, at defined intervals after rapid mixing cells with a stimulating agent. A spray-freezing device based on this quench flow principle is available commercially (Balzers Model SFD 010). After spraying the stimulated cells into vigorously stirred propane and evaporating the cryogen, samples may be processed by freeze substitution in methanol containing glutaraldehyde and then either embedded and sectioned or rehydrated and refrozen for freeze fracture (Knoll, 1995).

C. Jet Freezing

In *jet freezing*, instead of moving the specimen rapidly through the cryogen, the reverse is done; cold propane is squirted at high velocity onto the stationary specimen (for review, see Gilkey and Staehelin, 1986). Most versions of commercially available equipment have dual jets, which simultaneously squirt liquid propane at each side of a sample (typically a cell or membrane suspension) sandwich mounted between a pair of thin copper supports. A double-jet machine from Balzers (Model JFD 030) incorporates a thermostatically controlled specimen environmental chamber, allowing freezing of the specimen from any chosen starting temperature between +10 and +90°C, a feature of particular importance for lipid research. As an alternative, one-sided propane jet freezers may be constructed with the aid of workshop facilities and have been used successfully in a number of laboratories. The safety precautions outlined in Section III,A apply equally to this freezing method.

D. Metal Block Freezing

The *metal block freezing technique*, also known as *slam freezing* or *metal mirror freezing*, has seen wide application in cell biology. The principle of the technique is to bring the biological specimen into rapid and firm contact with the highly polished surface of a pure copper block, cooled by liquid helium (boiling point 4 K; –269°C) to a temperature of ~18 K (–255°C). Variations on this theme include the use of a silver block in place of copper and cooling by means of liquid nitrogen instead of liquid helium. Various designs of slam freezing machine have been developed, notably by Heuser *et al.* (1979) and Escaig (1982), and made available commercially. In the Heuser-type apparatus (Fig. 2b), the specimen is fixed beneath the lower end of a vertical plunger, which is then allowed to fall under the influence of gravity. As the specimen falls, a shutter (which protects the liquid helium-cooled copper block from condensation) is opened, the specimen strikes the copper block, and freezing of the surface layer of the specimen is completed within 2 ms. The Escaig device is more sophisticated, using an electromagnetic plunger to propel the specimen, and protection of the helium-cooled block under vacuum until the instant the shutter opens just prior to specimen contact. Both machines are designed to ensure that the specimen does not bounce on impact, but remains applied firmly to the block until removed into liquid nitrogen. Specimen-mounting systems for slam freezing vary according to the apparatus employed, the requirements of the specimen, and its subsequent processing. Most incorporate features to cushion the specimen from the full force of the impact and to limit its flattening, e.g., by mounting within a spacer ring on a piece of rubber foam or fixed lung tissue.

If a sophisticated automated slam freezer is not available, an effective alternative is to use a simple, hand-held copper block (Dempsey and Bullivant, 1976). The block, fitted with a handle, is cooled in liquid nitrogen and is then raised just above the liquid surface. The upper surface is wiped with absorbent tissue and the specimen is then rapidly pushed onto it manually before being dropped into the nitrogen.

Metal block freezing using automated slammers reproducibly gives excellent cryofixation in the surface 10-μm layer of the sample, and satisfactory results can, with experience, also be obtained using simple manual-freezing blocks. Deeper regions of noncryoprotected specimens will always be badly damaged by large ice crystals and compression shock, and so, for freeze-fracture replication, the samples have to be fractured with precision by microtome through the well-frozen surface layer.

IV. HIGH-PRESSURE FREEZING

In high-pressure (hyperbaric) freezing, a sandwich-mounted specimen is frozen by double-sided jetting with liquid nitrogen while briefly being subjected to a pressure of 2100 bar (Galway *et al.*, 1995; Kiss and Staehelin, 1995). At such high-pressure, the critical cooling rate needed to limit ice crystals to a size below that causing ultrastructural damage is reduced from 10,000°C/s to approximately 100 to 500°C/s. This cryoprotective effect is achieved because high-pressure lowers the freezing point and reduces the rate of ice nucleation and growth to a degree equivalent to that achieved by using 20% glycerol for cryoprotection with conventional immersion freezing. Although high pressure is potentially lethal to cells, major artifacts from this source appear to be avoidable. High-pressure freezing requires specialist equipment, available from Balzers Union (Model HPM 010) and from Leica

(Model PI 32-165). The former device freezes specimens up to 0.5 mm in thickness and 1 mm^3 in volume; the latter use specimens of up to 0.6 mm in thickness and 1.5 mm^3 in volume.

The major advantage of high-pressure freezing is that structure is well preserved to a much greater depth than is possible with any of the ultrarapid freezing techniques discussed previously. True vitrification to an average depth of 200 μm has been reported in test specimens [catalase crystals in sugar solutions; Sartori *et al.* (1993)]; in plant specimens, no ice crystal damage is apparent to a depth of 600 μm in planar samples and 1 mm in spherical samples (Gilkey and Staehelin, 1986). High-pressure freezing is thus of particular value in the direct freezing of solid tissue specimens.

V. ADVANTAGES OF ULTRARAPID AND HIGH-PRESSURE FREEZING METHODS

Ultrarapid and high-pressure freezing methods offer a multitude of advantages as preparation methods in cell biology. By avoiding the need for chemical fixation, these cryofixation techniques potentially permit the study of cell structure in a condition close to that existing in life. Because one particular instant in a biological process can be captured, the accumulation of intermediate stages, which may occur during slow death in aldehyde fixatives, is avoided. Living specimens can thus be frozen for ultrastructural examination at known intervals after application of a biological stimulus. This has made it possible to use the electron microscope for studies of transient biological events that are completed within a few seconds or even, in favorable instances, within a few milliseconds. The ability to undertake such direct kinetic studies was a significant breakthrough in cell biology, as previously, sequences of such rapid events could only be guessed at indirectly from images of chemically fixed specimens. Metal block impact freezing, spray freezing, plunge freezing, and jet freezing methods have all been adapted to permit time-resolved analysis of rapid events (for review, see Knoll, 1995).

Another important advantage is that ultrarapid-frozen specimens can be subjected to *deep etching* or freeze drying, a technique in which water molecules are allowed to sublime from the frozen surface of a fractured (or, in some cases, unfractured) specimen before replication (see article by Shotton). Glycerol cannot be sublimed, but by directly freezing specimens in dilute aqueous solutions, the outer surfaces of membranes, extracellular matrix components, and intracellular cytoskeletal elements can be exposed by deep etching or freeze drying. For deep-etch observations of the cytoskeleton and internal membrane surfaces of cells, a compromise has to be made in order to obtain clean views unobscured by cytoplasmic components. Typical procedures for cultured cells attached to a substrate involve lysing them with Triton X-100 or physically tearing them open by peeling off a strip of nitrocellulose membrane that has been allowed to adhere to their dorsal surfaces. This is followed by rinsing in dilute buffer to remove cytoplasmic components, light fixation with aldehydes, and then immersion in 10–15% methanol immediately prior to freezing. The methanol acts as a cryoprotectant, increasing the depth of adequate freezing, and also has the advantage of being volatile under vacuum at –100°C, thus facilitating the etching process. This application is thus quite distinct from studies aiming to preserve structure in the native state, but it is a fundamentally important one, as it provides access to structural information that cannot be obtained by other electron microscopical methods (Heuser, 1981). Deep etching has also been adapted to study macromolecules absorbed to microscopic mica flakes and other substrates (Heuser, 1989).

In addition to freeze fracture, deep etching, and cryoelectron microscopy, other key routes to the examination of ultrarapid-frozen specimens are freeze substitution and cryoultramicrotomy. Here the ability to preserve epitopes is of prime importance for immunocytochemical studies (see article by Roos *et al.*). The complementary application of these approaches, together with freeze-fracture cytochemistry (Severs, 1995; Fujimoto, 1997), has wide application in cell biology today.

Freeze Fracture and Freeze Etching

David M. Shotton

I. PRINCIPLES OF FREEZE-FRACTURE TECHNIQUE

The technique of freeze fracture is unique among electron microscopic (EM) methods in that it gives *en face* views of the internal organisation of biological membranes, allowing the study of the in-plane distribution of integral proteins spanning the lipid bilayer and of other membrane features, as a function of developmental stage, experimental conditions, or onset of disease. Although freeze fracture can be undertaken using very simple equipment that can be constructed in any workshop, in conjunction with a standard vacuum coating unit (Bullivant and Ames, 1966; Bullivant *et al.*, 1979), or using a commercial attachment to such a coating unit, it is normally performed within a specialized high vacuum freeze-fracture apparatus, with a temperature-controlled, liquid nitrogen-cooled holder for specimens. The standard procedure for specimen preparation by freeze fracture in such an apparatus is summarised in Fig. 1 and can be described briefly as follows.

A. Freezing

Conventionally, a small block of biological tissue (approximately $2 \times 2 \times 1$ mm) or a droplet of cell suspension on a copper or gold support (Fig. 1a), stabilised by glutaraldehyde fixation and cryoprotected by infiltration with 25–30% glycerol, is first rapidly frozen by plunging it manually into nitrogen slush or a liquified cryogen cooled to near its freezing point by liquid nitrogen (Fig. 1b). Full details of specimen supports and alternative rapid freezing methods are found in the article by Severs and Shotton and in Severs *et al.* (1995).

B. Fracturing

After storage for an unlimited period in liquid nitrogen, the frozen specimen is transferred quickly to the precooled, temperature-controlled specimen table within the high vacuum chamber of a freeze-fracture apparatus, either via an airlock or, more usually, after venting the chamber with dry nitrogen gas, which is then reevacuated to better than 2×10^{-6} mbar (Fig. 1c) (1 mbar = 100 pa = 0.75 torr). Freeze fracture is traditionally achieved by striking the specimen, maintained at –110°C, with a cold razor blade clamped within the jaws of the hollow microtome knife blade holder, which is itself filled and cooled to below –150°C with circulating liquid nitrogen. As when a log of wood is cleaved by an axe, a plane of free fracture precedes the blade edge, following a line of least resistance through the frozen specimen (Fig. 1d). When this fracture plane encounters a cell, it frequently passes along the centre of the lipid bilayer of the plasma membrane, as this is a line of weakness at cryogenic temperatures, splitting the asymmetric membrane into an extracellular (E) half and a protoplasmic (P) half (nomenclature of Branton *et al.*, 1975). Integral proteins, which span the membrane, may partition with one or other half of the membrane, from which they will protrude to form small freeze-fracture intramembrane particles (IMPs), leaving complementary pits in the other half membrane from which they were wrenched. Internal cell membranes may be similarly fractured, if the fracture plane initially passes through the plasma membrane and into the cell. Alternative specimen supports, including "double replica" specimen holders that provide tensile fracture of the frozen specimen, are detailed in the article by Severs and Shotton.

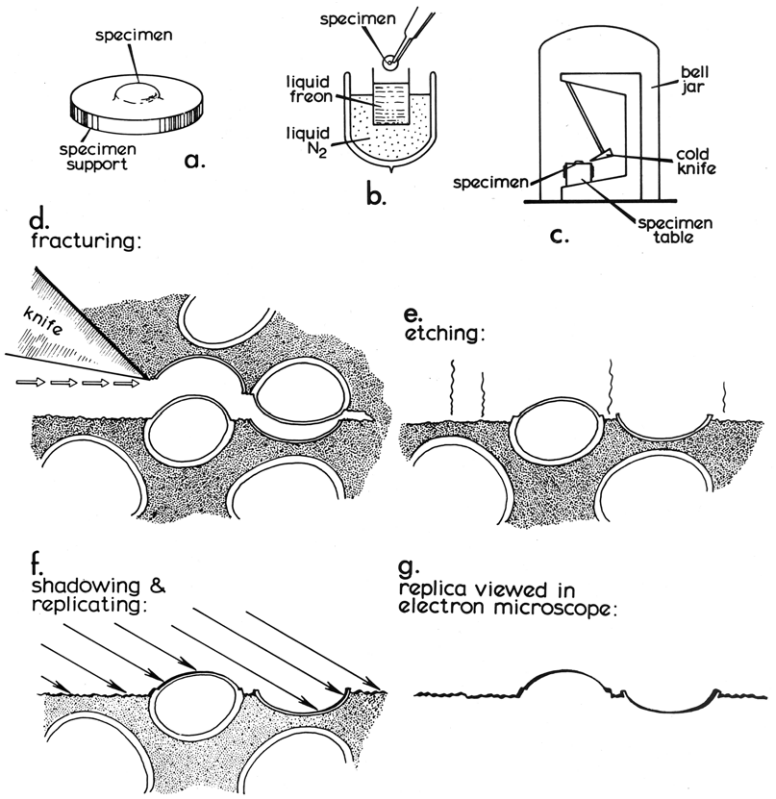

FIGURE 1 Basic steps in the conventional freeze-fracture procedure described in the text. Diagram courtesy of Daniel Branton, first published by Shotton (1982), reproduced by permission.

C. Etching

The specimen may then optionally be etched after fracturing (Fig. 1e). During etching, water molecules are allowed to sublime from the frozen surface of the fractured specimen, which for this purpose is fractured at a slightly higher temperature, at which the sublimation pressure of ice exceeds the partial pressure of the residual water molecules in the vacuum atmosphere by about 10-fold (typically –100°C for a vacuum of 2×10^{-6} mbar), leading to an etching rate of about 2 nm per second. The sublimed water molecules are condensed on a nearby cold trap, typically the underside of the cooled knife, which is positioned for this purpose above the fractured specimen. Etching lowers the specimen ice table and exposes the true surfaces of freeze-fractured membranes, thereby revealing membrane surface features of interest that were obscured previously by the overlying ice. The introduction of ultrarapid freezing techniques (see previous article by Severs and Shotton) has made it possible to freeze a wide variety of living tissue sufficiently rapidly to achieve good cryofixation of the surface layer of cells in the absence of chemical fixation and glycerol cryoprotection, enabling their subsequent etching. More extensive etching for up to 30 min at –100°C (deep etching or freeze drying) may be used to reveal more extensive cytoskeletal, extracellular, or membrane features or macromolecular structure (see Heuser, 1989; Hawes and Martin, 1995; and chapters in Severs and Shotton, 1995).

D. Replication

The frozen surface of a freeze-fractured or freeze-etched specimen is rich in topographical detail, but is extremely labile. In order to convert this labile structural information into stable contrast information accessible in the electron microscope, the specimen is obliquely shadowed with a thin layer of atomic platinum (typically with an average thickness of 1.5 to 2 nm), deposited from an evaporative source, usually an electron bombardment gun (Fig. 1f). The platinum atoms landing upon the frozen surface of the replica do not form a homogeneous layer, even upon smooth surfaces. Instead, after travelling short distances laterally on the membrane surface as they lose kinetic energy, the atoms coalesce to form small platinum

grains, about 1 nm in diameter, leaving the immediately adjacent surface free from platinum. The deposited film contains 5% (w/w) carbon with the platinum, which limits the maximum size of the grains to about 1.5 nm. These frequently form upon existing surface particles, giving a "decoration" effect, which may accentuate specimen detail in a useful way. The presence of these grains effectively limits the resolution of the replica to approximately 2.5 nm.

Alternative shadowing materials may be used, most commonly a mixture of tantalum and tungsten (approximate stoichiometry 80:20, w/w), which provides replicas of somewhat smaller grain size and higher resolution. However, such replicas are hard to make reproducibly, as the composition of the tantalum–tungsten anode of the electron bombardment gun changes from one evaporative shadowing run to the next due to the higher vapour pressure of the molten tantalum. The replicas are also of much lower contrast and have more limited chemical stability than conventional platinum replicas, and hence their use is confined almost exclusively to high-resolution ultrastructural studies (e.g., Abermann *et al.*, 1972; Zingsheim and Plattner, 1976; Gross, 1987).

With conventional unidirectional platinum shadowing of stationary specimens, the platinum atoms accumulate on the near side of protrusions, leaving platinum-free "shadows" in their lee. Alternatively, the specimen may be rotated during replication while maintaining the platinum deposition angle constant relative to the plane of fracture. Such rotary shadowing, which results in a uniform distribution of platinum grains around protrusions and an absence of shadows, is particularly useful for deep etched specimens. In either case, this discontinuous and physically fragile platinum surface replica is then strengthened by a uniform backing of electron-translucent carbon (about 15 to 20 nm thick; not shown in Fig. 1), deposited either unidirectionally from above or, for additional strength, from an angle of 80° while the specimen is rotating. This combined platinum–carbon replica is then removed from the vacuum chamber, is cleaned free of all the original biological material by digestion of the underlying thawed specimen with bleach or chromic acid followed by washing with distilled water, and is viewed directly in the transmission electron microscope (Fig. 1g).

II. TECHNICAL ADVICE

Precise details of the operation of the freeze-fracture apparatus, replication conditions, gun adjustments, and so on will vary between different models of freeze-fracture apparatus and should be conducted according to the manufacturers' instructions. Detailed comparative descriptions of different types of freeze-fracture equipment are given by Newman (1995). The following advice, based on experience with the Balzers BAF 300 machine, should be of general applicability.

A. Before the Freeze-Fracture Run

Check that there is enough liquid nitrogen to complete the run and prepare the electron bombardment guns for use according to the manufacturer's instructions. Check the incident shadowing angle of the platinum gun, changing it if necessary. The normal angle of incidence for unidirectional platinum shadowing of freeze-fracture replicas is 45°; from 6° to 26° is most useful for rotary shadowing of deep-etched specimens, depending upon the nature of the specimen; and 9° and 6° are used for unidirectional and rotary low-angle shadowing, respectively, of individual macromolecules absorbed onto mica sheets. For microtome fracture, fit an appropriate specimen stage and a reusable tungsten blade or a new single-edged carbon steel razor blade. Do not use stainless steel razor blades, as their edges bend on contact with ice and thus do not fracture well. Using a binocular dissecting microscope, ensure that the blade is horizontal above the specimen positions. Alternatively, fit a double-replica opening device in place of the blade and an appropriate double-replica specimen stage. Good thermal contacts should be ensured by the use of small amounts of a thermal conductive paste or high vacuum grease. If appropriate for your machine, prepare and fit a "shadow paper" (a piece of thin card with a central cutout, placed as a collar around the specimen stage where it will intercept some of the evaporated material), which will provide a permanent record of the replication run, to supplement any chart recorder trace made of the stage temperature and quartz crystal replica thickness monitor output.

B. Precooling the Stage and Specimen Preparation

Close and evacuate the chamber. Turn on the quartz crystal replica thickness monitor to warm up. At a vacuum of 10^{-4} mbar or better, turn on the chart recorder (if used), start the stage cooling, and briefly test fire both guns. Under liquid nitrogen, mount the specimen supports bearing the frozen specimens in the appropriate specimen holder in preparation for transfer to the specimen stage of the apparatus.

C. Loading Specimens

After the stage has been allowed to equilibrate at its minimum temperature (below –170°C) for 5 min, turn off the high vacuum gauge, vent the chamber with dry nitrogen gas (conveniently generated by running liquid nitrogen through a length of uninsulated copper tubing) in order to prevent the water vapour contamination that would otherwise occur if venting with air, open the chamber door or specimen access port, quickly transfer the specimens from liquid nitrogen to the cold specimen table, close the chamber, and immediately reevacuate. Modern freeze-fracture machines are often equipped with an airlock so that specimens may alternatively be loaded directly into the chamber without breaking the vacuum.

D. Specimen Temperature Adjustment

At a vacuum of 10^{-4} mbar or better, start the knife cooling and raise the specimen temperature to –110°C (for freeze fracture) or –100°C (for freeze etching). For the standard specimen stage, the indicated temperature and the actual stage temperature should correspond fairly exactly. However, the poor thermal contacts that may occur when using certain designs of double-replica specimen holders mean that the specimens may in practice be 5 to 15° warmer than indicated so that the indicated specimen stage temperature must be set low to compensate. One should predetermine these temperatures, etching rates, and contamination conditions using test specimens such as erythrocyte ghosts frozen in distilled water (ghost preparation is described by Shotton, 1998) and/or a digital thermometer with the thermocouple clamped in place of one of the specimens for direct measurements. Note that the specimens may take 10 min to reach temperature equilibrium after a large change in temperature and 5 min to reach equilibrium after a small (<10°C) change.

E. Fracture Process

When fracturing with a microtome blade, observe the specimens with the binocular microscope and use the microtome controls to lower the knife blade until it is just clear of the tops of the specimens. Then make a series of progressively lower passes of the blade over the specimens. If possible, it is preferable to make the actual cuts slowly by hand rather than using the motor drive, thus enabling one to get a feel of the blade passing through the ice of the specimens. Reduce the cutting depth to a minimum as soon as any appreciable area of specimen is being cut and continue cutting until all specimens show large smooth fractured areas. For elongated cells such as nerve and muscle fibres, extensive fracture planes are best obtained by orienting the specimens so that the fibres are parallel with the edge of the blade and by cutting fast by motor using only a few deep cuts. When using a double-replica device, fracturing is a single event that should be done after temperature equilibration and preparation for shadowing.

Prior to the final cut (or to fracture in the double-replica device), check the specimen temperature, ensure that the vacuum is better than 2×10^{-6} mbar, and prepare for shadowing. (Modern freeze-fracture machines may achieve vacuum of 2×10^{-7} mbar or better.) Then make the final cut, check through the binoculars that the specimen surfaces are clear of debris, and either shadow immediately or reverse the knife over the specimens to act as a cold trap while etching.

F. Etching

Normally, etching is conducted immediately after fracture at –100°C for 60 s in a vacuum of better than 2×10^{-6} mbar, with a cold trap (below –160°C) in close proximity to the specimen surfaces. This lowers the ice level approximately 120 nm. Deep etching, used, for example, to expose macromolecules adsorbed to the surfaces of mica flakes or to reveal the cytoskeleton of permeabilized cells, is performed for longer, at a higher temperature (–95°C), or both. If taken to completion, this is equivalent to freeze drying.

G. Replication

A quartz crystal replica thickness (thin film) monitor, positioned adjacent to the specimen stage in the path of the shadowing beams, is usually used to monitor replica deposition rates and amounts. Sequentially, operate the platinum and carbon guns according to the manufacturer's instructions to deposit the desired thickness of material, with the specimen stage stationary or rotating, as required. It is usual for unidirectional shadowing to deposit 1.5 to 2 nm thickness of a 95% Pt – 5% C mixture from the platinum gun. The amount of platinum deposited is critical and should not be more than the minimum required to generate good contrast. It is best to deposit the platinum at as rapid a rate as possible, starting to fire the platinum gun immediately prior to moving the knife away from its position over the specimens or just before opening a double-replica device, thus immediately exposing the specimens to a stream of platinum

vapour, reducing to a minimum the time during which contamination might occur.

Immediately after platinum shadowing, strengthen the replica with a 10- to 20-nm-thick layer of carbon from the carbon gun. Quite large differences in the amount of carbon deposited make little obvious difference to the final appearance of the replica, except in the case of deep-etched filamentous structures, where too much carbon creates a large semitransparent "ghost" replica surrounding the thin carbon replica. However, for maximum contrast, the carbon thickness should be kept to the minimum required to maintain the structural integrity of large replica fragments during the subsequent cleaning process. During the carbon deposition, heating of the crystal by radiation from the carbon gun, which has a larger anode and uses a higher electron bombardment current, is significant and will lead artifactually to a competing increase in the crystal frequency, which is "recovered" after the carbon evaporation ceases. Once this behaviour is recognised, it can be accommodated for easily by starting the carbon shadowing as a small positive beat frequency. On initial heating the beat frequency will drop. It will then rise to a predetermined cutoff point as carbon is deposited and will finally "overshoot" by an amount equal to the initial drop as the crystal cools at the end of the carbon deposition.

Rotary shadowing is conducted as for unidirectional shadowing except that a commutator unit is used to rotate the specimen about an axis perpendicular to the fracture plane during both platinum and carbon deposition. A little over half the amount of platinum normally used for unidirectional shadowing is usually sufficient to give good contrast for rotary-shadowed freeze-etch replicas, with the normal amount of carbon.

After carbon shadowing, return all gun controls to zero, switch off the high tension supply, the monitor and recorder, the knife cooling and the high vacuum gauge, and prepare to remove the specimens. Stage cooling may be continued until the specimens have been removed.

H. Specimen Removal and Apparatus Shutdown

Vent the chamber and remove the specimens, minimising frosting on the specimens after venting by working fast. Then treat the specimens for replica removal as described later. Only when this has been done, shut down the apparatus. Turn off the stage cooling and reevacuate the chamber. If appropriate, turn on the stage and knife heating. When both are warm, revent the chamber, safely discard the disposable razor blade (if used), remove any water condensation droplets from the stage or microtome with paper tissues, and complete the drying process with a hot air gun. Finally, close the chamber and reevacuate. If appropriate, raise the knife to its upper limit, ready for the next run. When the vacuum is better than 10^{-5} mbar, the pumping unit may be turned off, following the manufacturer's instructions. Complete the run record log sheet.

I. Retrieval and Cleaning of Replicas

Replica cleaning is often the most difficult stage of the entire procedure, during which replica fragmentation is frequently experienced. All dishes, implements, and solutions must be scrupulously clean to avoid replica contamination.

For replicas of cell suspensions, hold the specimen support above or just in contact with the surface of clean distilled water in a white ceramic spotting tray or a small petri dish, wait for it to thaw and the frost on top of the replica to evaporate, and then slowly immerse the specimen support into the water at approximately a 30° angle to the horizontal. The hydrophobic replica of the fractured surface will float off intact onto the water surface, surrounded by junk from the surrounding nonfractured (and hence rough) surfaces of the specimen, from which it may be separated easily. Transfer the floating replica (without any of the surrounding junk) onto the surface of a solution of sodium hypochlorite [technical grade, 10–14% (w/v) available chlorine] diluted to 50% with 10 mM sodium hydroxide, and leave covered at room temperature for at least 30 min (or overnight). (Commercial bleach should only be used if free from detergents, which tend to wet the replica and cause it to sink.) Then rinse the cleaned replica by transferring it sequentially onto two changes of distilled water and finally mount on an EM grid. Replica fragmentation upon transferring to and from cleaning solution is minimised if the replica is picked up on the upper surface of a bent round-ended glass rod formed using a Bunsen flame or the bent sealed tip of a Pasteur pipette formed in the flame of a small alcohol lamp to resemble an ice-hockey stick in shape. This method transfers less liquid than the use of a platinum loop, and any violent mixing of cleaning solution and water occurs at the underside of the rod while the replica is still safe on the upper surface. More thorough replica cleaning may be achieved, if necessary, by acidifying the hypochlorite with concentrated hydrochloric acid to form a stronger oxidising solution, by warming the hypochlorite to 60°C, or by using chromic acid. Concentrated sulphuric acid alone will digest the cellulose

of plant specimens. Replicas of deep-etched, rotary-replicated specimens are among the most difficult to clean, having a layer of platinum–carbon almost totally enveloping many of the biological structures, and prolonged exposure to strong acids may be required to achieve complete cleaning. Swelling of enclosed structures during this cleaning process can lead to severe replica fragmentation, but even the smallest of visible replica fragments can hold valuable structural information and so should all be kept, washed, and mounted on formvar-coated grids (see Section II,J). Other methods of cleaning replicas of difficult specimens are described in Shotton (1998b).

J. Mounting of Replicas

Floating replicas may be picked up from the meniscus of distilled water on bare EM grids either from above or from below. In the latter case, the EM grids should first be made hydrophilic by glow discharge, by brief immersion in a 0.1-mg/ml bacitracin solution, or by washing in alcoholic sodium hydroxide (30 g NaOH dissolved in 30 ml distilled H_2O, added to 250 ml 98% EtOH) followed by vigorous agitation in two changes of distilled water. Replicas are then mounted by careful manipulation of the submerged grid below the replica fragment, followed by slow withdrawal of the grid through the water surface. If, during this withdrawal, the grid is rotated to be at ~90° to the meniscus, with the replica fragment centrally located on it, little water will accompany removal of the grid. This can subsequently be removed by gently blotting the back of the grid onto a circle of filter paper and then by drying between the tips of the forceps holding the grid with a pointed piece of the filter paper, before placing the grid box. If the replica is to be picked up from above, the EM grid should be brought down flat onto the replica and then removed

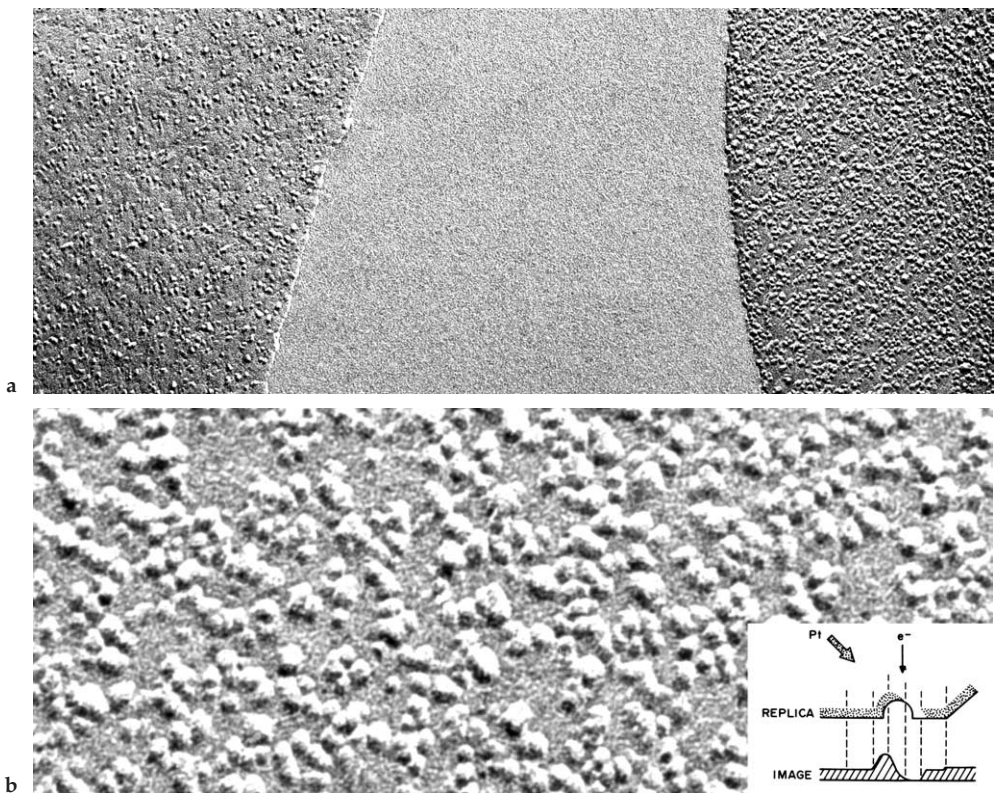

FIGURE 2 Freeze-fracture replica showing the appearance of erythrocyte fracture faces and intramembrane particles. (a) On the right, the protoplasmic fracture face (P face), and on the left, the extracellular fracture face (E face) of normal erythrocyte ghost membranes from two adjacent cells separated by a region of ice. Positive contrast image with the platinum shadowing direction from below. Magnification ×67,200 (b) An erythrocyte P face shown at a higher magnification to reveal individual intramembrane particles (IMPs), which throw short white shadows upward. Magnification ×255,000. From Steere and Rash (1979), reproduced by permission of Raven Press.

with a twist of the wrist to rotate it upside down at the meniscus, with partial submersion to ensure good adhesion of the replica with the grid. For certain investigations, it is important to know the orientation of the replica and hence the handedness of its projected image. For this, one should adopt a convention of always mounting replicas in the same orientation on one of the surfaces of the EM grid (either the dull or the shiny surface) and of orienting this surface facing to the right in one's grid storage box.

Bare 400 mesh hexagonal thin-bar EM grids are ideal for observing replicas of cell suspensions, but do not allow uninterrupted observation of extensive fracture faces of long myotubes or other large cells. For such replicas, formvar-coated 150-mesh or slot EM grids may be used, which have been coated lightly with carbon on their reverse side (i.e., on the side of the grid bars not covered with formvar, as opposed to the conventional method of depositing the carbon on top of the formvar layer, out of contact with the metal grid itself). This has the advantage that the flat surface of the formvar film remains hydrophilic and can be used to pick up floating replicas from below with ease.

Replicas should be observed at an intermediate magnification (×20,000–×90,000) in a transmission electron microscope and should appear crisp, clean, and of high contrast (Fig. 2). More in-depth descriptions of the technique, of the interpretation of freeze-fracture images, and of the potential artefacts that accompany the freeze-fracture technique, involving variations in replica quality, etching artifacts, specimen contamination, and plastic distortion, are discussed more fully in the longer original edition of this article in Shotton (1998b) and in earlier publications by Fisher and Branton (1974), Southworth *et al*. (1975), Sleytr and Robards (1977), Rash and Hudson (1979), Robards and Sleytr (1985), Abysekera and Robards (1995), and Shotton and Severs (1995).

Electron Microscopy Studies of the Cytoskeleton

CHAPTER

27

Electron Microscopy of Extracted Cytoskeletons: Negative Staining, Cryoelectron Microscopy, and Correlation with Light Microscopy

Guenter P. Resch, J. Victor Small, and Kenneth N. Goldie

I. INTRODUCTION

Our understanding of the function of the cytoskeleton and its associated proteins has been much advanced by developments in imaging methods for light microscopy. With the advent of probes, such as green fluorescent protein, the localisation of gene products in living cells under different physiological conditions is now readily feasible (e.g., Vignal and Resch, 2003). However, to extend our understanding of the functional interactions taking place, parallel information about cellular ultrastructure is essential. Here, electron microscopy (EM) is required to provide information about cell architecture at the nanometre level.

Three major filament systems make up the cytoskeleton: actin filaments, microtubules, and intermediate filaments. When not in organised bundles, actin filaments are poorly preserved after dehydration and embedding in plastic. This fact, taken together with the open, three-dimensional nature of the cytoskeleton networks, has limited the information obtainable by conventional EM methods based on thin sectioning. The methods of choice for studying the cytoskeleton of cultured cells have therefore centered on "whole mount" procedures, involving the culturing of cells on plastic films or coverslips and the preparation of entire cytoskeletons, or their replicas, for electron microscopy. Methods that deliver useful structural information about cytoskeleton organisation include quick freezing and deep etching (Heuser and Kirschner, 1980), critical point drying followed by metal shadowing (Svitkina *et al*., 1995), and negative staining (reviewed in Small, 1988; Small *et al*., 1999). More recently, advances in cryoelectron microscopy have opened the way to the study of cytoskeletal structures under conditions that obviate processing steps that could produce artefactual distortions of filament networks (Resch *et al*., 2002; Medalia *et al*., 2002). In particular, these latter approaches, involving cryoelectron tomography, promise to deliver new information about ultrastructural interactions in three-dimensional space unobtainable by other means.

This article describes the application of negative staining and cryo-EM to studies of the cytoskeleton; taking advantage of the developments in light microscopy, we also highlight the feasibility of correlating information on the living cell with electron microscopy (see also Svitkina and Borisy, 1999) for delivering meaningful structural information.

II. MATERIALS AND INSTRUMENTATION

A. General

Chloroform (Cat. No. 1.02445.1000), disodium hydrogen phosphate (Cat. No. 1.06580.1000), ethanol (Cat. No. 1.00983.2511), glucose (Cat. No.

Copyright 2006, Elsevier Science (USA).
All rights reserved.

1.04074.1000), sodium chloride (Cat. No. 1.06404.1000), and sodium dihydrogen phosphate (Cat. No. 1.06345.1000) are from Merck EGTA (Cat. No. E3889), MES (Cat. No. M2933), taxol ("paclitaxel," Cat. No. T7402), and Triton X-100 (Cat. No. X100) are from Sigma. Phalloidin was a generous gift from Professor H. Faulstich (Heidelberg) and is obtainable from Sigma (Cat. No. P2141). EM-grade glutaraldehyde (Cat. No. R1020) and Formvar (Cat. No. R1201) are from Agar Scientific, Stanstead, UK; nickel 200 mesh hexagonal or nickel H2 finder grids are from Graticules Ltd., Tonbridge, UK; and steel and titanium forceps (number 5) are from Dumont & Fils., Switzerland. Thirteen-millimeter-diameter plastic coverslips (Cat. No. 174950) are from Nunc, Rochester. Further materials required include Dow Corning silicone-based high vaccum grease and Whatman Qualitative No. 1 filter paper. The following are from local suppliers: glassware (50-ml bottle, measuring cylinder, a glass through minimum 7 cm deep, a rod or pipette), object slides with frosted ends, Parafilm, transfer pipets, scalpels, and blades. Additionally, cell culture equipment (media, incubators, inverted phase contrast microscope), a basic workshop setup (for producing coverslips with holes), and a routine transmission electron microscope are required.

B. Negative Staining

Sodium silicotungstate (Cat. No. R1230) is from Agar Scientific, Stanstead, UK. Minisart 0.2-µm filters are from Sartorius.

C. Cryo-EM

1,2-Dichlorethane (Cat. No. 8.22346.2500) and methanol (Cat. No. 1.06009.2511) are from Merck, and 87% glycerol (Cat. No. G7757) is from Sigma. Additional laboratory equipment required for producing holey films is a microprobe sonicator and a vacuum evaporator for carbon coating (e.g., Edwards E306).

A freeze-plunging device, either home made (drawings and materials list available upon request) or a commercial apparatus housed in a chemical extractor hood, is needed. At the base of the plunger is a polystyrene box for liquid nitrogen and into this sits a small container for condensing ethane (see Fig. 3). Frost-free liquid nitrogen, gaseous ethane, and a regulator valve with a length of silicon tubing, 4 mm inner diameter and 6 mm outer diameter (Tygon 3603, Norton Performance Plastics Corporation, Akron, OH), with one end fitted with a pipette tip with its end cut at a 45° angle, are needed. *Note: Remove any sources of ignition from the working area as ethane is highly flammable and explosive.* Safety glasses for eye protection or a Plexiglas full face shield, which additionally helps prevent inadvertent breathing onto the cold surfaces, a cause of ice contamination, are required.

Use Whatman qualitative No. 1 filter paper (Cat. No. 1001055), cut to rectangular strips of approximately 1 × 4 cm. Grid box (Agar Scientific, Cat. No. G276A) cut into small squares of 15 mm so that there are four grid holes arranged symmetrically within the square, fitted with a clear plastic lid, 13 mm circular diameter and 1 mm thick, with a 4-mm square notch cut out to allow access to one grid hole at a time is required. This is fitted with metal or nylon screw attached through the center to the grid box base so it can be rotated from one hole to the next and fixed tight for storage. Obtain 50-ml polypropylene conical tube with two approximately 8-mm-diameter holes in the lid to allow nitrogen to enter the tube and for retrieval using long tweezers. Small, portable industrial quality vacuum dewars (do *not* use houshold vacuum flasks as they can dangerously implode) or a polystyrene container for transporting grids in the grid box is needed. Purchase a large vacuum dewar for long-term storage; it is useful to have a dewar that has numbered and colour-coded holders of the correct size to hold storage tubes.

Additional tools needed are large tweezers (200 mm long; Bochem, Weilberg, Germany) and small screwdrivers. At least two sets of tools that contact liquid nitrogen should be available, as they will frost after they have been cooled in the nitrogen and then removed and left on a bench. If you then reintroduce them back into the liquid nitrogen, they will contaminate the nitrogen with the ice crystals.

For electron microscopy, a transmission electron microscope fitted with cryo blades to protect the frozen grid from ice contamination, as well as a cryo holder, cryo transfer station, and temperature controller (Gatan, Pleasanton, USA), are needed.

III. PROCEDURES

A. Negative Staining

1. Preparation of Formvar-Coated Grids

Thin plastic films on grid supports, as used for conventional EM, can be used as a growth substrate for cultured cells. For alternative protocols, see Small and Herzog (1994) and Small and Sechi (1998).

Solution

Dissolve 0.4 g Formvar in 50 ml chloroform and stir vigorously in a tightly closed bottle for at least 1 h. To produce films without holes, this solution and all glassware used should be kept as dry as possible.

Steps

1. Clean an object slide with a frosted end first with distilled water and then with 70% ethanol and allow to dry completely.
2. Transfer the Formvar solution into a measuring cylinder wide enough for the slide and submerge the slide, holding it on the frosted end by a clamp or peg attached to a thread, to just below the frosted area. After 30 s, lift the slide smoothly out of the solution and let it dry for 3 min hanging just above the solution surface.
3. Drain the excess solution at the bottom of the slide with filter paper and cut the film at the bottom, the left and the right edges, around 1–2 mm inside the edge of the slide. (Do the same for the back side *before* wetting the film, if both films are to be floated off together.)
4. Prepare a large vessel filled to the lip with distilled water, clean the surface with a glass rod from dust, and float off either one or both of the films simultaneously at an angle of 45° resp. 90° onto the surface. A black background below the vessel improves visualisation for this and the following steps. (*Note*: If difficulties are encountered with floating off the film, try another brand of slides or a different washing protocol; see also Small and Herzog, 1994.)
5. Place 200 mesh Ni grids with the dull side downwards onto the film. For easy handling of the magnetic nickel grids, the use of titanium forceps is recommended. Retrieve the film from the water surface with a piece of Parafilm that is put on top of the floating grids/film assembly and then lifted up carefully from one end. (An alternative way to do this is to use a microscope slide: with an address sticker adhered to one side and trimmed at the the edges, hold the slide at a 45° angle (paper side down), touch the film a few millimetres within one of the narrow ends, and slowly submerge the slide into the water. The film with the grids will follow the slide and stick very well.)
6. Remove excess water by blotting carefully with filter paper and allow the filmed grids to dry completely. To separate them without damaging the film, cut the film around each individual grid with the tip of a pair of forceps.

2. Cell Culture

Cells are plated onto the grids the same as for coverslips, and the density is chosen to give one or two cells per grid square after attachment and spreading. In general, cells spread more slowly on plastic film than on glass; to encourage attachment and spreading, the filmed grids may be coated with matrix molecules or serum (depending on cell type) prior to plating. Check for adequate cell spreading in an inverted microscope with phase-contrast optics prior to further processing.

In order to render the film more stable in the electron beam, an additional layer of carbon deposited onto the grid can be used. However, under these conditions, we experience a decrease in quality of the negative stain so that we usually apply a thin carbon layer *after* staining (see later).

To avoid the problem of loose, floating grids, it is an advantage to immobilise them in one way or another (see also Small and Sechi, 1998). To immobilise single grids, we sandwich them between a plastic coverslip with a 2.5- to 2.7-mm hole in the center of a petri dish. Dots of vacuum grease are used to fix the plastic coverslip to the petri dish.

Steps

1. Prepare plastic coverslips >12 mm diameter with a central hole of 2.5–2.7 mm; this is best done by fixing a stack of them tightly in a holder prepared separately for this purpose (Fig. 2a) before drilling. Clean the coverslips by washing them twice with 70% EtOH and once with water, both of them heated in a microwave oven until boiling.
2. For cell culture over periods of more than 12 h, sterilise grid sets under UV light in an open petri dish for 5 min. Air bubbles get trapped easily in the mesh, which makes observation of the spreading cells (e.g., in phase contast) difficult. This can be avoided by incubating the grids in sterile water in the fridge overnight before use. This step should be performed individually for each grid in grid boxes (volume per slot approximately 15 µl) to avoid the grids adhering to each other.
3. Transfer the grids, with the filmed side up, to sterile (and dry) petri dishes and fasten them with the plastic coverslips: Apply small spots of high vacuum grease onto the edge of the coverslips and press them down into the petri dishes, with the grid trapped below the hole. Only coverslips with a regular hole and flat edge should be used.
4. After they are mounted, the films can be protein coated and cell culture can be carried out as usual.

3. Extraction/Fixation

Solutions

1. Prewarmed phosphate-buffered Saline (PBS, 150 m*M* NaCl, 3 m*M* NaH_2PO_4, 8 m*M* Na_2HPO_4, pH 7.4)

2. Prewarmed extraction buffer [0.25% Triton X-100 (diluted from a 20% stock) and 0.5% EM-grade glutaraldehyde (diluted from a 25% stock) in CB: 10 m*M* MES, 150 m*M* NaCl, 5 m*M* EGTA, 5 m*M* $MgCl_2$, 5 m*M* glucose, pH 6.1]
3. Fixation buffer at room temperature (1.0% EM-grade glutaraldehyde from a 25% stock in CB)
4. Phalloidin, 1 mg/ml in MeOH, stored at –20°C
5. Taxol, 10 m*M* in dimethyl sulfoxide, stored at –20°C

Steps

1. Remove cover glasses and transfer grids to a small petridish with prewarmed PBS for a brief wash. To avoid bending in the transfer step, a magnetised steel forceps is useful for initially lifting the grid so that it can be grabbed more easily with another pair of (titanium) forceps.

2. Aspirate the PBS carefully, do not allow to dry, and replace it with prewarmed extraction buffer; incubate for 1 min.

3. Replace the extraction buffer with fixation buffer and fix for >20 min up to overnight at 4°C; to improve the preservation of actin and microtubules, 10 µg/ml phalloidin or 10 µg/ml taxol can be added.

4. Negative Staining and Electron Microscopy

Solution

2% sodium silicotungstate in ddH_2O, adjusted to pH 7 with NaOH (equilibration of pH can take a long time) and filtered through a 0.20-µm filter.

Steps

1. Clamp the grid in a pair of forceps using a large paper clip over the shaft to hold the tips together; do not allow the sample to dry at this step!

2. Rinse with a few drops of the negative stain from a transfer pipette. After a few seconds, drain the stain from the *entire* back side of the grid with filter paper to remove it as completely as possible. On the front, drain only from the edges to leave a thin film so as not to damage the sample. Special care has also to be taken to drain excess stain from between the tips of the forceps: Bring the edge of the filter paper into contact with the edge of the grid at the contact point with the forceps.

3. Allow to air dry and observe in a routine TEM (Fig. 1a). To avoid drift of the plastic film upon exposure to the electron beam, a thin layer of carbon can be deposited onto the film in a vacuum evaporator.

B. Cryo-EM

This section describes the method from Resch *et al*. (2002) in more detail.

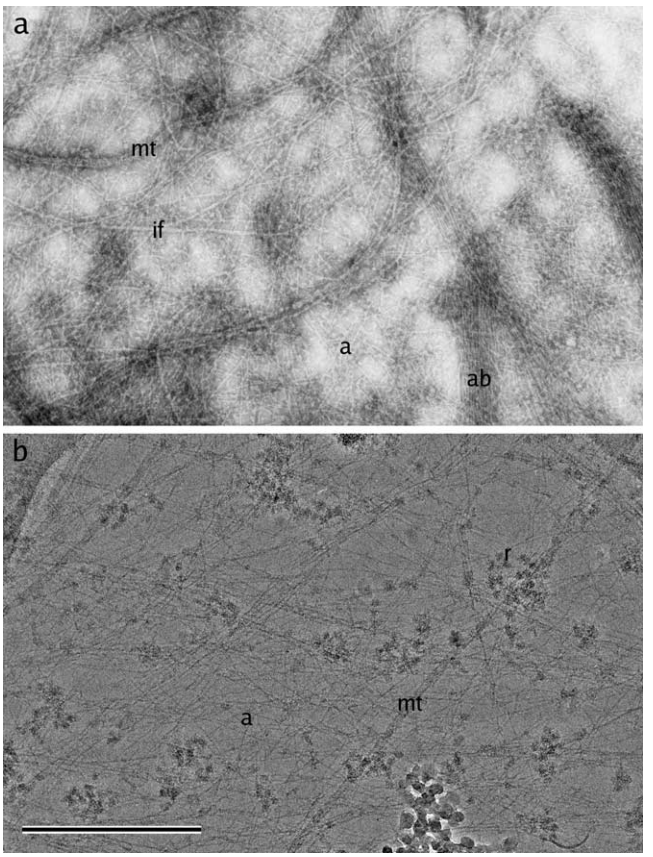

FIGURE 1 Extracted cytoskeletal networks in thin regions of cells visualised by (a) negative staining with sodium silicotungstate and (b) cryoelectron microscopy. a, actin; ab, actin bundle; mt, microtubule; if, intermediate filaments; r, ribosome aggregation. Bar: 500 nm.

1. Preparation of Holey Films

For unstained specimens, the support film itself contributes a significant background noise in the electron microscope image. To improve contrast conditions in the cryo-EM, we have therefore used holey films to support cells and have selected areas for structural analysis where parts of cells span the holes. The method for making holey films was derived from that described in Hodgkinson and Steffen (2001); it was optimised for a hole/film ratio that was significantly lower than for films used for molecular suspensions to allow the cells to attach and spread.

Solution

Dissolve 0.25 g Formvar in 50 ml chloroform and stir in a tightly closed bottle for at least 1 h. After the Formvar is dissolved, add 150 µl of 50% glycerol in water; shake the solution vigorously for 1 min.

Steps

1. Prepare a clean object slide as described previously.
2. Sonicate the Formvar/glycerol solution for 3 min.
3. Rapidly transfer the solution to a staining jar, dip the slide into it, remove, and allow to air dry for a few minutes.
4. Float off both sides of the film as described earlier and place 200 mesh Ni grids with the dull side facing the film on top. In this case, the grids should not be placed too close together on the film, as the filter paper used to retrieve the grids will not adhere sufficiently!
5. Retrieve the grids and the film with a piece of filter paper, *not* with Parafilm or a slide, and allow to dry.
6. Prepare a stack of filter paper in a large glass petri dish saturated with MeOH and incubate the grid set on this, with the film up, for 10 min. This serves to perforate the pseudoholes. Remove and allow to air dry completely before proceeding.
7. At this stage, we recommend checking the film with a phase-contrast microscope for the size and distribution of holes, which is affected by the amount of glycerol as well as by the power and duration of the sonication. If neccessary, vary these factors.
8. Coat the grids with a thick (dark grey) layer of carbon in a high vacuum evaporator.
9. Prepare a bed of filter paper saturated with 1,2-dichlorethane. Place the set of grids, film side up, onto the filter paper and leave for 2 h to dissolve the plastic film. If the filter paper bends up at the edges, either cut it into smaller pieces or use small pieces of glass to hold it down.
10. After final drying, check a few grids in the EM (see Fig. 2b) and store them individually in grid boxes.

2. *Cell Culture*

For preparation of cells for cryo-EM, the same procedure is used as for negative staining. However, making the cells attach and spread on perforated films might require additional steps, including coating with matrix molecules (for general strategies, see also Resch *et al*., 2002; and Vignal and Resch, 2003).

It can save a lot of time and effort prior to preparing the cryo-frozen grids if they are screened beforehand in a phase-contrast microscope. This allows the possibility to roughly assess the quality and number of cells grown on the surface. The proximity of likely cell candidates for the electron microscopy can also be mapped at this stage (see later).

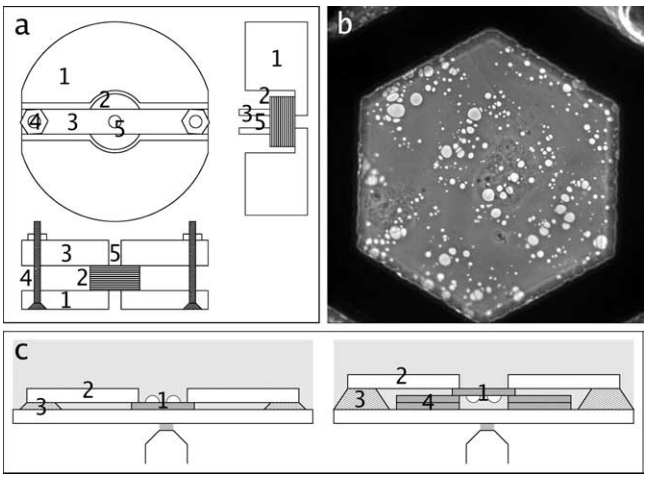

FIGURE 2 (a) Device used for mounting the plastic coverslips for drilling consists of a plastic body (1) with an elongated grove (here horizontal) and a central round indentation (2) in which a stack of cover glasses sit. They are mounted by a Plexiglas bar (3) on top of the groove, which is pressed down firmly onto them by two screws at its end (4). Drilling is done via a central hole (5) in the Plexiglas bar. (b) Perforated carbon film as typically used for cultivating cells for cryo-EM on a 200 mesh hexagonal Ni grid. (c) Two setups to mount grids for correlative LM/EM in petri dishes with a coverslip inset in the bottom on an inverted microscope; samples are covered with medium, the objective is coming from below. (Left) Upright setup: The grid with cells up (1) is mounted by a plastic coverslip with a central hole (2) that is attached via high vaccuum grease (3). (Right) Inverted setup for fluorescence microscopy: The grid with cells on it facing downwards (1) is put on top of two other nickel grids (4) that serve as spacers for the cells and fixed with the coverslip as described earlier.

3. *Extraction/Fixation*

For cryo-EM as outlined here, removal of the membrane and cytosolic protein is necessary to visualise the cytoskeletal networks and actin filament subunit structure clearly. It is also necessary to fix the cytoskeletons lightly during this extraction process to stabilise the networks. Medalia *et al*. (2002) have applied cryoelectron tomography to unextracted cells, in which case filament networks are visible only after complex image-processing regimes.

Here, the extraction/fixation protocol is the same as for negative staining, except that postfixation seems not to be neccessary.

4. *Cryo Plunging of Specimen Grids*

The objective of plunge freezing is to obtain a well distributed, quick frozen specimen in a homogeneously thin layer of vitrified ice uncontaminated with frost. For this, the blotting regime is critical. The amount of blotting required can be sample/buffer dependent so this might have to be adapted for dif-

ferent preparations. It is important to remain consistent but because in some cases even subsecond differences in blotting times can cause variability with ice thickness, differences between grids are unavoidable. In order to counter this, make several grids at each session.

If a washing buffer is to be used, it is important that it is at the same osmolarity as the cell culture media, as the integrity of the cells could be compromised.

Steps

1. Set up your workspace with all the required tools close at hand prior to freezing (Fig. 3). It is important to have good light and it is useful to have additional light (e.g., equipoise lamp) that can be positioned facing toward the grid for observing the blotting step when plunging. Frost in the liquid nitrogen and ethane can be a source of contamination on your grids so always try to minimise exposure to water vapour. Always keep the nitrogen containers sealed with lids and do not breathe onto the nitrogen or ethane surfaces. Precool all tools that come into contact with the grid or grid box, as they may heat the specimen, causing cubic or hexagonal ice to form.

2. Set up the plunger. Check the alignment of the forceps in the plunging arm so that the forceps will plunge the grid a few millimetres below the surface of the liquified ethane. Do not adjust the drop height so that the grid gets too near the base of the ethane container as ethane ice forms there, which will damage the grid if it comes into contact with it.

3. Put on eye protection or a face shield and fill the polystyrene container with liquid nitrogen. Also fill the portable transfer dewar with liquid nitrogen and submerge the polypropylene conical tube into this. Keep a lid on the transfer dewar to minimise contamination.

4. Precool the small ethane container with liquid nitrogen. Make sure all liquid nitrogen is removed from the inside of the container as it interferes with the liquifying of the ethane. Place one of the grid storage boxes into the liquid nitrogen.

5. Place the pipette tip from the ethane supply into the bottom of the small ethane container and slowly open the regulator valve. After a short time, the ethane gas will start to condense on the bottom of the container. This is normally accompanied by a high-pitched squeal. Keeping the pipette tip just below the surface of the liquid ethane and gently moving it around the inner walls allow the level to rise to the top of the ethane container. Keep the tip moving in the ethane so that the tip does not ice up and block. Do not allow the liquid ethane to spill over into the nitrogen. You can use a double-walled ethane container with a small gap between the walls to avoid this. *Note: Liquid ethane can cause serious burns if it comes into contact with your skin or eyes so always exercise caution and regulate the ethane to a slow and gentle flow.*

6. After a short time, the liquified ethane will start to solidify. If this happens, you must deice by inserting the pipette tip into the ethane. Slowly open the ethane gas supply as you do not want to splash ethane into the nitrogen. Gently move the pipette tip around the edges of the ethane container until the ethane liquifies.

7. Pick up a grid by the edge, sample side up with forceps. The samples are usually washed briefly, immediately prior to plunging. Cut a piece of Parafilm, place on a flat surface, and apply 2 × 50-µl drops of washing buffer, e.g., prewarmed PBS. Keeping the grid in the tweezers, blot the grid side on with a piece of filter paper. Apply the grid, sample side down to the surface of the washing droplet, blot, and place onto the second drop. Remove the grid; a droplet from the washing buffer should remain on the grid surface. Place the forceps into the clamp of the plunger arm with the sample (and droplet) facing towards you.

8. Using a strip of the Whatman qualitative No. 1 filter paper, carefully blot the surface of the grid. Use a visual assessment to roughly gauge the degree of blotting (Fig. 4): When first touching the grid, the filter paper will pull onto the droplet by surface tension and you should see the outline image of the grid, through the paper. Once most of the surface liquid is adsorbed

FIGURE 3 Working setup as typically used for freeze plunging. (1) Gaseous ethane bottle, (2) regulator valve with Tygon tubing and pipette tip, (3) full face shield, (4) filter paper strips, (5) polystyrene box for liquid nitrogen, (6) small container (sitting on an aluminum block) for condensing ethane, (7) plunger arm, fixed with a pair of forceps holding the grid (arrowhead), (8) 50-ml conical tube for grid box storage, (9) tools (fine and large forceps, screwdrivers), and (10) sample transport dewar. For details, see text.

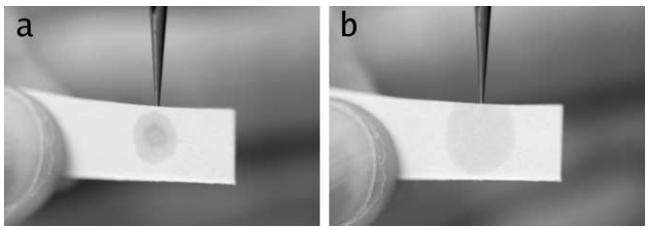

FIGURE 4 Blotting of the grid immediately prior to freeze plunging: (a) when first touching the grid and droplet with a strip of filter paper, an outline of the grid is clearly visible through the paper and (b) as the liquid is absorbed by the filter paper, the droplet imprint will increase in diameter until most of the liquid is removed from the grid surface. The grid outline will disappear and the paper will pull away from the grid. At this moment, plunge the grid immediately. For more details, see text.

by the paper you will reach a point where the grid outline will suddenly disappear and the paper will also pull away. This is the time when the sample should be plunged rapidly into the ethane. Waiting even a few seconds after the pull-away point can result in excess removal of liquid, sample damage, and drying.

9. While keeping the grid under the surface of the ethane, remove the tweezers from the plunging arm. Raise the plunging arm away from the tweezers. Carefully remove the tweezers and grid from the ethane and immediately hand plunge the grid into the liquid nitrogen. Make sure the grid stays under the cold nitrogen vapour cloud to keep it from warming and frosting. This can be achieved by having sides on the polystyrene liquid nitrogen box that are higher than the top level of the liquid ethane container.

10. Transfer the grid, keeping it submerged under the liquid nitrogen, into one of the storage slots in the grid box. After all samples have been loaded, close the lid firmly with a screwdriver. Place the liquid nitrogen-filled transfer dewar containing the polypropylene tube close to the plunger. Using a large pair of tweezers, quickly transfer the grid box from the plunger into the tube. Screw the lid onto the tube.

11. Move the tube and grid boxes holding the samples into a long-term storage dewar. As long as the nitrogen is kept topped off the grids can remain here for long periods (sometimes years) without deterioration until you are ready to view them in the microscope. We totally dry our dewars once a year with a stream of dry nitrogen gas to remove any frost that may accumulate with time. Transfer all grids to another frost-free container while drying the original dewar.

5. Electron Microscopy

Steps

1. Using a precooled pair of large tweezers, remove the grid storage box holding the frozen grids and place in a liquid nitrogen-filled transfer dewar.

2. At the electron microscope, fill the anti-contaminator and cryo-blade dewars.

3. If the cryo holder has been pumped (it is recommended to continually vacuum pump the cryo holder dewar when not being used), remove it from the vacuum pump stand. Insert the holder carefully into the loading station. Connect the cable for temperature measurement between the cryo holder and the temperature controller.

4. Remove the clip ring from the cryo holder with the clip ring tool.

5. Put on eye protection or a face shield.

6. Fill the specimen holder dewar and the loading station dewar with liquid nitrogen. After each filling with liquid nitrogen, replace the Plexiglas lid on the loading station dewar to minimise frost contamination. Keep the cap on the holder dewar, as it keeps the outer sides from cooling. Make sure you open and close the tip shutter as you cool as this prevents the shutter from jamming. You will need to keep topping off the level so that nitrogen sits just below the tip of the sample holder. Wait for the temperature controller to read at least –160°C before loading your sample.

7. Placing the transfer dewar as close as possible to the specimen holder dewar, rapidly transfer the grid box holding the frozen specimens to the specimen holder dewar. Use a precooled pair of large tweezers.

8. Precool a screwdriver and loosen the lid of the grid box.

9 Check that the level of the liquid nitrogen is just below the tip of the holder; cool a pair of No. 5 forceps and the clip ring tool in the loading station dewar.

10. Using the forceps, remove a grid from the grid box. Making sure you keep the grid within the cold nitrogen vapour, place the grid into the recess in the cryo holder tip. Centre the grid in the recess and fasten with the clip ring. Immediately close the holder tip shutter.

11. Replace the Plexiglas lid on the loading station dewar and lift the loading station and cryo holder and place onto the console desk of the microscope. We protect the console surface from nitrogen damage with a metal splash guard (Gowen and Burger, 1998).

12. Cycle the roughing pump on the microscope so that the pump lines to the microscope sample stage (e.g., compustage on an FEI machine) are under good vacuum before insertion of the cryo holder.

13. Remove the holder from the loading station and carefully insert into the microscope stage for preevacuation. (It can be useful to pretilt the stage to around –60° so that the holder dewar neck is positioned at "3 o'clock" instead of "6 o'clock" to lessen nitrogen spillage when the holder is introduced.) Wait for the vacuum to be restored and then insert the holder all the way into the microscope.

14. Allow at least 20 min for the temperature to stabilise and the vacuum to recover. Temperature variations cause the holder to drift. Connect the cable from the temperature controller and monitor the temperature. During the transfer the temperature should not warm to above about –150°C. Normally the holder will stabilise at around –180°C. Do not leave the cable connected to the holder as this can also cause drift effects.

6. Image Acquisition

To reduce damage when viewing cryo grids in the electron microscope, it is necessary to have low-dose software, which allows you to minimise the electron dose applied to the sample. Always use the beam blanker when you are not observing the specimen. The microscope should be well aligned and set up for low-dose conditions. To lower the electron intensity at the sample, you can use a small condenser aperture, small spot size, and low emission settings.

Steps

1. Once the holder temperature has equilibrated and drift minimised, the grid should be screened at low magnification (usually at around 3000× or less) to find promising cell areas for imaging.

2. Images can be acquired either digitally using a CCD camera system or taken onto plate film. If required, images on plate film can be scanned digitally using a suitable high-resolution film scanner.

3. In some instances, micrographs may appear to have an uneven intensity difference across the image due to local variations in ice thickness. Applying a high-pass filter helps even the intensity, which allows subsequent contrast adjustments to be made more easily (Fig. 1b).

C. Correlation with Light Microscopy

For situations in which the cell shape cannot be visualised clearly (e.g., frozen hydrated samples) or in which the function cannot be deduced solely from the morphology but only from a marker protein (e.g., GPF-VASP for protruding lamellipodia; Rottner *et al*., 1999), correlative light and electron microscopy on the same cell can be very helpful in establishing the structure–function link as discussed earlier. This correlation should be relatively straightforward for the classical methods, where cells are grown directly on glass coverslips with etched finder patterns; appealing examples can be found in Svitkina and Borisy (1999). For negative staining and cryo-EM, where cells are grown directly on grids, finder grids with indexed grid holes have to be used (Fig. 5).

Steps

1. Prepare grids with a Formvar or a holey carbon film as described earlier; use H2 Ni finder grids instead of hexagonal 200 mesh grids to be able to relocate your samples.

2. Spread cells on these grids. For correlative LM/EM, it is essential to remove any air bubbles trapped in the mesh by preincubating them in water as described previously.

3. Mount the grids individually for light microscopy; how exactly this is done depends on the setup and the cell line used. As a general guide, care has to be taken to (1) mount the grid flat (e.g., by using the method described earlier with coverslips with a hole drilled in the center), (2) have the cells as close to the objective to avoid problems with focus, and (3) mount grids with a carbon film upside down for epifluorescence to avoid loss of intensity. Two sample setups using petri dishes with a glass coverslip at the bottom are shown in Fig. 2c.

4. For the light optical observation of the cells, there are several possibilities available: (1) living cells in phase contrast, (2) living cells expressing a fluorescent protein (conjugate), and (3) fixed cells after staining with a fluorescent probe. For the latter method, it is essential to minimise the damage of the substructure

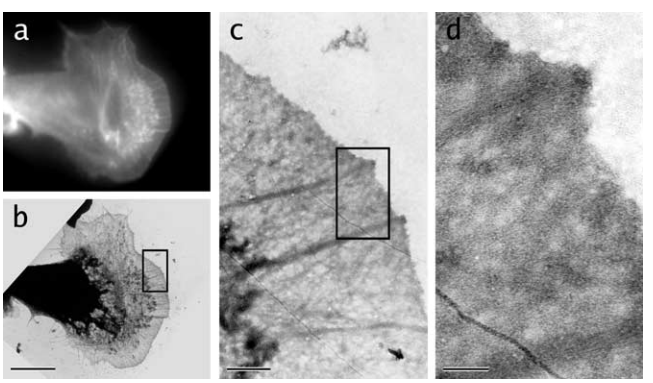

FIGURE 5 Correlative light and electron microscopy as demonstrated by a B16 mouse melanoma cell: (a) Cell stained with fluorescently labelled phalloidin and visualised by epifluorescence microscopy, (b) corresponding view of the same cell afer negative staining, (c and d) higher magnification insets of the previous images. Bars (a and b) = 10 µm, (c) = 1 µm, (d) = 250 nm.

by prolonged incubation steps in the staining protocol, e.g., fluorescently labelled phalloidin can be included directly in the fixative.

5. Record the position of each cell observed in a map of the finder grid; such a map for the H2 grids is provided by the authors at ftp://cellix.imba.oeaw.ac.at/Protocols/findergrids.zip.

6. Proceed as described earlier for negative staining or cryo-EM.

Acknowledgments

The authors thank Johanna Prast, Institute of Molecular Biology, Salzburg, for her continuous support, Marietta Schupp, Photo Lab, EMBL Heidelberg, for her contributions (Figs. 3 and 4), and Johann Diendorfer, Institute of Molecular Biology, Salzburg, for his help with producing coverslips with holes. Correlative Light and Electron Microscopy of the Cytoskeleton

Tatyana M. Svitkina and Gary G. Borisy

I. INTRODUCTION

Light and electron microscopy (EM) each have certain advantages and limitations for the investigation of the cytoskeleton. Light microscopy allows for kinetic observations in living cells; in particular, modern fluorescence technology affords imaging of single fluorophores with high temporal resolution. However, the spatial resolution of light microscopy is limited to approximately 200–300 nm. In contrast, EM affords high spatial resolution but provides only static images and is not applicable to living cells. Correlative light and EM is a way to combine the advantages of these two techniques and link cell structure and dynamics. The main strategy of this approach is to follow the dynamics of a living cell by time-lapse imaging and subsequently analyze the same cell by EM.

The success of correlative microscopy imposes special demands at both the light and the EM level. To allow for precise identification of corresponding features in EM, light microscopy should be performed at the highest possible resolution and allow for the fast cessation of dynamic cellular processes at the end of the light microscopic observation. For fluorescence light microscopy, issues of photodamage and phototoxicity become more critical, as EM is able to reveal damage not recognizable at the light microscopic level. The key requirements for the EM procedure are quality, reproducibility, and yield. Yield is essential because detailed observation of individual living cells places a high investment of investigator time and effort in a single cell. If the efficiency of recovering a cell for EM is low, the investment is lost.

For studying cytoskeletal components, we have chosen detergent extraction–chemical fixation–critical point drying (CPD)–TEM of platinum replicas as a basic procedure (Svitkina *et al.*, 1995) because it allows a higher yield of successful results in comparison with alternative approaches. In the replica EM technique, the contrast is created by shadowing of three-dimensional (3D) samples with metal. The purpose of detergent extraction is to uncover the cytoskeleton and make it available to metal coating, yet to preserve it in its entirety as in the living state (Lindroth *et al.*, 1992). The composition of the extraction solution is designed to achieve this goal. Chemical fixation provides cell structures with physical resistance against subsequent harsh procedures. Our fixation procedure includes consecutive treatment with glutaraldehyde, tannic acid, and uranyl acetate. Drying exposes surfaces of the specimen for vacuum shadowing. The preservation of 3D structure is the major concern during EM processing, especially during drying. The main source of problems is the surface tension at the liquid–gas interface, which will crush fragile cytoskeletal structures if the interface passes through the sample. CPD is a simple and reliable technique, which circumvents this problem and preserves the complicated 3D structure of the cytoskeleton (Ris, 1985).

This article describes the procedure for preparation of cells for correlative EM after light microscopic observation, as well as the combination of this approach with immunostaining. Direct comparison of

living cells and platinum replicas of their cytoskeletons using a number of different markers demonstrated that our protocol does not introduce alterations in the distribution of several cytoskeletal elements (Svitkina *et al*., 1997; Svitkina and Borisy, 1998, 1999).

II. MATERIALS AND INSTRUMENTATION

1. Leibovitz's L-15 medium (Cat. No. 21083-027, GIBCO)
2. Phosphate-buffered saline (PBS) (Cat. No. 21-040-CV, Cellgro)
3. PIPES (Cat. No. 528131, Calbiochem)
4. Triton X-100 (Surfact-Amps X-100, Cat. No. 28314, Pierce)
5. Polyethelene glycol (PEG), MW 40,000 (Cat. No. 33139, Serva Electrophoresis) or MW 35,000 (Cat. No. 81310, Fluka)
6. Taxol (paclitaxel) (Cat. No. T7402, Sigma)
7. Phalloidin (Cat. No. P2141, Sigma)
8. Glutaraldehyde (Cat. No. 01909-10, Polysciences)
9. Sodium cacodylate (Cat. No. C-4945, Sigma)
10. Tannic acid (Cat. No. 1764, Mallinckrodt)
11. Uranyl acetate (J. T. Baker Chemical Co.)
12. $NaBH_4$ (Cat. No. 213462, Aldrich)
13. Bovine serum albumin (BSA) (Cat. No. A-7906, Sigma)
14. Tween 20 (Cat. No. X251-7, J. T. Baker Chemical Co.)
15. Tris (Trizma–HCl) (Cat. No. T-3253, Sigma)
16. Gold-conjugated antibodies (Cat. Nos. G-7777, G-3779, G-5527, G-5652, Sigma; Cat. Nos. 115-215-068, 111-215-144, Jackson Immunoresearch Laboratories)
17. Ethanol (Cat. No. 15055, Electron Microscopy Sciences)
18. Molecular sieves (4 Å, 8–12 mesh) (Cat. No. M514-500, Fisher)
19. Hydrofluoric acid (HF) (Cat. No. A147-1, Fisher)
20. 35-mm tissue culture dishes
21. 22 × 22-mm glass coverslips (No. 1.5)
22. Silicon vacuum grease (Dow Corning)
23. Gold wire (Cat. No. 21-10, Ted Pella)
24. Platinum wire (Cat. No. 23-10, Ted Pella)
25. Tungsten wire (Cat. No. 27-3-20, Ted Pella)
26. Carbon rods (Cat. No. 61-13, Ted Pella)
27. Platinum loop
28. Diamond pencil
29. Double-sided tape (Scotch)
30. Lens tissue (Kodak)
31. Post-It notes
32. Electron microscopic grids (e.g., Cat. No. G50, Ted Pella)
33. Locator grids (e.g., 7GC200, Ted Pella)
34. Holders for critical point drying. We use a homemade holder (Fig. 1), which consists of a wire basket that fits the size of the critical point dryer's chamber. Such a design is good for correlative EM, as it is not very demanding to the shape and size of the coverslips. For noncorrelative EM, commercially available holders can be used (e.g., Cat. No. 8762 for coverslips under 7 mm or Cat. No. 8766 for round 12-mm coverslips, Tousimis).
35. 50-ml glass beakers
36. Homemade scaffolds (Fig. 1)
37. Stirrer bars (Fig. 1)
38. Fine tip forceps
39. Dissection microscope
40. Critical point dryer. We use a semiautomatic Samdri-795 or manual Samdri PVT-3 (Tousimis). Other devices have also been used successfully. As a source of liquid CO_2, we use high-quality carbon dioxide (Cat. No. CD 4.8SE, Praxair); however, lower quality grades can also be used if they have low water and carbohydrate contamination. The cylinder should be equipped

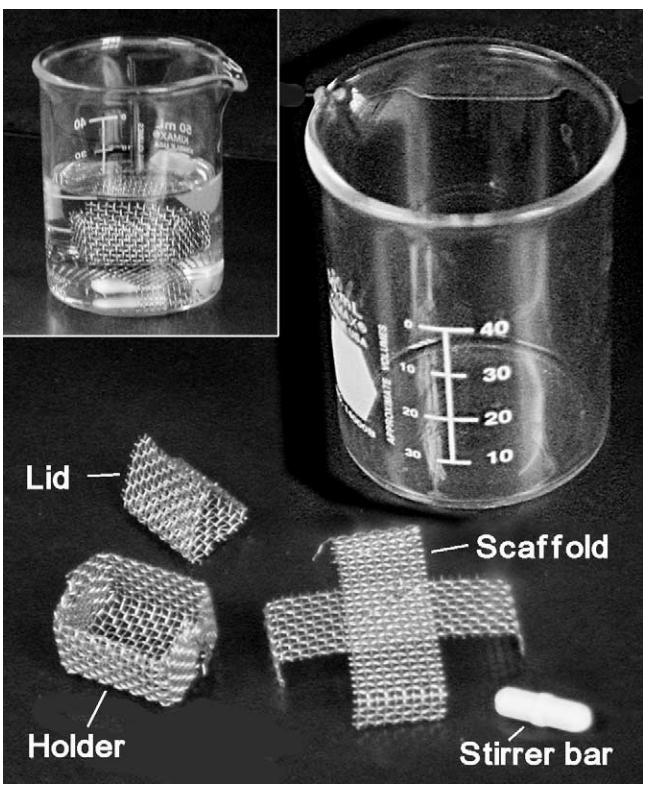

FIGURE 1 Accessories for CPD: specimen holder, lid for holder, and scaffold are made from stainless steel mesh. Inset shows an assembled set.

with water and oil absorbing filter (Cat. No. 8781/82A, Tousimis).

41. Vacuum evaporator. We use an Edwards 12E1 evaporator equipped with rotary and diffusion pumps, power supply, rotary stage, and thickness monitor (Cat. No. QM-311, Kronos, Inc.). Newer models with suitable configuration are now available from Edwards and other sources.

III. PROCEDURES

A. Cell Culture and Light Microscopy

Details of cell cultivation, introduction of fluorescent probes into cells, and light microscopic observation are beyond the scope of the present description. However, certain issues are specific to correlative microscopy and these we discuss.

1. Preparation of Locator Coverslips

Locator coverslips are helpful in facilitating the relocalization of the same cells. The reference marks on the coverslip should be recognizable by both light and EM. We use glass coverslips coated with a thin layer of gold through a locator grid (Fig. 2). Cells are selected within clear uncoated glass areas corresponding to the solid parts of the locator grid.

Steps

1. Put one or two locator grids in the center of 22 × 22-mm glass coverslip. Place coverslips onto the stage of vacuum evaporator.
2. Evaporate gold onto coverslips using a procedure suitable for the particular evaporator. Thickness of gold coating may vary. It should be clearly visible by eye as a purple transparent deposit. Avoid too thick of a coating because the gold may then contaminate the clear glass area under the grid.
3. Remove grids, collect coverslips, and bake them at 160°C overnight. Baking prevents dislocation of gold grains by cultured cells.

2. Cultivation chambers

The locator coverslips may be mounted into different types of chambers suitable for cell cultivation and observation. For correlative microscopy, the chamber design should allow for the fast exchange of media. In our laboratory, we typically mount coverslips onto the hole in the bottom of 35-mm tissue culture dishes (Fig. 2) and perform light microscopic observations in open dishes. Compared to any kind of sealed chambers, this design allows faster processing for EM and decreases the lapse between light and EM observations. To prevent pH shift in the medium during observation, we use Leibovitz's L-15 medium.

Steps

1. Smooth edges of the hole before mounting the coverslip.
2. Apply a thin line of vacuum grease along the edges of the hole inside the dish. Use the minimum amount of grease required to prevent leakage to avoid complications during subsequent excision of the central area of the coverslip with the desired cells (see later).
3. Mount the coverslip with gold-coated side facing upward. Press firmly along the line of grease until grease forms a continuous clear circle around the hole without any air bubbles, which may cause

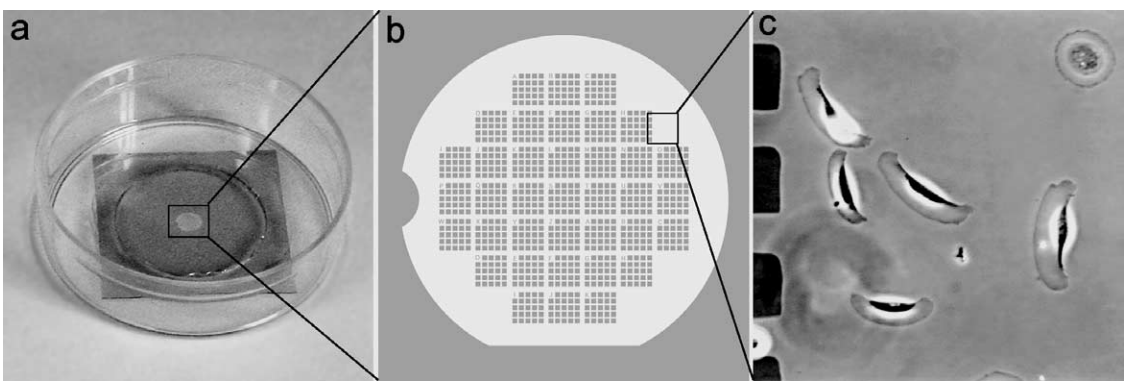

FIGURE 2 Locator coverslip for relocalization of cells. (a) A 22 × 22-mm coverslip was coated with gold through the locator grid and mounted over the 18-mm hole in a 35-mm plastic dish with vacuum grease. (b) Diagram showing gold pattern on the coverslip. (c) Xenopus epidermal keratocytes growing on a coverslip with gold pattern. The imaged area corresponds to the box in b. Dark squares at left are gold islands corresponding to holes in the locator grid, which was used for shadowing.

leakage. Sterilize with UV irradiation before plating cells.

B. Preparation of Cytoskeletons

1. Extraction and Fixation

Solutions

1. *PEM buffer:* 100 m*M* PIPES, pH 6.9; 1 m*M* $MgCl_2$; and 1 m*M* EGTA. To make 100 ml of 2× stock solution, mix ~70 ml of distilled water and 6 g of PIPES. While stirring, add concentrated KOH to this turbid solution until it almost clears. Add 76 mg of EGTA and 200 µl of 1 *M* stock of $MgCl_2$, adjust pH to 6.9 with 1 *N* KOH, and complete with distilled water until 100 ml. Store at 4°C.
2. *Extraction solution:* 1% Triton X-100, 4% PEG in PEM buffer supplemented (optionally) with 2 µM taxol and/or 2 µ*M* phalloidin. To make 10 ml, combine 5 ml of 2× PEM, 1 ml of 10% Triton X-100, 400 mg PEG, and complete to 10 ml with distilled water. Stir for ~10–15 min until dissolved. Store at 4°C and use within 1 week. Add 10 µl of 2 m*M* taxol (paclitaxel) in dimethyl sulfoxide (DMSO) or 10 µl of 2 m*M* phalloidin in DMSO before use.
3. *Sodium cacodylate stock:* 0.2 *M* Na-cacodylate, pH 7.3. Dissolve 4.28 g of Na-cacodylate in distilled water, adjust pH to 7.3 with HCl, and complete until 100 ml. Store at 4°C.
4. *Glutaraldehyde:* 2% glutaraldehyde in 0.1 *M* sodium cacodylate, pH 7.3. To make 10 ml, combine 5 ml of 0.2 *M* Na-cacodylate, 0.8 ml of 25% glutaraldehyde, and 4.2 ml of distilled water. Store at 4°C and use within a week.
5. *Tannic acid:* 0.1% aqueous tannic acid. Weigh 10 mg of tannic acid and dissolve in 10 ml of distilled water. Use within a day.
6. *Uranyl acetate:* 0.1% aqueous uranyl acetate. Weigh 10 mg of uranyl acetate and dissolve in 10 ml of distilled water. Remove undissolved salt by centrifugation. Store at room temperature.

Steps

1. Using a pipette or vacuum aspirator, aspirate culture medium from a dish while it is on the microscope stage. Immediately, but gently, add prewarmed to 37°C PBS with a wide-mouth pipette or pour from a beaker.
2. Aspirate PBS and immediately add extraction solution at room temperature. Exchange of media should be fast to avoid cell damage by drying and to decrease the lapse between living and lysed state of the cell. Incubate for 3–5 min at room temperature.
3. Rinse cells with PEM buffer at room temperature two or three times, 1 min each.
4. Add glutaraldehyde and incubate for at least 20 min at room temperature. If necessary, specimens can be refrigerated at this stage and stored for several days in sealed dishes to prevent drying. Before further processing, specimens should be brought back to the room temperature. If immunogold staining is required, it is best to do it after this step (see later).
5. Remove glutaraldehyde and add tannic acid. No washing is necessary before application of tannic acid, although it is not contraindicated. Incubate for 20 min at room temperature, rinse in three changes of distilled water, and incubate for 5 min in the last change of water.
6. Remove water and add uranyl acetate; incubate for 20 min at room temperature. Replace uranyl acetate with distilled water.

2. Immunostaining

Platinum replica EM is compatible with immunoelectron cytochemistry and with the use of colloidal gold as an electron-dense marker. The difference in electron density between colloidal gold particles and the platinum layer is sufficient for detection of the immune reaction in coated specimens. The specific protocol for immunogold EM depends on the primary antibody and its ability to recognize antigen under particular conditions. Initial evaluation of the quality of staining at the light microscopic level is strongly recommended. For most antibodies we use immunostaining after glutaraldehyde fixation because it provides the best structural preservation. We do not recommend using formaldehyde or methanol fixation, as they are generally inadequate for preserving structure at the EM level.

Solutions

1. *Sodium borohydrate $NaBH_4$:* 2 mg/ml $NaBH_4$ in PBS. Weigh 20 mg of $NaBH_4$ and complete with 10 ml of PBS. Use immediately.
2. *Primary antibody:* The required antibody concentration should be estimated in preliminary light microscopic experiments. For EM, use the antibody concentration that produces a bright immunofluorescence signal.
3. *Buffer A:* 20 m*M* Tris–HCl, pH 8.0, 0.5 *M* NaCl, and 0.05% Tween 20. To make 100 ml of 5× stock solution, dissolve 1.2 g Trizma–HCl and 14.5 g NaCl in distilled water. Adjust pH to 8.0. Add 250 µl of Tween 20 and complete to 100 ml with distilled water. Store at 4°C.

4. *Buffer A with 0.1% BSA:* To make 50 ml, combine 10 ml of 5× stock buffer A, 50 mg BSA, and 40 ml of distilled water. Store at 4°C for 1 month.
5. *Buffer A with 1% BSA:* To make 10 ml, combine 2 ml of 5× stock buffer A, 100 mg BSA, and 8 ml of distilled water. Store at 4°C for 1 month.
6. *Secondary antibody:* Colloidal gold-conjugated secondary antibody diluted 1:5 to 1:10 in buffer A with 1% BSA.

Steps

1. After glutaraldehyde fixation (step 4 of Section III.B.1), wash specimens with PBS (two brief rinses and 5 min in the third change of PBS).

2. Quench specimens by $NaBH_4$ for 10 min at room temperature. Shake off bubbles occasionally. Rinse in PBS (three changes, 5 min in the last change).

3. Remove PBS from the dish. Using cotton swabs, wipe the buffer from the dish and coverslip, leaving wetness on only a small (approximately 5–7 mm) central area containing the locator grid. However, be careful to avoid allowing this area to dry out. Apply primary antibody and incubate for 30–45 min at room temperature. Rinse in PBS (three changes, 5 min in the last change).

4. Rinse once in buffer A with 0.1% BSA. Wipe coverslips as before and apply colloidal gold-conjugated antibody. Incubate overnight at room temperature in a sealed dish in moist conditions. Rinse in buffer A containing 0.1% BSA (three changes, 5 min in the last change) and fix with glutaraldehyde, tannic acid, and uranyl acetate (steps 4–6 in the Section III.B.1) (Fig. 3).

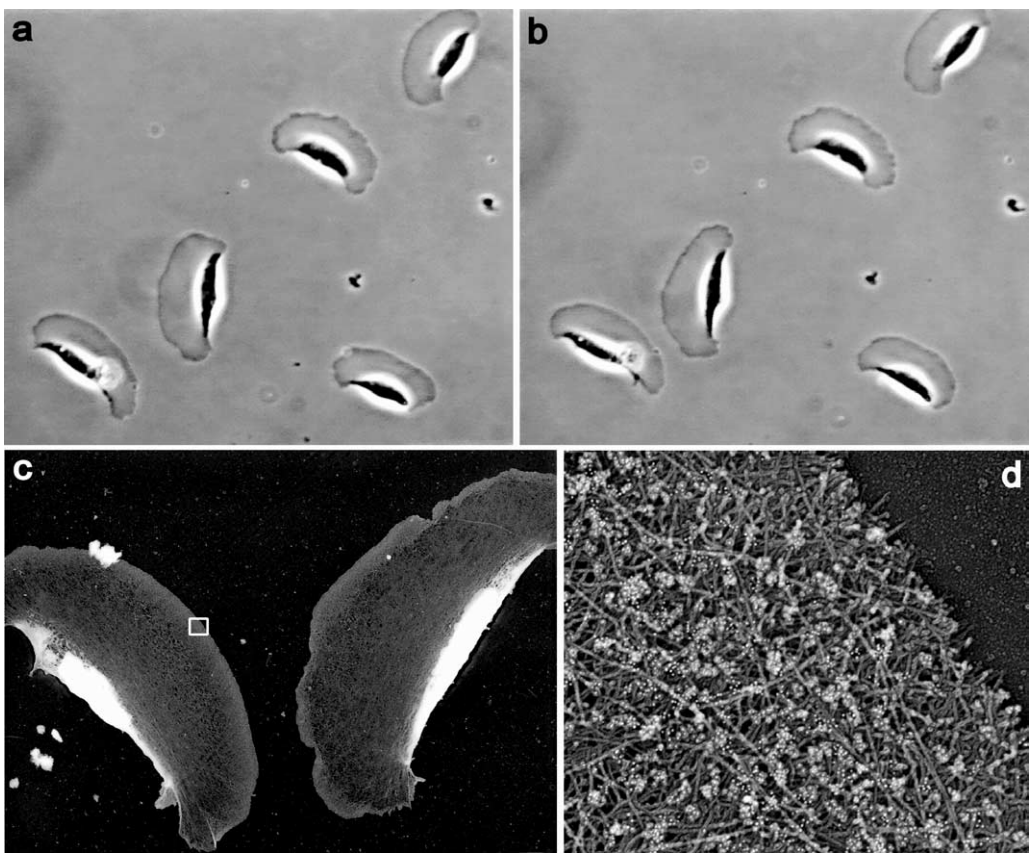

FIGURE 3 Correlative immuno-EM of locomoting Xenopus keratocytes. The phase-contrast time-lapse sequence was acquired with 6-s intervals. The two phase-contrast images shown (**a** and **b**) were taken 1 min apart. After acquisition of the second image, cells were immediately extracted, fixed with glutaraldehyde, quenched with $NaBH_4$, stained with rabbit antibody to Xenopus ADF/cofilin and secondary antibody conjugated with 10 nm colloidal gold, and processed for platinum replica EM. Low-magnification EM (**c**) shows two keratocytes from lower left corner in **b**. Boxed region from **c** is enlarged in **d**. Gold particles appear as white dots because of the reversed contrast of the original image. Distribution of gold particles demonstrates that ADF/cofilin is excluded from the narrow zone at the extreme leading edge (Svitkina and Borisy, 1999).

C. Critical Point Drying

The idea of the technique is to remove liquid from the sample without exposing it to high surface tension. This is accomplished by bringing the sample to or above the critical point, a specific combination of temperature and pressure for the particular liquid where phase boundary does not exist. For most liquids, including water, the critical point is too extreme to be of practical use. In contrast, carbon dioxide has a critical point at 31.3°C and 1072 psi (72.9 atm) and represents the fluid of choice for CPD of biological samples. Because CO_2 has limited solubility in water, ethanol (or acetone) is used as a transitional liquid, which is miscible with either water or CO_2 in any proportion.

Solutions

1. *Graded ethanols:* 10, 20, 40, 60, or 80% ethanol. Combine 10, 20, 40, 60, or 80 ml of 100% ethanol, respectively, with distilled water until a final volume of 100 ml. Allow to stand until all air bubbles are gone and temperature is equilibrated to ambient conditions.
2. *Uranyl acetate in ethanol:* 0.1% uranyl acetate in 100% ethanol. Weigh 25 mg of uranyl acetate, add 25 ml of 100% ethanol, and stir until dissolved. Use within several hours.
3. *Dried ethanol:* 100% ethanol dried over molecular sieves. Wash molecular sieves free of dust with multiple changes of water and bake overnight at 160°C. After cooling, combine 50–100 g of molecular sieves with 500 ml of 100% ethanol. Seal with Parafilm. Store at room temperature for 2 days before use.

Steps

1. If oil objectives are used for light microscopy, remove the immersion oil from the bottom of the coverslip with cotton swabs soaked in ethanol.

2. Detach the coverslip from the bottom of a dish and quickly transfer it into a wide petri dish filled with water. Some silicone grease will remain on the lower side of the coverslip. Lightly press the coverslip down to the petri dish bottom, making sure that the grease does not contaminate the central area of the coverslip containing the cells of interest. Using a diamond pencil, cut off the greased edges of the coverslip to obtain a clean central part of the coverslip with the locator grid. It is helpful to use a razor blade as a guide for making cuts. Use a sharp diamond pencil and avoid glass crumbs around the cutting area to prevent coverslips from shattering. The optimal size of the central piece of the coverslip containing cells of interest is 6–8 mm.

3. Place a specimen holder for CPD into a wide beaker filled with water. Cut lens tissue into pieces fitting the size of the holder. Put a sheet of lens tissue on the bottom of the holder and place the coverslip onto it. Load other coverslips one after another using additional lens tissue sheets as spacers. The lens tissue separates samples and helps retain a layer of liquid over the specimens during transfer. Keep the whole stack loose to allow for easy liquid exchange. Up to 12 coverslips with dimensions 6–8 mm may be processed simultaneously. Overloading the holder makes the exchange of liquid difficult. Loosely put on a lid to prevent the last sheet of lens tissue from flowing away.

4. Put a stirrer bar into a 50-ml beaker. Place a wire scaffold over the stirrer. Add 10% ethanol in amount sufficient to cover the specimen holder when it is placed onto the scaffold. Quickly transfer the holder from water to the beaker (Fig. 1). Stir for 5 min.

5. Prepare another beaker with 20% ethanol in the same way. Transfer the holder and stir for 5 min. Repeat this step for 40, 60, 80, and twice for 100% ethanol. Two sets of beaker/stirrer bar/scaffold are sufficient for dehydration, as they can be alternated in successive steps.

6. Place holder into uranyl acetate in ethanol and incubate for 20 min. No stirring is necessary.

7. Prepare beaker as in step 4 but with 100% ethanol, put in holder, and stir for 5 min. Repeat once more. Then, repeat twice with dried 100% ethanol.

8. Fill the specimen chamber of the CPD device with dried 100% ethanol. The amount of ethanol in CPD chamber should be just enough to cover the holder. Place holder into the chamber. If the CPD device is equipped with a stirrer, put a stirrer bar underneath the holder. Close chamber and open CO_2 cylinder and inlet valve on CPD machine. Cool down the chamber to 10–15°C to keep CO_2 in liquid state. Maintain this temperature until the heating step. Turn stirrer on. Wait until the chamber is filled.

9. Slightly open exhaust valve for 30 s, keeping inlet valve open to allow for exchange of ethanol to liquid CO_2. If the CPD is not equipped with a stirrer, shake CPD manually during this step. Close exhaust valve. Repeat this washing step 10 times every 5 min to remove all traces of ethanol. Keep the level of CO_2 always above the upper edge of the holder.

10. Turn off stirrer and cooler. Turn on heat to raise pressure and temperature above the critical point for CO_2, usually until 40°C and 1200 psi (80 atm). Then slowly release pressure by opening exhaust valve. A fast decrease of pressure may cause condensation of CO_2 back to liquid and ruin the dried samples.

11. Remove holder from the CPD chamber and immediately place it in a sealed desiccated container.

Dried cells can easily absorb moisture from air, which will introduce artifacts similar to those created by air drying. Therefore, it is important to keep samples inside the desiccator until ready for replica preparation.

D. Platinum Replica Preparation

1. Shadowing

Rotary shadowing at an angle creates a gradation of metal thickness depending on the 3D organization of the sample. Platinum is a popular metal for vacuum evaporation because it represents a reasonable compromise between melting temperature and grain size. Platinum grains deposited onto the specimen surface are not cohesive and can be distorted easily during subsequent manipulations or under the electron beam. The platinum layer should be stabilized by carbon, which forms a cohesive film and thus keeps platinum grains in place. The specific procedures for platinum and carbon shadowing depend on the particular device. Therefore, we describe just some important issues.

Mounting of Coverslips

Rotation of the stage will dislodge samples if they are not secured on the stage. Double-sided sticky tape is too strong and does not permit easy and safe detachment of samples, especially after being in vacuum. To make a mild mounting tape, sandwich double-sided tape between sticky parts of two Post-It notes so that the glued side of paper sheets is exposed. Cut off the unglued paper. To mount coverslips, attach a piece of this sandwich to the evaporator stage and attach coverslips. It is sufficient to attach just a corner or an edge of a coverslip to the paper. It is helpful to put marks on the paper to identify samples.

Platinum Shadowing

Source. Our system is set up to use platinum wire wrapped around tungsten wire as a source for shadowing. When voltage is applied, the tungsten wire heats up and the platinum melts and evaporates. Alternatively, platinum-carbon pellets can be used as a source. An advantage of pellets is that they produce finer grains.

Angle. Low angles from the source of platinum to the specimen stage provide high contrast, but reveal only the very top of the sample. High angles result in less contrast but allow for better visualization of the cell interior because of increased penetration of metal into deep hollows. We found a 45° angle to be most useful for whole mount cytoskeleton preparations, as it represents a reasonable compromise between contrast and penetration.

Thickness. Thicker coating reduces resolution but increases contrast and 3D range. In our experiments, a platinum layer thickness of 2.5–2.8 nm produces a fair balance between contrast and resolution. Thickness of the platinum layer can be monitored using a quartz crystal-based thickness monitor. If a thickness monitor is not available, approximate settings of the system may be established by a trial-and-error approach. In our system, 10 mg of platinum wire completely evaporated from a distance of 100 mm produced a layer of the required thickness.

Carbon Coating

Evaporate carbon at 90° with or without rotation to obtain a 2- to 3-nm-thick layer. The thickness of carbon is not very critical, as it is practically transparent to electrons. However, a layer thicker than 10 nm becomes visible and interferes with the formation of image. Too thin a carbon layer may be insufficient for stabilization and result in crumbling of replicas after the removal of coverslips.

2. Mounting of Replicas on Grids

Platinum-carbon replicas of the cytoskeleton are released from the coverslip with hydrofluoric acid. If cell areas that are going to be studied are thin and have low electron density, such as lamella in spread cultured cells (Fig. 4), removal of glass is sufficient. For thick and electron-dense cell regions, organic components can be depleted with a strong oxidative agent, e.g., household bleach. For correlative microscopy, it is easier to select the area of interest while the replica is still attached to the coverslip. After drying and metal coating, cells have good contrast and are visible even under the dissection microscope.

Solutions

1. *Hydrofluoric acid:* ~5% HF in water. Concentrated (49%) HF solution is supplied by the manufacturer in a plastic dispenser bottle. Work with HF in a fume hood, use plastic (not glass) dishes and pipettes, and wear gloves. Store in the fume hood. Prepare working solution in a 12-well dish (diameter 25 mm) before use. Drip several drops (~0.5–1.0 ml) of concentrated HF from the dispenser bottle into a well. Add distilled water almost to the top.
2. *0.01% Triton X-100:* Take 10 ml of distilled water and add 10 µl of 10% Triton X-100. Store at room temperature not longer than 1 month.

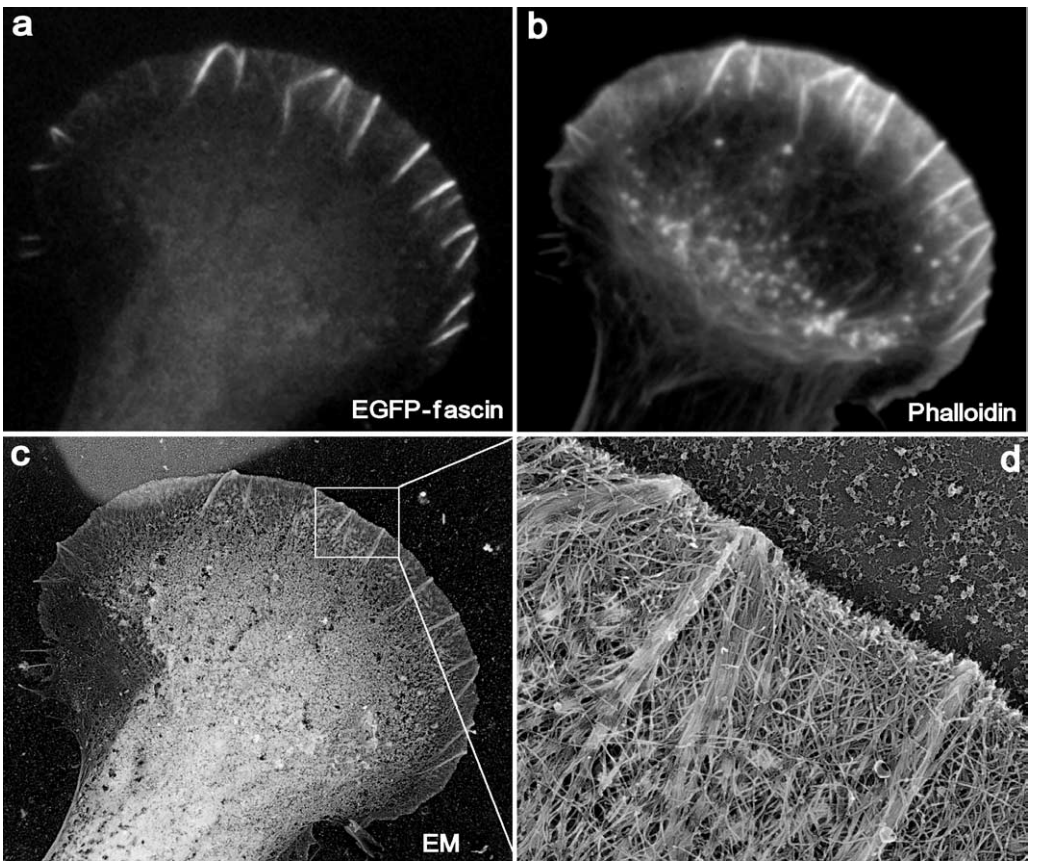

FIGURE 4 Correlative fluorescence and EM of mouse melanoma B16F1 cells. The cell shown was transiently transfected with EGFP-fascin (a) and, after extraction and fixation, stained with Texas red phalloidin (b). After EM processing, the same cell was identified at low magnification (c). Lighter background at the upper left corner is due to gold evaporation through a hole of the locator grid. (d) High-magnification view shows actin filament organization in the leading lamellipodium. Several microspikes within lamellipodium, which are enriched in fascin (see a), have actin filaments organized into tight bundles, whereas lamellipodium between microspikes, which is depleted in fascin, has actin filaments organized into the dendritic network.

3. *Clorox bleach (optional):* Dilute in distilled water 1:2 to 1:10 depending on the strength of bleach.

Steps

1. Using mild double-sided tape (see earlier discussion), immobilize a platinum-carbon-coated coverslip on the bottom of a wide petri dish with cell side up, leaving a region of interest unobstructed.

2. Under the dissection microscope, localize cells of interests using the gold pattern. Make cuts with any sharp tool (razor blade or needle) in the platinum-carbon layer around cells of interest. Continue the cuts up to the edges of the coverslip to facilitate release of the selected area from the rest of the replica.

3. Float a coverslip with cell side up onto the surface of the HF in a well. In minutes the coverslip falls down, leaving the replica floating. After separation of the coverslip, the replica falls apart along the introduced cuts. The pattern of the gold shadowing on the resulting pieces helps identify the desired replica fragments.

4. Fill another well with distilled water (~5 ml). Add ~2 µl of 0.01% Triton X-100. Using a platinum loop, transfer replica pieces onto the surface of water. Traces of detergent in the water prevent the replica from breaking apart, which usually happens because of a large difference in surface tension between HF and water. An overdose of detergent, however, can result in shrinkage and drowning of replicas. Wait 1 min or more.

5. Fill a well with distilled water. Transfer replica pieces onto the surface of pure distilled water. Wait 1 min or more. For electron-dense specimens, go through additional steps:

   a. Fill a well with diluted household bleach and transfer replica pieces onto its surface. Wait 2

to 20 min depending on the cell type and the strength of the bleach.

b. Fill another well with distilled water. Transfer replica pieces onto the surface of pure distilled water. Wait 1 min or more. Repeat the step once more.

Note: Depletion of organic material by bleach is not compatible with immunogold labelling, as it causes the degradation of antibody associated with colloidal gold particles and consequent elimination of gold label from replicas.

6. Mount replica pieces onto Formvar-coated EM grids with lower side of the replica to the Formar film. Use low mesh or single slot grids to reduce the chance of getting the region of interest onto a grid bar. Control under the dissection microscope is helpful for the targeted mounting of replicas on grids.

7. Examine samples in TEM. (Fig. 4) Present images in inverse contrast (as negatives) because it gives a more natural view of the structure, as if illuminated with scattered light.

IV. PITFALLS

1. *Cytoskeletal elements look distorted.* Most likely, extraction was not performed gently enough. Explore different extraction conditions comparing living and extracted cell images.

2. *Cytoskeletal elements look fragmented.* One possible reason is inadequate fixation. Check your reagents for fixation capacity. Another possibility is photodamage or phototoxicity during live cell imaging. Decrease light and/or exposure and close field diaphragm as much as possible to the area of interest during sequence acquisition.

3. *Cytoskeletal elements look flattened and fused with each other.* This is an artifact introduced by surface tension (Ris, 1985). To avoid this problem, always keep a layer of liquid over the specimens when they are transferred from one solution to another. The problem may also occur because of incomplete replacement of water to ethanol or ethanol to liquid CO_2 during dehydration and CPD. Any remaining traces of ethanol or water dry out below their critical points after CPD and ruin the structure. Another possible reason is high ambient humidity. Dried samples are highly hygroscopic. They may absorb moisture from air, which will subsequently dry below the critical point. Loading the evaporator is a step when samples are most susceptible to humidification, as it takes some time to get coverslips from the CPD holder and mount them onto the evaporator stage. Keep humidity in the room as low as possible. In our experience, it is sufficient to keep it under 50%. Also, prepare evaporator for coating in advance, before getting samples from the desiccator.

Immunoelectron Microscopy

CHAPTER

29

Immunoelectron Microscopy with Lowicryl Resins

Arvid B. Maunsbach

I. INTRODUCTION

Lowicryl resins (Carlemalm *et al.*, 1982) are well suited for electron microscope immunocytochemistry of formaldehyde or formaldehyde/glutaraldehyde-fixed tissues. They provide both good ultrastructural preservation and preserve to a large extent tissue antigenicity. Embedding in acrylic resins is carried out at low temperature either by progressively lowering the temperature during dehydration and resin infiltration or by cryofixation followed by freeze substitution and UV polymerization at low temperature (Carlemalm *et al.*, 1985; Schwarz and Humbel, 1989; Sitte *et al.*, 1989). Thin Lowicryl sections can then be cut on an ultramicrotome at room temperature and labeled with the appropriate primary antibody, which can then be detected with a secondary antibody (or protein A) coupled to colloidal gold particles. A number of labeling principles and protocols have been developed and discussed (Griffiths, 1993; Larsson, 1988; Newman and Hobot, 1993; Roth, 1986; Schwarz and Humbel, 1989). The protocol given here represents a standard procedure we have applied in our laboratory for the localization of several different antigens at the ultrastructural level (Maunsbach and Afzelius, 1998).

Unstained sections of biological tissues show low contrast when examined in a transmission electron microscope. Almost invariably immunogold-labeled sections are therefore contrasted, or stained, by interaction with one or more solutions containing salts of heavy metals, such as uranyl acetate (Watson, 1958) and/or lead citrate (Reynolds, 1963). The staining is unspecific from a chemical point of view, but serves to enhance the contrast of cellular components in the microscope. In immunogold electron microscopy, section staining is important in order to determine the precise relationship between colloidal gold particles and tissue fine structure.

II. FREEZE SUBSTITUTION IN LOWICRYL HM20

A. Materials and Instrumentation

Liquid nitrogen
Lowicryl HM20 kit (Agar Scientific Ltd) containing HM20 resin (monomer E), HM20 cross-linker (D), HM20 initiator (C)
Water-free methanol (CH_3OH, Merck 106007)
Silica gel beads (Sigma S7651)
Sodium chloride (NaCl, Merck 106404)
Sodium dihydrogen phosphate monohydrate ($NaH_2PO_4 \cdot H_2O$, Merck 106346) Disodium hydrogen phosphate dihydrate ($Na_2HPO_4 \cdot 2H_2O$, Merck 106580)
Sucrose ($C_{12}H_{22}O_{11}$, BHD, Analar 102745c)
Uranyl acetate dihydrate [$(CH_3COO)_2UO_2 \cdot 2H_2O$, Polysciences 21477]
Fine forceps with cold-insulated shaft
Polyethylene capsules with pyramid shape and hinged lids for low-temperature embedding (BEEM capsules G360-1, Agar Scientific Ltd., Figs.1a and 1b)

Copyright 2006, Elsevier Science (USA).
All rights reserved.

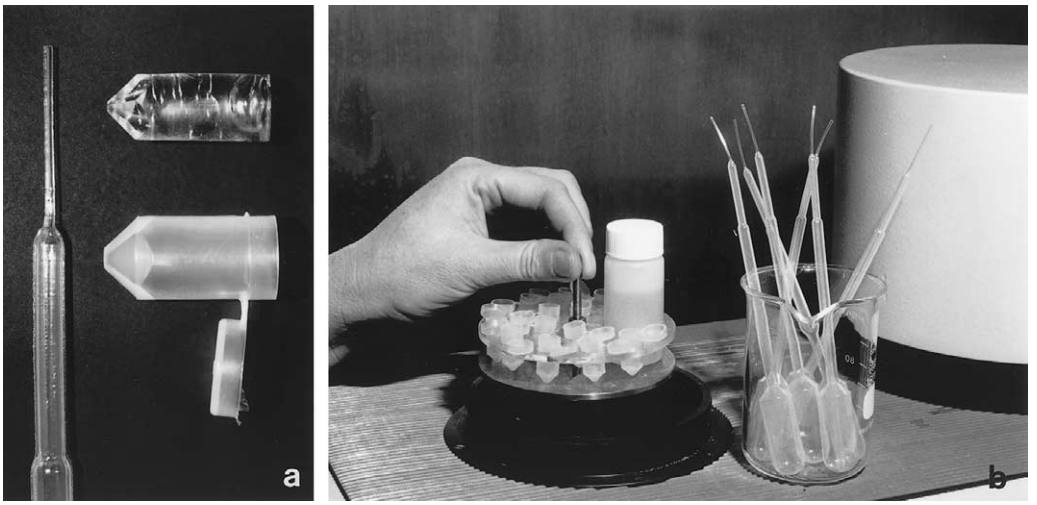

FIGURE 1 Freeze substitution in HM20. (a) Polyethylene Pasteur pipette with elongated tip (left), polyethylene capsule with hinged lid (lower right), and polymerized Lowicryl block after removal of capsule (upper right). (b) Holder with polyethylene capsules and vial for substitution fluid before being lowered into the Balzers FSU 010 freeze-substitution apparatus. To the right beaker with polyethylene Pasteur pipettes and to the far right part of a UV polymerization unit.

Disposable beaker for mixing resin
Polyethylene Pasteur pipettes with extended fine tips (Figs. 1a and 1b)
Freeze-substitution apparatus with temperature regulation between –85 and 0°C

Freeze-substitution unit (Leica EM AFS, Leica AG) or equivalent (e.g., home-made) freeze-substitution apparatus

UV lamp for polymerization with 350-nm UV light (if not built into the freeze-substitution apparatus)

B. Procedure for Freeze Substitution in Lowicryl HM20

Freeze substitution and Lowicryl HM20 embedding combine good preservation of cell ultrastructure and antigenicity (Figs. 2 and 4). For immunoelectron microscopy the tissue is usually fixed for short time with 4 or 8% paraformaldehyde or 4% paraformaldehyde plus 0.1% glutaraldehyde but is never postfixed in osmium tetroxide. The tissue blocks should not exceed 1.0 mm in any direction.

Solutions

Lowicryl HM20: To make about 20 g, gently mix 3.0 g cross-linker D and 17.0 g monomer E. Bubble dry nitrogen gas into the mixture for 5 min to exclude O_2, which inhibits Lowicryl polymerization. Add 0.1 g initiator C and mix gently until it is dissolved. Avoid making air bubbles.

Methanol: Dry the methanol with silica gel.

Methanol: Lowicryl HM20 mixtures in proportions 2 : 1 and 1 : 1

2.3 M sucrose in phosphate-buffered saline (PBS): To make 100 ml solution, weigh out 0.038 g sodium dihydrogen phosphate monohydrate, 0.128 g disodium hydrogen phosphate dihydrate, 0.877 g sodium chloride, and 78.7 g sucrose. Add water to about 95 ml. Use a magnetic stirrer until the sucrose is dissolved, or heat the solution in a microwave oven. Adjust pH if necessary to pH 7.2 and fill up with water to 100 ml.

0.5% uranyl acetate in methanol: To make 100 ml, dissolve 0.5 g uranyl acetate dihydrate in methanol to a total of 100 ml

Steps

1. Transfer the tissue directly from the aldehyde fixative to the buffered sucrose solution. Place the specimens in the sucrose for 2 h or overnight. Stir the solution occasionally to improve infiltration.

2. Cryofix the tissue in liquid nitrogen. Hold the specimen gently with the fine forceps provided with the cold-insulated handle. Remove excess sucrose solution. Move the forceps quickly into the liquid nitrogen and shake until bubbling stops. The specimen is either left temporarily for immediate processing or is placed in a tube for further storage in liquid nitrogen for weeks or months. Carefully follow the safety regulations when handling liquid nitrogen.

3. Transfer the frozen tissue very rapidly with a precooled forceps from the liquid nitrogen to the 0.5%

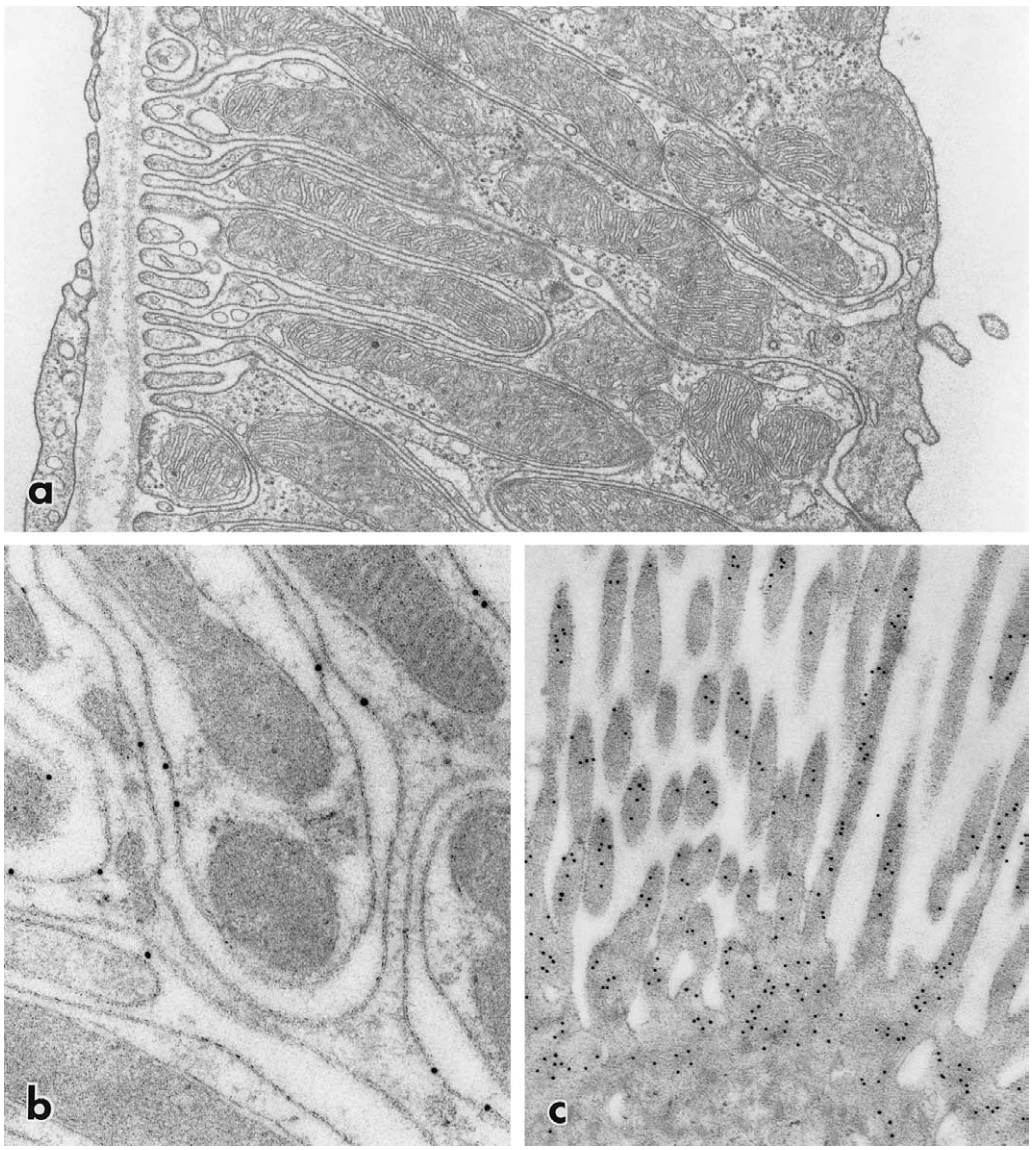

FIGURE 2 Electron micrographs of kidney cells following freeze substitution and embedding in Lowicryl HM20. (a) Thick ascending limb of the renal distal tubule perfusion fixed with 4% paraformaldehyde containing 0.4% picric acid. Cell fine structure is well preserved and cellular membranes stand out in good contrast. Magnification 30,000×. (b) Immunolocalization of Na,K-ATPase to basolateral membranes of distal tubule in rat kidney cortex. Perfusion fixation with 4% paraformaldehyde. The monoclonal antibody against the α subunit of Na,K-ATPase was detected with goat antimouse IgG on 10 nm colloidal gold. Note the precise association between basolateral membranes and gold particles. Magnification 80,000×. From Maunsbach (1992). (c) Apical part of proximal tubule cell in kidney perfusion fixed with 2% paraformaldehyde. Intracellular actin was immunolabeled with rabbit antiactin antibody, which was then detected with goat antirabbit IgG on 10 nm colloidal gold. Magnification 40,000×.

uranyl acetate/methanol solution, which is kept at –85 to 90°C in the capsules in the freeze-substitution unit. During this transfer great care must be taken not to warm the specimen. For this purpose the vessel with the liquid nitrogen must be placed immediately adjacent to the substitution unit.

4. Withdraw most of the substitution fluid from the capsules with a polyethylene Pasteur pipette. The diameter of the tip of the Pasteur pipette should be smaller than the size of the specimens, as the specimens are difficult to observe at this step and may otherwise be removed. Fill the capsules with temperature-equilibrated substitution fluid of the same composition as before and increase the temperature to –80°C for 24 h. Adjust the following rinsing and infiltration periods to suit regular working hours.

5. Rinse the specimens with one change of methanol at –80°C for about 20 h.

6. Rinse the specimens with one change of methanol at –70°C for 8 h.

7. Rinse the specimens three times with methanol at –45°C over a period of 20 h.

8. Infiltrate the specimens with a 2:1 mixture of methanol and Lowicryl HM20 at –45°C for 6 h.

9. Infiltrate the specimens with an 1:1 mixture of methanol and Lowicryl HM20 at –45°C for about 4 h.

10. Infiltrate the specimens with pure Lowicryl HM20 at –45°C for 8 h with three changes.

11. Infiltrate the specimens with pure Lowicryl HM20 at –45°C for 24 h.

12. Fill up the capsules completely with fresh Lowicryl HM20 and close the lids. Polymerize with indirect UV light at –45°C for 48 h.

13. Increase the temperature to 0°C and continue UV polymerization for 48 h. The specimens are now ready for conventional ultramicrotomy at room temperature.

C. Comments

1. Chemicals used during dehydration and embedding resins are toxic (mutagenic, allergenic, and, in some cases, perhaps carcinogenic) and should be handled with adequate safety precautions (Ringo *et al.*, 1982). Work in a well-ventilated hood and use gloves. Note that resins can penetrate most types of gloves within a short time.

2. Cryosectioning and freeze substitution followed by Lowicryl embedding are alternative procedures for immunoelectron microscopy. Immunolabeling of sections from freeze-substituted and Lowicryl embedded tissues usually provides a very high precision in probe localization (Figs. 2b, 2c, and 4). A major advantage is that Lowicryl blocks are stable and can be stored at 4 or –20°C and repeatedly resectioned and immunolabeled.

D. Pitfalls

1. It is necessary that the specimen is frozen ("cryofixed") without ice crystal formation, which will leave holes in the tissue. Tissue blocks should therefore be small and completely infiltrated with 2.3 *M* sucrose before freezing.

2. In order to avoid recrystallization of the tissue water during freeze substitution it is important that the temperature of the specimen does not increase when it is tranferred to the freeze-substitution unit or in connection with fluid changes. Fluids must be properly temperature equilibrated in the freeze-substitution unit before being added to the samples.

3. The size of the specimen for freeze substitution must be small to allow complete removal of water and of methanol. Remaining water or methanol will result in soft Lowicryl or holes in the tissues. Substitution times may require adjustment according to the tissue studied.

4. Capsules should be completely filled with Lowicryl and the lids closed to exclude oxygen during polymerization. Oxygen interferes with polymerization, which results in soft blocks.

III. IMMUNOLABELING OF LOWICRYL SECTIONS

A. Materials and Instrumentation

Disodium hydrogen phosphate dihydrate ($Na_2HPO_4 \cdot 2H_2O$, Merck 106580)
Sodium dihydrogen phosphate monohydrate ($NaH_2PO_4 \cdot H_2O$, Merck Cat. No. 1.06346)
Glycine ($C_2H_5NO_2$, Sigma G-7126)
Bovine serum albumin, BSA (fraction V, Sigma Cat. No. A 4503)
Skimmed milk powder (Merck 115363)
Gelatin (from cold water fish skin, Sigma Cat. No. G7765)
Polyethylenglycol 20,000
Goat antirabbit IgG (or other appropriate antibodies) conjugated to 10-nm (or, e.g., 5 nm) colloidal gold particles
Protein A conjugated to 10-nm colloidal gold particles (alternatively)
Uranyl acetate dihydrate [$(CH_3COO)_2UO_2 \cdot 2H_2O$, Polysciences 21477]
Trisodium citrate dihydrate [$(C_6H_5Na_3O_7 \cdot 2H_2O)$, Merck 106448]
Lead(II) nitrate [Pb $(NO_3)_2$, Merck 107398]
Sodium hydroxide (NaOH, Merck 106498)
Sodium azide (NaN_3, Merck 106688)
Sodium chloride (NaCl, Merck 106404)
Redistilled water
Parafilm (or dental wax)
Nickel grids (necessary for immunolabeling)
Fine forceps, antimagnetic
Disposable Pasteur pipettes
Filter paper, 0.2 µm
Magnetic stirrer

B. Procedures

Ultrathin sections of aldehyde fixed and Lowicryl HM20 or K4M-embedded tissue can be used reproducibly and conveniently for immunocytochemical detection of many antigens. Depending on the sensitivity of the antigen, the tissue is fixed either with

formaldehyde or mixtures of formaldehyde and glutaraldehyde (see article by Maunsbach). The Lowicryl-embedded tissue can be stored, preferably in the cold room, and resectioned repeatedly.

C. Solutions

a. *Rinsing solution*: phosphate-buffered saline (0.01 *M* sodium phosphate buffer containing 0.15 *M* sodium chloride) with 0.1% skimmed milk (or 1% BSA). Mix 0.7 ml 0.2 *M* $NaH_2PO_4 \cdot H_2O$ and 1.8 ml 0.2 *M* $Na_2HPO_4 \cdot 2H_2O$, 0.438 g NaCl. Adjust pH to 7.4 and fill up with redestilled H_2O to make 50 ml. Add 0.05 g milk powder (or 0.5 g BSA).

b. *Preincubation solution*: Rinsing solution with 0.05 *M* glycine. Add 0.375 g glycine per 100 ml rinsing solution.

c. *Solution for dilution of primary antibody*: Same as rinsing solution if skimmed milk is used. If BSA is used, the concentration should be 0.1%.

d. *Solution for dilution of gold-conjugated antibodies (or protein A)*: Same as solution for dilution of primary antibody but with the addition of 1.5 ml of 1% polyethyleneglycol and 0.555 g fish gelatine per 25 ml solution (to reduce aggregation of gold particles). The stability of solutions for preincubation, rinsing, and dilution of antibodies can be improved by adding 0.02 *M* sodium azide (NaN_3).

D. Steps

1. Place nickel grids with ultrathin sections of Lowricryl section side down on small drops (each 10–25 µl of the appropriate solutions). Place the drops on a piece of Parafilm (Fig. 3), and transfer the grids successively between drops. At each transfer most of the previous solution is removed by quickly touching the grid to a filter paper, but without allowing the grid to dry. Transfer the grid between the following drops.

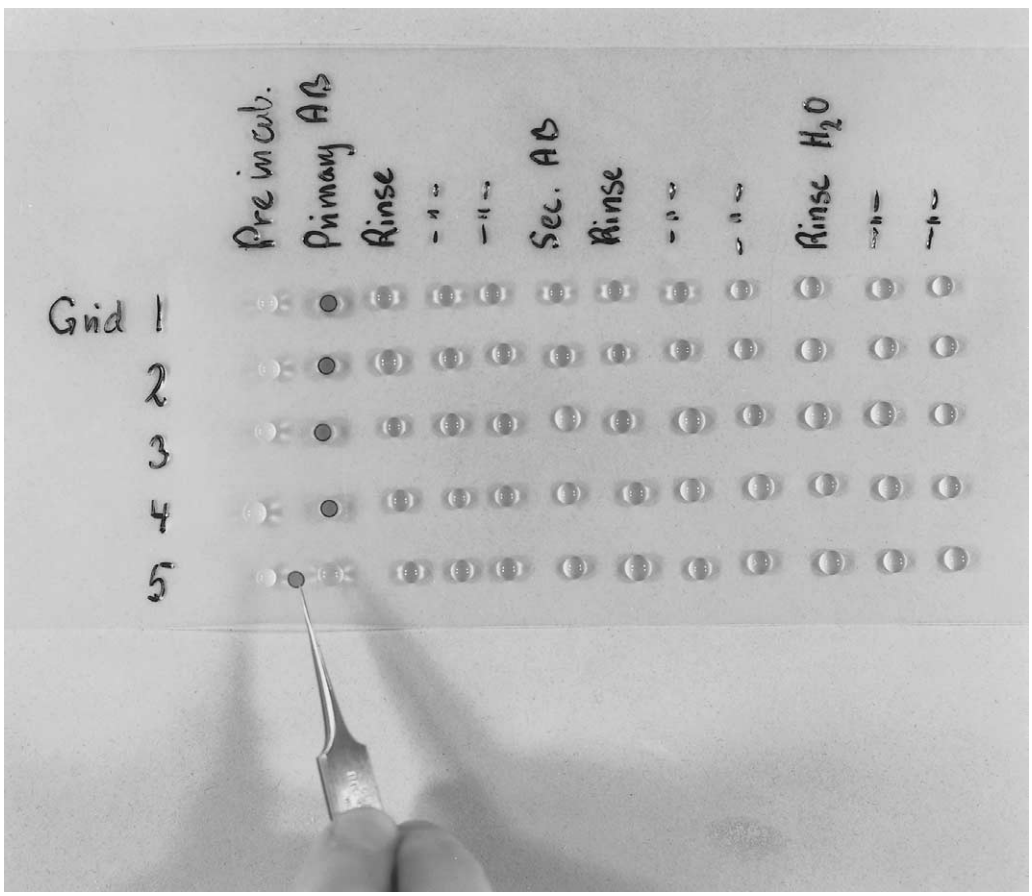

FIGURE 3 Immunolabeling of five grids on series of drops containing preincubation solution, rinsing solution, solution with primary antibodies (AB), rinsing solution, secondary antibody, and distilled water. The grids are transferred between the drops with a forceps. In practice, all drops are not placed at the Parafilm from the very beginning but are applied shortly before use.

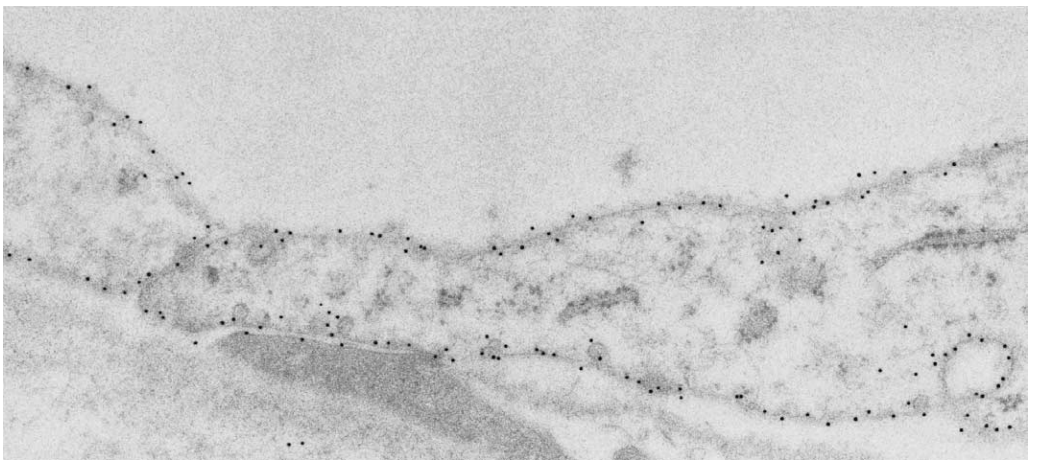

FIGURE 4 Cells in descending thin limb of inner medulla of human kidney labeled with polyclonal antibody against aquaporin-1 water channel. The tissue was fixed in paraformaldehyde and freeze substituted and embedded in Lowicryl HM20. The primary antibody was visualized with goat antirabbit IgG conjugated to 10-nm colloidal gold particles. Cells exhibit strong labeling of both apical and basal plasma membranes. Magnification 60,000×. From Maunsbach *et al.* (1997) with permission.

2. Preincubation solution for 15 min at room temperature.

3. Solution of primary antibody diluted 1:50–1:5000 depending on the characteristics of antigen and antibody. Incubate for 1 h at room temperature or at 4°C overnight in a moist chamber.

4. Rinsing solution three times, 5 min on each drop.

5. Secondary antibody (or protein A) conjugated to colloidal gold. Dilution 1:50–1:200, incubation time 1 h at room temperature.

6. Rinsing solution three times, 5 min on each drop.

7. Rinsing water (redestilled and filtered) 5 min on each of three drops.

8. Remove excess water with filter paper and air dry the grid.

9. Stain for 10 min on saturated and filtered uranyl acetate (see Section IV).

10. Rinse with 15–20 drops of redestilled water.

11. Dry the grid, which is now ready for examination in the electron microscope. Additional contrast can be obtained with lead citrate staining (see Section V).

E. Comments

Electron microscope immunocytochemistry requires careful control of the experimental conditions. As initial steps make sure that the antigen is present in the tissue by immunoblotting and that the antibody specifically and selectively recognizes the appropriate antigen. It is also advisable to apply immunofloures-cence and/or immunoperoxidase for overall localization of the antigen. Initial controls at the electron microscope level should include replacement of the primary antibody with buffer solution, with nonimmune serum, and, if possible, with preimmune serum from the same animal that produced the antibodies. Also, if at all available, the antibody should be absorbed with purified antigen before use (usually preabsorbed overnight in the cold room). Some common pitfalls or problems in electron microscope immunocytochemistry are listed next.

F. Pitfalls

1. Abscence of labeling or weak labeling may be due to destruction of antigen during fixation and/or embedding. Suggested remedies include (a) decrease concentration of fixative, (b) use formaldehyde alone instead of glutaraldehyde or glutaraldehyde/formaldehyde, (c) shorten fixation time, (d) use another type of Lowicryl, e.g., K4M, (e) use smaller gold particles (e.g., 5 nm; see Giberson and Demaree, 1994), (f) utilize different etching procedures (see Matsubara *et al.*, 1996; Maunsbach and Afzelius, 1998), (g) reduce the salt concentration in the solutions used for dilution of antibodies, and (h) turn to the alternative method of cryoultramicrotomy and labeling of cryosections. Make sure by Western blotting that the antigen exists in the tissue.

2. Abscence of labeling or weak labeling may also be due to no or low affinity of the antibody to the antigen, poor titer of the antibody, or the antibody is aged, has been stored improperly, or frozen and thawed repeatedly.

3. High backgound labeling may be due to insufficient rinsing of the grid during labeling or too high titer of the primary antibody or secondary antibody (or protein A).

4. High background staining may, in some cases, be prevented by increasing the sodium chloride concentration or the pH in the incubation solution for the primary antibody and/or the secondary gold conjugate. If the tissue contains high concentrations of free aldehyde groups following glutaraldeyde fixation, the sections should be exposed to 0.5 m*M* ammonium chloride before incubation.

5. Clustered colloidal gold particles may be observed if the primary antibody has aggregated or if the colloidal gold conjugate has aggregated and needs to be renewed.

IV. SECTION STAINING WITH URANYL ACETATE

Uranyl acetate staining (Watson, 1958) results in a uniform but fairly weak general staining of cellular components. There is a slight preference for increased contrast of DNA and RNA.

A. Materials

Uranyl acetate dihydrate [$(CH_3COO)_2UO_2 \cdot 2H_2O$, Polysciences 21477]
Trisodium citrate dihydrate [$(C_6H_5Na_3O_7 \cdot 2H_2O)$, Merck 106448]
Lead(II) nitrate [Pb $(NO_3)_2$, Merck 107398]
Sodium hydroxide (NaOH, Merck 106498)
Redistilled water
Parafilm (or dental wax)

B. Solution

Saturated solution of uranyl acetate: To make 100 ml, dissolve 7.69 g of uranyl acetate in 100 ml distilled water and stir for some hours. Store the solution at room temperature in the dark in a closed glass vial covered by aluminium foil.

C. Steps

1. Filter a suitable volume of stain solution through a 0.2-µm filter immediately before use.
2. Place a series of drops on the Parafilm with a clean Pasteur pipette. The number of drops should equal the number of grids to be stained (Fig. 5a).
3. Place the grids section side down on the drops with an interval of 1 min between each grid.
4. Leave the grids on the stain drops for 10 min.
5. Remove and rinse the grids in the same order they were placed on the staining solution. Lift the grid with a clean forceps and hold vertically. Jet slowly a stream of 15–20 drops of filtered water from a Pasteur pipette onto the grid (Fig. 5b).

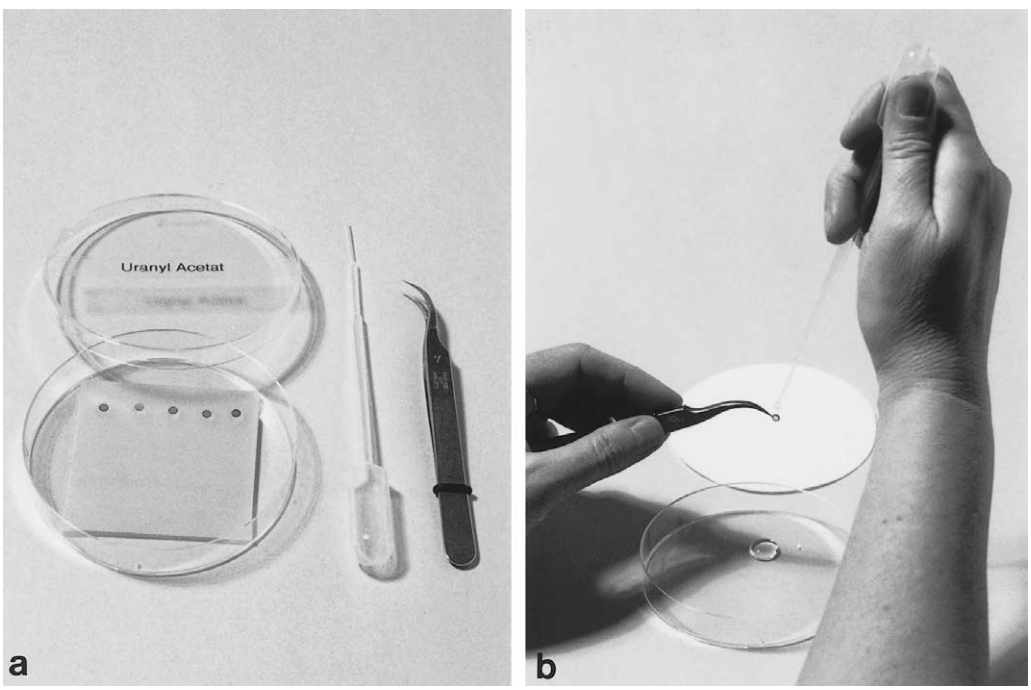

FIGURE 5 (a) Equipment for section staining with uranyl acetate (or lead citrate). With a clean Pasteur pipette, stain drops are placed on dental wax in a petri dish. (b) Rinsing of a stained grid with a stream of drops of redistilled water. Immediately afterward the edge of the grid is touched to filter paper to remove excess water.

6. Remove the last drop of water by touching the edge of the grid with a filter paper. Place a small piece of filter paper between the legs of the forceps to remove additional excess water.

7. Let the grid dry for 5 min while still clamped in the forceps.

V. SECTION STAINING WITH LEAD CITRATE

Lead staining (Reynolds, 1963) is used when a general survey of tissue ultrastructure is aimed at and gives a general increase in contrast of membranes and other tissue components.

A. Materials and Instrumentation

Trisodium citrate dihydrate [$(C_6H_5Na_3O_7{\cdot}2H_2O)$, Merck 106448]

Lead (II) nitrate [Pb $(NO_3)_2$, Merck 107398]

Sodium hydroxide (NaOH, Merck 106498)

Redistilled water

Parafilm (or dental wax)

B. Solution

Lead citrate solution: Boil about 50 ml redistilled water for 5 min in a beaker. Dissolve 1.33 g lead nitrate and 1.76 g sodium citrate in 40 ml of the boiled water. Stir the solution rapidly for 30 min with a magnetic stirrer or shake vigorously. The solution should become clear by adding 8.0 ml 1 *N* sodium hydroxide freshly prepared with redistilled water. Fill up to 50 ml with water. The solution should stand for 2 or 3 days before use. Store the solution at 4°C and use within 6–12 months.

C. Steps

1. Before use, filter 10 ml stain solution through filter paper into a 10-ml cylinder. Close the cylinder with a piece of Parafilm. Handle the cylinder carefully without shaking.

2. Take out the stain solution with a clean Pasteur pipette. Remove the solution from the middle of the cylinder to avoid precipitate.

3. To stain four grids, place four drops of stain on Parafilm. Do not stain more than four grids at a time, as a precipitate forms easily on the surface of the drops. (Surface precipitate can be minimized by placing NaOH tablets around the grids, but in practice we do not find this necessary.)

4. Immediately place the grids on the drops with an interval of half a minute.

5. Stain the sections for 2 min (range: 15 s to 20 min depending on desired contrast).

6. Remove the grids with intervals of half a minute with fine forceps. Hold the forceps with the grid vertically and squeeze gently from a Pasteur pipette 10–15 drops of redistilled water on the grid (Fig. 5b).

7. Touch the grid with filter paper and leave the grid to dry in the forceps with a small piece of filter paper between the legs of the forceps.

D. Pitfalls

1. Dirt may contaminate the sections unless all glassware, Parafilm, and pipettes are *meticulously clean* and all solutions filtered.

2. Excess rinsing of lead stain may gradually remove stain and may, in addition, make the staining more susceptible to beam damage in the electron microscope.

3. The surface of lead citrate drops rapidly acquires surface contamination due to interaction with carbon dioxide in the air. This will appear as contamination on the section. Therefore, drops must be placed on the Parafilm immediately before the grids are applied to surface of the drops.

E. Comments

The chemicals used for section staining are toxic and should be handled with adequate safety precautions. Staining should be performed in a well-ventilated hood, using gloves. The results of section staining depend in part on the preceding fixation of the tissue and on the characteristics of the embedding medium as well as the protocol of the staining process. Thus if uranyl acetete staining is carried out at 60°C instead of room temperature, contrast is greatly enhanced, which may reveal new tissue components but overstain others. Various instruments and procedures have been described for simultaneous staining of many grids, e.g., a full grid box. The author has never found these procedures helpful.

CHAPTER

30

Use of Ultrathin Cryo- and Plastic Sections for Immunocytochemistry

Norbert Roos, Paul Webster, and Gareth Griffiths

I. INTRODUCTION

The identification of cell surface and intracellular molecules for light and electron microscopic observations is an important technique for studying their location and function in the cell. A wide range of methods has therefore been developed to identify and localize molecules at the subcellular level. The term "immunocytochemistry" describes a set of methods that use molecules with specific binding ability to other molecules. The binding molecules, called "affinity markers," are diverse, but have in common the ability to specifically bind, and thus identify, other molecules. One special class of affinity markers that are widely used are antibodies. These are produced naturally by mammals and can be produced to bind to a large range of molecules, called antigens (e.g., a protein in the cell membrane) for indirect visualization. The antibodies are applied to specimens so that they will bind to its target molecules. For examination in an electron microscope, the antibody molecules are subsequently labelled with an electron-opaque marker, usually colloidal gold. However, for light microscopic examination, the use of fluorescent markers is recommended. As a prerequisite, these methods have to ensure the accessibility of the antigen to the antibody, preferably without compromising either the structure or the original localization of the target molecule. For electron microscopic examination, the specimen has to be thin (usually ultrathin sections of 50–100 nm), stained (heavy metal salts), dehydrated, and embedded in a supporting and stabilizing matrix.

Immunocytochemical methods can be divided into two classes: preembedding and postembedding methods. Preembedding methods are those in which the cell, or isolated organelle, is labelled before embedding and sectioning. While the outside layer of the cell/organelle may be accessible to antibodies, the labelling of intracellular structures must be preceded by a solvent or detergent permeabilization step. It is also possible to immunolabel purified small particles (e.g., viruses, coated vesicle) or cell fragments adsorbed onto the support film of a metal specimen grid. Although these are very useful methods for cytoskeletal elements (by definition, detergent/solvent insoluble), these approachs cannot be recommended as a general method for all antigens and are not considered further here (for a review, see Griffiths, 1993).

The term "postembedding" refers to techniques in which the material of interest (may it be tissues, cells, or purified organelles) is usually either frozen rapidly or fixed chemically, embedded in either a resin or a concentrated solution of cryoprotectant, and hardened by either polymerizing the resin or freezing the cryoprotected sample in order to be sectioned. Sections are subsequently labelled using specific antibodies and a visualization marker. There is now a general consensus that the labelling of sections is the best general approach to take for any immunocytochemical study (for more theoretical background, see Griffiths, 1993). The two most important advantages of postembedding over preembedding are (1) when the labelling is carried out on thin sections, the whole surface of the section has equal access to the reagents and (2) there is significantly less need to improve the accesibility of the reagents to the antigen by using a permeabilization protocol, which may destroy fine structural details or even remove or redistribute the antigen under study. This article discusses the practical aspects involved in the labelling of thin sections for electron microscopy.

Essentially all the reagents mentioned are widely available from all EM supply companies.

II. PROCEDURES

A. Conventional Preparation Procedures

For conventional electron microscopy preparation procedures, the cells or tissues are fixed chemically using aldehydes (e.g., glutaraldehyde and/or formaldehyde). This is usually followed by postfixating with osmium tetroxide, dehydrating in an organic solvent (ethanol or acetone), and subsequent embedding in a hydrophobic, epoxy resin such as Epon or Spurr. The resin is polymerized at elevated temperatures (60° to –70°C), and the cured, hardened blocks are sectioned at room temperature. The ultrathin sections are placed on metal support grids, stained using heavy metal salt solutions (uranyl acetate/lead citrate) and observed in the electron microscope. In general, because of the harsh treatment applied to the specimens, this approach is not useful for immunolabelling. However, there are exceptions to this statement. The most striking example of this involves an extensive and elegant series of studies by Ottersen and colleagues (1992) who performed immunolocalization experiments of amino acid neurotransmitters in brain tissue.

During the 1980s a new class of acrylic or methacrylate-based resins were developed for immunocytochemistry. The two key advantages of these resins over epoxy-based resins are that they are more hydrophilic and, in some cases, can be polymerized at low temperatures. There are two main "families" of these resins, namely Lowicryl resins and London resins (LR). In conjunction with the cryosectioning technique pioneered by Tokuyasu (1973, 1978), these resins have become widely and successfully applied for immunolabelling since the early 1990s. We will now point out the key practical features involved in using these two approaches.

B. Embedding in Acrylic Resins

London resins are perhaps the simplest to use, as in the case of LR white, the resin can be heat polymerized. Both LR white and LR gold are now widely used, and the manufacturers give detailed instructions on their use. A protocol for LR gold is as follows. In this example, infiltration and embedding are carried out at low temperature:

Solutions

1. *0.1 M phosphate-buffered saline (PBS) buffer, pH 7.4:* To make 1 liter, dissolve 2.25 g of $Na_2HPO_4 \cdot 2H_2O$, 0.257 g of $NaHPO4 \cdot H_2O$, and 8.767 g NaCl in 1000 ml distilled water
2. *0.5 M ammonium chloride:* To make 1 liter, dissolve 26.75 g of NH_4Cl in 1 liter PBS

Steps

1. Fix tissue pieces (less than 1 mm^3) with the fixative of your choice, e.g., 0.5% glutaraldehyde in phosphate buffer for 30 min to 2 h [note that for all immunocytochemical techniques the fixation step is critical [see Griffiths (1993) for discussion)].
2. Immerse in 0.5 *M* ammonium chloride in PBS (to quench free aldehyde groups) for 30 min.
3. Immerse in PBS for 15–60 min.
4. Immerse in 50% (vol) methanol at 0°C for 10 min.
5. Immerse in 80% (vol) methanol at –20°C or at 4°C for 60 min.
6. Immerse in 90% (vol) methanol at –20°C or at 4°C for 60 min.
7. Immerse in methanol and LR gold (1:1) at –20°C or at 4°C overnight.
8. Immerse in methanol and LR gold (1:2) at –20°C or at 4°C for 4 h.
9. Immerse in pure LR gold resin at –20°C or at 4°C for 2 h.
10. Immerse in pure LR gold resin + catalyst at –20°C or at 4°C for 2 h.
11. Immerse in pure LR gold resin + catalyst at –20°C or at 4°C overnight.
12. Immerse in pure LR gold resin + catalyst at –20°C or at 4°C and polymerize for 24 h.

LR white is similar but can be polymerized by heat (50°C), by a chemical accelerator at 4–20°C, or by UV light (see manufacturer's instructions). Heat polymerization in a microwave oven, where fully polymerized blocks are available in less than an hour, is also possible with LR white (McDonald, 1999). Polymerization using methods other than UV light enables specimens to be contrasted with osmium tetroxide. For impressive examples of combining LR white with the use of osmium tetroxide, see Tanaki and Yamashina (1994).

C. Progressive Lowering of Temperature (PLT) in Lowicryl Resins

The specimen is fixed chemically with aldehydes (postfixation with osmium tetroxide is omitted, as it can interfere with the polymerization process) and dehydrated with increasing concentrations of alcohol. During dehydration the temperature is lowered pro-

gressively to finally reach –25 to –35°C. Infiltration of the specimens with resin and subsequent polymerization can be performed at low temperatures, as Lowicryl resins have been designed to have an extremely low viscosity at low temperatures and can be polymerized using UV light instead of heat. The blocks can be sectioned at room temperature using standard equipment. The PLT method preserves antigenicity much better than conventional preparation methods and has been used extensively. A PLT regime is summarized here.

Steps

1. Use any of the standard aldehyde fixation procedures.
2. Immerse in 30% (vol) ethanol at 0°C for 30 min.
3. Immerse in 50% (vol) ethanol at –20°C for 60 min.
4. Immerse in 70% (vol) ethanol at –35°C (–50°C)[1] for 60 min.
5. Immerse in 95% (vol) ethanol at –35°C (–50°C to –70°C)[1] for 60 min.
6. Immerse in 100% (vol) ethanol at –35°C (–50 to –70°C)[1] for 60 min.
7. Immerse in 100% (vol) ethanol at –35°C (–50 to –70°C)[1] for 60 min.
8. Immerse in ethanol and resin (1:1) at –35°C (–50 to –70°C)[1] for 60 min.
9. Immerse in ethanol and resin (1:2) at –35°C (–50 to –70°C)[1] for 60 min.
10. Immerse in pure resin at –35°C (–50 to –70°C)[1] for 60 min.
11. Immerse in pure resin at –35°C (–50 to –70°C)[1] overnight.
12. Polymerize for 2 days at low temperature (–50 and –70°C, respectively)[1] with UV light.

The whole procedure can be performed with homemade equipment or, more reproducibly, using commercially available systems from Balzers or Leica microsystems Inc.

D. Cryopreparation Methods (See Fig 1)

1. Rapid Freezing

Chemical fixation of biological specimens is invariably prone to lead to the formation of artifacts. These artifacts can be avoided if biological structures are physically fixed by very rapid freezing. Rapid freezing is a prerequisite for obtaining a frozen specimen that is not destroyed by ice crystals, which would inevitably grow at too low cooling rates. Typically, biological specimens have to be cooled at a rate of 10^5 K/s in order to obtain vitrification, i.e., a state of ice in the cell that is amorphous, i.e., lacks ice crystals. Different freezing techniques have been developed to achieve this goal and the reader is referred to Robards and Sleyter (1985) and to Roos and Morgan (1989) for detailed descriptions of the available methods. However, to summarize, it is possible to freeze biological specimens rapidly with most of the available freezing techniques, provided that they are thin enough (virus suspensions, etc.). The only freezing method that allows bulk specimens to be vitrified is the high-pressure freezing technique (see Studer *et al.*, 1989; Dahl and Staehlin, 1989).

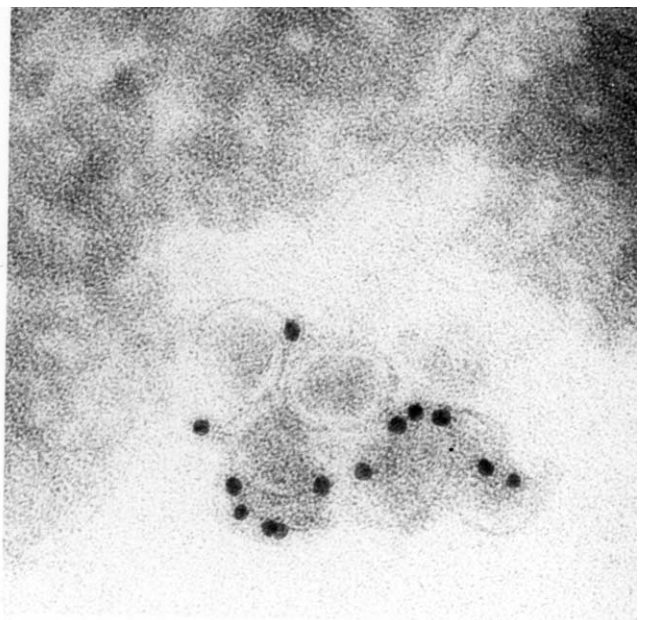

FIGURE 1 Cryoimmuno-EM of BHK-21 cells incubated with equine arteritis virus (EAV), Bucyrus strain. Cells were fixed, sectioned, and labelled for the EAV surface glycoprotein GP_5. Bar: 0.2 mm.

Courtesy of Dr. Ketil W. Pedersen, Department of Molecular Cell Biology, Biology Institute, University of Oslo.

2. Freeze Substitution

Bulk-vitrified specimens can be subjected to a dehydration regime called freeze substitution. In this procedure, the vitrified ice is slowly substituted by an organic solvent, preferably at low temperatures. The cold organic solvent is then subsequently replaced by a suitable resin that is kept at temperatures between –40 and –85°C, followed by polymerization with UV light at the same temperature. The resulting resin blocks can be sectioned and the sections labelled at room temperature. However, high-pressure freezing devices are not standard equipment for the average electron microscopy facility and one may have to

[1] for HM23 and K11M.

resort to a method that allows vitrification of the specimen at lower cooling rates by employing cryoprotectants, such as sucrose. Cryoprotectants used at reasonably high concentrations will prevent the formation of ice crystals in the specimen even at very low cooling, such as those achieved by immersion in liquid nitrogen. However, in order to allow the cryoprotectant to infiltrate the entire specimen, it has to be fixed chemically prior to infiltration. A freeze-substitution schedule for Lowicryl HM20 (van Genderen *et al*., 1991) is as follows.

Solution

2.3 M sucrose solution in PBS: To make 500 ml, dissolve 393.64 g of sucrose in PBS and adjust volume to 500 ml

Steps

1. Fix cell pellets and grow cells on filters or tissue (e.g., with 4% formaldehyde ± 0.1% glutaraldehyde in buffer) for 1 h. A recommended alternative is to add the fixative for 5–10 min to the culture medium at the culture temperature before switching to having the fix in a buffer.
2. Infiltrate the specimen with a cryoprotectant (e.g., 2.3 *M* sucrose) for 30–60 min depending on its size.
3. Cut specimen into small pieces (no more than 1 mm^3).
4. Mount specimen on specimen stubs and freeze in liquid nitrogen.
5. Transfer to methanol at –90°C supplemented with 0.5% uranyl acetate for 36 h.
6. Raise temperature to –45°C (at about 5°C/h).
7. Rinse several times with fresh methanol at –45°C.
8. Infiltrate with Lowicryl HM20 in the following series of Lowicryl/methanol mixtures: 1:1 for 2 h, 2:1 for 2 h, pure Lowicryl for 2 h, and than overnight.
9. Polymerize for 2 days at –45°C with UV light.
10. Section block at room temperature using a glass or preferably a diamond knife in an ultramicrotome.
11. Label with antibodies and gold (see later); all subsequent steps are done by floating the grids on drops as small as 5 µl.
12. Stain with 4% aqueous uranyl acetate for 10 min.
13. Rinse with distilled water.
14. Stain with lead citrate for 1–5 min.
15. Rinse in water, dry, and examine.

3. The Cryosectioning Technique (Tokuyasu Technique)

The thawed frozen section technique offers a number of advantages over most other methods for high-resolution immunolabelling. For more details, see Griffiths (1993).

1. It is potentially the most sensitive technique for immunolabelling, as initial aldehyde fixation is the only denaturation step for the antigen (freezing and thawing of the specimen do not seem to affect the antigenicity)
2. Because the sections are not embedded in resin, they offer the highest access of the antigen to the antibody relative to other techniques. Consequently, this approach is the most sensitive one for those antigens that are retained in the section; this is an important point, as many small soluble antigens may be very difficult to maintain in the sections.
3. The possibilities for staining/contrasting are greater than for any other method.
4. The entire procedure, including photographic documentation, can be performed in one working day.

As mentioned earlier, chemical fixation of the specimen prior to infiltration is a prerequisite. Usually a solution containing 4–8% paraformaldehyde in phosphate, HEPES, or PIPES buffer is used (pH between 6 and 8, determined by the buffer and the specimen to be fixed). The formaldehyde is often supplemented with 0.1–0.5% glutaraldehyde, which is a stronger cross-linker. Cryoprotected, vitrified biological specimens can be sectioned easily at low temperatures, provided the choice of cryoprotectant does not compromise the sectioning properties of the block. The most widely used cryoprotectant is sucrose. Employed at concentrations between 2.1 and 2.3 *M*, the blocks are usually easy to section. High concentrations of sucrose will give softer tissue blocks and will have to be sectioned at lower temperatures. For more difficult specimens (such as plant or insect tissues), an alternative cryoprotectant mixture developed by Tokuyasu consisting of 1.8 *M* sucrose and 20% (w/v) polyvinylpyrrolidone (PVP, MW 10,000) is recommended. Detailed descriptions of the cryosection method are available (Webster, 1999).

Solution

Sucrose/PVP infusion mixture: To make 100 ml, prepare a paste consisting of 20 g of PVP, 4 ml of 1.1 *M* Na_2CO_3 in a buffer such as 0.1 *M* phosphate (Na_2HPO_4) (total volume 20 ml), prepare 80 ml of 2.3 *M* sucrose in the same buffer, mix the paste and the sucrose solution thoroughly, cover the mixture and leave at room temperature overnight so that minute air bubbles can escape, and adjust pH to neutrality using 1 *M* NaOH (use pH indicator paper).

Infusion of small tissue blocks with sucrose solutions usually takes 15–60 min, whereas with

sucrose/PVP, at least 2 h are required. Overnight infiltration may offer more uniform infiltration of the cryoprotectant. Infiltrated specimens are cut to size and mounted on specimen stubs made of aluminium, silver, or copper and frozen by simply plunging them into liquid nitrogen. The stub is inserted into its position in the specimen arm of the cryomicrotome and the block is sectioned at temperatures in the range of −60 to −80°C for semithin sections or −80 to −120°C for ultrathin sections.

Sections are picked up using a wire loop (any pliable metal with a diameter of 1–2 mm) containing a drop of 2.3 *M* sucrose in PBS. Ideally, the sucrose is still fluid at the moment it makes contact with the section(s). The surface tension of the fluid will help stretch the compressed and wrinkly section(s). (*Note*: Stretching will not occur if picking up is done with an already frozen droplet, even if it is subsequently warmed up to room temperature.) Sections picked up in this way have one face exposed to the sucrose and the other face to the air. The latter will stick avidly to the surface of a formvar/carbon-coated EM specimen grid or a glass slide. One significant problem with pure sucrose pick up is that some parts of cells, notably the Golgi complex and endosomes, tend to overstretch during the picking up stage. In order to reduce the magnitude of this problem, Liu *et al*. (1996) developed the technique of picking up sections with a loop containing a 1:1 mixture of methyl cellulose (exactly the same solution used for embedding, see later) and 2.3 *M* sucrose. This is now the method of choice for picking up cryosections. One added advantage of retrieving sections with the sucrose/methyl cellulose mixture is that they can be stored, attached to specimen grids, and covered with dried sucrose/methyl cellulose for up to 6 months (Griffith and Postuma, 2002).

The sections are usually stained after labelling, embedded, and dried. Staining and embedding are achieved by exposing the sections to an inert organic polymer mixed with the stain, usually uranyl acetate. The most used polymer for embedding is methyl cellulose (polyvinyl alcohol and even resins have also been used for this purpose) containing 0.2–0.3% uranyl acetate.

Solution

0.2% methyl cellulose solution: Mix low-viscosity (25centipoise) methyl cellulose powder with cold triple-distilled water to make a 2% solution, leave refrigerated (methyl cellulose is more soluble at low temperatures) for 2–3 days, centrifuge the mixture at 100,000 *g* at 40°C for 1 h, store the solution in the fridge, where it will be stable for up to 6 weeks, and mix nine parts of the solution with one part of a 3% solution of uranyl acetate in water for contrasting/embedding

Use the following a labelling procedure for electron microscopy, in all cases, float the grids on drops (as little as 5 µl) on a strip of parafilm. The upper (non-section) side of the grids must be kept clean and dry, while the lower surface, with sections attached, should always be kept hydrated.

Steps

1. Collect grids by floating them on 1–5% fetal calf serum(FCS)/PBS on ice; wash in PBS once before going further. Note that many other reagents can be used to block nonspecific binding of antibodies such as 1% fish skin gelatin or 2% gelatin.
2. If the cells have been glutaraldehyde fixed, free aldehyde groups can be quenched in 0.02 *M* glycine in 5–10% FCS/PBS for 10 min; rinse twice in PBS for a total of 5 min.
3. Centrifuge antibody solution (1 min at 13,000 *g*), dilute in 1–5% FCS/PBS, and incubate sections for 15–60 min. Use the highest concentration of antibody that does not give background labelling over structures that do not contain the antigen.
4. Wash six times in PBS for a total of 15 min.
5. Incubate grids in protein A–gold for 20–30 min. Dilute protein A–gold in 1–5% FCS/PBS. The concentration is critical. Too high a concentration gives nonspecific binding.
6. Wash six times in PBS for a total of 25 min.
7. Wash four times in distilled water for a total of 5 min.
8. Incubate three times with 2% methyl cellulose solution (25cp) containing 0.1–0.4% uranyl acetate for 10–20 min (on ice!).
9. Pick the grid up with a 3-mm loop and remove excess fluid with filter paper.
10. Air dry the grid suspended in the loop.
11. The thickness of the methyl cellulose film determines the contrast and the extent of drying artefacts.
12. The grids can now be examined.

For double labelling, after step 6, float the grids on 1% glutaraldehyde in PBS for 5 min followed by many rinses in PBS (Slot *et al*., 1991). Repeat steps 2 to 6 using a different size of gold, followed by steps 7 to 12.

III. COLLOIDAL GOLD

Colloidal gold coupled to antibodies or other affinity markers is now the marker of choice for EM immunolabelling, as it is very electron opaque and

easily prepared reproducibly in a range of sizes. The gold particles can be conjugated to antibodies directly or to protein A. We prefer the latter, as we find it more stable and reproducible than IgG gold. However, a disadvantage of protein A is that it binds strongly only to certain species of IgG (rabbit, human, pig, and guinea pig always work; for a more detailed list, see Griffiths, 1993). When using a species of antibody that binds poorly (such as those from rat and mouse), an intermediate antibody step, such as a rabbit antimouse antibody, extends the usefulness of protein A gold. These reagents are now widely available from many commercial sources. For more details on the preparation of colloidal gold markers, see Griffiths (1993).

IV. PITFALLS

One common reason why EM methods are not applied more routinely is the amount of time and effort required to obtain a result. In recent years there have been many experiments using microwave ovens to aid in chemical fixation and embedding protocols. Although the effect of microwaves on biological specimens is still not fully understood, it is clear that routine embedding into epoxy resin or LR white is possible in less than 4 h (Giberson and Demaree, 1999).

1. There is no labelling. The first thing to consider is to try immunolabelling with a light microscopical approach (e.g., cryostat sections). If thick sections of lightly fixed specimens do not work (provided the secondary, visualizing antibodies are good), there is usually no point in continuing to the EM level. One exception to this statement is for small antigens that may be lost during the preparation for light microscopy. For these it is better to use an embedding approach, perhaps after freeze substitution. Provided one has a strong positive, specific signal at the LM level, a negative result at the EM level can be due to a number of reasons. In the case of plastic (e.g., Lowicryl) sections, a common reason is that the antibody has no access to the fixed antigen on the surface of the section. Usually, this is less of a problem with thawed cryosections. In the latter approach, fixation conditions can be reduced drastically (e.g., 5 min in 2% formaldehyde). While this will deleteriously affect the structure, it will help the investigator to decide if the problem is due to the fixation preventing access to the antigen. A second reason for a negative signal at the EM level, already alluded to, is that the antigen may have been washed away during the rinsing steps. This is a problem for small molecules, especially with the Tokuyasu approach. In this case one should crosslink the cells/tissues more severely (1–2% glutaraldehyde). For such antigens the resin approach is preferred. The third reason for lack of labelling is the quantitative aspect: the concentration of the antigens may be too low to detect. Note that the surface of a thin section provides a very small amount of antigen for the antibody when compared to, say, a whole cell at the immunofluorescent level. For more details, see Griffiths (1993).

2. There is too much labelling/"nonspecific" binding. Both the antibody and the gold may not have been diluted sufficiently. It is best to use a standardized gold reagent at its optimal concentration with a characterized primary antibody. If both are unknown, measure the OD_{520} of the diluted gold reagent (e.g., a 1:100 to 1:500 dilution). The commonly used range of final concentration gives an adsorbance of 0.1 at a 520-nm wavelength (generally 1:10 to 1:100 final concentration). The optimal concentration is the highest that does not give background labelling in the absence of a primary antibody. When the gold concentration has been standardized, combine this with a dilution series of the antibody and use the highest concentration that does not give background labelling. The definition of background is, of course, at the discretion of the investigator and assumes some knowledge of the antigen: a membrane protein, for example, would not be expected in the nucleoplasm. Background labelling can often be due to impurities in the antiserum. In this instance, the only solution is to purify the antibody, either by preparing an IgG fraction (e.g., ammonium sulfate precipitation) or by affinity purification. It should be noted that the latter approach often results in a significant, or even total, loss of the highest titre antibody molecules (they remain on the column during the elution procedure).

V. FINAL COMMENT

A positive signal in immuno-EM is only significant when independent proof is provided that the gold labelling one sees is really due to the antigen of interest. Such proof of specificity should be obtained by two different approaches (for more detail, see Griffiths 1993).

1. Immunochemical characterization to show that the antibody recognizes the antigen using an independent method such as immunoblotting or immunoprecipitation.

2. Biological proof of specificity. The best control here is to be able to correlate the labelling pattern with

structures known to contain or not contain the antigen. Any treatment that blocks or removes the antigen should eliminate the labelling.

CHAPTER

31

Direct Immunogold Labeling of Components within Protein Complexes

Julie L. Hodgkinson and Walter Steffen

I. INTRODUCTION

Immunolabeling has long been applied to the study of localization and distribution of antigens within cells and tissues. Perhaps the most exciting recent development, however, is in the use of gold-conjugated antibody labeling in localizing the position of subcomponents in macromolecular complexes. As metal clusters are small and dense and can be specifically targeted to residues within molecular complexes, they can significantly enhance the structure–function information obtained from electron micrographs of macromolecular complexes. Colloidal gold can be prepared in sizes ranging from 1 nm to over 30 nm (e.g., Baschong *et al*., 1985; Slot and Geuze, 1985), allowing a simultaneous detection of several antigens within the same electron microscope preparation.

Gold particles can either be linked covalently to fortuitously placed reactive groups within, or added to, the protein complex under study or be conjugated with primary or secondary antibodies, which in turn bind to exposed epitopes on proteins, so-called indirect immunolabeling. When whole cells or ultrathin sections are labeled using an indirect immunogold labeling method, the distance between the colloidal gold and the epitope is normally below the level of resolution of these techniques. However, in terms of labeled protein complexes in a transmission electron microscope, the large distance between gold and antigen-binding site can be problematic in specifically localizing the epitope in question. The size of an antibody is about 15 nm, therefore the distance of a gold particle (centre of the particle) from the epitope will still be of the order of about 30 nm, even when a small gold particle such as 1 nm of gold is used. To identify a subunit within a complex of about 40 to 50 nm, such as cytoplasmic dynein, it is necessary to bring the gold particle much closer to the epitope. Use of a gold-conjugated primary antibody will bring the gold particle within a range of about 15 nm. Further improvement in resolution can be achieved when the colloidal gold is bound to an Fab fragment, obtained by a papain digest of IgGs (Mage, 1980).

This chapter article details our methods of preparing colloidal gold-conjugated primary antibodies (Fab fragments), which, in combination with a modified technique of negative staining, can be employed to identify subunits within protein complexes.

II. MATERIALS AND INSTRUMENTATION

1,2-Dichloroethane (VWR), bacitracin (Sigma, B0125), borax (Sigma, B3545), bovine serum albumin (BSA, Sigma, A7030), carbon rods (Agar, E416), Centricon-30 microconcentrators (Amicon), centrifuge rotor (Beckman, 80Ti), centrifuge tubes (Nalgene, 3118-0010), chloroform (VWR), column (MoBiTec, 2.5 ml), dimethylchlorosilane (Sigma, D6258), dithiothreitol (DTT, Sigma, D5545), EDTA (Sigma, E9884), filter paper (Whatman, 1001-150, 1004-150), forceps (Agar, T5268), Formvar (Agar, R1201), glass microscope slides (Agar, L4242), glycerol (Sigma, G6279), gold chloride (Sigma, G4022), grid storage boxes (Agar, G276A), grids (Taab Lab's), iodoacetamide (Sigma, I6125), lens tissue (EMS), magnetic stirrer (Agar, G3784), methanol (VWR), mica sheets (Agar, G250-1), Oak Ridge centrifuge tubes (Nalgene, 3118-0010), papain (Sigma, P4742), petri dishes (VWR, 402/0062/06, 02/0066/01), potassium

carbonate (Sigma, P5833), potassium chloride (Sigma, P9333), protein G (Sigma, P3296), protein G–Sephadex (Sigma, S1235), razor blades (Agar, T5016), Schott bottles (VWR, 215/0150/10), sodium azide (Sigma, S8032), sodium chloride (Sigma, S7653), sodium phosphate (Sigma, S8282, S7907), sodium thiocyanate (Sigma, S7757), microprobe sonicator (Jencons-PLS, Sonics Vibracell), staining jar (Agar, L4108), staining jars (Sigma, S6016), staining trough (VWR, 406/0230/10), ultracentrifuge (Beckman, LE80K), uranyl acetate (Agar, R1260A), and carbon evaporation unit (Edwards 306).

III. PROCEDURES

A. Preparation of Specimen Support for Transmission Electron Microscope

Ideally, very thin but stable support films are required for high-resolution transmission electron microscopy; however, this is problematic as very thin films are extremely fragile. It is for this reason that more robust holey films with an overlay of ultrathin carbon only over the holes are often used. The methodology is as follows.

1. Preparation of Holey Formvar Film

Solutions and Equipment (Materials)

1. 0.5% (w/v) Formvar in chloroform (freshly prepared)
2. 50-ml Schott bottle (wide neck)
3. 50% (w/v) glycerol in dH_2O
4. Forceps, self-closing
5. Glass staining trough spray-painted black of 7 cm depth and 12 cm width (or larger)
6. Grids, 300-mesh copper Maxataform HF35
7. Lens paper, lint free
8. Magnetic stirrer
9. Methanol
10. Microprobe sonicator
11. Microscope slides
12. Petri dishes, glass, 150 mm diameter
13. Razor blades
14. Staining jar (Coplin)
15. Whatman filter papers #1; #4, qualitative circles, 150 mm diameter

Steps

1. Freshly prepare 50 ml Formvar solution in a Schott bottle; stir to dissolve with magnetic stirrer for about 15–20 min.

2. Prepare fresh 50% glycerol solution and add 15–20 drops to dissolved Formvar; shake vigorously for 30 s. Sonicate for 2 min at full power using a microprobe sonicator. Probe should be placed one-third from bottom of solution in a 50-ml Schott bottle. The amount of glycerol and sonication time will vary depending on size and density of holes required. The bottle should feel warm after sonication.

3. Place Formvar–glycerol solution into a staining jar. Clean several microscope slides with lint-free lens tissue. Dip slides one at a time into the Formvar solution, remove rapidly and vertically to ensure an even film, stand on their ends on filter paper, and let dry completely. (*Note:* Prepare all of the slides at one time because the dispersion of glycerol solution is unstable and the droplets slowly coalesce.)

4. Test the film quality. As soon as a slide is dry, float off the film (see later), pick up a couple of grids (see step 6 for details), dry briefly, and check in EM for hole size, number, and distribution. The holes should be just larger than the photographic field at the desired working magnification.

5. Fill glass staining trough to the brim with clean dH_2O. Wipe surface with sheet of lint-free lens tissue.

6. Score edges of a slide with clean single-edged razor blade. Breath lightly onto the slide and then, with that side uppermost, carefully float off the film on to the water surface by slowly sliding the slide into the water at a 45° angle. Place grids on film, rough (dull) surface down using self-closing forceps. Cut a rectangular piece of #4 Whatman filter paper approximately 30% larger than the floated plastic film; slightly bend the ends up to use as handles. Pick grids and film up with filter paper rectangle by gently touching the paper horizontally to floating Formvar film. Place the strip of filter paper on more filter paper to dry. After the grids are dry, place filter paper/grids/Formvar on a bed of #1 filter paper saturated with methanol in a glass petri dish for 10 min. This "etching" procedure removes any glycerol/water droplets and dissolves any very thin plastic lying across the holes.

7. After the grids are dry, check a grid in the scope to ensure the spread and size of holes.

8. Place filter paper with grids in a glass petri dish and store in a refrigerator.

Comments and Pitfalls

Do not overload floating Formvar film with grids, as it will sink! As a rough guide, use no more than 25–30 grids per slide-sized piece of Formvar, neither should one place grids too close to the edge of the plastic. Reflected light from a lamp and/or a dark surface underneath the glass dish will help in observing films clearly. Because plastic films tend to be unsta-

ble in the electron beam, the holey Formvar can be substituted by holey carbon film to obtain more stable grids as follows. This is particularly important for high-resolution work.

2. Coating of Holey Formvar Grids with Thick Carbon for Additional Stability

Solutions and Equipment

1. 1,2-Dichloroethane
2. Carbon evaporation unit (Edwards 306)
3. Carbon rods, spectrographically pure
4. Grid storage box
5. Petri dishes, glass, 150 mm diameter

Steps

1. Place filter paper with grids in a carbon evaporator.
2. Coat grids heavily with carbon at a vacuum in the range 10^{-6} Torr.
3. Place filter paper/grids/Formvar/carbon on a bed of filter paper saturated with 1,2-dichloroethane in a glass petri dish for 2 h. This removes the Formvar, leaving the holey carbon. Remove and dry in a glass petri dish.
4. Store grids in a grid storage box. They are stable for several months.

3. Preparation of Ultrathin Carbon Support Films on Mica Sheets

Solutions and Equipment

1. Carbon evaporator unit
2. Carbon rods, spectrographically pure
3. Mica sheets, 75 × 25 mm
4. Petri dishes, plastic, 100 mm diameter

Steps

1. Freshly cleave mica sheets. Keep cleaved side clean; do not touch with fingers at any time!

2. In a carbon evaporator, expose mica sheets with new surface towards the carbon source. Coat mica sheets at a vacuum of 1×10^{-6} Torr or better with thin (about 10 nm) carbon film (*Note:* Gradual deposition over several evaporations produces stronger and better quality carbon film.) Avoid sparking during carbon deposition to ensure a smooth deposition.

3. Remove coated mica sheets from carbon evaporator, place in a plastic petri dish, and store in a refrigerator (careful, very delicate).

Comments and Pitfalls

From some mica brands, carbon may not float off easily. Cleave mica just before coating and do not expose to air for longer than absolutely necessary. Position a screw on the corner of the filter paper so that a shadow will fall on the paper when the carbon is evaporated. The area where the paper is shielded from the carbon source will appear light compared to the rest helping to judge thickness.

B. Digest of IgG with Papain (Fab)

The protocols to obtain Fab fragments vary depending on the type and isotype of antibody used. We have used the protocol described here successfully to generate Fab fragments from rabbit IgG and mouse IgG1.

Solutions and Equipment

1. 1 m*M* DTT
2. 100 m*M* EDTA
3. 1 *M* iodoacetamide (freshly prepared)
4. 5 mg/ml papain (can be stored as aliquots at –80°C)
5. Phosphate-buffered saline (PBS): 150 m*M* NaCl, 2.7 m*M* KCl, 50 m*M* phosphate, pH 7.5
6. Protein G–Sephadex column

Steps

1. Adjust antibody concentration to 1–2 mg/ml with PBS and add up to 2 m*M* EDTA and up to 1 m*M* DTT (depending on IgG type, use β-mercaptoethanol, DTT, or glycine as reducing agent).
2. Prepare a 5-mg/ml papain stock solution. Please note that some commercial papain does not dissolve readily and will therefore yield a much lower level of digestion.
3. Add papain to antibody solution; IgG : papain = 100 mg : 1 mg.
4. Incubate at 37°C for 30–60 min.
5. Stop reaction by adding up to 30 m*M* iodoacetamide and incubate in the dark on ice for 60 min.
6. Dialyze against PBS at 4°C.
7. Check efficiency of digest by SDS–PAGE (12% gel under reducing conditions).
8. Test antibody by immunochemistry.
9. Remove Fc from Fab via protein G or protein A column (use protocol according to manufacturer).

Comments and Pitfalls

In our view the most reliable method to generate Fab fragments is by using a papain digest; however, care should be taken when choosing the reduction medium and the source of papain as there can be a considerable variation in potency of the reaction. Other enzymes, which can be used to cleave antibodies, include ficin and pepsin (e.g., Mage, 1980; Marianai *et al.*, 1991). Please also note that protein A may not be used with all IgG isotypes and that some mouse IgG might bind to protein G via the Fab portion rather than the Fc.

C. Preparation of Colloidal Gold

Colloidal gold can be prepared easily in different sizes (e.g., Baschong and Wrigley, 1990; Slot and Geuze, 1985). We describe here our adaptation of the method by Baschong *et al*. (1985) to prepare 2–3 nm colloidal gold.

Solutions for Gold Preparation

1. 0.2 *M* K_2CO_3, 0.22 µm filtered
2. 1% (w/v) $HAuCl_4$ in dH_2O
3. 1.0 *M* NaSCN, 0.22 µm filtered
4. 200-ml siliconized Erlenmeyer flask

Steps [Modified According to Baschong et al. (1985)]

1. Siliconize an Erlenmeyer flask by rinsing it with a 5% solution of dimethylchlorosilane in chloroform in fume hood, rinse with water after evaporation of solvent in a fume hood, and bake at 180°C for 2 h.
2. Add 0.5 ml of 1% $HAuCl_4$ to 100 ml dH_2O in a siliconized Erlenmeyer flask followed by 0.75 ml of 0.2 *M* K_2CO_3 to gold solution while stirring.
3. Finally add 0.3 ml of 1 *M* NaSCN while stirring (note that the solution will become yellowish).
4. Leave solution in a dark place overnight and use the following day for binding to antibodies.

D. Binding of Gold to Antibody

In order to bind a single gold particle per IgG or Fab fragment it may be necessary to experiment in varying the protein colloidal gold ratio and/or adding varying amounts of an unspecific protein, e.g., BSA (Baschong and Wrigley, 1990) or bacitracin (Steffen *et al*., 1997). Newly developed gold probes from Nanoprobes (Stony Brook, NY), e.g., the 1.4 nm colloidal gold within an organic shell, allow the coupling of the gold probe covalently to an antibody.

Solutions for Gold Labeling of the Antibody

1. 10 mg/ml bacitracin
2. 10 mg/ml BSA
3. 10% (w/v) NaCl
4. 10% (w/v) NaN3 (kept in a dark bottle)
5. 10% (w/v) sucrose in PBS
6. 10X TBS: 100 m*M* Tris–HCl, 1.5 *M* NaCl, pH 7.4
7. 10-ml Oak Ridge centrifuge tubes
8. 2 m*M* borax
9. 5% dimethylchlorosilane in chloroform
10. Centricon-30 microconcentrator
11. Fume hood
10. PBS: 150 m*M* NaCl, 2.7 m*M* KCl, 10 m*M* phosphate, pH 7.5
11. Spectrophotometer
12. Ultracentrifuge, 80Ti rotor

Steps

1. Dialyse antibody into 2 m*M* borax or use Centricon microconcentrator for buffer exchange.
2. Adjust colloidal gold solution to pH 8.0.
3. Determine the minimum amount of antibody needed to stabilize the gold.
   a. Prepare a serial dilution of antibody from 100 to 5 µg IgG per 100 µl dH_2O.
   b. Add 0.5 ml colloidal gold solution and incubate for 2 min.
   c. Add 0.5 ml of 10% NaCl and incubate for 30 min.
   d. Measure the turbidity (formation of aggregates) using a spectrophotometer at $OD_{550\,nm}$. (An increase in turbidity will mark the minimal concentration to stabilize gold particles.)
4. Add antibody at determined minimal concentration (usually about 20 µg/ml) to colloidal gold solution while stirring and incubate on ice for 15 min.
5. Add 100 µg/ml bacitracin or BSA to cover the free surface of gold particles and incubate on ice for 60 min.
6. Add 1/10th of volume of 10X TBS and centrifuge through a 1-ml 10% sucrose cushion in a Beckman 80Ti rotor at 47,000 rpm (150,000 g_{ave}) for 30 min.
7. Aspirate supernatant and resuspend soft pellet in about 200 µl TBS containing 0.02% NaN_3 and store in a refrigerator.

Comments and Pitfalls

The 2- to 3-nm colloidal gold requires some time to develop. However, if the colloidal gold is stored for an extended period of time, it tends to form aggregates. We normally stabilise to colloidal gold with a protein solution, i.e., antibody, 12 to 24 h after initiation of the reduction of the gold solution.

E. Negative Staining of Immunogold-Labeled Protein Complexes

A hydrophilic carbon support film is critical in achieving uniform high-quality negative staining, but carbon films tend to become more hydrophobic over time when exposed to air. The carbon film can be exposed to ionised gas (glow discharge) to revitalize its hydrophilic property. In our method (see also Marchese *et al*., 1995), negative staining is carried out on a carbon surface that has never been exposed to air, thus maintaining the hydrophilic nature of the carbon. This is achieved by floating the carbon film first onto the protein solution and then onto uranyl acetate. An

example of an immunogold-labelled protein complex is illustrated in Fig. 1.

Solutions and Equipment

1. 1% (w/v) uranyl acetate in dH_2O (kept in the dark)
2. 1.5-ml Eppendorf reaction vials, painted black
3. Carbon-coated mica (see earlier discussion)
4. Forceps (several pairs of self-closing, fine-tipped forceps)
5. Grids with holey carbon film or holey Formvar film (see earlier discussion)
6. Single-edged razor blades
7. Small, adjustable angled lamp
8. Whatman filter paper #1

Steps

1. Paint the outside of a 1.5-ml Eppendorf reaction vial black.
2. Mix gold-conjugated primary antibody with isolated purified protein complex and incubate at room temperature for 10 min.
3. Dilute protein complex–antibody mixture to about 10 to 20 µg/ml and place about 250 µl of the mixture into the cap of a 1.5-ml Eppendorf reaction vial (Fig. 2, step 1).
4. Fill the reaction vial with freshly filtered (0.22-µm syringe filter) 1% uranyl acetate. Note that the meniscus of the staining solution should be slightly above the rim of the reaction vial (Fig. 2, step 1).
5. Reflect light from a lamp off the surface of the liquid at an angle of about ~45°.
6. Cut a thin carbon-coated mica sheet into about 3 × 5-mm pieces and score the carbon film with a clean single-edged razor blade about 2 mm from one side of the small mica sheet.
7. Using a pair of self-closing, fine-tipped forceps, partially float off the thin carbon film from the supporting mica sheet onto the surface of the protein solution (Fig. 2, step 2).
8. Withdraw the carbon film after 2–3 s and float the carbon film completely free of the mica onto the surface of the staining solution (Fig. 2, step 3).
9. Pick up the carbon film immediately with a 300-mesh grid coated with a holey Formvar or holey carbon film. [*Note:* Use a small adjustable angle light source to help visualise the thin carbon by reflection (Fig. 2, step 4)].
10. Remove excess uranyl solution by touching edge of grid with the edge of a torn filter paper (Fig. 2, step 5).
11. Let dry in a humid chamber (Fig. 2, step 6).

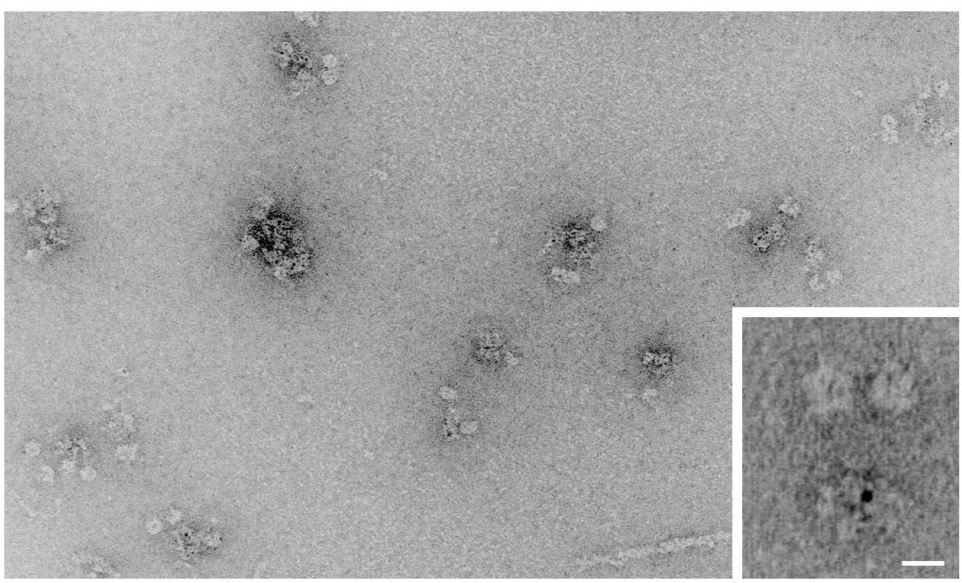

FIGURE 1 Immunogold labeling of cytoplasmic dynein. The image shows the formation of clusters caused by the antibody–gold complex. In this case the gold was stabilised primarily by the presence of antibodies. Cytoplasmic dynein with a single gold particle could be observed (insert), if gold probes were used, where the antibody was supplemented with a nonspecific protein during the antibody–gold complex formation. Magnification bar in insert 10 µm.

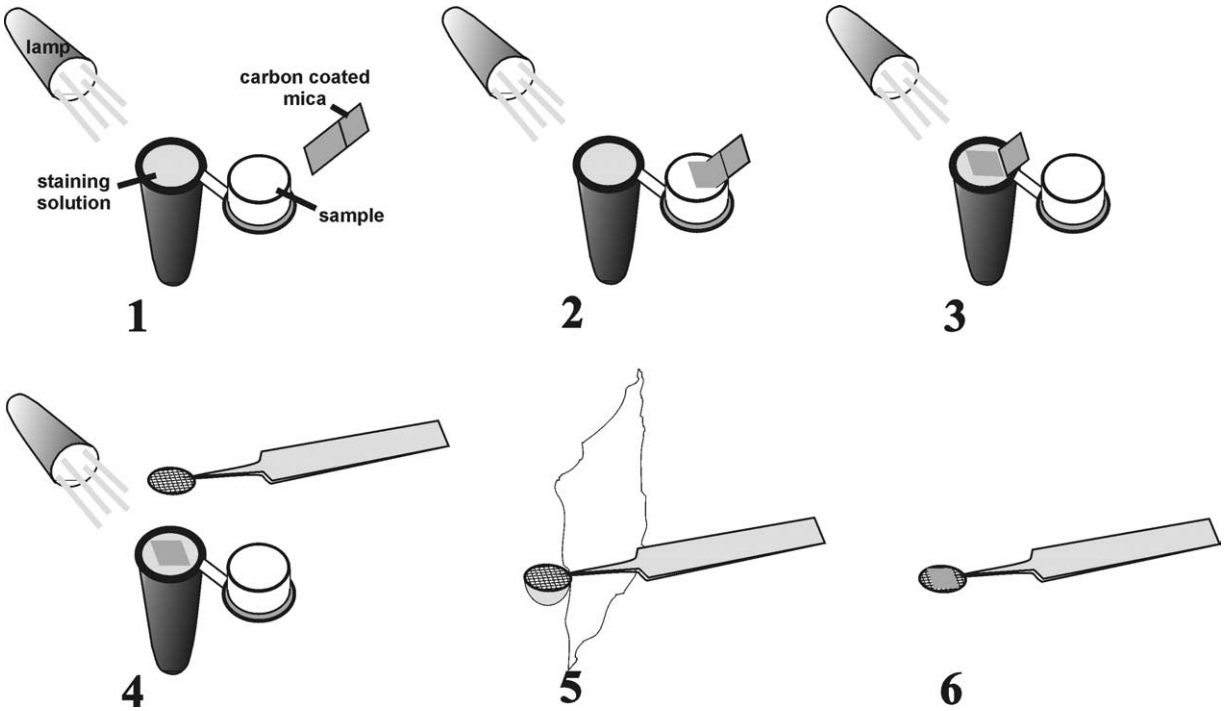

FIGURE 2 Diagram illustrating the procedure for negative staining of protein complexes. See text for details of the procedure.

IV. Outlook

Understanding the structural organization of a large protein complex is of increasing importance in our aim to understand their functional properties. Three-dimensional image reconstruction by single particle analysis has proven to be a useful tool to achieve this goal. A potential development in the use of immunogold-conjugated antibodies is in the high-resolution three-dimensional image reconstruction of macromolecular complexes, allowing for the specific localisation of functional epitopes within molecular complexes. Technological developments in the production and specificity of heavy metal clusters (Nanoprobes Inc.), and advances in transmission electron microscopy and image analysis have enabled for the orientation of actin subunits within actin filaments to be investigated (Steinmetz *et al*., 1998). Thus far such studies have only been carried out with gold particles directly (covalently) linked to the molecule of interest via incorporated His tags (Hainfeld *et al*., 1999) or fortuitously exposed, or added, cysteines (Zlotnick *et al*., 1997). In the case of antibodies, disulphide bonds can be employed to attach a gold particle at a specific site, thereby making single epitope labelling more reliable.

Atomic Force Microscopy in Biology

Dimitrios Fotiadis, Patrick L. T. M. Frederix, and Andreas Engel

I. INTRODUCTION

In the last decade the atomic force microscope (AFM) (Binnig *et al.*, 1986) has become a powerful tool in structural biology. The unique possibility of acquiring the topography of biological samples at high resolution under physiological conditions, i.e., in buffer solution, at room temperature, and under normal pressure, makes this instrument outstanding. The high signal-to-noise ratio of AFM topographs has not only allowed the observation of whole cells, chromosomes, nucleic acids, and proteins, but also the tracking of conformational changes of biomolecules during the exertion of their function (Engel *et al.*, 1999; Engel and Müller, 2000). Furthermore, time-lapse AFM imaging has enabled the monitoring of dynamic changes in the conformation, association, and functional state of individual proteins (Stolz *et al.*, 2000).

The principle of the AFM is relatively simple: A sharp tip mounted at the end of a flexible cantilever is raster scanned over a sample surface in a series of horizontal sweeps. The bending of the cantilever caused by the probe–sample interaction is detected by the deflection of a laser beam that is focused onto the end of the cantilever and reflected into an optical detector. This signal, termed deflection signal, is coupled to a servo system that moves the sample vertically to maintain the cantilever deflection at a constant value. The surface topography is then reconstructed from the vertical movement of the scanner. In this imaging mode, called contact mode, the probing tip always touches the surface with a constant force during scanning. An alternative and widely used imaging mode in biology is the tapping mode. Here, the AFM tip is oscillated rapidly in the vertical direction while scanning the sample. Oscillation of the tip reduces frictional forces, thereby minimizing artifactual deformation and displacement of the sample. Therefore, the tapping mode is used frequently to image the surface topography of weakly immobilized biomolecules, e.g., single proteins and fibrils. However, for imaging of biological membranes, the highest resolution so far obtained has been in contact mode.

This article focuses on the application of contact mode AFM to acquire subnanometer resolution structural information of membrane proteins from membrane specimens in liquid. Most of these proteins are fragile structures comparable to a submerged sponge. To prevent their damage by the scanning tip, soft cantilevers with spring constants of 0.01–0.1 N/m must be used, and scanning must be performed with minimal applied force to the tip (≤100 pN). An additional crucial factor for successful high-resolution imaging is the correct adjustment of the imaging buffer (Müller *et al.*, 1999). By optimizing these factors that minimize the force experienced by the sample, lateral resolutions down to 0.41 nm and vertical resolutions down to 0.10 nm have been achieved on biological membranes in solution (Stahlberg *et al.*, 2001). However, application of higher forces can be of advantage to perform precise and controlled "dissections" of biological samples by manipulation with the AFM tip (Fotiadis *et al.*, 2002).

In this article, contact mode AFM is illustrated using membranes that contain the heptahelical protein bacteriorhodopsin (BR). This 26-kDa integral protein acts as a light-driven proton pump in Haloarchaea (Oesterhelt and Stoeckenius, 1973). Photoisomerization of the chromophore from all-*trans* to 13-*cis* retinal initiates the unidirectional translocation of one proton across the cell membrane (reviewed by Oesterhelt *et al.*, 1992; Lanyi, 1997). This establishes an electrochemical

proton gradient across the membrane that can then be used for ATP synthesis and other energy-requiring processes in the cell. BR forms trimers and highly ordered two-dimensional (2D) trigonal crystal lattices (parameters: $a = b = 6.2\,\text{nm}$, $\gamma = 60°$) in the native membrane of the bacterium *Halobacterium salinarum*, these crystalline patches are termed purple membrane because of their color (Blaurock and Stoeckenius, 1971). The flatness of these crystalline membrane patches makes them very suitable for AFM. High-resolution three-dimensional structures of BR (Fig. 1) have been determined by electron and X-ray diffraction (for a review, see Cartailler and Luecke, 2003). In BR, the prosthetic group retinal (see Fig. 1; arrowhead) is bound covalently by a protonated Schiff base to K216 of helix G of the protein (the seven transmembrane α helices are generally denoted A to G). With the AFM it is the protruding domains, i.e., the termini and connecting loops between the helices, that are visualized, not the helices themselves that are embedded in the lipid bilayer. On the cytoplasmic side, the major protrusions of BR are the loop connecting the transmembrane α helices A and B and that connecting E and F (AB and EF loops; Fig. 1), of which the EF loop appears to be highly flexible (Müller *et al.*, 1995a). On the extracellular side the protruding B–C interhelical loop (BC loop; Fig. 1) forms a β hairpin and is fairly rigid.

The procedures described for BR in this article constitute a basis for sample preparation and application of AFM on other biological membranes.

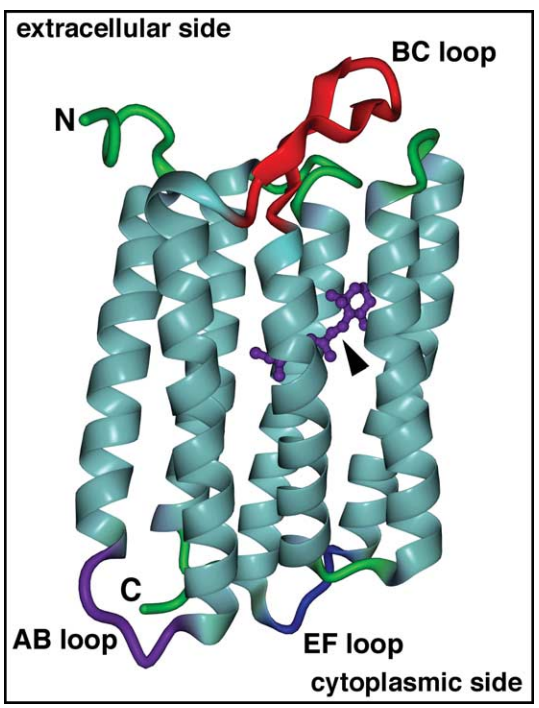

FIGURE 1 Bacteriorhodopsin with its retinal chromophore (arrowhead). The extracellular (top) and the cytoplasmic side (bottom) of BR with their prominent loops and termini are indicated. This illustration of BR was calculated using the coordinates of Kimura *et al.* (1997) and the visualization program DINO (http://www.dino3d.org/).

II. MATERIALS AND INSTRUMENTATION

A. Materials: Preparation of Mica Supports

Polished ferromagnetic stainless steel disks of 11 mm diameter (manufactured by the internal workshop services of the Biozentrum, Basel, Switzerland)
Teflon sheets of 0.25 mm thickness (Maag Technic AG, Birsfelden, Switzerland)
Mica sheets with a thickness between 0.3 and 0.6 mm (Mica House, 2A Pretoria Street, Calcutta 700 071, India)
"Punch and die" set from Precision Brand Products Inc. (2250 Curtiss Street, Downers Grove, IL 60515)
Ethanol [purity: >96% (v/v)]
Loctite 406 superglue (KVT König, Dietikon, Switzerland)
Araldite Rapid: Two-component epoxy glue from Ciba-Geigy, Basel, Switzerland
Scotch tape (3M AG, Rüschlikon, Switzerland)

B. Materials: Bacteriorhodopsin and Buffers

Sodium azide (NaN_3, Fluka Cat. No. 71289)
Tris [$H_2NC(CH_2OH)_3$, Merck Cat. No. 1.08382.2500]
Magnesium chloride hexahydrate ($MgCl_2{\cdot}6H_2O$, Fluka Cat. No. 63064)
Potassium chloride (KCl, Merck Cat. No. 1.04936.1000)
Purple membranes of *H. salinarum* (source: see Acknowledgments)
Stock suspension of purple membrane fragments: 0.25 mg/ml in double-distilled water containing 0.01% NaN_3 (stored at 4°C and protected from unnecessary light irradiation)

C. Instrumentation

A commercial multimode AFM equipped with a 120-µm scanner (j-scanner) and a liquid cell (Digital Instruments, Veeco Metrology Group, Santa Barbara, CA)
Oxide-sharpened Si_3N_4 micro cantilevers of 100 and 200 µm length, and nominal spring constants of 0.08

and 0.06 *N*/m from Olympus Optical Co. Ltd., Tokyo, Japan, and from Digital Instruments, Veeco Metrology Group, respectively.

III. PROCEDURES

A. Preparation of Mica Supports for Sample Immobilization

Steps

1. Punch Teflon disks of 0.5 in. and mica disks of 0.25 in. diameter using the "punch and die" set and a hammer.
2. Clean the steel and Teflon disks with ethanol and paper wipes.
3. Glue a Teflon disk centrally on a steel disk using the Loctite 406 superglue and allow the glue to dry.
4. Glue a mica disk centrally on the Teflon surface of the Teflon-steel disk with the Araldite two-component epoxy glue.
5. Let the supports dry overnight.

B. Preparing Bacteriorhodopsin for AFM Imaging

Solutions

1. *Adsorption buffer*: 20 m*M* Tris–HCl (pH 7.8), 150 m*M* KCl
2. *Imaging buffer for the extracellular side (ES-imaging buffer)*: 20 m*M* Tris–HCl (pH 7.8), 150 m*M* KCl, 25 m*M* $MgCl_2$
3. *Imaging buffer for the cytoplasmic side (CS-imaging buffer)*: 20 m*M* Tris–HCl (pH 7.8), 150 m*M* KCl

Steps

1. Dilute and mix 3 µl of purple membrane stock solution with 30 µl of adsorption buffer in an Eppendorf tube.

2. Cleave the mica by applying Scotch tape to the upper surface and then peeling off until a new smooth intact mica surface is exposed. This new surface is clean and molecularly flat, suitable for deposition of the specimen to be imaged.

3. Pipet 33 µl of the diluted purple membranes on the hydrophilic surface of the freshly cleaved mica support.

4. Allow the sample to adsorb for 15 to 30 min.

5. Wash away purple membrane fragments that are not firmly attached to the mica by removing approximately two-thirds of the fluid volume from the mica surface and readding the same volume of the desired imaging buffer. Repeat this washing procedure at least three times.

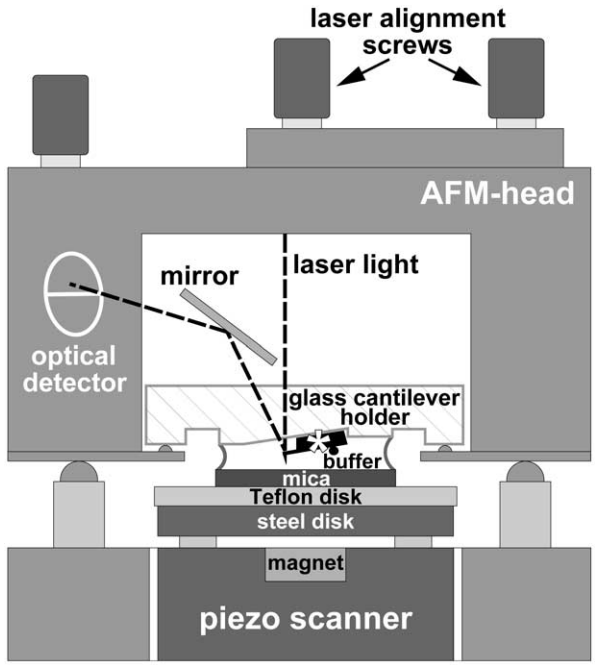

FIGURE 2 Schematic diagram of the atomic force microscope setup for imaging in liquid. The piezo scanner moves the sample in *xyz* directions under the fixed cantilever (marked by an asterisk).

6. Transport the specimen support and its associated fluid onto the piezo scanner of the AFM.

7. Place the AFM head with its mounted fluid cell and cantilever on the scanner (see Fig. 2).

8. Make sure that the space between the mica surface and the cantilever-fluid cell contains enough of the corresponding imaging buffer to avoid drying of the specimen during the imaging experiment. An experiment may last several hours.

9. Align the laser spot onto the cantilever and the reflecting beam into the photodiode with the appropriate laser alignment screws. *Caution*: It is very important not to put any reflective objects into the laser trajectory in order to avoid reflection of the laser light into your eyes! Additionally, wear appropriate protection glasses!

C. Operation of the AFM

All measurements are carried out under ambient pressure and at room temperature.

Steps

These steps assume basic knowledge of AFM operation.

1. Let the instrument equilibrate thermally.
2. Set the scan size to zero to prevent specimen deformation and contamination of the tip after engagement.
3. Initiate engagement process, i.e., permit the tip to approach the surface.
4. As soon as the tip is engaged, and prior to scanning the surface, set the operating point of the instrument to forces below 100 pN, i.e., minimal force.
5. Calibrate the deflection sensitivity of the cantilever using the force calibration menu of the control computer.
6. Start imaging and keep the forces during scanning as small as possible by correcting manually for thermal drift.
7. Optimize the feedback parameters of the system, i.e., the integral gain and the proportional gain, by increasing their values. If the feedback loop starts to oscillate, introducing noise, reduce these gains until the noise goes away.
8. Record two images of 512 by 512 pixels simultaneously at low magnification (frame size >1 µm), one showing the height signal in the trace direction and the other the deflection signal in the retrace direction. Set the scan speed to two to four lines per second. Crystalline structures are usually recognized more easily in the deflection signal image than in the height image.
9. Find and centre a suitable purple membrane fragment. Zoom in and set the scan speed to four to six lines per second. Record images of the height signals in both the trace and retrace directions at high magnification (frame size <1 µm). Comparison of the trace and the retrace images allows deformation of the sample in the fast scan direction to be detected. Such deformations can be minimized by working at minimal force. At such high magnifications, the scan range of the z piezo can be reduced to avoid limitation of the axial z resolution that might otherwise occur because of rounding errors during (16-bit) digitalisation of the analogue signal (AD conversion).

IV. COMMENTS

The following sections explain and help understand the features observed on the topographies acquired during the AFM experiment.

A. Morphology of Purple Membranes

Figure 3 shows a typical low-magnification topograph of purple membrane fragments adsorbed on mica. The diameter of the BR crystals varies between 0.5 and 1.5 µm. The number of adsorbed membrane fragments depends on the adsorption buffer and time and on the concentration of the purple membrane suspension deposited on the mica. It is advantageous not to adsorb membranes too densely on the mica surface; this decreases the probability to contaminate

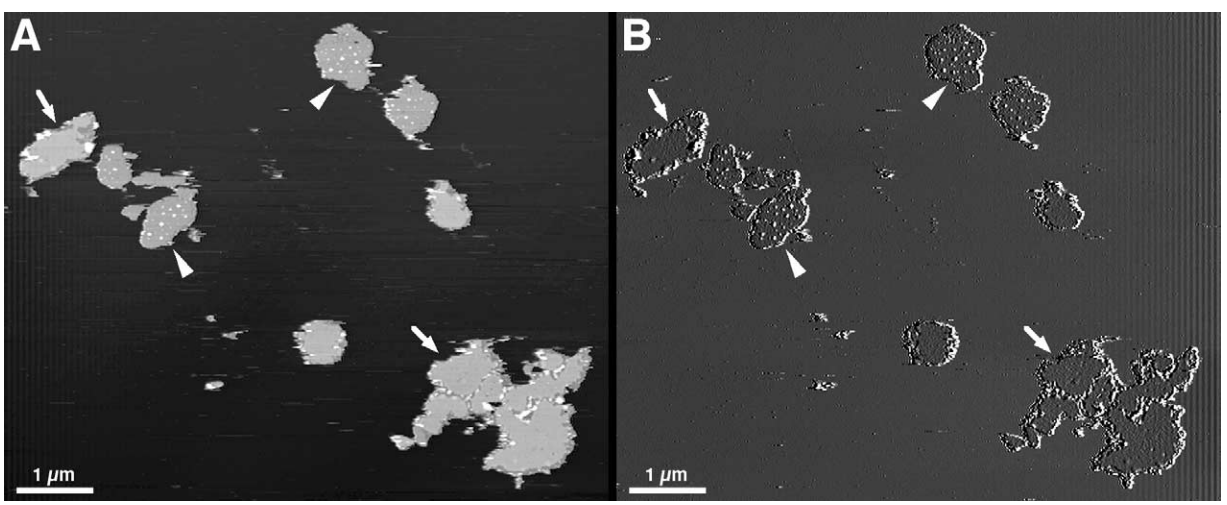

FIGURE 3 AFM images of purple membrane at low magnification: height (A) and deflection (B) signals recorded in trace and retrace directions, respectively. Membrane patches exposing the cytoplasmic side (arrowheads), which are decorated by small debris, can be distinguished from patches exposing the flat extracellular side (arrows). The membrane patches have a height of ~6 nm when imaged in CS-imaging buffer. Vertical brightness ranges: 12 nm (A) and 1 nm (B).

the AFM tip. Two different surfaces can be discerned: The extracellular side of purple membrane is fairly flat (Fig. 3; arrows), whereas the cytoplasmic side is characterized by protruding bumps of 10–30 nm in diameter (Fig. 3; arrowheads) (Müller *et al.*, 1995b, 1996). A feature that can be used to differentiate further between the two sides is the small difference in thickness seen when scanning in CS-imaging buffer. Purple membranes exposing the cytoplasmic side appear slightly thinner than those exposing the extracellular side. As described by Müller and Engel (1997), pH and electrolyte concentration affect the apparent height measured between the mica and the cytoplasmic or the extracellular side of the purple membrane. This results from different surface charge densities.

B. The Extracellular Surface of Purple Membrane

At high magnification, the appearance of the extracellular side of BR is characterized by protrusions extending 0.5 ± 0.1 nm out of the lipid bilayer (Fig. 4A and inset). The β hairpin in the loop connecting the transmembrane α helices B and C of BR constitutes the main portion of the observed protrusion.

C. Estimating the Resolution of AFM Topographs

The resolution of a micrograph containing a regular structure can be estimated from its power spectrum, i.e., its 2D Fourier transformation image. This was calculated from the topograph of the extracellular side of BR (Fig. 4A) and is displayed in Fig. 4B. Most software packages delivered with atomic force microscopes enable calculation of power spectra from recorded AFM topographs. Various public domain programs such as NIH image or ImageJ, both from the National Institutes of Health (Bethesda, MD), or SXM from the University of Liverpool (Liverpool, United Kingdom), have such algorithms implemented and can be downloaded for free (NIH image: http://rsb.info.nih.gov/nih-image/; ImageJ: http://rsb.info.nih.gov/ij/; and SXM: http://reg.ssci.liv.ac.uk/).

The larger the distance of the discernable spots from the origin in a power spectrum, the higher the resolution of the topograph. Here, spots extend beyond the 1-nm resolution limit (see broken circle in Fig. 4B). To calculate the resolution at a selected diffraction spot, Eq. (1) can be used. This equation is applicable to all lattice types, e.g., for trigonal, hexagonal, square, or orthorhombic lattices, which occur frequently in native

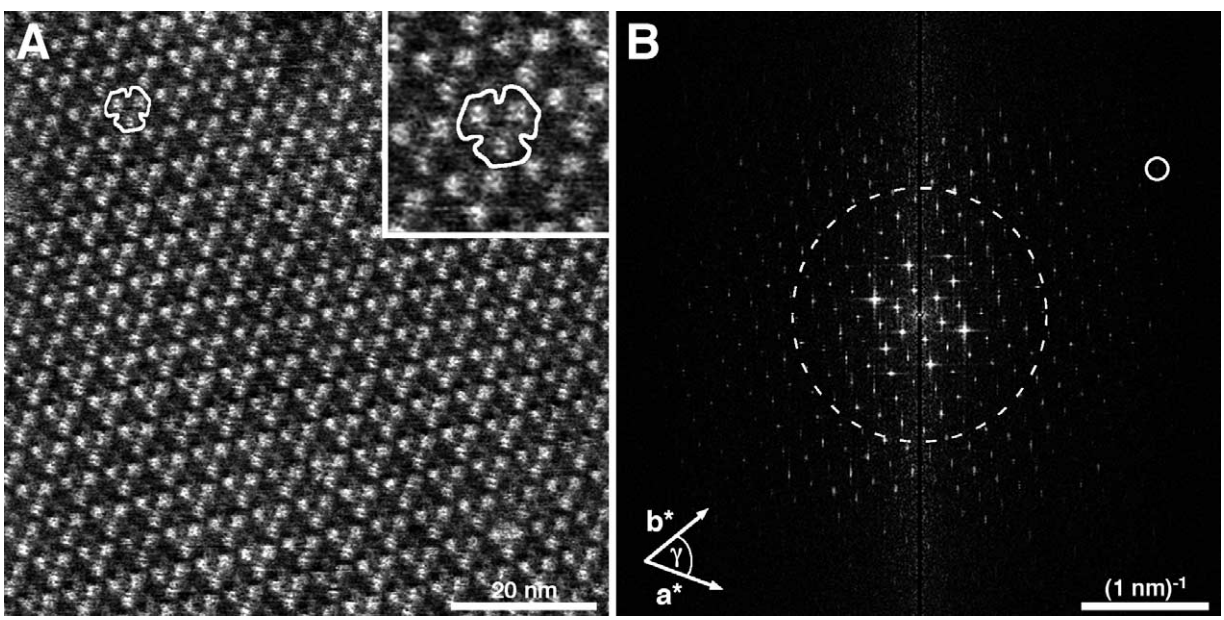

FIGURE 4 (A) The extracellular side of purple membrane at high magnification. For clarity, the area around the contoured BR trimer was enlarged and is displayed in the inset (frame size: 17 × 17 nm). (B) Power spectrum calculated by Fourier analysis from the image in A. The (3, 10) diffraction spot (small circle) is marked and represents a resolution of 0.46 nm. The broken circle represents the 1-nm resolution limit. Vertical brightness range: 0.8 nm (A and inset in A).

and reconstituted 2D crystals of membrane proteins (for further reading on crystallography, see Misell and Brown, 1987).

$$\delta = \frac{1}{|\vec{r}|} = \frac{\sin\gamma}{\sqrt{\frac{h^2}{a^2} + \frac{2 \cdot h \cdot k \cdot \cos\gamma}{a \cdot b} + \frac{k^2}{b^2}}} \quad (1)$$

where δ is resolution; $\vec{r}$ is vector from origin to the diffraction spot in Fourier space; a and b are basic lattice vectors in real space; γ is the angle between the basic lattice vectors; and h and k are Miller indices of the diffraction spot.

Example: The encircled spot (h, k) = (3, 10) in Fig. 4B corresponds to a lateral resolution of 0.46 nm assuming the lattice parameters of BR ($a = b = 6.2$ nm, $\gamma = 60°$).

D. The Cytoplasmic Surface of Purple Membranes

Imaging of the cytoplasmic surface of BR is force dependent because of the flexible EF loop (Müller *et al.*, 1995a). At minimal force (≤100 pN) applied by the AFM stylus (Fig. 5; area above the broken line and inset top left), the fully extended EF loops can be discerned as protrusions of 0.8 ± 0.2 nm height. These become less prominent or even disappear if the loading force is increased to ~200 pN (Fig. 5; area below the broken line and inset bottom left). At this force, the AB loops become visible with a height of 0.6 ± 0.1 nm above the lipid bilayer. The advantage of such force-induced conformational changes is that shorter loops otherwise covered by the bigger ones can be visualized.

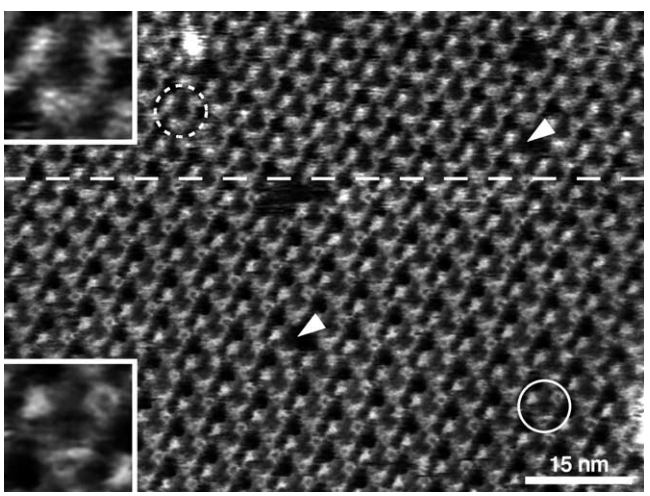

FIGURE 5 Force-dependent topography of the cytoplasmic surface of a purple membrane. The area above the broken line was recorded at minimal force applied to the AFM stylus (≤100 pN). At this force, the flexible EF loop is fully extended, whereas at a stylus force of ~200 pN (area below the broken line) the loop is pushed away by the scanning tip and is therefore almost not visible anymore. For clarity, areas (frame size: 7 × 7 nm) around the contoured trimers recorded at minimal force (broken circle; inset top left) and at a force of ~200 pN (solid circle; inset bottom left) are displayed enlarged as insets. Occasionally, defective BR trimers with a monomer missing can be found (arrowheads). Vertical brightness range: 1.2 nm.

V. PITFALLS

A. Damping of Vibrations

For high-resolution AFM imaging, a vibrationally and acoustically isolated setup of the microscope is crucial. Antivibration and damping tables or lead platforms suspended by bungee cords offer excellent vibration damping. Acoustic isolation of the AFM can be achieved efficiently by installing a vacuum bell jar around the microscope.

B. Adjustment of Buffer for High-Resolution AFM Imaging

Topographs of this membrane protein with a lateral resolution of 0.41 nm (Stahlberg *et al.*, 2001) can be recorded reproducibly with the AFM, provided the imaging buffer is adjusted correctly (Müller *et al.*, 1999) and the force applied to the tip is minimized. Under nonoptimal imaging conditions, even the smallest force that is adjustable by the instrument can be too high, leading to deformation of the biomolecules, e.g., concealing the EF-loop in BR (Fig. 5, lower portion). The effective interaction force acting between the AFM stylus and the specimen is determined by the force applied to the stylus, the electrostatic repulsion, and the van der Waals attraction between the two surfaces. By adjusting pH and ionic strength of the imaging buffer, van der Waals attraction and electrostatic repulsion between tip and sample can be balanced. The best imaging conditions are determined by recording and analyzing force–distance curves between tip and sample in different buffers. Conditions that yield force curves showing a small repulsion are ideal for high-resolution imaging. Under these conditions the tip is assumed to surf on a cushion of electrostatic repulsion, thereby minimizing the deformation experienced by the biomolecules. This screening method revealed the two slightly different imaging buffers for BR mentioned earlier, i.e., CS- and ES-imaging buffer. For further reading on this topic, see Müller *et al.* (1999), where buffer conditions for different biological samples are discussed.

C. Tip Effects and Artefacts

At this time, no commercial AFM tips are available with ideal point probes and perfect geometries in the subnanometer range. Therefore, tip effects and artefacts arising from the tip geometry are unavoidable and have to be considered when interpreting AFM topographies (for further reading on tip effects and artefacts, see Xu and Arnsdorf, 1994; Schwarz *et al.*, 1994). Tip effects occur when the probe does not have a single, small, and sharp interaction area with the sample. This leads to an AFM image that represents a convolution of the sample features with the tip shape. To be sure of having acquired the correct surface structure and not an artefact, the same surface topography of the object being investigated has to be reproduced several times using different tips from different batches. Tip artefacts can also be identified by changing the direction in which the AFM tip scans the sample (scan angle), as artefacts will rotate correspondingly (Xu and Arnsdorf, 1994). Ordered structures, e.g., mosaic 2D crystals, that are differently oriented with respect to the scan direction of the AFM tip, are also good indicators for tip artefacts. Ideally, the building blocks of the crystal, e.g., the BR trimer, should look the same in the differently oriented crystals. Finally, structures of samples that have been determined by other methods, e.g., the structure of BR by electron and X-ray crystallography, can be used to further compare and confirm AFM data.

Figure 6 displays topographs of the extracellular side of BR recorded with an artefact-free tip (Fig. 6A) together with images acquired with artefacteous tips (Figs. 6B–6D). Tentative explanations of the observed artefacts are omitted because the statements would be too speculative. We restrict ourselves to a comparison of artefacteous surfaces with the nonartefacteous one. Compared to Fig. 6A, the depression at the three-fold symmetry axis of the trimer in Fig. 6B is completely missing. The trimer seems to consist of a single plateau. The BR trimers in Fig. 6C have lost their trigonal shapes and resemble tetramers. In Fig. 6D the BR trimer is distorted, displaying a Y shape. The lipid areas that separate the neighbouring BR trimers cannot be resolved by the artefacteous tip, and instead ridges of constant height are seen (broken straight line).

VI. CONCLUDING REMARKS

This article presented procedures for sample preparation and AFM imaging of native 2D crystals of bacteriorhodopsin. The experience gained will enable the readers to perform similar AFM experiments with other biological membranes.

Acknowledgments

This work was supported by the Swiss National Research Foundation, the M. E. Müller Foundation, the Swiss National Center of Competence in Research (NCCR) "Structural Biology," and the NCCR "Nanoscale Science." The authors are indebted to Dr. Ansgar Philippsen for Fig. 1 and to Professors Dieter Oesterhelt (Max-Planck-Institut für Biochemie, Martinsried, Germany) and Georg Büldt (Forschungszentrum Jülich, Jülich, Germany) for kindly providing us with BR. The authors acknowledge Dr. David Shotton for constructive comments on the manuscript.

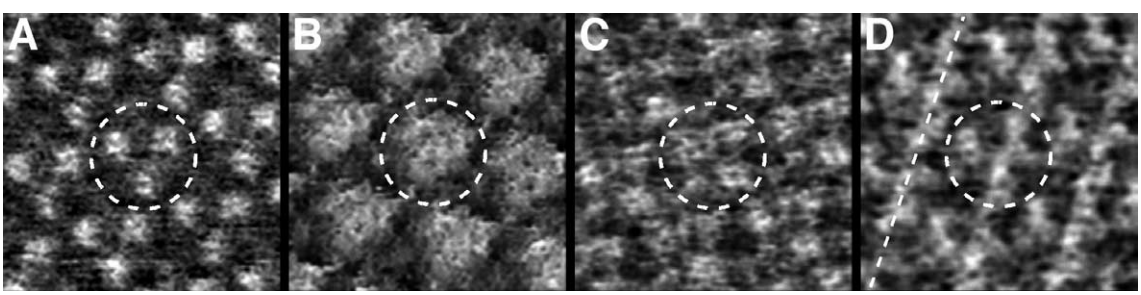

FIGURE 6 Tip-induced effects and artefacts on the extracellular surface of bacteriorhodopsin. (A) Artefact-free and (B–D) artefacteous topographies of BR. In B the characteristic central depression at the three-fold axis of the BR trimer is absent. The central trimer in C resembles a tetramer. In D the protrusions are not clearly separated, but connected along the broken line. In all images the central trimers are marked by broken circles. The frame sizes in A to D are 17 nm. The heights are 0.8 nm (A), 1.3 nm (B), 0.8 nm (C), and 0.8 nm (D).

Field Emission Scanning Electron Microscopy and Visualization of the Cell Interior

Terence Allen, Sandra Rutherford, Steve Murray, Siegfried Reipert, and Martin Goldberg

I. INTRODUCTION

Resolution in scanning electron microscopy (SEM) has improved dramatically in recent years so that for the majority of biological material, no significant differences exist in resolution between SEM and conventional transmission electron microscopy (TEM). High brightness sources (field emission) and novel final lens configurations have resulted in instrument resolutions of 0.5 to 1 nm, allowing direct, *in situ*, three-dimensional visualization of surface detail at molecular resolution. As all this technology relies on field emission sources of the electron beam, either by "cold" field emission or thermally assisted "Schottky" field emission, we refer to it as FESEM.

Surface imaging allows bulk samples to be examined without limitation of specimen thickness. Visualization of intracellular surfaces requires some means of access, such as isolation of cell fractions or macromolecules, or *in situ*, via fracture, or sectioning techniques. Cell-free systems, e.g., *in vitro* nuclear formation, allow biological interfaces such as developing nuclear envelopes to be imaged directly (Goldberg *et al*., 1992). True three-dimensional (3D) surface visualization can be achieved by tilting the specimen to make stereo pairs, and accurate surface measurements can be made from computerized 3D reconstructions. The surfaces can be characterized further by immunogold labeling, which can be unequivocally localized by the strong backscatter signal of the gold probes. For specimens that are thin enough to allow electron penetration, a scanning TEM (STEM) image can also be obtained readily and displayed simultaneously alongside the secondary electron image, producing complementary information from the transmitted beam/specimen interactions. The use of low accelerating voltages in FESEM has also been shown to be of advantage, reducing charging and penetration of the electron beam, but maintaining a high-resolution information content. High-pressure freezing, freeze substitution, and examination of cryohydrated specimens may all be used for FESEM (Muller and Hermann, 1990; Walther, 2003) but can be considered specialized and are not covered in this article, although we do describe the use of cryoultramicrotomy and cryoabrasion as techniques to access internal surfaces within the cell prior to conventional imaging by FESEM. Basically, we deal with techniques that rely on chemical preservation, followed by dehydration, critical point drying, and coating. Conventional SEM coating (up to 20 nm thickness) with sputtered gold completely obscures fine surface detail in HRSEM and must be replaced by high-resolution coating. We routinely coat with a 1- to 2-nm film of chromium or tungsten, which has a grain size of 0.3 to 0.5 nm (Apkarian *et al*., 1990).

II. MATERIALS AND INSTRUMENTATION

1. Glutaraldehyde (Agar Scientific)
2. Tannic acid (TAAB Laboratories)
3. TCH (Cat. No. T-2137. Sigma)

Copyright 2006, Elsevier Science (USA).
All rights reserved.

4. Osmium textroxide (Agar Scientific)
5. Uranyl acetate (Agar Scientific)
6. Molecular sieve (Merck Ltd.)
7. Arklone (trichlorotrifluoroethane) Taab Labs UK
8. HEPES (Sigma)
9. PIPES (Sigma)
10. Phosphate-buffered saline (PBS)
11. Tris–HCl
12. EDTA (Sigma)
13. Phenylmethylsulfonyl fluoride (PMSF, Sigma)
14. Percoll (Sigma)
15. Sorensen's phosphate buffer
16. Poly-L-lysine HBR, MW 150,000–300,000 (Cat. No. P-1399 Sigma)
17. Glass coverslips, 5–7 mm diameter
18. Silicon chips, $5 \times 5\,mm^2$ (Agar Scientific Ltd.)
19. Carbon-coated support grids
20. Fine forceps for handling
21. Microcentrifuge to spin suspended material onto coverslips
22. Microcentrifuge tubes, 1.5 ml, half-filled with polymerized EM resin, ideal for supporting coverslips, chips, and grids during specimen deposition by centrifugation
23 High-resolution scanning EM. Conventional "pinhole" final lens instruments with field emission sources will allow subcellular imaging, as will conventional transmission instruments with scanning attachments. To date, the highest resolution achieved has been in field emission instruments with the facility to position the specimen in, or very close to, the final lens. Recent technology has significantly improved the resolution of field emission instruments at lower accelerating voltages (1 kV), from around 4 to 1.5 nm, facilitating imaging without the need for metal coating. The microscope should also be equipped with a suitable high-resolution backscatter detector for immunogold labeling. The main suppliers for these instruments are Hitachi, Jeol, Philips, and Leo.
24. Critical-point drier, with high-purity CO_2 (<5 ppm water). Liquid CO_2 should be passed through a filter to remove water (Tousimis Research Corp., filter 8782).
25. Coating units. Oxygen, hydrocarbons, and water vapor all adversely affect the grain size of chromium or tantalum deposited by sputter coating (Apkarian *et al.*, 1990). We use an Edwards Auto 306 12-in. coating unit with cryopump, magnetron head, and suitable power source (Edwards High Vacuum International). Similar configurations using Denton HiVac and Balzers equipment with cold-trapped turbopumping have also been successful. Any system should use high-purity argon and have a shutter and a specimen table that tilts and rotates. Film thickness monitoring of coating deposition is an advantage. Several "benchtop" systems are currently on the market, many untested by the highest resolution. In our own very recent experience, the provision of a suitably performing coating system has often proved to be a limitation of the perceived performance of a newly acquired microscope, and suitable resources for a high-resolution coating system should be incorporated in any application for a field emission instrument. If possible, get in touch with an established group and get advice before committing to any particular coating system.

Pitfalls

It is crucial to visit manufacturers' demonstrations with the material that will be investigated to ascertain that suitable performance can be assured from the chosen equipment.

III. PROCEDURES

A. Exposing Surfaces within the Cell

1. Subcellular Fractionation

Organelles and macromolecules can be isolated by standard procedures, possibly requiring subsequent modifications in the light of HRSEM visualization, which are beyond the scope of this article. Basically, the specimens must be undamaged by osmotic shock, proteolysis, or unsuitable isolation buffers. They must also be clean. The surface of organelles should, for instance, be free of attached cytoskeletal remnants or cytoplasmic contamination. Where the specimens are available as purified macromolecules or viruses, they may be deposited on carbon-coated TEM grids in the conventional manner and viewed by HRSEM. In this situation, TEM negative staining will usually be replaced by fixation for SEM and air drying replaced by critical-point drying followed by chromium coating. If a STEM detector is available, the virus/macromolecule can be recognized as a transmitted "reference image" after this protocol and compared directly with the secondary electron (SEM) image. The thin coating of chromium applied for the secondary electron imaging does not interfere with the STEM imaging.

Adhering Sample to Support

Many cell components naturally adhere to glass coverslips, silicon chips, or carbon support film on grids. Glass coverslips may be a useful initial prepar-

ative substratum, as they can be checked in the phase-contrast microscope for the density and distribution of specimens and for the progression of various protocols such as detergent extraction of cytoplasm. Once the isolation protocol is established, coverslips should be replaced with silicon chips as specimen substrates, as silicon is a conductive substratum in contrast to glass, an insulator, which can generate problems with charging in the SEM. Tissue culture cells will grow in identical fashion on silicon as they do on glass or plastic, and isolated cytosol or organelles will also adhere naturally to silicon in the same way as they do to glass. If samples are fixed in suspension it may be necessary to coat the support with poly-L-lysine to facilitate adherence. Different samples may require slight modification, but the basic technique is as follows (Fig. 1).

Solution

Poly-L-lysine: Make a fresh 1-mg/ml solution of poly-L-lysine in sterile distilled water; use within 24 h.

Steps

1. Mark the surface of chip or coverslip with identification number using a diamond marker.
2. Place a 50-µl drop of poly-L-lysine on coverslip or chip; allow to stand for at least 60 min in a moist chamber to avoid drying. Rinse in sterile distilled water. The surface will retain its adhesive properties for up to 2 weeks in a refrigerator.
3. Place a 50-µl drop of suspended material (fixed and rinsed) on coverslip/chip. Allow to settle and attach at 4°C and unit gravity in a moist chamber (1 h to overnight). Alternatively, spin directly (see isolation of nuclei) onto silicon chip.
4. Allow bulk of drop to run off, put chip/coverslip back in fixative, and continue as for fresh tissue. Unfixed living samples (e.g., whole cells) may be distorted by poly-L-lysine. To spin down materials from suspension, use minicentrifuge tubes half-filled with polymerized EM resin to support the coverslip/silicon chip/grid.

2. *"In Situ" Exposure of Intracellular Surfaces*

Dry Fracture

This is a simple but extremely effective way of exposing internal surfaces in both tissues and cells. After fixation, dehydration, and critical-point drying,

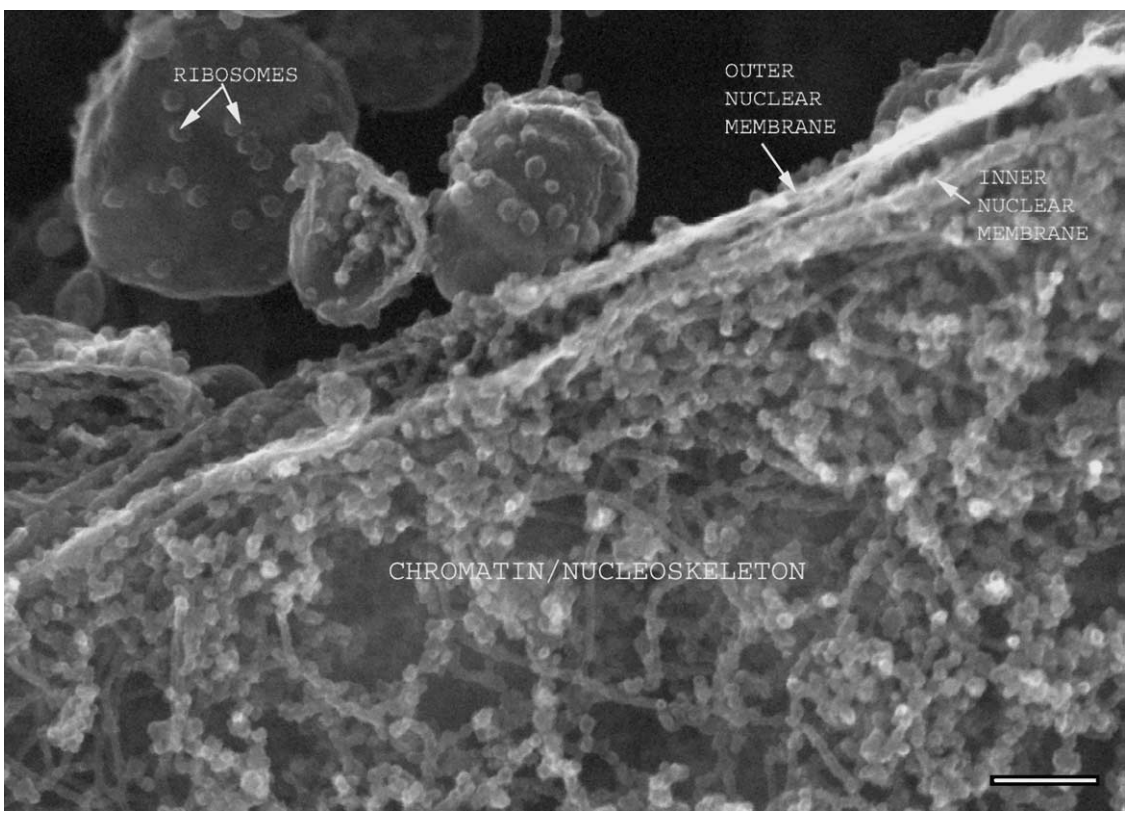

FIGURE 1 *Xenopus* nuclear assembly egg extract spun onto a silicon chip, fixed, frozen, and sandpapered while frozen showing a section through the edge of a nucleus where the two membranes of the nuclear envelope can be seen, as well as the chromatin and nucleoskeletal fibres on the nuclear interior. Bar: 125 nm.

merely gently press the surface of the specimen to a square of double-sided tape mounted to a second silicon chip and pull away without shearing, coat both chips as normal, and examine in the SEM. The fracture will remove material on the surface of the adhesive and leave fractured material "*in situ*." This technique may be enhanced by pretreatment with detergent (0.5% Triton X-100, 2–3 min for tissue culture cells), either alone or mixed with the primary fixative (2.0% paraformaldehyde and 0.1% glutaraldehyde), and subsequently refixed as described (Allen *et al*., 1998).

Resinless Sections

These methods involve sectioning of embedded specimens followed by exposure of internal surfaces by removal of the supporting material. This may vary among epoxy resins, various waxes, and even ice. Resins that require corrosive solvents for removal will tend to be prone to surface etching. A mixture of 50% propylene oxide and 50% sodium methoxide (dissolve 2 g NaOH pellets in 100 ml absolute methanol) will remove most resins.

3. Cryo Methods to Expose Internal Surfaces for FESEM

Surface imaging by FESEM may be achieved by isolating the cellular component of interest, such as mitochondria, but this approach does not allow access to the interior structure of such an organelle (see later). One way to expose such surfaces is to freeze the cells or tissue and cut cryo sections, which themselves can be viewed in the SEM, to "cryoplane" and expose the whole blockface in the SEM, or to "cryoabrade" the surface of the frozen sample and expose surface features in a different way. Samples are then thawed and processed for FESEM as normal. This gives a cross-sectional view but with much greater depth of information than in a resin-embedded thin section viewed in the TEM because the sections can be very thick, they are resin free, and there is a greater depth of focus. Information can also be gathered quite simply in 3D simply by taking stereo pairs, which also allows computerized 3D reconstruction and measurement of the surface. This method is also compatible with immunogold labelling (Fig. 2).

Cryomicrotomy is an adaptation of the widely used "Tokyasu" technique (Tokyasu, 1986, 89) for immuno-TEM.

Materials

Silicon chips
4% paraformaldehyde in PBS
2 *M* sucrose in PBS
Cryo stubs

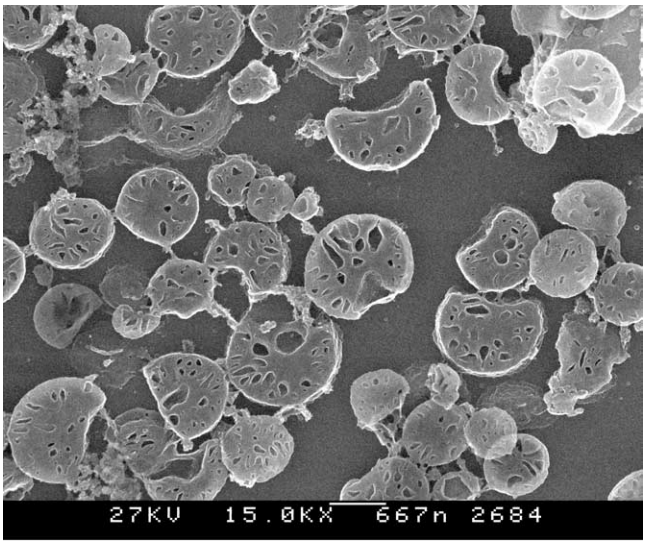

FIGURE 2 Low-power image of cryo-planed block face of a mitochondrial pellet where the internal cristae structure has been exposed. Scale bar: 667 nm.

Liquid nitrogen
Cryo ulramicrotome (e.g., Leica Ultracut R with FCS cryo attachment)

Steps

1. Fix samples (e.g., pellet of organelles) with 4% paraformaldehyde in PBS at room temperature for 30 min.
2. If possible, trim to a cube of about 1 mm^3.
3. Transfer to 2 *M* sucrose in PBS overnight at 4°C.
4. Mount sample on cryo stub for ultramicrotome and wick off excess sucrose.
5. Plunge into liquid nitrogen.
6. Mount into a cryo ultramicrotome, which has been precooled to –100°C.
7. Cut sections of 100–300 nm thickness.
8. As in the Tokyasu technique, pick up sections off the knife on a drop of sucrose suspended from a loop, where they thaw, and then touch the sucrose drop to a silicon chip where the sections adhere.
9. Place chip in PBS to wash off sucrose.
10. This can then be immunogold labeled, refixed, and processed for FESEM.

Pitfalls

These problems are associated with the Tokuyasu technique.

1. Poor infiltration of sample with sucrose leading to crumbly blocks.
2. Curling of sections.
3. Static.

4. Frosting.
5. Small sample size.

When processing the sample remaining on the pin for SEM, the specimen always detaches from the pin. This leaves a very small specimen that is easily lost during the dehydration and CPD steps. An additional problem is the attachment of the sample to a silicone chip after CPD. The sample is very fragile and it is not always easy to identify the "planed" side. Adhere the sample to the chip using a thin smear of silver dag. It is possible for the sample to flip over during this process. Also, because of the irregular shape of the sample, ensuring good contact and therefore a good earth path from specimen to chip can be tricky. It is easy to submerge the specimen in too much dag.

Cryo Abrasion

1. Centrifuge organelles onto a silicon chip.
2. Fix (e.g., 4% paraformaldehyde in PBS, room temperature for 30 min).
3. Transfer to 2 *M* sucrose in PBS for 2 h to overnight at 4°C.
4. Remove from sucrose and place on filter paper to dry the back of the chip.
5. Wick off most of the sucrose from the sample, leaving as thin a film as possible without drying.
6. Plunge into liquid nitrogen.
7. The sucrose step can be avoided if the sample can be frozen ultra-rapidly by plunging into liquid propane or ethane. The chip can then be held under liquid nitrogen or on a liquid nitrogen-cooled platform (such as the Leica EM CPC) while it is abraded with fine sandpaper (400–600 grade wet and dry abrasive as per automobile body and paintwork).
8. Thaw into fix and process for FESEM.

Specific Protocol for Mitochondrial Isolation and Exposure of Internal Structure by FESEM

Isolate mitochondria using the differential centrifugation method (Gottlieb *et al*., 2003). Harvest and place cells ($2.5–5 \times 10^8$) on ice for 15 min, centrifuge at 500 *g* for 5 min at 4°C, wash with ice-cold PBS, and subsequently wash with ice-cold mitochondrial isolation buffer (MIB) (200 m*M* mannitol, 70 m*M* sucrose, 1 m*M* EGTA, 10 m*M* HEPES, 0.5 mg/ml BSA; pH 7.4). Resuspend cells in ice-cold MIB and then homogenize in a syringe-driven cell disruptor. Spin the lysate at 800 *g* for 10 min at 4°C. Remove supernatants and spin at 10,000 *g* for 10 min at 4°C. Add fixative (3% glutaraldehyde) to the pellets and keep samples at 4°C for 1 h. Remove the fixative carefully and infiltrate the pellet with sucrose/PVP solution overnight (Tokuysau, 1989). During this process, leave the pellet undisturbed. Then carefully excise small (>1 mm^2) pieces of sample from the pellets and mount onto aluminium plunge freezing pins (Leica Microsystems, Milton Keynes). Mount the pins into a plunge freeze unit (Leica CPC) and freeze in liquid propane at a temperature of −182°C. Transfer the frozen specimen and pin under LN2 into a cryo ultramicrotome (Leica Ultracut S with FCS attachment). Using a diamond trimming knife (Diatome Cryotrim 45), trim several semithin sections (350 nm) from the sample in order to remove surface sucrose. Cut further semithin sections (350–400 nm) from the sample using a diamond cryo knife. Collect each section on a sucrose loop according to the "Tokuyasu" technique (Tokuyasu, 1986). Thaw the frozen sections onto 5-mm silicone chips and process for SEM as follows.

1. Transfer the chips with attached sections using a metal loop (2–3 mm diameter) and invert such that the chip is floated, section side down, in a plastic Petri dish (35-mm Falcon) containing double-distilled water.
2. Wash 3× over 15 min in order to rinse out the sucrose.
3. Fix by floating in 1% OsO4 in double-distilled water for 1 h.
4. Wash in double-distilled water 3× for 5 min each.
5. Then dehydrate the sections and critical point dry as described later.

Pitfalls

Aligning the cryo abrasive pad with the specimen is very tricky and must be done with care. It is very easy for the protruding abrasive shards of the wet and dry paper to embed themselves into the frozen block. Also, if the section advance is too great, the sample block can be literally ripped from the specimen pin. A few micrometres must be shaved off the sample face in order to ensure that all surface sucrose has been removed. This only leaves a few micrometres of well-frozen vitrified sample to work with. Once again, the sample size is very small and is easily damaged or lost in subsequent processing and mounting steps.

Identifying the abraded face can be tricky even under a stereomicroscope. The swirled pattern of the specimen pin that has been embossed into the underside of the sample can look very similar to the abraded face, leading to the specimen being mounted pin side up.

B. Fixation

Solutions

All fixatives are ideally made up just before use or at least the same day; both glutaraldehyde and

glutaraldehyde-tannic acid solutions should be filtered before use through a 0.22-µm filter. The 1% aqueous uranyl acetate should be stored in a brown bottle. Osmium tetroxide is made by breaking the glass ampoules in which the crystals are delivered, having previously washed them free of label and adhesive under the tap, in a fume cupboard. The ampoules plus crystals are dropped in the correct amount of buffer or distilled water where the osmium dissolves to give the appropriate final concentration. (*Note*: Osmium is extremely hazardous and appropriate precautions must be observed.) Thiocarbohydrazide or tannic acid solutions should also be made just prior to use (Allen *et al.*, 1988).

Pitfalls

Always use glutaraldehyde of EM-grade quality from a high stock concentration (50%) stored in a freezer. Low concentration stock solutions and storage in large bottles at room temperature will reduce the cross-linking properties of the glutaraldehyde.

Steps

1. Isolated Proteins and Nucleoproteins

1. Proteins and nucleoproteins on carbon support films on TEM grids may be floated on top of drops (25–50 µl) of the appropriate solutions spread on Parafilm.
2. Place in 1% glutaraldehyde in appropriate buffer for 10 min.
3. Wash in double-distilled water for 5 min.
4. Transfer to 1% uranyl acetate for 5 min.
5. Transfer to 100% ethanol for 1–2 min.
6. Air dry or critical point dry (see later).

2. Small and Easily Preserved Structures

Steps

1. Fix in 3% glutaraldehyde in Sorensen's phosphate buffer for 30 min.
2. Wash in Sorensen's for 5 min.
3. Postfix in 1% $Os0_4$ (in Sorensen's for 30 min).
4. Wash in double-distilled water for 5 min.
5. Dehydrate through ethanol series for 5 min each.
6. Place in Arklone for 5 min.
7. Critical point dry (see later).

3. Large and/or Fragile Structures (e.g., Whole Cells, Organelles, Cytoskeletal Preparations, Isolated Cells, or Nuclear Membranes)

Steps

1. Attach whole cells to specimen supports such as silicon chips and handle by changing the solutions in 35-mm-diameter petri dishes.
2. Fix in 2% glutaraldehyde, 0.2% tannic acid, and 0.1% HEPES, pH 7.4, for 10 min.
3. Wash in double-distilled water for 5 min.
4. Postfix in 0.1% $Os0_4$ in water for 10 min.
5. Wash in water for 5 min.
6. Stain with 1% aqueous uranyl acetate for 10 min.
7. Dehydrate through ethanol series and Arklone and critical point dry.

4. Isolation of Nuclei from Tissue Culture Cells

Steps

1. Take approximately 10 million tissue culture cells (usually from suspension culture), cool to 4°C, and pellet in a swing-out centrifuge (1000 *g* for 10 min).

2. Wash the pellet in PBS buffer and then resuspend in 8 ml ice-cold swelling/shearing buffer (50 m*M* Tris–HCl, pH 7.4, 5 m*M* MgCL, 1.3 m*M* EDTA, and 5 m*M* phenylmethylsulfonyl fluoride added shortly before use) in which nuclei are allowed to swell for 5 min.

3. Mechanically homogenize the cells using a plunger-type tissue grinder (e.g., Kontes Dounce), checking the number of strokes required for nuclear release by phase-contrast light microscopy (usually 10–20 strokes). Precool the plunger in ice prior to use. Alternatively, nuclei may be isolated by a single passage through a 26-G3/8 syringe needle (Microlance).

4. Prepare a Percoll gradient as follows: use a 13.5-ml Beckman centrifuge tube filled with 0.86 ml Percoll, density 1.130 g/ml, 2.74 ml 10 m*M* Tris–HCl (pH 7.4), and 0.40 ml 2.5 *M* sucrose. Add density marker beads to monitor gradient, red beads (1.12 g/ml) in Percoll containing 0.25 *M* sucrose, and yellow beads (1.049 g/ml) in Percoll containing 0.25 *M* sucrose. Spin for 30 min at 30,000 *g* at 4°C with a 60° angle head rotor; red beads will form a line 5 mm from the bottom of the tube, with the yellow beads a further 12 mm above.

5. Gently layer the homogenate on top of the gradient and spin for 10 min at 30,000 *g*, which generates two bands from the homogenate. Damaged nuclei and whole cells are found in the upper band 7 mm above the red beads, whereas the pure nuclear fraction is found 0.5 mm below the red beads. Remove this fraction and wash gently in 150 m*M* Tris–HCl (pH 7.4) for 5 min at 4°C.

6. Spin the isolated nuclei onto 5-mm poly-L-lysine-coated silicon slips. Spin the silicon chips in 1.5-ml Eppendorf tubes previously half-filled with polymerized resin. Overlay the Si chips with 0.5 ml of freshly isolated nuclear suspension and spin for 5 min at 1000 *g*.

7. Fix the whole chip (+nuclei) in 6% glutaraldehyde in 0.15 *M* Sorensen's buffer for 20 min, rinse

gently in buffer, and postfix in 1% osmium tetroxide in 0.15 *M* Sorensen's buffer for 1 h. Dehydrate, critical point dry, and coat with 3–4 nm of tantalum or chromium.

Pitfalls

1. Low yield of nuclei. Dounce tissue homogenizers are produced with different clearance distances between the polished tube and the pestle. Some homogenizers are designed just to disrupt tissues as a necessary step prior to homogenization of nonsuspension cells. Make sure that the clearance distance of the Dounce tissue homogenizer for the final release of the nuclei is small enough to disrupt whole cells. Some manufactures offer pestles with two different clearance distances to allow tissue disruption and release of the nuclei within one and the same tube. For certain cell types, making the buffer more hypotonic can help increase the yield of nuclei.

2. Enzymatic degradation of structures. It is good practice to ensure cooling for every preparation step prior to the fixation of nuclei on silicon chips. Moreover, the homogenate should be processed without delay. Therefore, preparation of the Percoll gradient before homogenization is recommended. To ensure a suitable ratio between biological material and buffer, a homogenizer with a sufficient capacity (for 8 ml) should be selected. Do not reduce the number of cells significantly to keep this ratio in a homogenizer with lower capacity, as this might cause problems with recognition of the nuclear layer after gradient centrifugation.

5. Preparation of in Vitro-Assembled Organelles for FESEM

Organelles, such as nuclei, endoplasmic reticulum (ER), and Golgi, can be assembled in cell-free extracts. Extracts made from frog eggs are a particularly powerful system for studying the assembly, dynamics, and functions of these organelles. Organelles can be isolated cleanly from the extract and their surfaces can be examined by FESEM. *In vitro*-assembled nuclei, as well as ER, can be prepared for FESEM as follows.

Solutions

1. *Membrane wash buffer (MWB)*: 250 m*M* sucrose, 50 m*M* KCl, 50 m*M* HEPES–NaOH (pH 8.0), 1 µg/ml aprototin, and 1 µg/ml leupeptin

2. *Fix buffer*: 150 m*M* sucrose, 80 m*M* PIPES–KOH (pH 6.8), 1 m*M* MgCL, 2% paraformaldehyde, and 0.25% glutaraldehyde

Steps

1. Prepare *Xenopus* egg extracts (Newmeyer and Wilson, 1991) and incubate extract with demembranated *Xenopus* sperm chromatin to assemble nuclei. ER and Golgi will also assemble in the same extract.

2. After the required time, remove a 4-µl extract, place in a 1.5-ml Eppendorf tube, and resuspend very gently in 1 ml of MWB. At this stage, centrifugation of *in vitro* nuclei and organelles onto 5-mm^2 silicon chips requires a simple modification of the 1.5-ml Eppendorf centrifuge tubes as follows. Remove lid from tube and cut tube with a sharp knife at a level where the cut end fits tightly into the lid, thus creating a "flat-bottomed" tube. Snap the cut end into the lid, having placed a silicon chip in the lid first.

3. Pipette the 1 ml of MWB containing the extract into the modified tube, spin in a swing-out rotor, inside a 10-ml centrifuge tube (with a single tissue as cushion), and spin for 10 min at 4°C or room temperature at 2000 *g*. Some leakage of the suspension at the joint between the cut end of the tube is not a problem at this point.

4. Pipette off most of the buffer, break open the tube, and remove the chip. Place the chip in 5 ml of fix buffer in a small petri dish for 10 min at room temperature.

5. Wash chip in 0.2 *M* cacodylate (pH 7.4), place in 1% OsO_4 in 0.2 *M* cacodylate for 10 min, wash twice in distilled water, and place in 1% aqueous uranyl acetate for 10 min (at room temperature) and then dehydrate, critical point dry, etc.

C. Critical-Point Drying

All traces of water should be removed from ethanol, Arklone, and CO_2. Let 100% ethanol and Arklone stand over molecular sieve for more than 24 h prior to use. High-purity liquid CO_2 (less than 5 ppm water) should be used and passed through a water filter as a precaution.

Steps

1. Exchange Arklone for CO_2.
2. Flush six times.
3. Leave in CO_2 for 30 min.
4. Flush six times.
5. Raise temperature to 40°C.
6. Release gas slowly (over about 15–20 min).
7. Transfer to coating unit as soon as possible.

Pitfalls

Critical-point-dried samples should be transferred immediately into the sputter coater to avoid rehydration, and coated samples are best viewed in the microscope directly. However, if it is known that the microscope cannot be accessed, it is better to pause

preparations after critical-point drying and store preparations under vacuum.

D. Sputter Coating

Steps

1. Pump specimen to at least 5×10^{-7} mbar.
2. Introduce high-purity argon to a pressure of 8×10^{-3} mbar.
3. Start specimen rotation (60 rpm).
4. Sputter at 50–100 mA current (voltage 450 V) and 60 rpm; specimen table should be tilted at 30°. Presputter onto the shutter for 20–60 s to remove the chromium oxide layer from the target.
5. Open shutter and deposit 2 nm chromium as indicated by a film thickness monitor (usually 20–30 s).
6. Examine in microscope as soon as possible, preferably within a day or two. Coatings are variable according to the specimen, but a general rule is that they deteriorate with time, usually over a few days to about 2 weeks.

E. Microscopy

Steps

1. A liquid nitrogen-cooled decontaminator (if present) should always be used; this is more likely to be fitted on an "in-lens" electron optical column configuration. Many recent field emission instruments are of conventional "pinhole configuration," but with very short working distances to optional decontamination devices.

2. Spot size and apertures should be as small as possible, consistent with a sufficient signal to visualize high resolution of specimen at photographic collection rates (e.g., 40-s scans).

3. An appropriate accelerating voltage must be selected. High-resolution scanning electron microscopes usually work in the range of 1–30 kV. Instrument resolution decreases with decreasing accelerating voltage; however, at high voltage there may be problems with charging and specimen penetration, leading to a nonspecific signal from below the specimen surface. At low voltage, penetration and charging are reduced, but so are resolution and signal. Signal is generated almost completely from the surface at 1.0 kV so there is no problem of a "bulk" signal from underlying structures. In general, we use high kilovolts for thin and conductive specimens and lower kilovolts for bulky or less conductive specimens; however, a wide range of kilovolts should be experimented with for each type of sample. The more recently produced field emission instruments have vastly improved low kilovolt performance, and specimens that have some inherent conductivity as a result of osmium fixation can be viewed uncoated at low kilovolts, without compromising signal and resolution.

F. Immunogold Labeling

The basics of specimen preparation for immunogold labeling are beyond the length limits for this article and are adequately covered elsewhere (see article by Roos *et al*. for additional information). For immunogold labeling for HRSEM, the following points are important.

1. Size of Probe

The choice of probe size is a compromise between sensitivity and subsequent detection. Very small gold probes (around 1 nm) have minimal steric hindrance and consequently label with maximum sensitivity. One-nanometer gold has been visualized by backscatter imaging in HRSEM (Hermann *et al*., 1991), but this is at the limits of resolution and is best increased in diameter *in situ* by silver or gold enhancement to a size at which it can be visualised more easily (around 5–10 nm). We have used both 5- and 10-nm gold as a good compromise between sensitivity and localization. Because most modern instruments will discriminate easily between 5- and 10-nm labeling, these can be used together successfully for double-labeling studies.

2. Coating

Using gold probes obviously prohibits gold coating for SEM. In the past, gold-labelled specimens have been coated with carbon, mainly to inhibit charging, but carbon produces a severely limited secondary electron signal and, consequently, little topographical information. We have found that a 1.5-nm chromium coating provides the ideal solution, retaining the full secondary electron-generated surface information, without compromising the detection of gold by backscattered electron detection (Allen and Goldberg, 1993).

In this situation, having found that "mixed" imaging of SE and BSE signals was not satisfactory, we have chosen to collect each signal separately (but simultaneously) and then to superimpose the gold BSE signal onto the secondary signal (retaining register) in Adobe Photoshop, often altering the colour to improve the appearance of label against the monochrome background. In modern instruments with good low kilovolt performance, uncoated or carbon-coated imaging will generate such a strong signal from gold probes that they are observed easily in secondary electron imaging.

IV. COMMENTS

Although field emission SEM has been available for some time, it is still a relatively new technique in cell biology. The procedures given here may need to be modified to optimize the preservation of some structures. Probably the most difficult step is exposing recognizable and undamaged intracellular surfaces. Isolation of organelles offers the possibilities of further characterization by other methods, but gives no "*in situ*" information and may involve extensive biochemical protocols. Resinless sections and dry fracture give *in situ* information, but only after some initial extraction of the cell. Freeze fracture, followed by frozen hydrated coating and visualization, may alleviate these problems but is limited by the plane of fracture, as the structure of interest may not be exposed. It is also technically difficult and expensive. Osmium etching results in spectacular images of intracellular membranes, but the uncertainty of what is removed makes interpretation difficult. Direct visualization of biological interfaces in cell-free systems (e.g., *in vitro* nuclear formation) is a particularly promising area (Goldberg *et al*., 1992, 1997). Considerable fresh structural information has also been demonstrated for nuclear pore complexes and associated structures (Ris, 1991; Goldberg and Allen, 1992, 1996; Kiseleva *et al*., 1996).

Laser Capture Microdissection

Virginia Espina and Lance Liotta

I. INTRODUCTION

Laser capture microdissection (LCM) is a technology for procuring pure cell populations from a heterogeneous tissue or cytological preparation under direct microscopic visualization. One of the most common problems encountered by the investigator involved in the proteomic or genetic analysis of tissue samples arises from the heterogeneous nature of the tissue and the need for a pure cell population for studies. There are often many cell populations in a single tissue. When working with malignant or premalignant tissues, the abnormal cells of interest may lie within, or very close to, areas of totally normal cells.

LCM enables the investigator to isolate single cells or multiple cells, representing specific malignant, premalignant, or normal tissues. The ability to analyze pure cell populations permits analysis of molecular events representative of the tissue at the time of sample procurement. Comparisons of molecular events at tissue interfaces may be analyzed in relation to the microtumor environment using LCM technology. The isolated cells may be assayed for DNA, RNA, or protein by any method with sufficient sensitivity.

A stained section of the heterogeneous tissue is mounted on a glass microscope slide and viewed under high magnification. The slide position is manipulated via a joystick, allowing visualization of the cells for microdissection. Cells of interest are directed under an infrared (IR) laser, mounted in the optical axis of the microscope. A thermoplastic film, placed in direct contact with the tissue section, is melted with a laser pulse. The molten polymer surrounds and embeds the cells in the vicinity of the laser pulse, forming a polymer–cell composite. When the film is lifted away from the tissue, the cells of interest are sheared from the tissue section and remain adhered to the polymer. Incorporation of an energy-absorbing dye into the thermoplastic film, coupled with the low energy of the IR laser, prevents damage to the cellular constituents. Extraction buffers are applied to the film for solubilization of DNA, RNA or protein contained in the captured cells (Fig. 1).

Automated LCM (AutoPix, Arcturus Bioscience, Mountain View, CA) combines the features of LCM, robotics, and imaging software to facilitate the visualization and microdissection of tissue. Quantitation of the laser spot size and percentage overlap of the laser pulses add a level of standardization to the microdissection technology. Cell recognition software enhances LCM technology for fluorescent immunostained tissues.

The AutoPix makes it possible for the operator to conduct "hands off" microdissection once the relevant cells are marked by the operator or are recognized by the computer image recognition software.

II. MATERIALS AND INSTRUMENTATION

A. Specimen

1. For protein analysis of microdissected tissue, use frozen tissue sections cut at 2–15 µm or cytospin preparations.
2. For RNA or DNA analysis of microdissected tissue, use frozen tissue sections cut at 2–15 µm, cytospin preparations, or ethanol or formalin-fixed paraffin-embedded tissue sections.

Copyright 2006, Elsevier Science (USA).
All rights reserved.

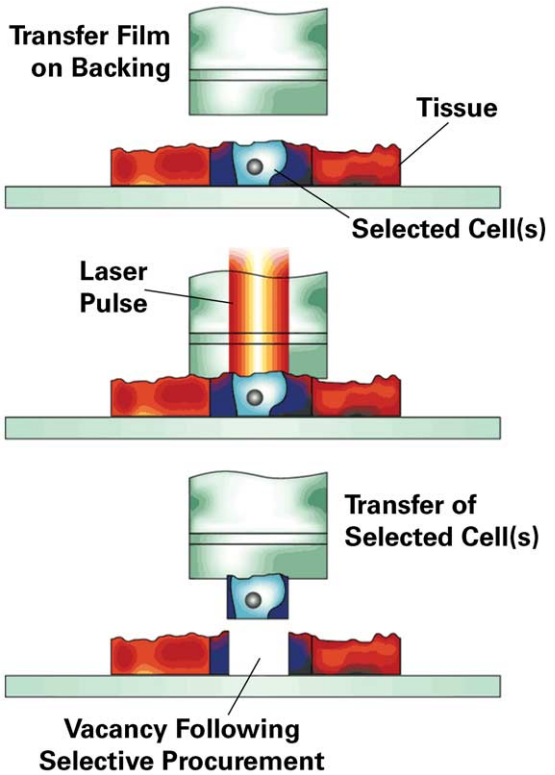

FIGURE 1 A polymer film is placed in direct contact with the tissue. A pulsed infrared laser melts the polymer, allowing the polymer to surround and embed the cells in the vicinity of the laser pulse. The polymer–cell composite is removed from the tissue section, resulting in microdissection of the cells.

3. Precleaned, uncoated glass microscope slides (Cat. No. G15978A, A. Daigger & Co.)
4. Hematoxylin and eosin (H&E) stain:
   a. Mayer's hematoxylin solution (Cat. No. MHS-128, Sigma Diagnostics)
   b. Hematoxylin is an inhalation and contact hazard. Wear gloves when handling.
   c. Eosin Y solution, alcoholic (Cat. No. HT1101-128, Sigma Diagnostics)
   d. Eosin Y is flammable. Store away from heat, sparks and open flames.
   e. Scott's tap water substitute blueing solution (Cat. No. CS410-4, Fisher Scientific)
5. Ethanol gradient: 70% (v/v in purified H_2O), 95%, and 100% ethanol
   a. Ethyl alcohol, absolute 200 proof for molecular biology (Cat. No. E702-3 Sigma-Aldrich Chemical Co.)
   b. Ethanol is flammable. Store away from heat, sparks and open flames. Do not ingest.
   c Contact hazard, wear gloves when handling.
   d. Purified water (type I reagent grade water)
6. Xylene or Sub-X xylene substitute xylene (Cat. No. 8671-10, Mallinckrodt Baker, Inc.;
   a. Sub-X Xylene substitute, (Cat. No. 03670, SurgiPath Medical Industries, Inc.)
   b. Xylene vapor is harmful or fatal, use with appropriate ventilation, and discard in appropriate hazardous waste container. Xylene and Sub-X xylene substitute are flammable; store and use away from heat, sparks, and open flame.
7. 500-µl microcentrifuge tubes (Safe-Lock Eppendorf tubes Cat. No. 22 36 361-1, Brinkmann Instruments; or GeneAmp 500-µl thin-walled PCR reaction tubes Cat. No. 9N801-0611, Perkin-Elmer Applied Biosystems)
8. 50-ml polypropylene tubes (Cat. No. 352070 Falcon Blue Max Becton-Dickinson and Co.)
9. Extraction buffer for constituent of interest
10. Tweezers or hemostat
11. 100-ml graduated cylinder

B. Instrumentation

1. PixCell II, IIe, or AutoPix laser capture microdissection system (PixCell IIe Cat. No. LCM1105 or AutoPix Cat. No. LCM1110, Arcturus Bioscience)
2. CapSure Macro LCM caps or HS CapSure LCM caps (CapSure Macro caps Cat. No. LCM0201; HS CapSure caps Cat. No. LCM0204, Arcturus Bioscience)
3. –80°C freezer
4. Vortex
5. 37–70°C oven
6. Microcentrifuge

III. PROCEDURE

A. Preparing Tissue Section

1. Prepare staining solution and ethanol gradient. Dispense approximately 50 ml each of Mayer's hematoxylin, eosin (optional for protein analysis), purified H_2O, and Scott's tap water into appropriately labeled covered containers, such as polypropylene Falcon tubes.
2. Dispense 50 ml of xylene or xylene substitute into a suitable labeled, covered container. Do not place xylene in polystrene containers, as xylene will dissolve the polystrene. Polypropylene tubes are recommended.
3. To prepare 70% ethanol, dispense 30 ml of purified H_2O into a 100-ml graduated cylinder. Add 70 ml of 200 proof ethyl alcohol. Mix well. Pour approximately 50 ml into two suitable labeled containers.

4. To prepare 95% ethanol, dispense 5 ml purified H_2O into a 100-ml graduated cylinder. Add 95 ml of 200 proof ethyl alcohol. Mix well. Pour approximately 50 ml into two suitable labeled containers.

5. Use tweezers or hemostats to dip slides in each solution for the indicated time. Blot slides on the short edge of the slide with an absorbent paper between each solution. Eosin is optional for staining tissue intended for protein analysis.

B. Protocol for Staining Frozen Tissue

a. 70% ethanol: 5 s
b. Purified water: 10 s
c. Mayer's hematoxylin: 15–30 s
d. Purified water: 10 s
e. Scott's tap water: 10 s
f. 70% ethanol: 10 s
g. Eosin-Y (optional): 3–10 s
h. 95% ethanol: 10 s
i. 95% ethanol: 10 s
j. 100% ethanol: 10 s
k. 100% ethanol: 1 min
l. Xylene or xylene substitute: 30–60 s

C. Protocol for Staining Paraffin-Embedded Tissue

a. Xylene: 5 min
b. Xylene: 5 min
c. 100% ethanol: 30 s
d. 95% ethanol: 30 s
e. 70% ethanol: 30 s
f. Purified water: 20 s
g. Mayer's hematoxylin: 15–30 s
h. Purified water: 20 s
i. Scott's tap water: 20 s
j. 70% ethanol: 20 s
k. Eosin-Y (optional): 3–10 s
l. 95% ethanol: 20 s
m. 95% ethanol: 20 s
n. 100% ethanol: 20 s
o. 100% ethanol: 1 min
p. Xylene or xylene substitute: 30–60 s

D. Conducting Microdissection

1. To begin operation of the PixCell II or IIe, turn on the power switches for:

PixCell II/IIe (switch is located at the right back of the microscope)
Controller (located on the back of the controller)
Video monitor (located on the lower front right) for PixCell II only
Computer (located on the front of the CPU)
Computer monitor (located on the front of the computer monitor)

There is no warm-up period required for the PixCell II/IIe. The instrument is ready for operation. The AutoPix requires a warm-up period of 1 h prior to use.

2. Load the CapSure cassette module with a CapSure cartridge.

a. Remove the CapSure cassette module from the platform.
b. Press in the locking pins on each end to hold the cassette in the load position.
c. Slide a CapSure cartridge onto the cassette until it stops. Two cartridges may be loaded onto the cassette module.
d. After the cartridges are loaded, pull the locking pins out to lock the cartridges in place. Load the cassette module onto the PixCell II/IIe.

3. Move the joystick into the vertical position to ensure proper positioning of the cap in relation to the capture zone.

4. Place the air dried microscope slide containing the prepared and stained specimen for microdissection on the stage. After the target area for dissection is in the viewing area, press the "vacuum" switch on the front of the controller to activate the vacuum and hold the slide in place during microdissection.

5. Slide the CapSure cassette backward or forward so that a cap is sitting at the "load" position. Swing the placement arm over the cap. While placing one hand over the weight to prevent jarring of the cap and improper seating, lift the placement arm and place the cap onto the slide.

6. Access the LCM software program by double clicking on the Arcturus software icon.

7. Enter your user name or select a name from the list. Click on "acquire data".

8. Enter a study name or select a study name from the list. Click on "select".

9. Enter the slide number and cap lot number. If desired, notes concerning the slide or study may be entered as "notes."

10. Click the checkbox for "stamp images with name, date, and time" if this information is to be imprinted on the images created during LCM. Click "continue." The live video screen displays the current image on the microscope. The images may be saved as you work.

Map image: lower power objective image of the general area to be microdissected
Before image: intact tissue prior to microdissection
After image: tissue after microdissection
Cap image: microdissected tissue only

11. Enable the laser by turning the key switch located on the front of the controller and then press the "laser enable" button. Pressing this button will activate the target beam when the placement arm is in the transfer position.
12. Verify that the laser is in focus.
    a. Select 7.5-µm spot size using the "spot size adjust" lever found on the left side of the microscope.
    b. Rotate the objectives of the microscope until the 10× objective is in use.
    c. Reduce the intensity of the light through the optics until the field viewed on the monitor is almost dark and the target beam is viewed easily.
    d. Using the "laser focus adjust" located just below the size adjustment lever, adjust the target beam until the beam reaches the point of sharpest intensity and most concentrated light with little or not "haloing." The laser should now be focused for any of the three laser sizes. Select the laser spot size suitable for the microdissection and cell size.
13. Press the red pendant button to fire a test laser pulse. Observe the spot as the laser is fired. Firing the laser pulse causes the polymer to melt or wet in the vicinity of the laser pulse. There should be a distinct clear circle surrounded by a dark ring. This dark ring is produced by a dye impregnated in the polymer film. The dye is concentrated around the edges of the melted polymer, permitting visualization of the melted polymer in the area of the laser pulse. This pattern indicates proper laser focusing, operation of the laser, and the performance of the CapSure film. The ring should be sharp in appearance. A "fuzzy" ring could indicate improper focusing of the laser.
14. Adjust the "power" and "duration" of the laser pulse with the up-and-down arrows on the front of the controller to obtain a wetted polymer spot with the same diameter as the selected laser size. Use the suggested ranges as a reference point. These settings can be adjusted up or down to customize the wetted polymer spot to the type and thickness of the tissue to be dissected. The suggested settings are as follow

Spot size	Power	Duration
7.5 µm	25 mW	3.0 ms
15 µm	30 mW	5.0 ms
30 µm	30 mW	8.0 ms

15. Single cell microdissection is possible by adjusting the power and duration settings such that a very narrow area of the polymer is melted with each laser pulse. Suggested settings for single cell microdissection are power 45 mW and duration 650 µs.
16. To perform the microdissection, locate the cells of interest. Using the target beam to guide the dissection, press the pendant switch for single shots. For a rapid fire of pulses, hold the pendent switch down. The frequency interval can be adjusted on the controller by selecting "repeat" and then selecting the desired time between laser pulses.
17. After the desired number of shots has been collected on a cap, remove the cap by lifting it off the slide using the placement arm. Lift and rotate the arm until the cap is over the "cap removal site." Lower the arm and then rotate the arm back toward the slide. The cap will remain sitting in place on the removal site. Remove the cap and blot the polymer surface using the LCM CapSure pad to remove any nonspecific tissue or debris that may have adhered to the surface (Fig. 2).
18. Insert the polymer end of the cap into the top of a 500-µl microcentrifuge tube. The sample is now ready for extraction of the desired components or to be frozen at –80°C for analysis at a later date.
19. Click the "done" button on the image toolbar. Another slide may be microdissected, another study initiated, or the program may be terminated.
20. Click "save images" to save the images on the C drive of the PC. The images may be copied to a PC-formatted, 100-mb zip disk as a .JPEG or .TIFF format after saving the image on the C drive.
21. Click on "save data."
22. After all dissections are completed, the PixCell II/IIe should be put in shutdown by first pressing the "laser enable" button to disable the laser. Turn off the power to the PixCell II/IIe, the controller, and the video monitor.

IV. COMMENTS

When using the 30-µm laser spot size, the operator can expect to collect on average five to six cells per laser pulse. Using this information, it is possible to estimate the number of cells captured based on the number of pulses fired during the collection of cells:

Number of pulses × 5 = total cells captured

V. PITFALLS

At least three classes of adhesive forces are acting on the selected cells during microdissection: (1) adhesion upward to the locally melted polymer, (2) adhesion laterally to the surrounding tissue elements, and

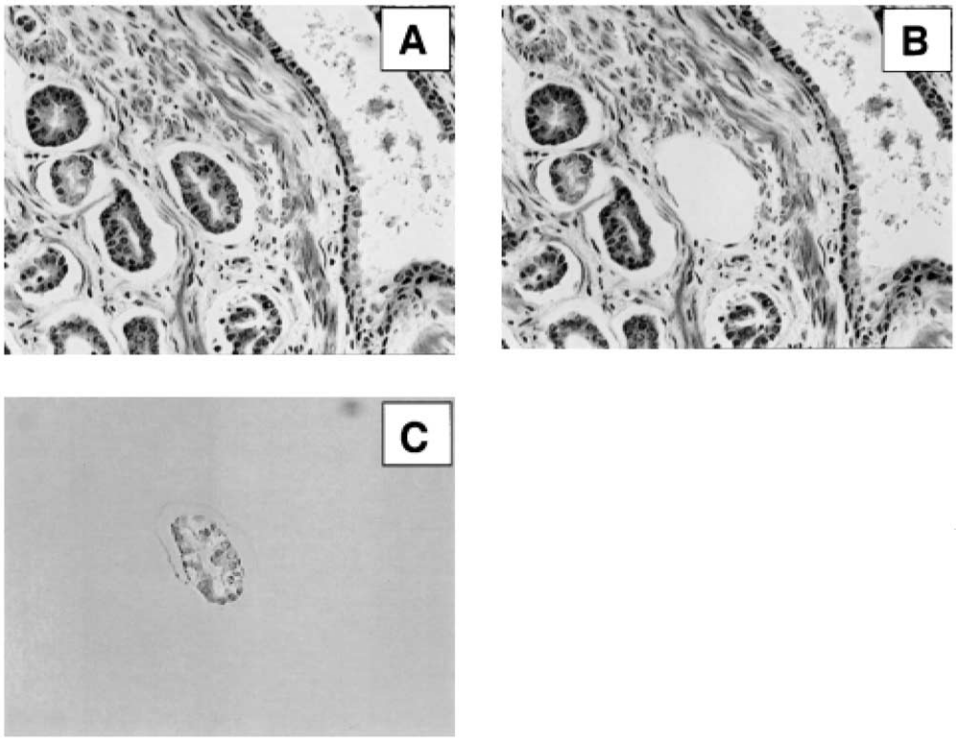

FIGURE 2 Laser capture microdissection of an individual gland in breast ductal carcinoma. (A) H&E stain of heterogeneous human breast tissue, (B) microdissection of the gland of interest, and (C) polymer–cell composite after transfer to film.

(3) adhesion downward to the glass slide. If adhesive forces #2 and #3 are too great, then microdissection may be incomplete. Lateral adhesive forces are largely a function of the extracellular matrix composition and tissue architecture. The operator does not have much control over lateral adhesive forces. However, slide coatings and treatments can markedly influence adhesion to the glass slide.

1. Maintaining upward adhesive forces:
   a. Tissue sections should be flat and free of folds and wrinkles. Unevenness can prevent proper seating of the polymer cap and limit effective cell capture.
   b. Incomplete deparaffinization of embedded tissues limits the amount of tissue transferred during microdissection. Deparaffinization times listed are minimal times and, if necessary, may be extended, allowing complete removal of the paraffin from the tissue section.
   c. Improper focusing of the laser may cause unsuccessful microdissection. The laser should be focused on the 7.5-μm spot size with the 10× objective. The laser should be focused at the beginning of each LCM session and whenever the slide type being used is changed or the cap is repositioned on the slide.
2. Limiting lateral adhesive forces: Tissue section thickness should be between 2 and 15 μm. Optimal microdissection is achieved with tissue sections cut at 5–8 μm.
3. Minimizing downward adhesive forces:
   a. Use plain, uncharged glass microscope slides for optimal microdissection. While some success has been achieved using poly-L-lysine, silanized, or charged slides with lung tissue, best results for the majority of tissues are obtained with plain glass slides.
   b. Preparation of frozen sections requires the slides to be frozen at −80°C or to proceed immediately with staining after placing the tissue section onto the slide. Never allow the tissue to dry on the slide. Drying the tissue on the slide makes LCM almost impossible and will denature the analyte molecules.
   c. Incomplete dehydration of the tissue section prior to LCM limits the operator's success in microdissection. The xylene rinse is essential for complete dehydration of the tissue on the slide. It is imperative that each staining proto-

col for LCM incorporates a thorough rinse in xylene or xylene substitute. If it is suspected that the slide is not completely dehydrated, allow it to sit in xylene for additional time.

Chromosome Microdissection Using Conventional Methods

Nancy Wang, LiQiong Li, and Harindra R. Abeysinghe

I. INTRODUCTION

During cytogenetic analysis there are frequently complex chromosomal structural aberrations, which are unidentifiable by chromosome banding analysis. Fluorescence *in situ* hybridization (FISH) combined with G-banding analysis (Xu and Wang, 1994) has significantly improved the accuracy of chromosome identification. However, the efficacy of FISH analysis depends on the probes chosen, which in turn depend on the G-banding result. It is very difficult to choose the adequate probe(s) for FISH analysis when no clue is available from banding analysis. Therefore, FISH can serve as a tool for verification and confirmation. The recently developed multicolor or spectral karyotyping highly facilitates the identification of complex interchromosomal structural abnormalities. However, its application is limited to nonhomologous rearrangements and its efficacy depends on the size of the chromosome segment involved. Furthermore, it can identify the chromosomes involved but not the specific segment or breakpoints involved.

In contrast, the chromosome microdissection approach provides a straightforward method for identifying any chromosomal segment of unknown origin by dissecting the segment of interest and isolating, amplifying, fluorescence labeling, and reverse *in situ* hybridizing DNA to normal metaphase spreads (Ludecke *et al*., 1989; Bohlander *et al*., 1992; Carter *et al*., 1992; Meltzer *et al*., 1992; Ruano *et al*., 1992; Telenius *et al*., 1992; Guan *et al*., 1993; Zhang *et al*., 1993). Once the components of the aberrant chromosome are identified, conventional FISH with whole chromosome painting probes can be applied to define the relative position of the components in the marker chromosome. This micro-FISH approach has been applied successfully in the identification of ring chromosomes (Xu *et al*., 1995, 1998), homogeneous staining regions (Xu *et al*., 1996; Abeysinghe *et al*., 1999), and double minutes (Sen *et al*., 1994). Thus, micro-FISH can be used to identify not only the origin of the marker chromosome, but also the regions and breakpoints.

However, in the reverse FISH the specificity of the probe generated relies on the accurate recognition and dissection of the specific target chromosome/segment and on the precise extraction, amplification, and labeling of the DNA with minimum background contamination. The skills, procedures, and setup involved in micro-FISH are too complicated to be established in the routine clinical cytogenetic laboratory. This is the major limitation to the application of reverse FISH by chromosome microdissection. With a modified fixation procedure (Xu *et al*., 1995), however, specimens can be stored and shipped to experienced laboratories or diagnostic centers. In addition to its clinical application, chromosome microdissection can be used to generate band-specific probes (Guan *et al*., 1993) that can be used in establishing intrachromosomal spectral karyotyping. A combination of interchromosomal spectral karyotyping with intrachromosomal spectral banding analysis would be ideal for chromosome analysis in neoplasia.

II. MATERIALS AND INSTRUMENTATION

A. Materials

Methyl alcohol (Fisher Scientific, #MD3017-4)

Acetic acid, glacial ACS (Fisher Scientific, #A38-500)
Colcemid 10 µl/ml in HBSS (GIBCO, #15210-040)
Trypsin (1:250) (GIBCO, #27250-018)
KaryoMax Giemsa stain (Lab Chem Inc., #2C 14840-7)
Hank's balanced salt solution ×1; without $CaCl_2$ + Mg (Sigma, #119349)
Buffer tablets "GURR" (GIBCO, #10582-013)
Deionized distilled (dd) water
T7 DNA polymerase (Sequenase, Version 2.0, USB #70755Y)
Topoisomerase 1 (Promega, #M2851)
Biotin-16-dUTP (Boehringer Mannheim, #1093070)
Taq DNA polymerase (Applied Biosystems, #4311816)
Universal primer 5'-CCGACTCGAGNNNNNNNNAT GTGG-3' (Telenius *et al*., 1992)
15-ml sterile polystyrene tubes (Corning, #43005)
Microneedle (Sutter Instrument Co., #BR100-15)
Coverslips (VWR, 24 × 60 mm #48393-106)

B. Instrumentation

Incubator, 37°C
Inverted microscope (Nikon DIAPHOT-TMD)
9-in. Pasteur glass pipettes (VCR, #53283-915) and bulbs
Micromanipulators (Narashige, Models MM-88 and MO-302)
Micropipete puller (Narishige, Model PB-7)
Thermal cycler (MJ Research Inc., Model PTC-200)
Slide warmer (VWR)
Coplin jars (0.50-ml capacity)
Thin-walled microtubes (Laboratory Products Sales, #430)
Microcon YM-100 columns (Millipore, #42413)

III. PROCEDURES

A. Preparation of Cells for Microdissection

This procedure is modified from those of Wang and Federoff (1972) and Xu *et al*. (1994).

Solutions

1. *Colcemid metaphase arresting solution*: 10 µg/ml (Sigma D1925)
2. *Hypotonic solution*: Prepare daily by mixing 0.4% KCl (EM Science PX1405-1) (in dd H_2O) and 0.4% sodium citrate (EM Science PX0445-1) (in dd H_2O) in equal volume
3. *Fixation solution*: Prepare daily by mixing methanol (Mallinckrodt CAS 67-56-1) and glacial acetic acid (Fisher Scientific A38-500 CAS 64-19-7) in a ratio of 3:1 (v/v)
4. *Trypsin solution*: 0.625 g trypsin (1:250; GIBCO #27250-018) in 100 ml dd H_2O
5. *GURRS buffer solution*: Dissolve one GURRS buffer tablet (GIBCO 10582-013) in 1 liter dd H_2O, adjust pH to 6.8
6. *Giemsa staining solution*: 2–3 ml Giemsa (LabChem Inc. LC14840-7) in 50 ml GURRS buffer solution

Steps

1. Grow cells in cell culture medium supplemented with 10% fetal bovine serum at 37°C in a 6% CO_2 humidified incubator.
2. Prepare chromosome metaphase spreads from a proliferative cell population using colcemid (5–10 µl/ml) for metaphase arresting, hypotonic treatment followed by fixation for chromosome harvesting.
3. Harvest cells either *in situ* or in suspension and then drop on 24 × 60-mm #1.5 coverslips.
4. Perform Giemsa–trypsin–G-banding analysis (GTG) by standard procedure (Wang and Federoff, 1972) for identification of the target chromosome or chromosome segment for microdissection using an inverted microscope.

B. Chromosome Microdissection Combinded with FISH Analysis (Micro-FISH)

The procedure of micro-FISH is performed according to Guan *et al*. (1993) with modification (Xu *et al*., 1995).

Solutions

1. *0.625% banding trypsin*: Add 0.25 g trypsin (1:250) powder to 100 ml dd H_20, mix well, aliquot to 2.0 ml, and store at –20°C
2. *GURR buffer*: Reconstitute with ddH_20 (1 tablet/1 liter), adjust pH to 6.8
3. *Collection buffer (5 µl)*: 40 m*M* Tris–HCl, pH 7.5, 20 m*M* $MgCl_2$, 50 m*M* NaCl, 200 µ*M* of each dNTP, 1 unit Topo 1, and 5 pmol of universal primer
4. *PCR reaction mixture (50 µl)*: 10 m*M* Tris–HCl, pH 8.4, 2 m*M* $MgCl_2$, 50 m*M* KCl, 0.1 mg/ml gelatin, 200 µm of each dNTP, 50 pmol universal primer, and 2 units *Taq* DNA polymerase.
5. *T7 DNA polymerase working solution*: Dilute T7 DNA polymerase (13 U/µl) with dilution buffer to 1.5 U/µl.
6. *Labeling solution (50 µl)*: 100 m*M* Tris–HCl, pH 8.4, 2 m*M* $MgCl_2$, 50 m*M* dcl, 0.1 mg/ml gelatin, 200 µl 4 dNTP, 50 pmol universal primer, 20 µ*M* biotin-16-dUTP, and 2 units *Taq* DNA polymerase.
7. Whole chromosome painting probes obtained from commercial laboratories (Vysis)

1. Chromosome Microdissection and DNA Amplification

Steps

1. Prior to microdissection, fix cells in fixative solution by three washes.
2. Prepare metaphase spreads on 24 × 60-mm #1.5 coverslips and stain by GTG banding.
3. Make microneedles with the micropipette puller according to the manufacturer's manual and UV treat overnight to rule out background DNA contamination.
4. Perform microdissection on the target chromosome/segment, which is identified by its specific G-banding pattern, with glass microneedles (Fig. 1) controlled by a Narashige micromanipulator (Models MM-88 and MO-302) attached to an inverted microscope.
5. Transferr the dissected chromosome adherent to the microneedle to a 0.2-ml microcentrifuge tube containing 5 µl of collection buffer.
6. Cover the collection buffer with 45 µl of mineral oil and incubate at 37°C for 30 min, followed by heat soak at 94°C for 30 min.
7. Use a gene Amp PCR System 9600 (Perkin-Elmer Atus) for DNA amplification.
8. Perform an initial eight cycles of PCR (denaturation at 94°C for 1 min, anneling at 30°C for 2 min, and extension at 37°C for 2 min) by adding approximately 0.3 units of T7 DNA polymerase (Sequence Version 2.0, USB) at each cycle.
9. Add 50 µl of PCR reaction mixture to the tube.
10. Heat the reaction to 95°C for 3 min followed by 35 cycles at 94°C for 1 min, 56°C for 1 min, 72°C for 2 min, with a final extension at 72°C for 5 min.

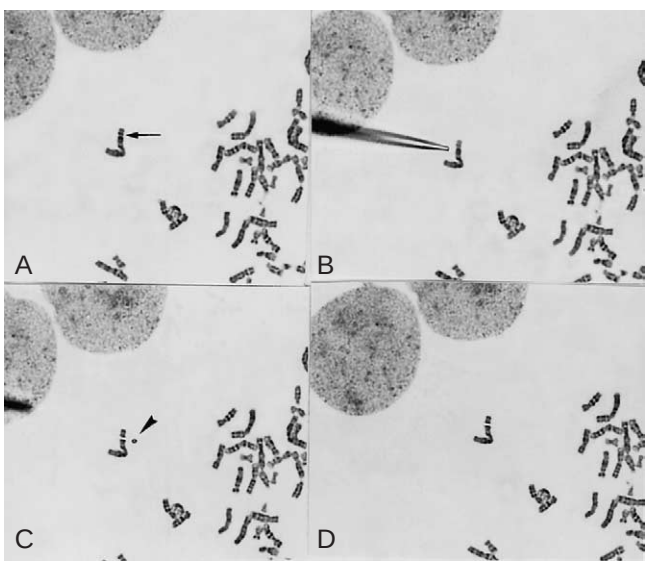

FIGURE 1 Microdissection procedure in progress. The glass needle is aligned using a micromanipulator and the chromosome band or region is dissected. The needle is then used to pick up the dissected piece (C) and transfer it into a collection tube.

2. Fluorescence Labeling of the PCR Product (Fig. 2)

Steps

1. Label a 2-µl aliquot of the PCR product for 16 cycles in a 50-µl secondary PCR with the same procedure

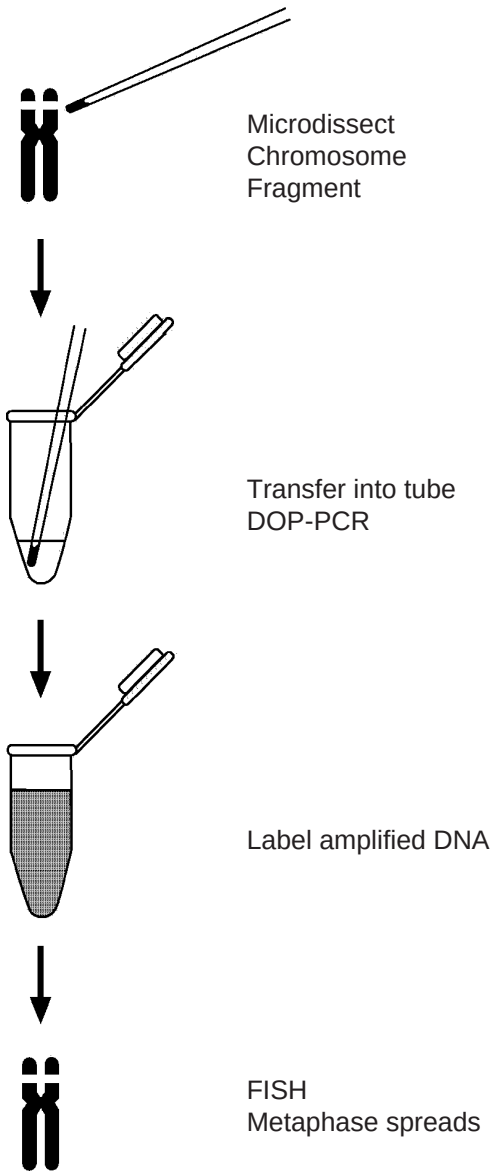

FIGURE 2 Diagram and flowchart of the micro-FISH procedure. Once the whole chromosome or segment is dissected, it is transferred into a collection tube and PCR amplified using random primers. An aliquot of this reaction is then reamplified by PCR with the addition of biotin/digoxigenin dUTP. The labeled PCR products are column purified for use as FISH probes.

as described earlier, except for the addition of 20 m*M* biotin-11-duTP (BMB).
2. Purify the labeled PCR products using a Centricon 100 (Amicon) filter.
3. Add 100 µg of the probe to a 10-µl hybridization mixture containing 55% formamide, 10% detran, 1 × SSC, and 5–10 µg COT-1 DNA (BCL).

3. Verification of the Specificity of the Dissected Chromsome/Segment

Steps

1. Grow the cells with the dissected chromosome/segment on 22 × 22-mm coverslips in 35 × 10-mm petri dishes.
2. Block the cells by treatment with colcemid (Gibco), 0.1 µg/ml for 1 h, hypotonically treated, fixed, and harvested using standard procedures.
3. G-band the chromosomes following trypsin treatment and stain with Giemsa stain.
4. After GTG-banding and karyotyping, destain slides with xylene, xylene/ethanol (1/1, v/v), and methanol/acetic acid (3/1, v/v), refix in 3.7% formaldhyde/phosphate-buffered saline (PBS), air dry, and reuse for FISH as described by Klever *et al*. (1991) using the biotin-labeled probe generated from the dissected chromosome/segment to verify the specificity of the probe.
5. Once the specificity of the probe is confirmed, the probe can be hybridized back to normal metaphase spreads to identify the origin of the dissected chromosome segment.

4. Identification of the Origin of the Dissected Chromosome/Segment(s)

Steps

1. Analyze normal metaphase spreads by GTG banding.
2. Apply FISH analysis with the probe specific for the dissected chromosome/segment to normal metaphase spreads after GTG-banding analysis using the procedure described in the previous section.
3. Combine the result obtained from GTG banding with that obtained from FISH analysis to identify the origin or components of the chromosome/segments dissected.

5. Forward FISH Analysis to Identify the Relative Position of the Components of the Dissected Chromosome

Steps

1. Apply FISH analysis with the commercially available whole chromosome painting probes specific for each of the chromosome components, which are identified by microdissection to the GTG-banded metaphase spreads containing the dissected chromosome.
2. Combining the G-banding and FISH results obtained from each probe determines the relative position of the components on the chromosome dissected.

Micromanipulation of Chromosomes and the Mitotic Spindle Using Laser Microsurgery (Laser Scissors) and Laser-Induced Optical Forces (Laser Tweezers)

Michael W. Berns, Elliot Botvinick, Lih-huei Liaw, Chung-Ho Sun, and Jagesh Shah

I. INTRODUCTION

Individual chromosomes in living cells can be manipulated by optical scissors and optical tweezers. Early experiments (Berns *et al*., 1969) demonstrated that a low power-pulsed argon laser focused onto chromosomes of living mitotic salamander cells resulted in the production of a 0.5-μm lesion in the irradiated region of the chromosome. In these studies, the chromosomes were photosensitized with a low concentration of the vital dye acridine orange. Subsequent studies on salamander and rat kangaroo cells (PTK_2) indicated that the laser microbeam could be used to selectively inactivate the nucleolar genes (Berns, 1978). Using the 266-nm wavelength of a Nd:YAG laser, not only could the nucleolar genes be selectively deleted, causing a loss of nucleoli in the subsequent cell generation, but also a corresponding lack of one light-staining Giemsa band in the nucleolar organizer region of the chromosome could be demonstrated in cells descended from the single irradiated cell (Berns *et al*., 1979). With the further development of cloning techniques specific for single irradiated cells, cellular sublines with deleted ribosomal genes resulting from laser microbeam irradiation of the rDNA on the mitotic chromosome were established (Liang and Berns, 1983). In more recent studies it has been possible to use a picosecond laser to induce two-photon ablation of the ribosomal genes (Berns *et al*., 2000). These studies confirmed the earlier suggestion that short pulsed green lasers could be used to produce nonlinear multiphoton effects on cellular organelles (Calmettes and Berns, 1982). This nonlinear multiphoton effect was also demonstrated by Tilapur and Konig (2002) using a femtosecond laser to transiently disrupt the outer cell membrane.

In addition to the selective manipulation of chromosomes for both genetic studies and studies on chromosome movements during mitosis, pulsed lasers have been used to alter mitotic spindle structures such as centrosomes, microtubules, and chromosome kinetochores (see Berns *et al*., 1981). A major advance in subcellular irradiation occurred in 1997 when Khodjakov *et al*. (1997) described the use of green fluorescent protein (GFP) to light up microtubules and centrosomes in live cells so that these organelles could be selectively targeted. The advent of the use of GFP and its mutant constructs has become a major additive tool to laser microscopy because it permits visualization and targeting of a large number of cell structures and molecules in living cells that were not visualized and targeted easily with either conventional light or fluorescence microscopy.

In 1987, Ashkin and colleagues first used a tightly focused laser beam to generate optical trapping forces to move biological objects. The manipulation of chromosomes in living cells and in isolation buffer was reported by Berns *et al*. (1989). In this study, laser optical tropping force was applied to metaphase

All rights reserved.

chromosomes in order to study the generation of forces within the mitotic spindle. (Liang *et al*., 1991). The combination of laser cutting and laser tweezers was demonstrated by Wiegand-Steubing *et al*. (1991). The combined scissors and tweezers system was used for the fusion of two different mammalian cells and subsequently for chromosome cutting and trapping (Liang *et al*., 1993, 1994). Several good review articles on the use of laser ablation and laser traps should be consulted for a broader overview of this field and these technologies (Weber and Greulich, 1992; Berns *et al*., 1998; Schutze *et al*., 2002). Biologists now have a more complete set of optical tools to manipulate cells and their internal structures such as chromosomes and other structures involved in organelle movement.

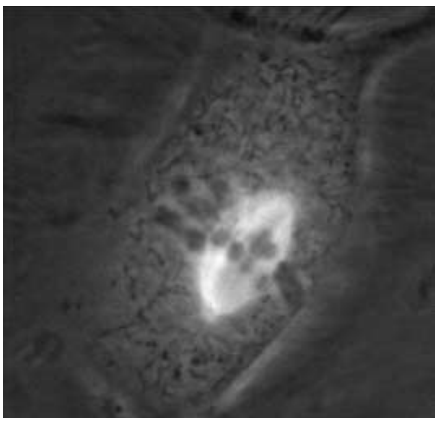

FIGURE 1 Dual-phase contrast and fluorescence image of a live PTK2 (rat kangaroo, *Potorous tridactylis*) cell in mitotic metaphase. The phase-dark chromosomes are aligned at the metaphase plate. Spindle microtubules contain the yellow fluorescent protein (YFP) variant of green fluorescent protein (GFP). Spindle microtubules can be seen attaching to the chromosomes and converging at each pole. See Fig. 7 for laser ablation of a microtubule bundle and transmission electron micrograph of the lesion in this cell.

II. MATERIALS AND INSTRUMENTATION

A. Cells

Rat kangaroo (*Potorous tridactylis*) kidney cells PTK_2 or PTK_1 are well suited for these studies because they have a low chromosome number (12–13) and they remain very flat throughout the entire cell cycle, allowing visualization of cytoplasmic and mitotic structures under phase, fluorescence, or DIC microscopy. The cells can be either standard lines available from the American Type Culture Collection (ATCC-CCL 167) or special sublines that have been transfected to express GFP or genetic variants of the GFP that absorb and emit wavelengths in other regions of the spectrum (Fig. 1).

B. Media, Chemical, and Supplies for Cell Culture

Modified Eagle's medium (Cat. No. 410-1500 ED), penicillin-G (Cat. No. 600-5140AG) 100 units/ml (working concentration for experiment, same as follows), streptomycin sulfate (Cat. No. 600-5140AG) 100 µg/ml, trypsin (Cat. No. 610-5050AJ) 0.25%, L-glutamine (Cat. No. 320-5030AJ) 2 m*M*, pancreatin (Cat. No. 610-5720AG), phenol red (Cat. No. 15-100-019), (phosphate-buffered saline) (PBS) without Ca^{2+} and Mg^{2+} (Cat. No. 310-4200), colcemid (Cat. No. 120-5210AD), and fetal bovine serum (Cat. No. 230-6140AJ) are from GIBCO. EDTA (Cat. No. 34103) and piperazine-*N*,*N*′-bis-2-ethane sulfonic acid monosodium monohydrate (PIPES) (Cat. No. 528132) are from Calbiochem. $CaCl_2$ (Cat. No. 07902) is from Sigma. Hexylene glycol (2-methyl-2,4-pentanediol) (Cat. No. 1134329) is from Eastman Chemical. Culture flasks T_{25} (Cat. No. 25106) and T_{150} (Cat. No. 25126) are from Corning. Centrifuge tubes, 15 ml (Cat. No. 2097) and 50 ml (Cat. No. 2098), are from Falcon. Hemacytometer "Bright Line" (Cat. No. B3180-2) is from Baxter. Centrifuge Dynac II is provided by Clay Adams.

C. Cell Culture Chambers

Chamber tops and bottoms, screws, sterile gaskets, sterile needles, and sterile syringes are components of the multipurpose culture chamber (see Fig. 2). For perfusion of cells with an exogenous agent during or immediately following laser exposure, the exit needle may be coupled to an empty receiving syringe or some other receptacle. The compounds and agents to be applied to the cells are in the injection syringe.

D. Lasers and Microscopy

The lasers and connecting optical system may be interfaced with either an upright or inverted microscope of any major microscope manufacturer. Historically, we have used Zeiss microscopes of various types (upright photomicroscope, inverted Axiomat, Universal M). The current system is built around an inverted Zeiss axiovert S100 microscope (Fig. 3). The mercury arc lamp was moved distally from the epi-illumination optics to accommodate a beam splitter (BS) to combine arc lamp illumination and the laser-trapping beam. A dual-view image module (not shown) and a Quantix

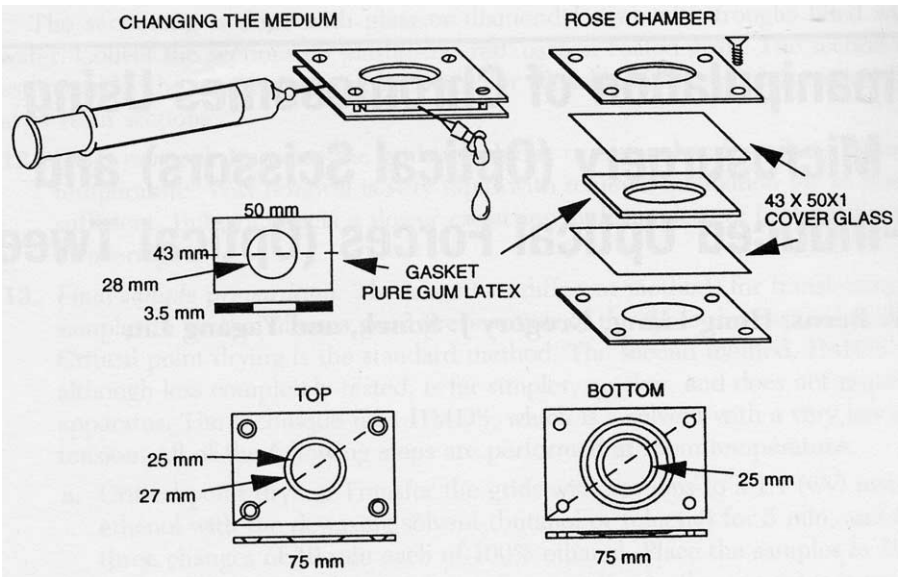

FIGURE 2 Multipurpose cell culture chamber with its component parts *(investigators may use any of a number of different cell chambers that are specifically adapted for their experiments).*

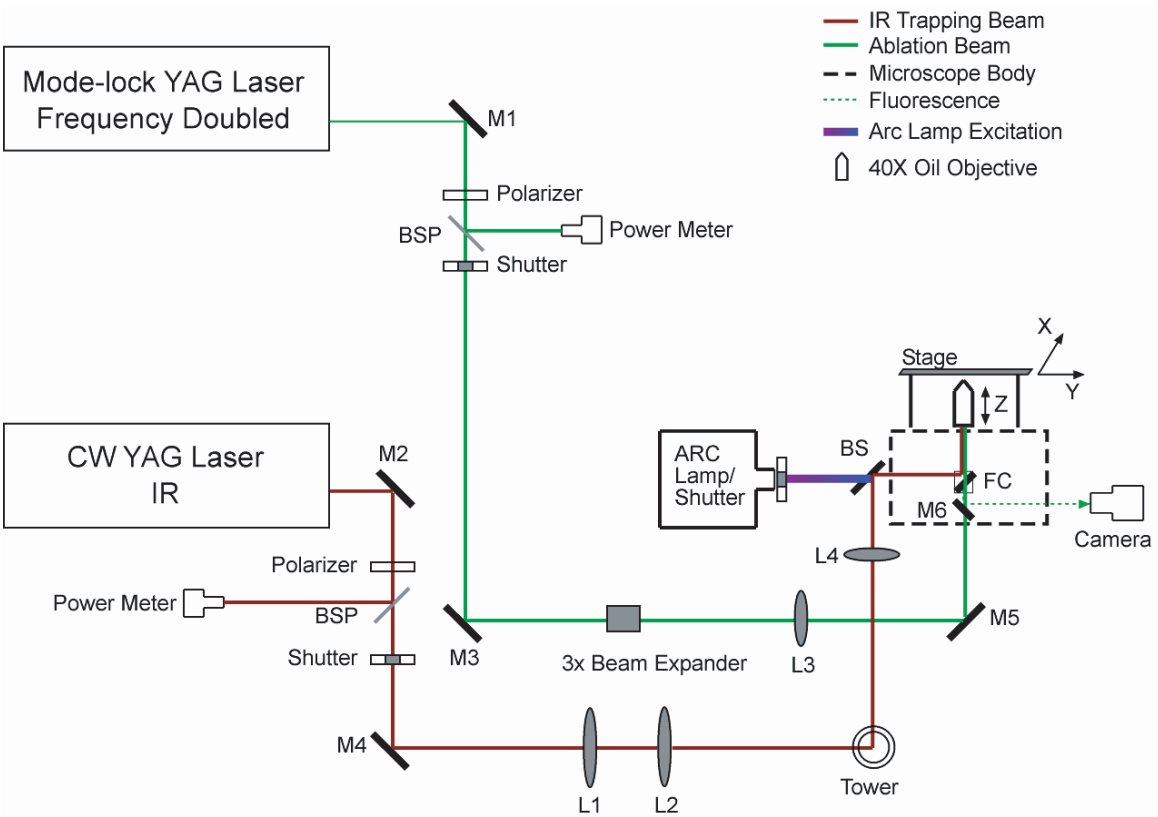

FIGURE 3 Schematic diagram of optical scissors and optical tweezers. M1–M6, mirrors; L1–L4, lenses; BSP, beam samplers; FC, filter cube; BS, beam splitter. Lasers from a variety of manufacturers may be used (see discussion in text). The YAG laser trapping beam can be divided into several beams that are reflected off of different motor-driven mirrors, resulting in multiple individually controlled trapping beams (Berns *et al.*, 1998).

Q-57 back-thinned, cooled CCD are mounted on a camera port of the microscope. Microscope risers (not shown) raise the microscope to access the underneath "Keller" port.

Two different laser systems are used for the cutting scissors beam. Both systems generate 532-nm green light by frequency doubling of the primary 1064-nm wavelength. One system is a Coherent Inc. mode-locked Antares Nd:YAG laser at a repetition rate of 76 MHz with a pulse duration of 100 ps (1064 nm) and 80 ps (532 nm). The other cutting system is a Spectra-Physics Inc. mode-locked Vanguard laser with a repetition rate of 76 MHz and a pulse duration of 10 ps at 532 nm.

Two different trapping lasers have been used: a Spectra-Physics Millenia IR continuous mode ND:YVO_4 laser at 1064 nm, with a maximum power of 10 W, and the primary 1064 wavelength of the pulsed Antares Nd:YAG laser operating at 76 MHz. The maximum power of the Antares laser is 18 W. For either laser, the actual power entering the microscope for the trapping experiments is 1–2 W, and the average power at the objective focal point in the sample is 10–300 mW. The high power of the primary output beam allows for splitting the beam into two beams (not shown in Fig. 3) so that multiple collinear trapping beams can be reflected off of precision motor-drive mirrors and directed into the microscope (Berns *et al*., 1998). This permits simultaneous application of forces on either different objects in the same microscope field or different points on the same object (Fig. 4). The 1064-nm wavelength has the beneficial properties of low water absorption and relatively good cell viability following exposure to the trap. Also, there is a particularly good cellular optical "window" for trapping at 800–820 nm and a lethal window at 740–750 nm (Vorobjev *et al*., 1993; Liang *et al*., 1996). Additionally, diode lasers are now available in useful wavelength ranges for optical trapping. They are more compact and less costly than the large YAG laser systems.

The cutting and trapping laser beams are sampled by partial reflection off a beam sampler (BSP) and monitored with a photodiode power meter. Power control is achieved with Glan polarizers in a motorized rotary mount. The two laser lines are shuttered individually with a minimum exposure time of 3 ms using a mechanical shutter. It should be mentioned that the lasers described earlier are just a few of many different types and models available from several different companies. Investigators may chose from a wide variety of different laser systems depending on individual investigator needs.

Two two-phase dual axis stepper motors operate the *x,y* microscope stage with several micrometer resolution. The stage is driven by a National Instruments stepper motor driver and a flex-motion PXI motion controller.

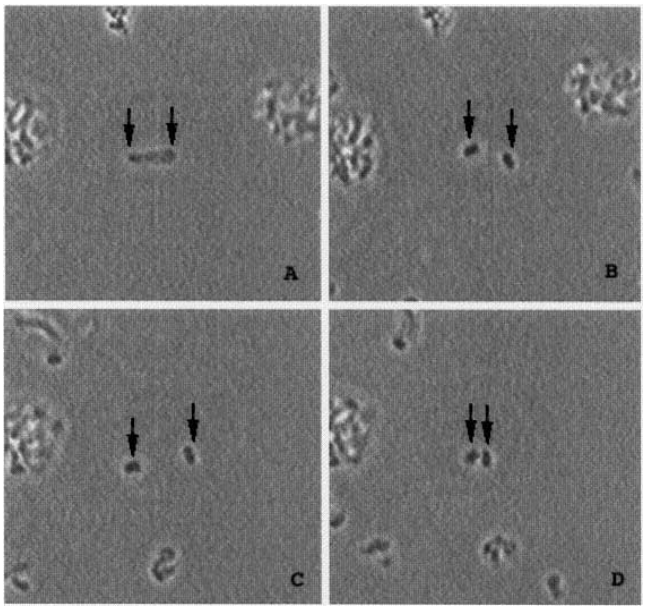

FIGURE 4 Model illustrating laser trapping and cutting of chromosomes in suspension. (A) A single chromosome is held in position using two different laser traps to hold each end of the chromome in the horizontal optical plane of the microscope field (arrows). (B) Two chromosome pieces immediately after being cut with the laser scissors beam; each piece is being held by a laser trap. (C) The two laser traps are used to move the two chromosome pieces apart. (D) The laser traps are used to move both chromosome pieces toward each other. Chromosome width is 2 µm.

1. Microscope and Microscope Modifications

1. A Zeiss Axiovert S100 inverted microscope with a motorized stepper motor stage (joystick controller) and motorized stepper motor for fine focus. A Ph3 Neofluar 40X, 1.3 NA or 63X, 1.4 NA oil immersion microscope objective lens is used.

2. Microscope risers (not shown) are used to lift the microscope 4.25 in. above the table for access to the underneath Keller port.

3. A RS-170 format CCD camera (SONY) for high-resolution, video frame rate imaging of the specimen is used. A Ropert Scientific Quantex Q-57 back-thinned and cooled CCD is used for low-light imaging of fluorescence.

4. An Optical Insight's dual view system is used for simultaneous imaging of two spectral bands on the Q-57 camera (not shown).

5. A modified epi-illumination light path is used whereby the arc lamp is removed from the Zeiss epi-illumination lens system and mounted 4 in. away. A

motorized shutter system (Vincent Associates) to shutter arc lamp illumination is used.

6. A short-pass dichroic BS centered at 1064 nm to combine the visible spectrum from the arc lamp with the IR trapping beam is used.

7. Customized fluorescent filter cubes (FC) with exciters and dichroic beam splitters designed to pass/reflect both the excitation band and a narrow band around the IR laser (centered at 1064 nm) are used.

2. *Laser Interfaces with Microscope*

1. Both the laser scissors and tweezers have their own variable attenuator to control laser power external to the main laser cavity. The attenuator, consisting of a glan laser linear polarizer (CVI Laser, LLC), is mounted in a stepper motor rotational mount (National Instruments) with motion driver and motion control hardware/software (National Instruments) to automate laser power contol.

2. Both laser lines pass through their own beam sampler (BSP) (CVI Laser, LLC), which reflects a small percentage of the attenuated laser beam toward a large area photodetector power meter (New Focus). The detector outputs a voltage proportional to the average power of the attenuated beam.

3. Both laser lines have a motorized shutter placed beyond the beam sampler and share a shutter driver with either RS-232 or TTL control (Vincent Associates). The IR shutter is controlled by a button on the joystick.

4. The 532-nm laser is expanded with a 3X beam expander (Newport) and is focused into the image plane of the Keller port with a f = 300-mm plano-convex lens, L3.

5. The 1064 laser is expanded with a custom-made 4X beam expander consisting of a f = 25.4-mm plano-convex lens, L1, and a f = 100-mm plano-convex lens, L2, which is mounted to allow axial displacement and thus control of divergence from a collimated beam for the purpose of focusing the laser relative to visible light in the microscope objective. The expanded beam is focused at the back focal plane of the Zeiss epifluorescent lens system, after reflection off of BS, with a f = 150-mm biconvex lens, L4.

6. An IR finder scope (FJW Optical Systems, Inc.) and an infrared sensor card (Coherent) are used for detecting and monitoring the IR laser. Some commercial home-use camcorders have a "night vision" mode, which will also visualize scatter of the beam. Please note that the finder scope or camcorder should never directly visualize the beam, only the scatter from optical elements.

7. A computer with appropriate software for recording images, controlling stepper motors, and controlling the shutters is used. A VCR or digital video recorder captures the RS-170 signal at video frame rates.

III. PROCEDURES

A. Preparation of PTK_2 Dividing Cells in Culture Chamber

Solution

0.125% viokase solution: To make 100 ml, dissolve 5 ml of pancreatin, 0.1 g of EDTA, and 0.25 ml of phenol red into 95 ml of PBS without Ca^{2+} and Mg^{2+}, adjust PH to 7.4.

Steps

1. Select a healthy, confluent or nearly confluent flask of cells.
2. Remove the old medium from the flask of cells using an unplugged sterile pipette attached to a vacuum flask.
3. Add 1.0 ml of viokase solution to the flask of cells.
4. Place the flask of cells with viokase in the 37°C incubator for 7–10 min. When the cells begin to lift free from the flask, rap the flask sharply two or three times to dislodge the cells completely.
5. Add 5 ml MEM to inactive the viokase and wash any adhering cells free.
6. Transfer the medium, viokase, and cell mixture to a sterile centrifuge tube.
7. Centrifuge the cell suspension for 4–5 min at 800–1000 rpm.
8. After centrifugation, carefully remove the stopper from the tube and very carefully aspirate the supernatant from the tube.
9. Resuspend the cell pellet in the drop remaining in the tube bottom.
10. Add 5 ml of MEM to the resuspended pellet and count a sample onto a hemocytometer. Count all four corners (i.e., four groups of 16 squares each), divide the result by 4, and multiply by 10^4. This gives the concentration of cells per milliliter of resuspended material.
11. Adjust the cell concentration to give 2.5–3.5 $\times$ 10^4 cells/ml and inject these into the chambers using a sterile syringe and 23-gauge needle (see Fig. 2)
12. Incubate the chambers (cell side down) at 37°C in a 5–7.5% CO_2 incubator. After 36–60 h, select chambers with dividing cells for experimentation.

B. Transfected Cell Lines

Generation of cell lines stably expressing fluorescent protein fusions of human α-tubulin were generated by amphotropic retroviral infection. The following procedures were used to generate two GFP mutants specific to our studies: yellow fluorescent protein (YFP) and cyan fluorescent protein (CFP). Investigators may use other methods to generate fluorescent genetic constructs specific to their needs

1. Excise the human α-tubulin cDNA fused at its N terminus to the enhanced yellow variant of green fluorescent protein (YFP) from a commercially available plasmid (Clontech) via an *Afe*I/*Mfe*I digest.
2. Ligate this fragment into the *Sna*BI/*Eco*RI sites of pBABEbsd, a retroviral vector based on pBABEpuro with a blasticidin resistance marker.
3. Generate the cyan version of the tubulin fusions (CFP-α-tubulin) by insertion of the α-tubulin cDNA into the CFP-C1 vector (Clontech) and then excise by *Afe*I/*Mfe*I and insert into pBABEpuro.
4. Cotransfect the retroviral plasmids containing the fluorescent protein–tubulin fusions into 293-GP cells (a human embryonic kidney cell line harbouring a portion of the murine Moloney leukemia virus genome) along with a VSV-G pseudotyping plasmid to generate amphotropic virus.
5. Forty-eight hours after transfection, collect, filter, and place the tissue culture supernatant into a subconfluent culture (30–40%) of PTK2 cells in 35-mm dishes.
6. Forty-eight hours after infection, split and replate cells in 10-cm dishes and subject to selection in 100 µg/ml puromycin (CFP-tubulin) or 10 µg/ml blasticidin (EYFP-tubulin) for 14 days.
7. Select high expressors (top 10%) by fluorescence-activated cell sorting (FACS).

C. Alignment of Laser Microbeam System

See Fig. 3 for a diagram of the system.

1. Aligning, Expanding, and Focusing the Trapping Beam

1. The key to bringing a laser into the microscope is to use the built-in light path of the microscope to define the optical axis outside of the microscope. With proper Köhler alignment and a 10X objective, close down the field aperature and insert a filter set with a deep red reflector. The narrow beam of light (from the halogen lamp of the microscope) emitting from the epi-illumination lens system will define the optical axis. Two iris diaphragms (not shown) are placed along the light path to define the optical path of the microscope. The laser is brought into the microscope so that it is centered within the same irises, thus aligning it with the optical axis.
2. The laser beam must be expanded to employ the full numerical aperture of the 40x NA1.3 objective lens. Mount lens L2 first and ensure that the beam is still aligned with the optical axis. Repeat procedure with lens L2, also ensuring that light emanating from L2 is collimated. Note that light emitting from the objective turret (with no objective in place) is not focused to infinity.
3. A third lens, L4, was added to the light path to collimate light through the objective turret. Remove the 40x objective and leave the turret empty. Position L4 until light from the turret is parallel, i.e., neither converging nor diverging.
4. Put a culture chamber with test sample under the microscope and bring into focus. Five- to 10-µm diameter beads (of polystyrene or other suitable material) make useful targets for fine-tuning the laser trap.
5. Slightly defocus the laser beam toward the specimen side. The bright spot of the laser beam will appear on the screen of the video monitor. Draw a cross with an erasable marker pen at the bright spot on the screen. The trap is now coincident with the cross hair on the monitor screen. Alternatively, a computer-generated cross hair can be positioned on the screen.
6. By mounting lens L2 in a *z*-translation mount, the relative focus between the image plane and the laser trap can be adjusted.

2. Alignment of Scissors Beam

1. As with the trapping beam, use the built-in light path of the microscope to define the optical axis outside of the microscope. With proper Köhler alignment and a 10X objective, close down the field aperture. Remove any fluorescent filter sets from the microscope stand so that light will exit the microscope via the underneath "Keller" port. The narrow beam of light (from the halogen lamp of the microscope) emitting from the Keller port will define the optical axis.
2. Two iris diaphragms (not shown in Fig. 2) are placed along the light path (at least 12–14 in. of separation between them). If the laser is brought into the microscope so that it is centered within the same irises, then the laser will be aligned and parallel to the optical axis of the microscope.
3. The laser beam must be expanded to employ the full numerical aperture (NA) of the 40 and 63X objective lenses. Place the 3X BS in the optical path using an adjustable mount and the irises to ensure that the laser beam is parallel and runs along the optical axis of the microscope.

4. Remove the 40x objective and leave the turret empty. Position L3 until light from the turret is parallel, i.e., neither converging nor diverging.

5. Put a culture chamber with a test sample under the microscope and bring it into focus.

6. Ensure that on the monitor the scissors beam coincides with the cross hair of the trapping beam. If not, carefully adjust L3 until it does. The laser scissors and tweezers are now aligned.

3. Microsurgery of Chromosomes and Cell Cloning[1]

1. After alignment of the laser microbeam, place a dried smear of red blood cells under the microscope objective and locate a monolayer region. The blood smear should be made on a cover glass, which may either be the bottom glass of a cell chamber (see Fig. 1) or be a cover glass that is simply mounted on a regular microscope slide with the red blood cell surface facing the slide so that the laser beam passes through the cover glass before contacting the red blood cell. Fire a burst of pulses of the laser beam on the red blood cell to produce a small hole (<1 μm) to verify that the cross hair on the TV screen is directly over the lesion. If the hole is too large, attenuate the laser output until a small threshold lesion of 0.25–0.5 μm is produced. For a high-quality single mode laser beam, this small threshold lesion spot represents the center of the laser beam Gaussian profile.

2. Remove the red blood cell slide and place the experimental sample under the microscope.

3. Select dividing cells that appear healthy. For PTK2 cells the cytoplasm should be free of vacuoles and the cells well flattened. The nuclear envelope and mitochondria should be clearly resolvable in interphase cells. In mitotic cells the chromosomes are dark when viewed under phase-contrast microscopy, and spindle micrtotubule bundles are clearly visible using fluorescence microscopy (Figs. 1 and 7).

4. The mitotic stage of dividing cells should be determined by the specific needs of the experiment.

5. Move the microscope stage so that the specific target site of the selected chromosome is under the cross hair on the monitor screen.

6. Fire the laser on the selected chromosome site. Gradually increase the laser power until a lesion appears. At the lesion-threshold energy density ($nJ/\mu m^2$), the lesion will appear as a small phase lightening at the point of laser focus. As the threshold energy density is surpassed, a phase-dark spot may appear in the center of the lesion, and at highest energy densities the chromosome can actually be cut into fragments (Fig. 4). Although the precise physical mechanisms of the laser ablation are not fully understood, it seems likely that multiphoton absorption and other nonlinear processes, such as plasma-induced cavitation bubbles and stress waves, are occurring in the laser focal volume (Vogel and Venugopalan, 2003).

7. Videotape the entire experiment or acquire images using a digital camera and a computer frame grabber. Record the image before and after irradiation. *In the case of genetic studies, the irradiated cell may be isolated and cloned into a viable population using either a laboratory-specific cloning procedure or a procedure similar to steps 8 to 12 (see Fig. 5).*

8. Under sterile conditions, remove nonirradiated cells from near the target cell using a micromanipulator.

9. Reseal the cell culture chamber.

10. Check the chamber at 12 h, and use the 532-nm laser beam to ablate cells migrating into the area of the cell being followed.

11. Monitor the proliferation of the target cell using the acquired images or simply by observation.

12. Collect descendent clonal cells by 0.125% viokase solution and then transfer into 1 well of a 12-well culture cluster containing normal medium.

13. Collect clonal cells with the 0.125% viokase solution until they are confluent and transfer them into a T_{25} culture flask.

14. When the proliferation of descendent clonal cells reaches a sufficient number they can be subjected to standard karyotypic and/or biochemical analysis. Additionally, selective regions may be cut from the chromosomes and subjected to polymerase chain reaction, gene cloning, and analysis (Shutze *et al*., 2002; He *et al*., 1997).

4. Optical Trapping of Chromosomes

1. Place a culture chamber under a microscope that contains either live dividing cells or chromosomes suspended in isolation buffer.

2. Select a specific chromosome under the microscope for experimentation.

3. In the case of a living cell, flat and large cells are especially good for micromanipulation. The selection of the mitotic stage depends on the specific goal of the experiment.

4. Locate the specific site of the selected chromosome at the cross hair on the monitor screen.

5. Open the shutter, allowing the trapping beam to enter the microscope. The trapping laser is focused at the prealigned site, which is located in the image plane of the microscope objective.

6. The chromosome near the focal point of the trapping beam will be drawn into the focal point.

[1] The cloning procedure just described is one that we have found useful. However, with recent developments in microfluidics and nanotechnology, these technologies may be used for cell isolation and cloning.

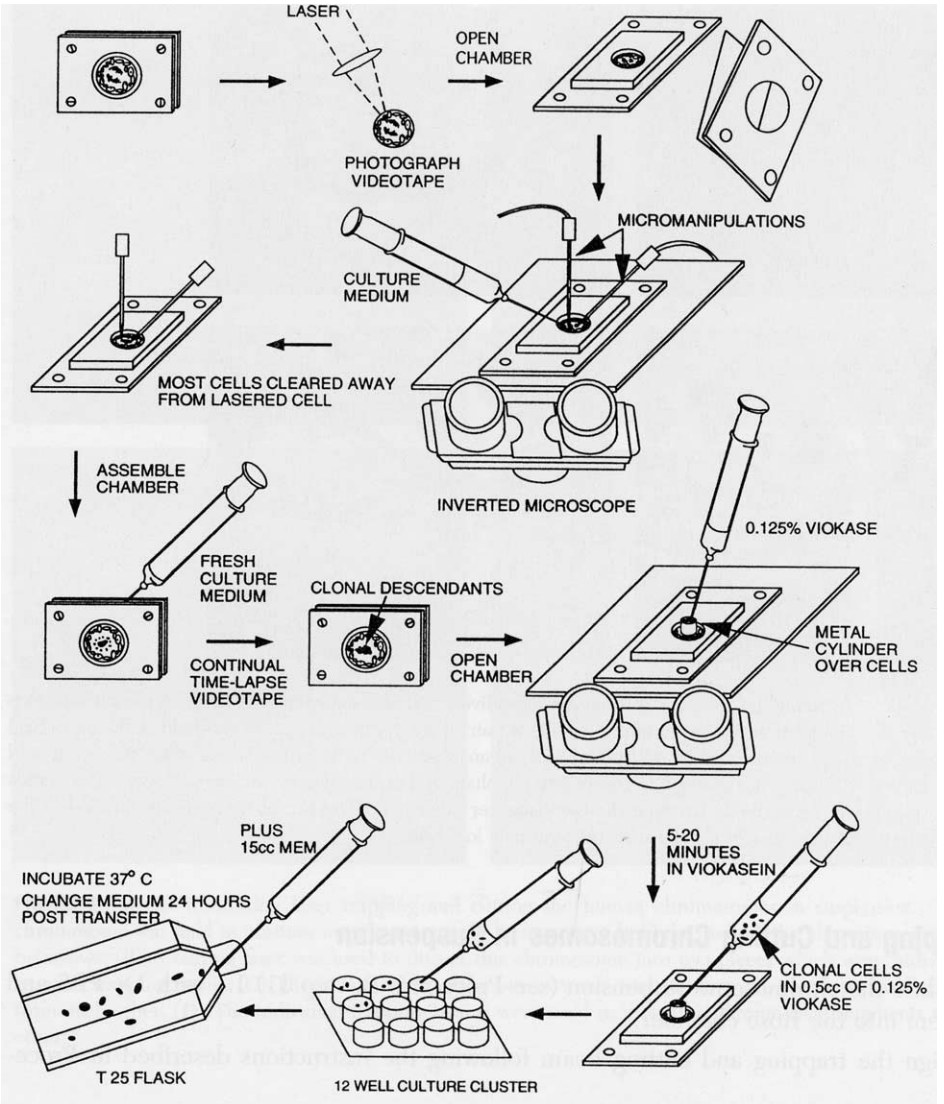

FIGURE 5 Diagram of the procedures for cloning single cells that have been irradiated at a specific chromosomal site. A variety of individualized procedures and technologies may be used depending on the investigator and laboratory needs.

7. Move the specimen stage at a speed less than 25 μm/s in the desired direction. The chromosome will be held at the trapping position. (Usually the sites on which the largest trapping force can be applied are at either ends of the chromosome.)

8. If the trapping force is not large enough to hold the chromosome, increase the power of the trapping beam by rotating the polarizer. (The trapping force is linearly proportional to the incident power of the trapping beam.)

9. Either videotape or digitally record the experiment. Individual digital should be acquired with the frame grabber. Record data before, during, and after manipulation by the optical trapping force.

10. The laser trap can be combined with the laser scissors. A chromosome can be held in the trap while the cutting (scissors) laser is used to cut it into fragments, each of which can be moved by laser traps (Fig. 4).

5. Irradiation of Mitotic Spindle

1. Because of low light levels from fluorescent structures, a sensitive digital camera is used for these experiments (Q-57 camera). Images are acquired using the computer frame grabber and are displayed on the computer monitor. Place a dried smear of red blood cells under the microscope objective and locate a monolayer region. Fire a series of pulses of the abla-

tion laser beam on the red blood cells to produce a small hole (<1 μm) to locate the laser focus while viewing on either the computer screen or the video monitor. Either mark cross hairs on the computer monitor to determine the focus location or note the pixel coordinates on the screen. A computer-generated cross hair may also be used to denote the point of laser focus.

2. Place a culture chamber under the microscope that contains either YFP or CFP microtubule-transfected cells.

3. Locate a cell in the desired stage of the cell cycle. This will depend on the nature of your experiment.

4. Move the stage to position the desired target under the cross hairs or onto the laser scissors pixel location.

5. Remove the fluorescent filter set by sliding the fluorescent slider to an empty position and push in the lever of the microscope stand to open the Keller port.

6. Open the shutter for a 3-ms pulse and immediately slide the appropriate filter set into place.

7. Acquire and save images before and after each ablation (Fig. 7)

6. Single Cell Serial Section Transmission Electron Microscopy

This is a very useful, but tedious, technique that allows precise ultrastructural definition of the nature and extent of laser damage at the sublight microscope level (Figs. 6 and 7). These methods may be adapted to individual investigator needs and vary between laboratories (Rattner and Berns, 1974; Liaw and Berns, 1981; Khodjakov *et al*., 1997).

1. Allow cells inside the culture chamber to become nearly confluent.

2. Insert one 23-gauge needle into the gasket on each side of the culture chamber; one for withdrawing culture medium and one for injecting Karnofsky fixative into the chamber. Bend the exit needle to approximately a 30° angle and attach a 5-ml syringe without a plunger. Attach the input needle to a 20-in.-length of i.d. 0.63-mm, o.d. 1.19-mm, silastic laboratory tubing (Fisher Scientific) coupled to a 10-ml syringe containing fixative. Attach a Nalgene polypropylene pinch clamp (Fisher Scientific) to the tubing between the syringe and the needle in order to prevent flow of any fixative into the chamber.

3. Photograph or digitally store at high and low magnification images of single cells selected for irradiation.

4. Perform the laser irradiation experiment.

5. Inject Karnofsky fixative into chamber immediately after irradiation.

6. Photograph/digitally store image of irradiated cell at high and low magnification.

7. While on the microscope stage, etch a 0.5-mm circle around the region containing the cell using a Carl Zeiss (Germany) diamond marking objective. This provides an etched circle that will be used for subsequent relocation of the irradiated cell. In addition, draw a 1- to 2-mm circle around this circle using either a wax pencil or a water-resistant felt-tip marking pen. This facilitates rapid location of the etched circle.

8. Wash the chamber (while still assembled) with saline.

9. Inject fresh Karnofsky fixative into the chamber.

10. After 30 min in fixative, remove the solution and inject the chambers with cacodylate buffer.

11. Place the chamber back under the microscope where the irradiated cell is relocated and digitally record under 63 and 10X magnification.

12. Change buffer, disassemble culture chamber, and put the bottom cover glass, which includes cells, diamond circle, and ink mark circle, in a petri dish with cells side up for embedding.

13. Postfix in 1% Os O_4, *en bloc* stain with uranyl acetate, dehydrate in ETOH, and embed in a 1- to 2-mm thin layer of Epon/Bed 812.

14. With a diamond marking pen, scribe a small circle on the plastic side matching the exact site of the diamond circle/ink circle on the cover glass.

15. Remove cover glass from plastic with cell by dipping the cover glass/plastic into liquid nitrogen. The differential contraction and expansion of the two materials result in the plastic containing the cells to separate cleanly from the glass.

16. From the nonscribed side of plastic, relocate the irradiated cell inside the new diamond pen scribed circle through the microscope and match with postfixation photographs. Make a smallest possible circle with the diamond marking objective around the cell. Make a square ink mark around the circle.

17. Cut out the piece of plastic along the square ink mark and glue onto a blank embedded plastic block with diamond circle side up.

18. Carefully trim the block face to include the irradiated cell. Take extra attention to align the knife and block face to get the perfect whole block face at first section as possible.

[2] A 3-ms shutter exposure of a 76-MHz laser allows 228,000 laser pulses onto the target. If experiments require single pulse exposure, either lasers operating a lower pulse repetition rate should be used (i.e., nanosecond pulse lasers operating at 10 Hz) or expensive pulse selection optoelectronics may be used.

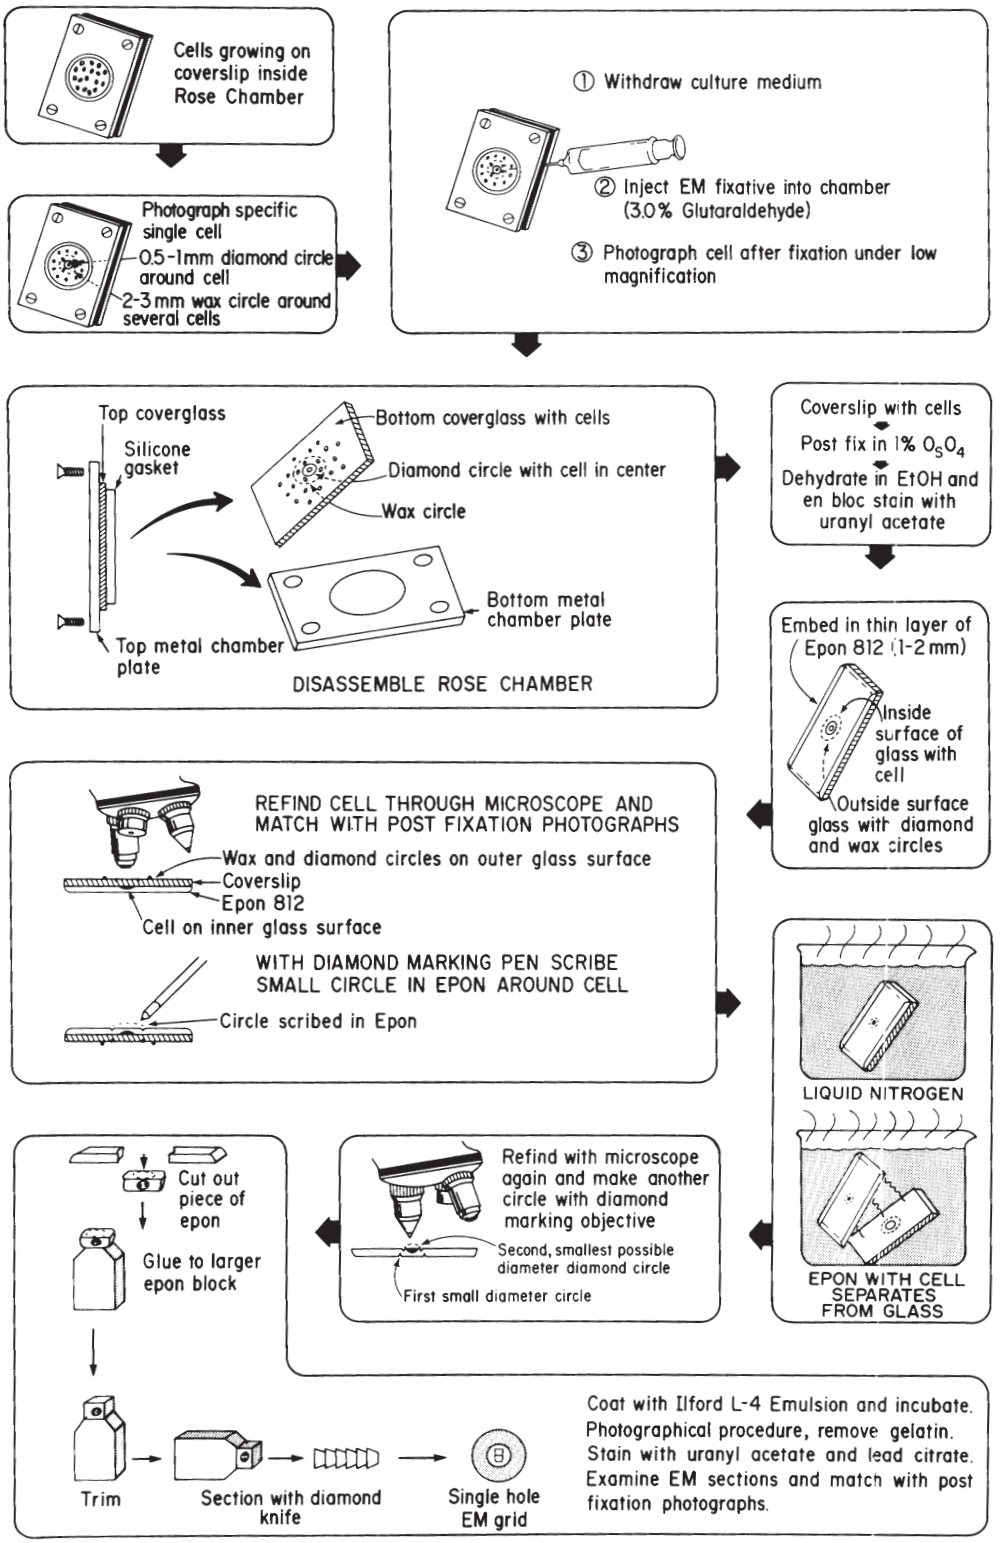

FIGURE 6 Diagram of the procedures used for single cell electron microscopy resulting in the recovery and observation of the laser-irradiated cell and organelle (see Fig. 7). This series of procedures was originally developed for EM autoradiography, thus the last step may not be needed in specific studies.

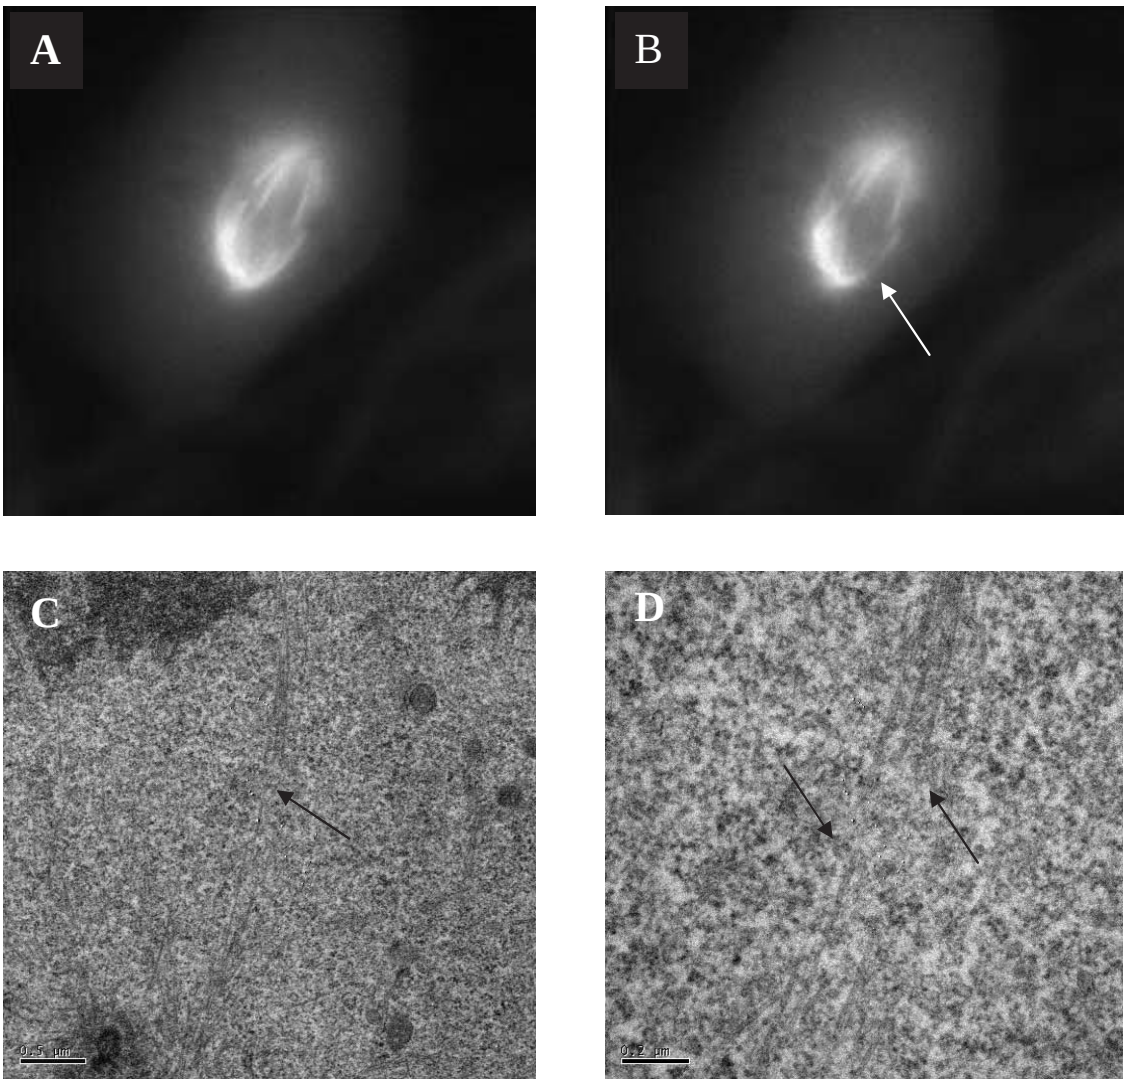

FIGURE 7 Fluorescent images of a PTK2 cell containing yellow fluorescent protein in the tubulin of metaphase microtubules. A microtubule bundle extending from the mitotic pole (centrosome region) to a single chromosome has been cut with the laser scissors, and the specific cut region has been imaged by electron microscopy. (A) Fluorescent microtubule spindle prior to laser exposure. (B) Microtubule bundle cut (arrow) using 0.5 nJ/pulse of the laser scissors; total energy needed to cut the bundle was 610 µJ/µm^2. (C) Low-magnification transmission electron micrograph (TEM) illustrating cut zone (arrow). (D) High-magnification TEM illustrating cleanly cut microtubule in the region corresponding to the loss of fluorescence following laser exposure (see image "B"). Note that individual microtubles that have been cut/ablated continue intact on either side of the ablation zone (arrows). Scale bar: 0.2 µm.

19. Serial section in 60 nm thick and place sections on 1 × 2-mm Formvar-coated slot EM grids in order. The linear ribbon of the sections will help keep sections and grids in perfect order. The slot grid will not obscure the specific cell.
20. Stain with uranyl acetate and lead citrate.
21. Examine sections through TEM. Match with postfixation images to find the irradiated cell/organelle.

IV. COMMENTS

The procedures described in this article, by in large have either been specifically developed for use in the authors laboratories or have been developed as a result of many years (1980–2004) of collaborations with investigators who have used the NIH LAMMP Biotechnology Resource at the Beckman Laser

Institute, Irvine, California. Thus, many of the procedures have evolved over the years and have been adapted to new technologies and to many different needs of the collaborating investigators. Also, as noted throughout this article, many of the precise methods can be modified and adapted further to specific needs of experimenters and laboratories. We would rather consider the procedures and techniques that we have described as *precise guidelines* as opposed to hard-and-fast protocols. Where possible, we have used very simplistic language so as to make execution and duplication of the procedures as simple as possible.

V. PITFALLS

1. Variation in laser output power can cause inconsistent experimental results. Turn on the lasers 30 min to 1 h before the experiment and continue to monitor the output power throughout the laser experiments. Laser power/energy may vary as much as 20–30% during the day and may be particularly affected by changes in environmental temperature, which subsequently can cause very small changes in intercavity mirror alignments. Temperature can also affect optical alignments on vibration tables and in the microscope. All of these changes can affect the amount of energy in the focused laser spot and therefore the results of the experiment. It is suggested that laser output power and energy in the microscope focal point be checked periodically as well as before and after the experiment.

2. Living cells will be damaged if exposed to the laser beam either for long periods of time or at too high irradiances. The average power <200 mW for the trapping beam and energy in the nJ – μJ/pulse in the focused spot for the scissors beam are recommended as exposure parameters. However, these are only rough guidelines, as the lasers now available have pulse durations in the femtosecond regime. The mechanisms of interaction of these short-pulse systems are not well understood.

3. Unwanted photo damage to cells should also be considered. Choose a laser with the appropriate wavelength to avoid regions of unwanted photon absorption. Also, limit the exposure of the cells to normal unfiltered microscope illumination as much as possible, as this light may also affect cell physiology, especially if a standard IR filter is not used in conjunction with normal microscope illumination. As a rule of thumb, use the minimal amount of illumination light necessary to generate a useable image. Where possible, use sensitive digital and analog detectors so as to minimize the amount of illumination light on the cells.

4. Microscope optics can be damaged if the laser beam is too intense. In order to prevent damage to the objective lens, do not adjust optical components (e.g., mirrors, beam splitters) while the objective is being exposed to the intense laser beam. The cement used to hold the small optical lenses in the objective absorbs laser light, creating thermal and/or stress wave damage to the lenses.

5. Laser exposure may produce eye injury and/or physical burns. Never view a laser beam directly or by specular reflection. Use laser safety glasses whenever possible. Be sure that the laser microscope has appropriate filtration or beam blocks so that the laser beam does not directly go through the oculars into the eyes. Where possible, enclose external beam paths and/or surround the optical table with appropriate laser safety curtains. There have been reported and unreported cases of retinal burns due to laser exposure. These have occurred when either aligning optics on the table surface or not blocking laser light from coming through the microscope ocular.

CHAPTER

37

Tissue Microarrays

Ronald Simon, Martina Mirlacher, and Guido Sauter

I. INTRODUCTION

Tissue microarray (TMA) technology significantly facilitates and accelerates *in situ* analysis of tissues (Bubendorf *et al*., 1999; Kononen *et al*., 1998) as it allows the simultaneous analysis of up to 1000 tissue samples on a single microscope glass slide. In this method, minute tissue cylinders (typical diameter: 0.6 mm) are removed from hundreds of different primary tumor blocks and subsequently brought into one empty "recipient" block. Paraffin-embedded tissues are optimal for TMA making, but frozen tissue samples can also be utilized (Simon and Sauter, 2002). Sections from such TMA blocks can be used for simultaneous *in situ* analysis of hundreds to thousands of tissue samples on the DNA, RNA, and protein level. The TMA technique has a number of distinct advantages as compared to the "sausage" block technique that has been suggested previously for analyzing multiple different tissues on one slide (Battifora, 1986). The regular arrangement of samples of identical shape and diameter on TMA sections greatly facilitates automated analysis and also orientation during manual analysis of staining. The cylindrical shape and the small diameter of the specimen taken out of the donor block maximize the number of samples that can be taken out of one donor block and minimize the tissue damage inferred to it. The latter is important for pathologists because they can give researchers access to their tissue material and at the same time retain their tissue blocks. Punched tissue blocks remain fully interpretable for all morphological and molecular analyses that may subsequently become necessary, provided that the number of punches is reasonably selected. Dozens of punches can be taken from one tumor without compromising interpretability (Bubendorf *et al*., 2001).

Virtually all tissues are suitable to be placed into a TMA. The range of TMA applications, therefore, is very broad. One of the most distinct advantages of TMAs is that one set of morphologically and clinically highly characterized tissues can be used for an almost unlimited number of studies. As of yet, TMAs have been used predominantly in cancer research. Most TMAs used in this field fall into one of three categories: prevalence, progression, and prognostic TMAs. Prevalence TMAs contain tumor samples lacking attached clinicopathological data. Despite this limitation, they are highly useful in determining the prevalence of a given alteration in tumor entities of interest. In the optimal case, such TMAs will contain tissue samples from various different tumor entities (multitumor TMAs) (Schraml *et al*., 1999). Progression TMAs allow for studies on molecular alterations in different stages of one particular tumor type (Bubendorf *et al*., 1999a,b; Kononen *et al*., 1998; Richter *et al*., 2000). Ideally, such a TMA would contain samples from normal tissues, precancerous lesions including carcinoma *in situ*, carcinomas of all different stages, and nodal and hematogenous metastases, as well as recurrences after initially successful treatment (Bubendorf *et al*., 1999a). Prognosis TMAs contain samples of tumors for which clinical follow-up data are available (Richter *et al*., 2000; Torhorst *et al*., 2001; Bremnes *et al*., 2002). Other TMA applications are obviously important but have not been largely exploited as of yet. For example, the normal expression pattern of gene products can optimally be tested on TMAs containing all kinds of normal tissues. Similarly, as for patient tissues, TMAs can be used for cell lines (Simon *et al*., 2002) and other

experimental tissues such as xenograft tumors or tissues from animal models.

II. TMA MANUFACTURING

Manufacturing TMAs is a four-step process, including sample collection, preparation of recipient blocks, construction of TMA blocks, and sectioning. Material requirements and the laboratory procedures for all of these steps are described separately.

A. Materials and Instrumentation

Sample Collection

Standard routine histology microscope for review of tissue sections
Colored pens to mark representative areas on stained slides, e.g., red for tumor, blue for normal, and black for premalignant lesions
Sufficient working space especially for large-scale projects that require extensive sorting of thousands of slides and blocks (For frozen tissue TMA making, sufficient empty freezer space is needed.)

B. Preparing Recipient Blocks

1. Paraffin-Embedded and Frozen Tissue

Slotted processing/embedding cassettes for routine histology (Electron Microscopy Sciences Inc., PA, e.g., EMS Cat. No. 70070)
Stainless-steel base molds for processing/embedding systems (Electron Microscopy Sciences Inc., e.g., EMS Cat. No. 62510-30)

2. Paraffin-Embedded Tissue Only

PEEL-A-WAY embedding paraffin pellets, melting point: 53–55°C (Polysciences Inc., PA, Cat. No. 19797)
Filter/filter paper (Schleicher & Schuell, Dassel, Germany; Faltenfilter diameter 185 mm, Cat. No. 311647)
Oven for paraffin melting

3. Frozen Tissue Only

OCT Tissue-Tek compound embedding medium (Sakura BV, The Netherlands; Cat. No. 4583)
Dry ice

C. TMA Block Making

1. Paraffin-Embedded and Frozen Tissue

Tissue arrayer (currently there are two commercial vendors for tissue arrayers: http://www.beecherinstruments.com; http://www.chemicon.com) and supplies (extra needles, block holder). Several groups have introduced inexpensive modifications to the existing commercially available manual non-automated arrayers, which improve performance markedly and facilitate frozen tissue arraying.
Premade empty recipient blocks (paraffin or frozen)
Illuminated magnifying lenses and supplies (e.g., Luxo U wave II/70, Cat. No. 27950, Luxo Inc., Switzerland) (optional)

2. Frozen Tissue Only

Dry ice to cool punching needles, tumor samples, and recipient block

D. TMA Block Sectioning

1. Paraffin-Embedded and Frozen Tissue

Boxes for slide storage
Refrigerator/freezer for slide storage

2. Paraffin-Embedded Tissue Only

Standard routine histology microtome and supplies (e.g., Leica SM2400, Leica Microsystems Inc., IL)
Sectioning Aid-System (Instrumedics Inc., NJ, Cat. No. PSA) containing ultraviolet curing lamp, adhesive-coated PSA slides, TPC solvent, TPC solvent can, hand roller, tape windows (optional)

3. Frozen Tissue Only

Standard routine histology cryostat and supplies (e.g., Microm, HM560, Walldorf, Germany)
CryoJane consumables: adhesive-coated slides (Instrumedics Inc., Cat. No. CS4x, tape windows, Cat. No. TW) (optional)

III. PROCEDURES

A. Sample Collection

Although a device is needed to manufacture TMAs, it must be understood that most of the work (approximately 95%) is traditional histology work. Therefore, the use of automated tissue arrayers cannot accelerate TMA production. This preparatory work is similar to what is needed for traditional studies involving "large" tissue sections. The major difference is the number of tissues involved, which can be an order of magnitude higher in TMA studies than in traditional projects. The different tasks related to sample collection include the following.

1. Exactly define the TMA to be made. Include normal tissues of the organ of interest and, if possible, of a selection of other organs as well.

2. Generate a list of potentially suited tissues.
3. Collect all slides from these tissues from the archive. In case of frozen tissues, representative slides of potential donor tissues may not be available and must be newly made.
4. One pathologist must review all sections from all candidate specimens to select the optimal slide. If possible, tissues (especially in the case of tumors) should be reclassified during this review process according to current classification schemes. Tissue areas suited for subsequent punching should be marked. It is advisable to prepare a freshly HE-stained section if the actual block surface is not well reflected on the available stained section. Different colors are recommended for marking different areas on one section (e.g., red for tumor, black for carcinoma *in situ*, blue for normal tissue).
5. Collect the required tissue blocks. These blocks and their corresponding marked slides must be matched and sorted together in the order of appearance on the TMA.
6. Define the structure (outline) of the TMA and compose a file that contains the identification numbers of the tissues together with their locations and real coordinates (as they need to be selected on the arraying device). As a distance between the individual samples, 0.2 mm is recommended for paraffin-embedded materials and 0.4 mm for frozen tissues if standard punching needles (diameter of 0.6 mm) are used. To facilitate navigation on the TMA, arranging the tissues in multiple sections (e.g., quadrants) is recommended. The distance between the quadrants may be 0.8 mm for paraffin-embedded materials and 1.0 mm for frozen tissues. For unequivocal identification of individual samples on TMA slides, it is important to avoid a fully symmetrical TMA structure. In our laboratory, capitalized letters define quadrants, whereas small letters and numbers define the coordinates within these quadrants. Examples of a TMA structure (outline) and data file containing the necessary information for making a TMA are given in Fig. 1 and Table I.

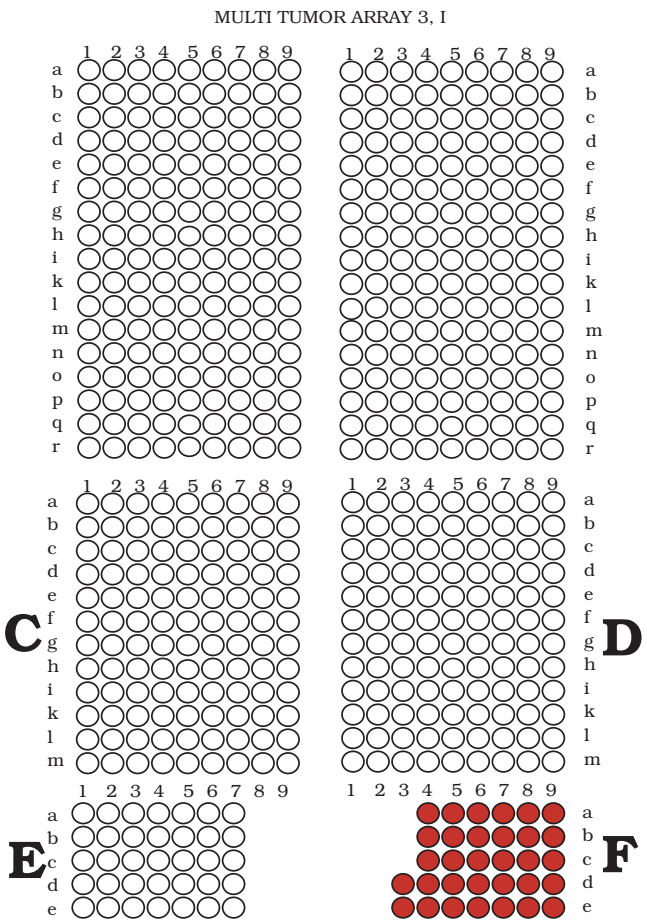

FIGURE 1 TMA outline example. The TMA has been divided into six subsections to facilitate navigation during microscopy. Dark gray spots represent a control subsection containing various normal tissues.

B. Preparing Recipient Blocks

1. Paraffin-Embedded Tissue

In contrast to normal paraffin blocks, tissue microarray blocks are cut at room temperature. Therefore, a special type of paraffin is needed with a melting temperature between 53 and 55°C ("Peel-A-Way" paraffin, see Section IIA).

1. Melt paraffin overnight at 60°C, filtrate, and pour in a stainless-steel mold.
2. Place a slotted plastic embedding cassette (as used in every histology laboratory) on top of the warm paraffin.
3. Cool down recipient paraffin blocks for 2 h at room temperature and for another 2 hr at 4°C. Remove blocks from the mold. It is important not to cool down the paraffin on a cooling plate because of the risk of block damage.
4. Quality check the recipient blocks to make sure that no air bubbles are included.

2. Frozen Tissue

Preparing recipient OCT blocks that are equally sized as paraffin recipient blocks ensures that the currently available tissue arrayers can be utilized for frozen TMA manufacturing.

1. Place OCT into a standard cryomold and cool down over dry ice to form recipient blocks.

TABLE I Simplified Example for a TMA Data File[a]

Tissue ID	Tissue type	Localization	Coordinates
1	Uterine cervix, pT2, G2, N0	A1a	0/0
2	Uterine cervix, pT3, G3, N1	A1b	800/0
3	Uterine cervix, pT1, G2, N0	A1c	1600/0
4	Uterine cervix, pT3, G3, N1	A1d	2400/0
5	Uterine cervix, pT3, G2, N0	A1e	3200/0
6	Uterine cervix, pT3, G3, N1	A1f	4000/0
7	Uterine cervix, pT1, G2, N0	A1g	4800/0
8	Uterine cervix, pT2, G2, N0	A1h	5600/0
9	Uterine cervix, pT3, G3, N1	A1i	6400/0
10	Uterine cervix, pT2, G2, N0	A1k	7200/0
11	Uterine cervix, pT3, G3, N1	A1l	8000/0
12	Uterine cervix, pT2, G2, N0	A1m	8800/0
13	Uterine cervix, pT1, G2, N0	A1n	9600/0
14	Uterine cervix, pT3, G3, N1	A1o	10400/0
15	Uterine cervix, pT2, G2, N0	A1p	11200/0
16	Uterine cervix, pT1, G2, N0	A1q	1200/0
17	Uterine cervix, pT1, G2, N0	A1r	12800/0
18	Uterine cervix, pT3, G3, N1	A2a	0/800
19	Uterine cervix, pT2, G2, N1	A2b	800/800
20	Uterine cervix, pT3, G2, N0	A2c	1600/800
21	Uterine cervix, pT1, G2, N0	A2d	2400/800
22	Uterine cervix, pT2, G2, N1	A2e	3200/800
23	Uterine cervix, pT1, G2, N0	A2f	4000/800
24	Uterine cervix, pT3, G2, N0	A2g	4800/800
25	Uterine cervix, pT3, G2, N0	A2h	5600/800
572	Prostate ca, hormone refractory	E7b	800/4800
573	Prostate ca, hormone refractory	E7c	1600/4800

575	Prostate ca, hormone refractory	E7e	3200/4800

[a] Coordinates refer to the punch positions selected on the arrayer device. Additional information, e.g., pathological or follow-up data, may be added.

2. Place an empty plastic biopsy embedding cassette on top of the freezing (but not yet completely frozen) OCT. This plastic cassette is subsequently filled with OCT.
3. After slight thawing, remove the completely frozen recipient block from the cryomold. Immediately place the recipient block on dry ice or in a freezer until used.

C. TMA Making

Only if all this preparatory work has been done can a tissue-arraying device be employed. Using these manually operated devices, excellent TMAs can be produced in the hands of a talented and experienced person. However, optimal arrays can be expected only after a significant training period, including several hundred, if not a few thousand, punches. A patient and enduring personality as well as keen eyesight are important prerequisites for operators of manual tissue arrayers. Early generation automated tissue arrayers are available but these devices are expensive, do not accelerate the TMA manufacturing process, and cannot be used for making frozen TMAs.

1. Paraffin-Embedded Tissue

The TMA manufacturing process consists of five steps that are repeated for each sample placed on the TMA.

1. Punch a hole into an empty recipient paraffin block.
2. Remove and discard the wax cylinder from the needle used for recipient block punching.
3. Remove a cylindrical sample from a donor paraffin block.
4. Place the cylindrical tissue sample in the premade hole in the recipient block.
5. Proceed to the new coordinates for the next tissue sample.

Exact positioning of the tip of the tissue cylinder at the level of the recipient block surface is crucial for the

quality and the yield of the TMA block. Placing the tissue too deeply into the recipient block results in empty spots in the first sections taken from the TMA block. Positioning the tissue cylinder not deep enough causes empty spots in the last sections taken from this TMA. However, a too superficial location of the tissue cylinder is less problematic than a too deep position, as protruding tissue elements can, to some extent, be leveled out after finishing the punching process. The use of a magnifying lens facilitates precise deposition of samples, especially for beginners.

As soon as all tissue elements are filled into the recipient block, the block is heated at 40° for 10 min. This improves adhesion between tissues and paraffin of the recipient block. Protruding tissue cylinders are then gently pressed deeper into the warmed TMA block using a glass slide.

2. Frozen Tissue

The recipient block must always be surrounded with dry ice to prevent melting. Make sure that the micrometer screws are not covered by ice. Malfunctions occur if the temperature of these elements gets too low. Continuously add more ice as melting occurs. The TMA manufacturing process consists of five steps that are repeated for each sample placed on the TMA.

1. Punch a hole into an empty recipient OTC array block.
2. Remove and discard frozen OTC from the needle.
3. Remove a cylindrical tissue sample (diameter 0.6 mm; height 4–5 mm) from frozen tissues. For this purpose, the same needle is used as previously for making a hole into the recipient array block. Switching to a larger needle is not needed. It is important to keep the tissue in the needle frozen during the procedure, e.g., by precooling the needle with a piece of dry ice before punching and while dispensing the tissue core into the recipient block. Use forceps for holding ice cubes for cooling needles.
4. Place the cylindrical tissue sample in the premade hole in the recipient OTC array block.
5. Proceed to the new coordinates for the next tissue sample.

Tissue arrayers that were initially designed for use on paraffin-embedded tissue can be utilized for frozen TMA making (Fejzo and Slamon, 2001). However, needles are at a higher risk of bending and breaking than in the case of paraffin-embedded tissues. Therefore, punching must be done slowly with minimal pressure to prevent needle damage. Despite this, frozen TMAs will become more irregular and distorted than TMAs from formalin-fixed material.

D. TMA Sectioning

Regular sections may be taken from frozen and paraffin-embedded TMA blocks using a standard microtome or cryostat. However, the more samples a TMA block contains, the more difficult regular cutting becomes. As a consequence, the number of slides of inadequate quality increases with the size of the TMA and, in turn, fewer sections from the TMA block can effectively be analyzed. Using a tape sectioning aid is therefore recommended.

The tape sectioning kit (Instrumedics) facilitates cutting and leads to highly regular nondistorted sections that are ideally suited for automated analysis. In addition, the tape system may prevent arrayed samples from floating off the slide if very harsh pretreatment methods are used. However, the sticky glued slides have the disadvantage of increased background signals between the tissue spots in some IHC analyses and of a slightly deteriorated morphology of some tissue samples because of small visible glue dots within the samples. The tissue samples themselves do not show increased nonspecific background in IHC. Use of the tape sectioning system is described next.

1. Paraffin-Embedded Tissues

1. Place an adhesive tape on top of the TMA block in the microtome immediately before cutting. Always use a hand roller in order to avoid bubbles.
2. Cut section (usually 5 µm). The tissue slice is now adhering to the tape.
3. Transfer the tissue slice on a special "glued" Instrumedics slide (use the hand roller for this purpose; stretching of the tissue in a water bath or on a heating plate is not necessary). It is important to store "glued" slides in darkness before usage. Adhering slide properties deteriorate rapidly under light exposure.
4. Expose the slide (tissue on the bottom) to UV light for 35 s in order to polymerize the glue on the slide and on the tape.
5. Dip the slides into TPC solution (Instrumedics) at room temperature for 5–10 s. The tape can then be removed gently from the glass slide. The tissue remains on the slide.
6. Air dry slides at room temperature.

2. Frozen Tissues

Slides, adhesive tape, and hand roller are optimally stored within the cryostat microtome. They can only be used if their temperature is identical to the temperature within the cryostat microtome.

1. Place a precooled adhesive tape on top of the TMA block in the cryostat microtome using a precooled hand roller immediately before cutting.

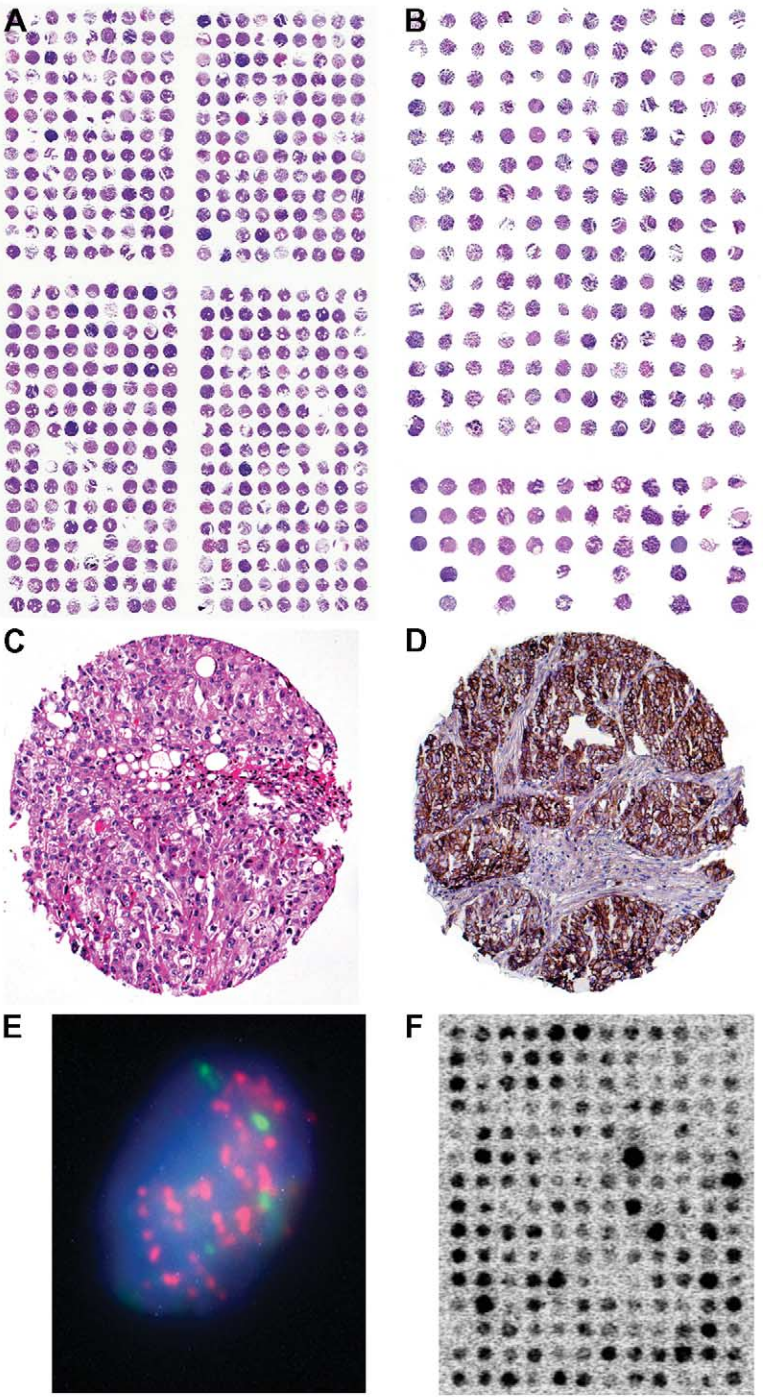

FIGURE 2 Examples of stained tissue sections. Hematoxylin and eosin (H&E)-stained sections of (A) a TMA from formalin-fixed, paraffin-embedded tissues containing 540 tissue spots and (B) a TMA from frozen tissue containing 228 tissue spots. Each tissue spot measures 0.6 mm in diameter. Missing samples result from the sectioning/staining process or indicate samples that are already exhausted. Note that the spot-to-spot distance is larger on the frozen TMA as compared to the paraffin TMA. (C) Magnification of a H&E-stained 0.6-mm tissue spot of a bladder carcinoma. (D) Immunohistochemistry against the EGFR protein in a pharynx cancer sample using the DAKO HercepTest. (E) FISH analysis of centromere 7 (green signals) and the EGFR gene (red spots) in cell nuclei (blue staining) of a tissue spot (630×). The high number of EGFR signals indicates gene amplification. (F) RNA *in situ* hybridization on a frozen TMA made from breast cancer tissues. A radioactively labeled oligonucleotide was used as a probe against mRNA of a lipoprotein-binding protein. The black staining intensity indicates the level of mRNA in each tissue spot.

TABLE II Troubleshooting

Problem	Possible cause	Paraffin embedded	Frozen
Missing tissue samples on first series of TMA sections taken from TMA blocks (same samples missing on all sections)	Tissue cores placed too deeply into the recipient block	As long as the TMA making is not completed, a too deeply placed tissue core can be removed using the thinner needle. Then another sample taken from the donor block can be used as a replacement	Removal of the too deeply positioned tissue is not recommended. Consider adding an additional sample of this tissue to the TMA block
Missing tissue samples on deeper sections taken from TMA blocks (same samples missing on all sections)	Tissue cores were not pushed into the recipient block deeply enough	Careful leveling out of the TMA block surface after finishing the punching process and placing the TMA block in an oven (10 min 40°C).	Careful leveling out of the TMA block surface after finishing the punching by gently pressing an empty glass slide on the surface (Do not use oven!)
	Tissue cores were too short	Check tissue blocks for presence of sufficient tumor material before final block selection	
Missing tissue samples on deeper sections taken of TMA blocks (different samples missing on different sections)	Samples float off the slide during harsh pretreatments	Use adhesive-coated slides	
	Samples come off the slide during the sectioning process	Avoid air bubbles between block and tape and between tape and adhesive-coated slide by using the hand roller. Slides and tapes may have irregular quality; it is important to check the material quality before use. Poor quality slides have inhomogeneous glue distribution	
Some tissues on the TMA section are very thin and partially destroyed	Tissue damage incurred during removal of the adhesive tape	Do not cut sections thinner than 5 µm. Exact timing of the tape removal process	Do not cut sections thinner than 10 µm
		Quality control of the unstained TMA slides under the microscope before use	Quality control of the unstained TMA slides under the microscope before use
Tissue on TMA section is not representative	Wrong area punched	Correct marking of areas on the HE-stained section that can be easily found on the block Careful selection of the marked area for punching	
Irregular distribution of samples on the TMA block	Needle is bent	Change needle	To some extent irregular sample arrangement must be accepted Changing the needle improves the regularity of the TMA Complete frozen TMA within 1 working day
Tissue cylinder cannot be removed from donor block	Needle is blunt	Change needle	Change needle
Paraffin cylinder cannot be removed from recipient block	Needle is blunt	Change needle	Change needle
Array block protrudes in the center ("hillock formation" in paraffin arrays)	Premade holes in the TMA recipient block are too short	Make deeper holes	
	Too small a distance between tissue cylinders	Select sufficiently large distance between different cylinders Careful leveling out of the TMA block surface after finishing the punching process and placing the TMA block in an oven (10 min 40°C).	
Paraffin recipient blocks crashes	Samples placed too closely to the border of the block	Select a distance of at least 3 mm between recipient block border and first tissue sample Use larger recipient blocks	
Tissue core cannot be placed into the recipient block	Paraffin: needles are not aligned properly	Align needles (see manual)	
	Frozen: tissue melts during the punching process		Carefully cool the needle before and during the punching process
Micrometer screw malfunction during arraying	Battery exhausted	Change battery	Change battery
	Frozen: Dry ice is covering micrometer screw		Remove dry ice from micrometer screw

2. Cut section (usually 10–12 µm). The tissue slide is now adhering to the tape.
3. Transfer the tissue slice on a special "glued" slide using a hand roller.
4. Put the slide on dry ice for 60 s.
5. Remove the tape gently (TPC solution is not required for removal of tape after ice pretreatment).
6. Immediately place slides into freezer (–70°C).

IV. COMMENTS

TMAs are suited for all types of *in situ* analysis methods, including immunohistochemistry, fluorescence *in situ* hybridization (FISH), and RNA *in situ* hybridization. All protocols that can be used on large sections will also work on TMAs. Extended deparaffinization is recommended, e.g., xylene exposure for 60–120 min. Examples of stained TMA sections are shown in Fig. 2. One of the most significant differences as compared to traditional large section studies is the high level of standardization that can be achieved in TMA experiments. All slides of one TMA study are usually incubated in one set of reagents, assuring absolutely identical concentrations, temperatures, and incubation times. Other minor variables that may have an impact on the outcome of *in situ* analyses such as the age of a slide (time between sectioning and use) or section thickness are also fully standardized if all tissues of one study are located on the same TMA section. As a result of this unprecedented standardization within each experiment, intralaboratory variations may occur if experiments are repeated under slightly different conditions. Significant differences that were observed after using TMA sections stored for different time spans may represent just one example of how minor variables can significantly affect the results of molecular *in situ* analyses (M. Mirlacher *et al*., unpublished observations, 2002).

CHAPTER

38

Basic Cytogenetic Techniques: Culturing, Slide Making, and G Banding

Kim Smith

I. INTRODUCTION

During metaphase of the cell cycle, the condensed chromosomes align along the metaphase plate prior to chromatid separation and then move along the spindle fibres to the poles of the spindle. A spindle inhibitor, colchicine, can be added during metaphase, which disrupts the polymerisation of the spindle fibres, arresting the cell cycle at the stage when the chromosomes are fully condensed. It is possible to increase the number of metaphases by synchronising the cell cycle with a chemical blocking agent such as thymidine. The addition of excess thymidine results in the inhibition of DNA synthesis and the cells collecting in S phase. When the thymidine block is removed by washing the cells in fresh medium or by the addition of deoxycytidine, the synchronised cells progress to M phase and, by careful timing of the addition of colchicine and subsequent harvest, a large number of longer chromosomes in early metaphase can be collected.

In order to visualise the chromosomes, these cells are harvested with hypotonic and fixative stages. The hypotonic solution swells the cells, allowing the chromosomes to separate. The cells are fixed with glacial acetic acid/methanol, which removes water and hardens the cell membrane. The final fixed cell suspension is dropped onto a microscope slide where evaporation of the acetic acid/methanol fixative results in bursting of the cells and spreading of the metaphase chromosomes. Humidity plays a key role in the rate of evaporation of fixative and control of chromosome spreading, hence an optimal microenvironment is vital to the production of well-spread chromosomes (Fig. 1).

Routine G banding with trypsin gives each chromosome a distinct banded pattern that allows identification of discrete regions along each chromosome and the opportunity to screen for chromosomal imbalance of at least 3–5 Mb by standard microscopic analysis.

Diagnostic cytogenetic investigations are used routinely within the clinical setting to screen for chromosomal imbalance in a wide range of patients. These methods describe a synchronised suspension culture of blood and an unsynchronised adhesion culture of tissue.

II. MATERIALS AND INSTRUMENTATION

RPMI with 20 m*M* HEPES (52400-017), penicillin (10,000 U/ml)/streptomycin (10,000 µg/ml)/glutamine (29.2 mg/ml) (10378-016), trypsin 2.5% (15090-046), phytohaemagglutinin (10576-015), Hanks BSS (14180-046), and colcemid (15212-012) are from GIBCO. Hams F10 (N6013), thymidine (T9250), 2-deoxycytidine (D3897), colchicine (C9754), EDTA 0.02% (E8008), amphotericin B (A9528), and phosphate-buffered saline (PBS), pH 7.4 (P3813) are from Sigma. Heparin (101929) is from ICN. Ultroser G (15950-017) is from Biosepra. Fetal calf serum is from various sources, including Sigma, GIBCO, and Seralab. Methanol (101586B), glacial acetic acid (10001CU), KCl (101983K), Leishman's stain solution (350226N), buffer tablets, pH 6.8 (331992P), XAM mountant (361194V), and washed glass slides (406/0181/02) are from BDH. Difco trypsin (215320) is from Becton-Dickinson. Virkon (R330003/Q) is from Radleys. Tissue culture

flasks (25 cm^2, Nunc 163371), blood culture tubes (Falcon 35-2027), 1-ml plastic pastettes (Alpha LW4010), sterile petri dishes (Sterilin 101R20), sterile scalpels (Swan Morton) and needed. Gas (5% CO_2/95% air) is required if a CO_2 incubator is not being used.

Equipment includes a class II laminar flow hood, incubator, centrifuge, inverted microscope, light microscope with phase 10 and 100× objectives, hot box oven, hot plate. Local humidity control can be helped by humidifiers, dehumidifiers, or controlled environment equipment.

III. PROCEDURES

A. Synchronised Cell Culture of Human T Lymphocytes

Blood should be collected into heparinised, ideally lithium heparin, tubes to prevent coagulation. Although whole blood is cultured, T lymphocytes are used routinely for blood cytogenetic investigations. As these cells are not spontaneously dividing, phytohaemagglutinin (PHA), a mitogen, must be added to transform the T lymphocytes and start cell division. PHA is only required during the first 24 h of cell culture and so is omitted from postsynchronisation release medium. Blood is routinely cultured for 72 h.

Solutions

1. *Phytohaemagglutinin* must be used within 2–3 weeks after rehydration.
2. *Phosphate-buffered saline pH 7.4*: Add one sachet to 1 litre distilled water
3. *Working stock solutions: Heparin* (1250 units/ml in distilled water), *thymidine* (10 mg/ml in PBSA), *2-deoxycytidine* (10 µg/ml in distilled water), and *colchicine* (250 µg/ml for blood in distilled water)
4. *Complete medium*: 100 ml RPMI, 20 ml fetal calf serum, 1 ml penicillin/streptomycin/glutamine, 0.2 ml heparin, and 2 ml phytohaemaglutinin
5. *Release medium*: 100 ml RPMI, 10 ml fetal calf serum, 2 ml penicillin/streptomycin/glutamine, and 2 ml deoxycytidine
6. *KCl hypotonic*: 0.056 M (4.2 g/litre)
7. *Fixative*: 3 : 1 methanol : glacial acetic acid

Steps

Day 1 Establishing Cultures

1. Dispense 5 ml of complete medium into a labelled sterile culture tube. Add 0.25 ml of blood with a sterile plastic pastette. Replace lid and invert to mix.
2. Place in a culture rack and incubate in a 37°C incubator. A culture rack with a slanted edge allows the tubes to lie at a 20–30° incline and increases the media/cell pellet surface area for improved exchange of gas and nutrients.

Day 3 Synchronisation. Add 0.2 ml thymidine to each culture in the late afternoon and reincubate for 17–18 h overnight.

Day 4 Synchronisation Release and Harvest

1. Centrifuge cultures at 1200 rpm for 5 min. Remove the supernatant from the culture tube, leaving approximately 1 cm depth of supernatant. Add 4 ml release medium and resuspend cells. Note time of release and reincubate.

2. Four hours after synchronisation release, add 0.1 ml colchicine per tube, invert culture tubes to mix, and reincubate cultures.

3. After 20 min incubation, centrifuge at 1200 rpm for 5 min. Remove supernatant, leaving approximately 0.5 ml in the tube. Resuspend cells and gently add 5 ml KCl hypotonic. Replace lid and invert the tube to ensure thorough mixing. Reincubate culture tubes for 5 min.

4. Centrifuge at 1200 rpm for 5 min. Remove supernatant. Resuspend cells thoroughly. Very gently, add 5 ml fixative (drop by drop at first and then more quickly) whilst continuously mixing the cell pellet either by flicking the tube or by mixing on a whirlimixer to prevent cell clumping. This stage is critical in producing clean preparations.

5. Centrifuge culture tubes at 1200 rpm for 5 min. Pour off supernatant. Resuspend cells thoroughly and

add 5 ml fixative. Centrifuge culture tubes again, resuspend cells, and add 5 ml fixative. If the cell suspension looks faintly brown, repeat centrifuging and fixing once more before slide making. The cells are ready for slide making or may be stored at –20°C.

B. Unsynchronised Cell Culture of Fibroblasts

Tissue viability is improved if the tissue sample is transported in transport medium supplied by the laboratory.

Solutions

1. *Working stock solutions: Heparin* (1250 units/ml), *amphotericin B* (0.25 mg/ml), and *colchicine* (500 µg/ml for tissues)
2. *Transport medium*: 100 ml Hams F10, 1 ml penicillin/streptomycin/glutamine, 0.2 ml heparin, and 1 ml amphotericin B
3. *Complete medium*: 100 ml Hams F10, 20 ml fetal calf serum, 1 ml penicillin/streptomycin/glutamine, 1 ml amphotericin B, and 2 ml Ultroser
4. *Trypsin/EDTA*: 10 ml of trypsin 2.5% added to 100 ml EDTA 0.02%
5. *KCl hypotonic*: 0.056 M (4.2 g/litre distilled water)
6. *Fixative*: 3 : 1 methanol : glacial acetic acid

Steps

Day 1 Establishing Cultures

1. Remove the tissue from the transport medium with a sterile pair of forceps and place in a sterile plastic petri dish. Using a sterile plastic pastette, add a few drops of medium to the tissue to prevent the sample from drying out. Mince the tissue finely with a sterile scalpel into ~0.5- to 1-mm^3 pieces.

2. Using a pastette, resuspend the minced tissue in a small volume (~0.25 ml) of medium and place on the growth surface of two labelled 25-cm^2 flasks. Ensure that the tissue pieces are as evenly spread as possible. Gently invert the flask so that tissue adheres to the surface in a minimal amount of medium. Add 5 ml of complete tissue medium to each flask by running the medium down the lower side of the inverted flasks. Gas (5% carbon dioxide/95% air) the flasks if using a standard non-CO_2 incubator, replace lids, and incubate at 37°C.

3. After several hours (or overnight if cultures are set up late in the day), carefully turn the flasks the right way up so medium now covers the tissue.

Days 6–8+ Processing and Harvesting of Cultures

1. Cultures are examined for the first time when they are 6–8 days old. Replace the medium with 5 ml of complete tissue medium. Gas (5% carbon dioxide/95% air) the flasks if using a standard non-CO_2 incubator, replace lids, and incubate at 37°C.

2. When sufficient cells have grown from the explants (covering one-half to two-thirds of the flask), the cells can be directly harvested or subcultured. Subcultured cells usually give a higher mitotic index.

Subculturing

1. Prewarm trypsin/EDTA to 37°C. Remove culture medium and gently rinse flask with ~1 ml of trypsin/EDTA. Add 0.5 ml of prewarmed trypsin/EDTA and reincubate for several minutes. Examine the flask under low magnification on an inverted microscope. The cells should appear either rounded up or floating in the medium. Tap the flask lightly two or three times to dislodge any remaining cells. Add 1 ml of medium and divide the cell suspension between two new labelled flasks.

2. Add 5 ml of complete medium to each flask, including the original, which can be retained as a backup. Gas (5% carbon dioxide/95% air) the flasks if using a standard non-CO_2 incubator, replace lids, and incubate at 37°C.

Harvesting of Cultures. Subcultured flasks are usually fed with 5 ml fresh medium the following day and harvested on the second day. The cells should be in logarithmic growth phase with a high mitotic activity.

1. Add 0.1 ml colchicine to each flask and reincubate for 2 h. Prewarm trypsin/EDTA to 37°C.

2. After 2 h, examine the cells under low magnification with an inverted microscope. A number of rounded, dividing cells should be present. Pour off the medium from the flask into a labelled centrifuge tube. Add 1 ml of trypsin/EDTA and rinse the flask, adding this to the centrifuge tube. Add 0.5–1 ml of trypsin/EDTA to each flask and incubate for 2–5 min. Tap the flask two or three times. Examine the flasks to check that cells are in suspension. Add 2 ml of culture medium to the flask and transfer all medium and cells to the centrifuge tube.

3. Centrifuge the tube at 1200 rpm for 7 min. Pour off the supernatant from the tube. Resuspend the pellet by flicking the tube. Add 5 ml KCl hypotonic solution to the tube and invert gently to mix. Centrifuge at 1200 rpm for 7 min. Pour off the hypotonic, resuspend the cell pellet, and gently and slowly add fixative whilst flicking the tube to prevent cell clumping. After approximately 0.5 ml has been added, top up more quickly to 5 ml. The cells are ready for slide making or may be stored at –20°C.

C. Slide Making

It is advisable to wipe the precleaned slide with a tissue soaked in either methanol or fixative immediately prior to slide making. Optimal conditions are 40–45% humidity in temperatures of 20–22°C.

Solution

Fixative solution: 3:1 methanol:glacial acetic acid

Steps

1. Centrifuge cell suspensions at 1200 rpm for 5 min. Pour off supernatant and resuspend the cell pellet by tapping the tube and add three drops of fixative.
2. Using a plastic pipette, place a single drop of cell suspension in the middle of a labelled slide from a height of 1 cm. The slide can be held flat, allowing the drop to spread as a circle or the slide can be held at 20–30° so that the drop runs down the length of the slide.
3. Add a single drop of fixative from the same height in the same manner when the area of cells becomes visible as a cloudy area and Newton's rings appear on the periphery. Allow the fixative to evaporate.
4. Check the cell density and metaphase spreading using a phase microscope.
5. If the slide has sufficient metaphases of an appropriate length, continue with slide making. If the cell density is too high, add a few more drops of fixative and check by making another slide. If the cell density is too low, add 5 ml fixative, centrifuge the suspension again, and repeat but add less fixative. Cell spreading can be altered by changing cell density, local humidity, or the rate of drying. Underspreading can be improved by breathing on the slide before adding the cell suspension, adding two drops of fixative to the cells on the slide, or placing the slide on a wet paper towel. Overspreading can be reduced by omitting the second drop of fixative, using cold fixative cooled in a freezer before use, or increasing local air flow and speed of drying.
6. Add 5 ml fixative to any remaining cell suspension and store at –20°C.
7. Age slides either overnight by putting in metal racks in a hot box oven at 70°C or for 1 h on a hot plate at 80°C or on the bench for several days.

D. G Banding

Solutions

1. *Hanks pretreatment solution*: 8 ml of Hanks BSS (10×) plus 40 ml of distilled water
2. *Phosphate-buffered saline pH 7.4*: Add one sachet of powder to 1 litre of distilled water
3. *Banding trypsin solution*: Rehydrate bottle of Difco trypsin with 10 ml of distilled autotoclaved water. Add 1 ml of trypsin solution to 40 ml PBSA.
4. *pH 6.8 buffer solution*: Add 1 tablet to 1 litre of distilled water
5. *Leishman's staining solution*: 40 ml, pH 6.8, buffer solution plus 8 ml Leishmans' stain

Steps

1. Place a test slide in the Hanks pretreatment solution for 3 min. Rinse the test slide in tap water for 5 s. Place the slide in the trypsin solution for 33 s (move slide gently in the solution). Whilst slide is in the trypsin solution, remove surface film from the stain by skimming with a piece of filter paper. Rinse slide in tap water. Place the slide in Leishman's staining solution for 2 min. Rinse slide in tap water. Blot carefully with filter paper and leave to dry or dry on a hot plate for a short time.
2. When dry, place three drops of XAM or similar mountant onto the slide along its length. Place a 22 × 50-mm coverslip onto the slide and blot gently to remove excess mountant.
3. Assess banding using the light microscope at 1000× magnification and adjust times for Hanks, trypsin, and stain as appropriate. If the chromosomes appear generally grey with indistinct banding, increase the Hanks pretreatment time. If the chromosomes are bloated and the chromatids appear to be separating, reduce trypsin time. If they appear generally dark with little banding, increase the trypsin time. Staining should be modified so there is a clear distinction between pale staining and dark staining regions of the chromosomes.

IV. COMMENTS

1. All culture work should be performed under the appropriate containment level (e.g., class 2 laminar flow cabinet).
2. All waste material from cell cultures should be decontaminated prior to disposal. Waste media and hypotonic can be decontaminated in 2% Virkon for a minimum of 10 min.
3. Fetal calf serum is variable in supporting good cell growth and should be batch tested prior to bulk purchase and use. It is advisable to combine smaller aliquots from two different batches or suppliers rather than a single volume from one supplier in preparing complete medium.

4. All complete culture media should be stored at 4°C and ideally used within 1 week of preparation.

5. Our laboratory routinely uses colchicine. Many laboratories use the less toxic colcemid, adding 0.1 ml of stock solution to 5 ml culture.

6. The methanol/glacial acetic acid fixative should be freshly made before harvesting and slide making.

7. Slides should be grease free to ensure optimal chromosome spreading. Precleaned slides may be purchased.

V. PITFALLS

If the first fixation stage of a blood culture results in a gelatinous cell suspension, add an equal volume of distilled water, mix, recentrifuge, and continue with protocol.

CHAPTER

39

A General and Reliable Method for Obtaining High-Yield Metaphasic Preparations from Adherent Cell Lines: Rapid Verification of Cell Chromosomal Content

Doris Cassio

I. INTRODUCTION

In vitro studies are becoming more and more frequent in numerous domains of cell biology. For such purposes, a great variety of cell lines have been established either from normal tissues or, more frequently, from tumours. Very few of these cells present a normal karyotype: they are generally hyperdiploid and often contain rearranged chromosomes. Moreover, depending on the length of time in culture and on the culture conditions, populations of these cell lines can change and drift. Therefore, some general culture rules have to be respected (Ian Freshney, 1987), and it is highly recommended to avoid working with cells maintained in culture for a large number of generations.

Because of possible drift, cell lines need to be followed and controlled, with one fundamental control being the stability of their chromosomal content. Unfortunately, such control is not systematic. Moreover, in the case of new cell lines, it is frequent that their phenotype is described in detail with little or no information on their karyotype. It should be noted that even if karyotyping methods have long been described in the literature (for the history of human cytogenetics, see Jeening Lawce and Brown, 1997), it is not always easy to obtain metaphasic preparations from some cell lines. We were confronted with such a situation for some hybrid lines, in particular polarized rat hepatoma–human fibroblast WIF clones (Cassio *et al*., 1991; Shanks *et al*., 1994). This article describes a new method for obtaining, at a high yield, metaphasic preparations from delicate cell lines. This method is easy and reliable and has been applied successfully by many people to more than 50 different cell lines from different species.

A. Principles of the Method

This method is a combination of the two methods described by Worton and Duff (1979), the suspension method generally used for nonadherent and adherent cells and the "*in situ*" method that has been specifically developped for adherent cells (Cox *et al*., 1974; Peakman *et al*., 1977). When we tried to prepare metaphases from the well-polarized hybrid cell line WIF-B (Shanks *et al*., 1994), we only succeeded with the "*in situ*" one. We performed many assays using the suspension method and they all failed: from two to three petri dishes containing 10^6 cells/dish in exponential phase, we obtained, at the best, a dozen metaphases (yield < 10^{-5}). In contrast, with the *in situ* method, the metaphase yield was very good and attained 1.5% of the total cell number (the maximal

expected value for cells with a generation time of 2.5 days).

In the suspension method, mitoses are detached (mechanically or by proteolysis), whereas in the *in situ* method, mitoses stay in place. As polarized WIF-B cells have a highly differentiated plasma membrane, organized in different domains, we hypothesized that mitotic cells from this line are very fragile and are lost during or after detachment (may be during centrifugation). Therefore, to isolate metaphases from this line, a new method was developped that avoids cell detachment, at least during the early steps. The first steps of this method (metaphase arrest, hypotonic swelling, and first fixation) are performed *in situ* and it is only after the first fixation that cells are detached.

B. Advantages of the Method

This method presents several advantages. First, it is applicable to every adherent cell line and does not depend on the adherent properties of the mitosis, as all mitoses (floating and adherent ones) are collected. Second, as with the *in situ* method, the yield in metaphases is very good (Fig. 1A) and therefore the metaphasic preparations are representative of the whole cell population. Third, this method requires fewer cells and is less wasteful in cells than the suspension method, an advantage for slow-growing cell lines where mitotic cells are rare or for cells where the results of karyotyping are required as soon as possible. Finally, as with the suspension method, the quality of the metaphase spreading is good (Fig. 1B) and can be adjusted, whereas with the *in situ* method, which allows only one attempt per culture, the spreading cannot be controlled and is very sensitive to cell overcrowding. Moreover, the chromosomes obtained by this new method are quite suitable for G banding, Giemsa 11 staining (Buys *et al.*, 1984) (Fig. 1C), and fluorescent *in situ* hybridization (FISH) (Fig. 1D).

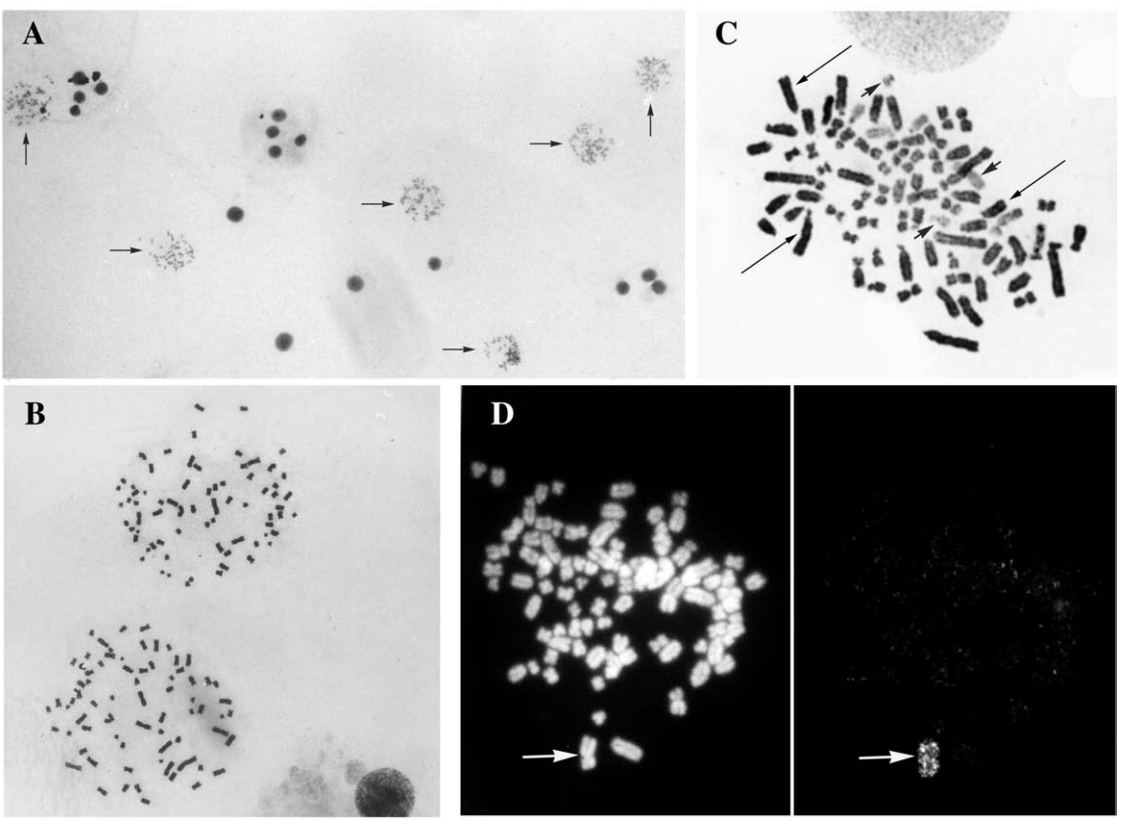

FIGURE 1 **Metaphases from HT29 and hybrid WIF lines.** (**A**) HT-29 cells at low magnification; metaphases were obtained at a high yield as attested by the presence of six metaphases (arrows) among some 30 cells. (**B**) HT-29 metaphases at a higher magnification to illustrate chromosome spreading. (**C**) Detection of human (pale staining, small arrows) and rat (dark staining, long arrows) chromosomes by Giemsa 11 staining in a metaphase of the human × rat hybrid WIF-B. (**D**) Detection by FISH (right) of one copy of the human chromosome 2 (arrow) in a WIF 12-E metaphase that was counterstained with propidium bromide to show all the chromosomes (left).

II. MATERIALS AND INSTRUMENTATION

Growth medium (available from local suppliers)
Colcemid (10 µg/ml; GIBCO, Cat. No. 2465)
Gurr buffer tablets, pH 6.8 (BDH, Cat. No. 33199)
Giemsa solution (Merck, Cat. No. 1.09204.0100)
10-cm tissue culture dishes (Falcon, Cat. No. 3003)
15-ml tubes (Falcon, Cat. No. 352099)
Precleaned, ground edge, microslides (ESCO, Cat. No. 2951R)
Glass jars

A low-speed centrifuge with a swinging-backet rotor for 15-ml tubes (as the IEC clinical centrifuge) is needed for harvesting cells, and a phase-contrast microscope is needed for examining cells and slides.

III. PROCEDURES

A. Cleaning and Frosting of Microscope Slides

Steps

1. Dip microscope slides in a jar containing 100 ml methanol plus two to three drops of concentrated HCl for 12–24 h.
2. Dry the slides one by one, place them in an appropriate jar, and freeze them at –20°C for at least 4 h and at the most 7 days.

B. Optimization of Growth

Step

Grow cells in 10-cm Petri dishes in appropriate medium so that cells will be in midexponential phase with many mitoses on the day of harvest. Renew the dishes with 10 ml of medium the day before the harvest.

C. Metaphase Arrest

Step

Add 0.2 ml of colcemid for 1 h at 37°C to the dish containing the maximal number of mitotic cells. The other dishes can be used later if necessary.

D. Hypotonic Swelling

Solutions

1. *Hypotonic solution (0.075 M KCl)*: add H_2O to 0.56 g KCl to make 100 ml
2. *Fixative*: Make **fresh** 3:1 methanol:glacial acetic acid; keep it at –20°C in an appropriate closed glass vessel and transfer to 4°C just before use.

Steps

1. Collect the culture medium of the Petri dish in a 15-ml tube and centrifuge at room temperature, at approximatively 1000 rpm (200 g) for 5 min, to collect the floating mitoses.
2. Immediately after starting centrifugation, add 5 ml of warm (37°C) hypotonic solution to the cells in the petri dish.
3. Incubate the cells in the hypotonic solution at 37°C.
4. As soon as the centrifuge stops, aspirate and discard the supernatant and add 1 ml of warm hypotonic solution to the pellet (depending on the cell line this pellet could be well visible or almost nonexistent). Resuspend the pellet rapidly by pipetting and add this suspension to the cells in the Petri dish, which now contain all the starting cells. Incubate at 37°C for a further 20–30 min.

Note: The swelling of the cells can be verified by examination under a microscope.

E. Fixation

Steps

1. Add very carefully to the petri dish 6 ml of cold (4°C) fixative with a **glass** pipette and place the dish on ice for 10 min.
2. Detach the cells from the dish with a **glass** Pasteur pipette by repeated pipetting. Depending on the cell line, this step could be very easy or more laborious. Control the detachment under the microscope. If the cells are very sticky, try gentle use of a cell scraper.
3. Transfer the cold cell suspension to a cold (4°C) 15-ml tube.
4. Centrifuge at approximatively 1000 rpm (200 g) for at least 5 min.
5. Remove all but about 0.2 ml of supernatant and resuspend gently by shaking cell pellet in this small volume (no pipetting). Add 1 ml of cold fixative slowly and then another 4 ml of cold fixative and leave on ice for at least 5 min.
6. Repeat steps 4 and 5 (with a smaller volume of fixative) twice; the fixative can be added more quickly on the last fixations. At this point preparations can be stored overnight at 4°C or slides can be made immediately.

F. Spreading and Air Drying

Spreading is done by air drying onto frozen slides.

Steps

1. Centrifuge the fixed cells at approximatively 1000 rpm (200 g) for at least 5 min.
2. Remove the supernatant and gently resuspend the pellet in about 0.5 ml of cold fixative (make fresh fixative if cells have been stored overnight).
3. Using a Pasteur pipette, drop two to three drops of the suspension at the top of a frozen slide inclined 20–30° from vertical. Let the drops run down the length of the slide as they spread. Wipe excess liquid from the underside of slide and let it dry at room temperature.
4. Check this first slide under phase contrast so that adjustments can be made on subsequent slides if cells are too crowded or if the spreading is poor.

G. COLORATION

As the present technique was developed to verify the cell chromosomal content, we use Giemsa "solid staining" (Worton and Duff, 1979), which gives uniform staining of the chromosomes and makes it easy to count them. However, other staining methods can be applied (Fig. 1).

Solutions

1. *Gurr buffer, pH 6.8*: Dissolve one Gurr buffer tablet, pH 6.8, in 1 liter H_2O
2. *5% Giemsa*: Add 5 ml of Giemsa to 95 ml of Gurr buffer (or 10 m*M* phosphate pH 6.8)

Steps

1. Dip the slides in 5% Giemsa at room temperature for 15 min.
2. Rinse twice with water and let dry at room temperature

IV. COMMENTS

Using this method, metaphasic preparations from of a panel of well-known and frequently used lines, including polarized lines (Caco-2, MDCK, HT-29) and hepatic ones, were isolated and analyzed (Table I).

TABLE I Chromosomal Content of a Panel of Cell Lines[a]

Cell line	Origin	Chromosome mean number[b] (range)	Published chromosome mean number[c] (range)
BW1-J	Hepatoma, mouse	64 (60–72)	64 (60–72)
Caco-2	Adenocarcinoma, colon, human	85 (78–98) 84 (67–102)	98 (91–107)
L (cl 1-D)	Connective tissue, mouse	51 (50–55)	51 (50–55)
Fao	Hepatoma, rat	51 (48–53)	52 (50–55)
HeLa	Epitheloid carcinoma, cervix, human	73 (68–79) 64 (61–68) 62 (43–83)	82 (70–86)
Hep G2	Hepatocellular carcinoma, human	52 (49–56) 50 (44–55)	55 (50–56)
HT-29	Adenocarcinoma, colon, human	71 (68–73)	70 (68–72)
MDCK	Normal kidney, canine	75 (68–82) 74 (68–77) 112 (80–144)	78 (65–89)
V79-4	Lung, chinese hamster	22 (22–23)	22 (20–23)
WI-38	Normal embryonic lung, human	46 (42–46)	46 (39–46)
WIF 12-E	Human fibroblast × rat hepatoma hybrid (WI-38 × Fao)	83 (79–86)	84 (79–92)

[a] Metaphases were prepared using the method described in this article.
[b] Mean and range obtained by analyzing at least 20 metaphases.
[c] According to the ATCC catalogue, Cassio and Weiss (1975) for BW1-J and Fao, Weiss and Green (1967) for cl 1-D, Knowles *et al*. (1980) for Hep G2, and Griffo *et al*. (1995) for WIF 12-E.

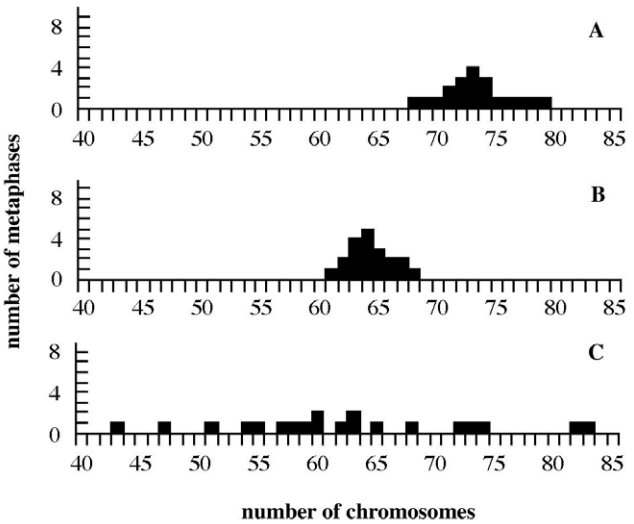

FIGURE 2 Chromosomal content of HeLa cells. Metaphases were prepared from HeLa cells (ATCC collection) cultured routinely in three different laboratories (A–C). The chromosomal content of each cell population is different, and in all cases the chromosome number is lower than expected (published mean chromosome number 82, range 70–86). Note the very heterogeneous karyotype of HeLa cells in C. These results show how cells of a same line can change and drift.

Some lines (BW1-J, cl 1-D, HT-29) displayed a chromosomal content similar or very near to that published previously, but the mean number of chromosomes, as the range, of other lines (Caco-2, HeLa) differed greatly from those published. Morever, in some cases, big differences were observed from the same line obtained from different laboratories. This was the case for HeLa cells (Fig. 2) and, to a lesser extent, for MDCK. In this latter case, one population over the three tested was very heterogeneous and greatly differed from the two others. Although both L and HeLa lines were established a long time ago (in 1940 and 1951, respectively) and thus cultured for a very large number of generations, the first line seems to be very stable, whereas the second one has considerable drift.

V. PITFALLS

1. Use only **glass** pipettes for adding the fixative and for detaching cells after the first fixation. Fluffy and fuzzy chromosomes are obtained using plastic pipettes.
2. Well-adherent cells can be detached by gentle pipetting at the end of the hypotonic shock before fixation.
3. The presence of a thin layer of cytoplasm embedding the chromosomes can be avoided by performing additional fixations and by improving the spreading (increase the distance between the drop and the slide and adjust the angle of the slide).

Acknowledgments

I thank C. Delagebeaudeuf for pushing me to develop this method, C. Hamon-Benais, and V. Bender for the illustrations, and L. Sperling for careful reading of the manuscript. This work was supported in part by the Curie Institute (PIC Signalisation Cellulaire Grant 914), CNRS, and INSERM (contrat Prisme 98-09).

Mapping Cloned DNA on Metaphase Chromosomes Using Fluorescence *in Situ* Hybridization

Margaret Leversha

I. INTRODUCTION

Fluorescence *in situ* hybridization (FISH) provides a quick means of placing almost any recombinant DNA clone onto a physical map. Clones can be mapped onto banded metaphase chromosomes for regional localization, to assign new markers to a chromosomal segment, to validate clones selected using previously assigned markers, or to characterize chromosomal rearrangements.

In genome mapping, unrecognized clone chimerism causes considerable problems with contig assembly and can result in much wasted effort when trying to extend or link contigs. For example, as many as 30–40% of YAC clones may contain coligated sequences from different genomic regions (Selleri *et al*., 1992). The shift to large-insert, single-copy plasmids such as PACs and BACs has substantially reduced the problem of clone chimerism. However, large-scale genome sequencing projects are revealing significant levels of regional homology that can confound mapping analyses at all levels (Cheung *et al*., 2001; Bailey *et al*., 2002). Preliminary FISH screening of clones is a simple and useful precaution.

DNA clones can also be ordered by FISH at increasing levels of resolution. Clones separated by 1–2 Mb can be ordered by pairwise, two-color FISH on metaphase chromosomes (Trask *et al*., 1991; Inazawa *et al*., 1994). Hybridization of sets of three clones to interphase nuclei provides mapping information down to about 50–100 kb (Lawrence *et al*., 1990; Trask *et al*., 1991), while the highest resolution is for overlapping clones on linear DNA molecules (Raap *et al*., 1996).

II. MATERIALS AND INSTRUMENTATION

DNase I (D-4527), DNA polymerase I (D-9380), bovine serum albumin (BSA, B-4287), dextran sulfate (D-8906), Denhardt's solution (D-2532), dithiothreitol (DTT, D-9779), SDS or sodium lauryl sulfate (L-4390), mouse antidigoxin FITC (F-3523), goat anti-mouse-FITC (F-0257), rabbit anti-mouse-FITC (F-7506), and DAPI (D-9542) are from Sigma. Deoxyribonucleotides (100 m*M* solutions of dATP, dCTP, dGTP, and dTTP) are from Amersham Biosciences (Cat. No. 27-2035-01). Human Cot-1 DNA (Cat. No. 15279011) is from Invitrogen. Formamide is from Fluka (Cat. No. 47670). Molecular biology grade mixed bed resin AG 501-X8 is from Bio-Rad (Cat. No. 143-6424). Biotin-16-dUTP (Cat. No. 1093070) and digoxigenin-11-dUTP (Cat. No. 1573152) are from Roche Diagnostics.

Berliner Glas microscope slides are from H. V. Skan Ltd., Solihull. Glass coverslips (No. 1–22 × 22 mm, 22 × 32 mm, 22 × 50 mm) and Nescofilm are from Fisher Scientific. Rubber cement can be obtained from art suppliers or from cycle shops (e.g., Halfords). Plastic syringes are from Becton-Dickinson, and 0.2-µm syringe filters are from Nalgene (Cat. No. 190-2520). Plastic slide boxes (50 slide capacity, Cat. No. 406028600), self-indicating silica gel (Cat. No.

Copyright 2006, Elsevier Science (USA).
All rights reserved.

300624V), Tween 20 (Cat. No. 66368 4B), glycerol (Cat. No. 101186M), 96% ethanol, and 99% ethanol are from BDH (VWR International).

Fine forceps suitable for handling slides and coverslips comfortably, without mishap (13 mm, Cat. No. E12), glass Coplin jars (Cat. No. E94), Hellendahl jars (Cat. No. E95), slide racks (Cat. No. E89.03, E89.055), and diamond marking pencils (Cat. No. E17) are from Raymond A. Lamb.

Cy3-streptavidin (Cat. No. PA43001) is from Amersham Biosciences. Texas red avidin DCS (Cat. No. A-2016), biotinylated antiavidin (Cat. No. BA-0300), and Vectashield (Cat. No. H-1000) are from Vector Laboratories Ltd. Filter paper discs, grade 4 (Cat. No. 1004 240), are from Whatman. Nonfat milk powder (e.g., Marvel) is widely available. Similarly, nail varnish from any inexpensive source should be adequate.

DNA concentrations are determined using a Hoefer TKO minifluorimeter. The slide drying bench (Cat. No. E18.1) is from Raymond A. Lamb. Also needed are at least two water baths (to be set at 37 and 65°C), a microcentrifuge for both 0.5- and 1.5-ml tubes, a 37°C oven, and facilities for performing agarose gel electrophoresis, as well as countup/countdown timers (e.g., Smiths), thermometers, micropipettes and sterile tips, domestic air-tight plastic freezer boxes, and lint-free tissues (Kimwipes). Incubation chambers are prepared using 245 × 245-mm^2 bioassay dishes (Nunc, Cat. No. 240835). Racks to accommodate a maximum of 16 slides are made by trimming four plastic 10-ml pipettes to fit and fixing them in place with rubber cement.

We use a Zeiss Axioskop epifluorescence microscope fitted with a 100-W mercury arc lamp, triple bandpass/dichroic filter blocks for both rhodamine (or Cy3) and Texas red (Chroma Technologies, sets 82000 and 83000), and a motorized excitation filter wheel (Ludl) and a Photometrics KAF1400 cooled CCD camera controlled by SmartCapture imaging software. Similar imaging systems can be obtained from Applied Imaging. SmartCapture software is supplied by Digital Scientific.

III. PROCEDURES

A. Probe Labeling

Solutions

1. *10× nick translation buffer*: 0.5 *M* Tris–HCl, pH 7.5, 0.1 *M* $MgSO_4$, 1 m*M* DTT, and 500 µg/ml BSA. To make 10 ml, mix 5 ml 1 *M* Tris–HCl (pH 7.5), 1 ml 1 *M* $MgSO_4$, 10 µl 1 *M* DTT, 500 µl 10 mg/ml BSA, and make up to 10 ml with sterile deionized water. Store 1-ml aliquots at –20°C.

2. *DNase I stock solution*: Resuspend 10,000 units in 1 ml 0.3 *M* NaCl and add 1 ml sterile glycerol. Store at –20°C.

3. *DNase I working solution*: To make 1 ml, mix 100 µl 10× nick translation buffer with 400 µl sterile deionized water and 500 µl sterile glycerol; then add 1 µl DNase I stock solution. Mix thoroughly and store at –20°C.

4. *0.5 mM dNTPs*: To make 1200 µl, mix 2 µl each of 100 m*M* dATP, dCTP, and dGTP and then add 1194 µl sterile deionized water. Store 50-µl aliquots at –20°C.

5. *1 mM biotin-16-dUTP or digoxigenin-11-dUTP*

6. *DNA polymerase I (10 units/µl)*

7. *0.5 M EDTA, pH 8.0*: To make 100 ml, mix 18.61 g EDTA in 80 ml deionized water, adjust to pH 8.0 with NaOH (the salt will not dissolve until near pH 8), and make up to volume with deionized water. Sterilize by autoclaving.

8. *1 M Tris–Cl, pH 7.4*: To make 100 ml, dissolve 12.11 g Tris base in 80 ml deionized water, adjust to pH 7.4 with HCl, and make up to volume with deionized water. Sterilize by autoclaving.

9. *3 M sodium acetate, pH 7.0*: To make 100 ml, dissolve 24.6 g sodium acetate (anhydrous) in 80 ml deionized water, adjust to pH 7.0 with glacial acetic acid, and make up to 100 ml with deionized water. Sterilize by autoclaving. Use small aliquots as working stock, replacing frequently.

10. *Absolute ethanol*: Store in a sterile 50-ml Falcon tube at –20°C.

11. *70% ethanol*: Store in a sterile 50-ml Falcon tube at –20°C.

12. *TE buffer (10 mM Tris–Cl, 1 mM EDTA)*: To make 100 ml, mix 1 ml of 1 *M* Tris–Cl, pH 7.4, and 0.2 ml of 0.5 *M* EDTA and make up to 100 ml with deionized water. This is best made prior to sterilizing the stock solutions of Tris and EDTA. Sterilize by autoclaving.

Steps

1. Prepare a water bath at 14°C. A robust polystyrene box (or ice bucket) with a lid is a suitable container (although some are not reliably water tight).

2. Place approximately 1 µg of each DNA sample to be labeled in 1.5-ml microfuge tubes and make up the volumes to 10 µl with sterile deionized water. Stand on ice.

3. Prepare 15 µl labeling master mix for each sample, allowing a little extra for dispensing. For 4 µg DNA, take 10 µl nick translation buffer, add 34 µl sterile deionized water, 7.5 µl dNTPs, 2.5 µl 1 m*M* biotin-16-

dUTP, 4 µl DNase I working solution, and 2 µl 10 U/µl DNA polymerase I. Mix thoroughly and pulse microfuge to collect all the solution in the base of the tube. Stand on ice.

4. Add 15 µl of master mix to each DNA sample and mix by pipetting several times.

5. Incubate the samples at 14°C for 40–60 min. The exact length of time must be determined for each new preparation of DNase I working solution.

6. Transfer the tubes to ice and add 2.5 µl 0.5*M* EDTA to each, mixing quickly with the pipette.

7. Add 2.5 µl 3*M* sodium acetate and 1 ml cold 100% ethanol to each tube. Mix by inversion.

8. Incubate at –20°C overnight.

9. Microfuge the tubes for 10 min at maximum speed. Remove the supernatants carefully so as not to disturb the visible pellets.

10. Carefully add 1 ml cold 70% ethanol to each tube. Microfuge again for 10 min. Carefully aspirate off the supernatant from the transparent pellets and air dry. Do not overdry.

11. Add 10 µl TE buffer to each tube and stand on ice for 15 min. Flick mix to resuspend.

12. Run 2-µl aliquots in a 1% agarose gel to assess the probe fragment length. A smear between 200 and 800 bp is satisfactory.

13. Store the probes at –20°C.

B. *In Situ* Hybridization

Solutions

1. *50% dextran sulfate*: To make 50 ml, weigh 25 g dextran sulfate into a graduated 100-ml pyrex bottle, add 20 ml deionized water, and heat in a 65°C water bath until dissolved. Make up to volume with deionized water and sterilize by autoclaving. Dispense 10-ml aliquots into sterile 50-ml Falcon tubes and store at –20°C.

2. *Deionized formamide*: Add 5 g Bio-Rad mixed bed resin AG 501-X8 to 100 ml formamide and stir in a fume hood for 60 min. Allow the beads to settle and decant the formamide. Store aliquots at –20°C.

3. *20× SSC (3 M NaCl, 0.3 M sodium citrate)*: To make 1 liter, dissolve 175.2 g sodium chloride and 88.2 g trisodium citrate in deionized water and make up to volume.

4. *10% SDS*: To make 50 ml, dissolve 5 g sodium dodecyl sulfate in 50 ml deionized water. Sterilize by filtering through a 0.2-µm filter.

5. *0.5 M Na_2HPO_4*: To make 100 ml, dissolve 7.098 g Na_2HPO_4 in deionized water and make up to volume. Sterilize working aliquots by filtration.

6. *0.5 M NaH_2PO_4*: To make 100 ml, dissolve 7.8 g $NaH_2PO_4.2H_2O$ in deionized water and make up to volume. Sterilize working aliquots by filtration.

7. *Hybridization buffer*: To make 50 ml, thaw a Falcon tube containing a 10-ml aliquot of 50% dextran sulfate, add 25 ml deionized formamide, 5 ml 20× SSC, 1 ml 50× Denhardt's solution, 4 ml 0.5*M* sodium phosphate buffer, pH 7.0 (2.308 ml Na_2HPO_4, 1.692 ml NaH_2PO_4), 0.5 ml 10% SDS, and 4.5 ml sterile deionized water. Mix very thoroughly by inversion, preferably on a rotator for 10 min. Dispense into 1-ml aliquots and store at –20°C. This should be stable for at least 1 year. Mix newly thawed aliquots thoroughly by vortexing.

8. *Cot-1 DNA*: Supplied at 1 mg/ml.

9. *70% formamide*: To make 100 ml, mix 70 ml formamide and 30 ml 2× SSC. Store at 4°C between uses and replace weekly. (Deionizing the formamide is not necessary.)

10. *70% ethanol in a Hellendahl jar*: Store at –20°C. Replace weekly.

11. *Ethanol series*: Hellendahl jars containing 70% ethanol (2×), 90% ethanol (2×), and 100% ethanol (1×).

12. *Coverslips*: 22 × 22-mm, 22 × 50-mm coverslips immersed in 100% ethanol in an air-tight plastic container.

Steps

1. Prepare a Coplin jar or Hellendahl jar containing 70% formamide. Place in a water bath and turn the temperature to 65°C. (The glass jars will not tolerate sudden temperature changes and should always be allowed to warm gradually.)

2. Set a second water bath to 37°C.

3. Prepare the probe hybridization mixes by adding 10 µl hybridization buffer to 0.5-ml microfuge tubes (dispensing will be aided by first warming the hybridization buffer). Stand the tubes on ice. Add 1 or 2 µl Cot-1 DNA to each tube, depending on whether one or two probes are to be added. Add 0.5 µl of biotinylated probe and/or 0.5 µl of another digoxigenin-labeled probe. Mix thoroughly by flicking the tubes and pulse microfuge the solutions to the bottom of the tubes.

4. Denature the probe mixes at 65°C for 10 min, ensuring that the tubes are fully sealed and not likely to take up water.

5. Transfer the probe mixes to the 37°C water bath to preanneal for at least 20 min (to several hours).

6. Check that the 70% formamide has reached 65°C using a thermometer reserved for the purpose.

7. Carefully immerse slides, paired back to back, into the 70% formamide at 5-s intervals. Start a count-up timer as the first pair of slides is immersed. Take

care to hold the slides clear of the steam from the water bath while preparing to place them in the formamide.

8. While the slides are denaturing, remove the Hellendahl jar of 70% ethanol from the freezer.

9. Denature the slides for 2 min. As the denaturation time elapses, remove the pairs of slides from the formamide and drain briefly against the inside of the jar. Immerse the slides, agitating briefly, in the cold 70% ethanol.

10. After 60 s in the cold 70% ethanol, transfer the slides with occasional agitation through an ethanol series at room temperature: 60 s each in successive jars of 70, 70, 90, 90, and 100% ethanol.

11. Separate the slide pairs and carefully wipe the backs of the slides dry. Air dry the slides standing in a rack on a slide-warming bench at 37–40°C.

12. Prepare the required number of 22 × 22-mm coverslips by removing them from the 100% ethanol and lightly polishing them dry with a lint-free tissue. Place the coverslips on a clean tissue on or by the slide-warming bench.

13. Place the dry slides flat on the slide-warming bench. Make sure that all are labeled and numbered clearly.

14. After the probes have preannealed at 37°C for at least 20 min, transfer the first hybridization mix to its target slide. As the volumes can be difficult to gauge accurately, set the micropipette for 12 µl and be careful to avoid bubbles when drawing up and discharging the mix onto the slide.

15. Using fine forceps, gently lower a clean coverslip over the mix. If bubbles are present, these can usually be disrupted by surface tension by allowing the hybridization mix to spread out under the upper half of the coverslip while the lower edge of the coverslip is still supported by the tip of the forceps. It is usually not worth trying to remove every last bubble as this may damage the chromosome preparations.

16. Repeat these steps for each remaining probe mix. If there are a large number to be processed, it may be preferable to station the slide bench next to the 37°C water bath and remove each mix from the water bath as required. Alternatively, the hybridization mixes can be placed on ice, but this can make the mixes more viscous and difficult to pipette.

17. Seal the edges of the coverslips with rubber cement. If the hybridization mix has not reached the edges of a coverslip because the coverslip cannot lie flat, it will be necessary to prevent the rubber cement from being drawn under the coverslip. If the coverslip cannot be flattened by gentle pressure over the high point, fill in the gap with extra hybridization buffer before sealing.

18. Place on a tray and hybridize overnight in a 37°C oven.

C. Visualization of Hybridization

Solutions

1. *50% formamide*: To make 200 ml, mix 100 ml formamide and 100 ml 2× SSC. Store at 4°C between uses and replace weekly.

2. *2× SSC*: To make 1 liter, take 100 ml 20× SSC and make up to volume with deionized water.

3. *4 × TNFM*: To make 1 liter, take 200 ml 20× SSC, add 700 ml deionized water, 500 µl Tween 20, and 50 g nonfat milk powder and mix vigorously, then make up to 1 liter with deionized water. Filter through several layers of Whatman No. 4 filter paper. (The solution should be a slightly translucent yellow-green color. If it remains cloudy try another brand of nonfat milk powder.)

4. *Immunochemical solutions*: Allow 100 µl per slide plus 50–100 µl excess. Protect from strong light.
   a. For biotinylated probes, make 2 aliquots of 4 µg/ml streptavidin-Cy3 and one aliquot of 4 µg/ml biotinylated antiavidin.
   b. For digoxigenin-labeled probes, make a 1:500 –1:1000 dilution of mouse antidigoxin-FITC and a 1:250 dilution of rabbit anti-mouse-FITC.
   c. For dual-color detection, use avidin-Texas red instead of streptavidin-Cy3. Combine the biotinylated antiavidin with the mouse antidigoxin-FITC, and the second avidin-Texas red with the rabbit anti-mouse-FITC.

5. *4 × T*: To make 200 ml, mix 40 ml 20× SSC, 160 ml deionized water, and 100 µl Tween 20.

6. *DAPI staining solution*: Prepare a Hellendahl jar with 75 ml of 2× SSC and 6 µl 1 mg/ml DAPI. Protect from light by wrapping in aluminium foil.

Steps

1. Place three Coplin jars or Hellendahl jars containing 2× SSC and two jars of 50% formamide into a water bath and warm to 42°C

2. Place a jar of 4 × TNFM to warm in a 37°C oven.

3. Prepare a humidified chamber by placing damp tissues in the bottom of an incubation dish and warm in a 37°C oven.

4. Prepare immunochemical solutions diluted in 4 × TNFM according to the haptens used. Stand at room temperature for 10 min and then microfuge for 10 min to pellet any protein complexes that might contribute to nonspecific background.

5. Remove the rubber cement from the slides using fine forceps and soak off the coverslips in the first jar of 2× SSC at 42°C, allowing approximately 5 min.

6. Transfer the slides to the first jar of 50% formamide for 5 min.

7. Repeat this incubation in the second jar of 50% formamide and then in each of the remaining jars of 2× SSC, agitating the slides briefly after each transfer.

8. Transfer the slides to the prewarmed jar of 4 × TNFM and incubate for 5–10 min at 37°C.

9. Remove the slides one by one from the 4 × TNFM and drain briefly, wipe the back, and blot excess liquid from the top and bottom edges. Place the slides on a rack in the prepared humidified chamber and apply 100 µl of the first immunochemical solution (streptavidin-Cy3 or mouse antidigoxin-FITC or avidin-Texas red). Overlay with a 25 × 50-mm strip of Nescofilm. *Note*: The slides must not dry out at any point during the procedure.

10. Incubate the slides at 37°C for 20–30 min.

11. Meanwhile, discard the three 2× SSC wash solutions and replace with 4 × TNFM, allowing the jars to warm to 42°C again.

12. Discard the Nescofilm strips, drain the slides, and rinse them in the three changes of 4 × TNFM at 42°C for 5 min each.

13. Repeat step 9 using the second antibody layer (biotinylated antiavidin, rabbit anti-mouse-FITC, or biotinylated antiavidin plus mouse antidigoxin-FITC).

14. Repeat steps 10–12.

15. Repeat step 9 using the final immunochemical layer (streptavidin-Cy3 or avidin-Texas red plus rabbit anti-mouse-FITC). If using only digoxigenin-labeled probes, proceed to step 17.

16. Repeat steps 10–12.

17. Wash twice in 4 × T at room temperature.

18. Stain the slides in DAPI for 2–3 min. Transfer the slides to a jar containing 2× SSC, rinse briefly, and pour off the 2× SSC (holding the slides in place with a gloved finger or forceps across the top of the jar). Rinse briefly with deionized water and pour off.

19. Dehydrate the slides by passing through an ethanol series, gently agitating 30–60 s in each of 70, 70, 90, 90, and 100% ethanol. Air dry.

20. Lightly polish 22 × 50-mm coverslips and lay them out on flat absorbant tissue. Apply 25–30 µl antifade solution to each coverslip.

21. Invert each slide over a coverslip, rest the bottom edge on the tissue, and gently lower until the slide touches the antifade droplet. Allow the coverslip to lift up to the slide before laying it flat. When the antifade has spread fully, gently blot any excess. Seal the edges of the coverslips with nail varnish. The slides can now be stored in the dark at 4°C for many weeks.

22. View the slides using an epifluorescence microscope equipped with the excitation and emission filters appropriate for the fluorochromes used.

IV. COMMENTS

A. Probe Labeling

Whole clone DNA preparations are usually the best material for nick translation. Bacterial clone DNA isolated by standard alkaline lysis should be satisfactory. Most matrix-binding protocols, as used by commercial kits, do not give very high yields for larger insert clones such as cosmids, PACs, or BACs (often only enough for one or two labeling reactions from 10 ml of bacterial culture) so be sure that sufficient DNA (of a concentration of at least 100 µg/ml) is obtained. Total yeast DNA gives good results for YACs, although the yeast genome may contribute excess ribosomal sequences that may not be fully suppressed during hybridization.

Different grades of DNase I have different levels of activity. New working solutions should be titrated to determine the best incubation time. A 50-µl reaction containing 2 µg DNA and 2 µl DNase I working solution in 1× nick translation buffer can be sampled at five intervals (e.g., at 20, 30, 40, 50, and 60 min) and the DNA fragments compared by electrophoresis. Even less expensive products, such as DN-25 (Sigma), are suitable for use after titration, allowing for the relative number of units per milligram of protein in the working solution. Enzyme activity is also affected by the amount of Ca^{2+} present in the reaction. Usually, sufficient Ca^{2+} is present in the original DNase I stock; however, higher grades of enzyme may need additional $CaCl_2$ to maintain active enzyme conformation during the nick translation reaction.

Approximately 70–80% of the original DNA is usually recovered after ethanol precipitation, giving a final probe concentration of 70–80 ng/µl. Probe concentrations can be verified by DNA fluorimetry if desired. Ethanol precipitation is not absolutely required for probe preparation and can be omitted after labeling repetitive DNA clones, such as chromosome-specific satellite DNAs, as these are routinely used at much lower hybridization concentrations (0.5–1 ng/µl) than "unique-sequence" clones (2.5–5 ng/µl). Ethanol precipitation enables the labeled probe to be concentrated so that it can be used without further precipitation prior to hybridization. This ensures more consistent results from one experiment to another.

Large insert clones can be mapped efficiently using direct labeling with fluorochrome-conjugated dUTPs. This avoids the time-consuming immunochemical detection steps described here, but may not be as effective in revealing smaller signals at secondary chromosomal sites.

B. Hybridization

The hybridization buffer can be dispensed more accurately after it is warmed to 65°C. The components may separate during freezing and the warmed solution should be mixed thoroughly before use. Probes will last several years if handled aseptically and stored at –20°C. They should be thawed and kept on ice when in use and returned to the freezer without delay (do not store in frost-free freezers). Routine metaphase mapping throughput can be increased by using pairs of biotin- and digoxigenin-labeled probes on two separate spots of metaphase cells on a single slide. The slide can be mounted in antifade under a single large coverslip.

C. Detection

The 4 × TNFM washes and the immunochemical incubations do not need to be performed at 37–42°C as the results are usually satisfactory at room temperature. However, it is preferable to protect the slides from bright light, and in a busy laboratory the slides can often be tucked away more safely and neatly by leaving them in an incubator or water bath.

If the clones to be mapped all localize to a small region, it may not always be possible to use a double-probe protocol as interpretation can be complicated by poor-quality probe. When performing dual-color analysis, it is easier to use fluorochromes that are spectrally well separated. Cy3 is a very stable, bright orange fluorochrome, but it can be difficult to use with FITC, as the Cy3 signals are often visible through FITC filters. This is a particular problem when imaging with black-and-white CCD cameras as strong Cy3 signals can be confused with FITC signals. Texas red is preferred for combinations with FITC (Fig. 1A).

The DAPI staining reveals a clear banding pattern, which permits chromosome identification, provided the slides are not overdenatured. If a digital image of the DAPI-stained metaphase is converted into a black-and-white inverted image, the chromosomes appear similar to a conventional G-banded metaphase (Fig. 1B).

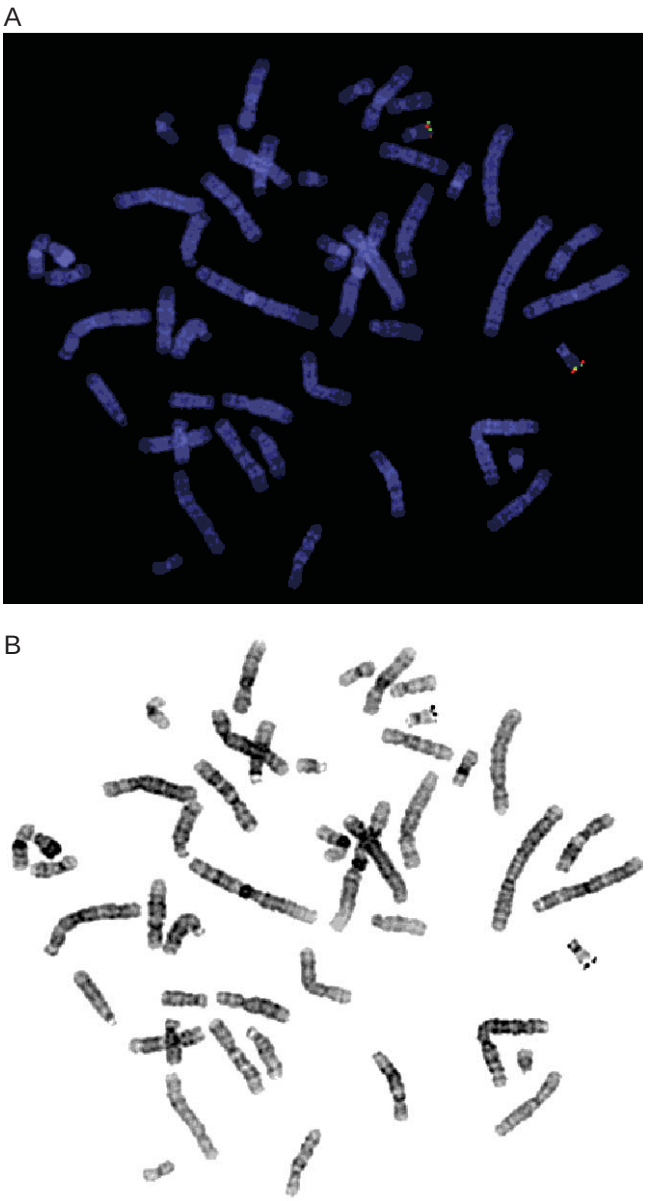

FIGURE 1 (A) Two-color hybridization of two cosmid clones mapping to chromosome 22. One cosmid was biotinylated and detected with avidin-Texas red (red) and the second cosmid was labeled with digoxigenin and visualized using FITC-conjugated antibodies (green). (B) Black-and-white inverted image of the metaphase shown in A. The chromosomes appear essentially G banded, although the 9qh region is dark in this example.

V. PITFALLS

1. If no signal is obtained, one possibility may be insufficient DNA. It is not unusual for spectrophotometric determinations of DNA concentration to be as much as 5–10 times higher than the real figure. Alternatively, the original DNA may have deteriorated. These problems are monitored easily by running approximately 100–200 ng of the original DNA next to the 2-µl aliquot of the precipitated nick-translated product in a standard 1% agarose gel. This will also reveal whether bacterial clones retain the expected size insert. When using labeled whole yeast DNA, it may be necessary to increase the amount of probe used per hybridization to ensure that there is sufficient YAC

probe present. Usually 80–100 ng of whole yeast probe will ensure clear YAC signals. Using additional amounts of probe may also assist the mapping of smaller insert clones.

Another major problem is poor hybridization efficiency because of poor-quality slide preparation. Probe accessibility is critical. Good-quality metaphase preparations, with well-spread chromosomes and a minimum of residual cytoplasm, are far more useful than any amount of protease pretreatment. RNase A digestion is not normally necessary at all.

It is always possible that the clone you are trying to map will never hybridize to your metaphase spreads. For example, human monochromosomal libraries made from material flow sorted from somatic cell hybrids may contain a small proportion of nonhuman clones. Try hybridizing a larger amount of probe (100–200 ng) without any Cot-1 DNA and no preannealing at 37°C. The abundant *Alu* short, interspersed repeat sequences are distributed throughout the human genome and should be present in most genomic clones. In the absence of preannealing, *Alu* signals should be distributed all over the chromosomes, concentrated in the G-light chromosome R bands.

It also appears that about 25–30% of cDNA clones cannot be localized by FISH (Korenberg *et al*., 1995). This may be due to the relatively short genomic extent of the target gene. Mapping cDNAs is a much more demanding process and every step must be rigorously optimized. Protease digestion around the chromosomal DNA may be useful here, but it must be carefully controlled to avoid loss of chromosome morphology (Fan *et al*., 1990). More sensitive detection systems, such as the use of tyramides, may also be useful (Raap *et al*., 1995).

2. If the cloned DNA does not cut well after nick translation, the large probe fragments will result in excessive background hybridization, which is seen as large, bright spots of signal all over the chromosomes and nuclei. Large spots of signal that appear to float above the spreads are nearly always indicative of excessive probe fragment length. Because DNase I digestion is affected by contaminants in the DNA, it may be necessary to repurify the sample before repeating nick translation. DNA that digests with restriction enzymes should be satisfactory. Try increasing the duration of the next nick translation reaction by at least 10 min. Check the concentration of your DNA also; the labeling reaction may have contained far too much DNA.

If the probe length is in the acceptable size range, it may be that one of the immunochemicals has deteriorated. These should always be kept in small aliquots and handled as aseptically as possible. Depending on the manufacturers' recommendations, it should be possible to store most reagents at –20°C, with a single working aliquot stored at 4°C. Avoid repeated freeze–thawing and, for this reason, do not store reagents in frost-free freezers. Using immunochemicals at too high a concentration can result in generalized nonspecific background over the slide. Similarly, precipitation of immunochemical complexes will occur if the slides are allowed to dry out during the detection procedure.

Certain clones may require increased amounts of Cot-1 DNA to suppress apparently nonspecific hybridization to other chromosomal regions. Another potential source of nonspecific background may be residual material in the fixed metaphase suspensions. This may be reduced by washing the cells in several changes of methanol/acetic acid fixative before preparing more slides. We routinely postfix slides in a Coplin jar of fixative, air dry, and then dehydrate through a fresh ethanol series before a final fixation in acetone.

Acknowledgment

My thanks to Dr. Nigel Carter for useful discussions over the manuscript.

Human Genome Project Resources for Breakpoint Mapping

Deborah C. Burford, Susan M. Gribble, and Elena Prigmore

I. INTRODUCTION

The announcement in April 2003 that the Human Genome Project was complete and was available publicly through intuitive genome browsers (e.g., see http://www.ensembl.org/Homo_sapiens/ and http://genome.ucsc.edu/cgi-bin/hgGateway) revolutionised experimental genome analysis. More precisely the study of chromosome rearrangements has been facilitated by the availability of easily accessible, ordered, fully sequenced tiling path clones covering the entire human genome. This resource enables chromosome breakpoints to be mapped more rapidly and with increased confidence.

Conventionally a chromosome rearrangement has been mapped by walking along a chromosome sequentially hybridising fluorescently labelled DNA clones (FISH) until the signal is no longer retained on one derivative chromosome but is seen on the reciprocal derivative chromosome. The genomic position of the breakpoint is then delineated by these two clones and the spanning clone can be found by FISHing clones at a higher resolution (McMullan *et al*., 2002). The genome annotation also now easily available on web browsers (e.g., http://vega.sanger.ac.uk/Homo_sapiens/) provides an additional level of information regarding the gene content of a genomic region of interest. Both known and predicted genes are detailed along with additional information, including repeat content, GC content, mouse homology, and many additional features. This information, together with the identification of breakpoint spanning clones linked directly to these databases, allows candidate genes involved in the phenotype of a patient to be identified readily.

Clones sequenced as part of the Human Genome Project are available readily to international researchers for minimal cost (e.g., BACPAC resources: http://bacpac.chori.org/, Invitrogen: http://clones.invitrogen.com/, and the Resources for Molecular Cytogenetics, University of Bari: http://www.biologia.uniba.it/rmc/). The sequence obtained from these clones is freely accessible (e.g., http://www.ncbi.nlm.nih.gov/genome/clone/, http://www.ensembl.org/Homo_sapiens/, and http://genome.ucsc.edu/cgi-bin/hgGateway).

The availability of such a comprehensive set of clones has not only greatly facilitated conventional approaches to breakpoint mapping studies but has also enabled the development of genome-wide, large insert clone DNA microarrays. The selection, DNA extraction, and labelling of clones for multiple sequential DNA clone *in situ* hybridisation experiments required to map breakpoints are often time-consuming processes. However, the clones can be used as ordered targets themselves for breakpoint mapping after gridded assembly on a DNA microarray (Fiegler *et al*., 2003a). DNA microarrays have been recently developed mostly with the aim of studying genome imbalance in tumour DNA samples (Solinas-Toldo *et al*., 1997). We have exploited this resource to study structural chromosome rearrangements, including rearrangements with no genomic imbalance. This type of analysis, termed array painting (Fiegler *et al*., 2003b), involves isolating derivative chromosomes away from other chromosome homologues by flow sorting (Carter, 1994) or microdissection prior to hybridisation onto the DNA microarrays.

The flow sorting strategy (see Fig. 1) enables large quantities of derivative chromosomes to be isolated before they are fluorescently labelled and hybridised

Copyright 2006, Elsevier Science (USA).
All rights reserved.

onto a target DNA microarray. Alternatively, smaller quantities (~500) of pure derivative chromosomes can be amplified using whole genome amplification. (WGA) procedures, such as DOP-PCR (Telenius *et al*., 1992; Fiegler *et al*., 2003a), Repli-G (Qiagen, 59043), or GenomiPhi (Amersham Biosciences, 25-6600-01) before they are fluorescently labelled and hybridised onto the array. Analysis of this type of hybridisation will then identify the components of each derivative chromosome according to the fluorescence intensities exhibited by the clones on the array (see Fig. 2).

The limit of array painting as a tool for mapping chromosome breakpoints is defined by the resolution of the clones gridded. At present we use a 1-Mb array to define the breakpoints to within a megabase (see Fig. 3) and then use conventional FISH methods (see article by Leversha) to refine the breakpoints and find the spanning clones. Clones that span the breakpoint show intermediate ratios on the array (see Fig. 2).

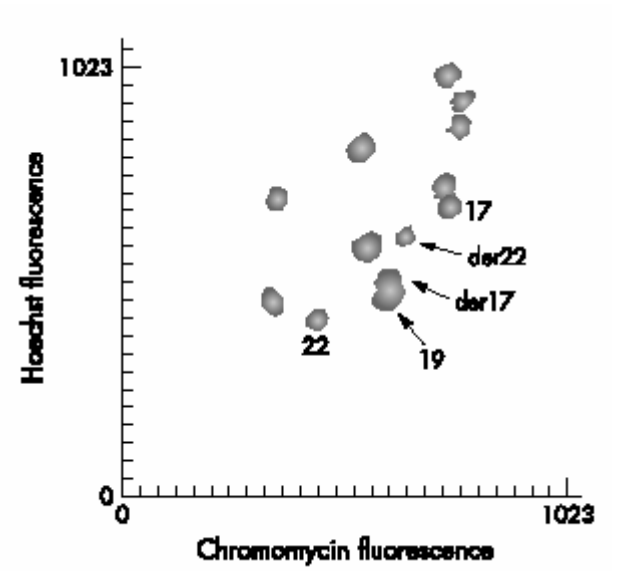

FIGURE 1 Partial flow karyotype of t(17;22)(q21.1;q12.2).

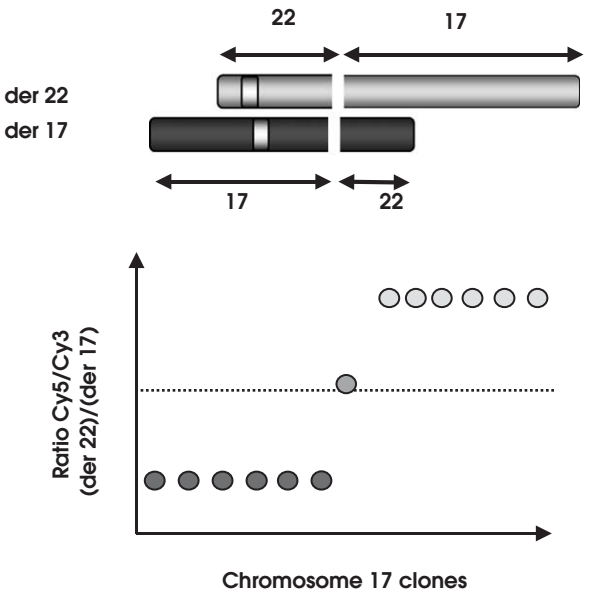

FIGURE 2 Basic principles of mapping translocation breakpoints by array painting.

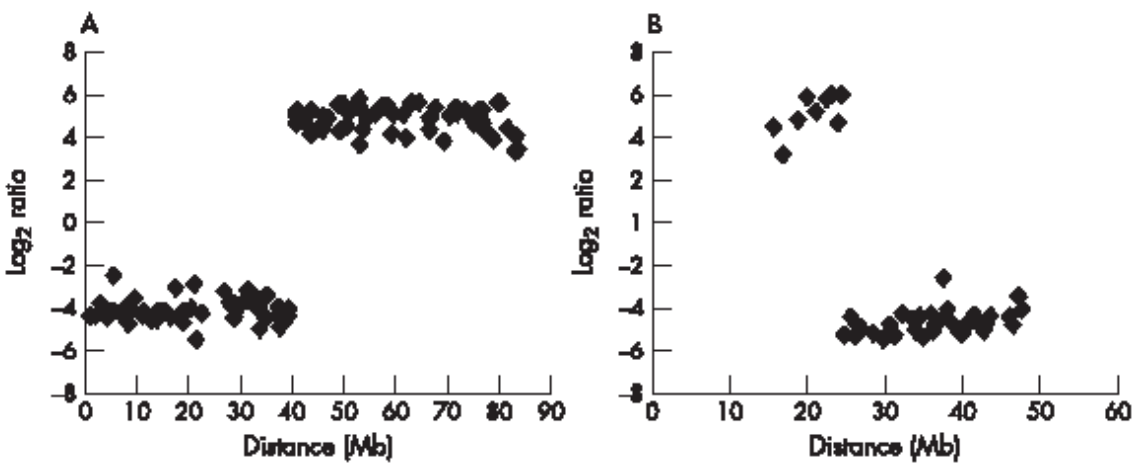

FIGURE 3 Array painting profiles for the derivative chromosomes of t(17;22): (A)1-Mb array chromosome 17 plot and (B)1-Mb array chromosome 22 plot.

Statistically, 1 in every 10 breakpoints will have spanning clones identified directly on the 1-Mb resolution array.

This technique has proven to be invaluable in the detailed study of chromosome rearrangements. When used in conjunction with array CGH, it can give an insight into rearrangements that might have been undetected by G-banding analysis. Increased array resolution, e.g., a tiling path array, in the study of simple chromosome rearrangements would identify spanning clones within a single experiment.

II. MATERIALS AND INSTRUMENTATION

A. Purification of Flow-Sorted DNA

N-Lauroylsarcosine sodium salt (Sigma, L5125)
Proteinase K (Invitrogen, 25530-015)
Phenylmethylsulfonyl fluoride (PMSF) (Sigma, P7626)
Pellet Paint nonfluorescent coprecipitant (Novagen, 70748)

B. Random Labeling of DNA for Array Painting

BioPrime DNA labeling kit (Invitrogen, 18094-011) contains 2.5× random primers solution, sterile water, Klenow fragment, and stop buffer
dNTPs (Amersham Biosciences, 27-2035-02)
Cyanine 3-dCTP (Perkin Elmer, NEL576001EA)
Cyanine 5-dCTP (Perkin Elmer, NEL577001EA)
Microspin G50 columns (Amersham Biosciences, 27-5330-01)

C. Array Hybridization

Herring sperm DNA (Sigma, D7290)
Human Cot-1 DNA (Roche, 1581074)
Deionised formamide for hybridisation buffer (Sigma, F9037)
Dextran sulphate sodium salt (Amersham Biosciences, 17-0340-02)
HPLC water (VWR International, 152736D)
Rubber cement (Weldtite, 02002)
Formamide (Sigma, 47670)
Yeast tRNA (Invitrogen, 15401-029)
Tween 20 (VWR International, 663684B)
Hellendahl jars (RA Lamb, E95)
Glass troughs (RA Lamb, E106 + E98)
Parafilm (Sigma, P7793)
Shake "n" stack hybridisation oven (Thermo Hybaid, HBMOJCT)

III. PROCEDURES

A. Purification of Flow-Sorted DNA

Solutions

1. *0.25 M EDTA/10% sodium lauroyl sarcosine*: For 10 ml, dissolve 1 g *N*-lauroylsarcosine in 5 ml filtered water and add 5 ml 0.5 *M* EDTA (pH 8.0). Store in 1 ml aliquots at 4°C.
2. *Proteinase K*: Resuspend 100 mg in 5 ml sterile water (final concentration of 20 mg/ml). Store 50 µl aliquots at –20°C. Do not freeze thaw.
3. *PMSF*: Resuspend 250 mg in 12.5 ml 96% ethanol (final concentration of 20 mg/ml). Store at 4°C up to a maximum of 6 months.
4. *5 M NaCl*: Dissolve 29.22 g NaCl (MW 58.44) in 100 ml sterile water. Autoclave and store at room temperature.
5. *Pellet Paint*: Store as 20 µl aliquots at –20°C. Avoid repeated freeze thawing. Working tube can be kept at 4°C.
6. *Absolute ethanol*: Store in a sterile 50 ml Falcon tube at –20°C.
7. *70% ethanol*: Store in a sterile 50 ml Falcon tube at –20°C.
8. *Sterile T1.0E (pH 8.0)*: For 100 ml, mix 1 ml 1 *M* Tris–HCl (pH 8.0), 1 ml 0.1 *M* EDTA (pH 8.0), and 98 ml water. Autoclave and store at room temperature.

Steps

Handle tubes containing flow-sorted material very gently!

Flow-sorted chromosomes come in batches of approximately 250,000 per 1.5 ml microfuge tube, sorted into chromosome sheath buffer [10 m*M* Tris–HCl (pH 8.0), 1 m*M* EDTA, 100 m*M* NaCl, 0.5 m*M* Na azide]. Sort 250,000 chromosomes into a volume of approximately 300 µl. Amounts of reagents will vary according to the quantity of sorted sample.

1. Add 30 µl 0.25 *M* EDTA/10% sodium lauroyl sarcosine and 3 µl proteinase K. Incubate overnight at 42°C.
2. Dilute stock PMSF to 4 mg/ml in 96% ethanol. Add 3.33 µl to sorted DNA tubes (40 µg/ml final). Incubate for 40 min at room temperature.
3. Add 13.44 µl 5 *M* NaCl (final 0.3 *M* including sheath buffer), 2 µl Pellet Paint, and 770 µl absolute ethanol. Mix gently by inversion. Precipitate overnight at –20°C or at –70°C for 30 min. (Tubes can be stored at this stage at –20°C if necessary.)
4. Pellet DNA in microfuge at full speed (11,000 *g*) at room temperature for 15 min. The hinge of the Eppendorf tube should face outwards so that the pellet is easily located.

5. Remove most of the supernatant with a P1000. Remove the remainder with P200, avoiding the pellet. Add 1 ml 70% ethanol without disturbing the pellet and then spin again for 7 min. Remove supernatant as before. Allow pellets to air dry (about 20 min).

6. Add 50 µl TE directly to the pellet to resuspend. DNA should separate from the wall of the tube immediately. Mix by *very* gentle flicking. Allow DNA to dissolve for at least 2 h.

B. Random Labeling of DNA for Array Palnting

Solutions

1. *2.5× random primer solution*: Found in BioPrime kit. Store at –20°C and use as supplied.
2. *Sterile water*: Found in BioPrime kit. Store at –20°C and use as supplied.
3. *10× dNTP mix*: To make 1 ml, mix 10 µl dCTP (1 m*M* final), 20 µl dATP (2 m*M* final), 20 µl dGTP (2 m*M* final), and 20 µl dTTP (2 m*M* final) in 930 µl TE buffer. Store 1 ml aliquots at –20°C.
4. *Cy3-dCTP*: Store as stock in the dark at –20°C.
5. *Cy5-dCTP*: Store as stock in the dark at –20°C.
6. *Klenow fragment*: Found in BioPrime kit. Store at –20°F and use as supplied.
7. *Stop buffer*: Found in BioPrime kit. Store at –20°C and use as supplied.

Tubes containing Cy dyes should be kept in the dark!

Steps

1. Labeling Reactions

1. To 50 µl resuspended chromosomes, add 60 µl 2.5× random primers solution and add 20.5 µl sterile water to make up to 130.5 µl.
2. Denature samples in a hot block for 10 min at 100°C and immediately cool on ice.
3. Add the following reagents on ice: 15 µl 10× dNTP mix, 1.5 µl Cy3- or Cy5-labelled dCTP, and 3 µl Klenow fragment. Mix thoroughly but gently.
4. Incubate the reaction at 37°C overnight.
5. Stop the reaction by adding 15 µl stop buffer.

2. Clean-up of Labeling Reactions

Use 3 columns per labelling reaction. Once the columns have been prepared, they must be used immediately to avoid the resin drying out.

Column Preparation

Steps

1. Resuspend the resin in the columns by gentle vortexing.
2. Loosen the cap one quarter turn and snap off the bottom closure.
3. Place the column in a 1.5 ml screw-capped tube.
4. Spin the columns for exactly 1 min at 735 *g*.

Sample Application

Steps

1. Place the columns in a new 1.5 ml tube and slowly apply 55 µl of the labelled sample to the centre of the angled surface of the resin bed, being careful not to disturb it. Do not allow any of the sample to flow around the side of the resin bed.
2. Spin the columns for 2 min at 735 *g*. Collect the purified samples in the support tube.
3. Discard the columns.
4. Combine the three samples.
5. Run 5 µl on a 1% agarose gel to check for correct labelling. Ideally, the fragments should range from 200 to 800 bp in size. Tubes containing the samples should be pink (Cy3) and blue (Cy5) in colour, indicating incorporation of the fluorescent dCTPs.

C. Array Hybridization

Solutions

1. *Human Cot-1 DNA*: Use as supplied (1 µg/ul). Store at –20°C.
2. *3 M NaAc pH 5.2*: For 200 ml, dissolve 49.2 g NaAc (anhydrous) in ~140 ml H_2O, pH to 5.2 with glacial acetic acid, make up to 200 ml, and then autoclave. Store at room temperature.
3. *Absolute ethanol*: Store in a sterile 50 ml Falcon tube at –20°C.
4. *Herring sperm DNA*: Use as supplied (10 mg/ml). Store at –20°C.
5. *40% formamide/2xSSC*: To make up 50 ml, mix 20 ml formamide, 5 ml 20 × SSC, and 25 ml sterile double distilled water (DDW). Store in a 50 ml Falcon at 4°C.
6. *Hybridisation buffer*: For 10 ml, mix 5 ml deionised formamide, 2 ml 50% dextran sulphate, 100 µl Tris, pH 7.4, 10 µl Tween 20, 1 ml 20 × SSC, and 1890 µl HPLC water.
7. *80% ethanol*: Store in a sterile 50 ml Falcon tube at –20°C.
8. *Yeast tRNA*: Make up to a final concentration of 100 µg/µl by dissolving in autoclaved water and store as 50-µl aliquots at –20°C.

9. *20% formamide/2xSSC*: To make up 50 ml, use 10 ml formamide, 5 ml 20 × SSC, and 35 ml DDW. Store in a 50 ml Falcon at 4°C.
10. *PBS/0.05% Tween 20*: Add 500 µl Tween 20 to 1 liter phosphate-buffered saline (PBS).
11. *50% formamide/2xSSC*: For 400 ml, mix 200 ml formamide, 40 ml 20xSSC, and 160 ml HPLC water. Incubate at 42°C prior to use.

1. Precipitation

Steps

1. Prepare 2 × 2 ml Eppendorfs.
2. Heat the herring sperm DNA on a 70°C hot block for 5 min before use.
3. To tube 1 add 180 µl Cy3-labelled DNA, 180 µl Cy5-labelled DNA, 135 µl human Cot-1 DNA, 55 µl 3*M* NaAc, pH 5.2, and 1400 µl 100% ice-cold ethanol.
4. To tube 2 add 80 µl herring sperm DNA, 135 µl human Cot-1 DNA, 23 µl 3*M* NaAc, pH 5.2, and 600 µl ice-cold 100% ethanol.
5. Mix the tubes gently and precipitate in the dark at –20°C overnight or at –70°C for 30 min.

2. Preparation of Slide

Steps

1. Place the slide over a dummy slide identifying the array area and apply a rubber cement ring closely around the grid using a small syringe, taking care not to go over the grid. Avoid thin threads of the cement going onto the array as you pull the syringe tip away.

2. After the first layer has dried, carefully apply a second layer over the first one.

3. Preparation of Humidity Chambers

Steps

1. In a fume hood, prepare a humidity chamber by pipetting a 40% formamide/2xSSC mix onto a Whatman paper strip until the paper is damp.

2. Leave the humidity chamber in the fume hood ready for use.

4. Prehybridization

Steps

1. Preheat the hybridisation buffer in a 70°C hot block.

2. Spin the precipitated DNAs for 15 min at 9500 *g*.

3. Remove the supernatant and add 500 µl 80% ice-cold ethanol.

4. Respin at 9500 *g* for 5 min.

5. Remove the supernatant with a P1000 and then a P200.

6. Respin at 9500 *g* for 1 min.

7. Remove any remaining supernatant with a P10 until the pellet is dry.

8. Resuspend the DNAs in 60 µl hybridisation buffer and 6 µl yeast tRNA (tube 1) and 140 µl hybridisation buffer (tube 2). This is best done by adding the hybridisation buffer and leaving the tube for 2–3 min in a 70°C hot block before resuspending the pellet using a displacement pipette. Ensure that the DNA is properly resuspended before continuing with the experiment. Denature the tube for 10 min at 70°C. Mix the sample after 5 min.

9. Pulse spin the tubes.

10. Place tube 1 into a 37°C hot block and incubate for 60 min in the dark.

11. Apply the contents of tube 2 onto the array grid and rock the slide to ensure even coverage within the well. Remove any air bubbles with a tip, but do not touch the grid. Work quickly to minimise drying of the slide.

12. Transfer the slide into the humidity chamber and place on the rocking table for 60 min shaking at 5 rpm.

5. Hybridization

Steps

1. Pulse spin tube 1.
2. Remove slide from humidity chamber.
3. Apply DNA onto the slide. Remove any air bubbles.
4. Rock the slide to mix the prehybridisation and hybridisation solutions and to ensure even coverage within the well.
5. Place the slide into a slide mailer humidified with 20% formamide/2xSSC.
6. Seal well with Parafilm and place into the hybridisation oven at 37°C.
7. Incubate with gentle rocking (5 rpm) for 48 h, turning the slide by 90° after 24 h.

6. Washing

Steps

1. Remove the slide from the incubator and increase the temperature of the hybridisation oven up to 42°C.
2. Remove the rubber cement.
3. Place the slide into a hellendahl jar containing PBS/0.05% Tween 20 to wash off excess hybridisation solution.
4. Transfer the slide into a glass trough and wash in PBS/0.05% Tween 20 for 10 min shaking at room temperature.
5. Transfer the slide into a preheated trough containing 50% formamide/2x SSC at 42°C. Incubate at 42°C with shaking for 30 min.

6. Transfer the slide into a trough of fresh PBS/0.05% Tween 20 and incubate at room temperature with shaking.
7. Transfer the slide into a metal rack and spin at 150 *g* for 5 min to dry.
8. Store the slide in a light-proof box at room temperature until ready to scan.

7. Scanning and Analysis

Our slides are scanned using an Axon 4000B scanner (Axon Instruments, Burlingame, CA) and the images are analysed by GenePix Pro 3.0 software (Axon Instruments, Burlingame, CA). Spots are defined using the automatic grid feature and adjusted manually where necessary. Fluorescence intensities of all spots are calculated after local background subtraction. The ratios of the intensities are then plotted in log 2 scale against the distance of the clones along the chromosomes from the p termini. Breakpoints are identified by a shift in ratio intensities typically from 4 log 2 to –4 log 2 (or vice versa), with a spanning clone showing an intermediate ratio close to 0 log 2.

IV. PITFALLS

Batches of Cot-1 DNA need to be tested before being used routinely in experiments. At present we order Cot-1 DNA from Roche (1581074) or Invitrogen (15279-011) and perform test hybridisations on the array using tumour cell line DNA with previously determined characteristic genomic copy number changes.

During array hybridisation, care must be taken to prevent the slides from drying out. Just before the hybridisation solution is added to the slide, some of the pre-hyb solution can be removed carefully with a pipette tip. However, this increases the chances of the slide drying out.

All gels used in this article are 1% agarose gels with ethidium bromide. It is advised that these gels are run before progression to the next step to check that each process has been performed successfully.

Fine Mapping of Gene Ordering by Elongated Chromosome Methods

Thomas Haaf

I. INTRODUCTION

Fluorescence *in situ* hybridization (FISH) can be used to localize specific DNA sequences on metaphase chromosomes, interphase nuclei, and experimentally extended DNA or chromatin fibers. Depending on the hybridization target, FISH techniques show widely different levels of DNA resolution (Table I). They provide a rapid and accurate alternative to traditional molecular approaches for long-range physical mapping, including pulsed-field gel electrophoresis and radiation hybrid mapping. One important application has been the visual construction of contig maps of regions of interest, such as disease gene loci or chromosome breakpoints. Differential fluorescent probe labeling allows the ordering of multiple DNA sequences on the same chromosome. The DNA resolution of standard metaphase FISH is in the 1- to 3-Mb size range. Hybridization on less condensed interphase nuclei increases the resolution to around 100 kb. The average distance between two probe signals in the three-dimensional nuclear space correlates with physical distance up to 1–2 Mb. This allows one to determine the relative order and proximity of closely juxtaposed sequences, which cannot be resolved on metaphase chromosomes (Trask *et al*., 1989). Protocols for stretching out DNA in solution (Bensimon *et al*., 1994) or the chromatin of interphase nuclei (Parra and Windle, 1993; Haaf and Ward, 1994b; Heiskanen *et al*., 1994) have pushed the limits of resolution even further. Hybridization to experimentally extended DNA or chromatin fibers provides a mapping power in the order of 1–10 kb. The maximum distance possible for clone ordering may be up to several megabases; however, the average size of intact fibers is considerably smaller. Most fiber FISH techniques are informative over genomic distances from 100 to 500 kb.

Mechanically stretched or elongated chromosomes fill the resolution gap between metaphase FISH and fiber FISH, allowing the rapid and straightforward ordering and localization of clones along the length of an entire chromosome with a 100- to 200-kb resolution. Elongated chromosomes for high-resolution FISH are prepared by centrifuging colcemid-arrested metaphase spreads in hypotonic solution to microscope glass slides. The mechanical forces generated during cytocentrifugation result in mechanical stretching of chromosomes to 5 to 20 times their normal length due to their elastic consistency under moist conditions (Haaf and Ward, 1994a,b). Elongated chromosome FISH can be applied to large numbers of probes and provides a more than 10-fold increase in DNA resolution compared to standard metaphase mapping. This makes it possible to create 100-kb physical maps of a chromosome(s) or chromosome region(s) of interest in relatively short time (Laan *et al*., 1995, 1996).

Although various genome projects have provided very high-resolution physical maps of human and important animal genomes, FISH is still an exceptionally versatile mapping tool. For example, working with duplicated or repetitive sequences at the molecular level can be extremely tedious and, therefore, accurate mapping and sequencing of these regions remain tremendous tasks in the postgenomic era. In addition, FISH has important applications for mapping chromosome regions that have been deleted, amplified, and/or rearranged in human pathology or evolution. Of course, FISH techniques are useful not only for mapping the human genome. They can be

TABLE I DNA Targets and Resolution of Standard FISH Mapping Techniques

Target	DNA resolution	Upper limit of utility range	Major advantages/ disadvantages
Metaphase chromosome	1–3 Mb	Chromosome	Whole genome screening Chromosome banding Multicolor approaches (>3 colors)
Interphase nucleus	50–100 kb	1–2 Mb	Relatively simple and fast No chromosome identification No centromere–telomere orientation Statistical analysis required
Extended chromosomes	100–200 kb	Chromosome	Centromere–telomere orientation Nonuniform chromosome stretching Cytocentrifuge required
Chromatin/ DNA fibers	1–10 kb	500 kb–1 Mb	Many different, but usually relatively simple protocols for fiber preparation Nonuniform DNA/chromatin stretching Interpretation of hybridization signals often difficult
Molecular combing	1–10 kb	500 kb–1 Mb	DNA molecules aligned in a single direction and stretched homogeneously DNA combing apparatus and silanized coverslips required; technique is relatively complicated No simultaneous DNA–protein detection

adapted easily for the study of map-poor genomes from primitive vertebrates to humans.

II. MATERIALS AND INSTRUMENTATION

All reagents for elongated chromosome preparation are standard laboratory chemicals that can be obtained from many different suppliers, i.e., NaCl (Sigma-Aldrich, Cat.No. S7653), KCl (Sigma-Aldrich, Cat.No. P5405), Na_2HPO_4 (Sigma-Aldrich, Cat.No. S9638), KH_2HPO_4 (Sigma-Aldrich, Cat.No. P5655), HEPES dry powder (Sigma-Aldrich, Cat.No. H9897), glycerol 99.5% ACS reagent (Sigma-Aldrich, Cat.No. G7893), $CaCl_2{\cdot}2H_2O$ (Sigma-Aldrich, Cat.No. C3881), $MgCl_2{\cdot}6H_2O$ (Sigma-Aldrich, Cat.No. M0250), acetic acid (VWR, Cat.No. 1.00058.1000), methanol (VWR, Cat.No. 1.06008.1000), acetone (VWR, Cat.No. 1.59005.0500), Biocoll (Ficoll) separating solution (Biochrom, Cat.No 2 6115), and colcemid (Roche, Cat.No. 295892).

The cytocentrifuge (Cytospin 3) and the filter blots are from Thermo Shandon Inc.

III. PROCEDURES

A. Preparation of Elongated Chromosomes for FISH Mapping

The following protocol describes the preparation of elongated chromosomes from human lymphoblastoid or fibroblast cells (Haaf and Ward, 1994a,b). This technique can be adapted for other cell substrates, producing suitable targets for high-resolution FISH mapping.

Solutions

1. *Phosphate-buffered saline (PBS)*: 136 m*M* NaCl, 2 m*M* KCl, 10.6 m*M* Na_2HPO_4, and 1.5 m*M* KH_2PO_4, pH 7.3. To make 10× PBS stock solution, weigh 79.5 g NaCl, 1.5 g KCl, 15 g Na_2HPO_4, and 2 g KH_2PO_4. After dissolving in distilled water, complete to 1000 ml, pH, and autoclave. Store at room temperature. To make 1× PBS, dilute stock solution 1 : 10 with distilled water and use within 1 day.

2. *Hypotonic solution (for cell swelling)*: 10 m*M* HEPES, 30 m*M* glycerol, 1 m*M* $CaCl_2$, and 0.8 m*M* $MgCl_2$. To make 1000 ml, add 2.4 g HEPES, 2.2 ml anhydrous glycerol, 147 mg $CaCl_2{\cdot}2H_2O$, and 163 mg $MgCl_2{\cdot}6H_2O$. After dissolving, complete to 1000 ml with distilled water, pH, and filter if necessary. Store at 4°C and use within 1 week.

3. *Carnoy's fixative*: Mix one part acetic acid and three parts methanol. Store at –20°C and use within 1 day.

Steps

1. After harvesting a mitotically dividing cell culture(s), wash the cells one time in 1× PBS and resuspend the cell pellet in hypotonic solution to a concentration of 10^3 to 10^4 cells/ml. Incubate the cells at ambient temperature for 5–10 min.

2. Centrifuge 0.5-ml aliquots of this hypotonic cell suspension onto microscope slides at 1000 rpm for 4 min using a Shandon cytospin. Specifically, place the cell suspension in the cytobuckets of the centrifuge, the bases of which are formed by a filter blot and a glass slide (cleaned with ethanol). The whole structure is held together by a clip. During centrifugation the suspension fluid is absorbed by the filter blot and the cells become attached to the glass slide. After cytocentrifugation, the slide should carry a visible monolayer of cells in a designated area about 5 mm in diameter. Use a diamond pencil to mark the back of the slide to indicate the area on which the cells are sedimented.

3. Fix the slides for 30 min at –20°C in methanol and then overnight at –20°C in Carnoy's fixative. Air-dried slides stored at 4°C can be kept for months before use.

4. Select slides suitable for FISH mapping using a phase-contrast microscope at low magnification (10 to 20× lens without oil). A higher density of cells per slide results in poor chromosome stretching and cytoplasmic background ("dirt"). A lower density of cells results in disruption of metaphase spreads and individual chromosomes. Chromosomes extended to 5 to 20 times their normal length but still intact are most useful for high-resolution chromosome mapping. Good slides should contain 3–10 metaphase spreads with stretched chromosomes without broken arms. If less than half of the slides obtained after cytocentrifugation meet these criteria, the cell density in the hypotonic solution was either too high or too low.

5. Standard FISH protocols are used for mapping cloned DNA sequences such as cosmids, BACs, or YACs to acid-fixed elongated chromosomes (Haaf, 2000). Usually one probe is detected with a green fluorescent dye, a second probe with a red dye, and the chromosomes are counterstained in blue with DAPI (Figs. 1A and 1B). However, using modern FISH workstations for M-FISH or spectral karyotype analysis (SKY), many more DNA targets can be distinguished in different colors.

6. Determine the relative order of two hybridized clones that are <1 Mb apart on at least five elongated chromosomes. Because mechanically stretched chromosomes can be highly deformed, not all hybridized chromosome copies may be informative. If the order is not consistent on all five chromosomes, analyze five additional chromosome copies. In most cases, one slide should be sufficient for ordering probes that are 100–200 kb apart.

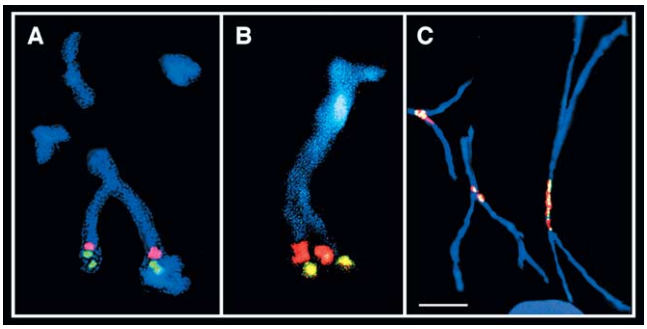

FIGURE 1 (A and B) Two-color FISH with two closely juxtaposed (<1 Mb) YACs from the 5q34-q35 region to chromosomes mechanically stretched to 5–10 times their normal length. (C) Colocalization of centromeric proteins (green) and α-satellite DNA (red) on chromosomes stretched to 10–20 times their normal length. Centromeric proteins were detected by indirect immunofluorescence staining with CREST antiserum and FITC-labeled antihuman IgG. α-satellite DNA was hybridized *in situ* with a digoxigenated human α-satellite cocktail probe and detected with rhodamine-conjugated antidigoxin antibody. Bar: 10 μm.

B. Preparation of Elongated Chromosomes for Combined Protein Immunofluorescence and FISH

The combined application of protein staining by immunofluorescent techniques and DNA staining by FISH provides a powerful tool for mapping chromosomal proteins to specific DNA sequences.

Steps

1. Harvest mitotic cells and centrifuge them onto slides as described earlier.

2. Fix the slides in methanol at –20°C for 30 min and then immerse in ice-cold acetone for a few seconds. After brief air drying, process the preparations for immunofluorescence staining. Because most protein antigens are not very stable, it is not recommened to store the slides before use.

3. Perform immunofluorescent staining of a protein of interest, i.e., as an example only, labeling of centromeric proteins (CENPs) by specific anti-CENP antibodies (Fig. 1C). Standard immunofluorescent protocols are used for incubation of the slides with primary and fluorescent-labeled secondary antibodies (Haaf, 1995). However, do not counterstain the preparations with DAPI.

4. Immediately after immunofluorescent staining, refix the preparations by incubating them in Carnoy's fixative overnight at –20°C and then hybridize them with a DNA probe(s) of interest.

IV. COMMENTS AND PITFALLS

1. The most suitable source of mitotic cells are long-term *in vitro* cell cultures such as EBV-transformed lymphoblasts, fibroblasts, or established cell lines. Usually, 10 µg/ml colcemid (Roche) is added to the culture medium 10–15 min before cell harvest to arrest cells in metaphase. Whole blood cultures cannot be used as a cell substrate because the erythrocytes are not destroyed by the hypotonic treatment required for elongated chromosome preparation. Therefore, it is necessary to separate white blood cells from red cells by density gradient centrifugation (in Biocoll/Ficoll separating solution) prior to short-term lymphocyte culturing.

2. Elongated chromosomes constitute a compromise between different demands. The mechanical stretching procedure inevitably impairs chromosome morphology. The chromosomes are deformed and cannot be banded; however, they provide a greater DNA resolution and allow the ordering of probes from the short-arm to the long-arm telomere. Usually, better chromosome morphology goes along with poor stretching and vice versa.

3. Chromosome elongation is not uniform over the entire length of a stretched chromosome and the same metaphase spread may contain both well-extended and poorly stretched chromosomes. Therefore it is very difficult to correlate the micrometer distance between two mapped loci or the relative distance from the short arm telomere (Flpter value) with physical distance in kilobases. Some regions, i.e., telomeres, which are usually attached to the surface of the glass slide, are more resistant to stretching than others.

4. Carnoy's fixation of immunofluorescent preparations and subsequent FISH do not grossly interfere with the fluorecent-labeled protein antigen–DNA complex. Although the intensity of the fluorescent protein signal is reduced to a certain extent, it is still visible after the relatively harsh *in situ* hybridization procedure. This allows one to analyze the results of protein immunofluorescence and DNA *in situ* hybridization simultaneously on the same elongated chromosomes.

In Situ Hybridization Applicable to mRNA Species in Cultured Cells

Roeland W. Dirks

I. INTRODUCTION

RNA *in situ* hybridization (ISH) techniques allow the study of gene expression at the individual cell level in a histocytomorphological context. These techniques often involved the use of radioactive-labeled probes. However, because of resolution drawbacks limiting their applicability in the study of RNA distribution at (sub)cellular sites, these probes are replaced more frequently by hapten- or fluorophore-labeled ones. Nevertheless, radioactive ISH is still useful for detecting relatively low abundant RNA transcripts in tissue sections.

From the early 1980s, several nonisotopic-labeling methods have been developed that are most often based on the introduction of haptens (e.g., biotin and digoxigenin) or fluorochromes (e.g., fluorescein, rhodamine, coumarin, Cy3, and Cy5) that are conjugated to allyl or alkylamine-dUTP in DNA or RNA probes. Such probes provide a high spatial resolution and allow simultaneous detection of multiple RNA sequences (Dirks *et al*., 1991; Levsky *et al*., 2002) or RNA sequences together with proteins (Dirks, 1998; Snaar *et al*., 1999).

Direct ISH techniques, using fluorochrome-labeled probes, are used to detect relatively abundant mRNA species by conventional fluorescence microscopy. Using more advanced digital imaging microscopy, visualization of single RNA transcripts proved even possible when oligodeoxynucleotide probes were labeled with five fluorochromes per molecule and 10 oligonucleotide probes were hybridized to adjacent sequences on an RNA target (Femino *et al*., 1998).

Indirect ISH techniques, using haptenized probes, are often the method of choice because of their better sensitivity compared to direct fluorescence ISH approaches (Dirks *et al*., 1993). Furthermore, enhancement of ISH signals can be accomplished by applying multiple antibody layers or by the use of a tyramide-based detection method (Adams, 1992; Raap *et al*., 1995; van de Corput *et al*., 1998). Tyramide-based detection methods involve the use of an antihapten peroxidase-labeled antibody as a first antibody layer and a biotin, DNP, or fluorochrome tyramide that serves as a peroxidase substrate to generate and deposit many reporter molecules close to the hybridization site.

This article describes a protocol that allows sensitive detection of RNAs at cytoplasmic as well as at nuclear sites of cells that are grown or attached to microscopic slides.

II. MATERIALS AND INSTRUMENTATION

Dulbecco's modified Eagle medium without phenol red (DMEM, Cat. No. 1188-36), fetal bovine serum (FBS, Cat. No. 1050-64), l-glutamine (Cat. No. 2503-24), penicillin–streptomycin (Cat. No. 1514-22), and trypsin (Cat. No. 2509-28) are from Invitrogen Life Technologies. Salmon testes DNA (Cat. No. D-7656), dithiothreitol (DTT, Cat. No. D-0632), thimerosal (Cat. No. T-5125), polyvinylpyrrolidone (PVP, Cat. No. PVP-40), Tween 20 (Cat. No. P-1379), mouse monoclonal antidigoxin (Cat. No. D-8156), rabbit antimouse fluorescein isothiocyanate (FITC) (Cat. No. F-7506), Streptavidin-FITC (Cat. No. S-3762), and goat antirabbit FITC (Cat. No. F-9262) are from Sigma. Ficoll PM 400 (Cat. No. 1-30-0) is from Amersham Biosciences.

Bovine serum albumin fraction V (BSA, Cat. No. 44155) is from BDH. Formamide (Cat. No. 7042) and acetic acid (Cat. No. 6052) are from J. T. Baker. Amberlite MB1 ion exchanger (Cat. No. 40701) and 4,6,-diamidino-2-phenylindol 2HCl (DAPI, Cat. No. 18860) are from Serva. Acid-free formaldehyde (Cat. No. 3999) is from Merck. dATP (Cat. No. 1051 440), dCTP (Cat. No. 1051 458), dGTP (Cat. No. 1051 466), dTTP (Cat. No. 1051 482), DNase I (Cat. No. 104 158), digoxigenin-11-dUTP (Cat. No. 1093 088), sheep antidigoxigenin HRP (Cat. No. 1207 733), and blocking reagent (Cat. No. 1096 176) are from Roche. DNA polymerase I (Cat. No. M2051) is from Promega. Vectashield mounting medium is from Vector. Staining jars (100 ml) for object slides (Cat. No. L4110) are from Agar Aids Ltd. TSA fluorescein system (Cat. No. NEL701), TSA tetramethylrhodamine NEL702), TSA coumarin system (Cat. No. NEL703), and TSA biotin system (Cat. No. NEL700) are from NEN.

Fluorescence ISH results were examined with an epifluorescence microscope (DM, Leica) equipped with a 100-W mercury arc lamp and a triple excitation filter for red, green, and blue excitation (Omega). Digital images were captured with a cooled CCD camera (Photometrics).

III. PROCEDURES

A. Labeling of DNA by Nick Translation

Solutions

1. *Nick translation buffer (10x)*: 0.5 *M* Tris–HCl, pH 7.8, 50 m*M* $MgCl_2$, and 0.5 mg/ml BSA. To make 10 ml of the solution, add 5 ml of an autoclaved 1 *M* stock solution of Tris–HCl, pH 7.8, 0.5 ml of an autoclaved 1 *M* solution $MgCl_2$, and 5 mg of nuclease-free BSA and complete to 10 ml with autoclaved distilled water. Aliquot in 100-µl portions and store at –20°C.

2. *0.1 M DTT*: To make 10 ml, dissolve 150 mg of DTT in 10 ml of 0.01 *M* sodium acetate (pH 5.2). Filter the solution through a 0.2-µm filter, aliquot in 1-ml portions, and store at –20°C.

3. *Nucleotide mix*: 0.5 m*M* dATP, 0.5 m*M* dCTP, 0.5 m*M* dGTP, and 0.1 m*M* dTTP. To make 1 ml of the solution, add 5 µl each of 100 m*M* stock solutions dATP, dCTP, and dGTP and 1 µl of 100 m*M* stock solution dTTP. Complete to 1 ml with autoclaved distilled water and store at –20°C.

4. *1 mg/ml DNase I*: To make 1 ml, add 1 mg of DNase, 20 µl of a 1 *M* stock solution of Tris–HCl, pH 7.6, 50 µl of a stock solution of NaCl, 10 µl of a 100 m*M* stock solution of DTT, 0.1 mg of BSA, and 0.5 ml of glycerol. Complete to 1 ml with autoclaved distilled water and store at –20°C.

5. *10 mg/ml salmon testes DNA*: To make 10 ml, dissolve 100 mg DNA in 100 ml 0.3 *M* NaOH in TE, pH 7.8 (10 m*M* Tris–HCl, pH 7.8, 1 m*M* EDTA). Boil for 20 min at 100°C. Neutralize the solution by adding 5 ml of 2 *M* Tris–HCl, pH 7.5, 7.5 ml of 4 *M* HCl, and 12 ml of 2 *M* sodium acetate. Precipitate the DNA by adding 2 volumes of 100% –20°C ethanol and incubate for 1 h on ice. Centrifuge for 10 min at 2600 *g*, remove the ethanol, and dissolve the DNA pellet in 10 ml TE buffer.

6. *Deionized formamide*: To make 100 ml, add 5 g of ion exchanger to 100 ml formamide. Stir for 2 h and filter twice through Whatmann No. 1 filter paper. Aliquot in 1-ml portions and store at –20°C.

7. *20x SSC*: To make 1 liter, add 175.3 g NaCl and 88.24 g sodium citrate to distilled water. Adjust to pH 7.0 and complete to 1 liter. Autoclave the solution and store at room temperature.

8. *50X Denhardt's solution*: 1% PVP, 1% Ficoll (type 400), and 1% BSA. To make 500 ml of the solution, add 5 g Ficoll, 5 g PVP, 5 g BSA (fraction V), and distilled water to 500 ml. Sterilize the solution by filtration and store at –20°C.

Steps

1. Thaw the required stock solutions and keep them on ice. Prepare the labeling solution on ice and mix well. To make the labeling mixture, combine 26 µl autoclaved distilled water, 5 µl 10x nick translation buffer, 5 µl 100 m*M* DTT, 4 µl nucleotide mix, 2 µl digoxigenin-11-dUTP (0.25 m*M* stock solution), 1 µl probe DNA (1 µg, e.g., cDNA), 2 µl DNA polymerase I, and 5 µl of a 1 : 1000 DNase I dilution from a 1-mg/ml stock solution.

2. Place the labeling mixture for 2 h in a 16°C water bath.

3. Add 250 µl distilled water and precipitate the labeled probe by adding 30 µl of 3 *M* sodium acetate, pH 4.8, 5 µl salmon testes DNA, and 750 µl –20°C 100% ethanol. Mix well and place the solution on ice for 30 min.

4. Centrifuge for 30 min at 4°C in an Eppendorf centrifuge at maximum speed. Remove the ethanol completely and resuspend the pellet in 200 µl hybridization mixture to reach a probe concentration of 5 ng/µl. To make 10 ml hybridization mixture, combine 5 ml deionized formamide, 1 ml 20X SSC, 1 ml of 0.5 *M* sodium phosphate buffer, pH 7.0, 1 ml 50x Denhardt's solution, and 2 ml autoclaved distilled water. The probe mixture can be stored at 4°C for at least 1 year.

B. Culturing and Fixation of Cells

Solution

10x PBS (pH 7.2): Add 80 g NaCl, 2 g KCl, 15 g $Na_2HPO_4.2H_2O$, and 1.2 g KH_2PO_4 and adjust to 1 liter. Autoclave the solution and store at room temperature.

Steps

1. Trypsinize subconfluent cells that are grown in tissue culture flasks as a monolayer in DMEM supplemented with 10% FCS, 100 U of penicillin/ml, and 100 µg of streptomycin/ml and seed into petri dishes containing five microscopic object slides and 20 ml medium. Grow cells to subconfluency at 37°C in a humidified 5% CO_2 atmosphere.
2. Wash the object slides containing cells in PBS for 1 min at room temperature.
3. Fix the cells in PBS containing 3.7% formaldehyde, 5% acetic acid for 20 min at room temperature. To make 100 ml fixative, combine 75 ml distilled water, 10 ml 10x PBS, 10 ml formaldehyde (37% stock), and 5 ml acetic acid.
4. Wash the cells in PBS for 5 min at room temperature and transfer the object slides to a 100-ml staining jar.
5. Wash the cells in 70% ethanol and store the object slides in 70% ethanol at 4°C until use.

C. Pretreatment and Hybridization

Solution

0.1% pepsin: To make 100 ml, dissolve 0.1 g pepsin in distilled water, adjust pH to 2.0, and bring to 100 ml. Make this solution about 15 min before use and place in a 37°C water bath.

Steps

1. Wash the cells in PBS for 3 min at room temperature.
2. Incubate the cells in 0.1% pepsin solution for 2 min at 37°C.
3. Wash the cells in 70% ethanol for 30 s.
4. Wash twice in PBS for 30 s each.
5. Incubate in 1% formaldehyde in PBS for 5 min at room temperature.
6. Wash in PBS for 5 min and dehydrate the cells successively in 70, 90, and 100% ethanol for 3 min each.
7. Denature the probe dissolved in hybridization mixture for 5 min in an 80°C water bath.
8. Place the probe for 1 min on ice and spin down in a table centrifuge.
9. Apply 10 µl of the denatured probe mixture on the object slide and hybridize overnight at 37°C in a moist chamber, which consists of a 1-liter beaker covered with aluminium foil containing tissues moistened with 50% formamide/2x SSC, pH 7.0.

D. Posthybridization Washes

Solutions

1. *50% formamide/2x SSC wash solution*: To make 400 ml, add 200 ml formamide, 40 ml 20x SSC, and 160 ml distilled water and adjust the pH to 7.0.
2. *10x TBS*: To make 1 liter, dissolve 121.4 g Tris and 87.4 g NaCl in 800 ml distilled water. Adjust the pH to 7.4 with 6 *N* HCl and bring to a total volume of 1 liter.

Steps

1. Wash the slides in the 50% formamide/2x SSC solution at room temperature until the coverslips are released.
2. Transfer the slides to a new jar filled with 100 ml 50% formamide/2x SCC and wash for 10 min.
3. Wash the slides for 10 min each in 50% formamide/2x SSC at 42°C and in the same solution at room temperature.
4. Wash the slides in 2x SSC for 5 min at room temperature.
5. Wash the slides in 1x TBS for 5 min at room temperature.

E. Conventional Immunocytochemical Detection

Solution

Blocking solution: To make 100 ml, add 0.5 g blocking reagent and 100 µl thimerosal (to prevent bacterial growth). Complete to 100 ml with 1x TBS. Heat the mixture for 1 h at 60°C to dissolve the blocking reagent and aliquot in 10-ml portions. Store at –20°C.

Steps

1. Take a slide from the TBS solution and apply 100 µl blocking solution. Cover it with a 24 × 50-mm^2 coverslip and incubate for 30 min at 37°C in a moist chamber (1-liter beaker covered with aluminium foil containing tissue moistened with water).
2. Wash briefly with TBS to remove the coverslips.
3. Drain of as much of the TBS solution as possible and incubate the slides with mouse antidigoxigenin, diluted 1:500 in blocking solution under a coverslip for 45 min at 37°C in a moist chamber.
4. Remove the coverslips by a brief wash in TBS and wash the slides 3 × 5 min with TBS at room temperature.

5. Drain of as much of the washing solution as possible and incubate the slides with rabbit anti-mouse FITC diluted 1:500 in blocking solution as described in step 3.
6. Wash the slides as described in step 4.
7. Drain of as much of the washing solution as possible and incubate the slides with goat anti-rabbit FITC, diluted 1:500 in blocking solution, as described in step 3.
8. Wash the slides as described in step 4.
9. Dehydrate the slides for 3 min each in 70, 90, and 100% ethanol and air dry.
10. Apply 30 µl Vectashield containing 10 ng/µl DAPI (blue fluorescent DNA counterstain) on a slide and cover with a 24 × 50-mm^2 coverslip.
11. Examine the slides with a fluorescence microscope equipped with appropriate excitation and emission filters for FITC and DAPI fluorescence.

F. Tyramide Signal Amplification

Solution

10x TNT: To make 1 liter, dissolve 121.4 g Tris and 87.4 g NaCl in 800 ml distilled water. Ad 0.5 ml Tween 20. Mix thoroughly, adjust the pH to 7.4, and bring to a total volume of 1 liter.

Steps

1. Take slides from the TBS solution and apply 100 µl blocking solution. Cover with a coverslip and incubate for 30 min at 37°C in a moist chamber.
2. Wash briefly with TBS to remove coverslips.
3. Drain of as much of the washing solution as possible and incubate the slides with antidigoxigenin-HRP, diluted 1:500 in blocking solution, under a coverslip for 45 min at 37°C in a moist chamber.
4. Remove the coverslips by a brief wash in TNT and wash the slides 3 × 5 min with TNT at room temperature.
5. Drain of as much of the TNT solution as possible and apply 300 µl of a 1:50 dilution of a fluorescent (red, green, or blue) or biotin tyramide in 1x amplification diluent on each slide. Incubate the slides for approximately 10–30 min at room temperature without a coverslip.
6. Wash the slides 3 × 5 min with TNT at room temperature.
7. For detection of biotin tyramide, incubate the slides with steptavidin FITC diluted 1:1000 in blocking solution as described in step 3.
8. Wash the slides as described in step 4.
9. Dehydrate the slides in ethanol, air dry, and mount in Vectashield.

IV. COMMENTS

The protocol just described allows sensitive detection of specific mRNAs in a variety of cell types, including cultured cells, trypanosomes (Chaves *et al*., 1998), malaria parasites (Vervenne *et al*., 1994), and blood cells. The various steps in this protocol have been optimized for detecting RNA molecules in cultured mammalian cells by trial and error (Dirks *et al*., 1993) and may need some adjustments for specific applications. For example, if RNA FISH is applied at the electron microscopic level of resolution, sample preparation, fixation, and pretreatment conditions need to be adjusted (Macville *et al*., 1995,1996).

Compared to conventional immunocytochemical detection systems, the use of tyramide-based detection systems results in an at least a 10-fold increase in signal intensity (Raap *et al*., 1995). This is illustrated in Fig. 1, showing hybridization signals of human elongation factor (HEF) mRNA in HeLa cells and of IL-6 and G-CSF mRNA in human bladder carcinoma cells grown on microscope slides. If required, the localization properties of tyramides can be improved by the addition of dextran sulfate to the amplification diluent (Van Gijlswijk *et al*., 1996).

This hybridization protocol also allows bright-field microscopic visualization of hybridization signals when conjugates with peroxidase or alkaline phos-

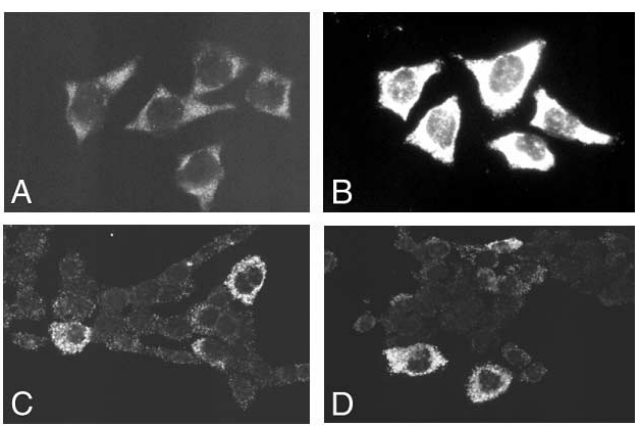

FIGURE 1 (**A**) Detection of HEF mRNA in HeLa cells using a digoxigenin-labeled DNA plasmid probe. The hybridized probe was visualized using a fluorescein-conjugated secondary antibody. (**B**) A hybridized HEF probe was visualized using a peroxidase-labeled antidigoxigenin antibody and fluorescein-tyramide. (**C**) Detection of IL-6 mRNA in 5637 bladder carcinoma cells using a cocktail of three HRP-labeled oligodeoxynucleotides and the TSA biotin system. (**D**) Detection of G-CSF mRNA in 5637 cells using a cocktail of three HRP-labeled oligodeoxynucleotides and the TSA biotin system (for details, see van de Corput *et al*., 1998).

phatase are used instead of fluorochrome antibody conjugates (Dirks *et al*., 1993).

As a positive control on the procedure, probes specific for housekeeping gene transcripts, like human elengation factor and actin mRNA, or for rRNA, such as 28S rRNA, can be used.

Finally, in order to study dynamic aspects of RNA localization, methods have been developed that allow hybridization of probes to RNAs and its subsequent visualization in living cells (Molenaar *et al*., 2001; Pederson, 2001).

V. PITFALLS

1. Probe labeling can be checked by performing a filter spot test. Spot 1 µl of a dilution series of the labeled probe on a nitrocellulose filter and incubate with sheep antidigoxigenin-alkaline phosphatase. After performing the NBT/BCIP reaction, a probe concentration of 5 to 1 pg/µl should be visible.

2. We noticed that it is important to use for the fixation of cells a good source of formaldehyde. Formaldehyde solutions of poor quality may lead to poor cell morphology, high levels of autofluorescence, or weak hybridization signals.

3. It is important to titrate the pepsin concentration and/or time of incubation in order to find a balance between morphology and signal intensity.

4. For optimal results it is sometimes necessary to denature the target mRNA. This is done just before hybridization, after applying the probe solution and coverslip on the slide, by placing the slide on an 80°C hot plate for 2 to 3 min.

5. The dilution and reaction time of labeled tyramides need to be optimized for each application. To diminish nonspecific background staining, the first antibody may be diluted further.

In Situ Hybridization for Simultaneous Detection of DNA, RNA, and Protein

Noélia Custódio, Célia Carvalho, T. Carneiro, and Maria Carmo-Fonseca

I. INTRODUCTION

Fluorescence *in situ* hybridisation enables the detection of RNA and DNA in the cellular context, therefore allowing the study of gene expression at the single cell level. *In situ* hybridisation was described for the first time in 1969 in two independent studies (Gall and Pardue; 1969; John *et al*., 1969) that used radiolalelled probes and autoradiographic methods to detect abundant sequences. During the early eighties, nonisotopic probe-labelling methods were developed based on the introduction of haptens (such as biotin and digoxigenin) and fluorochrome-conjugated antibodies (for review, see Schwarzacher and Heslop-Harrison, 2000). The use of different probe labels and detection systems with multiple fluorochromes made possible the simultaneous detection of several target sequences in the same cell, including the detection of a specific gene and the corresponding pre-mRNA and/or mRNA (Custódio *et al*., 1999; Johnson *et al*., 2000; Xing *et al*., 1993, 1995). A combination of fluorescence *in situ* hybridisation with immunofluorescence further allows the simultaneous visualisation of genes, transcripts, and proteins.

A major problem when conjugating protocols to simultaneously detect DNA, RNA, and proteins is to achieve good preservation of the different targets throughout the procedure and, at the same time, make them accessible for the probes. This article describes protocols that have been optimised over the years for the simultaneous detection of DNA, RNA transcripts, and proteins involved in RNA metabolism in the nucleus of mammalian cultured cell lines.

II. MATERIALS AND INSTRUMENTATION

35 × 10-mm (P35) tissue culture dishes (Sarstedt, Cat. No. 83.1800)
10 × 10-mm glass coverslips
Tweezers (style #7, sharp, hooked, Sigma, Cat. No. T 4912)
Water bath (variable temperature)
Heat block
Incubator at 37°C
Moist chamber (plastic box with lid containing some wet tissues inside)
Vacuum pump
Milli-Q ultrapure or bidistilled water
dNTPset, 100 m*M* each dNTP (Qbiogene, Cat. No. NTACG100)
Digoxigenin-11-dUTP, alkali stable (Roche, Cat. No. 1093088)
Dinitrophenyl(DNP)-11-dUTP (Molecular Probes, Cat. No. C-7610)
Alexa Fluor 488-5-dUTP (Molecular Probes, Cat. No. C-11397)
Fluorescein-12-dUTP (Roche, Cat. No. 137 3242)
BIOTAQ DNA polymerase (BIOLINE, Cat. No. BIO-21040)
Oligonucleotide probes with amino-modified bases (MWG Biotech)
Cy3 monoreactive dye (Amersham Biosciences, Cat. No. PA23001)
Cy5 monoreactive dye (Amersham Biosciences, Cat. No. PA2500)
Alexa Fluor 488 oligonucleotide amine-labelling kit (Molecular Probes, Cat. No. A-20191)

Formamide p.a. (Merck, Cat. No. 1.09684)
Fluorescein-conjugated sheep antidigoxigenin (Roche, Cat. No. 1 333 062)
Alexa Fluor 488-conjugated goat antifluorescein (Molecular Probes, Cat. No. A-11090)
Cy3-conjugated mouse antidigoxin (Jackson ImmunoReseach Labs, Inc., Cat. No. 200-162-156)
Cy5-conjugated mouse antidigoxin (Jackson ImmunoReseach Labs, Inc., Cat. No. 200-172-156)
FITC-conjugated rabbit anti-DNP (Molecular Probes, Cat. No. A-6423)
Rabbit anti-DNP (Molecular Probes, Cat. No. A-6430)
Alexa Fluor 488-conjugated goat antirabbit (Molecular Probes, Cat. No. A-11034)
TRITC-conjugated donkey antirabbit (Jackson ImmunoReseach Labs, Inc., Cat. No. 711-025-152)
Other fluorochrome-conjugated secondary antibodies (Jackson ImmunoReseach Labs, Inc.)
Formaldehyde solution min. 37%, p.a. (Merck, Cat. No. 1.04003.1000)
Vectashield mounting medium (Vector, Cat. No. H-1000)
Microscopy glass slides
Nail polish

III. PROCEDURES

A. Labeling of Probes

There are several methods to label DNA probes. Choosing a specific method depends on the kind of probe to be labelled. For example, whole recombinant plasmids or purified inserts are easily labelled by nick translation, whereas it is more advantageous to label shorter DNA fragments (100–600 bp) by polymerase chain reaction (PCR). Oligonucleotides can be synthesised with amino-modified nucleotides (amino-allyl thymine) at specific positions in the sequence and labelled by conjugation with activated fluorophores.

1. Labelling of Probes by PCR

Solutions

1. *Sodium acetate 3 M, pH 5.5*. Weigh 40.81 g of $NaCH_3COOH$ to 100 ml of solution. Adjust the pH to 5.5 with acetic acid. Sterilise by autoclaving.
2. *10 mg/ml E.coli tRNA*. Dissolve 0.1 g of tRNA in 10 ml of sterile water. Aliquot and store at –20°C.

Steps

1. Make up the following PCR reaction:
   Sterile water to bring the final volume (including enzyme) to 50 µl
   5 µl 10 × PCR buffer (supplied with the enzyme)
   1.5 µl 50 m*M* $MgCl_2$ (the optimal concentration of $MgCl_2$ must be determined empirically; initially try 1.5 m*M*, taking into account that some PCR buffers already contain $MgCl_2$)
   1 µl 1 ng/µl template DNA
   2 µl primer mix, 10 µ*M* (10 pmol/µl) each
   1 µl 10 m*M* dATP
   1 µl 10 m*M* dCTP
   1 µl 10 m*M* dGTP
   3.75 µl 2 m*M* dTTP
   2.5 µl 1 m*M* dig-11-dUTP (or other modified nucleotide)
   2.5 units *Taq* DNA polymerase
   The ratio dTTP : modified nucleotide in the previous mixture is 3 : 1. This ratio is ideal for generating highly labelled probes necessary to detect target sequences present at a low copy number. To generate moderately labelled probes the ratio of dTTP : modified nucleotide in the PCR reaction should be increased.
2. Mix the reagents and centrifuge briefly to collect the mixture into the bottom of the tube.
3. Place the reaction in a termocycler and perform the PCR under the following conditions:
   Denaturation before the first cycle: 3 min at 95°C
   30 cycles of denaturation for 30 s at 95°C, annealing for 30 s at 60°C, and elongation for 1 min at 72°C
   Final elongation: 10 min at 72°C
   Cycling conditions will depend on the template and primers used. Other cycling conditions may be required to get optimal results.
4. Stop the reaction by chilling at 4°C. Run 5 µl of the reaction on an agarose gel and estimate the amount of product generated in the PCR reaction.

5. Add water to adjust the volume of the PCR reaction to 100 µl and purify the labelled probe by ethanol precipitation: add 5 µl of sodium acetate 3*M*, pH 5.5, 1 µl of 10 mg/ml *E.coli* tRNA (this will act as a carrier RNA to help precipitation), and 200 µl of cold 100% ethanol (–20°C).

6. Incubate for 15 min at –70°C or for 1 h at –20°C to allow precipitation of the labelled fragments.

7. Centrifuge at 13,000 rpm for 15 min at 4°C. Remove the supernatant and add 200 µl of cold 70%(v/v) ethanol. Centrifuge for 5 min in the same conditions.

8. Discard the supernatant completely and air dry the pellet. Dissolve the pellet in sterile water to achieve a concentration of probe of 10 ng/µl. Store at –20°C.

2. *Labelling of Modified Oligonucleotide Probes by Conjugation with Activated Fluorophores*

The oligonucleotide probes should be at least 40–50 nucleotides long to minimize the possibility of unspecific binding to nontarget cellular RNAs. When choosing the sequences, avoid regions that may form highly stable secondary structures or dimmerise. If more than one oligonucleotide is used in the same hybridisation, they all should have similar GC content. The oligonucleotides should be synthesised with four or five thymines in the sequence changed to amino-allyl thymine. The modified nucleotides should be at least 10 bases apart to prevent quenching (Long *et al*., 1995; Singer, 1998). The amino-modified thymine can then be coupled chemically to fluorophores as described.

Solutions

1. *Carbonate buffer*: 0.1*M* $NaHCO_3$, pH 8.8. Weigh 0.84 g of $NaHCO_3$ to 100 ml of solution. Adjust the pH with NaOH. Make aliquots and store at –20°C.
2. *Fluorophore solution*: Dissolve one vial of the activated fluorophore (Cy3 monoreactive dye, Cy5 monoreactive dye, or Alexa Fluor 488 from the oligonucleotide amine-labelling kit) in 30 µl of dimethyl sulfoxide. Store at –20°C.
3. *TE, pH 8.0 (10 mM Tris, 1 mM EDTA, pH 8.0)*: Add 1 ml of 1*M* Tris, pH 8.0, and 0.2 ml of 0.5*M* EDTA. Adjust the volume to 100 ml with water. Sterilise by autoclaving.

Steps

1. In a microtube, dilute 5 µg of the modified oligonucleotide (higher oligonucleotide concentration will decrease the yield of the labelling reaction) with carbonate buffer to a final volume of 35 µl (buffers containing primary amino groups, such as TRIS, should be avoided as they inhibit the conjugation reaction).

2. Add 15 µl of fluorophore solution and mix well by vortexing. Allow the labelling reaction to proceed for 24 h in the dark at room temperature.

3. Add sterile water to adjust the volume of the labelling reaction to 100 µl and purify the labelled oligonucleotide by two rounds of ethanol precipitation as follows. Add 10 µl of 3*M* sodium acetate, pH 5.5, 1 µl of 10 mg/ml *E.coli* tRNA, and 300 µl of cold 100% ethanol (–20°C). Incubate overnight at –20°C to allow precipitation of the labelled oligonucleotide probe.

4. Centrifuge at 13,000 rpm for 15 min at 4°C. Remove the supernatant and wash with 200 µl of cold 100% ethanol (do not use 70% ethanol as it will dissolve the precipitated oligonucleotide). Centrifuge for 5 min in the same conditions.

5. Remove the supernatant and dissolve the pellet in 100 µl of sterile water.

6. Reprecipitate by adding 10 µl of 3*M* sodium acetate, pH 5.5, and 300 µl of cold 100% ethanol and incubate for 4 h at –20°C.

7. Repeat step 4, then discard the supernatant completely, and air dry the pellet. Dissolve the labelled oligonucleotide in 100 µl of sterile water to achieve a final concentration of 50 ng/µl (assuming no losses during the procedure).

B. Preparation of Hybridization Mixture

Solutions

1. *20 × SSC (saline sodium citrate)*: 0.3*M* sodium citrate, 3*M* NaCl, pH 7.4. Weigh 88.24 g of sodium citrate and 175.32 g of NaCl for 1 liter of solution. Sterilise by autoclaving.

2. *50% dextran sulfate*: Dissolve 5 g of dextran sulfate in 4 ml of water. Adjust the volume to 10 ml and sterilise by autoclaving. Store at 4°C. Heat at 55°C and mix well before taking an aliquot.

3. *0.5M sodium phosphate buffer, pH 7.0*: 0.31*M* NaH_2PO_4 and 0.19*M* Na_2HPO_4. Weigh 1.84 g NaH_2PO_4 and 1.37 g Na_2HPO_4 for 50 ml of solution. Adjust the pH to 7.0 with 10*M* NaOH if necessary. Sterilise by autoclaving.

4. *10% bovine serum albumin (BSA)*: Dissolve 1 g of BSA in 7 ml of sterile water. Adjust the volume to 10 ml. Aliquot and store at –20°C.

5. *1 mg/ml sonicated herring sperm DNA (100–200 bp)*. Dissolve 0.1 g of herring sperm DNA in 10 ml of sterile water. Sonicate until the average fragment size is 100–200 bp (control the fragment size on agarose gel electrophoresis). Measure ODs at 260 nm to determine the concentration of the DNA and dilute to 1 mg/ml. Aliquot and store at –20°C.

6. *Deionized formamide*: Add 5 g of ion-exchange resine to 100 ml of molecular biology grade formamide. Stir for 3 h, wait for the resine to settle down, and filter through 0.22-µm or Whatmann No. 1. Aliquot and store at –20°C.

7. *50% formamide hybridization buffer*: 50% formamide, 2 × SSC, 10% dextran sulfate, and 50 m*M* sodium phosphate, pH 7.0. Add 5 ml of deionised formamide, 2 ml of 50% dextran sulfate, 1 ml of 20 × SSC, and 1 ml of 0.5 *M* sodium phosphate buffer, adjust the pH to 7.5 with 1 *N* HCl, and add sterile water to 10 ml. Mix well, aliquot, and store at –20°C.

8. *20% formamide hybridization buffer*: 20% formamide, 2 × SSC, 10% dextran sulfate, 0.2% BSA, and 1 µg/µl tRNA, pH 7.0. For 1 ml, add 200 µl of deionised formamide, 200 µl of 50% dextran sulfate, 100 µl of 20 × SSC, 20 µl of 10% BSA, 100 µl of 10 mg/ml tRNA, and 380 µl of sterile water. Mix well and store at 4°C.

1. PCR or Nick Translation-Labeled Probes

Long genomic cloned sequences can be used as probes, but they often contain repetitive sequences that can produce a high background due to cross-hybridization. To reduce this background, a suppressive hybridisation must be performed. In this case, an excess of unlabelled DNA enriched in repetitive sequences (e.g., COT-1 DNA and herring sperm DNA) is included in the hybridization mixture. For probes that do not contain repetitive sequences, a nonsuppressive hybridization is performed. In this case, tRNA is used as a carrier for probe precipitation.

Steps

1. For suppressive hybridization, add per hybridisation 10–100 ng of labelled probe, 5.6 µg of COT-1 DNA, and 2.4 µg of sonicated herring sperm DNA. For nonsuppressive hybridization, add 8 µg of *E.coli* tRNA to the labelled probe (the amount of probe in the hybridization must be determined empirically).

2. Precipitate by adding 0.05 volumes of 3 *M* sodium acetate, pH 5.0, and 2 volumes of cold ethanol (–20°C). Incubate for 15 min at –70°C or 1 h at –20°C.

3. Centrifuge at 13,000 rpm for 15 min at 4°C. Remove the supernatant and wash with cold 70%(v/v) ethanol. Centrifuge for 5 min in the same conditions.

4. Discard the supernatant completely and air dry the pellet. Dissolve the pellet in 50% formamide hybridization buffer (use 8 µl per hybridization) and store at –20°C. Note that before taking an aliquot of the hybridisation buffer this must be warmed up to 37°C and vortexed to homogenise all the components.

2. Oligonucleotide Probes

Prepare the hybridization mixture by diluting the labelled oligonucleotide in the 20% formamide hybridization buffer to the appropriate concentration (1–2 ng/µl of each oligonucleotide). If the oligonucleotide stock solution is too diluted, dry it in the Speed-Vac and then dissolve in the hybridization buffer.

C. Preparation of Cells

Solutions

1. *10× phosphate-buffered saline (PBS)*: 1.37 *M* NaCl, 26.8 m*M* KCl, 80.6 m*M* Na_2HPO_4, 14.7 m*M* KH_2PO_4. Weigh 80 g NaCl, 2 g KCl, 11.44 g Na_2HPO_4, and 2 g KH_2PO_4 for 1 liter of solution. Sterilise by autoclaving.

2. *7.4% paraformaldehyde (2 × PFA)*: Weigh 7.4 g of PFA into a glass flask, add water to 100 ml, and stir at 60°C for several hours with the flask closed. Add 100 µl of 1 *M* NaOH dropwise and keep stirring until the solution is completely clear (pH should be around 7.5). Let it cool down to room temperature and filter through a 0.22-µm filter. Store at –20°C in 5-ml aliquots. Thaw at 60°C and use within 1–2 days.

3. *3.7% formaldehyde in PBS*: Add 5 ml of 2 × PFA, 1 ml of 10 × PBS, and sterile water to 10 ml.

4. *3.7% formaldehyde/5% acetic acid/0.9% NaCl*: Add 5 ml of 2 × PFA, 0.5 ml of acetic acid, 0.3 ml 5 *M* NaCl, and sterile water to 10 ml.

5. *10% (w/v) Triton X-100*: Weigh 1 g of Triton X-100 and add sterile water to 10 ml. Dissolve by warming to 37°C and vortexing.

6. *0.5% Triton X-100 in PBS with 2 mM vanadyl–ribonucleoside complex*: Add 0.5 ml of 10% Triton X-100, 1 ml 10 × PBS, 100 µl of 200 m*M* vanadyl–ribonucleoside complex, and sterile water to 10 ml.

7. *0.01% (w/v) pepsin in 0.01 M HCl*. Prepare immediately before use with HCl at 37°C. Dissolve 5 mg of pepsin in 50 µl of 0.01 *M* HCl and then adjust the volume with 0.01 *M* HCl to 50 ml.

Steps

All the procedures are performed with cells attached on 10 × 10-mm glass coverslips placed in 35 × 10-mm tissue culture dishes. One dish can accommodate four of these coverslips, and 1 ml of solution is enough for each fixation, permeabilisation, and washing step.

1. Grow monolayer cells to subconfluent density directly on 10 × 10-mm coverslips and wash them in serum-free medium. Alternatively, wash suspension cells in serum-free medium and allow them to adhere

onto 10 × 10-mm poly-L-lysine-coated glass coverslips for 1 min at room temperature (approximately 2 × 10^5cells in 30 µl of medium per coverslip).

2. Fix and permeabilize the cells according to one of the following protocols.

   a. Fix with 3.7% formaldehyde in PBS for 10 min at room temperature, wash 3 × 5 min with PBS, permeabilise with 0.5% Triton X-100 in PBS with 2 m*M* vanadyl–ribonucleoside complex for 10 min, and wash again 3 × 5 min with PBS. **Proceed to protocols D, E, or F** (when conjugating more than one protocol, go sequentially from D to E to F).

   b. Fix with 4% formaldehyde, 5% acetic acid, and 0.9% NaCl for 20 min at room temperature, wash 4 × 5 min with PBS (include 2 m*M* vanadyl–ribonucleoside complex in the last wash), and leave in 70% ethanol at –20°C for at least 1 h. Before hybridization, rehydrate the cells in PBS and digest with 0.01% pepsin in 0.01 *M* HCl for 5 min at 37°C. Rinse with PBS and inactivate the protease by fixation with 3.7% formaldehyde in PBS for 5 min at room temperature. Wash 3 × 5 min with PBS and **proceed to protocol D or E** (cannot be used with protocol F).

Step 2b allows a better access of the probe to the target RNA sequences in the cell. Therefore, this protocol may be required when hybridizing with oligonucleotide probes that detect the splice junctions of mRNA. Note that monolayer cells may detach from the coverslip during treatment with pepsin.

D. Hybridization to RNA

Solutions

1. *20% (w/v) Tween 20*: Weigh 2 g of Tween 20 and add sterile water to 10 ml. Dissolve by warming to 37°C and vortexing.

2. *20% (w/v) gelatin from cold water skin fish*: Weigh 0.2 g of gelatin and add sterile water to 1 ml. Mix well, aliquot, and store at –20°C.

3. *50% formamide, 2 × SSC, 0.01% Tween 20, pH 7.0*: Add 5 ml of formamide, 1 ml of 20 × SSC, 5 µl of 20% Tween 20, and sterilile water to 10 ml. Adjust the pH to 7.0 with 1 *M* HCl (use deionised formamide and add 2 m*M* vanadyl–ribonucleoside complex for prehybridisation incubation and formamide p.a. in posthybridisation washes).

4. *20% formamide, 2 × SSC, 0.01% Tween 20, pH 7.0*: Add 2 ml of formamide, 1 ml of 20 × SSC, 5 µl of 20% Tween 20, and sterile water to 10 ml (use deionised formamide and add 2 m*M* vanadyl–ribonucleoside complex for prehybridization incubation and formamide p.a. in posthybridization washes).

5. *2 × SSC, 0.01% Tween 20*: Add 1 ml of 20 × SSC, 5 µl of 20% Tween 20, and water to 10 ml.

6. *4 × SSC, 0.1% Tween 20*: Add 100 ml 20 × SSC, 2.5 ml 20% Tween 20, and sterile water to 500 ml.

7. *4 × SSC, 0.1% Tween 20, 1% BSA, 0.2% gelatin*: To 1 ml add 200 µl 20 × SSC, 5 µl 20% Tween 20, 100 µl 10% BSA, 10 µl 20% gelatin, and 685 µl of sterile water.

Steps

1. Denature double-stranded DNA probes by heating the hybridization mixture at 75°C for 5 min (use 8 µl per coverslip). Place on ice for nonsupressive hybridization or at 37°C for 10 min for suppressive hybridization to allow preannealing of repetitive DNA sequences.

2. Incubate the cells in 50% formamide, 2 × SSC, 0.01% Tween 20, and 2 m*M* vanadyl–ribonucleoside complex for 5 min at 37°C (when hybridizing with oligonucleotides, use 20% formamide).

3. Aspirate the solution as much as possible, especially around the coverslip, without allowing the cells to dry. Place 8 µl of hybridisation mixture in the center of the coverslip and incubate at 37°C in a moist chamber for 3–16 h (1–3 h for oligonucleotides).

4. Perform posthybridisation washes at the desired stringency. The washes described here are just a guideline. For optimal results, the percentage of formamide, salt concentration, and temperature should be optimized for each probe. Wash sequentially as follows:

   Wash I: 3 × 5 min at 45°C with 50% formamide p.a., 2 × SSC, and 0.01% Tween 20

   Wash II: 3 × 5 min at 45°C with 2 × SSC and 0.01% Tween 20

   When hybridizing with oligonucleotides, the washes should be less stringent, e.g., wash at 37°C or at 42°C with only 20% formamide in wash I. Perform washes with all the solutions prewarmed at the desired temperature. This step can be performed either in an incubator or in a water bath with the dishes inside a floating metal platform.

5. Proceed to step 7 if the probe is labelled directly with a fluorescent dye and no amplification step is required. Alternatively, wash with 4 × SSC and 0.1% Tween 20 for 5 min at 37°C and proceed to step 6 for detection with the appropriate antibodies.

6. Aspirate the solution, place 5 µl of diluted antibody in the center of the coverslip, and incubate for 30 min at 37°C in a moist chamber. Following each incubation step wash 3 × 5 min with 4 × SSC and 0.1% Tween 20 at 37°C. For digoxigenin-labelled probes, use fluorescein-conjugated sheep antidigoxigenin (1/100) followed by Alexa Fluor 488-conjugated goat antifluo-

rescein (1/200) if an amplification step is required. Alternatively, use Cy3- or Cy5-conjugated mouse antidigoxin (1/250). For DNP-labelled probes, use FITC-conjugated rabbit anti-DNP or rabbit anti-DNP followed by Alexa Fluor 488-conjugated goat antirabbit or TRITC-conjugated donkey antirabbit. Dilute antibodies in 4 × SSC, 0.1% Tween 20, 1% BSA, and 0.2% gelatin.

7. Wash briefly in PBS, fix the signal with 3.7% PFA in PBS for 10 min at room temperature, and wash 3 × 5 min in PBS.

8. Proceed to **protocols E or F** or mount in a microscopy glass slide with Vectashield mounting medium and seal with nail polish.

E. Hybridization to DNA

Solutions

1. *70% formamide, 2 × SSC, 50 mM sodium phosphate, pH 7.0*: Add 7 ml of deionized formamide, 1 ml of 20 × SSC, 1 ml of 0.5 *M* sodium phosphate buffer, and sterile water to 10 ml. Adjust the pH to 7.0 with 1 *M* HCl.
2. *50% formamide, 2 × SSC, 50 mM sodium phosphate, pH 7.0*: Add 5 ml of deionized formamide, 1 ml of 20 × SSC, 1 ml of 0.5 *M* sodium phosphate buffer, and sterile water to 10 ml. Adjust the pH to 7.0 with 1 *M* HCl.

Steps

1. Denature the double-stranded DNA probes by heating the hybridization mixture at 75°C for 5 min (use 8 µl per coverslip). Place on ice for nonsupressive hybridization or at 37°C for 10 min for suppressive hybridization to allow preannealing of the repetitive DNA sequences.
2. Incubate the cells in 2 × SSC at 40°C for 5 min (this step is to prewarm the cells and avoid lowering the temperature in the denaturation step).
3. For denaturation, incubate at 73°C in 70% formamide, 2 × SSC, and 50 m*M* sodium phosphate, pH 7.0, for 3 min followed by 50% formamide, 2 × SSC, and 50 m*M* sodium phosphate, pH 7.0, for 1 min.
4. Aspirate the solution as fast as possible and place 8 µl of hybridization mixture in the center of the coverslip. Incubate for 16 h at 37°C in a moist chamber.
5. Perform posthybridization washes at the desired stringency. The washes described here are just a guideline. For optimal results, the percentage of formamide, salt concentration, and temperature should be optimized for each probe. Wash sequentially as follows:
   - Wash I: 3 × 5 min at 45°C with 50% formamide p.a., 2 × SSC, and 0.01% Tween 20
   - Wash II: 3 × 5 min at 45°C with 0.5 × SSC and 0.01% Tween 20
6. Proceed to step 8 if the probe is directly labelled with a fluorescent dye and no amplification step with antibodies is required. Alternatively, wash with 4 × SSC, 0.1% Tween 20 for 5 min at 37°C and proceed to step 7 for detection with the appropriate antibodies.
7. For detection of hybridization sites, follow step 6 of protocol D. When conjugating several protocols it is essential to avoid cross-reactivity between the antibodies used in the different protocols and to choose different fluorescent dyes for each detection.
8. Wash briefly in PBS, fix the signal with 3.7% PFA in PBS for 10 min at room temperature, and wash 3 × 5 min in PBS.
9. Proceed to **protocols F** or mount in a microscopy glass slide with Vectashield mounting medium and seal with nail polish.

F. Detection of Proteins by Indirect Immunofluorescence

Solutions

1. *PBS, 0.05% Tween 20*: To 500 ml add 50 ml 10 × PBS, 1.25 ml 20% Tween 20, and 450 ml of sterile water.
2. *PBS, 0.05% Tween 20, 0.2% gelatin*: Add 10 µl of 20% gelatin to 1 ml of PBS and 0.05% Tween 20.
3. *2% formaldehyde in PBS*: Prepare by adding 2.7 ml of formaldehyde solution at 37% to 50 ml of PBS.

Steps

1. Wash cells with PBS, 0.05% Tween 20 for 5 min.
2. Incubate with the primary antibody (diluted in PBS, 0.05% Tween 20, 0.2% gelatin) for 1 h at room temperature in a moist chamber.
3. Wash 3 × 5 min in PBS, 0.05% Tween 20 at room temperature.
4. Incubate with the appropriate secondary antibody (diluted in PBS, 0.05% Tween 20, 0.2% gelatin) for 30 min at room temperature in a moist chamber.
5. Wash 3 × 5 min in PBS, 0.05% Tween 20 at room temperature.
6. Wash briefly in PBS. Fix with 2% formaldehyde in PBS for 10 min.
7. Wash 3 × 5 min in PBS, mount in a microscopy glass slide with Vectashield mounting medium, and seal with nail polish.

For visualization of β-globin gene expression, see Fig. 1.

IV. COMMENTS

The methods described in this article can be used to detect RNA and DNA, RNA and protein, DNA and

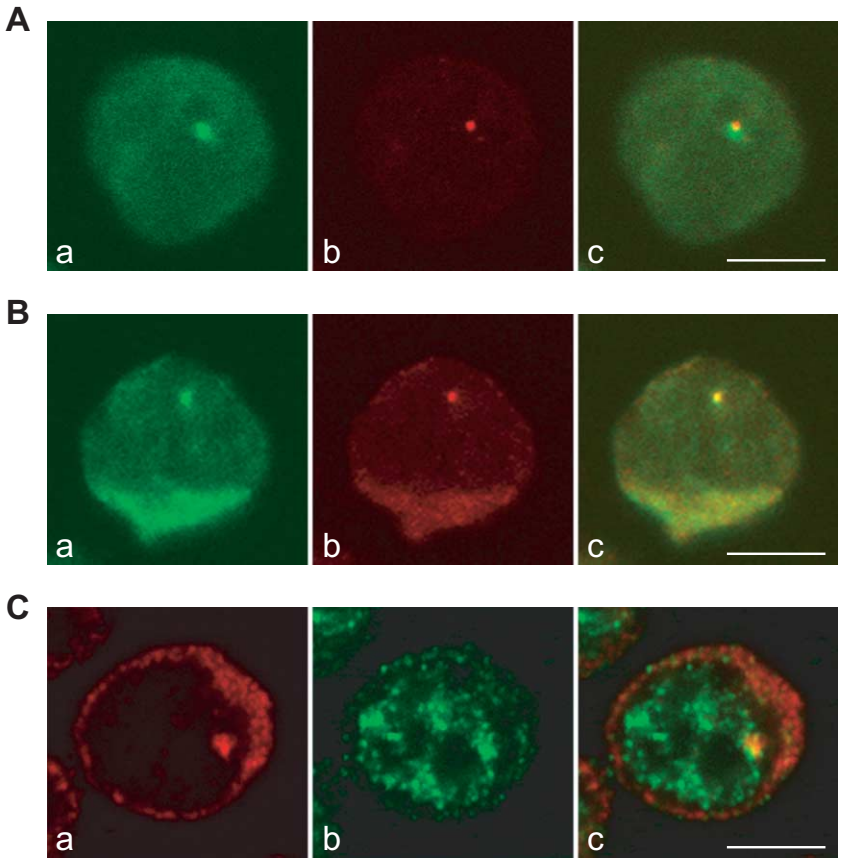

FIGURE 1 Visualization of β-globin gene expression at the single cell level. (A) Simultaneous detection of human β-globin RNA and DNA. Murine erythroleukaemia (MEL) cells were stably transfected with multiple copies of the human β-globin gene cloned in the micro-LCR expression vector (Collis *et al*., 1990; Custódio *et al*., 1999). After induction of β-globin gene expression, cells were fixed with formaldehyde/acetic acid, treated with pepsin, and hybridised with a probe complementary to the transcribed sequence of the gene, labeled with digoxigenin (a, signal detected with fluorescein). A bright fluorescent focus is detected in the nucleus. Following fixation of the RNA signal with formaldehyde, cells were denatured and hybridized with a probe that recognizes the micro-LCR, labelled with DNP (b, signal detected with Texas red). A fluorescent focus in the nucleus indicates the integration site of the transfected gene locus. Overlay of the green and red images in c shows colocalization of the two focal signals, indicating that the human β-globin RNA is detected in the nucleus at the site of transcription. (B) Simultaneous detection of human β-globin nascent transcripts and spliced mRNA. MEL cells expressing the human β-globin gene were fixed with formaldehyde/acetic acid, treated with pepsin, and hybridized sequentially to detect human β-globin nascent transcripts and spliced mRNA. The cells were first hybridized with a mixture of two splice junction oligonucleotide probes (SJ I/II probe complementary to the last 12 nucleotides of exon I and the first 12 nucleotides of exon II; SJ II/III complementary to the last and first 12 nucleotides of exons II and III, respectively) labeled with DNP (a, signal detected with fluorescein). Cells expressing the human β-globin gene for 4 days contain a fluorescent focus in the nucleus and additional cytoplasmic staining. Following fixation of the signal with formaldehyde, cells were incubated with a probe that hybridizes to the full-length human β-globin RNA, labeled with digoxigenin (b, signal detected with rhodamine). (c) A superimposition of the two images. The focal signals colocalize in the nucleus, indicating that splicing of β-globin pre-mRNA is taking place in close proximity to the site of transcription. (C) Simultaneous detection of human β-globin transcripts and an RNA processing factor. MEL cells expressing the human β-globin gene were fixed with formaldehyde, permeabilised with Triton, and hybridized with a probe that spans the transcribed sequence of the human β-globin gene (a, signal detected with Cy3). RNA is detected in the nucleus as a focus and in the cytoplasm. After fixation of the RNA signal with formaldehyde, cells were incubated with an antibody against the splicing coactivator SRm160 (rAb-SRm160; Blencowe *et al*., 1998) (b, signal detected with Alexa Fluor 488). SRm160 labels the nucleoplasm with a speckled pattern. Overlay of the two signals (c) shows colocalization of the nuclear RNA signal with a speckle of SRm160, indicating recruitment of this protein to the site of human β-globin RNA transcription and splicing. Bars: 5 μm.

protein, or RNA, DNA, and protein. In double RNA/DNA hybridization, hybridization to RNA is always performed first (without DNA denaturation, RNA is the only target for the probe). Then, the cellular DNA is denatured and hybridization to DNA is performed. The ideal probe for DNA detection should target nontranscribed regions of the genome and should not produce a signal if hybridised without prior denaturation of cellular DNA. The same probe, labelled with different reporters, can alternatively be used to simultaneously detect a DNA region and the corresponding transcripts. In this case, an RNase treatment must be introduced after the detection of the probe hybridized to RNA (Xing *et al*., 1995). An alkaline denaturation of DNA can also be performed instead of heat denaturation because it simultaneously degrades the cellular RNA (see Johnson *et al*., 2000). To minimise loss of the RNA signal during DNA denaturation, the probe hybridized to RNA should be detected with two layers of antibodies and fixed with formaldehyde. Direct labelling of the probe with fluorescent dyes without any step of signal amplification with antibodies is not recommended for this procedure. For multiple hybridisation and immunofluorescence experiments, different labels for the probes and fluorescent dyes coupled to antibodies must be combined. Particular attention should be taken to avoid cross-reactivity between antibodies used at different steps. For example, if a mouse antibody is used in detection of the RNA signal, antimouse immunoglobulin antibodies cannot be used either in the detection of the DNA signal or in immunofluorescence. When combining *in situ* hybridization with protein detection, the immunofluorescence is usually performed after the hybridization steps. This is especially important when conjugating RNA and protein detection because primary antibodies used for immunofluorescence are often contaminated with RNases, resulting in a significant decrease of the RNA signal. However, some epitopes are no longer recognised by the antibodies after incubation of the cells with formamide, especially after a denaturation step. In this case, immunofluorescence must be performed first and the signal fixed before hybridization. An important control to guarantee that the pattern of the antibody labelling is not changed by formamide is to stain cells using standard immunofluorescence conditions and to compare the pattern with the one obtained after RNA or DNA hybridization. The methods presented here were partly adapted from an original protocol reported by Zirbel *et al*., (1993). The pepsin treatment was introduced for the specific detection of splice junctions on nascent RNA transcripts in the nucleus (Wijgerde *et al*., 1995).

V. PITFALLS

Appropriate negative controls are essential to distinguish specific signals from fluorescent noise due to unspecific hybridization. For RNA hybridization the best control is to use cells that do not transcribe the target RNA. To overcome unspecific hybridisation, the stringency of the hybridization and posthybridization washes can be increased until no signal is obtained in the negative control cells, but without eliminating the signal in the cells that express the target RNA. If this is not possible, a new probe should be designed and tested in the same way. Control probes are also very important, especially when very small oligonucleotide probes are used. One example is splice junction probes. These probes are designed to hybridise with the last nucleotides of one exon and the first nucleotides of the following exon and to produce a stable hybrid only if the two halves of the probe hybridize. An appropriate control probe should be designed to exclude that only half of the probe is capable of producing a stable hybrid. Other negative controls for RNA hybridization include mock hybridization (no probe in the hybridization mixture) and RNase treatment before hybridization (0.1 mg/ml DNase-free RNase in 2 × SSC at 37°C for 1 h). Additional controls should be performed when using probes that contain plasmid sequences. Namely, the plasmid backbone (without insert) should be labelled and used as a probe. If this produces a signal (which happens frequently if the cells have been transfected with related plasmids), the insert should be isolated from the recombinant plasmid before labelling.

Fluorescent Visualization of Genomic Structure and DNA Replication at the Single Molecule Level

Ronald Lebofsky and Aaron Bensimon

I. INTRODUCTION

DNA fibre fluorescent *in situ* hybridization (FFSH) techniques provide kilobase resolution for physical mapping, genomic structure, and/or DNA replication analysis at the single molecule level (Caburet *et al.*, 2002; Herrick and Bensimon, 1999). Objectives of DNA fibre preparation are similar for most techniques: (1) a high degree of stretching to obtain optimal resolution, (2) long fibres for long range studies, and (3) sufficient numbers of molecules to enable a population overview. DNA preparation by molecular combing constitutes an important advance in this area (Bensimon *et al.*, 1994). Molecules are stretched uniformly by a constant stretching force regardless of sequence content whereby 1 μm of stretched DNA represents 2 kb. Uniform stretching is important because the arduous task of calibrating each slide or areas within a slide with external controls is not required. Because the stretching force is one order of magnitude less than that needed to break the double helix, molecules that range between hundreds of base pairs to over one megabase are combed. The stretched DNA and molecule length provide a maximal resolution of 1–4 kb over megabase distances. In addition, DNA binding to slides used for molecular combing is very efficient. Tens of thousands of DNA molecules corresponding to between 30 and 100 mammalian genomes are combed per surface. Therefore, population data are obtainable without compromising the sensitivity of single molecule analysis. This article provides all the necessary protocols to set up molecular combing and to carry out physical mapping, genomic structure, and DNA replication studies using combed DNA as a substrate (Anglana *et al.*, 2003; Gad *et al.*, 2002; Herrick *et al.*, 2000; Maho *et al.*, 1999; Monier *et al.*, 1998; Pasero *et al.*, 2002).

II. MATERIALS AND INSTRUMENTATION

7-Octenyltrichlorosilane (539279), hydrogen peroxide solution 35 wt. % in water (H_2O_2) (349887), ammonium hydroxide solution (NH_4OH) (A6899), chloroform (C-5312), 5-bromo-2′-deoxyuridine (BrdU) BrdU (B-9285), 5-chloro-2′-deoxyuridine (CldU) (C-6891), 5-iodo-2′-deoxyuridine (IdU) (I-7125), EDTA (E-9884), sodium dodecyl sulfate (SDS) 10% solution (L-4522), 2-morpholinoethanesulfonic acid (MES) (M-2933), ethanol (EtOH) (E-7023), sodium hydroxide (NaOH) (S-8045), sodium acetate (NaAc) (71183), glacial acetic acid (45726), Hybri slips (Z36,590-4), trizma hydrochloride (Tris) (T-5941), sodium chloride solution (NaCl) 5 M (S-5150), Tween 20 (P-9416), and *N*-lauroylsarcosine sodium salt (L-9150) are from Sigma-Aldrich. The 22 × 22-mm cover glass (coverslip) (2865-22) is from Corning. Miscroscope slides (4951) are from Erie Scientific Company. Plug molds (1703706) are from Bio-Rad. Low melting temperature (LMT) Nusieve agarose (50081) is from Cambrex. Proteinase K (1.24568) is from Merck Biosciences. β agarase I and buffer (M0392S) are from New England Biolabs. Phosphate-buffered saline (PBS) 10× (PBS10X03), TE 1× (TE1X5000), deionized formamide

(FORMD003), dextran sulfate, sodium salt 50% (w/v) solution (DEXT5100), and SSC 20× (SSC20X02) are from Qbiogene. BioPrime DNA labelling kit (18094011) and human Cot-1 DNA (15279011) are from Invitrogen/Gibco-BRL. DIG High Prime (1585606), blocking reagent (1096176), FITC-conjugated sheep antidigoxigenin Fab fragments (1207741), antidigoxigenin-AP Fab fragments (1093274), antibiotin-AP Fab fragments (1426303), and dig-labelled control DNA (1585738) are from Roche. Herring sperm DNA (D1815) is from Promega. HybChamber mica (HYB-04) is from Genemachines. YOYO-1 iodide (Y3601), streptavidin, Alexa 350 conjugate (S11249), streptavidin, Alexa 488 conjugate (S32354), streptavidin, Alexa 594 conjugate (S32356), streptavidin, Alexa 750 conjugate (S21384), Alexa 350 goat antimouse IgG (A21049), Alexa 350 donkey antigoat IgG (A21081), Alexa 594 donkey antirat (A21209), Alexa 488 goat antimouse (A11029), Alexa 488 donkey antisheep (A11015), and SlowFade light antifade kit (S7461) are from Molecular Probes. Biotin-conjugated rabbit antistreptavidin (200-4695) and FITC-conjugated rabbit antidonkey (616-4202) are from Rockland. Mouse anti-BrdU (347580) and FITC-conjugated mouse anti-BrdU (347583) are from BD Biosciences. Rat anti-BrdU (ab6326) is from Novus Biologicals. Texas red-conjugated donkey antirat (712-075-153) is from Jackson. HybondN+ (82 mm), 50 discs (RPN82B) is from Amersham. Alkaline phosphatase substrate kit IV (SK-5400) is from Vector Laboratories.

The following can be purchased from a local laboratory equipment specialist: argon gas tank, oxygen gas tank, gas hydration device, UV lamp covered with quartz, 1000-µl glass syringe (Hamilton), water baths, rotating wheel, tissue culture incubator, hood for tissue culture, facilities for performing gel electrophoresis, plastic polypropylene jars for slides, tweezers, Kim Wipes, parafilm. Nail polish and Superglue can be bought from a local supermarket.

Teflon reservoirs with a 25 × 25 × 2-mm interior (approximately 1.3 ml volume), ceramic coverslip racks for 12 coverslips each, tubing with appropriate valves, and a treatment vessel for glass silanisation were all custom made at Institut Pasteur.

The combing machine, shown in Fig. 1, must have the following characteristics.

1. Coverslip holders that grip the silanised surface by an edge.
2. The capability to quickly descend the coverslip holders so that the coverslip is inserted into a combing reservoir.
3. The capability to lift the coverslip holders so that the coverslip is removed from the reservoir at a constant speed of 300 µm/s.

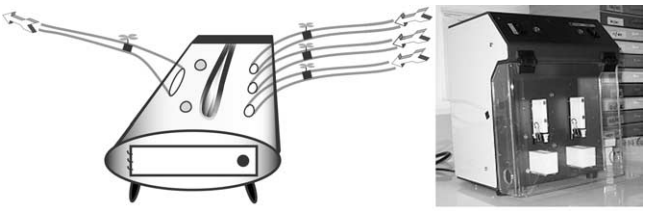

FIGURE 1 (A) The schematic of a glass treatment vessel shows all the required components: housing for a quartz-covered UV lamp, three tube entrances for pressurised gas flow, one tube exit, appropriate tubing and valves, entry ports along the roof of the vessel to inject silane via a syringe, and a door to introduce and remove racks of glass coverslips. (B) This combing machine, which can comb two coverslips at a time from two different reservoirs, is currently used at Institut Pasteur.

Fluorescent signals were examined with a Zeiss Axioplan 2 microscope equipped with a 75-W xenon arc lamp. Filter sets consisting of excitation, emission, and dichroic filters are from Omega Optical: XF03 for blue, XF100-2 for green, XF102-2 for red, and XF143-2 for infrared. Photos were taken using Smartcapture 2 software and a Photometrics HQ Coolsnap CCD camera. The optical capabilities of any other chosen hardware should be at least equal to the aforementioned system, as resolution and sensitivity must be optimal for single DNA molecule visualisation. An inverted microscope, a Zeiss Axiovert equipped with a xenon arc lamp and filters for green fluorescence, was used for DNA combing quality control. See Section IV,E for why this is used rather than an upright microscope.

III. PROCEDURES

A. Coverslip Silanisation for Molecular Combing

Solution

Pirana solution: Add 390 ml of NH_4OH and 360 ml of H_2O_2 immediately prior to each round of slide preparation.

Steps

1. Work in a fume hood.
2. Distribute seventy-two 22 × 22-mm coverslips into six ceramic racks.
3. To clean the surface, place racks with coverslips into the pirana solution and leave for 2 h.
4. Briefly rinse the coverslips three times with sterile ddH_2O.

5. Dry coverslips and racks with a stream of oxygen.
6. Place the racks in the treatment vessel.
7. Place one small aluminium pocket (holds less than 1 ml) next to each pair of ceramic racks.
8. Close the vessel, rendering it airtight.
9. Open the exit valve.
10. Fill the vessel with oxygen by (1) administering a flow of oxygen at a rate of 15 litre/min for 1 min, (2) applying an 8 litre/min flow for 5 min, and (3) reducing the flow to 0.160 litre/min. Keep this flow constant for the duration of the following step.
11. Cover the vessel with aluminium and turn on UV lamp for 1 h. UV converts oxygen to ozone, which helps cleanse the glass further.
12. Remove ozone by flushing vessel with a 2 litre/min flow of inert argon.
13. Apply an argon flow that is hydrated by 10% at a rate of 1 litre/min for 20 min.
14. Close all entry and exit valves. Allow hydration to continue for 10 min in the closed vessel.
15. Open the exit valve. Remove excess water vapour with a 0.9 litre/min flow of argon.
16. Using a syringe, inject 150 µl of 7-octenyltrichlorosilane into the vessel through the small ports by dispensing 50 µl into each aluminium pocket.
17. When finished, rinse the syringe three times with chloroform and then three times in 100% ethanol.
18. Shut off the argon flow and allow the pressure in the vessel to return to zero.
19. Close all valves. The silane will begin to vaporise naturally. Let this process occur overnight. This gas silanises the glass coverslips.
20. The following day, open the exit valve and rinse the vessel with an 8 litre/min argon flow for 5 min.
21. Open the vessel, remove the racks, and allow the slides to dry for 1 h at room temperature.
22. Store coverslips with aluminium wrapping in a dust-free environment.

B. Preparing High Molecular Weight DNA in Agarose Blocks

Solutions

1. *NaOH 30% (w/v)*: Dissolve 15 g of NaOH in 40 ml of ddH_2O. Bring the total volume to 50 ml.

2. *0.5 M EDTA, pH 8*: To make 1 litre, dissolve 186.12 g of EDTA in 900 ml of ddH_2O. Adjust the pH to 8 by adding NaOH 30% (w/v). Add ddH_2O for a final volume of 1 litre.

3. *1× PBS*: Add 900 ml of ddH_2O to 100 ml of 10× PBS to make 1 litre.

4. *1% LMT agarose*: Prepare 50 ml by adding 0.5 g to 50 ml of 1× PBS. Heat and mix to dissolve the agarose. Store at 4°C.

5. *10 mg/ml proteinase K stock*: Dissolve 500 mg of proteinase K in 50 ml of 0.5 *M* EDTA, pH 8. Make 1-ml aliquots and store at –20°C.

6. *Proteinase K digestion (PKD) solution*: *2 mg/ml proteinase K, 1% SDS, and 100 mM EDTA.* On the day of cell harvesting for DNA extraction, prepare 5 ml of PKD by adding a thawed 1-ml aliquot of proteinase K stock and 0.5 ml of 10% SDS to 3.5 ml of ddH_2O. Vortex. This is sufficient for 20 agarose blocks. Adjust the amount accordingly.

Steps

1. Prechill 50 ml of sterile 1× PBS in an ice bucket.
2. Turn on a 37°C water bath in the laboratory.
3. Melt LMT agarose in microwave and leave molten in 50°C water bath.
4. Preheat PKD solution at 50°C.
5. Cover bottom of plug molds with tape.
6. In tissue culture, harvest cells and collect pellet according to cell type and laboratory protocols.
7. Take off supernatant.
8. Resuspend cells in ice cold 1× PBS so that there are 250,000 cells/50 µl, i.e., for 2 million cells, resuspend in 400 µl of 1× PBS. Leave on ice until all samples have been resuspended in appropriate volumes.
9. Put cell suspension in 37°C water bath for 5 min.
10. Add an equal volume of 50°C molten LMT agarose and mix gently but thoroughly with a pipette.
11. Fill plug molds with cell/agarose mix (approximately 90 µl per plug).
12. Put the mold at 4°C for 20 min to allow blocks to solidify.
13. Eject plugs and add adequate amounts of the preheated PKD solution so that there is a minimum of 250 µl per block.
14. Leave overnight at 50°C to allow for deproteination of DNA.
15. The following day, remove the proteinase K digestion solution and replace it with 10 ml of 500 m*M* EDTA, pH 8.0. Blocks can be stored indefinitely at 4°C.

C. Labeling DNA for Replication Studies

Solutions

1. *1× PBS*: see Section III,B.

2. *10 mM CldU stock*: Dissolve 262.7 mg of CldU in 100 ml of 1× PBS. Make 2-ml aliquots and store indefinitely at –20°C.

3. *10 mM IdU stock*: Dissolve 354.1 mg of IdU in 100 ml of 1× PBS and store indefinitely at 4°C

4. *Media with 100 μM CldU/IdU (for adherent cell cultures)*: On the day of the experiment, prepare tissue culture tubes with a volume of media that corresponds to the size of the tissue culture flask. Add appropriate volume of CldU stock to make a 100 μ*M* final concentration, i.e., for a T75 flask, add 150 μl of CldU stock to 15 ml of media. Repeat with IdU. After addition, mix the media well and keep at 37°C in close proximity to the tissue culture hood.

1. Adherent Cell Cultures

Steps

1. Carry out steps 1–5 in Section III/B prior to the following.
2. Preheat a nucleotide-free media bottle in the same 37°C waterbath as media/CldU and media/IdU mixes.
3. Aspirate off media from the cell culture.
4. Add media/IdU mix and restore flask to 37°C incubator. Start a timer.
5. At t = 30 min, aspirate media/IdU and wash cells three times with warm nucleotide-free media as quickly as possible.
6. Add media/CldU mix and put the flask back in the 37°C incubator.
7. At t = 60 min, aspirate media/CldU mix.
8. Go step 6 in Section III,B and complete that protocol.

Suspension Cell Cultures

Steps

1. Carry out steps 1–5 in Section III/B prior to the following.
2. In a 37°C water bath with easy access to a tissue culture hood, warm a sufficient quantity of IdU and CldU to produce a 100 μ*M* final concentration of the cell culture volume, i.e., for a T75 containing 15 ml of cell suspension, warm 150 μl of IdU and CldU each.
3. To an exponentially dividing cell culture add warm IdU stock so that final concentration is 100 μ*M*.
4. Mix gently with a pipette and restore to 37°C incubator. Start the timer.
5. At t = 30 min, add warm CldU stock so that final concentration is 100 μ*M*.
6. Mix gently with a pipette and put back in 37°C incubator.
7. At t = 60 min, go step 6 in Section III,B and complete that protocol.

D. Putting DNA in Solution, Ready for Combing

Solutions

1. *NaOH 30% (w/v)*: see Section III,B.
2. *Combing buffer, 0.5 M MES, pH 5.5*: For 250 ml, dissolve 24.4 g of MES in 225 ml of sterile ddH_2O. Adjust the pH to 5.5 using NaOH 30% (w/v). Bring the final volume to 250 ml with sterile ddH_2O. Autoclave and store at room temperature.
3. *YOYO-1/TE mix*: On the day of the experiment, for each block to be prepared dilute 1 μl of YOYO-1 stock in 200 μl of TE. Scale according to how many agarose blocks are to be used. Keep in the dark at room temperature.
4. *10× β agarase buffer*: Included with β agarase enzyme

Steps

1. Remove one agarose block containing DNA from EDTA storage buffer and put in a 50-ml sterile tube (for DNA replication studies, see Section IV,E).
2. To remove residual proteinase K and SDS, wash five times in 50 ml TE on a rotating wheel.
3. Transfer agarose block to a sterile round-bottom 2-ml Eppendorf tube.
4. To stain DNA, add the YOYO-1/TE mix (200 μl) and leave sit at room temperature for 1 h in the dark.
5. Transfer block to sterile 15 ml and remove excess YOYO-1 by washing twice in 10 ml of TE on a rotating wheel protected from light.
6. Put the block in a new round-bottom 2-ml Eppendorf tube and add 200 μl of TE.
7. Heat the block at 69°C for 20 min to melt the LMT agarose.
8. Reduce temperature by putting the Eppendorf tube in a 42°C water bath for 10 min.
9. Warm the 10× β agarase buffer to 42°C during this period.
10. Add 30 μl of 10× β agarase buffer to the molten agarose/DNA mix, put back at 42°C, and wait for 5 min to allow the buffer to diffuse.
11. To digest agarose, add 1.5 μl of β agarase and incubate overnight at 42°C.
12. The following day, slowly add 900 μl of MES combing buffer to the DNA solution.
13. Put back in the 42°C water bath and allow the solution to mix for one 1 h.
14. Gently pour the DNA solution in a Teflon combing reservoir.
15. Add MES buffer so that the DNA solution nearly fills the reservoir.
16. Store DNA solution at room temperature in the dark for up to 1 month.

17. Once the DNA solution is in the reservoir, prevent evaporation when not combing by covering with Parafilm.
18. When finished with a DNA solution, empty and clean combing reservoir by boiling for 45 min in ddH_2O.

E. Molecular Combing

Steps

1. Place a silanised surface in the coverslip holder attached to the combing machine.
2. Let the machine lower the coverslip into the combing reservoir that contains the DNA to be combed.
3. Wait 5 min to allow DNA free ends to bind to the surface.
4. Release the ascent function of the combing machine to remove the coverslip. During removal, the meniscus moving along the hydrophobic surface is combing the DNA.
5. With an inverted microscope, visualise the YOYO-1 stained DNA as a combing quality check.
6. Bake the combed DNA at 65°C overnight with the surface untouched by the inverted microscope facing up.
7. Use Superglue to stick the coverslip to a slide and store at –20°C (see Fig. 2).

F. Labeling Probes with Biotin and/or Digoxigenin

1. Probe Labeling with Biotin-16-dUTP

Steps

1. All components are included in the BioPrime DNA labelling kit. Thaw components and keep on ice.
2. Add sterile ddH_2O to 500 ng of template DNA to a final volume of 24 µl.
3. Add 20 µl of 2.5× random primers and boil for 10 min to denature DNA.
4. Quickly place tubes on ice for 10 min.
5. Vortex and spin briefly.
6. Add 5 µl of 10× dNTPs (includes biotin-16-dUTP) and 1 µl of Klenow enzyme. Mix thoroughly with a pipette and spin to collect the reaction mix.

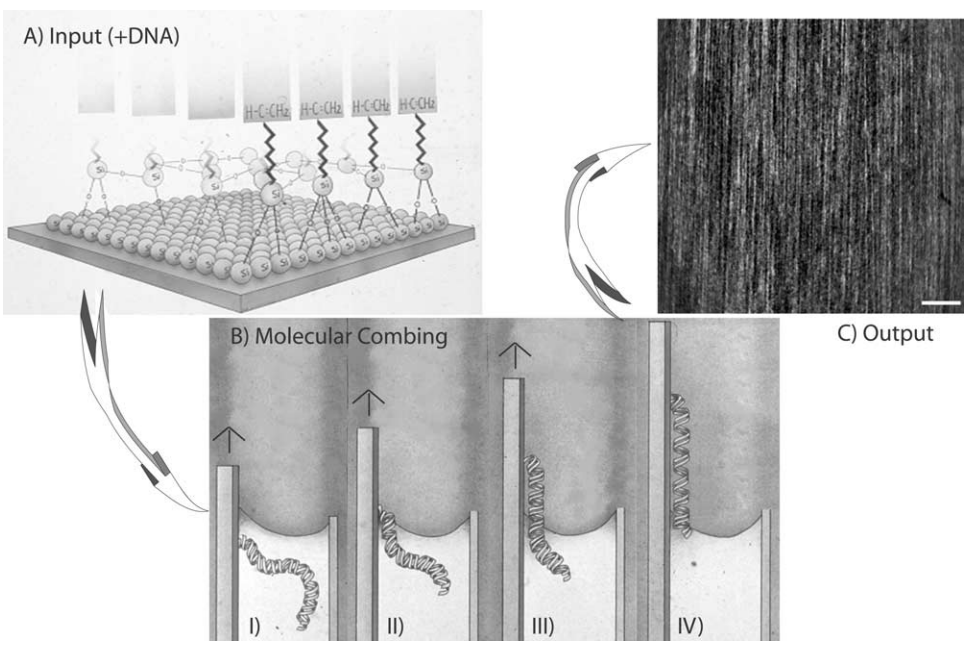

FIGURE 2 At the core of molecular combing is the silanised coverslip (A). An organic monolayer is covalently attached to inorganic glass via Si groups. At the terminal end of the carbon chains reside vinyl groups. It is a combination of the hydrophobic nature of the silanised glass and the terminal vinyl groups, which allow all the following processes of molecular combing to occur (B). DNA in solution attach to the coverslip by a free-end only (I). As the coverslip is removed from the reservoir, a meniscus is formed due to the interaction between the hydrophobic surface and the liquid DNA solution (II). This meniscus provides a constant force along the length of the DNA that yields evenly stretched molecules irrespective of sequence content (III). When the DNA is completely removed from the reservoir, it is immobilised in its stretched form (IV). The end product is a surface that is coated by stretched single DNA molecules (C). Bar: 20 µm.

7. Incubate at 37°C overnight. Once completed, store at –20°C.

2. Probe Labeling with Digoxigenin-11-dUTP

Steps

1. The Dig High Prime kit contains all the necessary components. Thaw components and keep on ice.
2. Add 1 µg of template DNA and sterile ddH_2O to a final volume of 16 µl.
3. Denature DNA by boiling for 10 min.
4. Chill on ice for a further 10 min.
5. Add 4 µl of Dig High Prime solution that contains random primers, dNTPs including digoxigenin-11-dUTP, and Klenow enzyme. Mix well with a pipette and spin quickly to collect the reaction mix.
6. Incubate at 37°C overnight. Once completed, store at –20°C.

G. Slide Preparation for Hybridization and/or Fluorescent Detection of DNA Replication

Solutions

1. *1× PBS*: See Section III,B. Keep at 4°C.
2. *1 M NaOH*: For 50 ml, dissolve 2 g of NaOH in 50 ml of sterile ddH_2O. Keep at room temperature and replace every 2 weeks.
3. *70, 90, and 100% ethanol (EtOH) dilution series*: Keep at –20°C

Steps

1. Remove slides to be used from –20°C and leave at room temperature for 1 h.
2. Place slides in 1 *M* NaOH for 30 min to denature combed DNA.
3. Rinse three times in 1× PBS from 4°C fridge and once for 3 min to neutralise the NaOH.
4. To help fix DNA, put slides through 70, 90, and 100% EtOH series for 5 min at each dilution.
5. Remove excess EtOH with a Kim Wipe and air dry at room temperature. Use slides immediately once dried (go to Section III,H step 11 or, if only detecting replication, proceed directly to fluorescent detection protocols and use Table No. 5 in Table I).

H. Hybridization and Posthybridization Washes

Solutions

1. *3 M NaAc, pH 5.2*: For 1 litre, add 246.1 g of NaAc to 800 ml of sterile ddH_2O and adjust pH to 5.2 using glacial acetic acid. Bring volume to 1 litre, autoclave, and store at room temperature.

TABLE I Probes, Labels, and Detection[a]

1. Dig and Biot probes and two replication labels: Four colour detection

Layers→	1	2	3	4
Dig (GR)	shαdigF	dαsh488		
Biot (IR)	SAV750	rbαSAVB	SAV750	
IdU (BL)			mαBrdU	gαm350
CldU (RD)			rαBrdU	dαrTR

2. Biot probes, two replication labels: Three colour detection

Layers→	1	2	3
Biot (GR)	SAV488	rbαSAVB	SAV488
IdU (BL)	mαBrdU	gαm350	dαg350
CldU (RD)	rαBrdU	dαrTR	

3. Dig and Biot probes, one replication label: Three colour detection

Layers→	1	2	3
Dig (GR)	shαdigF	dαsh488	
Biot (BL)	SAV350	rbαSAVB	SAV350
CldU (RD)	rαBrdU	dαrTR	

4. Dig and Biot probes: Two colour detection

Layers→	1	2	3
Dig (GR)	shαdigF	dαsh488	rbαdF
Biot (RD)	SAV594	rbαSAVB	SAV594

5. Two replication labels: Two colour detection

Layers→	1	2
IdU (GR)	mαBrdUF	gαm488
CldU (RD)	rαBrdU	dαr594

[a] Fluorophores or biotin conjugated to an antibody is represented by their symbol following the antibody abbreviation. Biot, biotin-labelled probe; Dig, digoxigenin-labelled probed; BL, blue; GR, green; RD, red; IR, infrared; α, anti; m, mouse; r, rat; rb, rabbit; g, goat; sh, sheep; d, donkey; SAV, streptavidin; 350, Alexafluor 350; 488, Alexafluor 488; 594, Alexafluor 594; 750, Alexafluor 750; TR, Texas red; F, FITC; and B, biotinylated.

2. *100% ethanol at –20°C*
3. *Hybridisation buffer: 50% formamide, 10% w/v dextran sulfate, 2XSSC, and 0.1% SDS.* To make 1 ml, add 500 µl of formamide, 200 µl of 50% dextran sulfate solution, 100 µl of 20× SSC, and 10 µl of 10% SDS solution to 190 µl sterile ddH_2O. Store at –20°C for up to one month.
4. *50% formamide/2× SSC*: For 1 litre, dilute 100 ml of 20× SSC in 400 ml sterile ddH_2O. To this add 500 ml of formamide. Solution can be stored in dark at 4°C for 1 month.

5. *2× SSC*: For 1 litre, add 100 ml of 20× SSC to 900 ml of sterile ddH_2O

Steps

1. Chill to 4°C a centrifuge for 1.5-ml Eppendorfs that can reach a speed of 15,000 rpm.
2. In a 1.5-ml Eppendorf add 1 µg of each probe, 5× the total probe amount of human 1× cot DNA, and 1 µl of herring sperm stock. Bring to a final volume of 50 µl with sterile ddH_2O. Vortex and centrifuge briefly.
3. To precipitate DNA, add 5 µl of 3 *M* NaAc, pH 5.2, and 150 µl of –20°C EtOH. Vortex and spin.
4. Put at –80°C for 30 min to complete precipitation.
5. Spin at 15,000 rpm in the 4°C chilled centrifuge for 30 min to pellet the DNA.
6. Remove the supernatant, not touching the white pellet, and air dry.
7. Once the pellet starts to turn translucent, add 25 µl of hybridisation buffer.
8. Vortex for 20 s to thoroughly mix. Spin briefly.
9. Place Eppendorf in boiling water for 5 min to denature DNA.
10. Immediately place in ice water for 10 min. Probes are ready for hybridisation.
11. Take slide from Section III,G step 5. Place probe/hybridisation mix on surface and cover with a Hybri-slip (light-weight plastic coverslip).
12. Place the slide in the HybChamber and add 50 µl of 2× SSC to the reservoir to prevent evaporation of the probe during incubation.
13. Close the HybChamber and incubate overnight at 42°C.
14. The following day remove 50% formamide/2× SSC from 4°C and leave at room temperature for 1 h.
15. Remove the slide from the HybChamber and carefully displace the Hybri-slip with tweezers.
16. In a fume hood, wash three times in 50% formamide/2× SSC 5 min each.
17. Wash three times in 2× SSC for 3 min each. Slides are ready for detection with fluorescent antibodies.

I. Detection with Fluorescent Antibodies

Solutions

1. *1× PBS*: See Section III,B and make 1 litre
2. *1× PBS 0.05% Tween 20*: For 1 litre, add 500 µl of Tween 20 to 1 litre of 1× PBS. Store at room temperature indefinitely.
3. *Detection buffer: Blocking reagent 1% (w/v) in 1× PBS 0.05% Tween 20*. For 100 ml, dissolve 1 g of blocking reagent in 100 ml 1× PBS 0.05% Tween 20 by heating and mixing alternatively. Autoclave and store 1-ml aliquots at –20°C.
4. *Antibody stocks*: All antibodies are prepared and stored according to the manufacturer's instructions. When received in powder format and where instructions are not indicated, dissolve antibodies in 1× PBS to give a concentration of 2 mg/ml. Store these diluted antibodies at –20°C in single-use aliquots.

Steps

The following steps are repeated for each layer (except for step 9 which ends the detection). Refer to Table 1 for antibodies used to detect replication and/or probes.

1. Immediately prior to use, thaw antibody aliquots, mix with a pipette, and spin briefly.
2. Dilute 1 µl of each antibody used for a layer in 25 µl of detection buffer. The only exception to this rule is mouse anti-BrdU (FITC), which is diluted 5:25.
3. Mix antibody mix with a pipette and spin briefly.
4. Place the antibody mix on the surface and cover with a glass coverslip.
5. Put in a humid chamber and leave at 37°C for 30 min. The only exception is the primary antibody layer to detect CldU and/or IdU, which is carried out at 37°C for 1 h.
6. Gently remove the coverslip by giving the slide a shake.
7. Wash slides three times in 1× PBS 5 min each.
8. Proceed to the next layer.
9. When finished washing the final layer, mount slides in Slowfade Light antifade mounting media and seal with nail polish (Fig. 3).

IV. COMMENTS AND PITFALLS

A. Coverslip Silanisation for Molecular Combing

1. DNA binding, a constant stretching force, the immobilisation of DNA, and its availability for further manipulation are all critically dependent on optimal glass silanisation. If the various cleaning steps (pirana, ozone) are not carried out properly, irregularities on the glass may cause poor silanisation. Furthermore, before putting the coverslips in the reaction vessel, slides must be completely dry, as wetness may also cause heterogeneous silanisation. When opening the ports for the syringe containing the silane, care must be taken to be as quick as possible, as contamination of the vessel by the surrounding air can affect the silanisation process.

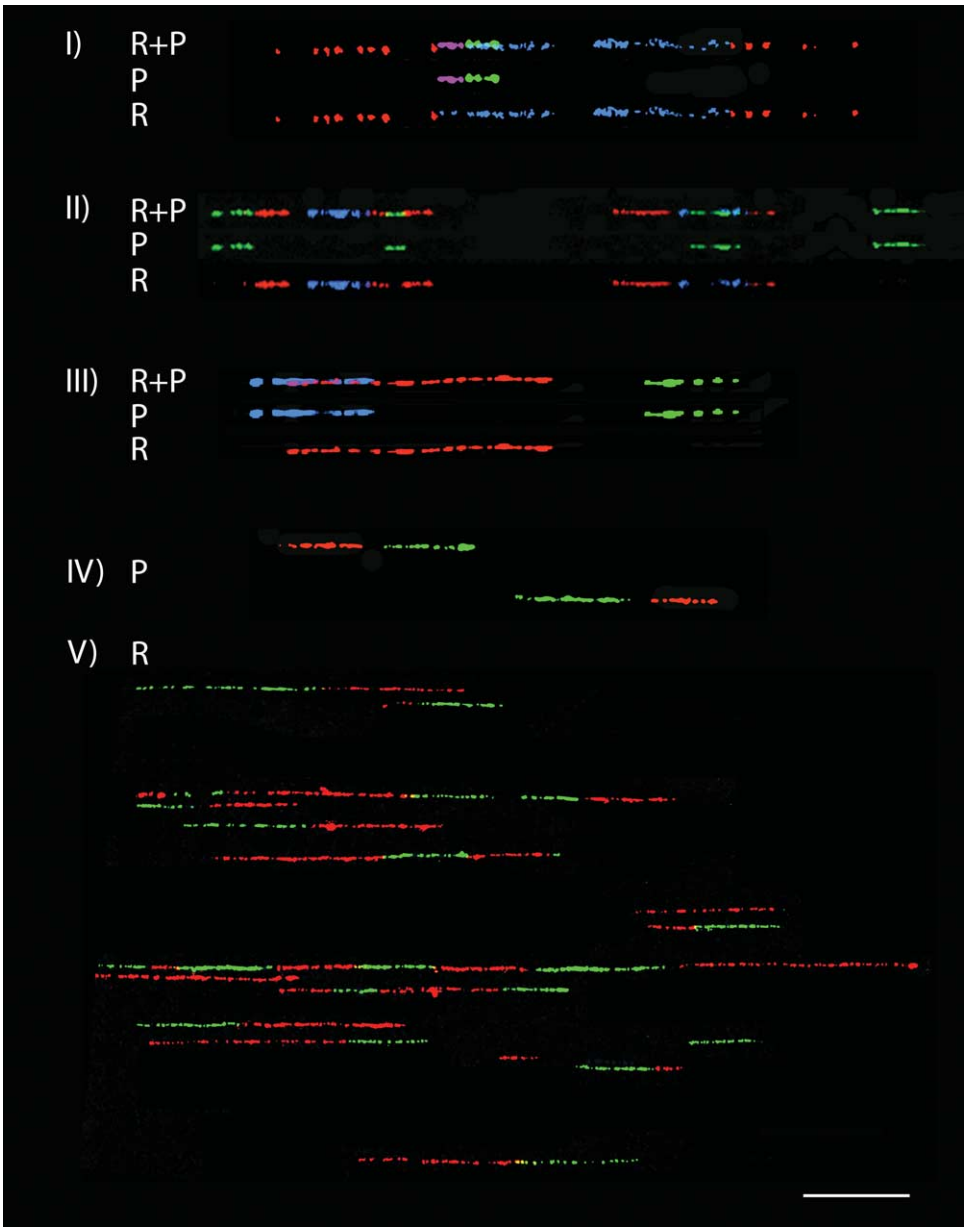

FIGURE 3 Results from all detection schemes. The first molecule in the triad found in I, II, and III are probes (P) and replication (R) together. This molecule has been decomposed digitally to provide probe and replication signals only (we have done this because looking at P + R together can be confusing). In IV, two probe sets on different molecules with different orientation are provided as they were found on the same field of view. A typical field of view with the 40× objective of DNA replication using the paradigm outlined in this article is shown (V). See Table I for details on what colours represent. Bar: 25 µm.

2. The materials used for coverslip preparation have been chosen because they are easy to clean and are chemically inert.

B. Preparing High Molecular Weight DNA in Agarose Blocks

1. The protocol given is for mammalian tissue culture cells only (for yeast, see Lengronne *et al.*, 2001).

2. In step 9, putting the cell suspension at 37°C for 5 min is required to raise the temperature sufficiently so that upon addition of molten agarose the agarose will not solidify before dispensing into blocks.

C. Labeling DNA for Replication Studies

1. Yeast DNA can be labelled by using a specific strain and some modified protocols (Lengronne *et al.*, 2001).

2. DNA replication protocols provided are for double labelling DNA from an asynchronous population of cells. Data obtainable from this type of labelling paradigm are origin position (when a region is localised using fluorescent hybridisation), interorigin distance, timing of firing of neighbouring origins, fork speed, and obstacles to fork progression (Anglana *et al.*, 2003). Time of labelling and synchronisation can be personalised according to needs.

3. It can be difficult to dissolve IdU and CldU in 1× PBS. The manufacturer recommends a basic solvent; however, addition of 1× PBS to cell culture when labelling cells is much less harsh to cells. Vortex and heat to 37°C to fully dissolve the nucleotides in 1× PBS.

4. When preparing for an experiment, only heat the correct amount of IdU and CldU to avoid degradation of the stock.

5. When mixing IdU and CldU with a suspension cell culture, mix well to evenly disperse the nucleotide. Do not mix with too much vigour so as not to break the cell–cell attachments with which many suspension cultures form and need to grow. In this way cells are not shocked during labelling and will proceed normally through S phase, providing robust DNA replication results.

6. It is important to be efficient when carrying out all steps after $t = 0$, as tardiness can affect the time of nucleotide incorporation and, therefore, how interpretable results are.

D. Putting DNA in Solution, Ready for Combing

1. Optimal DNA binding to the slides is achieved at pH 5.5 (Allemand *et al.*, 1997). Precision in combing buffer preparation is needed.

2. If sediment forms during MES preparation, filter the buffer using a sterile syringe and a 0.2-μ*m* filter. Store the MES combing solution at room temperature.

3. When preparing DNA with replication labels, protect from light whenever possible, i.e., wrap the tube in aluminium when washing out proteinase K and SDS. Labeled DNA is sensitive to light and omission of light protection can lead to shorter molecules.

4. Once the agarose has been melted, DNA is no longer protected from physical agitation. To attain the highest molecular weight DNA possible, avoid knocking the tube, handling it violently, or adding any solutions by a pipette quickly.

5. When adding the β agarase buffer or the β agarase itself, do not vortex or mix with a pipette as this will greatly shear the DNA. Allow the buffer and enzyme to naturally diffuse throughout the molten agarose/DNA mix.

6. It is critical that MES buffer is added as slowly as possible, as the currents generated are known to break DNA.

7. Teflon reservoirs are used because they do not absorb DNA and are easy to clean.

E. Molecular Combing

1. The combing machine needs to remove the coverslip at a constant rate of 300 μm/s. This speed generates the constant perpendicular force of the meniscus that aligns and stretches the DNA. Because it is not greater than the force needed to break the double helix, the combing process in itself is not responsible for short DNA molecules. Nonsterile materials at any step during DNA preparation and excessive physical agitation are the principal causes for DNA shearing. Avoid both whenever possible to attain the longest possible length of combed DNA.

2. When visualising the combed DNA under a microscope, an inverted microscope is preferred, as only one side is dirtied. The other side is preserved for use in hybridisation and fluorescent detection.

3. The density of combed DNA is a function of the concentration of the DNA solution. The 250,000 genomes that are used per combing solution yield approximately 100 genomes per 22 × 22-mm surface. This is an optimal combing density for physical mapping and genomic structure studies, as a maximum number of probes can be scored with one slide. For DNA replication studies, however, a lower combing density is required to minimise the occurrence of overlapping replication signals that can confuse results. This is achieved by starting with only one-third to one-half of an agarose block when preparing DNA. The approximately 100,000 genomes provide an optimal combing density for DNA replication studies corresponding to about 30 genomes per 22 × 22-mm surface.

4. Combing density can be increased slightly by repeatedly combing on the same slide and decreased by reducing the incubation time prior to removing the coverslip. However, more or less agarose blocks can equally be reprepared to suit the researcher's needs.

F. Labeling Probes with Biotin and/or Digoxigenin

1. Because maximal resolution on combed DNA is 1–4 kb, it is not recommended to use probes smaller than 4 kb. Aside from this, there are essentially no limits as to what is selected as a probe, i.e., PCR product, cosmid, BAC, and/or YAC.

2. Holes may appear in the hybridisation signal when repeats are covered with competitor Cot DNA

(included in the hybridisation mix). A 20% repeat content for the probe is acceptable and attempts should be made to not exceed this value.

3. To estimate probe concentration and to quickly determine whether random primed labelling worked, run an electrophoretic gel. Compare band intensity to control DNA ladders to estimate the concentration of DNA products. Reaction products should appear between a few hundred to a couple thousand base pairs. If bands appear near the size of the DNA template, the random primed labelling did not work.

4. Poor hybridisation signals can be due to a low amount of biotin and digoxigenin hapten incorporation during random primed labelling. To check for probe labelling, on a Hybond N+ membrane, spot 1 µl of a probe dilution series next to a similar dilution series of control biotin/digoxigenin DNA (biotin control DNA is included in the BioPrime kit). Incubate with sheep antibiotin/digoxigenin alkaline phosphatase. Use NBT/BCIP components in the alkaline phosphatase substrate kit IV to visualise spots. Probes are well labelled if the spot intensity is similar to that of the control DNA.

G. Slide Preparation for Hybridization and/or Fluorescent Detection of DNA Replication

1. When denaturating DNA on a slide and fixating DNA, fill a plastic polypropylene jar for slides with 50 ml of the corresponding solutions. These jars and this volume are used for any of the slide washings in all protocols listed in this article.

2. If carrying out hybridisation on combed DNA, probe and slide preparation should be timed so that they are both ready for use at the same time. To help ensure that this is achieved, step 5 in Section III,G should coincide with step 10 in Section III,H. If slides are initially put at room temperature and if both protocols proceed according to the times indicated this will happen. If there is a time difference in the two preparations, it is not recommended to shorten incubation or procedure times. If the probes are being prepared more quickly than the slides, they can be left at –80°C, centrifuged, and/or left sitting in the hybridisation buffer for longer times. If slide preparation is proceeding faster than expected, slides can be left at room temperature and/or fixed in EtOH for longer periods of time.

H. Hybridization and Posthybridization Washes

1. The advantage of including dextran sulfate in the hybridisation buffer is to increase the hybridisation efficiency of the probe. However, this additive can result in large fluorescent background spots that may obscure signals on the slide. The background level can vary from slide to slide and it is the decision of the researcher as to whether the noise is tolerable. An optional hybridisation buffer containing 50% formamide, 33% detection buffer, 10 m*M* NaCl, 0.5% SDS, and 0.5% *N*-lauroyl sarcosyl was developed to overcome this problem. Because there is no dextran sulfate, large fluorescent background spots are absent from the slide but hybridisation is less efficient. Proteins and higher concentrations of detergents are included to prevent nonspecific binding of the probe to the slide, thereby increasing its availability for hybridisation. This buffer has been used successfully and it is once again the researcher's decision as to whether this option is suitable.

2. The hybridisation temperature of 42°C is standard for hybridising probes on combed DNA. However, the temperature can be tailored to successfully hybridise various probes of different size and sequence content.

I. Detection with Fluorescent Antibodies

1. The antibodies have been chosen according to their specificity and sufficient signal brightness on single DNA molecules. Antibodies that have been added or substituted in the various schemes will improve the brightness of the signal. However, they are only compatible with the antibodies for a given detection scheme.

2. The green signal in all schemes has been designed to provide enough brightness so that it can be found using the oculars on the microscope. Use the FITC filter to find signals and then take pictures using the camera with the relevant filters to reveal all fluorophore signals.

3. The stringency of the washing buffer can be increased by washing with 2× SSC 0.05% Tween 20 instead of 1× PBS after each layer. This helps remove nonspecifically bound antibody and, therefore, reduces the background, although true signal intensity is also decreased slightly. If signals are considered not very bright, it is recommended to continue using 1× PBS for washes.

Genomic DNA Microarray for Comparative Genomic Hybridization

Antoine M. Snijders, Richard Segraves, Stephanie Blackwood, Daniel Pinkel, and Donna G. Albertson

I. INTRODUCTION

DNA copy number aberrations are characteristic of many human cancers as well as developmental abnormalities. Array comparative genomic hybridization (CGH) can be used to quantitatively and precisely detect these DNA copy number aberrations (Solinas-Toldo *et al.*, 1997; Pinkel *et al.*, 1997). Bacterial artificial chromosome (BAC) clones have proven to yield sufficient signal intensity after hybridization to detect low-level DNA copy number aberrations as well as high-level amplifications (Snijders *et al.*, 2001). Also, when BAC clones are used that are mapped onto the sequence of the human genome, one can link aberrations directly onto the sequence.

However, because BAC clones are single copy vectors, their yield from a bacterial culture is relatively low, making it tedious to produce sufficient quantities of BAC DNA necessary to quantitatively detect DNA copy number aberrations. In addition, reliably depositing high molecular weight BAC DNA can be challenging due to the viscosity of the printing solution caused by the high concentration of the high molecular weight BAC DNA.

This article describes a polymerase chain reaction (PCR)-based method (Klein *et al.*, 1999) for producing large quantities of BAC DNA, which aims at maximizing the representation of each BAC (Snijders *et al.*, 2001). An overview of the procedure is shown in Fig. 1. In short, BAC DNA is cut with a frequently cutting restriction enzyme. Primers are ligated to the overhanging ends created by cleavage of the BAC DNA. A subsequent PCR is carried out to amplify the BAC DNA. Using only a fraction of the first PCR, a second PCR is performed, and this DNA product is made into spotting solution. This article also describes the DNA labeling and hybridization protocols used to obtain highly reproducible and quantitative data.

II. MATERIALS AND INSTRUMENTATION

A. Preparation of BAC DNA Spotting Solutions

10× One-Phor-All Buffer Plus [100 m*M* Tris–acetate (pH 7.5), 100 m*M* magnesium acetate and 500 m*M* potassium acetate] is from Amersham Pharmacia Biotech Inc. (Cat. No. 27-0901-02) and is stable at 4°C

*Mse*I restriction enzyme (50 U/µl) is from New England Biolabs (Cat. No. R0525M). Store at –20°C. Store on ice when in use return to –20°C as soon as possible.

20–500 ng of BAC DNA with minimal contamination from host DNA. A Qiagen plasmid minikit (Cat. No. 12125) can be used to purify BAC DNA by following a modification of the manufacturer's protocol (see Comment 1)

0.2-ml polypropylene PCR eight-tube strips with separate eight-cap strips (Cat. No. 1402-2700) and 96-well plate seal (Cat. No. 2920-0000) are from USA Scientific

Ultrapure agarose (Cat. No. 15510-027), ATP (10 m*M*) (Cat. No. 18330-019), T4 DNA ligase (5 U/µl) (Cat. No. 15524-041), dATP, dCTP, dGTP, and dTTP (100 m*M* each) (Cat. No. 10297-018) are from Invitrogen. Store ATP, T4 DNA ligase, and dNTPs at –20°C;

Copyright 2006, Elsevier Science (USA).
All rights reserved.

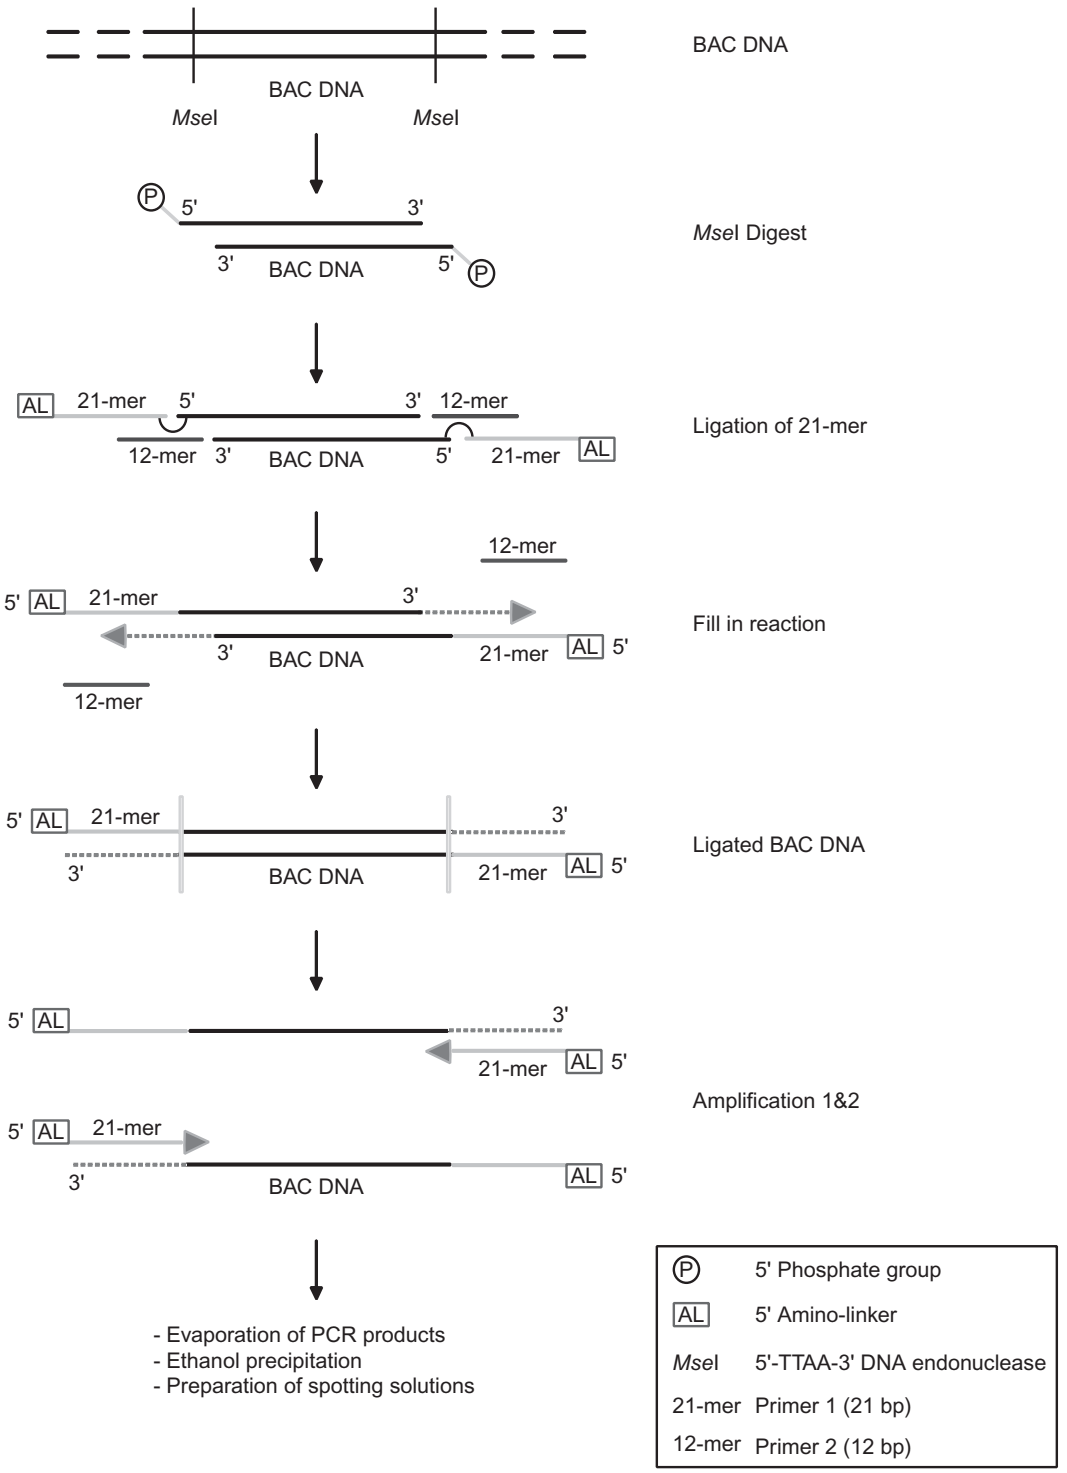

FIGURE 1 Overview of the ligation-mediated PCR procedure. BAC DNA is digested with the *Mse*I restriction enzyme, leaving a 5′-phosphorylated TA overhang. Primers are ligated to these overhangs. The 12-bp primer guides the amino linker containing the 21-bp primer to the overhang where the 21-bp primer is ligated by T4 DNA ligase. Because of the absence of a phosphate group at the 5′ end of the 12-bp primer, it will not get ligated to the BAC DNA. Primer 2 is melted off, after which DNA polymerase fills in the now single-stranded DNA overhang (as indicated with a dashed arrow). The now double-stranded, BAC DNA fragments are PCR amplified using a high-fidelity DNA polymerase; excess primer 2 from the ligation reaction will prime the reaction. A fraction of this ligation-mediated PCR is amplified in a second PCR reaction, which will be made into spotting solution.

when in use, keep the enzyme on ice. Return to –20°C as soon as possible.

Tris-base (Cat. No. BP152-500), Tris–Cl (Cat. No. BP152-1), boric acid (Cat. No. A74-1) and 1% ethidium bromide solution (1%) (Cat. No. BP1302-10) are from Fisher Scientific

Gel-loading solution (6×) (Cat. No. G7654; stable at 4°C), 3 *M* sodium acetate buffer solution (Cat. No. S7899), EDTA (Cat. No. E5134), and dimethyl sulfoxide (Cat. No. D8418) are from Sigma

φ X174 RF DNA/*Hae*III marker is from Promega (Cat. No. G1761)

Primer 1: 5′-AGT GGG ATT CCG CAT GCT AGT-3′ containing a 5′ amino linker (250 n*M* scale, HPLC purified) and primer 2: 5′-TAA CTA GCA TGC-3′ (100 n*M* scale, HPLC purified) are from IDT

Expand long template PCR system is from Roche (Cat. No. 1681842). Store at –20°C. Store on ice when in use; return to –20°C as soon as possible.

Reagent reservoirs with divider (Cat. No. 8095) and without divider (Cat. No. 8093) are from Matrix Technologies Corp.

10× *Taq* buffer II containing no $MgCl_2$, $MgCl_2$ (25 m*M*), and AmpliTaq Gold DNA polymerase (5 U/μl) are from PE Applied Biosystems (Cat. No. N8080245). Store at –20°C; when in use keep the enzyme on ice. Return to –20°C as soon as possible.

Ethyl alcohol (200 proof) is from Rossville Gold Shield Chemical Co.

Adjustable single channel pipettors are from Rainin (Cat. No. Gilson Pipetman P20, P200, P1000) and Eppendorf (Reference series 2000, Cat. No. 022470001)

Adjustable 8- or 12-channel multichannel pipettors are from Matrix Technologies (Cat. No. 6019, 0.5–12.5 μl; 6012, 5–250 μl; 6004, 15–1250 μl)

PCR machine capable of ramping at approximately 1.3°C/min is from PE Applied Biosystems (Model 9700, Cat. No. 4314878)

Electrophoresis power supplies (Cat. No. FBTIV816A) and UV transilluminator are from Fisher Scientific (Cat. No. FB-105)

Electrophoresis gel boxes are from USA Scientific (Cat. No. 3431-4000)

Fluorometer is from Bio-Rad (Versafluor, fluorometer, Cat. No. 170-2402)

Fan oven is from Techne (Model Hybridiser HB-1D)

Microwave is from General Electric

B. BAC Array-Based Comparative Genomic Hybridization

BioPrime DNA labeling systems (Cat. No. 18094011) [containing 2.5× random primers and Klenow fragments (40 U/μl)], dNTP solutions (100 m*M* each) (Cat. No. 10297-018), salmon sperm DNA (1 mg/ml) (Cat. No. 15632-011), and redistilled, ultrapure formamide (for preparation of hybridization mixture) (Cat. No. 15515-026) are from Invitrogen and stored at –20°C. Store Klenow fragments on ice when in use and return to –20°C as soon as possible.

Cy3 (Cat. No. PA53021)- and Cy5 (Cat. No. PA55021)-labeled dCTP (1 m*M*) are from Amersham Pharmacia Biotech Inc. Store at –20°C.

Tris base (Cat. No. BP152-500), dextran sulfate (Cat. No. BP1585-100), SDS (Cat. No. 5525-087), glycerol (Cat. No. BP229-1), formamide (for preparation of array wash solution) (Cat. No. F84-1), coverslips (24 × 50 mm) (Cat. No. 12531F), syringe (10 ml) (Cat. No. 14-823-28), monobasic monohydrate sodium phosphate (Cat. No. S369-500), dibasic heptahydrate sodium phosphate (Cat. No. S373-500), and microscope slides (Cat. No. 12-518-100B) are from Fisher Scientific.

Sephadex G-50 spin columns are from Amersham Pharmacia Biotech Inc. (Cat. No. 27-5330-01)

Human Cot-1 DNA is from Roche (Cat. No. 1581-074). Store at –20°C.

20× SSC (Cat. No. S6639), EDTA (Cat. No. E5134), DAPI stain (1 m*M*) (Cat. No. D9542) (store at –20°C), and 3 *M* sodium acetate buffer solution (Cat. No. S7899) are from Sigma

Ethyl alcohol (200 proof) is from Rossville Gold Shield Chemical Co.

Rubber cement is from Office Depot (Cat. No. 129791)

Silicone gasket (Press-to-Seal) is from PGC Scientific (Cat. No. 49698)

Binder clips are from OfficeMax (Cat. No. OM-211)

PBS (pH 7.4) lacking Ca^{2+} and Mg^{2+} is from the UCSF Cell Culture Facility (Cat. No. BG200). Store at 4°C.

Nonidet P-40 is from Fluka (Cat. No. 74385)

Slides for printing arrays (Corning GAP) are from VWR (Cat. No. 18888-302)

Adjustable single channel pipettors are from Rainin (Cat. No. Gilson Pipetman P20, P200, P1000)

UV Stratalinker 2400 is from Stratagene (Cat. No. 400676)

Rocking table (Cat. No. 40000-300) and 37°C incubator (Cat. No. 35824-756) are from VWR

Stereomicroscope is from Leica (Model MZ8)

III. PROCEDURES

Procedures for the preparation of spotting solutions are described in Sections III,A–III,E and are summarized in Fig. 2. Section III,F describes the labeling and hybridization procedure.

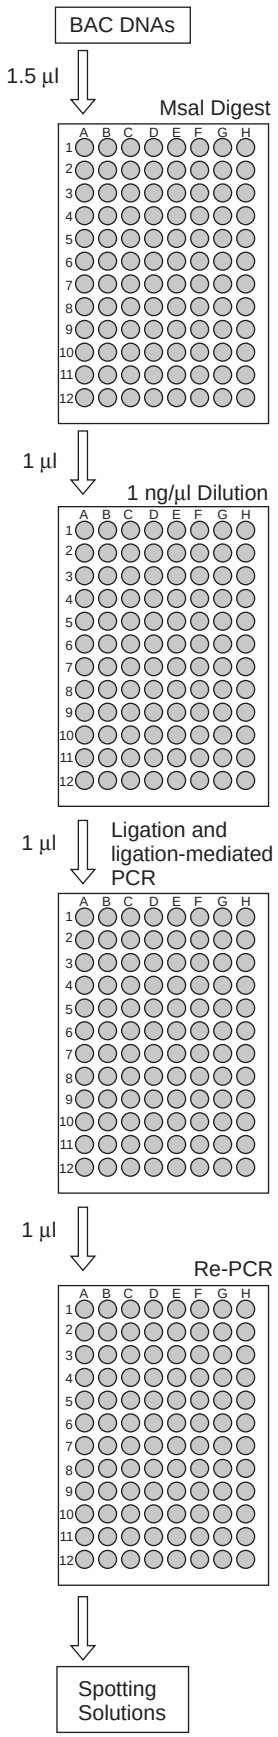

FIGURE 2 Flowchart of the ligation-mediated PCR procedure for 96 BAC clones. BAC DNA (1.5 µl) is digested. One microliter of each digest reaction is diluted to 1 ng/µl in H_2O. Note that due to varying BAC DNA concentrations, the amount of H_2O necessary to dilute 1 µl of digest reaction to 1 ng/µl can vary. A ligation and subsequent PCR reaction are performed using 1 µl (which equals 1 ng) of BAC DNA. A fraction (1 µl) of the ligation-mediated PCR is now reamplified in a second PCR reaction, which will be made into spotting solution.

A. Restriction Enzyme Digest of BAC DNA

The restriction enzyme digest is carried out in a 5-µl reaction volume containing 2.2× One-Phor-All Buffer Plus, 5 U *Mse*I restriction enzyme, and 20–500 ng BAC DNA.

Solutions

1. *Restriction enzyme buffer dilution:* Dilute the 10× One-Phor-All Buffer Plus to a final concentration of 0.8× in a final volume of 750 µl using sterile H_2O. Dispense 93 µl into each tube of an 8-tube strip. Leftover dilution can be stored at 4°C.
2. *Restriction enzyme diluion:* Dilute the *Mse*I restriction enzyme to a final concentration of 5 U/µl in a volume of 120 µl using 10× One-Phor-All Buffer Plus. Keep both the enzyme and the dilution on ice during this process. Return the enzyme to –20°C promptly after making the dilution and discard leftover dilution.
3. *TBE; electrophoresis buffer:* 0.089 *M* Tris–borate, 0.089 *M* boric acid, 0.008 *M* EDTA. To make 10 liters, dissolve 108 g Tris base, 55 g boric acid, and 40 ml 0.5 *M* EDTA (pH 8.0) in distilled H_2O. After dissolving, make up to 10 l with distilled H_2O. Store at room temperature.
4. *1% agarose solution:* Dissolve 1 g agarose per 100 ml of electrophoresis buffer. Mix and microwave until boiling and add ethidium bromide to a final concentration of 0.5 µg/ml.

Steps

1. Dispense 2.5 µl of the r*estriction enzyme buffer dilution* into each tube of twelve 8-tube PCR strips using a multichannel pipettor. Seal the tubes using a 96-well plate seal to prevent evaporation and possible contamination (see Comment 2).
2. Using a single channel pipettor (see Comment 3), add 1.5 µl BAC DNA (see Comment 1) to each tube. Only one 8-tube strip is handled at a time during this step. Keep the remaining eleven 8-tube strips covered using a 96-well plate seal. After adding the BAC DNA to each 8-tube strip, place the strip into a second 96-well plate rack and seal with a 96-well plate seal.

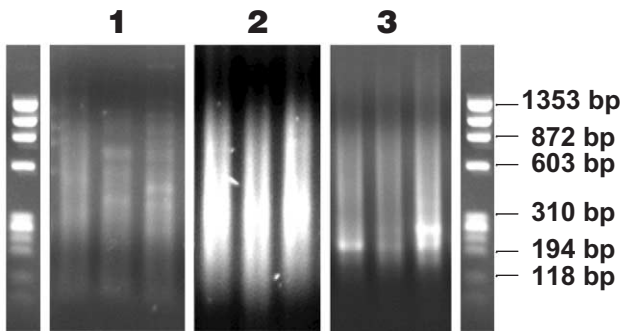

FIGURE 3 Agarose gel analysis of ligation-mediated PCR process. (1) Typical size range and DNA distribution of three *Mse*I digest reactions. (2) Three ligation-mediated PCR products. (3) Three Re-PCR reactions. All samples were run on a conventional 1% agarose gel containing 0.5 µg/µl ethidium bromide together with a φ X174 RF DNA/*Hae*III DNA marker, which has a size range from 72 to 1353 bp.

3. Dispense 1 µl of the *MSE*I *restriction enzyme dilution* into each tube using a single channel pipettor. Cap each 8-tube strip using an 8-cap strip and place on ice after adding the enzyme. The *restriction enzyme dilution* should stay on ice during this process.

4. Place the reaction into a PCR machine for an overnight incubation at 37°C, typically 12–16 h.

5. 1.75 µl of the digest reaction can be run on a conventional 1% agarose gel containing 0.5 µg/µl ethidium bromide along with a φ X174 RF DNA/*Hae*III marker to check fragment length. Sizes should range from 100 to 1500 bp (Fig. 3).

B. Ligation of Specific Primers to BAC DNA

The ligation reaction is carried out in a 10-µl reaction volume containing 5 µ*M* primer 1, 5 µ*M* primer 2, 0.5× One-Phor-All Buffer Plus, 1 m*M* ATP, 5 U T4 DNA ligase, and 1 ng digested BAC DNA.

Solutions

1. *TE:* 10 m*M* Tris–Cl (pH 7.4), 1 m*M* EDTA (pH 8.0). To make 100 ml, mix 1 ml 1 *M* Tris–Cl (pH 7.4) and 200 µl 0.5 *M* EDTA (pH 8.0) and make up to 100 ml with distilled H_2O. Autoclave to sterilize and store at room temperature.

2. *Primer 1*: 5′-AGT GGG ATT CCG CAT GCT AGT-3′ containing a 5′ amino linker. For stock solution, dissolve primer in TE (pH 7.4) to 500 µ*M*. For working solution, dilute stock solution to 100 µ*M* in distilled water. Store primer, stock solution, and working solution at –20°C.

3. *Primer 2*: 5′-TAA CTA GCA TGC-3′. For stock solution, dissolve primer in TE (pH 7.4) to 500 µ*M*. For working solution, dilute stock solution to 100 µ*M* in distilled water. Store primer, stock solution, and working solution at –20°C.

4. *Ligation solution*: Mix 56 µl primer 1, 56 µl primer 2, 56 µl One-Phor-All Buffer Plus, and 616 µl sterile water. Dispense 98 µl into each tube of an 8-tube strip. Store on ice.

5. *ATP solution*: Dispense ~62.5 µl of 10 m*M* ATP solution into each tube of an 8-tube strip. Cap with an 8-cap strip and keep on ice when in use. Store at 4°C.

Steps

1. Dilute 1 µl of each of the restriction digests to 1 ng/µl using sterile H_2O. Calculate the amount of sterile H_2O required to dilute 1 µl of each digest to a final DNA concentration of 1 ng/µl [e.g., if the BAC DNA concentration in the digest reaction is *X* ng/µl, the appropriate amount of sterile H_2O to add is (*X*-1) µl] (see Comment 4). Set up twelve new 8-tube strips: individually add the calculated amount of sterile H_2O to each new tube at the locations corresponding to the locations of each digest. Transfer 1 µl of each digest using a multichannel pipettor. Cover using a 96-well plate seal.

2. Dispense 7 µl of the *ligation solution* onto the bottom of twelve new 8-tube strips using a multichannel pipettor (see Comment 5). Seal the 8-tube strips using a 96-well plate seal.

3. Add 1 µl of the 1 ng/µl BAC DNA digest to the 7 µl *ligation solution* in each corresponding 8-tube strip (see Comment 6).

4. Place the twelve 8-tube strips into a PCR machine. Carry out the annealing reaction at 65°C for 1 min and then shift the temperature down to 15°C, with a ramp of ~1.3°C/min (in a Perkin-Elmer 9700 PCR machine this is a ramp rate of 5%).

5. As soon as the PCR machine reaches 15°C, promptly take out the tubes from the PCR machine and carefully open all 8-tube strips, including the 8-tube strip containing the ATP solution. Using a multichannel pipettor on the repeat pipetting mode, pick up 12.5 µl of 10 m*M ATP solution* and dispense 1 µl on the inside wall of each of the 96 tubes containing DNA. Gently tap the PCR rack so that the ATP slides into the DNA/primer solution. Seal with a 96-well plate seal. This procedure for adding the ATP reduces the probability of carryover contamination.

6. Using a single channel pipettor, dispense 1 µl of DNA T4 ligase enzyme (5 U) into each of the 96 tubes.

7. Place the reaction in a PCR machine for an overnight incubation at 15°C, typically 12–16 h.

C. Ligation-Mediated PCR

The ligation-mediated PCR is carried out in a reaction volume of 50 µl containing 0.6× 10×PCR buffer 1, 0.4 m*M* dNTP mixture, 3.5 U DNA polymerase mixture, and 10 µl ligation mixture (Section III,B).

Solutions

1. *10 mM dNTP solution*: For 250 µl, mix 25 µl of each of the nucleotide stock solutions (100 m*M* each) with 150 µl sterile H_2O. Keep on ice when in use, otherwise store at –20°C.
2. *PCR mix*: For 96 samples, mix 336 µl 10× PCR buffer 1, 224 µl *10 mM dNTP solution*, and 3920 µl sterile H_2O. Mix briefly by vortexing and place on ice.
3. *TBE; electrophoresis buffer:* 0.089 *M* Tris–borate, 0.089 *M* boric acid, 0.008 *M* EDTA. To make 10 liters, dissolve 108 g Tris base, 55 g boric acid, and 40 ml 0.5 *M* EDTA (pH 8.0) in distilled H_2O. After dissolving, complete to 10 liters with distilled H_2O. Store at room temperature.
4. *1% agarose solution:* Dissolve 1 g agarose in 100 ml TBE. Mix and microwave until the boiling point has been reached and then add ethidium bromide to a final concentration of 0.5 µg/ml.

Steps

1. Remove the ligations from the PCR machine. Pour the *PCR mix* into a reservoir. Uncap all 8-tube strips carefully. Using a multichannel pipettor on the repeat pipetting mode, pick up 205 µl of the diluted dNTP mixture and dispense 40 µl on the inside wall of five subsequent 8-tube PCR strips. Purge the remaining 5 µl PCR mixture back into the reservoir. Discard the pipette tips and repeat this process. For the last two remaining 8-tube strips, pick up 85 µl, while leaving the dispense volume at 40 µl. Dispense 40 µl on the inside wall of the two remaining 8-tube strips. Gently tap the PCR rack so that the diluted dNTP mixture slides into the DNA/primer solution. Seal with 8-tube strips.
2. Place PCR tubes in the PCR machine at 68°C for 4 min to melt off primer 2. After 4 min, take out the tubes and add 1 µl of DNA polymerase mixture (3.5 U/µl) to each tube individually using a single channel pipettor. Open one 8-tube strip at a time and close immediately after adding the enzyme mix and place on ice (see Comment 7).
3. Place the 8-tube strips in the PCR machine: 68°C for 3 min; 94°C for 40 s, 57°C for 30 s, 68°C for 1 min 15 s for 14 cycles, 94°C for 40 s, 57°C for 30 s, 68°C for 1 min 45 s for 34 cycles and 94°C for 40 s, 57°C for 30 s, and 68°C for 5 min for the last cycle, followed by incubation at 4°C (see Comment 8).
4. Run 3.5 µl of each PCR on a conventional 1% agarose gel containing 0.5 µg/ml ethidium bromide along with a φ X174 RF DNA/*Hae*III marker to check fragment length. Size of the PCR product should range from 70 to 2000 bp, with the highest concentration of product around 200 to 800 bp (Fig. 3) (see Comment 9).

D. Re-PCR of Ligation-Mediated PCR

Ligation-mediated PCR is used as a template in a Re-PCR reaction to generate DNA for spotting. Amplification is carried out in a 100-µl reaction containing 1× *Taq* buffer II, primer 1 (4 µ*M*), dNTP mixture (0.2 m*M*), $MgCl_2$ (5.5 m*M*), 2.5 U AmpliTaq Gold, and ligation-mediated PCR product (1 µl).

Solutions

1. *25 mM dNTP solution*: For 250 µl, mix 62.5 µl of each of the nucleotide stock solutions (100 m*M* each). Keep on ice when in use, otherwise store at –20°C.
2. *Primer 1*: 5′-AGT GGG ATT CCG CAT GCT AGT-3′ containing a 5′ amino linker. For stock solution, dissolve primer in TE (pH 7.4) to 500 µ*M*. For working solution, dilute stock solution to 100 µ*M* in distilled water. Store primer, stock solution, and working solution at –20°C.
3. *PCR mix*: For 96 samples, mix 1000 µl 10× *Taq* buffer II, 400 µl primer 1 (100 µ*M*), 80 µl dNTP solution (25 m*M*), 2200 µl $MgCl_2$ (25 m*M*), 50 µl AmpliTaq Gold (5 U/µl), and 6170 µl sterile H_2O. Mix briefly by vortexing and place on ice.
4. *TBE; electrophoresis buffer:* 0.089 *M* Tris–borate, 0.089 *M* boric acid, 0.008 *M* EDTA. To make 10 liters, dissolve 108 g Tris base, 55 g boric acid, and 40 ml 0.5 *M* EDTA (pH 8.0) in distilled H_2O. After dissolving, make up to 10 liters with distilled H_2O. Store at room temperature.
5. *1% agarose solution:* Dissolve 1 g agarose in 100 ml TBE. Mix and microwave until the boiling point has been reached and then add ethidium bromide to a final concentration of 0.5 µg/ml.

Steps

1. Pour the *PCR mix* into a reservoir. Using a multichannel pipettor, dispense 99 µl into each tube of twelve 8-tube strips. Seal using a 96-well plate seal.
2. Add 1 µl ligation-mediated PCR product to each corresponding 8-tube strip using a multichannel pipettor. Do this by unsealing one 8-tube strip of PCR mixture and one 8-tube strip containing the ligation-mediated PCR. Cap the 8-tube strip after adding the template and then cap the 8-tube strip containing the remaining ligation-mediated PCR. Move on to the next 8-tube strip.

3. Place the 8-tube strips, now containing 99 µl PCR mixture and 1 µl ligation-mediated PCR product, in a PCR machine: 95°C for 10 min; 45 cycles at 95°C for 30 s, 50°C for 30 s, 72°C for 2 min and a final extension at 72°C for 7 min, followed by an incubation at 4°C.

4. Run 4 µl of each reaction on a conventional 1% agarose gel containing 0.5 µg/ml ethidium bromide along with a φ X174 RF DNA/*Hae*III marker to check fragment length. Size of the PCR product should range from 200 to 1500 bp (Fig. 3) (see Comment 10).

E. Preparation of Spotting Solutions from Re-PCR Used for Array CGH

Steps

1. Dry down the Re-PCR products to a volume of approximately 50 µl by uncapping the 8-tube strips and placing the PCR rack face up in a hybridization oven set at 45°C (takes approximately 75 min). If you are using an oven in which the heat inlet is biased toward one side of the PCR rack, the rack should be rotated every 15 min to allow even evaporation. Reducing the volume of the Re-PCR is necessary to accommodate the ethanol and sodium acetate for DNA precipitation.

2. Precipitate the PCR products by adding 130 µl prechilled 100% ethanol and 5 µl 3*M* sodium acetate using a multichannel pipettor. Cap the 8-tube strips and invert the rack several times.

3. Chill the PCR rack at –20°C for 15 min.

4. Spin the plate at 1699 *g* for 90 min at 4°C.

5. Remove the supernatant carefully using a multichannel pipettor and add 100 µl 70% ethanol to the pellet using a multichannel pipettor and then recap the tubes.

6. Vortex each 8-tube strip until the pellets come loose. After vortexing all 8-tube strips, centrifuge rack at 1699 *g* for 45 min at 4°C.

7. Remove as much of the 70% ethanol as possible using a multichannel pipettor and dry the pellet at room temperature for approximately 90 min. The time depends on the amount of ethanol left on the pellet. Be careful not to overdry the pellets.

8. Add 15 µl of a 20% DMSO solution to the pellets using a multichannel pipettor. Handled only one 8-tube strip at a time at this stage. Cap the tubes and resuspend by flicking the bottom of the PCR tubes to loosen the pellet and briefly centrifuge.

9. Store the DNA solution at 4°C for an overnight (or longer) incubation. Use a multichannel pipettor to mix the solution until the pellet is completely in suspension. DNA solutions can be stored at 4°C (see Comment 11).

F. Random-Primed Labeling of Genomic DNA for Array CGH Analysis

Random-primed labeling is carried out in a 50-µl reaction volume containing 200–300 ng genomic DNA, 1× random primers, 40 U Klenow DNA polymerase, Cy3- or Cy5-labeled dCTP (40 µ*M*), and 1× dNTP mixture. The random-primed DNA product will typically range in size from 200 to 1500 bp, with the highest concentration around 400 bp.

Solutions

1. *Tris base*: For 1 liter of 1*M* Tris, dissolve 121.1 g Tris base in 800 ml of H_2O. Adjust the pH to 7.4 with concentrated HCl. Make up the volume to 1 liter with H_2O. Sterilize by autoclaving.

2. *EDTA*: For 1 liter 0.5*M* EDTA, add 186.1 g of disodium ethylenediaminetetraacetate·$2H_2O$ to 800 ml of H_2O. Stir vigorously and adjust the pH to 8.0 with NaOH. Sterilize by autoclaving.

3. *10× dNTP mixture*: 2 m*M* each of dATP, dTTP, and dGTP, 0.5 m*M* dCTP, 10 m*M* Tris base (pH 7.6), and 1 m*M* EDTA. For 200 µl 10× dNTP mixture, mix 4 µl each of 100 m*M* dATP, dGTP, and dTTP, 1 µl of 100 m*M* dCTP, 2 µl of 1*M* Tris, 0.4 µl of 0.5*M* EDTA, and 184.6 µl of dH_2O.

Steps

1. Mix ~200–300 ng of genomic DNA with 20 µl of 2.5× random primer solution and make up the volume to 42 µl with sterile H_2O.

2. Denature the DNA by heating the mixture at 99°C in a PCR machine for 10 min. Briefly centrifuge and place on ice.

3. Add 5 µl of the *10× dNTP mixture*, 2 µl of Cy3- or Cy5-labeled dCTP (1 m*M*), and 1 µl Klenow DNA polymerase (40 U/µl). Mix well, briefly centrifuge, and place tube in a PCR machine at 37°C for an overnight incubation.

4. Place the Sephadex G-50 column in a 1.5-ml tube and prespin the column at 730 *g* for 1 min.

5. Place the column in a clean 1.5-ml tube; apply the sample onto the column and spin at 730 *g* for 2 min to remove unincorporated nucleotides from the DNA mixture (see Comment 12).

G. Hybridization of Fluorescently Labeled Genomic DNA for Array CGH Analysis

Solutions

1. *Hybridization mixture*: Distribute 1 *g* of dextran sulfate (sodium salt, 500,000 MW) over the entire length of a 15-ml tube. While holding the tube horizontally, squirt in 5 ml of formamide. Close the tube

and shake vigorously for 30 s. Add 1 ml of 20× SSC and shake vigorously for 30 s. Dissolve overnight at room temperature. Add sterile H_2O to a final volume of 7 ml. The hybridization mixture should be stored in aliquots at –20°C.

2. *Formamide wash solution*: 50% formamide, 2× SSC in H_2O. For 50 ml, mix 25 ml formamide, 5 ml 20× SSC, and 20 ml H_2O, pH 7.0. Prepare fresh.

3. *PN buffer wash solution*: 0.1 *M* sodium phosphate, 0.1% Nonidet P-40, pH 8.0. Prepare 16 liters of 0.1 *M* Na_2HPO_4 and 0.1% Nonidet P-40, pH 9. While continuously measuring the pH, adjust the pH to 8.0 with 0.1 *M* NaH_2PO_4 and 0.1% Nonidet P-40 (approximately 1 liter). Make sure not to go below pH 8.0. Store at room temperature.

4. *DAPI solution*: 90% glycerol, 10% PBS, 1 µ*M* DAPI. For 1 ml, mix 900 µl glycerol, 100 µl PBS, and 1 µl (1 m*M*) DAPI. Vortex and store at –20°C.

Steps

1. Expose a printed array to 260,000 µJ of UV using a Stratalinker (see Comments 13 and 14).

2. Fill a 10-ml syringe with rubber cement and fit a 200-µl pipette tip on the syringe outlet. Apply a rubber cement ring around the array using a stereomicroscope to observe the area of the array. Air dry the rubber cement and apply a second thick layer of rubber cement on top of the first layer. Air dry the rubber cement.

3. Preparation of samples for hybridization to a ~12-mm square. Volumes should be increased for larger area arrays.
   a. Combine 50 µl labeled test genomic DNA, 50 µl labeled reference genomic DNA, and 35 µg (measured by fluorometry) of human Cot-1 DNA. Precipitate the DNA sample mixture with ethanol by adding 2.5 volumes of ice-cold 100% ethanol and 0.1 volumes of 3 *M* sodium acetate (pH 5.2). Mix the solution by inversion and collect the precipitate by centrifugation at 14,000 rpm for 30 min at 4°C.
   b. Carefully aspirate and discard the supernatant. Wipe excess liquid from the tube with a paper tissue, being careful not to disturb the pellet. Air dry the pellet for approximately 5–10 min. Dissolve the pellet in 5 µl sterile H_2O, 10 µl 20% SDS, and 35 µl hybridization mixture (see Comment 15).

4. Preparation of array blocking solution:
   a. Precipitate 50 µl of salmon sperm DNA (10 mg/ml) by adding 2.5 volumes of ice-cold ethanol and 0.1 volume of 3 *M* sodium acetate (pH 5.2). Mix the solution by inversion and collect the precipitate by centrifugation at 6400 rpm for 1–2 min.
   b. Carefully aspirate and discard the supernatant. Wipe excess liquid from the tube with a paper tissue, taking care not to disturb the pellet. Air dry the pellet for approximately 5–10 min. Dissolve the pellet in 5 µl sterile H_2O, 10 µl 20% SDS, and 35 µl hybridization mixture (see Comment 15).

5. Denature the DNA sample solution at 73°C for 10–15 min and incubate at 37°C for ~60 min.

6. Place a silicone gasket around the rubber cement and apply 50 µl of the salmon sperm DNA blocking solution to each array inside the rubber cement ring. Place a clean microscope slide on top to prevent evaporation (Fig. 4). Incubate at room temperature for 30 min.

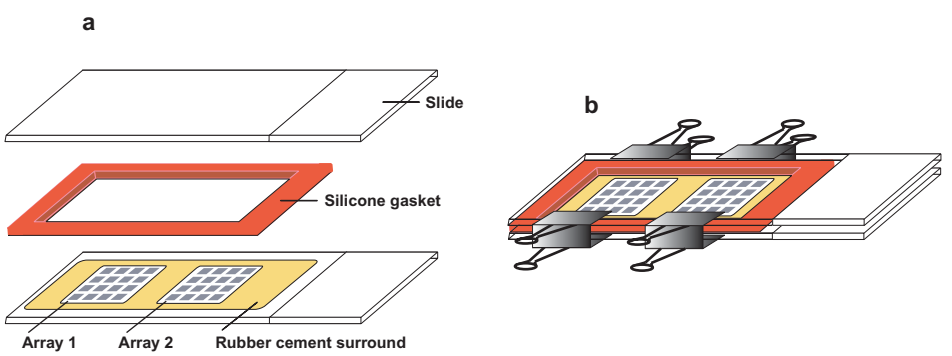

FIGURE 4 Array hybridization slide assembly. A ring of rubber cement is placed closely around each array. After applying the hybridization solution to each array, a silicon gasket is placed around the arrays, partly covering the rubber cement ring. A microscope slide is placed on top of the silicon gasket, and the whole slide assembly is clamped using binder clips. (a) Individual components of the slide assembly. (b) Complete slide assembly, including binder clips.

7. Carefully aspirate ~30–40 µl of salmon sperm hybridization mixture from the array and quickly apply the hybridization solution onto the array (see Comment 16).

8. Place a microscope slide on top of the gasket and clamp the assembly together (Fig. 4). Incubate the array for 1–2 nights at 37°C on a slowly rocking table.

9. Disassemble the slide assembly and rinse the hybridization solution from the slide under a stream of PN buffer.

10. Wash the slides in *formamide wash solution* (50% formamide, 2× SSC, pH 7) for 15 min at 45°C followed by a 15-min wash in *PN buffer wash solution* at room temperature.

11. Carefully remove the rubber cement with forceps while keeping the array moist with PN buffer.

12. If desired, arrays may be mounted in a *DAPI solution* to stain the array spots. Otherwise, rinse with sterile H_2O and allow to air dry.

13. Arrays are ready for imaging (see Comment 17).

IV. COMMENTS

1. BAC DNA is purified from 25-ml cultures using a modification of the Qiagen plasmid minipurification protocol. The volumes of buffers P1, P2, and P3 are increased from 0.3 to 1.5 ml. After adding buffer P3, incubate on ice for 10 min. Centrifuge at 4000 rpm for 45–60 min at 4°C. Filter the supernatant through a 35-µm nylon mesh (available from Small Parts Inc.) prior to loading onto Qiagen-tip 20 columns. Heat buffer QF to 65°C prior to adding it to the column. After elution, add 0.56 µl of isopropanol to the DNA, mix, and store at 4°C overnight. Mix and precipitate the DNA for 45 min at 14,000 rpm at 4°C. Air dry the pellet for 15–30 min. Then dissolve in 50 µl sterile H_2O. The BAC DNA concentration usually ranges from 20 to 400 ng/µl.

2. Roll back the plate seal of the 96-well plate (host plate) containing the digest buffer solution until the first 8-tube strip is exposed. Take out the first 8-tube strip and add BAC DNA to each tube. Place this 8-tube strip in a clean 96-well plate (recipient plate) and place a 96-well plate seal on top of the plate so that it covers the whole plate (one end of the plate seal will cover the 8-tube strip, the other end of the seal will stick to the 96-well plate). Go back to the host plate and roll back the plate seal until the next 8-tube strip becomes exposed. Take out the strip and add BAC DNA to each tube. Partially remove the 96-well plate seal of the recipient plate while leaving the first 8-tube strip covered. While holding the 96-well plate seal in one hand, place the next 8-tube strip in the recipient plate. Reseal the recipient plate and repeat this procedure until all 8-tube strips are done.

3. The use of a multichannel pipettor for pipetting small amounts (~1 µl) of enzyme has not been reliable. We found that by pipetting the enzymes *Mse*I, T4 DNA ligase, and the DNA polymerase mix separately using a single channel pipettor directly into the liquid in each tube has led to more reliable results. When the use of a multichannel pipettor is suggested, it is stated in the protocol.

4. To obtain accurate measurements of DNA concentration, a fluorometer should be used rather than a spectrophotometer.

5. Use a 12.5-µl multichannel pipettor to pick up 8 µl, dispense 7 µl, and throw away the remaining 1 µl and the pipette tips. The use of new pipette tips for each 8-tube strip is encouraged to ensure accuracy.

6. First carefully unseal the BAC DNA dilution plate and then, using a multichannel pipettor, pick up 1 µl of the first 8-tube strip. Unseal only the first 8-tube strip containing the primer solution, pick up the strip, and add the DNA directly into the 7-µl primer solution and cap both 8-tube strips after adding the DNA.

7. The 4-min incubation at 68°C will displace primer 2 (12-mer; T_m = ~40°C). It is essential to swiftly add the DNA polymerase mixture to each 8-tube strip, close the 8-tube strip with a 8-cap strip, and place the strip-tube on ice in order to prevent significant reannealing of primer 2. The subsequent 3-min incubation at 68°C will displace the reannealed primer 2 and extend the, now free, 3′ end of the digested BAC DNA. The process of taking twelve 8-tube strips out of the PCR machine, adding the enzyme mixture to each tube individually, placing the 8-tube strips on ice, and finally placing the 12 8-tube strips back into the PCR machine for amplification should take no longer than 10–15 min.

8. Depending on the type of PCR machine, cycle temperatures and times can be adjusted to obtain optimal results.

9. If a banding pattern appears in the smear, the ligation and/or ligation-mediated PCR has not been successful and should be repeated. All the products should have a smear ranging from 70 to 2000 bp. Any aberration from this smear, i.e., a small smear around 300–600 bp or a high molecular weight smear, is unacceptable and should therefore be discarded.

10. The Re-PCR will most likely have the highest concentration of product around 200–400 bp. The average PCR concentration should be 150 ng/µl as determined with a fluorometer.

11. The final concentration of the spotting solution should be approximately 0.8–1.3 µg/µl. After printing spotting solutions on a glass surface, the spots will

become nearly invisible due to the lack of salt in the spotting solutions. Breathing on the glass slide will make the arrays visible for a short period of time. Printed arrays should be left at room temperature for overnight to dry spots (see Comment 14).

12. The color of the DNA mixture is an indicator of the amount of labeled nucleotide incorporated during the labeling reaction.

13. Place the slide(s) in the Stratalinker, arrays facing up. The arrays should be given a fixed amount of *energy* (260,000 µJ) instead of the other available options the Stratalinker might have, such as *autocrosslink* or *time*. Overcross-linking the slide might result in a decrease in fluorescent hybridization signal (see Comment 14).

14. Depending on the type of slides used for arraying, the properties of the slide surface, as well as slide processing steps, may be different. Always follow manufacturers' recommended guidelines for handling slides. In this protocol the described slide processing steps were developed using, for example, Corning GAP slides.

15. Carefully pipette 5 µl sterile H_2O and 10 µl 20% SDS on the pellet. Incubate at room temperature for ~15 min. Add 35 µl of hybridization mixture while stirring the solution with the pipette tip. Do not dissolve the pellet by pipetting to prevent foam formation due to the presence of SDS.

16. Aspirate the salmon sperm DNA solution by tilting the array at approximately 45°, allowing the solution to slide to one side of the array. Aspirate approximately 30–40 µl of salmon sperm DNA solution using a 0.5- to 10-µl pipettor set at 10 µl. Discard each tip after aspirating salmon sperm DNA solution. Make sure the array does not dry out by swiftly removing the salmon sperm DNA solution and applying the sample solution. If more than one array is being hybridized on one slide, tilt the array at approximately 45°, aspirate 20 µl of salmon sperm DNA solution from array 1, aspirate 10 µl salmon sperm DNA solution from array 2, aspirate another 20 µl from array 1, and apply sample solution to array 1. Finally, aspirate 30 µl from array 2 and apply sample solution to array 2. Be careful not to generate bubbles when applying the sample solution to the array. This is to ensure that the microscope slide, which is placed on top of the silicone gasket (Fig. 4), does not touch the sample solution.

17. Images can be acquired using commercially available CCD or laser-scanning imaging systems (e.g., an Axon scanner 4000B). Image analysis and quantification can be done using commercially available image analysis programs (e.g., Genepix from Axon) or other programs, such as UCSF Spot (Jain *et al*., 2002).

Genotyping of Single Nucleotide Polymorphisms by Minisequencing Using Tag Arrays

Lovisa Lovmar, Snaevar Sigurdsson, and Ann-Christine Syvänen

I. INTRODUCTION

An alteration of one nucleotide in a DNA sequence gives different phenotypic outcomes depending on its genomic location. Genomic nucleotide substitutions present in more than 1% of a population are denoted single nucleotide polymorphisms (SNPs). SNPs in protein-coding regions may alter the amino acid sequence of a protein, introduce stop codons, or produce new alternative splice sites in mRNA, thereby affecting the structure and function of the protein. SNPs located in the regulatory regions of a gene may alter binding sites for transcription factors and subsequently the expression level of the gene. The consequences of SNPs located in noncoding regions of the genome still remain largely unknown, but with the increasing interest in the function of noncoding RNA (Mattick and Gagen, 2001), their impact may soon become unravelled.

Following the completion of the draft sequence of the human genome (Lander *et al.*, 2001; Venter *et al.*, 2001), as well as of an increasing number of other genomes, the need for large-scale and high-throughput methods has increased. A promising and today widely used approach is the microarray format, which allows highly multiplex analysis of DNA, RNA, and proteins. This article describes the use of microarrays of immobilised oligonucleotides for SNP genotyping. Most SNP genotyping methods used today still depend on amplification of the region to be interrogated by the polymerase chain reaction (PCR) to provide the required sensitivity and specificity. Even though PCR was the technique that first enabled effective SNP genotyping, it is now the major factor limiting the high throughput of the methods due to the difficulties of designing robust multiplex PCR (Shuber *et al.*, 1995).

Significant advantages of performing assays in the microarray format are the reduced genotyping costs due to the simultaneous analysis of many SNPs in each sample and the small reaction volumes employed. Three major reaction principles are currently used for SNP genotyping on microarrays; hybridisation with allele-specific oligonucleotide probes, oligonucleotide ligation, and DNA polymerase-assisted primer extension (for a review on genotyping techniques, Syvanen, 2001). Due to their high specificity, the enzyme-assisted methods are gaining acceptance as the reaction principle of choice for multiplex SNP detection.

In the minisequencing reaction, a DNA polymerase is used to extend detection primers that anneal immediately adjacent and upstream of the sites of the SNPs. The primers are extended with differently labelled nucleotide analogues that are complementary to the nucleotides at the SNP sites. The method was initially devised with microtiter plates as the solid-phase support and has later been adapted to multiple assay formats (Syvanen, 1999), including microarrays with detection primers covalently attached to the microarray (Kurg *et al.*, 2000; Lindroos *et al.*, 2001; Pastinen *et al.*, 1997).

II. PRINCIPLE OF THE METHOD

A flexible alternative minisequencing system is based on generic oligonucleotides ("cTags") immobilised on the microarray instead of specific detection primers. Cyclic minisequencing reactions with fluorescently labelled dideoxynucleotides (ddNTPs) are performed in solution using detection primers with 5′ tag sequences complementary to one of the cTags included in the array. Each SNP is then interrogated by hybridizing the extended detection primers to their corresponding cTags with known locations in the array and the genotypes are deduced (Fig. 1A). The concept of using tagged PCR primers was first described for analysis of gene expression in yeast by PCR (Shoemaker *et al.*, 1996) and was later been applied to SNP genotyping by primer extension and capture on fluorescent microparticles (Cai *et al.*, 2000), high-density oligonucleotide arrays [Affymetrix, GenFlex arrays (Fan *et al.*, 2000)], and medium-density, custom-made oligonucleotide arrays in different formats (Hirschhorn *et al.*, 2000; Lindroos *et al.*, 2002).

The format presented here uses an "array of arrays" formed by a silicon rubber grid (Pastinen *et al.*, 2000) giving separate reaction chambers, each covering a subarray, that allow 80 samples to be analysed simultaneously for up to 200 SNPs on the same microscope slide (Fig. 1B). In contrast to the conventionally used format for mRNA expression, where a large number of genes are analysed in a relatively low number of samples, the "array of arrays" format allows for a large number of samples to be analysed simultaneously for an intermediate number of SNPs. The main steps of the assay are illustrated in Fig. 2.

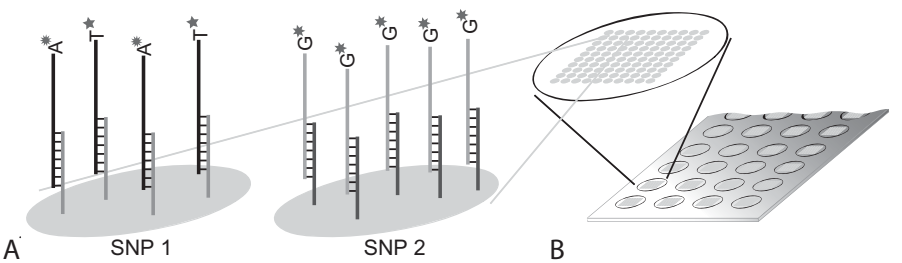

FIGURE 1 Schematic illustration of the microarray result for an individual that is heterozygote (A/T) for SNP 1 and homozygote (G/G) for SNP 2. The SNPs have been interrogated by hybridizing detection primers with 5′ tag sequences, extended with fluorescently labelled ddNTPs, to their complementary immobilised cTags (A). The format is an "array of arrays" with identical subarrays, allowing 80 samples to be analysed simultaneously for up to 200 SNPs on the same microscope slide (B).

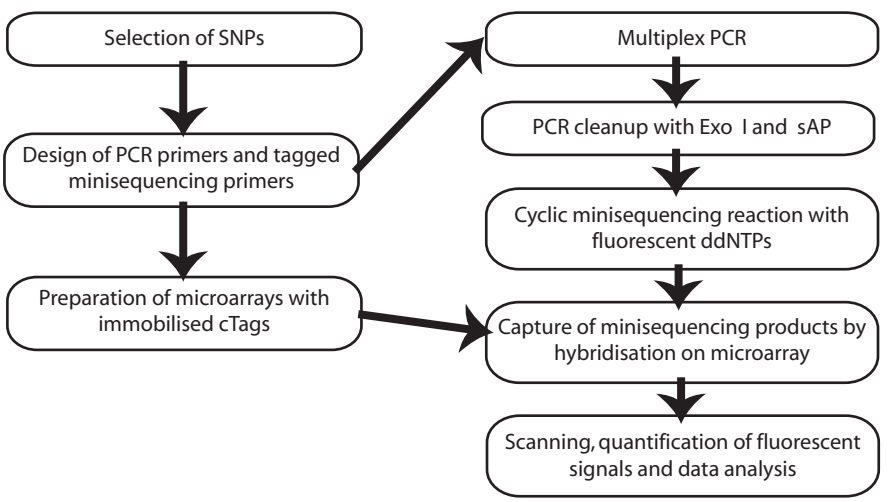

FIGURE 2 Steps of the procedure for genotyping of SNPs by minisequencing using tag arrays.

III. MATERIALS AND INSTRUMENTATION

The microarray slides are CodeLink-activated slides (reference number 25-6700-01) from Amersham Biosciences. The oligonucleotides are synthesized by Integrated DNA Technologies, and the tag sequences are obtained from Affymetrix. Elastosil (RT601) A (Cat.No. 60003804) and B (Cat.No. 60003815) are from Wacker-Chemie GmbH. In the multiplex PCR Ampli*Taq* Gold DNA polymerase, 5 U/µl, and GeneAmp 10× PCR gold buffer [100 m*M* Tris–HCl, pH 8.3, 500 m*M* KCl, 15 m*M* $MgCl_2$, and 0.01% (w/v gelatin)] (Part.No. N808-0245) from Applied Biosystems are used together with 10 m*M* dNTPs (Cat.No. 10297-018) from Invitrogen Life Technologies.

Exonuclease I (Ref.No. E70073Z), 10 U/µl, shrimp alkaline phosphatase (Ref.No. E70072Z), 1 U/µl, and ThermoSequenase (Ref.No. E79000Y), 32 U/µl, are from Amersham Biosciences. The fluorescent dideoxynucleotides used are Texas red-ddATP 85,000 $M^{-1}\,cm^{-1}$ (Prod.No. NEL 411), TAMRA-ddCTP 91,000 $M^{-1}\,cm^{-1}$ (Prod.No. NEL 473), R110-ddGTP 78,000 $M^{-1}\,cm^{-1}$ (Prod. No. NEL 495), and Cy5-ddUTP 250,000 $M^{-1}\,cm^{-1}$ (Prod. No. NEL 589), all from PerkinElmer Life Sciences. Reagents of the highest purity grade from various sources are used for preparation of buffers and other solutions.

A ProSys 5510A instrument from Cartesian Technologies Inc., with four Stealth Micro Spotting Pins (Cat.No. SMP3), from TeleChem International Inc., are used for microarray printing. A Tetrad programmable thermal controller from MJ Research is used for thermo cycling. For scanning of arrays, a ScanArray 5000 instrument from PerkinElmer Life Sciences is used. Additionally, a centrifuge, an incubation oven, a heat block at 42°C, and optimally a multichannel pipette and a pipetting robot are needed. For all instrumentation, other equivalent equipment could be used equally well.

IV. PROCEDURES

A. SNP Selection

SNPs can be identified either experimentally or in databases. Database searches may be aimed at genes of interest, candidate chromosomal regions, or randomly distributed SNPs with known allele frequencies (Table I).

Be aware that many of the SNPs are not validated and that the fraction of "real" SNPs in the databases is still unknown. Validation may be done in a particular population by analysing pooled DNA samples using quantitative minisequencing in microtiter plates or directly on the microarray as has been described (Lindroos *et al.*, 2002).

B. Primer Design

Design PCR primers flanking the SNPs of interest using available software. Primer 3, http://www.genome.wi.mit.edu/cgi-bin/primer/primer3_www.cgi, is freely available online or commercial software such as OLIGO: http://www.oligo.net/ can be purchased. The sequence of each PCR product should be "blasted" against the genome sequence (http://www.ncbi.nlm.nih.gov/BLAST/) and give a single hit only to the intended region.

Minisequencing primers anneal immediately adjacent and upstream of the SNP position. Minisequencing primers from both forward and reverse strands are helpful as internal controls for the genotyping results. Design the minisequencing primers to have a specific length of 18–22 bp and to have a common melting

TABLE I SNP Databases

Internet address	Comment[a]
http://www.ncbi.nlm.nih.gov/SNP/	The public SNP database, dbSNP, created and maintained by NCBI. Linked to additional resources within NCBI. Contains approximately 10 million human SNPs (5 million validated) as well as variations in several other genomes
http://snpper.chip.org/	Searches other databases such as dbSNP and the SNP consortium. Covers about 8 million SNPs (4.5 million validated) for which accurate positioning information is known
http://snp.cshl.org/	The SNP consortium is a public/private collaboration. Contains nearly 1.8 million SNPs
http://www.celeradiscoverysystem.com/	The Celera SNP reference database combines computed and validated variations in the human genome from work done at Celera and from public data sources. Contains a total of 4.1 million SNPs. Requires license to access

[a] The number of SNPs as of reported on Web pages January 2005.

temperature of 55–60°C to ensure specificity in the cyclic primer extension reaction. At the 5′ end of the primer add the tag sequences, complementary to the cTags, that will be spotted onto the microarray. The tags should be 20 bp long, have similar melting temperature, and not be complementary to either each other or the human genome. The Affymetrix GeneChip tag collection can be used as source for tag sequences. The complementary tag sequences (cTags) should have 15T residues as a spacer located 3′ of the specific sequence and a final 3′-amino group to enable covalent attachment of the cTags to the slides.

To avoid strong hairpin–loop structures, evaluate the final minisequencing primer, including the tag sequence, with primer design software that predicts secondary structures (mfold: http://www.bioinfo.rpi.edu/applications/mfold/old/dna/ or NetPrimer http://www.premierbiosoft.com/netprimer/netprimer.html). Secondary structures that involve the 3′ end of a primer may lead to misincorporation of nucleotides.

C. Microarray Preparation

Solutions

1. *2× print buffer:* 300 m*M* phosphate buffer, pH 8.5. Store at room temperature up to 1 month.
2. *Oligonucleotides:* Dissolve the cTags in 1× print buffer and dilute with dH_2O to a final concentration of 25 µ*M*. Store at –20°C but limit freeze–thaw cycles.
3. *1 M Tris–HCl, pH 9.0:* Dissolve 121.1 g Tris in 800 ml H_2O, adjust the pH to 9.0 with HCl, and adjust to a total volume of 1 litre.
4. *Blocking solution:* 50 m*M* ethanolamine, 100 m*M* Tris–HCl, pH 9.0, and 0.1% SDS. Prepare directly before use and preheat to 50°C. To make 500 ml, use 1.6 g ethanolamine, 50 ml 1 *M* Tris–HCl, 5 ml 10% SDS, and add water to 500 ml. Take care that the ethanolamine is highly corrosive and should be handled according to safety instructions.
5. *20×SSC:* 3 *M* NaCl and 300 m*M* sodium citrate, pH 7.0. Dissolve 175.3 g NaCl and 88.2 g sodium citrate in 800 ml H_2O. Adjust the pH to 7.0 with NaOH and adjust the volume to 1 litre. Autoclave and store at room temperature.
6. *10% SDS:* 10% (w/v) sodium dodecyl sulphate. Dissolve 100 g of SDS in 900 ml H_2O. Adjust the pH to 7.2 with HCl and adjust the volume to 1 litre. Store at room temperature.
7. *Washing solution:* 4×SSC and 0.1% SDS preheated to 50°C.

Prepare the arrays by contact printing the cTag oligonucleotides on CodeLink-activated slides (previously 3DLink slides). This may be done using a ProSys 5510A instrument with SMP3 pins that delivers 1 nl of the cTag solution to the slides as spots with a diameter of 125–150 µm and with a center-to-center distance of, for example, 200 µ*M*. For the possibility of using the "array of arrays" format, print spots in a subarray pattern of either a 384- or 96-well format (see Fig. 1). Mark the position of some subarrays on the back side of the slides using a diamond pen.

Postprocess the slides according to the instructions of the manufacturer. The following protocol for CodeLink-activated slides is given.

Steps

1. Prepare a saturated NaCl chamber with 75% relative humidity. In the bottom of a plastic container with an airtight lid, add as much solid NaCl to water as needed to form a 1-cm-deep slurry.
2. After printing, keep the arrays in the NaCl chamber between 4 and 72 h.
3. Deactivate the excess of amine-reactive groups by immersing the slides for 15 min in the blocking solution at 50°C.
4. Wash with dH_2O, washing solution at 50°C for 15–60 min, and dH_2O subsequently.
5. Spin dry the slides for 5 min at 900 rpm. Store the slides desiccated at 20°C until use.

A fluorescently labelled cTag may be included in the array as a spotting control. For each batch of printed slides it is useful to analyse a few subarrays by hybridisation as quality control of the spots. After deactivation of the slides, hybridize a 3′-fluorescently labelled oligonucleotide designed to hybridize to all cTags (5′-AAA AAA AAA ANN NNN NNN NN-3′) to some subarrays at 300 n*M* concentration in 6×SSC for 10 min with subsequent washing and scanning as described.

D. Preparation of Silicon Rubber Grid

Miniaturized silicon rubber (polydimethyl siloxan) reaction chambers are made using inverted microtiter plates with V-shaped wells as mould (Fig. 3).

Steps

1. Mix the two Elastosil RT 601 components in a 50-ml Falcon tube in a mass ratio of 9:1, i.e., 46.8 g of A and 5.2 g of B for 30 min (Elastosil RT625 may be used instead of RT601, thus giving a slightly softer silicon rubber).
2. Pour the mixture onto an inverted 384-well microtiter plate, leaving about 1–2 mm of the tip of the wells uncovered. Allow to harden overnight at room temperature.

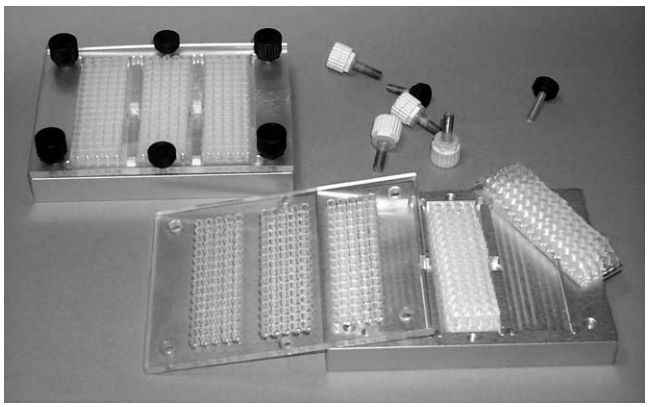

FIGURE 3 The arrayed slide is covered with a silicon rubber grid to give separate reaction chambers and is placed in a custom-made heat-conductive aluminium rack. A Plexiglas cover with a drilled hole through which the reaction chambers are accessed is tightly screwed on top the assembly, thus securing the silicon grid position during hybridisation.

3. Remove the silicon from the plate and use a scalpel to cut the silicon rubber into pieces of the size of microscope slides with the wells matching the printed subarrays.

The silicon is reusable, wash it with water and allow it to dry after each use.

E. Multiplex PCR

Primers for multiplex PCR should have as similar melting temperature and G/C content as possible. Different design programs, see earlier discussion, may be used to minimize primer–primer interactions. Complementary 3′ sequences in the primers can be avoided by designing primers with the same 3′ terminal nucleotides. Another possibility is the introduction of common tails on the 5′ ends of all PCR primers and subsequent amplification with one common primer for all the fragments at an elevated temperature (Brownie *et al*., 1997). An example of a protocol with the common tail approach that has been used for a 20-plex PCR reaction in 384-well format in our laboratory is given.

Primers with common tails for multiplex PCR should have 18–25 bp of specific sequence, have T_m 60–65°C, and give fragments about 100–200 bp long. On the 5′ end of both primers include a 26-bp-long common tail with T_m ~80°C (5′-GCG TAC TAG CGT ACC ACG TGT CGA CT-3′). In the PCR mixture use the tailed primers at 5 to 20 n*M* concentrations, depending on priming efficiency (trial and error), and use the primer complementary to the tail at 1 µ*M*. Amplify the genomic DNA using 1 ng/µl DNA, 0.04 U/µl Ampli*Taq* Gold DNA polymerase, and 200 µ*M* of dNTPs in 4 m*M* $MgCl_2$, 10 m*M* Tris–HCl, pH 8.3, 50 m*M* KCl, and 0.001% (w/v) gelatin and the primers as described earlier in a final volume of 10 µl. Amplify at 94°C for 5 min followed by four cycles of 94°C, 60°C and 72°C for 1 min each. Then do 35 cycles of 94°C for 1 min and 74°C for 2 minutes and finally do an extension at 72°C for 10 min. The success of the reactions may be verified on a 1% agarose gel for a subset of the samples.

TABLE II PCR Cleanup Reagents

Reagent (concentration)	Volume (µl)	Final concentration
PCR products	7	
$MgCl_2$ (50 m*M*)	1.5	7.1 m*M*
Tris–HCl, pH 9.5 (1 *M*)	0.5	0.05 *M*
ExoI (10 U/µl)	0.5	0.48 U/µl
sAP (1 U/µl)	1	0.10 U/µl
Total volume	10.5	

F. PCR Cleanup

Solutions

1. *$MgCl_2$ (50 mM):* To make a 1 *M* stock solution, dissolve 203.3 g $MgCl_3 \cdot 6H_2O$ in 800 ml of H_2O and adjust the volume to 1 litre. Autoclave and store at room temperature.
2. *Tris–HCl, pH 9.5:* Dissolve 121.1 g Tris in 800 ml H_2O, adjust the pH to 9.5 with HCl, and adjust to a total volume of 1 litre.
3. *Enzymes:* Keep the ExoI and sAP enzymes on ice during handling and store at –20°C.

Steps

1. For each sample, pool all multiplex PCR products.
2. Prepare a master mix of the PCR cleanup reagents (Table II).
3. To 7 µl of the pool, add 3.5 µl of the cleanup mixture to a total volume of 10.5 µl.
4. Incubate at 37°C for 30–60 min and inactivate the enzymes by heating to 95°C for 15 min.

Alkaline phosphatase (sAP) inactivates the remaining dNTPs and exonuclease I (ExoI) degrades the single-stranded PCR primers, thus limiting extension of them in the subsequent minisequencing reaction. Include negative PCR controls at this step.

G. Cyclic Minisequencing

Solutions

1. *Triton X-100 (0.5%, v/v):* Store at room temperature for up to 1 month.

2. *Tris–HCl, pH 9.5 (500 mM):* Dilute from 1 *M* Tris–HCl, pH 9.5.
3. *ThermoSequenase:* Keep on ice during handling, store at –20°C. Dilute the enzyme to required concentration directly prior to use.
4. *Fluorescent ddNTPs:* Keep light-protected aliquots in 4°C and store stock solutions at –20°C.

Steps

1. Prepare a master mix of the minisequencing reaction reagents (Table III).
2. After the cleanup step, add 4.5 µl of minisequencing reaction mixture to give a total volume of 15 µl.
3. Perform the minisequencing reaction using an initial 3 min at 95°C followed by 33 to 99 cycles of 20 s at 95°C and 20 s of 55°C in a thermocycler.

Additionally, an internal reaction control should be used. For that purpose, four synthesized single-stranded oligonucleotide templates differing only in one position mimicking the four possible alleles of a SNP are useful. Add the control template to the minisequencing reaction at a final concentration of 1.5 n*M*. A complementary-tagged minisequencing primer should be included with the other minisequencing primers and its cTag should be included in the array. Because fluorophores are light sensitive, protect all reaction mixtures containing fluorophores from light.

H. Capture by Hybridization

Solutions

1. *20×SSC:* See Section IV,C.
2. *Hybridisation control:* Oligonucleotide labelled with, for example, TAMRA, that hybridises to a corresponding cTag included in the array. Keep light-protected aliquots at 4°C and store stock solutions at –20°C.

TABLE III Minisequencing Reagents

Reagent (concentration)	Volume (µl)	Final concentration
PCR products after clean up	10.5	
Pool of tagged minisequencing primers (100 n*M* each)	0.75	5 n*M*
Fluorescently labelled ddNTPs[a] (5 µ*M*)	0.55	0.18 µ*M*
Triton X-100 (0.5%)	0.5	0.017%
Tris–HCl, pH 9.5 (500 m*M*)	0.5	17 m*M*
ThermoSequenase 1 U/µl	1	0.067 U/µl
H_2O	1.2	
Total volume	15	

[a] Texas red-ddATP, TAMRA-ddCTP, R110-ddGTP, and Cy5-ddUTP.

Steps

1. Position a silicon rubber grid over the arrayed slide with the aid of the diamond pen markings (see Fig. 3). Place the arrayed slides into the custom-made aluminium reaction rack and tighten the Plexiglas cover. Preheat the assembly on the side of a heat block to 42°C.
2. To the products from the minisequencing step, add 6.85 µl 20×SSC and 0.15 µl hybridisation control oligonucleotide at 45 n*M* concentration.
3. Transfer 20 µl of each sample to a separate reaction chamber on the microscope slide. A multichannel pipette is feasible for this step.
4. Hybridize for 2.5–3 h at 42°C in a humid environment accomplished, for example, by placing a wet tissue on the Plexiglas lid and cover it with plastic film and aluminium foil.

I. Washing

Solutions

1. *4×SSC:* Dilute from 20×SSC and store at room temperature
2. *2×SSC, 0.1% SDS:* Store at room temperature. Before use, preheat to 42°C.
3. *0.2×SSC:* Dilute from 20×SSC and store at room temperature.

Steps

1. After hybridization, take the slides from the reaction rack and rinse briefly with 4×SSC at 20–25°C.
2. Wash the slides twice for 5 min with 2×SSC and 0.1% SDS preheated to 42°C and twice for 1 min with 0.2×SSC at 20–25°C in 50-ml falcon tubes.
3. Finally, spin dry the slides for 5 min at 900 rpm and store them protected from light.

J. Scanning

If allowed by the scanner used, balance the signal intensity from each laser channel so that no signals are saturated and the signals from the four fluorophores are equally strong. Balancing is easy if a reaction control with signals from all four fluorophores is included on the array, as described earlier. An example of a scanning result is given in Fig. 4.

K. Data Analysis

A quantification program such as QuantArray handles the scanning images and quantitates the

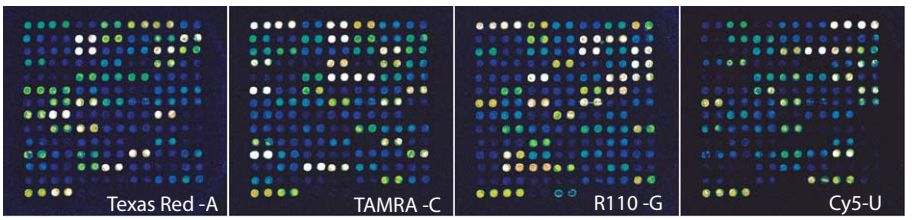

FIGURE 4 Scanning results for 45 SNPs in one subarray, i.e., one sample, after cyclic minisequencing with ddATP, ddCTP, ddGTP, and ddUTP labelled with Texas red, TAMRA, R110, and Cy5, respectively. Each cTag was spotted as horizontal duplicates, and both strands of all SNPs were analysed.

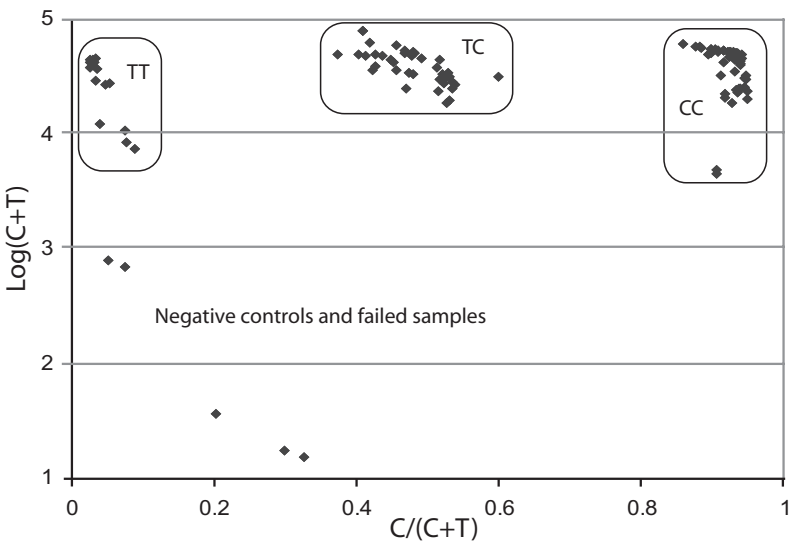

FIGURE 5 Scatter plot for one SNP with a C/T variation in 56 samples. The logarithm of the sum of the fluorescent signal from both alleles, C + T, on the *Y* axis has been plotted against the ratio, C/(C + T), on the *X* axis. The three distinct clusters represent the three different genotypes, whereas two negative controls and three failed samples fall outside the clusters.

signals from each spot. Raw data are collected as an Excel sheet. From the signals from each channel, subtract the background measured either around the spots or at negative control spots, i.e., spotted cTags without corresponding tagged primers. Assign the genotypes of the SNPs in each sample by calculating the ratios between the signals from one of the alleles and the sum of the signals from both the alleles: $\text{signal}_{\text{Allele 1}}/(\text{signal}_{\text{Allele 1}} + \text{signal}_{\text{Allele 2}})$. A scatter plot with this ratio on the *X* axis and the sum of the signals from both alleles on the *Y* axis is used for assigning the genotypes (Fig. 5). This scatter plot should give three distinct clusters with the homozygote samples clustering at each side and the heterozygotes in the middle. The ratios may vary between SNPs depending on the sequence surrounding it, the type of nucleotide incorporated, and the light intensity of the fluorophores.

V. PITFALLS

1. Hairpin and loop secondary structures in the primers can give rise to false signals. Some primers may occasionally fail to give signals, probably due to secondary structures either in the primer itself or in the PCR template.
2. Cy5-ddUTP can be used in higher concentrations than the other ddNTPs to compensate for its lower incorporation efficiency.
3. Insufficient amounts of the PCR products resulting in low signals may be compensated for by increasing the amount of cycles in the minisequencing step.
4. All solutions containing fluorophores are light sensitive and so are the slides after hybridization. To avoid bleaching, cover all reaction tubes and slides with aluminium foil.

5. Background problems can arise if the hybridisation chamber is not kept humid and the sample dries out on the slide.

6. If the Plexiglas cover is not tightened enough or if the silicon-rubber grid is damaged, leakage between reaction wells may occur. This can be controlled for by using differentially labelled hybridisation controls in adjacent reaction wells.

VI. COMMENTS

Depending on the available laboratory facilities or specific requirements of a project, this technique may be altered. Instead of multiplex PCR, single fragment PCR can be used with subsequent pooling of the amplified fragments, possibly after concentration using ethanol precipitation or spin dialysis. Different slides and attachment chemistries for the oligonucleotides have been tested, and new ones are continuously being developed (Lindroos *et al*., 2001). Depending on the number of SNPs to be interrogated, an inverted 96-well microtiter plate may be used as well for as silicon rubber mould to allow larger subarrays. When using the QuantArray program for signal analysing, the genotyping results can be visualised using the SNPSnapper software that has been custom made for this method (http://www.bioinfo.helsinki.fi/snpsnapper). Instead of using four differently labelled nucleotides in the same reaction, depending on the available microarray scanner, a single label or two labels may be used in four or two separate reactions, respectively (Liljedahl *et al*., 2003). It has been shown that the method described is quantitative and well suited to determine allele frequencies of SNPs in pooled DNA samples and is therefore a useful tool for rapid SNP validation (Lindroos *et al*., 2002).

CHAPTER

48

Single Nucleotide Polymorphism Analysis by Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry

Pamela Whittaker, Suzannah Bumpstead, Kate Downes, Jilur Ghori, and Panos Deloukas

I. INTRODUCTION

Modern humans as a species have a limited amount of genetic variation, most of which is attributable to common allelic variants. Any two haploid copies of the human genome differ at one site per kilobase on average (Sachidanandam *et al.*, 2001). Single nucleotide polymorphisms (SNPs) are the most abundant form of sequence variation, accounting for nearly 90% of all sequence variants in the human population. The remaining 10% consists of large and small insertions and deletions (indels). Simulation studies have estimated that there are between 10 and 15 million common (minor allele frequency greater or equal to 1%) SNPs in the human population (Kruglyak and Nickerson, 2001).

The identification and cataloguing of these common variants have been the objectives of the Human Genome Project (HGP; IHGSC, 2001). Systematic SNP discovery and mapping became feasible in the first instance with the availability of a draft sequence of the human genome (IHGSC, 2001). As a result, the International SNP Mapping Consortium reported a map of 1.42 million SNPs in 2001 (Sachidanandam *et al.*, 2001). With a finished reference sequence of the human genome now in hand (IHGSC, 2004), every identified variant can be mapped to a genomic location and correlated with genes and other functionally important sequences such as regulatory elements. Note that not all human sequence variants will have a unique map position in the genome due to the abundance of repeat elements such as LINEs and SINEs and extensive inter- and intrachromosomal segmental duplications (IHGSC, 2004). The presence of paralogous sequences, which are functionally important (e.g., gene families), throughout the genome further contributes to the complexity. Since 2001, systematic SNP discovery through both targeted and random genome-wide efforts has yielded over 7.2 million SNPs, which have unique map positions in the reference sequence and are available publicly (dbSNP; build 120). In addition to the publicly available SNP resources, a number of commercial entities have undertaken large-scale SNP discovery projects, most notably Celera and Perlgen.

A central goal of biomedical research is to identify and characterise the functional sequence variants with biochemical and phenotypic consequences. Although far from being complete, the existing collection of sequence variants already constitutes a rich genetic resource with the potential to accelerate discoveries in dissecting the molecular basis of common complex diseases and variable response to drugs as well as the study of population history. In this quest, SNPs have become the markers of choice due to their abundance and biallelic nature. The latter makes SNP typing amenable to both automation and high multiplexing. However, optimal use of SNPs as genetic markers requires knowledge of their distribution between and within populations. Furthermore, we need a better

Copyright 2006, Elsevier Science (USA).
All rights reserved.

understanding of the patterns of linkage disequilibrium (LD), which is the nonrandom association of SNP alleles, at a fine scale across the genome and in multiple populations. Studies have shown that by typing a sufficiently dense set of common SNPs (typically, minor allele frequency ≥5%) across a population sample (optimally above 50 unrelated individuals), one can construct a map in which most of the genome is represented as regions of high LD (Gabriel *et al*., 2002; Jeffreys *et al*., 2001; Ke *et al*., 2004; Patil *et al*., 2001). Note, however, that the degree and extent of LD are highly variable across the genome. Another important observation from these studies is that because the regions of high LD display a limited diversity of common haplotypes, it is possible to select a subset of the SNPs originally used to construct the map to capture (or tag) most or all of the information on common variation in the corresponding regions. These "haplotype tag SNPs" (htSNPs) (Johnson *et al*., 2001) could offer a three- to four-fold reduction in costs when conducting association studies.

Key to all studies of sequence variation is the availability of accurate, high-throughput, and inexpensive methods for assaying sequence variants. For the reasons described earlier, SNPs have become the markers of choice and in the last few years we have witnessed a true explosion in the number of techniques described in the literature for SNP typing. Broadly speaking though, there are four main reaction principles governing all SNP genotyping assays: hybridisation with allele-specific oligonucleotide (ASO) probes, oligonucleotide ligation (OLA), single nucleotide primer extension, and enzymatic cleavage (flap endonuclease; Invader assay). In contrast, there is an ever increasing choice of detection methods, such as fluorescence polarization, fluorescence resonance energy transfer (FRET), gel and capillary electrophoresis, matrix-assisted laser desorption/ionisation time-of-flight mass spectrometry (MALDI-TOF MS), denaturing high-performance liquid chromatography (DHPLC), DNA microarrays, and bead arrays (reviewed in Kristensen *et al*., 2001; Kwok, 2001; Mir and Southern, 2000; Syvänen, 2001).

Matrix-Assisted Laser Desorption / Ionisation Time-of-Flight Mass Spectrometry

Analysis of nucleic acids (>10 nucleotides long) by mass spectrometry became feasible with the introduction of ionization techniques, such as electrospray ionization (ESI) and matrix-assisted laser desorption / ionisation (Karas and Hillenkamp, 1988). Two key factors in terms of resolution and signal-to-noise ratio in the obtained mass spectra are sample preparation and the type of compound used to embed the sample, typically a small organic molecule that can crystalise (matrix). Introduction of the dried-droplet method for sample preparation (Nordhoff *et al*., 1992) and automated MALDI measurement (reviewed in Little *et al*., 1997) streamlined the use of MALDI-TOF MS in the analysis of DNA molecules. The principle of MALDI-TOF MS is shown in Fig. 1 (for a review, see Jurinke *et al*., 2004).

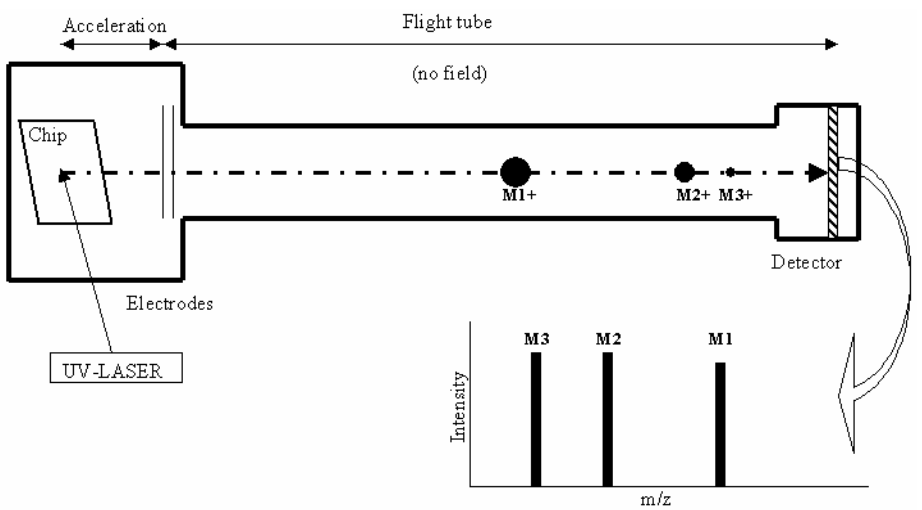

FIGURE 1 MALDI-TOF MS (modified from Pusch *et al*., 2001). Each spot on the chip consists of a matrix (e.g., 3-hydroxypicolinic acid) recrystallised in the presence of analyte. Firing UV laser pulses to a spot causes desorption and ionisation of matrix and analyte ions, which are accelerated prior to entering the flight tube by applying a potential. The time of flight of each ion is measured and converted into *m*/*z* (mass to charge ratio). The separation and detection of three positively, single-charged ions with different masses (M1, M2, and M3) are shown.

In SNP typing, MALDI-TOF MS has been coupled with assays based on primer extension. The two most common assays are the primer oligobase extension (PROBE; Fig. 2) (Brown *et al*., 1997) and the GOOD assay (Sauer *et al*., 2000)—for reviews, see Lechner *et al*. (2001) and Pusch *et al*. (2001). As a detection platform, MALDI-TOF MS has the rather unique feature, compared to other detection methods used in this field, of measuring an intrinsic property of the analyte, its mass. In addition, it requires only nanoliter quantities per sample. Among the commercially available platforms for SNP typing based on MALDI-TOF MS, the MassArray system (Sequenom, Inc.) has been widely used in many laboratories, including ours. The assay, homogeneous MassExtend, is based on PROBE and was developed to run as a homogeneous process with all steps performed in a single well. Up to 12 SNPs can be multiplexed per reaction, although four- to seven-plex reactions are currently the norm. The assay can be run manually or on a semiautomated platform for higher throughput.

II. MATERIALS AND INSTRUMENTATION

The MassArray system is from Sequenom, Inc. and is composed of a MassArray nanodispenser, a Brucker Biflex mass spectrometer, and a MultiMek. The system includes an ORACLE database and a suite of software tools for assay design (Spectrodesigner v.1.3.4) and real-time automated genotype calling (SpectroTyper v.2.0). Spectra acquisition occurs via the Brucker software installed on the mass spectrometer. The Roto-Shake Genie, 120 V, 60 Hz 0.5 amps is from Scientific Industries, Inc. (Cat. No. SI-1100). Thermocyclers, PTC-225 DNA Engine Tetrad with 384-well Alpha unit

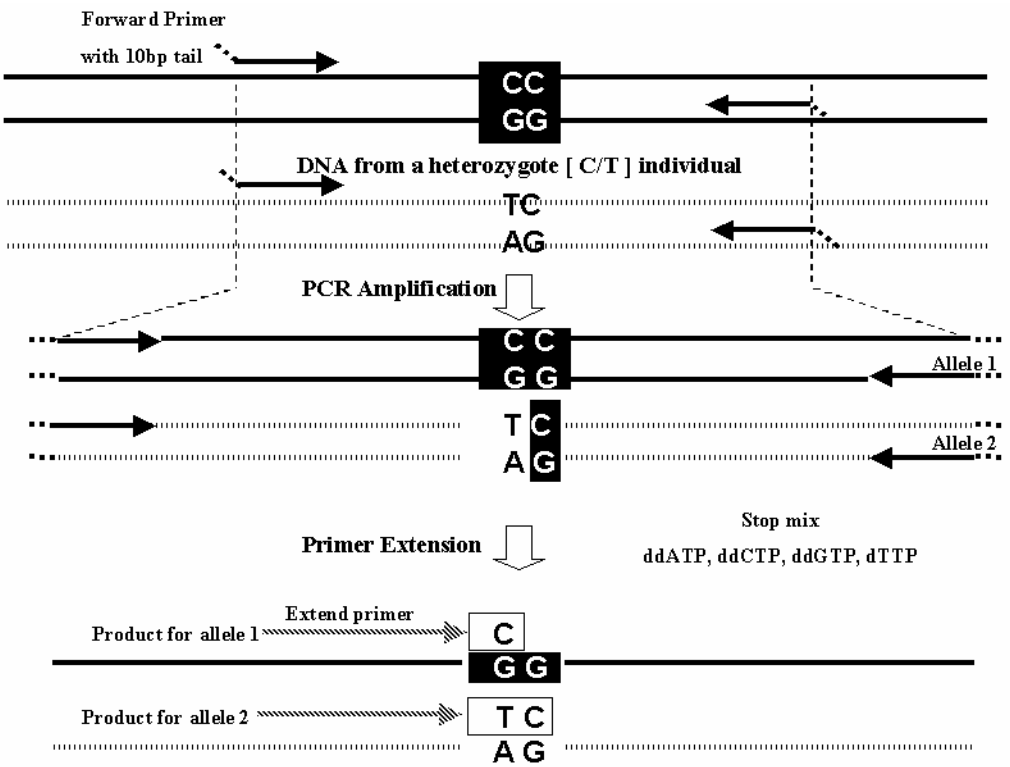

FIGURE 2 The PROBE assay for one SNP is shown. The assay works optimally with small amplicons 80–100 bp (specially in multiplex mode). Synthesizing the PCR primers with a universal 10-bp tail (not present in human DNA) increases their mass so that unused PCR primers do not interfere with product analysis. Post-PCR the unincorporated dNTPs are removed with shrimp alkaline phosphatase (not shown). Typically, the 3′ end of the extend primer is the base preceding the SNP. Multiplexing is achieved by varying the size of the extend primer used in each SNP assay, but the assays need to be compatible with the use of a single stop mix. In an optimal multiplex assay design, masses of all extend primers and possible extension products are chosen so that they differ by at least 30 Da from each other.

blocks, and Microseal "A" film (Cat. No. MSA-5001) are from MJ Research, Inc. The spectrofluorometer, the Cytofluor 4000 multiwell plate reader (any standard spectrofluorometer will work), optically clear microtitre plates (96-well cytoplate, Cat. No. CFCPN9610), and 10× polymerase chain reaction (PCR) buffer [10 m*M* Tris–HCl, 500 m*M* KCl, 15 m*M* $MgCl_2$, 0.01% (w/v) gelatine; Cat. No. N808-0189] are from Applied Biosystems. Multichannel electronic pipettors (Matrix Impact, 0.5–12.5 µl; Cat. No. 2009) are from Matrix. PCR primers (standard desalted oligonucleotides) and extend primers (reverse phase purified) are from Sigma-Genosys. The SpectroCLEAN kit (dimple 384-well plate; Cat. No. 11220), SpectroCHIP (384-well; Cat. No. 00601), SpectroCLEAN Resin (Cat. No. 10053), and 3-Oligo Calibrant mix (Cat. No. 00335) are from Sequenom, Inc. The PicoGreen dsDNA quantitation kit (Cat. No. P-7589) is from Molecular Probes. Titanium *Taq* polymerase (Cat. No. 8434-2) is from BD Biosciences—Clontech. Shrimp alkaline phosphatase 1 U/µl (Cat. No. 70092X), Thermosequanase DNA polymerase 32 U/µl (Cat. No. E 79000Z), ddNTPs (Cat. Nos. ddATP:27-2051, ddCTP:27-2061, ddGTP:27-2071, and ddTTP:27-2081), and dNTPs 100 m*M* (set of four: 27-2035-01) are from Amersham Biosciences (USB). Hotstart *Taq* DNA polymerase (Cat. No. 203203) is from Qiagen. THERMIPol DNA polymerase is from Solis Biodyne, Estonia. (no Cat No.). PCR 384-well microtitre plates (Thermo-Fast; Cat. No. TF-0384) are from ABgene. Source plates are from Bibby Sterilin (microtitre plates, 96-well V bottom, sterile; Cat. No. 612V96). HPLC grade H_2O (Cat. No. 152736D) and standard chemicals are from BDH.

Solutions

1. *TE buffer*: 10 m*M* Tris–HCl, 1 m*M* EDTA, pH75
2. *dNTP mix*: 5 m*M* each dNTP in H_2O
3. *DNA*: 1.75 ng/µl in T0.1E
4. *10x Thermosequenase buffer*: 260 m*M* Tris–HCl, pH 9.5, 65 m*M* $MgCl_2$
5. *Stop mix*: 500 µ*M* each appropriate ddNTP or dNTP in H_2O
6. *Extend primer mix*: 10 µ*M* each primer in H_2O

III. PROCEDURES

A. DNA Quantitation with PicoGreen

Accurate measurement of DNA concentration is not an important issue when genotyping individual samples by the homogeneous MassExtend protocol. In contrast, allele frequency estimation in pooled samples is completely dependent on the accurate measurement of DNA concentration in the samples used to form the pool. The following protocol is adapted from the PicoGreen dsDNA quantitation kit.

1. Dilute λ DNA standard solution to 5 ng/µl with TE buffer. In an optically clear microtitre plate, prepare the following dilutions of phage λ DNA in duplicate:

	1× TE	DNA Standard (µl)
Well 1	80	20
	84	16
	88	12
	92	8
	96	4
	98	2
	99	1
Well 8	100	0

2. Dilute each DNA sample to be measured with TE buffer to approximately 8 ng/µl (20 µl total) in duplicate. Aliquot 5 µl of each sample into two wells of the microtitre plate and add 95 µl of TE to each well (giving four wells per DNA in total).
3. Add 100 µl of 1× PicoGreen (kit solution diluted to 1× with TE) to each well with a multichannel pipette. Mix by spinning down plate at 4000 rpm (swing-out rotor) for 1 s. Note that this step needs to be executed as fast as possible.
4. Incubate plate in the dark (e.g., cover with aluminium foil) for 4 min.
5. Measure fluorescence in a standard spectrofluorometer: excitation: 480 nm and emission: 520 nm.
6. Subtract the fluorescence value of the blank from that of each sample. Use the λ dilutions (average value) to draw a standard curve of fluorescence versus DNA concentration.
7. Determine the DNA concentration of the samples from the standard curve. Compare duplicates for reproducibility.

B. SNP Genotyping with the Homogeneous MassExtend Protocol

The following protocol is a modification of the recommended protocol supplied by Sequenom, Inc. for use with the MassArray system. The experimental layout is based on a manual setup for typing 48 SNPs in four-plex reactions across a panel of 96 samples (95 DNAs and a negative control). The described setup includes dead volumes, whereas the volumes per single reaction are given in parentheses. Note that the procedure is amenable to many different formats in terms of SNPs vs samples vs level of multiplexing. For

example, assaying the same multiplex across 384 samples will require a single mix (see step 1) and adjustment of volumes accordingly. In addition, a number of standard robotic devices for liquid handling can be used to automate steps of the procedures.

1. SNP Selection and Assay Design

dbSNP is the main repository of publicly available SNP data and is maintained at the National Institute for Biotechnology Information (NCBI; http://www.ncbi.nlm.nih.gov/SNP) in the United States. dbSNP has three identifiers per SNP, namely the submitter SNP ID, the NCBI assay ID(ss) and the reference SNP ID(rs). Note that the same SNP can have more than one "ss" identifiers and hence it is recommended to always use the "rs" identifiers, which are unique. Typically, dbSNP will use the most recent and verified human genome sequence assembly, referred to as Golden Path or NCBI build, to obtain genome locations of all submitted SNPs. As the assembly of the human genome sequence is still evolving, it is possible that previously accessioned reference SNPs are either dropped (e.g., map to multiple locations) or two reference SNPs are merged to a new one with a different rs identifier. Although previous identifiers can be tracked, this remains an informatics challenge and should be monitored carefully in large-scale projects. Additional query tools such as dbSNP's "Entrez SNP" and the "EnsMart" of the Ensembl genome browser (http://www.ensembl.org/EnsMart/) allow the retrieval of SNPs with specified characteristics (e.g., experimentally verified, allele frequency cut off, coding, nonsynonymous, etc.) within a defined chromosomal region or gene. An additional source of validated SNP assays, allele frequencies, and, in the near future, common haplotypes and htSNPs is the international HapMap project (http://www.hapmap.org; International HapMap Consortium, 2003). Once SNPs have been selected and extracted from the database with 400 bp (minimum 120 bp) of flanking sequence either side of the SNP, it is recommended to perform a redundancy check with BLASTN. This is critical when dealing with large numbers of SNPs. Then, the sequences need to be parsed through a repeat masking programme such as RepeatMasker (http://repeatmasker.genome.washington.edu). Tag repeat sequences in lowercase to generate input SNP sequences for the SpectroDesigner v1.3.4 software. In general, the higher the number of SNP sequences in the input file, the higher the ability of SpectroDesigner to multiplex them successfully. For example, for 1000 of more SNPs and a four-plex level of multiplexing over 96% of SNPs get assays designed for. Optimal amplicon length is 80–100 bp but this is less critical when designing single-plex reactions. It is recommended to add a universal 10-bp tag to the PCR primers; this generates primers with masses outside the active window for analysis of the extended products (5–9 kDa). Note that newer versions of SpctroDesigner, e.g., v.2.0, support higher multiplexing, replexing of successful assays from different multiplexes, and assay design for triallelic SNPs and indels.

2. Marker and DNA Input Files

The output of SpectroDesigner lists the relationship of SNP assays in each multiplex, all designed primers and their masses, the appropriate Stop-Mixes (see step 5), and the masses of all expected products of primer extension. Read file into the MSPEC1 ORACLE database, which is the data repository of the MassArray system. In parallel, prepare a plate/sample input file and it into the database.

3. PCR Amplification of SNP loci (Four-plex Reactions)

1. Aliquot 2 µl of DNA (1.75 ng/µl) into each well of a 384-well PCR plate. For a panel of 96 samples, DNA1 is present in wells A1, A2, B1, and B2, DNA2 in wells A3, A4, B3, and B4, etc. To type 48 SNPs in four-plex reactions, prepare three plates. Centrifuge plates at 1000 rpm for 1 min. Prepare the following PCR mix:

1395.0 µl 10× PCR buffer (0.75 µl per reaction)
372.0 µl dNTP mix (0.2 µl per reaction)
18.6 µl H_2O (0.01 µl per reaction)
74.4 µl titanium *Taq* polymerase (0.04 µl per reaction)
1860.0 µl (1 µl per reaction)

Mix well and aliquot into 12 tubes (150 µl per tube). Label each tube according to a SNP multiplex and add 300 µl of the corresponding PCR primer mix (375 n*M* each primer; 2 µl per reaction). Use two 96-well source plates to aliquot the content of each tube (34 µl per well) across a plate row (i.e., tube 1 across A1–A12, tube 2 across B1–B12 . . . , tube 8 across H1–H12, tube 9 across A1'–A12', etc.; make a note of the exact order as it is needed in step 5).

2. We recommend placing a plastic template sheet colour coded according to the transfer pattern under the source and the PCR plate. Use a 12-channel pipette to transfer from the source to the PCR plates as follows: rows A–D and E–H of the first source plate and rows A'–D' of the second source plate will feed PCR plate 1, 2, and 3, respectively. Row A of the first source plate will feed positions 1, 3, 5, 7 . . . 23 in rows A, C, E, G, I, K, M, and O of PCR plate 1. Transfer 3 µl to each well (gently tap down plates and inspect that wells are filled uniformly). Seal plates with microseal mats (use a roller to ensure good and uniform adhesion of the

mat across the plate). Centrifuge plates at 1000 rpm for 1 min and place them on thermocyclers (for MJ Tetrads the programme parameters we use are: volume (µl) = 5 and heated lids: YES). Run PCR under the following conditions: 45 cycles each consisting of 20 s at 95°C, 30 s at 56°C, and 1 min at 72°C followed by one cycle for 3 min at 72°C followed by an indefinite cycle at 15°C (to prevent evaporation for overnight runs). Remove plates and spin down at 1000 rpm for 1 min.

4. Shrimp Alkaline Phosphatase Treatment

3. Prepare the following mix:

271.0 µl 10× Thermosequenase buffer (0.2 µl per reaction)
2032.5 µl H_2O (1.5 µl per reaction)
406.5 µl shrimp alkaline phosphatase (0.3 µl per reaction)
2710.0 µl (2 µl per reaction)

Aliquot 220 µl across a row of a 96-well plate. With a 12-channel pipette add 2 µl in each well of the reaction plates from step 2.

4. Seal each plate with a microseal mat and then centrifuge plates at 1000 rpm for 1 min. Incubate plates on a thermocycler under the following conditions: 20 min at 37°C followed by 5 min at 80°C followed by an indefinite cycle at 15°C. At this stage you can either seal and store plates at –20°C or proceed to the next step.

5. Oligobase Extention

5. Prepare the following mix:

479.0 µl 10× Thermosequenase buffer (0.2 µl per reaction)
914.9 µl H_2O (0.382 µl per reaction)
43.1 µl Thermosequenase (0.018 µl per reaction)
1437.0 µl (0.6 µl per reaction)

Label 12 tubes as in step 1 with the corresponding extend primer mix. Aliquot 114 µl of the aforementioned mix to each tube. To each tube add 95 and 171 µl of the appropriate extend primer mix (0.5 µl per reaction) and stop mix (0.9 µl per reaction), respectively. In the same order as in step 1 (i.e., match PCR to extend reactions), aliquot the content of each tube (26 µl per well) across a row of a 96-well source plate, referred to as extend source plates.

6. Aliquot the contents of the extend source plates into the reaction plates (from step 4) as described in step 2. Transfer 2 µl per well. Seal each plate with a microseal mat and then centrifuge plates at 1000 rpm for 1 min. Cycle plates under the following conditions: one cycle at 94°C for 2 min followed by 55 cycles each consisting of 5 s at 94°C, 5 s at 52°C, and 5 s at 72°C followed by an indefinite cycle at 15°C (to prevent evaporation for overnight runs). At this stage you can either seal and store plates at –20°C or proceed to the next step.

6. Desalting (Resin Step)

7. Add 16 µl of HPLC grade H_2O to each well of the reaction plates from step 6.

8. Use a spoon to apply resin onto a 384-well dimpled plate. Force the resin into the grooves of the dimpled plate using the spoon and the plastic scraper. Scrape off any excess resin and let the dimpled plate stand for 10–15 min at room temperature (resin becomes more compact as it dries out; timing will vary with each resin batch and needs testing).

9. Invert each 384-well reaction plate over a dimpled plate containing resin (allow time between plates if working alone). Align the wells of the two plates (it is easier to hold the two plates above eye level). Hold plates firmly and invert, ensuring no slippage. At this stage the resin should drop into the wells of the reaction plate—if you observe incomplete transfer, then tap the back of the dimple plate gently with a spoon.

10. Seal plates with "3 M scotch pad" adhesive sheets and put them in a plastic bag. Attach bag on the rotator using Velcro. Rotate for 10 min (typically, we set the rotator speed to 8).

11. Centrifuge plates for 4 min at 4000 rpm (maximum speed for centrifuge). At this stage samples are ready for spotting onto spectrochips.

7. Sample Spotting and Analysis by MALDI-TOF Mass Spectrometry

12. Spin the reaction plates from step 11 for 5 min at 4000 rpm.

13. Place plates into the holders of the SpectroPoint (spotting device) and an equal number of spectrochips on the black metal chip holder referred to as SCOUT plate (the Biflex mass spectrometer uses a SCOUT ion source). The spotting device should be operated according to the manufacturer's instructions. In brief, select the chip positions for the run in the "SCOUT plate" window. Click on the "Run" menu and enter the following settings:

Run type: Partial run
Spotting: Wet run
Transfer type: 384 to 384
Select "Main Spots"

Then click on the "Clean" menu and set "Clean cycles" to 1. Start the run. At the end of the run, add 3-oligo calibrant mix to each chip.

14. With tweezers, transfer the chips from the black SCOUT plate to the silver SCOUT plate by matching positions. We use a Biflex mass spectrometer, which runs both the original Bruker software and

Sequenom's SpectroTyper v.2.0 software (a switch box allows to change from one to the other). Note that newer instruments and software are available; follow the instructions provided by the manufacturer. In brief, select the Bruker software, open the mass spectrometer, and insert the loaded SCOUT plate. In the "Automatic probe introduction" window, click "Probe in." From the Auto X menu select "Teach Calib Posit" and look in the monitor if positions (A1 and P24 of chip 1) need adjusting. Switch to the SpectroTyper v.2.0 software, select the Plate Editor, and link the appropriate assay template(s) to the corresponding chip(s). Enter chip(s) into the queue (SpectroAcquire) and initiate the run.

8. Data Analysis

As spectra get acquired, genotype calling occurs in real time so that results are instantly available. Each call has an accompanying tag, namely conservative, moderate, aggressive, or bad spectra, which provides a measure of confidence of the underlying data (pick height, signal-to-noise ratio, etc.). Both conservative and moderate calls are of high quality, whereas aggressive calls may contain errors. Although it strongly depends on the marker assayed, there is a 2- to 10-fold increase in error rate in aggressive calls. Markers with more than 1–2% of aggressive calls are not robust. As a rule of thumb, data from SNPs with an overall call rate <70% should be excluded from further analysis. Robust assays yield a call rate of at least 80%. The software provides several tools to zoom into spectra and alter manually genotype calls.

IV. COMMENTS

One of the major issues relating to genotyping methods is the cost per genotype. Thermosequenase, which is used in the primer extension step in the aforementioned protocol, accounts for 20% of reagent costs per sample. We evaluated the THERMIPol DNA polymerase, which is 80-fold less expensive, as a one-to-one substitute for Thermosequenase (same buffer and cycling conditions). We found excellent concordance between the two enzymes, although we noted a slight drop in the average call rate: <1% with THERMIPol DNA polymerase.

For allele frequency estimation in pooled DNA samples (Ross *et al*., 2000; for review, see Jurinke *et al*.), we use the aforementioned protocol with the following modifications: PCR reactions contain 25 ng of DNA, 200 n*M* of each forward and reverse primer, and 0.04 U of HotStar *Taq* polymerase. Four aliquots per reaction are spotted on the Spectrochip. The laser of mass spectrometer is set to fire at five different areas of each matrix pad. Analysis requires MassARRAY quantitative gene analysis software. We conducted a statistical evaluation of the optimal design for association studies based on pooled DNA samples using this protocol (Downes *et al*., 2004).

V. PITFALLS

1. A problem encountered by all SNP typing methodologies that employ PCR amplification of the locus surrounding the variant to be assayed is allelic dropout. Typically, when screening nonvalidated SNPs we find that 2–3% of markers suffer from this problem. Appropriate controls during assay development, such as duplicate samples or DNAs from related individuals (families, trios), as well as analysis tests such as Hardy–Weinberg, should be applied to weed out nonrobust assays. Be cautious when calling a SNP monomorphic!

2. Although SpectroDesigner checks primers for self-complementarity, empirical data show that self-priming does occur, although with low frequency. Clearly, in the presence of a DNA template this type of reaction is suppressed. However, it is almost impossible without laborious side controls to know whether PCR amplification of a sample has occurred successfully for all the markers in a multiplex reaction. Typically, we test new assays against two positive and two negative controls prior to assaying a larger set of samples. In our experience, markers that trigger a reaction in both negative controls should be excluded (or redesign the assay).

TABLE I Relevant Masses in Da

	Deoxyribonucleotide				Dideoxyribonucleotide			
	dC	**dT**	**dA**	**dG**	**ddC**	**ddT**	**ddA**	**ddG**
ddC	16	31	40	56	0	15	24	40
ddT	1	16	25	41	15	0	9	25
ddA	8	7	16	32	24	9	0	16
ddG	24	9	0	16	40	25	16	0

Residue mass			
ddC	273	O	16
ddT	288	N	14
ddA	297	P	31
ddG	313	Fe	56
dC	289	*Na	23
dT	304	*K	39
dA	313		
dG	329		

3. DNA molecules are negatively charged due to their phosphate backbone, which in the presence of cations leads to adduct formation. For example, a sodium ion attached to an extended product will increase its mass by 23 Da (Table I). Typically, this will cause a split signal at the expected and the +23 Da mass positions. Adduct formation can lead to erroneous calling, especially at higher levels of multiplexing. Ensure that the desalting step is working, i.e., adjust rotation speed or increase incubation time.

Single Nucleotide Polymorphism Analysis by ZipCode-Tagged Microspheres

J. David Taylor, J. David Briley, David P. Yarnall, and Jingwen Chen

I. INTRODUCTION

With the completion of a representative human genomic sequence, emphasis is increasingly shifting toward rapid, cost-effective, high-throughput analysis of individual sequence variation. Although a portion of this variation occurs as nucleotide insertions and deletions, substitutions in the form of single nucleotide polymorphisms (SNPs) are the most common. The total number of SNPs in the human genome may exceed 10 million, if those occurring in only 1% of the population are included (Kruglyak and Nickerson, 2001). High-density analysis of SNPs may uncover a correlation between specific genotypic patterns and disease states (Irizarry, 2001).

Because of this potential payoff, much effort has been focused on the design of SNP analysis platforms and techniques (Syvanen, 2001). Microsphere-based platforms offer a high level of multiplexing capability and provide an "open" system in which reactions can be modified easily by combining different sets of reagent-bearing microspheres (Fulton *et al.*, 1997; Han *et al.*, 2001; Kettman *et al.*, 1998; Oliphant *et al.*, 2002). A plethora of genotyping techniques harness the ability of DNA polymerases to perform high-fidelity extension of a primer along a complementary template (Cai *et al.*, 2000; Chen *et al.*, 2000; Syvanen, 1999; Taylor *et al.*, 2001; Ye *et al.*, 2001).

The genotyping technique detailed here employs a bifunctional capture probe possessing a 3′ end complementary to the genomic target DNA and a 5′ end complementary to an oligonucleotide-covered microsphere. DNA polymerase extends the capture probe with a labeled dideoxynucleotide complementary to the polymorphic base. Reaction products are afterward sequestered onto microspheres and analyzed with a benchtop fluorimeter.

II. MATERIALS AND INSTRUMENTATION

N-(3-Dimethylaminopropyl)-N′-ethylcarbodiimide is from Pierce Biotechnology, Inc. (EDC, Cat. No. 22980). Tween 20 (Cat. No. P7949), 2-(*N*-morpholino)ethanesulfonic acid (MES, Cat. No. M2933), and 5 *M* NaCl (Cat. No. S5150) are from Sigma-Aldrich Corp. A 10% sodium dodecyl sulfate solution (SDS, Cat. No. 15553027), 20× SSC (Cat. No. 15557044), 1 *M* Tris-HCl, pH 8.0 (Cat. No. 15568025), 0.5 *M* EDTA (Cat. No. 15575020), and distilled water (Cat. No. 15230162) are from Invitrogen Corp. Unlabeled ddNTPs are ordered as a set of four separate 5 m*M* dideoxynucleotides from Amersham Biosciences Corp. (Cat. No. 27-2045-01), whereas unlabeled dNTPs are purchased as a blend of all four deoxynucleotides from Applied Biosystems (Cat. No. N808-0260). Biotin-11-ddATP (Cat. No. NEL548), biotin-11-ddCTP (Cat. No. NEL546), biotin-11-ddGTP (Cat. No. NEL549), and biotin-11-ddUTP (Cat. No. NEL547) are purchased as 1 m*M* solutions from Perkin-Elmer Life Sciences. Streptavidin, R-phycoerythrin conjugate (1 mg/ml) comes from Molecular Probes, Inc. (SA-PE, Cat. No. S-866).

Copyright 2006, Elsevier Science (USA).
All rights reserved.

AmpliTaq Gold DNA polymerase (Cat. No. 4311816) with accompanying GeneAmp 10× PCR Gold buffer and 25 m*M* $MgCl_2$ are from Applied Biosystems. Shrimp alkaline phosphatase (SAP, Cat. No. E70092Z), exonuclease I (Cat. No. E70073Z), and Thermo Sequenase DNA polymerase (Cat. No. E79000Y) with included 10× Thermo Sequenase reaction buffer are from Amersham Biosciences Corp.

Biotinylated and unmodified DNA oligonucleotides are synthesized by BioSource International. Amino-modified oligonucleotides are from Oligos Etc., Inc. Human genomic DNA from CEPH reference families is obtained from Coriell Cell Repositories.

The 96-well microtiter plates (Cat. No. AB-0800) and adhesive plate film (Cat. No. AB-0558) are from Marsh Bioproducts. A VWR Model 75D sonic water bath from VWR Scientific Products is used to sonicate microspheres. A Sorvall RT6000D tabletop centrifuge from Kendro Laboratory Products is used to spin microtiter plates. Sheath fluid (Cat. No. 40-50000), carboxylated microspheres (Cat. Nos. L100-C101-01 through L100-C200-01), and the Luminex 100 system are from Luminex Corporation. The RapidPlate 96/384 microplate pipetting workstation is from Zymark Corporation. The PTC-100 thermocyclers are from MJ Research.

III. PROCEDURES

A. Design and Preparation of Oligonucleotides

Steps

1. Design and synthesize forward and reverse PCR primers for amplification of each genomic polymorphism to be assayed. Primers should have a melting temperature (T_m) between 52 and 64°C. Designing all PCR primers to share a common T_m simplifies reaction setup and aids multiplex PCR strategies. Primer positions should be selected so that amplicons are as small as possible, ideally less than 100 bp, with the polymorphic base positioned centrally. Make 100 µ*M* stocks in distilled water.

2. Synthesize a complementary ZipCode (cZipCode) oligonucleotide for each microsphere type being used (up to 100 types). The sequences of a large set of compatible ZipCodes have been published (Iannone *et al.*, 2000). Oligonucleotides should have a 5′ amino group, followed by a 15 to 18-atom spacer. Good results are achieved with use of Uni-Link reagent (amino group plus 6-carbon spacer) followed by a 9-atom spacer. The spacer is followed by a 20 nucleotide tag sequence (LUC) common to all cZipCodes. Incorporation of this tag allows multiplexed quality assurance assays to be performed after microspheres are covalently coupled with oligonucleotides. The LUC tag is an arbitrarily selected portion of the luciferase reporter gene that does not share homology with human genomic targets. The LUC tag is followed by the 25 nucleotides complementary to the ZipCode. The T_m of the cZipCode, excluding the LUC tag, is between 61 and 66°C. The following cZipCode example has the LUC tag underlined: 5′—amino—15 carbon—CAG GCC AAG TAA CTT CTT CGC CGT ACC CTT CCG CTG GAG ATT TAC—3′. Make 1 m*M* stocks in distilled water.

3. Synthesize a biotinylated anti-LUC oligonucleotide with the sequence 5′—CGA AGA AGT TAC TTG GCC TG—3′. The 20mer is biotinylated at the 5′ end and has a T_m of 52°C. Make 10 µ*M* stocks in distilled water.

4. Design and synthesize a capture probe for each polymorphism to be assayed. Probes have a 25-nucleotide ZipCode at the 5′ end and a genomic target-specific 3′ end, terminating immediately before the polymorphic base. The T_m of the genomic target-specific portion should range between 51 and 56°C. The sequence of the positive control capture probe (step 5) serves as an example of these design rules. Make 100 µ*M* stocks in distilled water.

5. Synthesize a positive control capture probe with the sequence 5′—GTA AAT CTC CAG CGG AAG GGT ACG GAT CGG CGA TGC ACT TGG ATT—3′. The ZipCode (T_m = 61°C) is located at the 5′ end and the target-specific sequence (T_m = 52°C) is underlined. Make 10 µ*M* stocks in distilled water.

6. Synthesize a positive control target oligonucleotide with the degenerate sequence 5′—AAC CAG CGG GGC AAC CAA CNA ATC CAA GTG CAT CGC CGA T—3′. The sequence to which the positive control capture probe anneals is underlined. The incorporation of a fourfold degenerate base (N) allows use of a single positive control target, independent of the SNP allele being assayed. Make 10 µ*M* stocks in distilled water.

B. Covalent Coupling of Oligonucleotides to Carboxylated Microspheres

Solutions

1. *0.1 M MES, pH 4.0*: To make 50 ml, dissolve 0.976 g MES in 40 ml distilled water. Adjust pH to 4.0 and add distilled water up to 50 ml. Store at room temperature for months.

2. *30 mg/ml EDC*: Weigh 15 mg EDC directly into a microfuge tube, avoiding any clumps in the stock

bottle. Resuspend in 500 µl distilled water immediately before addition to microspheres. Solid EDC is highly hygroscopic and should be replaced each month. For large-scale couplings, always use a new bottle of EDC to minimize risk of failure in the coupling reaction. Do not prepare this solution in advance.

3. *0.1% SDS*: To make 50 ml, add 500 µl 10% SDS stock to 49.5 ml distilled water. Store at room temperature for months.

4. *0.02% Tween 20*: To make 50 ml, add 10 µl Tween 20 to 49.99 ml distilled water. Store at room temperature for months.

5. *1× TE, pH 8.0 (10 mM Tris–HCl, pH 8, 1 mM EDTA)*: To make 500 ml, combine 5 ml 1 M Tris–HCl, pH 8, 1 ml 0.5 *M* EDTA, pH 8, and 494 ml distilled water. Store at room temperature for months.

Steps

The following protocol has been used for coupling reactions of various sizes, ranging from 625,000 microspheres (50 µl of stock) to 100 million microspheres (8 ml of stock). The only reagent volume adjustment required with increasing microsphere number is a doubling of MES resuspension volumes to 100 µl (step 4) when more than 1 ml of microspheres is coupled.

1. Remove desiccant jar containing solid EDC from freezer and warm to room temperature before opening.
2. Pellet 1 ml of microspheres (12.5 million) by centrifugation in a benchtop microfuge for 5 min at full speed.
3. Carefully remove supernatant by pipette, leaving microsphere pellet completely dry.
4. Add 50 µl 0.1 *M* MES, pH 4.0, and resuspend microspheres.
5. Add 1.5 µl of the appropriate 1 m*M* amino-modified cZipCode oligonucleotide dissolved in distilled water.
6. Prepare a fresh 30-mg/ml solution of EDC in distilled water.
7. Immediately after solvation of the EDC, add 10 µl EDC solution to microspheres. Vortex and sonicate immediately.
8. Incubate at room temperature in the dark for 30 min. Vortex and sonicate every 10 min during this incubation step.
9. Repeat steps 6–8.
10. After the second 30-min incubation, add 800 µl 0.1% SDS, vortex, pellet microspheres, and remove supernatant.
11. Add 800 µl 0.02% Tween 20 to microspheres, vortex, pellet microspheres, and remove supernatant.
12. Resuspend microspheres in 1 ml 1× TE, pH 8.0, to make stocks of approximately 10,000 microspheres/µl. Keep individual microsphere types segregated until a quality control assay has been performed to assess coupling effectiveness for each microsphere.
13. Wrap tubes of microspheres in aluminum foil and store at 4°C.

C. Multiplexed Quality Control Assay for Newly Coupled Microspheres

Solutions

1. *Wash solution (1× SSC/0.02% Tween 20)*: To make 500 ml, combine 25 ml 20× SSC, 100 µl Tween 20, and 475 ml distilled water. Store at room temperature for months.
2. *Staining solution (8.33 µg/ml SA-PE)*: To make 50 ml, mix 417 µl SA-PE with 49.6 ml wash solution. Store wrapped in aluminum foil at 4°C for several months.

Steps

1. Mix together 1 µl of each microsphere type to be tested (up to a maximum of 20 microsphere types). Supplement with distilled water if final volume is less than 20 µl to create a final concentration of 500 microspheres of each type/µl.

2. If a previously tested microsphere is available that successfully passed the quality control assay and that is a different type from the multiplexed microspheres assembled in step 1, that microsphere can be used as an internal positive control. Dilute 1 µl of that microsphere with 19 µl of distilled water to create a solution of 500 microspheres/µl.

3. Combine in a single well of a 96-well plate the following: 2 µl of untested multiplexed microspheres (from step 1), 2 µl of a previously tested microsphere (from step 2), 2 µl 5 *M* NaCl, 0.5 µl of 10 µ*M* biotin-anti-LUC oligonucleotide for each microsphere type (maximum of 10.5 µl of oligonucleotide for 21 microsphere types), and distilled water up to 20 µl final volume.

4. Set up a second reaction that is similar to step 3, but omit the biotin-anti-LUC oligonucleotide. This reaction serves as a negative control.

5. Seal plate and incubate at 37°C for 1 h.

6. Add 120 µl wash solution to each well. Pellet microspheres by centrifuging plate at 2000 rpm for 5 min. Carefully remove supernatant.

7. Resuspend microspheres in 65 µl staining solution and incubate at room temperature in the dark for 30 min.

8. Place plate in LX100 and read 50 µl from each well. Successfully coupled microspheres will generally have mean fluorescent intensity (MFI) values of several thousand units. Microspheres with MFI values below 1000 should be recoupled.

D. Amplification of Genomic Targets and Amplicon Cleanup

Solutions

1. *1.3× PCR mix (261 µM dATP, 261 µM dCTP, 261 µM dGTP, 261 µM dTTP, 1.3× GeneAmp PCR Gold buffer (19.5 mM Tris–HCl, pH 8.0, 65 mM KCl), 3.91 mM $MgCl_2$)*: To make 1265 µl (enough for one 96-well plate), add 770 µl distilled water, 132 µl of 10 m*M* dNTP blend (2.5 m*M* of each dNTP), 198 µl 25 m*M* $MgCl_2$, and 165 µl GeneAmp 10× PCR Gold buffer. This solution can be made in large batches and stored in single-thaw aliquots at –20°C.

2. *PCR primer mix (1 µM each oligonucleotide primer)*: To make 330 µl (enough for one 96-well plate), combine 3.3 µl of each 100 µ*M* forward primer, 3.3 µl of each 100 µ*M* reverse primer, and dilute to 330 µl with distilled water. Carefully designed primer pairs that share a common T_m and that lack cross-complementarity may be multiplexed to robustly amplify up to 10 small amplicons simultaneously.

3. *PCR master mix (200 µM dATP, 200 µM dCTP, 200 µM dGTP, 200 µM dTTP, 3.0 mM $MgCl_2$, 1× GeneAmp PCR Gold buffer (15 mM Tris–HCl, pH 8.0, 50 mM KCl), 200 nM each PCR primer, 166.7 units/ml AmpliTaq Gold DNA polymerase)*: To make 1650 µl (enough for one 96-well plate), combine 1265 µl 1.3× PCR mix, 330 µl PCR primer mix, and 55 µl of 5 U/µl AmpliTaq Gold DNA polymerase. For best results, use master mix immediately.

4. *SAP/Exo digestion mix (1× GeneAmp PCR Gold buffer, 0.4 U/µl SAP, 0.8 U/µl exonuclease I)*: To make 550 µl (enough for one 96-well plate containing 15-µl PCR reaction volumes), combine 55 µl GeneAmp 10× PCR Gold buffer, 220 µl SAP, 44 µl exonuclease I, and 231 µl distilled water. For best results, prepare just prior to use.

Steps

1. Dispense 20 ng genomic DNA into each well of a 96-well plate. Heat to dryness by placing plates into a 55°C oven for 2 h. Dried plates may be safely stored at room temperature for up to 1 month.
2. Add 15 µl PCR master mix to each well of dried genomic DNA plate.
3. Seal plate and spin in centrifuge at 2000 rpm for 20 s.
4. Place plate in thermocycler and heat at 95°C for 10 min, followed by 40 cycles of 94°C for 30 s, 60°C for 30 s, and 72°C for 30 s, finishing with 5 min at 72°C and 4°C hold.
5. If multiplex PCR was not performed, combine equal volumes of all PCR amplicons generated across multiple plates into one common plate for multiplex cleanup. It is not necessary to combine the entire volume from the individual PCR reactions, but the total combined volume must be at least 15 µl per well.
6. For every 15 µl of PCR reaction volume per well, add 5 µl SAP/Exo digestion mix.
7. Mix thoroughly.
8. Incubate in thermocycler at 37°C for 30 min, followed by denaturation of enzymes at 80°C for 15 min and 4°C hold.
9. Plates may be safely stored at 4°C overnight or at –20°C for several days.

E. Polymerase Assay

Solutions

1. *20× positive control (250 nM positive control capture oligonucleotide, 250 nM positive control target oligonucleotide)*: To make 550 µl, mix 13.75 µl 10 µ*M* positive control capture oligonucleotide, 13.75 µl 10 µM positive control target oligonucleotide and 522.5 µl distilled water. Store at 4°C for up to 1 week or store frozen for several months, but avoid refreezing.

2. *20× capture probe multiplex (500 nM solution of each capture probe)*: To make 550 µl, combine 2.75 µl of each 100 µ*M* capture probe stock and add distilled water up to 550 µl. Store at 4°C for up to 1 week or store frozen for several months, but avoid refreezing.

3. *5× capture probe/positive control mix*: To make 2200 µl (typically enough for four 96-well plates of genotyping reactions), combine 550 µl of 20× positive control, 550 µl of 20× capture probe multiplex, and 1100 µl distilled water. Store at 4°C for up to 1 week or store frozen for several months, but avoid refreezing.

4. *1000× minus-A solution (1 mM ddCTP, 1 mM ddGTP, 1 mM ddTTP)*: To make 20 µl (enough for nine plates of reactions), combine 4 µl 5 m*M* ddCTP, 4 µl 5 m*M* ddGTP, 4 µl 5 m*M* ddTTP, and 8 µl distilled water. Store at 4°C for several days or store frozen for several months, but avoid multiple freeze–thaw cycles. Keep in mind that this solution is one specific example of the four solutions required to analyze all of the four possible alleles (A, C, G, and T). To assay an A/G biallelic SNP, you must also prepare a 1000× minus-G solution by substitution of 1 m*M* ddGTP with 1 m*M* ddATP.

5. *2.5× A mix (2.5× Thermo Sequenase reaction buffer, 2.5 µM ddCTP, 2.5 µM ddGTP, 2.5 µM ddTTP, 2.5 µM*

biotin-11-ddATP): To make 880 µl (enough for one 96-well plate of reactions), combine 220 µl 10× Thermo Sequenase buffer, 2.2 µl 1000× minus-A solution, 2.2 µl 1 m*M* biotin-11-ddATP, and 655.6 µl distilled water. Store at 4°C for several days or store frozen for several months, but avoid multiple freeze–thaw cycles. Keep in mind that this solution is one specific example of the four solutions required to analyze all of the four possible alleles (A, C, G, and T). To assay an A/G biallelic SNP, you must also prepare a 2.5× G mix by substitution of 2.5 µ*M* ddGTP with 2.5 µ*M* ddATP and replacement of 2.5 µ*M* biotin-11-ddATP with 2.5 µ*M* biotin-11-ddGTP.

6. *3× microsphere multiplex (100 microspheres of each type/µl, 1.5 M NaCl, 40 mM EDTA)*: To make 2200 µl (enough for two 96-well plates of reactions), combine 22 µl of each type of oligonucleotide-coupled microsphere (10,000/µl), 660 µl 5 *M* NaCl, 176 µl 0.5 *M* EDTA, and distilled water up to 2200 µl. If more than 62 microsphere types are being multiplexed, then the total volume will exceed 2.2 ml. In this case, combine all microsphere types, pellet the microspheres in a centrifuge, and carefully remove a sufficient volume of supernatant before the addition of NaCl and EDTA so that the final volume will equal 2200 µl. If protected from light by wrapping the tube in aluminum foil, this solution can be kept for over 1 year at 4°C.

7. *Wash solution*: See Section III,C, solution 1.

8. *Staining solution*: See Section III,C, Solution 2.

Steps

1. Retrieve plate of multiplexed, digested PCR amplicons from Section III,D, step 9. For every 20 µl of volume per well, add 10 µl of 5× capture probe/positive control mix.

2. From this plate containing PCR amplicons, capture probes and positive control, split out two allele-specific reaction plates by placing 12 µl/well into each of two 96-well plates.

3. Add 10 µl of Thermo Sequenase DNA polymerase to each 880-µl aliquot of 2.5× allele-specific mix. For example, add 10 µl Thermo Sequenase DNA polymerase to 880 µl 2.5× A mix and 10 µl Thermo Sequenase DNA polymerase to 880 µl 2.5× G mix.

4. Complete each allele-specific reaction plate by the addition of 8.1 µl/well of 2.5× A/enzyme mix to one plate and 8.1 µl/well of 2.5× G/enzyme mix to second plate. Each well contains a 20.1-µl reaction with 1× Thermo Sequenase reaction buffer, 1 µ*M* each of three unlabeled ddNTPs, 1 µ*M* of the fourth biotin-labeled ddNTP, multiplexed PCR products, multiplexed capture probes at 25 n*M* each, 12.5 n*M* positive control capture probe, 12.5 n*M* positive control target oligonucleotide, and 145 units/ml Thermo Sequenase DNA polymerase.

5. Seal plates, centrifuge briefly, and place into thermocyclers for a 2-min denaturation at 96°C, followed by 40 cycles of 94°C for 30 s, 55°C for 30 s, and 72°C for 30 s, finally holding at 25°C.

6. Remove plate sealers and add 10 µl/well of 3× microsphere multiplex to each plate. Mix well, reseal each plate, and place into thermocyclers. Incubate at 45°C for 1 h to sequester capture probes onto the microsphere surfaces.

7. Remove plate sealers and add 150 µl/well of wash solution. Centrifuge plates for 5 min at 2000 rpm to pellet microspheres. Carefully remove supernatant containing excess biotin-labeled ddNTPs using a RapidPlate 96/384 microplate pipetting workstation.

8. Resuspend each microsphere pellet in 65 µl of staining solution. Incubate at room temperature in the dark for 30 min.

9. Plates can be analyzed in the Luminex 100 system without further processing. Configure instrument settings to inject 50 µl of sample from each well and analyze at least 30 microspheres of each type per well (30 events).

IV. COMMENTS

Using the protocols described in this article, it is possible to routinely perform 50plex genotyping reactions, generating up to 4800 genotypes per pair of 96-well allele-specific plates.

V. PITFALLS

1. Failure to covalently couple oligonucleotides onto the carboxylated microspheres can frequently be traced to the EDC reagent. Dry EDC is a fine powder. Formation of clumps is a sign of water absorption and will result in poor coupling.

2. Another potential cause of failure in the coupling reaction is use of a poorly synthesized oligonucleotide. Always perform a small test coupling when a new oligonucleotide is synthesized. After an oligonucleotide has been demonstrated to couple effectively, freeze away small aliquots at –70°C for single-thaw use.

3. Microspheres can be photobleached by ambient laboratory light, causing them to lose their spectral identities. Because this is a cumulative process, long-term microsphere stocks, such as bulk carboxylated

microspheres and oligonucleotide-coupled stocks, should be rigorously protected by wrapping in aluminum foil. Coupling reactions in progress should always be placed inside a bench drawer or shaded under a sheet of aluminum foil. Likewise, polymerase reaction plates should not be left unprotected on the benchtop while waiting for availability of a centrifuge or Luminex 100.

4. Occasionally, a capture probe will consistently produce reaction products that display low signal strength or high backgrounds, resulting in poor signal-to-noise ratios. It is sometimes possible to correct this problem by redesigning the capture probe from the opposite genomic strand.

5. Effective removal of unincorporated biotinylated dideoxynucleotides during the wash step can be critical to maximize signal-to-noise ratios. This is especially true for SNPs with weaker signal strength. Remove the largest practical volume of supernatant from the microsphere pellet without risking disturbance of the pellet and resulting loss of microspheres.

CHAPTER

50

Polymerase Chain Reaction-Based Amplification Method of Retaining the Quantitative Difference between Two Complex Genomes

Gang Wang, Brendan D. Price, and G. Mike Makrigiorgos

I. INTRODUCTION

Technologies for analyzing gene expression and gene copy number changes are increasingly used in the detection, diagnosis, and therapy of cancer. The clinical outcome of various breast cancer therapies correlates closely with distinct mRNA expression profiles detected using DNA microarrays (Alizadeh *et al*., 2001; Perou *et al*., 1999; Ross and Perou, 2001; Sorlie *et al*., 2001; van't Veer *et al*., 2002). Array-based comparative genomic hybridization (array-CGH) can detect the amplification or deletion of candidate breast cancer genes as well as genomic instability within tumor cells (Albertson *et al*., 2000; Kallioniemi *et al*., 1992, 1994; Pinkel *et al*., 1998; Pollack *et al*., 1999). Subtractive hybridization methods, such as differential display or representational difference analysis, are also used for breast cancer gene discovery (Scheurle *et al*., 2000). Such genetic profiling–based diagnosis can potentially revolutionize the existing staging system and the management of early breast disease (Burki *et al*., 2000). However, analysis of genetic changes in tumors using these techniques requires "µgs" of pure tumor DNA (Klein *et al*., 1999; Lucito *et al*., 1998). Routine tumor biopsies often consist of inhomogeneous mixtures of stromal cells plus tumor cells with a wide range of genetic profiles (Rubin, 2002). Newer techniques, such as fine needle aspiration (FNA) and laser capture microdissection (LCM), allow for the removal of minute amounts of tissue from tumors (Rubin, 2002). LCM can isolate homogeneous populations of normal or tumor cells, potentially resolving tissue into single cells (Assersohn *et al*., 2002; Emmert-Buck *et al*., 1996). However, the yield of RNA/DNA from small cell numbers dictates that LCM must be coupled to a DNA amplification step, usually by use of the polymerase chain reaction (PCR) (Assersohn *et al*., 2002).

A major problem with PCR is that amplification occurs in a nonlinear manner and reproducibility is influenced by stray impurities (Heid, 1996). The exponential mode of DNA amplification and concentration-dependent PCR saturation are notorious for introduction of bias (Heid, 1996). As a result, when amplifying two complex DNA populations, the quantitative relationship between two genes after amplification is generally not the same as their relation prior to amplification. Real-time PCR strategies can retain the initial relation among alleles when a single gene is amplified from two sources (Celi *et al*., 1994). Further, methods exist to PCR amplify whole genomic DNA from as little as a single cell (Klein *et al*., 1999; Nelson *et al*., 1989; Zhang *et al*., 1992). However, the quantitative amplification of the entire population of DNA fragments ("alleles") from two different complex genomes is not possible using conventional PCR. Multiple strand displacement isothermal amplification (MDA) is an alternative to PCR that has shown promise in a number of investigations (Dean *et al*., 2002; Zhang *et al*., 1992). However, MDA requires long

DNA stretches to work effectively and therefore it is inefficient when formalin-fixed, archival genomic DNA is to be amplified (Lage *et al*., 2003) or when cDNA amplification for gene expression profiling on microarrays is required.

We have described balanced PCR (Makrigiorgos *et al*., 2002), a method that overcomes biases associated with PCR amplification of complex genomes and faithfully retains the difference among corresponding genes, or gene fragments over the entire sample. This approach, which can be applied to the amplification of both genomic DNA and cDNA, utilizes a simple principle (Fig. 1). Two distinct genomic DNA samples, a "target" sample and a "control" sample, are tagged with oligonucleotides (LN1, LN2) containing both a common (P1) and a unique DNA sequence (P2a, P2b). The genomic DNA samples are pooled and amplified in a single PCR tube using the common DNA tag, P1. By mixing the two genomes, PCR "loses" the ability to discriminate between the different alleles and the influence of impurities tends to cancel. The PCR-amplified pooled samples can subsequently be differentially labeled or separated using the DNA tag unique to each individual DNA sample. This balanced PCR approach has been validated with amplification of cDNA for gene expression profiling (Makrigiorgos *et al*., 2002) and genomic DNA for array CGH profiling (Wang *et al*., submitted for publication).

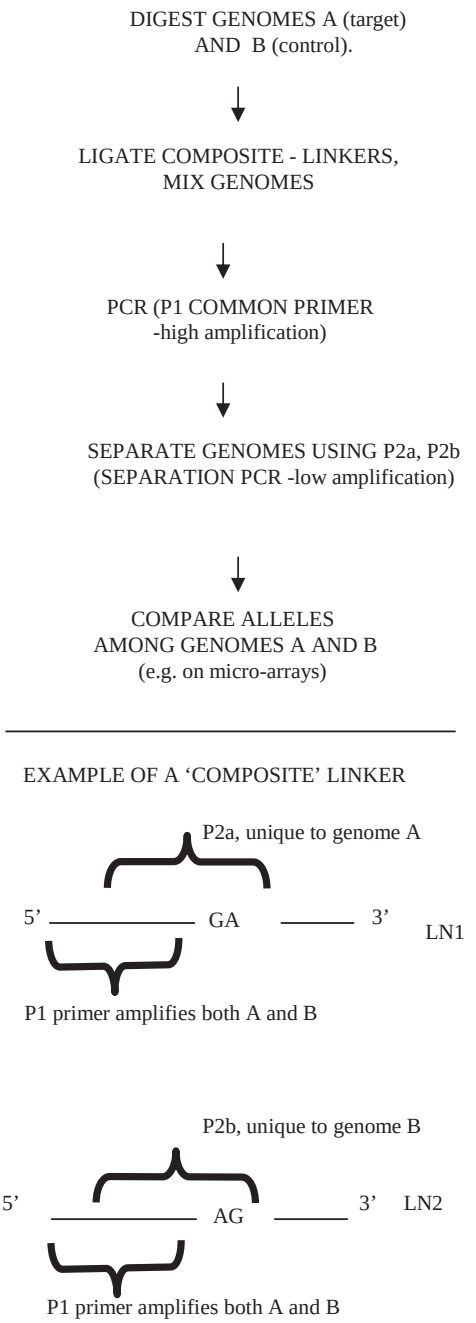

FIGURE 1 Outline of balanced PCR amplification of cDNA or genomic DNA. Reproduced with permission from Nature Publishing Group.

II. MATERIALS

*Nla*III (Cat. No. R0125S), *Dpn*II (Cat. No. R0543S), *Sau*3A (Cat. No. R0169S), and T4 DNA ligase (Cat. No. M0202T) are from New England Biolabs. Advantage 2 PCR kit (K1910-1) and TITANIUM *Taq* PCR kit (K1915-1) are from BD Biosciences. RNeasy minikit (Cat. No. 74104) and QIAquick PCR purification kit (Cat. No. 28104) are from Qiagen. The SuperScript double-stranded cDNA synthesis kit (Cat. No. 11917-020) is from Invitrogen. Picogreen dsDNA quantitation reagent (P-7581) is from Molecular Probes. Linkers are synthesized from Oligos Etc. PCR reactions are performed with a TechGene thermocycler (TECHNE).

III. PROCEDURES

A. Double-Strand cDNA Synthesis

The protocols recommended by the manufacturers were used to extract total RNA from breast or prostate cells (RNeasy minikit), to reverse transcribe to cDNA using Oligo(dT)$_{12–18}$ primers, and to synthesize double-stranded cDNA (SuperScript double-stranded cDNA synthesis kit).

B. Balanced PCR Protocol

This procedure is a modification of the one originally reported (Makrigiorgos *et al*., 2002) and can be

used for amplification of either cDNA or whole genomic DNA. The procedure has been tested with starting amounts of 1–10 ng total mRNA and with 1–10 ng of total genomic DNA extracted from target (e.g., tumor) and control (e.g., normal tissue) cells.

Steps

1. Digestion. The protocol described here employees either *Nla*III or *Dpn*II/*Sau*3A for double-stranded cDNA digestion. Mix 1 µl of 10 ng/µl cDNA from the target cells (e.g., tumor) or from the control cells (e.g., normal tissue) with 0.5 µl of 10× T4 DNA ligase buffer, 0.5 µl of 10 U/µl *Nla*III/*Dpn*II/*Sau*3A, and 3 µl of H_2O. Incubate this mixture at 37°C for 1 h.

2. Ligation. Add 0.5 µl of 10× ligase buffer, 0.3 µl of 2.8 µg/µl linker, and 3.7 µl H_2O into digestion solution. For digestion with *Nla*III, linker LN1 is used for control and LN2 for target cDNA (Table I). For digestion with *Dpn*II or *Sau*3A, linker LN1 and an equimolar amount LN1a are used for ligation to the control cDNA; and linker LN2 and an equimolar amount of LN2a are used for ligation to the target cDNA (Table II). Anneal the appropriate linkers to cDNA by serially decreasing temperature of the sample from 50 to 10°C at 5°C ramp in 5-min steps. Then add 0.5 µl of 2000 U/µl T4 DNA ligase and incubate at room temperature for 1 h.

3. Purification. Mix together cDNAs ligated to different linkers and purify the mixture with a QIAquick PCR purification kit. Purification is not needed if only a fraction of the ligation mixture (e.g., 10% of the total volume) is used in the subsequent coamplification PCR reaction.

4. Coamplification PCR. To 20 µl of purified-ligated DNA, add 5 µl of 10× Advantage 2 PCR buffer, 1 µl of 50× Advantage 2 polymerase mix, 1 µl of 50× dNTP mix (10 m*M* each), 1 µl of 10 µ*M* common primer P1, and 22 µl of H_2O. Perform PCR at 72°C for 8 min; 95°C for 1 min; 20 cycles of 95°C for 30 s; 72°C for 1 min; and then 72°C for 5 min. Purify the PCR product twice with QIAquick PCR purification kit and elute the DNA in 50 µl of H_2O. Quantify cDNA concentration with Picogreen. This procedure usually yields 2–3 µg cDNA from an original material of ~5 ng cDNA.

5. Separation. Mix 1 µl of 3 ng/µl DNA with 5 µl of 10× TITANIUM *Taq* PCR buffer, 1 µl of 50× TITANIUM *Taq* polymerase, 1 µl of 50× dNTP Mix (10 m*M* each), 5 µl of 4 µ*M* P2a for LN1-ligated cDNA or P2b for LN2-ligated cDNA, and 37 µl of H_2O. Separate and amplify cDNA at 95°C for 1 min; 10 cycles of 95°C for 30 s; 72°C for 1 min; and 72°C for 5 min. Each 10-cycle PCR reaction is expected to produce 1–1.5 µg cDNA. Scale the number of individual reactions as needed to produce the desired total amount of amplified cDNA.

IV. EXAMPLES

Microarray Screening for Prostate and Lung cDNA before and after Balanced PCR

As an example of the balanced PCR to retain the difference among alleles between two cDNA populations, microarray studies of human prostate (representing the "target") and lung-derived cDNA (representing the "control") were employed. Digested cDNA was ligated to linkers and screened directly on the Affymetrix Genechip cancer microarrays following the procedure described earlier (Zhang *et al*., 2001). Next, prostate and lung cDNA samples were mixed 1:1 and amplified via balanced PCR for three consecutive PCR rounds of 20 cycles each. The samples were then separated using the procedure of Fig. 1 and screened on microarrays. The ratio of signal intensities after balanced PCR was plotted versus the same ratio prior to balanced PCR (Fig. 2A). The ratio of expression levels for the majority of genes remained relatively unchanged after balanced PCR, as indicated by the distribution of data in Fig. 2A ($R^2 = 0.92$). Next the experiment was repeated the "traditional" way, i.e., by PCR amplifying separately the prostate and lung cDNA samples and screening each on microarrays (Fig. 2B). Data indicate that, for a substantial fraction of genes,

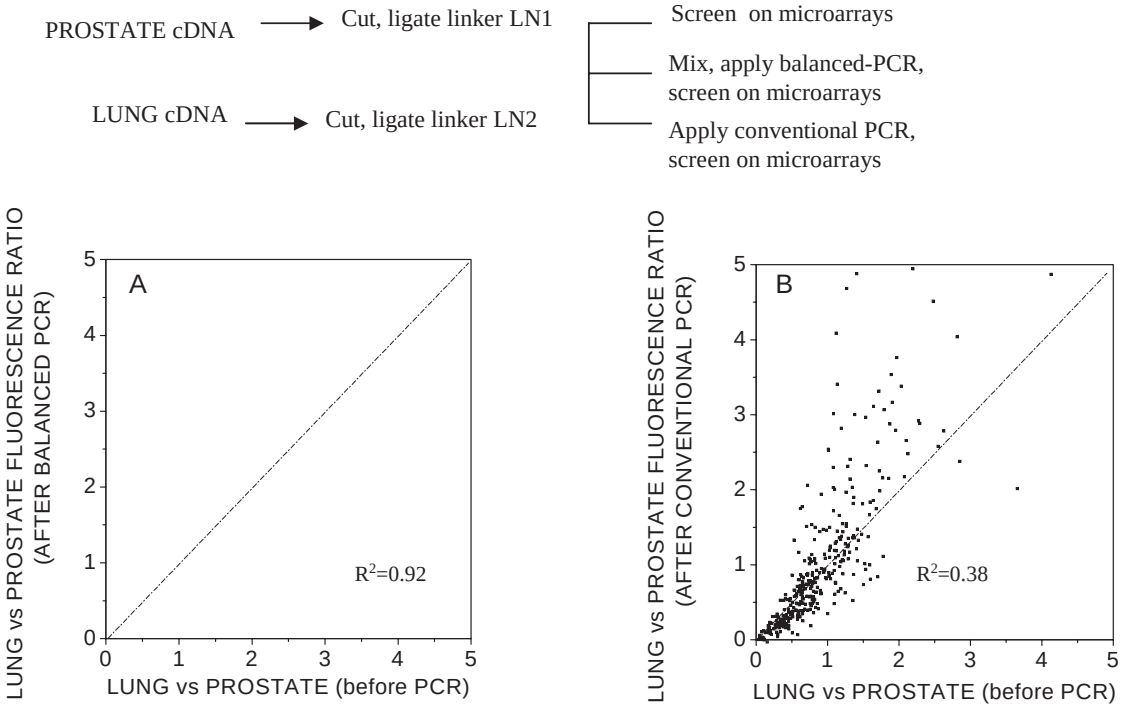

FIGURE 2 Comparison of relative expression of lung vs prostate tissue on microarrays before and after PCR amplification. (**A**) Amplification conducted using the current balanced PCR method. (**B**) Amplification conducted by performing conventional PCR, separately on lung and prostate cDNA samples.

the ratio of expression levels is substantially different from the original one, presumably due to PCR-introduced changes in the original relative expression levels among prostate and lung ($R^2 = 0.38$).

In Figs. 3A and 3B, the comparison between balanced PCR and conventional PCR is depicted for 30 genes that presented the highest upregulation in prostate versus lung. Most are widely known prostate—specific genes, such as the prostate-specific antigen (PSA), prostatic acid phosphatase, and prostatic kallikrein. Figure 3A indicates a good retention of the relative expression levels before and after balanced PCR for almost all these genes (correlation coefficient = 0.800). In contrast, Fig. 3B demonstrates that distortions are introduced if the samples are amplified separately, using conventional PCR, presumably due to a PCR-introduced change in the original relative expression levels among prostate and lung (correlation coefficient = 0.28). Genes important to prostate cancer development, such as PSA and prostatic acid phosphatase are overestimated by more than a factor of 10 when amplified via traditional PCR, but are quantitated correctly when amplified via balanced PCR prior to microarray screening. Of all 407 genes considered, the percentage of genes that had their relative signal change by more than 2-fold or by more than 1.3-fold after performing PCR amplification is depicted in Fig. 3C. Because the deviations observed using balanced PCR are less or equal to the microarray—related deviation [established by repeated application of a single sample on different arrays (Makrigiorgos *et al*., 2002)], it is concluded that balanced PCR introduced minimal distortion in the relative expression among prostate and lung (i.e., balanced PCR error < array error).

V. POTENTIAL PITFALLS USING BALANCED PCR

A. Efficiency of Enzymatic Treatments

A requirement for the success of balanced PCR is that treatment of target and control DNA is identical at all stages prior to mixing the samples. We conducted control studies and we included internal standards for digestion using *Sau*3A and ligation to derive the efficiency of digestion and ligation steps (Makrigiorgos *et al*., 2002). Both were found to be more than 95% efficient. However, if the enzymatic efficiency is reduced due to degradation of the enzyme stocks, impurities, or methylation sensitivity, bias may be introduced in

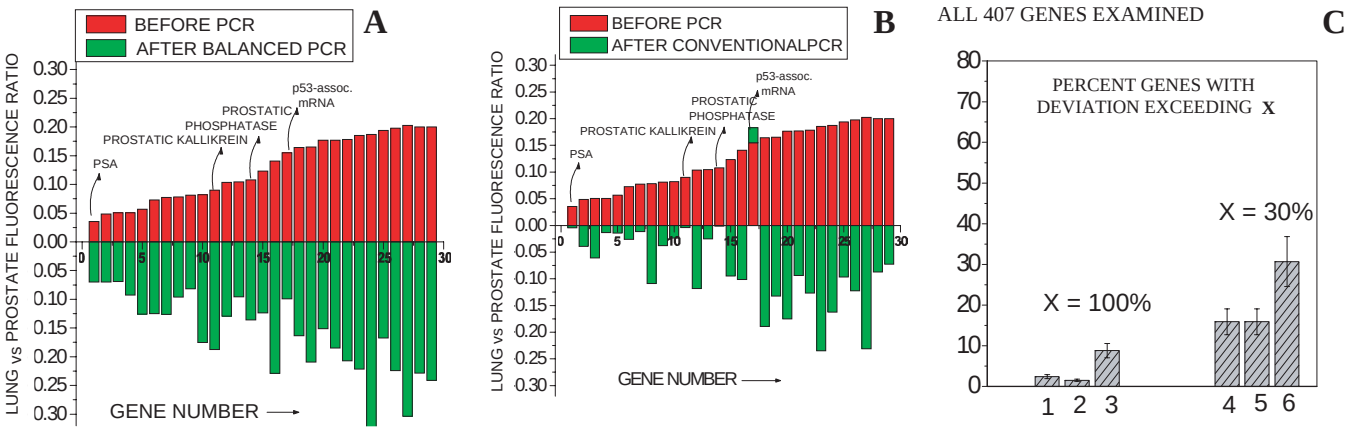

FIGURE 3 Comparison of relative expression of lung vs prostate specifically for the 30 genes highest upregulated in prostate vs lung. (**A**) Amplification conducted using the current balanced PCR method. (**B**) Amplification conducted by performing conventional PCR, separately on lung and prostate cDNA samples. (**C**) Fraction of genes whose relative expression among prostate and lung changes by more than 100% (**columns 1–3**) or 30% (**columns 4–6**) following PCR amplification. **Columns 1 and 4**, repeated application of the same sample on microarrays. **Columns 2 and 5**, amplification via balanced PCR. **Columns 3 and 6**, amplification via conventional PCR. Reproduced with permission from Nature Publishing Group.

the first step of the procedure. This can be avoided by using freshly obtained enzymes that are highly efficient and that are not sensitive to mammalian CpG methylation.

B. Post-PCR Separation

Another assumption is that the low cycle PCR used for reseparation of the two genomes following the common PCR step does not produce distortions among DNA samples. It is, in principle, possible that this PCR might itself produce some bias among alleles in the two populations. In practice, however, we have found that this 10 cycle separation PCR does not introduce significant distortion among alleles differing by at least 50-fold in initial concentration in any of the systems examined [plasmid, genomic DNA, cDNA (Makrigiorgos *et al*., 2002)]. However, it is not recommended to increase the separation PCR cycles to beyond 10.

C. The Effect of Mutations and Polymorphisms

Balanced PCR uses templates from enzyme-digested fragments. If mutations occur within the restriction sequences in the target or control cDNAs, then the enzyme will not digest at that position, but will act in the next available restriction sequence. As a result, certain gene fragments in the target genome will be different in size from their alleles in the control genome and PCR amplification may introduce bias if the fragment sizes are too different. Mutations that occur specifically at the restriction sites are not frequent. The most common form of mutations is single nucleotide polymorphisms (SNPs), which, between two given genomes, occur with a frequency of about 1:1000 bases. The chance that a four-base cutter enzyme used in balanced PCR encounters a SNP is roughly 4/1000 = 0.4%, and therefore it would affect only a small fraction of the sequences amplified. Because several SNPs are already tabulated in databases and more will become known in the near future, one can use computational methods to predict which restriction sites will be altered due to a SNP in order to anticipate potential PCR bias at these positions. If these sequences are vital, one may perform balanced PCR using a different restriction enzyme.

Production of Transgenic Mice by Pronuclear Microinjection

Jon W. Gordon

I. INTRODUCTION

The technique for introducing generic material into the mouse germ line by pronuclear microinjection was first developed by Gordon *et al.* (1980). These animals, subsequently called "transgenic" (Gordon and Ruddle, 1981) to indicate the presence of foreign DNA within their genomes, frequently express the donor genes highly efficiently (Brinster *et al.*, 1981), with the tissue distribution of expression determined primarily by *cis*-acting promoter enhancer elements within or in the immediate vicinity of the genes themselves (Brinster *et al.*, 1981; reviewed by Palmiter and Brinster, 1986; Gordon, 1989). This technique has proven extremely important for basic investigations of gene regulation, creation of animal models of human disease (e.g., Stacey *et al.*, 1988), and genetic engineering of livestock (Hammer *et a.*, 1985; Gordon *et al.*, 1987). This technique has also been described in extensive detail in several other publications (Gordon and Ruddle, 1983).

II. MATERIALS AND INSTRUMENTATION

The following reagents are required for the production of transgenic mice. All stock numbers denote compounds from Sigma unless otherwise indicated: NaCl (Cat. No. S-9888), KCl (Cat. No. P-4504), KH_2PO_4 (Cat. No. P-5379), $MgSO_4 \cdot 7H_2O$ (Cat. No. M-1880), sodium lactate syrup (60%, Cat. No. L-1375), penicillin G (PEN-NA), streptomycin (Cat. No. S-6501), bovine serum albumin (BSA) (fraction V, Cat. No. A-8022), HEPES (Cat. No. H-3375), $CaCl_2$ (Cat. No. C-3881), sodium pyruvate (Cat. No. P-5280), hyaluronidase (Cat. No. H-3506), mineral oil (Cat. No. M-3516), propylene glycol (Cat. No. P-5280), NaOH (Cat. No. S-5881), concentrated HC1 (Fisher, Cat. No. A144-500), 100% ethanol (any supplier), Na pentobarbital (60 mg/ml, Fort Dodge, Cat. No. 1206-1E), pregnant mares' serum (Cat. No. G-4877), human chorionic gonadotropin (Cat. No. CG-10), and Fluorinert (3M, Cat. No. FC-77).

Equipment includes 35-mm tissue culture dishes (Falcon, Cat. No. 3001), 100-mm bacterial culture plates (Falcon, Cat. No. 1029), 10-ml pipette (Falcon, Cat. No. 7551), 5-ml pipette (Falcon, Cat. No. 7543), 15-ml sterile conical centrifuge tube (Falcon, Cat. No. 2097), 50-ml sterile conical centrifuge tube (Baxter, Cat. No. C3920-50), mounted 0.22-mm filter syringe (USA Scientific, Cat. No. F192), sterile filter apparatus (Nalgene, 100 ml, Cat. No. 120-0020; 250 ml, Cat. No. 116-0020; 500 ml, Cat. No. 450-0020), 9-in. Pasteur pipette (Kimble, Cat. No. 72050), depression slides (Fisher, Cat. No. 12-565A), surgical needles with cutting edge (Anchor, Cat. No. 1834-9), 4-0 silk (Ethicon, Cat. No. A-303), surgical iris scissors (Stroz, Cat. No. E-3404), No. 5 Dumont watchmaker's forceps (Fullam, Cat. No. 14040), hemostat (Fisher SCM 1004), microcapillary tubing for DNA injection (Cat. No. 1211L Omega Dot, Glass Co. of America), microcapillary tubing for making holding pipettes (Mertex, 100 × 0.5 mm i.d.), spinal needle for filling barrel of microcapillary tubing (Popper & Sons Quinke Babcock 26G), polyethylene tubing for connecting syringe to microneedle (Intramedic PE60, PE90, PE160, PE190), plastic tubing adaptor with Luer lock for PE tubing (Clay Adams A-1026, size B fits PE60 and PE90, size C fits PE160 and PE 190), vertical or horizontal pipette puller (e.g., David Kopf No. 700C), microforge (e.g.,

DeFonbrune MF-1), mechanical microinjector (e.g., Narishige M5-A), micromanipulation apparatus with phase-contrast optics, two micromanipulators, and dissecting microscope (e.g., Leitz or Narishige). When one micromanipulation device is chosen over another, the choice may dictate the use of supplies that are especially compatible with the equipment available. Also needed is a CO_2 incubator from a suitable supplier.

III. PROCEDURES

A. Preparation of Culture Media and Related Reagents

These procedures are from Gordon and Ruddle (1983) and Quinn *et al.* (1982).

Solutions

Weigh solids into a clear flask or appropriate sized disposable conical centrifuge tubes and add appropriate quantity of distilled H_2O (18 MO).

1. *10× stock solution A for M16 and M2 culture media:* Combine 5.534 g NaCl, 0.356 g KC1, 0.162 g KH_2PO_4, 0.293 g $MgSO_4 \cdot 7H_2O$, 4.439 g or 2.61 ml Na lactate (60% syrup), 1.0 g glucose, 0.060 g penicillin, and 0.05 streptomycin. Add distilled H_2O to 100 ml. If Na lactate syrup is weighed, use a small weighing boat and decant contents into flask, rinse boat two to three times with distilled H_2O, and decant rinse into flask. Solution can be stored for 3 months.
2. *10× stock solution B for M16 and M2 culture media:* Combine 2.101 g $NaHCO_3$ and 1.0 ml phenol red (0.5% solution). Add distilled H_2O to 100 ml. Can be stored for 2 weeks.
3. *100× stock solution C for M16 and M2 culture media:* 0.180 g Na pyruvate. Add distilled H_2O to 50 ml. Can be stored for 2 weeks.
4. *100× stock solution D for M16 and M2 culture media:* 0.252 g $CaCl_2 \cdot 2H_2O$. Add distilled H_2O to 10 ml. Solution can be stored for 3 months.
5. *10× stock solution E for M2 culture medium:* Weigh out 5.958 g HEPES (solid) and add 0.010 ml phenol red (0.5% solution). Add 50 ml distilled H_2O and then bring the pH to 7.4 with 5 *N* NaOH. Add distilled H_2O to 100 ml. Solution can be stored for 3 months.
6. *M16 medium from concentrated stocks:* To make 500 ml, combine 50 ml of stock A, 50 ml of stock B, 5 ml of stock C, 5 ml of stock D, and 390 ml of H_2O. Add 2 g BSA; dissolve without excessive frothing. Sterile filter into 50-ml sterile disposable conical centrifuge tubes.
7. *M2 medium from concentrated stocks:* To make 100 ml, combine 10.0 ml of stock A, 1.6 ml of stock B, 1.0 ml of stock C, 1.0 ml of stock D, 8.4 ml of stock E, and 78.0 ml of H_2O. Make up as for M16, but recheck pH prior to sterile filtration and adjust to 7.3–7.4 with concentrated NaOH if needed.
8. *M16 supplemented with hyaluronidase to remove cumulus cells:* Add hyaluronidase to a final concentration of 1–2 mg/ml to M2 or M16. Filter sterilize before use.
9. *Sodium pentobarbital anesthesia for surgery:* Mix 100% EtOH (10 ml), propylene glycol (20 ml), and water (70 ml) to produce 100 ml of diluent. Add sodium pentobarbital stock solution (60 mg/ml) to a final concentration of 6 mg/ml. Administer to mice at 60 mg/kg or 0.1 ml/10 g body weight.

B. Preparation of Holding Pipettes for Micromanipulation

Steps

1. Heat microcapillary tubing in a microburner and pull by hand to yield a shaft about 150 µm in outer diameter with a length of about 3 cm.
2. Place the pulled tubing on the microforge and break the shaft cleanly such that the shards of glass are protruding from the cylindrical end of the shaft.
3. Fire polish the aperture such that the diameter of the lumen is reduced to about 20–30 µm.
4. Bend the shaft to 90° in the microburner and bend the portion of the tubing that has not been heated 90° in the opposite direction, about 2 cm distant from the point at which the shaft was pulled.
5. About 2 cm further away from the tapered shaft, break the tubing with a diamond pen and fire polish the end to yield an "S-shaped" holding pipette. When used the pipette shaft will extend, parallel to the floor of the culture dish, into the microdrop for manipulation (Gordon and Ruddle, 1983). The tubing will then extend vertically up and over the edge of the tissue culture dish and attach to the instrument collar of the manipulator.

C. Preparation of Microneedles

Step

Microneedles are pulled from appropriate microcapillary tubing and used directly without further processing.

D. Micromanipulator Setup

Steps

1. The micromanipulation microscope should be equipped with interference optics and should be

inverted; 4× and 32× objectives, with 10× eyepieces, are recommended.
2. The instrument collar for the holding pipette should be connected via tubing to a microinjection device. The instrument collar for the microneedle may be connected to a 10-cc syringe.

E. Recovery and Microinjection of Embryos

Steps

1. Superovulate 10 immature female mice (5–6 weeks old) with 2.5 IU of pregnant mares' serum (Sigma Cat. No. G4877) between 12 noon and 1 PM.

2. Forty-eight hours later, administer 5 IU of human chorionic gonadotropin (Sigma Cat. No. CG-10) between 12 noon and 4 PM and place with fertile males to mate. At this time, place 15 mature, randomly cycling females with vasectomized males to generate pseudopregnant recipients.

3. The morning after mating, check immature and mature females for vaginal plugs indicative of mating. Retain those that have mated.

4. Between noon and 2 PM the same day, prepare five 35-mm tissue culture dishes, each with 2 ml of M16 medium, a depression slide with about 300 ml M16 containing hyaluronidase, and a 100-mm culture dish for micromanipulation containing a drop of M2 medium covered with mineral oil. This drop should be rectangular with dimensions of about 1 × 4 cm. Place the M16 and hyaluronidase in the incubator for equilibration, and the M2 microdrop can be placed directly on the microscope equipped for micromanipulation.

5. Between 1 and 2 PM, sacrifice the donor females and remove the oviducts, with ovaries and a small portion of the uterus still attached, to one of the dishes of M16. On the dissecting microscope, identify the distended portion of each oviduct and tear it open to release zygotes and associated cumulus cells. All oviducts should be done in the depression slide containing the hyaluronidase.

6. Place the depression slide in the incubator for 5 min. During this incubation, pull a microinjection needle on the pipette puller and place the base in DNA solution for filling. After the tip is filled, fill the shaft behind the DNA with fluorinert using a spinal needle.

7. Wash the denuded zygotes several times in M16 medium and select those with visible pronuclei and/or second polar bodies. Place these together in the M2 microdrop at one end of the drop.

8. Attach the holding pipette and microneedle to the instrument collars and lower them into the microdrop at the opposite end from the zygotes. Brush the microneedle tip against the holding pipette to break it slightly. This will help establish the flow of DNA. Raise the microtools off the floor of the dish and move the microscope stage to bring the zygotes into the field of vision. Lower the holding pipette and use suction to grasp one of the zygotes. Under high power, release and regrasp the zygote until a pronucleus is positioned for microinjection. Lower the microneedle until the tip is in the same focal plane as the pronuclear membrane. Insert the microneedle under the zona pellucida and apply forward pressure. If the microneedle aperture is open, the perivitelline space will swell slightly.

9. Insert the microneedle into the pronucleus and allow the flow of DNA to cause swelling of the pronucleus. Microinjection should not be considered successful unless this swelling is seen. After microinjection, immediately remove the microneedle from the zygote.

10. Raise the microtools off the floor of the dish and move the stage so as to carry the microinjected zygote, still attached to the holding pipette, to the opposite end of the microdrop. Release the zygote by applying positive pressure on the holding pipette. Allow the microinjected zygote to drift down to the floor of the dish and then move the stage so as to repeat the process on the next embryo. When all embryos are microinjected, remove them to a dish of M16 for about 1 h of culture.

F. Embryo Implantation

Steps

1. Load the surgical transfer pipette with medium, and bubble marker, more medium, and then 10–30 embryos.

2. Approach the ovary through a dorsal incision about 1 cm lateral to the midline, 1–2 cm below the costal margin. The ostium lies immediately adjacent to the ovary and the opening is always oriented toward the tail of the animal.

3. Open the ovarian bursa, avoiding trauma to large blood vessels. Identify the opening of the ostium and insert the surgical transfer pipette. To assure successful embryo transfer, the pipette should be advanced beyond the point of bursal attachment. Embryos are then expelled until the air bubble marker enters the oviductal lumen. Repeat this procedure on the opposite side if sufficient numbers of embryos are available.

4. Close the wound with a single suture through both the peritoneum and the skin. Pups born 19–21 days after transfer are then reared to weaning age and evaluated by polymerase chain reaction or Southern blotting for integration of the transgene.

G. Surgical Vasectomy of Males to Generate Pseudopregnant Recipient Females

Steps

1. Make a ventral midline incision about 1 cm in length above the position of the preputial gland, which is situated under the skin and can be appreciated as a bulging of the skin in the lower abdomen.
2. Squeeze the scrotal sac to force the testes to the incision location and expose the testes by grasping the associated fat pads with the forceps. Identify the vas deferens and lacerate it by blunt dissection.
3. Secure a lacerate loop of the vas deferens in the jaws of a hemostat, crush it, and tear it away.
4. Close the animal with a single suture through both the skin and the peritoneum. After about 1 week the animal can be used as a breeder.

IV. COMMENTS

Human chorionic gonadotrophin is now considered an anabolic steroid and, as such, requires a license for ordering as a controlled substance in the United States. Although M16 and M2 culture media are listed as being stable for only 2 weeks, we have found that they can be used for at least 2 months without diminution of success in transgenic mouse production. The reason for this is that embryos are maintained in these media for only a short time.

CHAPTER

52

Gene Targeting by Homologous Recombination in Embryonic Stem Cells

Ahmed Mansouri

I. INTRODUCTION

Embryonic stem cells (ES) are derived from the inner cell mass of the mouse blastocyst and can be perpetuated in culture (Robertson, 1987). Chimeric embryos can be generated by injecting ES cells into blastocysts or by aggregating them with morulae. Adult mice develop normally from these embryos and ES cells contribute to all tissues, including the germline (Robertson, 1986; Gossler *et al.*, 1986). These unique characteristics allow the introduction of foreign DNA and the screening for rare integration events in ES cells, as well as ultimately the generation of ES cell-derived mouse strains. This strategy has been employed successfully for gene targeting by homologous recombination and has become a powerful tool in studying gene function. Using this procedure, designed mutations are introduced into particular genes and mouse lines carrying the mutated allele are generated (Capecchi, 1989). The use of site-specific recombination systems from the phage P1 (Cre recombinase and LoxP) and from *Saccharomyces cerevisiae* (Flp recombinase and FLP) has opened new avenues for a more sophisticated genetic engineering of mice (Utomo *et al.*, 1999).

II. MATERIALS AND INSTRUMENTATION

Dulbecco's modified Eagle's medium (DMEM, 4.5 g glucose/litre, Cat. No. 41965-039), glutanine (Cat. No. 25030-024), nonessential amino acids (Cat. No. 11140-035), sodium pyruvate (Cat. No. 11360-039), fetal calf serum (FCS, Cat. No. 10270106), geneticin (G418, Cat. No. 11811-064 for 10 g), trypsin/EDTA (Cat. No. 25300-054), and penicillin–streptomycin (Cat. No. 15140-122) are from In Vitrogen. Leukaemia inhibitory factor (LIF, Cat. No. ESG1107 LifESGROTM) is from Chemicon. EDTA (Cat. No. 8043) is from Roth, KCl (Cat. No. 0509) and Trizma base (Cat. No. 1414) are from Baker, NaCl (Cat. No. 1.0640.5000), KH_2PO_4 (Cat. No.1.12034), $Na_2HPO_4{\cdot}2H_2O$ (Cat. No. 6580.0500), and sodium dodecyl sulfate (SDS, Cat. No. 1.1.3760.1000) are from Merck, and D+glucose (Cat. No. G-5146), gelatine (Cat. No. G-1890), dimethyl sulfoxide (DMSO, Cat. No. D-8779), ganciclovir (Cat. No. G2536), mitomycin C (Cat. No. M-0503), and phenol red (Cat. No. P-5530) are from Sigma. Trypsin (Cat. No. L2103) is from Biochrom KG. Proteinase K (Cat. No. 1092766) is from Roche. Gene pulser and electroporation cuvettes (0.4 cm and 0.8 ml volume) are from Bio-Rad Laboratories GmbH and Endo free kit is from Qiagen.

Also needed are 13- to 15-day pregnant mice, sterile scissors and forceps, 50-ml sterilized gall beads (3-mm diameter), a stirring bar in a 500-ml Erlenmeyer flask, and 14.5-cm tissue culture dishes. The gene pulser and electroporation cuvettes are from Bio-Rad.

III. PROCEDURES

A. Preparation of Embryonic Fibroblasts

Solutions

1. *Phosphate-buffered saline (PBS):* To make 1 liter, add 8.0 g NaCl, 0.2 g KCl, 1.15 g $Na_2HPO_4 \cdot 2H_2O$, and 0.2 g KH_2PO_4 to distilled water, adjust pH to 7.2, and bring to a total volume of 1 liter. Sterilise by autoclaving and store at room temperature.
2. *Trypsin/EDTA:* For routine culture and for the preparation of embryonic fibroblasts from embryos, ready-to-use trypsin/EDTA from In Vitrogen can be used.
3. *Gelatine:* To make 1 liter, add 1 g to 1 liter of distilled water and autoclave. Mix after autoclaving and store at room temperature.
4. *Mitomycin C:* Resuspend 2 mg of mitomycin C in 2 ml of PBS and filter sterilise. Dilute with fibroblast medium to a concentration of 100 µg/ml (100 µl mitomycin C/10 ml medium) and store in 25-ml aliquots at –20°C. This is referred to as inactivation medium for fibroblasts. Thaw just before using. Use 10 ml for a 14.5-cm tissue culture dish.
5. *Medium for embryonic fibroblasts: [DMEM + 10% (v/v) FCS]:* To make 1 liter, add 100 ml of FCS (the serum is always heat inactivated at 56°C for 30 min before use for all media) to 900 ml of DMEM. Store at 4°C. When fresh embryonic fibroblasts are prepared from mouse embryos it is advisable to add antibiotics (penicillin/streptomycin). For routine tissue culture it is not necessary.
6. *Freezing medium (for fibroblasts and ES cells):* To make 10 ml of freezing medium, add 1 ml DMSO (cell culture grade) and 1 ml FCS to 8 ml of ES cell medium. After adding freezing medium, keep cells for 1 h at –20°C and tranfer to –70°C overnight before storing in liquid nitrogen.

Steps

1. Dissect ten 13- to 15-day embryos (we normally use NMRI or Balb/c mice) in PBS. Discard liver, head, and internal organs. Wash carcasses several times in PBS to remove blood.
2. Transfer carcasses to 5 ml of trypsin/EDTA and mince in small pieces.
3. Using a wide pipette, transfer the dissected embryo pieces to the Erlenmeyer flask containing the glass beads and add 50 ml of trypsin.
4. Incubate for 30 min at 37°C with gentle agitation on a magnet stirrer.
5. Using a pipette, remove the cell suspension from the flask and transfer to a sterile 50-ml tube. Leave the cell clumps in the flask.
6. Add 50 ml trypsin/EDTA to the remaining cell clumps in the flask and repeat step 4.
7. Spin down the cell suspension from step 5 at 1000 rpm for 10 min and resuspend pellet in embryonic fibroblast medium.
8. Remove the second cell suspension from the flask and treat as in step 7.
9. Pool cells from steps 7 and 8 and plate on 14.5-cm tissue culture dishes (about two embryos/dish).
10. Change medium after 24 h.
11. Once confluent (after 2 days), freeze cells by making five vials from each plate.
12. For routine culture, thaw one vial on an 8.5-cm plate. When confluent, passage the plate on 4 × 8.5-cm plates, which are again passaged (when confluent) on 4 × 14.5-cm plates. Treat the confluent 14.5-cm plates for 2.5 h with mitomycin C to inactivate the fibroblasts.

B. Inactivation of Fibroblasts

1. Thaw inactivation medium and warm to 37°C.
2. Change medium to inactivation medium (10 ml to each 14.5-cm plate) and place plates back into the incubator for 2.5 h.
3. Stop inactivation by washing the cells twice with 10 ml of PBS and add 20 ml of fresh medium to each plate.
4. Trypsinise cells and seed on gelatinised plates at a density of 8×10^4 cells/cm^2. Inactivated fibroblasts that are not needed can be frozen in liquid nitrogen and thawed when necessary. We normally freeze cells from one 14.5-cm dish in one vial.
5. To thaw inactivated feeder cells, warm vial quickly at 37°C, add 10 ml of feeder medium (mix well and take aliquot to determine cell density), and spin down for 5 min at 1000 rpm. After counting, reduce the number of the cells by 15% (taking into account dead cells during the freezing procedure) and plate as usual on gelatinised plates.
6. To gelatinise the plates, cover the surface with 0.1% gelatine for 15 min or longer at room temperature, remove before using, and leave plates to dry.

C. Routine Culture of Embryonic Stem Cells

ES cells should be cultured on a feeder layer of inactivated embryonic fibroblasts (Robertson, 1987) (typical morphology of ES cells is shown in Fig. 1). Embryonic fibroblasts should be used within a week when plated after inactivation. The ES cells should be split every second day (see later). To avoid differentiation, it is important that the ES cells are trypsinised to get a single cell suspension. Because totipotency in ES cells tends to be lost with passage number, it is advisable to subclone the cells after every 20 passages in order to recover the full potentiality. All ES cell lines are cultured in 15% serum except for R1 cells (provided by Dr. A. Nagy, Mount-Sinai Hospital in Toronto), which are cultured in 20% serum.

Solutions

1. *ES cell medium:* DMEM (4.5 g/litre glucose), 10^{-4} *M* β-mercaptoethanol, 2 m*M* glutamine, 1% of stock solution of nonessential amino acids, 1 m*M* Na pyruvate, 15% (v/v) FCS (tested batches), and 500 U/ml LIF. To make 500 ml, add 5 ml of glutamine, 5 ml of nonessential amino acids, 5 ml of sodium pyruvate, 5×10^5 units of LIF, and 0.5 ml of β-mercaptoethanol to DMEM. Adjust to 500 ml with DMEM and add 89 ml of FCS. Store at 4°C. This corresponds to 15% serum. If using RI-ES cells (provided by Dr. A. Nagy, Mount-Sinai Hospital in Toronto), use 100 ml of serum for a total volume of 500 ml medium.

2. *β-Mercaptoethanol stock*: To make 5 ml, add 35 µl of β-mercaptoethanol (14 *M*) to 5 ml of PBS, mix well, and filter sterilise. Store at 4°C in the dark (cover tube with aluminium foil) and use within 1 week.

3. *Saline/EDTA for dilution of trypsin:* To make 1 liter, add 0.2 g EDTA (disodium salt), 8.0 g NaCl, 0.2 g KCl, 1.15 g $Na_2HPO_4{\cdot}2H_2O$, and 0.2 g KH_2PO_4 to distilled water, check pH (7.2), bring to a total volume of 1 liter, and filter sterilise or autoclave. Store at room temperature.

4. *Trypsin/EDTA:* To make 1 liter, add 8.0 g NaCl, 0.40 g KCl, 0.10 g $Na_2HPO_4{\cdot}2H_2O$, 1.0 g glucose, 3.0 g Trizma base, 0.01 g phenol red, and 2.50 g trypsin (Difco 1:250) to distilled water, adjust pH to 7.6, bring to a total volume of 1 liter, filter sterilise, and store in aliquots at –20°C. Dilute this stock 1 : 4 in saline : EDTA for use as 0.05% trypsin/EDTA solution. Store at –20°C in 5- to 10-ml aliquots.

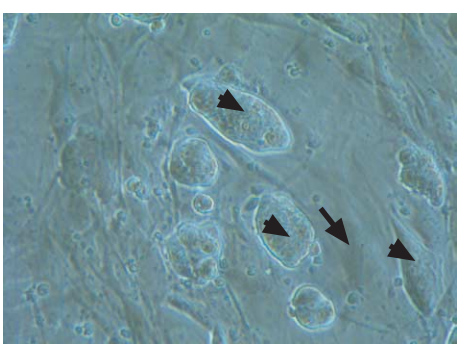

FIGURE 1 Typical morphology of ES cell colonies grown on embryonic fibroblasts. A black arrow indicates fibroblasts and arrowheads point to ES cells colonies.

Steps

1. On day 0, wash the confluent ES cells with PBS.
2. Add trypsin/EDTA (2,1, and 0.5 ml for a 8.5-, 6-, and 3.5-cm culture dish, respectively). Put back into the incubator for 5 min.
3. Using a plugged Pasteur pipette, pipette the cells up and down to get a single cell suspension.
4. Add an excess of medium to stop trypsinisation and mix well.
5. Spin down the cells at 1000 rpm for 5 min.
6. Remove the supernatant and resuspend the cells in new ES cell medium.
7. Split the cells one-fifth to one-eighth (depending on the growth rate, which can vary between serum batches and particular cell lines) on newly inactivated feeder plates.
8. On day 1, change medium.
9. On day 2, split cells on new feeder as in day 0.

D. Targeting Construct

The exogenous DNA fragment or so-called vector or targeting construct used for the targeting experiment consists of two domains of homology to the gene to be targeted: One on the 5′ end and the other on the 3′ end of the construct (Fig. 2). Between the 5′ end and 3′ end homologous parts, a neomycin resistance gene is introduced (1) as a selection marker to monitor the introduced DNA and (2) to interrupt the function of the gene analysed. The neomycin gene is therefore inserted into one exon or it may replace some of the coding sequences, which have to be deleted to abolish the function of the gene to be targeted. Two factors have been shown to influence the targeting efficiency: the size of the genomic fragment included into the construct (Deng and Capecchi, 1992) and the origin of the DNA (Riele *et al.*, 1992). Optimal targeting frequencies are often obtained with constructs, including more than 10 kb of homology. The length of DNA on each side of the *Neo* cassette should not be less than 1.5 kb. Increased targeting efficiencies have been observed when using isogenic DNA isolated from the 129SV

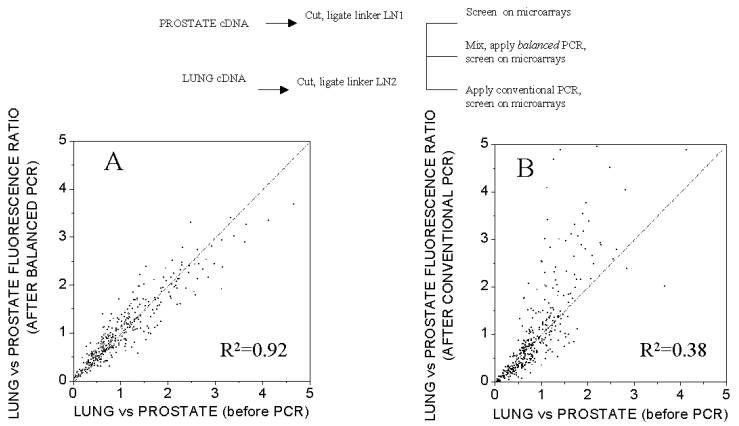

FIGURE 2 Targeting construct using the positive–negative selection procedure. Open boxes indicate exons. TK, HSV thymidine kinase genes; Neo, neomycin gene. Letters on the construct (A, B, C, and D) indicate restriction enzyme recognition sites. (a) Normal allele, (b) targeting construct, and (c) targeted allele. External probes for screening on the 5′ and 3′ ends are indicated by probe 1 and probe 2, respectively. The neo gene is flanked by LoxP sites (arrowheads) that can be recognised by the Cre recombinase. In this way the neo can be removed, if necessary.

genomic library, the mouse line from which most ES cell lines are derived.

The targeting frequency is variable depending on each particular locus. For some genes, the basic strategy described earlier gives an acceptable targeting frequency. However, for other loci, the frequency may be too low without enriching strategies. These strategies are designed to select against random integrations. Therefore, it is recommended to always design a construct using the positive–negative selection procedure (Mansour *et al.*, 1988). The herpes simplex thymidine kinase (TK) gene is added on either external side of the homologous parts of the basic *Neo*-containing construct (Fig. 2). A ubiquitous promoter, e.g., TK or PGK promoter (Soriano *et al.*, 1991), drives the TK. Selection with ganciclovir will kill all the cells that have retained the TK gene that are random integrations. The enrichment factor obtained is fivefold. The expression of the gene to be targeted can be followed by inserting β-galactosidase or green fluorescent protein (GFP) in front of *Neo* in the targeting construct. However, the targeting frequency in this case is lower in comparison to constructs containing only *Neo*.

The aforementioned strategy is already classical and now new methods are used. In fact, it turned out that the neo promoter/enhancer of the PGKneo may act on neighbouring genes and, hence, may interfere with the phenotype (Olson *et al.*, 1996). Therefore, taking advantage of the Cre recombinase of the phage P1, the neo can be removed after homologous recombination has occurred. DNA sequences flanked by LoxP sites (34 bp) that are in the same orientation are excised by the Cre recombinase. The Cre recombinase was shown to perform recombination at LoxP sites in ES cells (Sauer, 1999; Sauer and Henderson, 1990; Gu *et al.*, 1994) (Fig. 2).

In addition, the Cre recombinase opens the possibility of generating conditional knockouts. Specifically, in those cases, where gene targeting will result in a lethal or a phenotype with multiple defects, it is worth to generate a so-called floxed allele. The gene of interest will be modified according to the strategy shown in Fig. 3. Basically, a construct is generated, in which coding sequences are flanked by LoxP sites. One LoxP site is introduced in one intron using oligonucleotides. The second LoxP site is introduced in conjunction with the selection marker neo in another intron. We use the PGKneo that is flanked by FRT sites and carrying one LoxP site (Fig. 3). Flp recombinase from *S. cerevisiae* mediates site-specific deletion at directly repeated FRT sites. After successful homologous recombination into the locus of interest, the neo can be removed. Please check the targeted ES cells for the presence of the second LoxP site. This is practically achieved when mice are generated from targeted ES cells and mated to transgenic mice expressing Flp (Farley *et al.*, 2000). [These mice expressing Flp recombinase from the Rosa-26 locus are available at the Jackson Laboratory (http://tbase.jax.org/).]

Alternatively, a PGKneo that is flanked by two LoxP sites is used. Excision of the neo by Cre recombinase will result among other products into a floxed allele. However, to ensure that excision of the neo occurs, the neo cassette should also contain the TK gene. This will allow selection for excision of the neo after the first targeting experiment. To remove the neo, the targeted

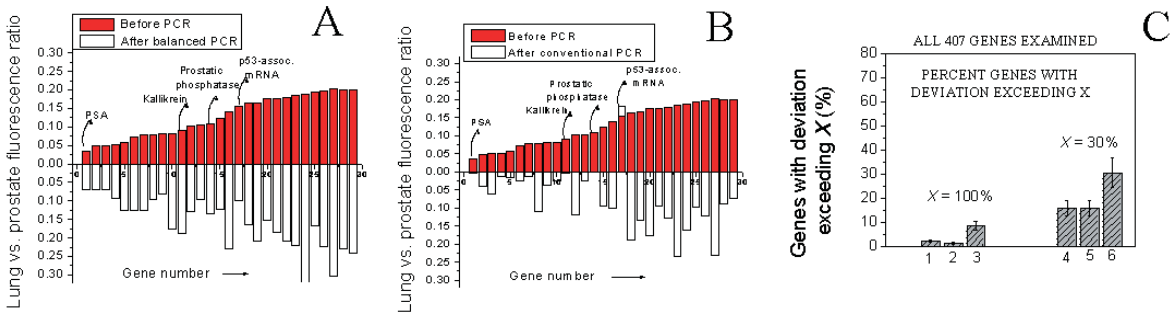

FIGURE 3 Currently used targeting construct to generate a conditional knockout. One LoxP site is inserted in front of the first exon, the neo gene that is flanked by FRT sites and carrying one LoxP site is introduced in one intron. After homologous recombination, targeted ES cells have to be checked for the presence of the second LoxP site. These targeted ES cells are used to generate chimeric mice and to derive a mouse line carrying the allele shown in C. Transgenic mice expressing Flp recombinase [e.g., under the Rosa26-locus; Farley *et al*., 2000; these mice are available at the Jackson Laboratory (http://tbase.jax.org/)] will be crossed to the mouse line carrying the genotype in C to excise the neo. Two LoxP sites will remain as shown in D, where the so-called floxed allele is indicated. Please do not forget to check if mice having both floxed alleles have a normal phenotype. (A) Normal allele; (B) targeting construct; (C) targeted allele in ES cells and mice; and (D) genomic structure of the floxed allele after excision of the neo by crossing to Flp-expressing mice. External probes at the 5'and 3' ends for screening are indicated by probes 1 and 2. Boxes indicated by E1 to E3 are exons. F, FLP site; L, LoxP site.

clones are subjected to a second electropration with a plasmid expressing Cre under the PGK promoter (Torres and Kühn, 1997). Ganciclovir selection will allow the specific removal of the LoxP sites flanking the neo. However, we think that it is more convenient to use the Flp strategy, as only one electroporation is required.

The construct should be linearised and introduced into ES cells by electroporation. DNA for electroporation should be prepared using the Qiagen endo free kit. The targeting vector should be linearised within the vector or outside the domain of homology (see Figs. 2 and 3) by the appropriate restriction enzyme. DNA is treated once with phenol/chloroform, precipitated, and resuspended in TE at 0.5 µg/µl. Check DNA integrity on agarose gel before electroporation.

E. Electroporation

Solutions

1. *G418:* Dissolve G418 (GIBCO) in PBS at a concentration of 250 mg/ml, filter sterilise, and store in small aliquots (1 ml) at –20°C. Thaw before use and add to the selection medium. G418 potency varies between batches and should be tested empirically with untransfected ES cells. The appropriate G418 concentration is usually between 200 and 350 µg/ml medium (100–175 µg active G418/ml medium). Ideally, control ES cells should die after 7 days and G418-resistant colonies will form by days 8 to 10, depending on the promoter driving neo expression.

2. *Ganciclovir:* Dissolve in distilled water at a concentration of 2 mg/ml. Dilute some aliquots to 2 m*M*, filter sterilise, and store at –20°C. The working concentration is 2 µ*M*.

Steps

See also Fig. 3

1. On day 0, split ES cells on a 8.5-cm feeder plate as described in Section III,C. Inactivate fresh feeder cells and prepare 8 × 8.5-cm feeder plates. The culture of the feeder for inactivation should be started 1 week before electroporation. The fibroblasts should be prepared from transgenic embryos carrying the Neo gene so that they are resistant to G418.
2. On day 1, change medium.
3. On day 2, change medium. Remove medium from the 8 × 8.5-cm feeder plates and add 6 ml of ES cell medium to each plate.
4. Four hours after changing medium, trypsinise the cells as described in Section III,C and add ES cell medium to 10 ml, mix well, and spin down for 5 min at 1000 rpm.
5. Aspirate the supernatant and resuspend the cells in 30 ml of PBS. Determine the cell number, which should be around 1.5×10^7 cells.
6. Spin down for 5 min at 1000 rpm.
7. Resuspend approximately 10^7 ES cells in 0.8 ml PBS containing 25 µg/ml of linearised DNA. Let suspension stand for 5 min at room temperature.
8. Pipette the cells up and down and transfer 0.8 ml of the suspension to one electroporation cuvette,

omitting air bubbles. Electroporate with one pulse of 500 µF and 250 V at room temperature. Let stand for 5 min at room temperature.

9. Using a plugged Pasteur pipette, transfer cells directly to ES medium (28 ml) and plate the cells on 7 × 8.5-cm feeder plates. Plate control ES cells (electroporated without DNA) at the same cell density.

10. Twenty-four hours after electroporation, change medium to selection medium with G418 or G418 with ganciclovir if using the PNS procedure.

11. Change medium every day.

12. At day 5 of selection, change selection medium in the PNS procedure to G418 only. Ganciclovir selection is only necessary for the first 4 days.

13. Eight days after selection, check control plate (there should be no ES cells left) and transfection plates for G418-resistant colonies. Big ES cell colonies (about 1000 cells) can be already picked. Do not let any colony get too large, as it would then differentiate.

F. Picking Clones

See also Fig. 4.

Steps

1. Using a microscope marker, make a circle under the desired clone.

2. Prepare a 96-well plate with 40 µl trypsin/EDTA in each well.

3. Under a dissecting microscope (in sterile hood), pick every marked clone individually and transfer to one well in the 96-well plate. We use a Gilson pipette and PCR 10-µl tip (FT 10 from SLG) to pick the colonies. Twelve to 24 cell clones can be handled in one step.

4. After the colonies are trypsinised (variable time), using a multichannel (12) pipette, transfer the 12–24 clones to a 24-well plate with fresh feeder layer (1 day old) and fresh ES cell medium (1 ml in each well). Mix well, replace in the incubator, and change medium every day. The transfer of clones from the 96-well plate to the 24-well plate is performed using only 6 channels of the pipette (leaving every second one empty). This permits the transfer of the contents of alternate wells from the 96-well plate to the 6-well plate.

5. Once the cells are confluent (3–5 days), they are trypsinised by adding 150 µl of trypsin/EDTA to each well and incubating for 5 min at 37°C.

6. Add 600 µl of ES cell medium to each well to stop trypsinisation, mix well, remove 400 µl from each well, transfer into a corresponding 24 well (for freezing), and add the remaining cells from the same clone to another 24 well (without feeder but the wells should

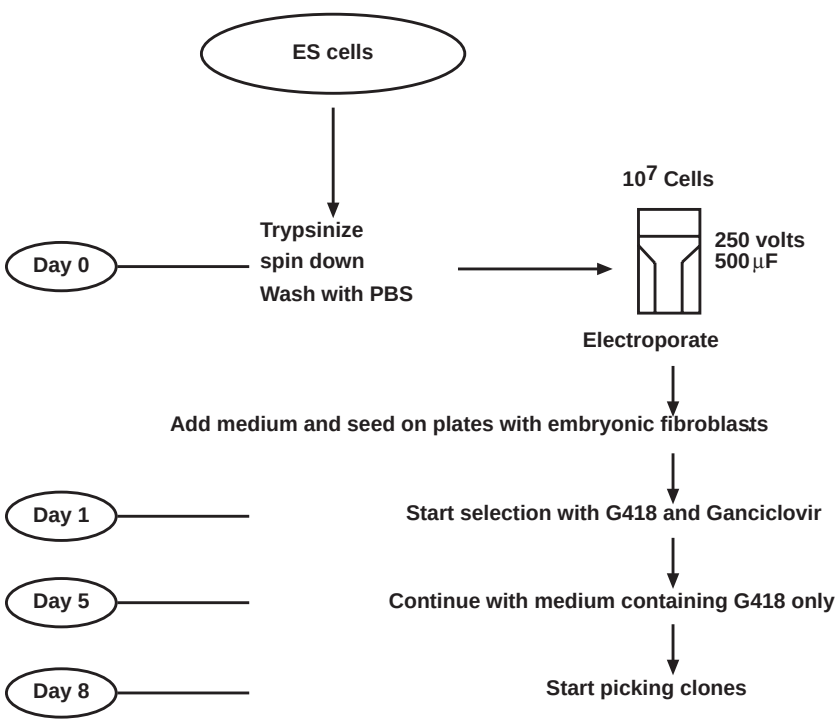

FIGURE 4 Scheme for the different steps of a standard electroporation.

be gelatinised) preequilibrated with 500 µl of ES medium.

7. When all wells are transferred, add 400 µl of 2× freezing medium to each well of the freezing plate. Mix to homogeneity, cover with a plastic bag and paper, and put into a Styrofoam box at –70°C. This is the master plate.
8. Proceed with all clones in this way.
9. The ES cells in the gelatinised plate will be used, when confluent, to prepare genomic DNA for screening (Fig. 5).

G. Analysis of Picked Clones by Southern Blot

Solutions

1. *Lysis buffer:* 100 m*M* Tris–HCl, pH 8.5, 5 m*M* EDTA, 0.2% SDS, 200 m*M* NaCl, and 100 µg/ml proteinase K
2. *Proteinase K stock solution*: 10 mg/ml H_2O
3. *TE*: 10 m*M* Tris–HCl, pH 8.0, and 1 m*M* EDTA (Laird *et al*., 1991)

The isolate clones should be checked individually to distinguish between random integrations and homologous recombination. We recommend genomic Southern analysis for this purpose. Genomic DNA is digested with an enzyme that will generate bands of different sizes from the wild type and the targeted allele and is probed with a genomic fragment not included in the targeting construct (see Fig. 2).

Steps

1. When cells in the gelatinised plates are confluent, remove medium and add 500 µl of lysis buffer to each well.
2. Leave overnight in the incubator at 37°C.
3. Transfer the DNA solution from each well to an Eppendorf tube and add 500 µl of lysis buffer to each well.
4. Spin down for 10 min and remove supernatant.
5. Add 500 µl 70% ethanol to wash pellet and spin down for 5 min.
6. Remove ethanol and dry pellet. Resuspend DNA in 50 µl 1/10 TE.
7. Use 15 µl from each sample for screening and digest with the appropriate restriction enzyme.

Positive clones will be expanded and rechecked. They can now be used to generate chimeras by

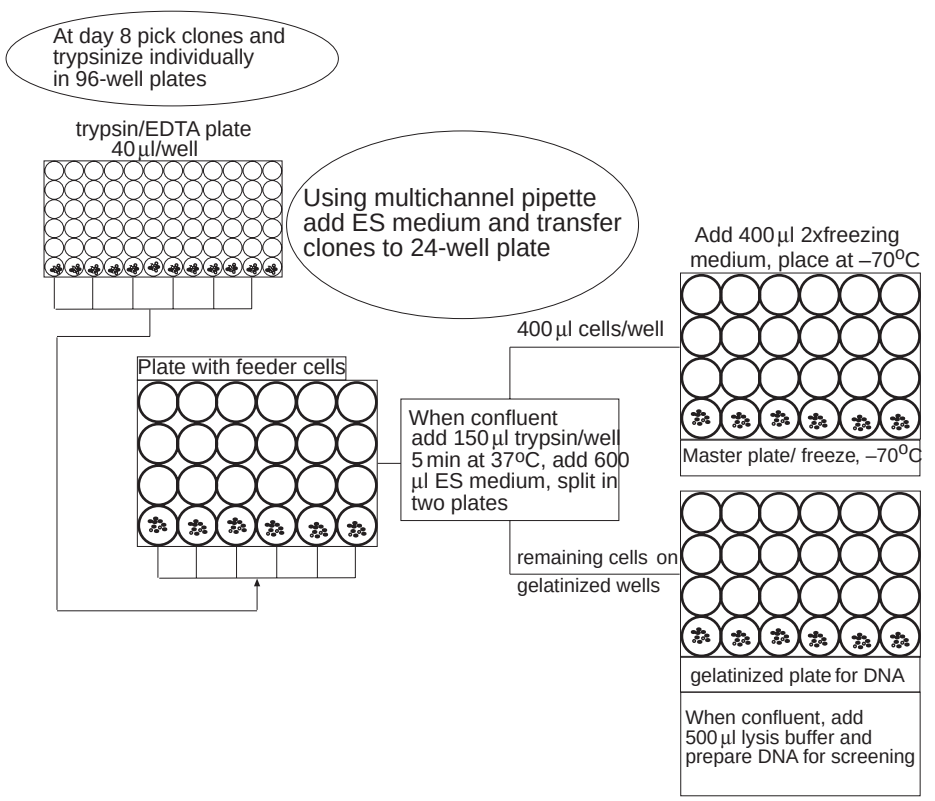

FIGURE 5 Scheme for picking clones and further handling until freezing. ES cell colonies are shown schematically as black dots in the 96 wells.

blastocyst injection or morula aggregation (Bradley, 1987).

H. Thawing Positive Clones from 24-Well Pates for Aggregation or Blastocyst Injection

Steps

1. Prepare 3.5-cm plates with an inactivated feeder layer.
2. The next day, prewarm ES cell medium at 37°C. Remove quickly the 24-well plate with the positive clones from the –70°C freezer and immediately add 1 ml of ES medium to the corresponding well. Pipette carefully up and down without taking the frozen cell into the pipette (it is just to go quickly with thawing). If there are several positive clones on the same plate, you can thaw them at the same time or put the 24-well plate back into the –70°C freezer after thawing one of them.
3. When thawed, transfer the cells to a Falcon tube (14 ml) and wash the well three to four times with ES medium. Add ES medium to adjust the total volume to 12 ml and spin down at 1000 rpm.
4. Plate the cells on a 3.5-cm plate and change the medium the next day.
5. When confluent, split cells and make frozen stocks. Check the clone by Southern blot before proceeding to aggregation or blastocyst injection.

I. Removing the neo Cassette from the Targeted Locus by the Cre Recombinase in ES Cells

In cases where the neomycin resistance gene has to be excised from the targeted locus, use PGK promoter-driven Cre to electroporate targeted ES cells.

Steps

1. Electroporate 10^7 targeted ES cells (Section III,E) with 25 µg of supercoiled Cre plasmid (we used PGK-Cre containing a nuclear localisation signal) and plate on one 14.5-cm dish containing inactivated feeder cells.
2. After 48 h trypsinise cells (see Section III,C) and plate 10^3 cells/8.5-cm dish with inactivated feeder cells. Make four plates and freeze the remaining cells. When colonies become visible and of reasonable size (it takes about 4 days), they should be picked and proceeded as described in Section III,F. We usually get about 10% positive clones.
3. Positive clones may be checked for their sensitivity to G418 by culturing one aliquot in a 96-well plate in ES medium containing G418.
4. Prepare DNA from positive clones and analyse by genomic Southern blot using appropriate probes.

IV. COMMENTS

It may happen that after the positive ES clones are thawed only few colonies are detected in the dish after a few days of culture. Do not subculture, just trypsinise the cells as usual and leave them in the same dish for another passage. In this way you can recover clones with few cells.

Plates are gelatinised in order to have an optimal attachment of the fibroblasts.

If the external probe for Southern blot contains repetitive sequences, use denatured mouse genomic DNA to block the repetitive elements. On the day of hybridisation, 1 ml of mouse tail genomic DNA (1 µg/µl) is heated at 95°C for 20 min (Eppendorf bench shaker). Keep on ice before use. Mix with the probe and denature for 5 min before adding to hybridisation mixture.

Each new batch of serum for ES cell culture should be tested before using. Therefore, several batches are tested. The following parameters have to be checked for each batch.

1. Plating efficiency. Trypsinise ES cells and plate about 1000 cells on a gelatinised 6-well plate. Make triplicates for each batch of serum. When colonies become apparent (about 5 to 6 days), fix with 4% PFA for 30 min and stain with giemsa. After drying, count colonies. The plating efficiency should be at least 20%. Do not forget to include your old batch of serum as a control.
2. Morphology of the cells and toxicity of the serum. Plate ES cells for normal culture on 6-well plates seeded with embryonic fibroblasts at different serum concentrations for each batch (15, 20, and 30%). Use duplicates. When ES cell become confluent, passage as usual. Check morphology of ES colonies for differentiation after each passage. Check also the difference in cell growth and death between 15 and 30%. It may show if a serum contains some toxic components. Passage the cells at least three times. We usually find that sera with the highest plating efficiency also have the best quality. Some companies offer already ES-tested serum for a higher cost, but this may not necessarily be the best one. When possible, always check serum at your own laboratory. A serum test takes about 3 to 4 weeks.

Acknowledgments

The author thanks Professor Peter Gruss for constant support and encouragement, Jens Krull and Sharif Mahsur for excellent technical assistance, and Anja Dietrich for critically reading the manuscript. This work is supported by the Max Planck Society.

Conditional Knockouts: Cre-lox Systems

Daniel Metzger, Mei Li, Arup Kumar Indra, Michael Schuler, and Pierre Chambon

I. INTRODUCTION

Site-directed gene targeting in the mouse has led to marked advances in understanding the function played by gene products in mammalian development, as well as in adult homeostasis and pathophysiology. However, targeting a given mutation in the germ line has some inherent limitations, such as those created by embryonic lethality, occurrence of developmental aberrations, or compensatory effects by functionally redundant genes. In many instances, these limitations may preclude the determination of the function of a given gene product in a defined subset of cells, at a given time during the life of the animal, and therefore to discriminate between cell-autonomous and noncell-autonomous functions. Furthermore, germ line mutations are inadequate to generate mouse models of human diseases resulting from somatic mutations, such as most forms of cancer (Jonkers and Berns, 2002; Metzger and Chambon, 2001). To avoid these limitations, methods to achieve conditional gene targeting have been developed, based mainly on the properties of the bacteriophage P1 site-specific Cre recombinase. As the Cre recombinase efficiently and faithfully excises in animal cells a DNA segment flanked by two loxP sites (floxed DNA), spatially or temporally controlled somatic mutations can be obtained by controlling its expression with a cell-specific or an inducible promoter, respectively (Rajewsky *et al.*, 1996). However, these conditional gene targeting systems have themselves a number of limitations, as they are only either spatially or temporally controlled. Fortunately, two systems have been developed that allow the generation of somatic mutations in a defined gene, at a selected time of the life of the animal, and in a specific cell type. In one instance, the Cre/loxP system has been combined with tetracycline-dependent regulatory systems. Spatiotemporally controlled Cre recombinase expression was obtained by doxycycline (a tetracycline analog) administration to transgenic mice bearing two transgenes encoding (i) a tetracycline-controlled transactivator under the control of a tissue-specific promoter and (ii) the Cre recombinase under the control of a minimal promoter that contains the operator sites of the tet operon. However, the generation of mice harboring both transgenes and the two LoxP-flanked alleles of a given gene requires complex breedings, and further improvements are required to eliminate basal noninduced Cre expression (Branda and Dymecki, 2004; Lewandoski, 2001; Zhu *et al.*, 2002). In the second instance, a fusion between the Cre recombinase and a mutated steroid receptor ligand-binding domain results in ligand inducibility of the recombinase activity *in vivo* (Branda and Dymecki, 2004; Garcia and Mills, 2002; Metzger and Feil, 1999). Among these fusion proteins, Cre-ER^{T2} (obtained by fusing Cre to an estrogen-nonresponsive mutated ligand-binding domain of the human estrogen receptor ERα) is particularly effective. Cell-specific expression of Cre-ER^{T2} in transgenic mice allows efficient tamoxifen-dependent Cre-mediated recombination at loci flanked by LoxP sites, without background activity, thus generating spatiotemporally controlled targeted somatic mutations (Metzger *et al.*, 2003). We illustrate here the generation of such mutations in the mouse by describing strategies and techniques used to create temporally controlled somatic mutations in target genes of epidermal keratinocytes. In the epidermis, a dynamic stratified epithelium mainly composed of keratinocytes, the innermost basal cells, form a proliferative layer, from which keratinocytes periodically

Copyright 2006, Elsevier Science (USA).

withdraw from the cell cycle and commit to terminally differentiate, while migrating into the suprabasal layers (Fuchs, 1997). Terminally differentiated keratinocytes forming the cornified layer are lost daily from the surface of the skin and are replaced continuously by newly differentiating cells. Hair follicles that develop through a series of mesenchymal–epithelial interactions during embryogenesis are also dynamic structures that are mainly composed of keratinocytes and whose outer root sheath (ORS) is contiguous with the basal layer of the epidermis. Once formed, hair follicles periodically undergo cycles of regression, rest, and growth, through which old hairs are replaced by new ones (Hardy, 1992; Paus and Cotsarelis, 1999).

As an example we describe the selective ablation of the retinoid receptor RXRα in basal epidermal keratinocytes of adult mice.

II. MATERIALS AND INSTRUMENTATION

RXRαaf2(I) (Mascrez *et al*., 1998) and RXRα$^{L2/L2}$ mice (Li *et al*., 2001) can be obtained from Pr. P. Chambon (chambon@titus.u-strasbg.fr). RosaR26R (Soriano, 1999) can be requested from P. Soriano (psoriano@fhcrc.org).

Triton X-100 (Cat. No. T8787), KCl (Cat. No. 31248), dimethylformamide (Cat. No. D4551), glutaraldehyde (25%) (Cat. No. 49630), $MgCl_2$ (Cat. No. 63068), PBS (Dulbecco's phosphate-buffered saline) (Cat. No. D5652), potassium ferricyanide (Cat. No. 244023), potassium ferrocyanide (Cat. No. P3289), tamoxifen (Tam) (Cat. No. T5648), proteinase K (Cat. No. P6556), and *Taq* DNA polymerase (5 units/μl) (Cat. No. D4545) are from Sigma-Aldrich; Tris (Cat. No. GAUTRI00-66), SDS (20%) (Cat. No. GHYSDS02-07), NaCl (Cat. No. GAUNAC01-66), and stabilized phenol (Tris saturated; pH 7.5–8) (Cat. No. 018335) are from Eurobio. Chloroform (Cat. No. 438603) and formaldehyde [40% (w/v), Cat. No. 415661] are from Carlo ERBA. No. histol + I) are from Shandon Inc. dATP (100 m*M*) (Cat. No. 27-2050-03), dCTP (100 m*M*) (Cat. No. 27-2060-03), dGTP (100 m*M*) (Cat. No. 27-2070-03), and dTTP (100 m*M*) (Cat. No. 27-2080-03) are from Amersham. Diamidino-2-phenylindole dihydrochloride (DAPI) (Cat. No. 236276), and X-Gal (5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside) (Cat. No. 745740) are from Roche Diagnostics. Dispase is from Invitrogen (Cat. No. 17105-041). Biotinylated mouse monoclonal 2CRE 2D8-1-2 antibody (Cat. No. MAB3120) and EDTA (Cat. No. EU0007B) are from Euromedex. CY3-conjugated streptavidin is from Jackson ImmunoResearch (Cat. No. 016-160-084). Vectashield mounting medium (Cat. No. H-1000) and normal goat serum (Cat. No. S-1000) are from Vector. Sunflower oil is from a grocery store.

Stericups (0.22 μm) are from Millipore (Cat. No. SCGPUOIRE). One-milliliter syringes (Cat. No. BS-01T) and 25-gauge needles (Cat. No. NN-2516R) are from Terumo. Histomolds 13×19 mm are from Leica (Cat. No. 14702218313).

The thermocycler (Gene Amp PCR system 9700) is from Perkin-Elmer Corporation. The cryostat (CM 3050S) and the fluorescent microscope (DM LB Type 307-072.057) are from Leica.

III. PROCEDURES

The following is an example of cell-specific temporally controlled somatic mutagenesis : excision of floxed genes in basal epidermal keratinocytes.

A. Establishment of Transgenic Mice Expressing Cre-ER^{T2} in Basal Epidermal Keratinocytes

1. Production of K14-Cre-ER^{T2} Transgenic Mice

To express Cre-ER^{T2} in epidermal basal keratinocytes, transgenic mice harboring Cre-ER^{T2} under the control of the keratin K14 (K14) regulatory sequences are established. To this end, a transgene encompassing the 2-kb human K14 promoter/enhancer, which is active in the dividing basal layer keratinocytes of the epidermis, the outer root sheath of hair follicles, and some other stratified squamous epithelia (e.g., oral and tongue epithelia) (Vassar *et al*., 1989), located upstream of the Cre-ER^{T2} encoding sequence (Fig. 1A), was injected into C57BL/6 × SJL zygotes (Li *et al*., 2000). The detailed description of the methods used to construct the transgene and to establish transgenic founder mice (F0) is not within the scope of this article (see Nagy *et al*., 2003; Sambrook and Russel, 2001).

2. Identification of K14-Cre-ER^{T2} Transgenic Founder Animals

Solutions

1. *Proteinase K stock solution at 10 mg/ml:* Dissolve 100 mg proteinase K in 10 ml distilled H_2O, and store as 0.5-ml aliquotes at –20°C.

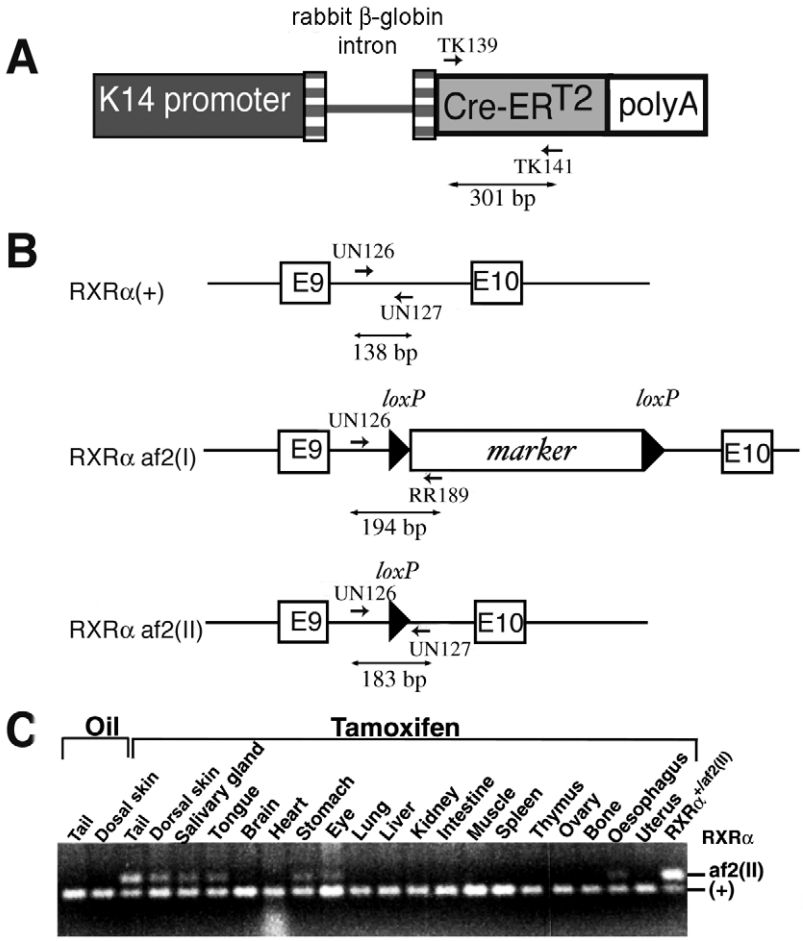

FIGURE 1 Characterization of the K14-Cre-ER^{T2} transgenic line. (A) Structure of the K14-Cre-ER^{T2} transgene. The human K14 promoter, the Cre-ER^{T2} coding sequence, and the simian virus 40 polyadenylation signal [poly (A)] are represented by black, grey, and open boxes, respectively. The rabbit β-globin intron and splice donor and acceptor sites are depicted by a line and hatched boxes, respectively. (B) Genomic structure of the RXRα WT, the RXRα af2(I) target allele, and the recombined RXRα af2(II) allele and the PCR strategies used to identify these RXRα alleles. (C) PCR detection of tamoxifen (Tam)-induced Cre-mediated DNA excision in mice. PCR was performed on DNA isolated from the indicated organs 1 day after oil- (vehicle) or Tam-treated K14-Cre-ER$^{T2\ (tg/0)}$/RXRα$^{+/af2(I)}$ mice, as well as from tail of RXRα$^{+/af2(II)}$ mice (last lane on the right), as indicated. Positions of the PCR products amplified from the WT RXRα allele (+) and the RXRα af2(II) allele are shown.

2. *Proteinase K digestion buffer*: 50 m*M* Tris (pH 8.0), 5 m*M* EDTA, 1% SDS; 0.2 *M* NaCl. To make 800 ml, assemble in the following order: 40 ml 1 *M* Tris–HCl (pH 8.0), 500 ml distilled water, 8 ml 0.5 *M* EDTA, 40 ml 20% SDS, 32 ml 5 *M* NaCl, and 180 ml distilled water. Store at room temperature.

3. *10× PCR buffer*: 500 m*M* KCl, 100 m*M* Tris–HCl, pH 8.8, 15 m*M* $MgCl_2$. To make 100 ml, add 50 ml 1 *M* KCl, 10 ml 1 M Tris–HCl (pH 8.8), and 1.5 ml 1 *M* $MgCl_2$ to 38.5 ml distilled water. Filter on a 0.22-µm stericup.

4. *Phenol/chloroform (1:1)*: Mix equal volume of stabilized phenol (Tris saturated, pH 7.5–8) and chloroform. Store at 4°C for a maximum of 2 weeks.

5. *dNTP mix (10 mM each)*: To make 1 ml, add 100 µl 100 m*M* dATP, 100 µl 100 m*M* dCTP, 100 µl 100 m*M* dGTP, and 100 µl 100 m*M* dTTP to 600 µl sterile distilled water. Store as 100-µl aliquots at –20°C.

6. *PCR Primers*: Oligonucleotides (1 µg/µl in H_2O) stored at –20°C.

For Cre PCR: TK139 (5′-ATTTGCCTGCATTACCG GTC-3′) and TK 141 (5′-ATCAACGTTTTCTTTTCG GA-3′).

Steps

1. Take a 0.5-cm tail biopsy from 2-week-old F0 mice and place them in a 1.5-ml microfuge tube.

2. To extract genomic DNA, add 250 µl proteinase K digestion buffer and 7.5 µl proteinase K stock solution (10 mg/ml) and incubate overnight at 55°C. Add an equal volume of phenol/chloroform (1:1), mix well, and microfuge at 15,000 *g* for 5 min at room temperature. Precipitate the supernatant with 500 µl ethanol (95%) and microfuge at 15,000 *g* for 5 min at room temperature. Wash the DNA pellet with 70% ethanol, air dry, and dissolve in 100 µl sterile distilled H_2O. DNA can be store at 4°C for weeks.

3. For genotyping, assemble in a 0.2-ml thermocycler tube 3 µl 10× PCR buffer, 0.6 µl dNTP (10 m*M* each), 0.06 µl 5′-primer (1 µg/µl) (TK 139), 0.06 µl 3′-primer (1 µg/µl) (TK 141), 0.2 µl *Taq* polymerase, 1 µl genomic DNA, and 20 µl H_2O. Place the tubes in a thermocycler and run the following procedure: 94°C, 5 min; 94°C, 20 s/55°C, 30 s/72°C, 5 s for 28 cycles; 72°C, 5–10 min.

4. Analyse the polymerase chain reaction (PCR) products on an ethidium bromide-stained 2.0% agarose gel (Feil *et al.*, 1996). A 301-bp product is indicative for the presence of the transgene (Fig. 1A; data not shown) and thus allows the identification of K14-Cre-ER^{T2} founder mice.

3. Identification of Founder Mice Transmitting the Transgene through the Germ Line

Transgenic founder mice are bred with C57BL/6 mice. Two week-old transgenic F1 offsprings are identified by genotyping (see Section III,A,2).

4. Identification of K14-Cre-ER^{T2} Transgenic Lines Exhibiting Tamoxifen-Dependent Cre Recombinase Activity in Basal Keratinocytes

a. Semiquantitative Analysis of Cre-ER^{T2}-Mediated LoxP-Flanked (Floxed) DNA Excision in Various Tissues. To analyse the recombinase activity of Cre-ER^{T2} transgenic mice in various organs, F1 K14-Cre-ER^{T2} mice are bred with mice bearing a floxed DNA segment within one of the two alleles of an autosomal gene, thus allowing identification of the WT and recombined alleles by PCR using a single primer pair. For that purpose, we use RXRα$^{+/af2(I)}$ mice (Mascrez *et al.*, 1998; see Fig. 1B).

Solution

Tamoxifen solution (1 mg/ml): Suspend 10 mg tamoxifen in 1 ml ethanol. Mix well by vortexing. Add 9 ml sunflower oil. Vortex for 2 min and sonicate for 30 min. Store as aliquots at –20°C for up to several months.

Steps

1. Breed F1 K14-Cre-ER^{T2} and RXRα$^{+/af2(I)}$ mice.

2. Genotype offsprings are as described in Section III,A,2. The PCR primers used to identify the RXRα af2(I) allele are UN126 (5′-CAAGGAGCCTC-CTTTCTCTA-3′) and RR189 (5′-AAGCGCAT-GCTCCAGACTGC-3′) (PCR product, 194 bp) (Fig. 1B).

3. Administer Tam to mice: Inject intraperitoneally 8-week-old K14-Cre-ER$^{T2(tg/0)}$/RXRα$^{+/af2(I)}$ mice daily with 100 µl Tam solution (0.1 mg) or oil (vehicle) for 5 days with a 1-ml syringe equipped with a 25-gauge needle (see also Comment 1).

4. Sacrifice Tam- and oil-treated mice by cervical dislocation 1 day after the last Tam injection and take organs/tissues (e.g., tail, brain, oesophagus, lung, heart, liver, tongue, salivary gland, intestine, kidney, thymus, eye, spleen, muscle, stomach, testis/ovary, and uterus).

5. Isolate genomic DNA from the various samples and analyze it by PCR as in Section III,A,2, except use UN126 (5′-CAAGGAGCCTCCTTTCTCTA-3′) and UN127 (5′-CCTGCTCTACCTGGTGACTT-3′) as PCR primers to amplify the 183-bp recombined RXRαaf2(I) allele [RXRαaf2(II)] and the 138-bp RXRα WT allele (see Figs. 1B and 1C).

K14-Cre-ER^{T2} lines exhibiting, after Tam treatment, efficient conversion of the RXRαaf2(I) allele into the RXRαaf2(II) allele in the dorsal skin and tail and no conversion in vehicle-treated (oil) control animals (Fig. 1C; data not shown) are selected for further analysis (see also Comment 2).

b. Characterization of Chimeric Cre Recombinase Expression Pattern in Skin of Selected K14-Cre-ER^{T2} Lines by Immunohistochemistry (IHC).

Solutions

1. *PBS (10×) solution*: Dissolve one bottle of PBS powder (95.5 g) in distilled H_2O and complete to 1 liter.

2. *PBS (1×) solution*: To make 1 liter, dilute 100 ml of 10 × PBS solution in 900 ml distilled water.

3. *Paraformaldehyde (8%)*: Dissolve 64 g paraformaldehyde in 500 ml distilled H_2O and add 8 ml of 1 *M* NaOH. Stir gently on a heating block (65°C) until the paraformaldehyde is dissolved. Add 80 ml 10 × PBS stock solution and allow the mixture to cool down to room temperature. Adjust the pH to 7.4 with 1 *M* HCl, and complete with H_2O to 800 ml. Filter the solution through a 0.22-µm stericup and store as 50-ml aliquots at –20°C. Avoid repeated freezing/thawing.

4. *Paraformaldehyde (2%)*: Dilute 50 ml paraformaldehyde (8%) fixation solution with PBS (1×) to a final volume of 200 ml.

5. *PBST solution: 0.1% (w/v) Triton X-100 in PBS*. To make 2 liters, add 200 ml 10 × PBS stock solution to 1500 ml distilled H_2O, 20 ml Triton X 100 [10% (w/v) in PBS], and complete to 2 liters with H_2O.

6. *5% normal goat serum/PBST*: Dilute normal goat serum in PBS to a final concentration of 5% (v/v). Aliquote and store at –20°C. Before use, add 40 µl Triton X-100 [10% (w/v) in PBS (1×)] to 4 ml 5% normal goat serum/PBS and keep on ice.

7. *DAPI (1 mg/ml) stock solution*: Dissolve 10 mg DAPI in 10 mg distilled water. Protect from light and store in aliquots (50 µl/tube) at –20°C.

8. *Vectashield containing DAPI (10µg/ml):* Add 10 µl DAPI (1-mg/ml stock solution) to 1 ml Vectashield. Mix well by vortexing for 1 min. Protect from light.

Steps

1. Administer Tam to K14-Cre-ER^{T2} mice as in Section III,A,4,a to induce Cre-ER^{T2} nuclear translocation (Brocard *et al*., 1997), thus facilitating Cre-ER^{T2} detection.
2. One day after the last Tam injection, take a tail biopsy from which bones are removed (or take shaved dorsal skin).
3. Place the samples into histomolds filled with Cryomatrix and freeze on dry ice. Store tissue blocks at –20°C until sectioning at 10 µm with a cryostat.
4. Perform Cre immunohistochemistry.
   a. Fix cryosections in paraformaldehyde (2%) for 5 min at room temperature.
   b. Wash with PBST (3 × 5 min) and then with PBS (5 min).
   c. Incubate for 30 min at room temperature in 5% normal goat serum/PBST.
   d. Incubate for 2 hr at room temperature or overnight at 4°C with the biotinylated mouse monoclonal 2CRE 2D8-1-2 antibody (1:1000 diluted in 5% normal goat serum/PBST).
   e. Wash slides with PBST (3 × 5 min) and with PBS (5 min).
   f. Incubate with CY3-conjugated streptavidine (1:400 diluted in PBS) for 1 h at room temperature.
   g. Wash with PBST (3 × 5 min) and with PBS (5 min).
   h. Mount the slides with Vectashield containing DAPI (10 µg/ml).
   i. Examine by fluorescent microscopy (excitation, 545 nm; emission 610 nm).

c. Characterization of Recombinase Activity at Cellular Level in K14-Cre-ER^{T2} Mice. Transgenic mice exhibiting Cre-ER^{T2} expression in most, if not all, basal keratinocytes are bred with transgenic lines that express a reporter gene such as LacZ, alkaline phosphatase (AP), or green fluorescent protein (GFP) after Cre-mediated floxed DNA excision. Note that the currently established Cre reporter lines (ACZL, RosaR26R, Z/AP, Z/EG, etc.) do not allow reporter gene expression in all cells/tissues of adult mice (Akagi *et al*., 1997; Brocard *et al*., 1997; Indra *et al*., 1999; Lobe *et al*., 1999; Novak *et al*., 2000; Soriano, 1999; Weber *et al*., 2001; unpublished results). Thus it is essential to breed the transgenic Cre-ER^{T2} lines to be analysed with appropriate reporter mice. For example, in epidermal keratinocytes, the ACZL (Akagi *et al*., 1997) is a good reporter line in suprabasal keratinocytes, but not in basal keratinocytes (Indra *et al*., 1999), whereas the RosaR26R (Soriano, 1999; hereafter called Rosa$^{fl/+}$) expresses LacZ in both basal and suprabasal cells after Cre-mediated recombination (Li *et al*., 2001).

Solutions

1. *LacZ fixation solution*: Prepare just before use and keep at 4°C. To make 50 ml, add 2.5 ml formaldehyde (40%) and 0.4 ml glutaraldehyde (25%) to 47.1 ml cold PBS (1×).
2. *Potassium ferricyanide (0.1 M)*: To make 100 ml, dissolve 3.29 g potassium ferricyanide in PBS and complete to 100 ml. Protect from light and store at 4°C.
3. *Potassium ferrocyanide (0.1 M)*: To make 100 ml, dissolve 4.22 g potassium ferricyanide in PBS (1×) and complete to 100 ml. Protect from light and store at 4°C.
4. *X-Gal (5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside) stock solution*: Dissolve X-Gal in dimethylformamide at a final concentration of 40 mg/ml. Protect from light and store at –20°C.
5. *β-Galactosidase staining solution*: Prepare just before use. Add 2.5 ml potassium ferricyanide (0.1 *M*), 2.5 ml potassium ferrocyanide (0.1 *M*), 0.1 ml $MgCl_2$ (1 *M*), and 1.25 ml X-Gal stock solution (40 mg/ml) to 43.65 ml PBS (1×). Filter with a 0.22-µm stericup and protect from light.
6. *Safranin counterstaining solution [0.05% (w/v)]*: Dissolve 0.05 g Safranin in 100 ml distilled water and store at room temperature.

Steps

1. Breed K14-Cre-ER$^{T2(tg/0)}$ with Rosa$^{fl/+}$ mice.
2. Select K14-Cre-ER$^{T2(tg/0)}$/Rosa$^{fl/+}$ double transgenic offsprings by PCR genotyping as described in Section III,A,2. The primers used for genotyping the ROSA fl allele are VD23 (5′-CGCCGACGGCACGCT GATTG-3′) and VD24 (5′-GTTTCAATATTGGCTTC ATC-3′).
3. Inject 8- to 10-week-old K14-Cre-ER$^{T2(tg/0)}$/Rosa$^{fl/+}$ mice for 5 days with 0.1 mg Tam or oil as in Section III,A,4,a.
4. Take tail biopsies at days 5, 30, and 60 after Tam treatment.
5. Prepare 10-µm cryosections as in Section III,A,4,b.
6. β-Galactosidase staining of the section:

a. Incubate the slides with LacZ fixation solution at 4°C for 15 min.
b. Wash 3 × 5 min with PBS at room temperature.
c. Incubate in β-galactosidase staining solution overnight at 37°C (protect from light).
d. Wash 3 × 5 min with PBS at room temperature.
e. Rinse 2 × 30 s in distilled H_2O.
f. Safranin counterstaining (optional): after step e, immerse the slides in Safranin counterstaining solution for 1 min and rinse 2 × 30 s in distilled H_2O.
g. Dehydrate the slides in 90% ethanol for 30 s, in 100% ethanol for 30 s, in 100% ethanol for 2 min, and in Histosol plus 2 × 3 min.
h. Mount the slides.
i. Examine by light microscopy.

The absence of X-Gal staining in skin of untreated or vehicle treated K14-Cre-ER$^{T2(tg/0)}$/Rosa$^{fl/+}$ mice demonstrates that the recombinase activity of K14-Cre-ER$^{T2(tg/0)}$ mice is tightly controlled (Metzger *et al*., 2003).

Suprabasal cells are renewed in 5–10 days in mouse tail epidermis. As keratinocytes of the basal and suprabasal layers of the epidermis and of the outer root sheath of hair follicle are X-Gal stained 5 days after the beginning of Tam injection, recombination is induced rapidly by Tam. Furthermore, the X-Gal staining observed in most, if not all, keratinocytes of the epidermis and ORS of the hair follicle 30 and 60 days after Tam treatment shows that recombination is induced efficiently in epidermal stem cells of this K14-Cre-ER^{T2} transgenic line (see Metzger *et al*., 2003).

B. RXRα Ablation as Example of Conditional Somatic Mutagenesis of Target Genes in Epidermal Keratinocytes of Adult Mice

To determine the function of RXRα in epidermal keratinocytes of adult mice, RXRα is conditionally disrupted in basal keratinocytes of 8- to 10-week-old mice.

Solution

Dispase solution (4 mg/ml): Dissolve 40 mg dispase in 10 ml PBS (1×). Prepare just before use.

Steps

1. Establishment of K14-Cre-ER$^{T2(tg/0)}$/RXRα$^{L2/L2}$ and control mice.
   a. Breed floxed RXRα mice (RXRα$^{L2/L2}$) with K14-Cre-ER$^{T2(tg/0)}$ mice.
   b. Identify K14-Cre-ER$^{T2(tg/0)}$/RXRα$^{L2/+}$ offsprings by genotyping as described in Section III,A,2. Primers ZO243 (5′-TCCTTCACCAAGCACATCTG-3′) and ZO244 (5′-TGCAGCCCTCACAACTGTAT-3′) are used to identify RXRα L2 allele (701 bp) and (+) allele (669 bp) (Fig. 2A); the PCR program is 94°C, 5 min; 94°C, 10 s/56°C, 30 s/72°C 1 min for 32 cycles; 72°C 5–10 min.
   c. Breed K14-Cre-ER$^{T2(tg/0)}$/RXRα$^{L2/+}$ mice with RXRα$^{L2/L2}$ and identify K14-Cre-ER$^{T2(tg/0)}$/RXRα$^{L2/L2}$ offspring (pre-mutant mice), as well as K14-Cre-ER$^{T2(tg/0)}$/RXRα$^{L2/+}$ and K14-Cre-ER$^{T2(0/0)}$/RXRα$^{L2/L2}$ littermates (control mice) by genotyping as described earlier.

2. Administer oil or tamoxifen to 8- to 10-week-old sex- and age-matched K14-Cre-ER$^{T2(tg/0)}$/RXRα$^{L2/L2}$ and control littermates as in Section III,A,4.

3. Analyse the excision efficiency of the target gene in the tail epidermis 2 and 8 weeks after Tam/oil treatment.
   a. Take tail biopsies.
   b. Remove bones.
   c. Incubate samples in dispase (4 mg/ml in PBS) overnight at 4°C (or for 2 h at 37°C).
   d. Separate the dermis from the epidermis with forceps.
   e. Extract genomic DNA and analyse it by PCR as in Section III,A,2. Primers ZO243 (5′-TCCTTCACCAAGCACATCTG-3′) and UD196 (5′-TCACCTGGACTTGTCACCTAG-3′) are used to amplify the RXRαL$^-$ allele (426 bp, Fig. 2A).

The example shown in Fig. 2B demonstrates that RXRα L2 alleles were fully converted into RXRα L$^-$ alleles in the epidermis, but not in the dermis of Cre-ER^{T2} expressing mice, 2 weeks after Tam treatment, demonstrating the selectivity and efficiency of the K14-Cre-ER^{T2} transgene for mediating somatic ablation of RXRα in epidermal keratinocytes after Tam treatment (RXRα$^{ep-/-}$ mice). The absence of L2 to L$^-$ allele conversion in control mice expressing the K14-Cre-ER^{T2} transgene without Tam treatment shows that RXRα ablation is strictly dependent on Tam (Fig. 2B). Moreover, the presence of only RXRα L$^-$ alleles in K14-Cre-ER$^{T2(tg/0)}$/RXRα$^{L2/L2}$ mouse epidermis 8 weeks after Tam treatment indicates that RXRα was disrupted in most, if not all, epidermal stem cells (data not shown).

Efficient RXRα protein ablation in the interfollicular keratinocytes and outer root sheath of the hair follicle in Tam-treated K14-Cre-ER$^{T2(tg/0)}$/RXRα$^{L2/L2}$ mice can be verified by immunohistochemistry in skin biopsies using an antibody directed against RXRα, according to standard procedures (see Metzger *et al*., 2003).

The phenotypic analysis of mice in which a target gene is ablated in adult mouse skin can be investigated by macroscopic examination and histological analysis. For example, weekly examination of mutant and

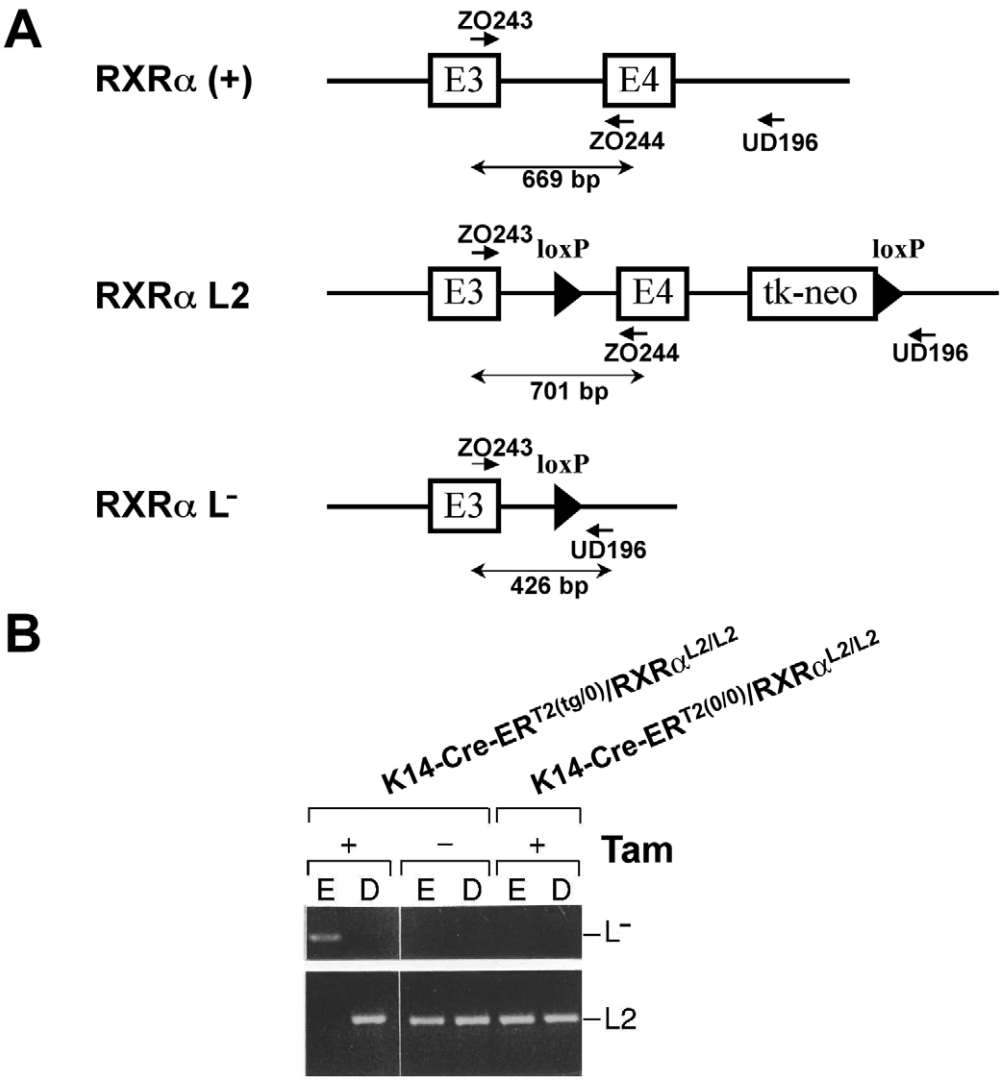

FIGURE 2 Temporally controlled RXRα ablation in epidermal keratinocytes. Schematic diagram of the RXRα WT (+) genomic locus, the floxed RXRα L2 allele, and the RXRα L⁻ allele obtained after tamoxifen (Tam)-induced Cre-mediated excision of exon 4. PCR primers to identify the RXRα +, L2, and L⁻ alleles are indicated. Arrowheads represent LoxP sites. (B) Efficiency of K14-Cre-ER^{T2}-mediated RXRα recombination in adult skin. L2 and L⁻ RXRα alleles were identified by PCR analysis of genomic DNA extracted from epidermis "E" or dermis "D" isolated from tail 2 weeks after administration of either Tam (+) or oil (vehicle; –) to K14-Cre-ER$^{T2(tg/0)}$/RXRα$^{L2/L2}$ and K14-Cre-ER$^{T2(0/0)}$/RXRα$^{L2/L2}$ mice, as indicated. PCR fragments corresponding to the RXRα L2 and L⁻ alleles are displayed.

control mice revealed hair loss in the ventral region of K14-Cre-ER$^{T2(tg/0)}$/RXRα$^{L2/L2}$ mice 6–7 weeks after Tam treatment, but not in oil-treated mice of the same genotype or in Tam-treated K14-Cre-ER$^{T2(tg/0)}$/RXRα$^{L2/+}$ mice. Twelve to 16 weeks after Tam treatment, large regions of ventral skin and smaller regions of dorsal skin of mutant animals were hairless. Cysts became visible under the skin surface, which enlarged and spread all over the body with time. With increasing age (>20 weeks), minor focal lesions appeared on hairless dorsal skin, on chins, and behind the ears. Histology of hairless skin showed disappearance of hair follicles and presence of utriculi and dermal cysts. Abnormal keratinocyte proliferation and differentiation were also observed, as well as inflammatory reactions (Li *et al.*, 2000; Metzger *et al.*, 2003).

IV. CONCLUSIONS

The K14-Cre-ER^{T2} mouse line generated and characterised according to the present procedure very

effectively allows Cre-mediated recombination of floxed DNA in basal epidermal keratinocytes upon low-dose Tam administration (0.1 mg for 5 days). As suprabasal keratinocytes are replaced continuously by basal cell-derived newly differentiated cells, the floxed DNA segment is deleted in all keratinocytes within 1 to 2 weeks. It is noteworthy that no background recombination was detected in the absence of Tam administration, which allows to tightly control the time at which the genetic modification is generated. Ablation of RXRα in adult mouse keratinocytes revealed important functions of this gene in epidermal keratinocyte proliferation and differentiation, hair cycling, and epidermal inflammation (Li *et al*., 2000). Importantly, selective induction of the recombinase activity of Cre-ER^{T2} proteins has been achieved in all mouse cell types as yet tested. We have established a number of mouse lines allowing temporally controlled somatic mutagenesis in various cell types and tissues, including adipocytes, hepatocytes, nervous system, male germ cells, skeletal myocytes, prostate epithelium (Imai *et al*., 2001a,b; Schuler *et al*., 2004; Weber *et al*., 2001, 2003; unpublished data). The only serious drawback resides in the availability of promoter-containing segments that allow the selective expression of the Cre-ER^{T2} transgene in all cells of a given cell-type, as using small promoter regions, no or mosaic transgenic expression is often observed. Flanking the transgene with insulator sequences or using large genomic promoter-containing segments, present in BACs or PACs, known to reduce gene silencing (Bell *et al*., 2001; Giraldo and Montoliu, 2001; Yang *et al*., 1997), appears to facilitate the establishment of potent Cre-ER^{T2} transgenic mice (unpublished data).

V. COMMENTS

1. The active form of tamoxifen, 4-hydroxytamoxifen, can also be administered, but as it is less soluble and more costly, but not more potent in the mouse, it is recommended to use tamoxifen, which is converted to 4-hydroxytamoxifen in the liver.

2. Recombination in the tongue, salivary gland, eye, stomach, and oesophagus is in agreement with the previously described promoter activity of the human K14 promoter (Vassar *et al*., 1989).

VI. PITFALL

Separate Tam-treated and untreated mice to avoid exposure of control mice to Tam.

Acknowledgments

We are grateful to P. Soriano for the generous gift of the RosaR26R mice. We thank present and past members of the laboratory who have contributed to developing the foregoing protocols, as well as E. Metzger and A. Van Es and the animal facility staff for animal care, the secretariat staff for typing, and the illustration staff for preparing the figures. This work was supported by funds from the Centre National de la Recherche Scientifique, the Institut National de la Santé et de la Recherche Médicale, the Collège de France, the Hôpital Universitaire de Strasbourg, the Association pour la Recherche sur le Cancer, the Fondation pour la Recherche Médicale, the Human Frontier Science Program, and the Ministère de l'Éducation Nationale de la Recherche et de la Technologie.

CHAPTER

54

RNAi-Mediated Gene Silencing in Mammalian Cells

Derek M. Dykxhoorn

I. INTRODUCTION

RNA interference (RNAi) is the sequence-specific silencing of gene expression in response to double-stranded (ds)RNA. The term RNAi was first coined by Fire and colleagues (1998) when they discovered that the injection of long dsRNA into the nematode *Caenorhabditis elegans* led to the inhibition of gene expression by the targeted degradation of the homologous mRNA. These results were recapitulated *in vitro* by the silencing of gene expression due to the targeted cleavage of the homologous mRNA when long dsRNA was introduced into *Drosophila melanogaster* embryo extracts (Tuschl *et al*., 1999). Although these experiments demonstrated that the presence of long dsRNA initiates the process of RNAi, it has become increasingly clear that the sequence-specific effector molecules that mediate the targeted disruption of the mRNA are short RNA species. The long dsRNA introduced into *Drosophila* extracts was shown to be rapidly cleaved into ~22 nucleotide dsRNAs, termed short interfering (si) RNAs (Zamore *et al*., 2000). These siRNAs were shown to be sufficient to guide the degradation of the corresponding mRNA (Elbashir *et al*., 2001a). Similar short RNA species have been found in *C. elegans* and *Drosophila* embryos injected with long dsRNA, as well as in *Drosophila* Schneider 2 (S2) transfected with long dsRNA (Hammond *et al*., 2000; Parrish *et al*., 2000, Yang *et al*., 2000) (Fig. 1).

Biochemical and genetic studies have begun to provide the molecular details for how dsRNA can lead to the targeted disruption and silencing of gene expression. In the first step of the RNAi pathway, long dsRNA is cleaved into siRNAs. These siRNAs are 21–23 nucleotide dsRNA duplexes that have 5′-phosphate and 3′-hydroxyl groups. Importantly, siRNAs were shown to have symmetric 2–3 nucleotide 3′ overhangs reminiscent of an RNase III-like cleavage pattern. (Elbashir *et al*., 2001a). This knowledge led to the identification of the highly conserved Dicer family of RNase III enzymes as the mediator of the dsRNA cleavage (Bernstein *et al*., 2001). Upon formation, the siRNAs are unwound and one of the strands becomes incorporated into the multisubunit RNA-induced silencing complex (RISC). The strand that enters RISC appears to be determined by the thermodynamic stability of the 5′ end of the two strands, the strand with the lower thermodynamic stability predominating in RISC (Schwartz *et al*., 2003; Khvorova *et al*., 2003). The antisense strand of the siRNA guides the endonuclease activity of RISC to the homologous site on the cognate mRNA, resulting in the cleavage of the mRNA in the center of the siRNA–mRNA recognition site (reviewed in Dykxhoorn *et al*., 2003).

Although the introduction of long dsRNA has been effectively used for the silencing of gene expression in a variety of organisms (e.g., plants, *Drosophila*, and *C. elegans*), the application of this technology has been limited in vertebrate cells by the dsRNA-mediated induction of the sequence-nonspecific interferon response. The binding of long dsRNA leads to the activation of the dsRNA-dependent protein kinase (PKR). Once activated, PKR phosphorylates the α subunit of the translation initiation factor, EIF2α, leading to a general inhibition of translation and suppression of protein synthesis. In addition, long dsRNA activates 2′-5′ oligoadenylate synthase, leading to the conversion of ATP into 2′-5′ oligoadenylates [pppA(2′p5′A)n]. These oligoadenylates in turn activate RNase L, which leads to the nonsequence-specific cleavage of several RNA species, including ribosomal (r)RNA. This results

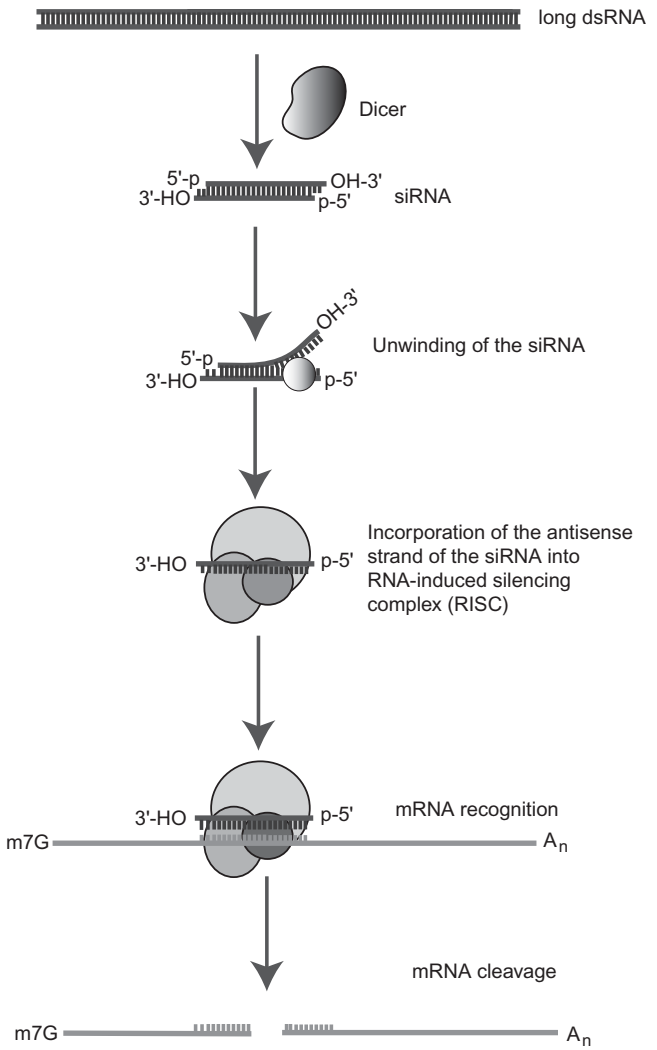

FIGURE 1 Schematic representation of the RNAi pathway. Long dsRNAs are cleaved by the RNase III-like enzyme Dicer into 21–23 nucleotide double-stranded short interfering (si)RNAs. The siRNAs are unwound into their single strands. The unwinding begins at the most thermodynamically unstable end of the siRNAs (Khvorova *et al.*, 2003; Schwarz *et al.*, 2003). Only one of the siRNA strands will predominate in the RNA-induced silencing complex (RISC). This choice appears to be based on the thermodynamic stability of the ends of the siRNA. The end of the siRNA that has the least stable binding at the 5′ end will preferentially enter RISC. The single strand of the siRNA incorporated into RISC will guide the protein–nucleic acid complex to the homologous site on the target mRNA. The mRNA is cleaved by the endonuclease activity of RISC.

in an inhibition of mRNA translation (Stark *et al.*, 1989). Activation of the interferon response can ultimately induce cells to undergo program cell death (apoptosis). However, the introduction dsRNA that is <30 nucleotides in length does not appear to induce the interferon pathway (Elbashir *et al.*, 2001b). Tuschl and colleagues demonstrated that the transfection of chemically synthesized siRNAs into mammalian cells effectively silenced gene expression without inducing the interferon response (Elbashir *et al.*, 2001b). This seminal discovery has led to the widespread use of RNAi for the targeted disruption of gene expression and the study of gene function, revolutioning the way reverse genetic experiments are performed in mammalian systems.

The demonstration that chemically or enzymatically synthesized siRNAs are capable of effectively silencing gene expression has led to the rapid development of RNAi-based technologies. These technologies have served to address two limitations inherent in the gene silencing by transfection of synthetic siRNAs, the transient nature of the silencing phenotype and the low efficiency of siRNA transfection in certain cell types, particularly primary cells. The transfection of siRNAs into rapidly dividing cells leads to a transient knockdown of the target gene. In rapidly growing cells (e.g., HeLa cells), the peak of silencing for most proteins occurs between 60 and 72 h posttransfection with a loss of silencing occurring approximately 5 days posttransfection (Dykxhoorn *et al.*, 2003). The decrease in the siRNA levels appears to correlate directly with the number of cell divisions, implying that it is a dilution of the siRNAs below a critical threshold level that leads to the loss of the silencing phenotype.

To increase the duration of silencing, DNA vector-based approaches have been developed that express siRNAs or precursors of siRNAs. The majority of these DNA-based RNAi systems rely on the expression of short RNA species from RNA polymerase III (pol III) promoters, particularly the U6 and H1 promoters. All of the elements required for efficient transcription from these promoters are located upstream of the transcription start site (+1), and the deletion of sequences downstream of the start site has no effect on the level of transcription (Paule and White, 2000). Although the U6 promoter has a requirement of a guanosine in the +1 position, the H1 promoter seems to have no such sequence constraints. Efficient termination of transcription is achieved in the absence of additional factors when the pol III encounters a simple run of four or more thymidine residues (Paule and White, 2000).

The siRNA expression constructs fall into two categories, those that express the individual strands of the siRNA in *trans* from tandem promoters and those that express sense and antisense strands in *cis* by expressing short hairpin (sh)RNAs that can be processed by dicer into active siRNAs. A number of groups have described the use of U6 promoters that express the sense and the antisense strands of a siRNA from separate transcription units (e.g., Lee *et al.*, 2002; Miyagishi and Taira, 2002). The strands will associate

in vivo to produce a functional siRNA. This mode of siRNA formation is completely independent of Dicer processing (Fig. 2).

The majority of siRNA-based expression systems have used pol III promoters to express hairpin RNA precursors that can be cleaved by Dicer to produce functional siRNAs. In addition to cleaving long dsRNA, Dicer has also been shown to process hairpin RNA, as demonstrated by the requirement of Dicer for the processing of the endogenous hairpin structures, e.g., the pre-let 7 micro(mi)RNA (Hutvagner and Zamore, 2002). Short hairpin RNA with fully complementary stems ranging between 19 and 29 nucleotides in length have been shown to produce active siRNAs when expressed from pol III promoters (e.g., Brummelkamp *et al*., 2002; Paddison *et al*., 2002). The expressed hairpin RNA serves as a substrate for Dicer cleavage producing siRNAs that can target mRNA cleavage by RISC.

These expression constructs have been cloned into a variety of vector systems, including plasmid, oncoretroviral, lentiviral, and adenoviral vectors, many of which are available commercially. The main advantage of the different vector systems is the ability to target different cell types and the ability to target cells that are refractory to the transfection of siRNAs (e.g., primary cells). Plasmids can be used to create cell lines that stably silence a particular gene of interest; however, the expression of siRNAs from plasmids requires the transfection of the plasmid into the cell type of interest. Like siRNAs, this approach is limited to cells that can be transfected easily. In contrast, the use of viral vectors greatly expands the range of cell types and cell lines that can be targeted for gene silencing, as these vectors rely on the infection of cells with the recombinant viral vectors, a process that is much more efficient than transfection. Although these vector systems facilitate transduction of cell types in different manners, the process of shRNA expression and the formation of active siRNAs is the same regardless of the vector system used.

The development of RNAi-based silencing approaches has made it possible to target virtually any gene of interest in an organism. This has opened up the potential to use RNAi-based technologies for large-scale genomic screens. This approach has been applied most successfully to *C. elegans* where RNAi-based approaches have been used to silence ~86% of the *C. elegans* genes (Kamath and Ahringer, 2003). Not only have RNAi-based gene silencing approaches been effective in gene function analysis, but these technologies also hold a great deal of potential as therapeutic

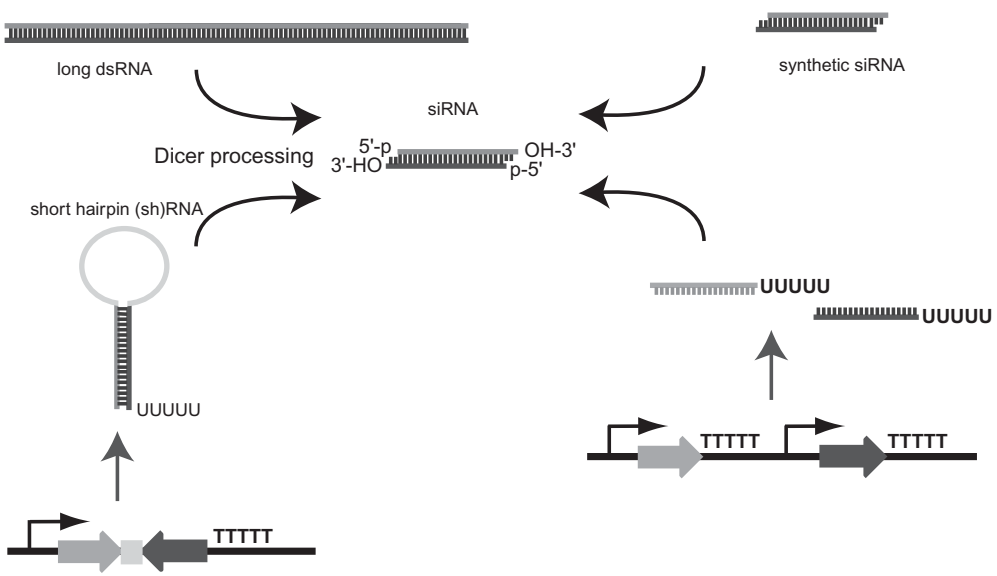

FIGURE 2 Strategies for siRNA formation. Long double-stranded RNAs and chemically synthesized siRNAs can be transfected directly into cells for a transient silencing phenotype. Unlike siRNAs, which can be unwound and incorporated into RISC, long dsRNA must be processed by Dicer to create active siRNAs. SiRNAs or siRNA precursors can be expressed from DNA vectors. The sense and antisense strands of the siRNA can be expressed from tandem pol III promoters. The strands can associate directly, forming an active siRNA. Alternatively, short hairpin RNAs can be expressed from pol III promoters. The shRNAs can be cleaved by Dicer to produce the active siRNAs. The RISC-mediated mRNA cleavage remains the same regardless of the method of siRNA production.

agents, such as the suppression of viral gene expression and replication (Novina *et al*., 2003).

II. MATERIALS AND INSTRUMENTATION

Oligofectamine (Cat. No. 12252-011), Lipofectamine 2000 (Cat. No. 12566-014), agarose (Cat. No. 15510-019), and bovine serum albumin (BSA, Cat. No. 15561-020) are from Invitrogen Corporation. Opti-MEM I reduced serum medium (Cat. No. 31985-062), Dulbecco's modified Eagle medium (DMEM, Cat. No. 11960-044), and fetal bovine serum (FBS, Cat. no. 10082-139) are from Gibco cell culture. *Apa*I (Cat. No. R0114S), *Eco*RI (Cat. No. R0101S), T4 DNA ligase (Cat. No. M0202S), and T4 DNA polymerase (Cat. No. M0203S) are from New England Biolabs. Nusieve GTG agarose (Cat. No. 50081) is from FMC. Phenol : chloroform : isoamyl alcohol (25 : 24 : 1) (Cat. No. 9730) is from Ambion. Chloroform (Cat. No. C2432), isoamyl alcohol (Cat. No. I9392), ammonium acetate (Cat. No. A1542), potassium acetate (Cat. No. P1190), magnesium acetate tetrahydrate (Cat. No. M2545), sodium acetate (Cat. No. S2889), sodium chloride (Cat. No. S7653), EDTA (Cat. No. E9884), glacial acetic acid (Cat. No. 45725), HEPES sodium salt (Cat. No. H7006), bromphenol blue (Cat. No. B0126), xylene cyanole FF (Cat. No. X4126), Ficoll 400 (Cat. No. F4375), ethidium bromide (Cat. No. E8751), ampicillin (Cat. No. A9518), and Tris borate–EDTA buffer (TBE, 5X concentrate, Cat. No. T6400) are from Sigma. Tris (Cat. No. 604200) and dNTP set, polymerase chain reaction (PCR) grade (Cat. No. 1969064), are from Roche. QIAquick gel extraction kit (Cat. No. 28704) is from Qiagen. One hundred percent ethanol (Cat. No. 111USP200) and 95% ethanol (Cat. No. 111000190) are from Pharmco products. Difco LB agar (Cat. No. 244510) is from BD Bioscience.

III. PROCEDURES

A. Designing effective siRNAs

siRNAs that target different regions of the same mRNA will differ markedly in the efficiency with which they silence gene expression. In order to achieve maximal levels of silencing, the choice of siRNAs is critical. Because mammalian RNAi is a cytoplasmic process, sequences corresponding to intronic regions should not be chosen. In addition, any regions of the mRNA that could potentially serve as binding sites for RNA-binding proteins should be avoided (e.g., the region surrounding the start codon and exon–exon boundaries). Traditionally, siRNAs were chosen that have an even representation and distribution of all the nucleotides within the antisense strand of the siRNA. Empirically, several sequence motifs have been consistently found to be associated with siRNAs that effectively silence gene expression, including $AAN_{19}TT$, $NAN_{19}NN$, $NARN_{17}YNN$, and $NANN_{17}YNN$ (where N = any nucleotide, R = a purine, and Y = a pyrimidine) (Martinez *et al*., 2002). Two groups have done an extensive analysis of the effect of different nucleotides and the entry of siRNA strands into RISC. They found that there were thermodynamic constraints upon the strands that governed the ability of one of the two strands to enter RISC and mediate effective silencing (Khvorova *et al*., 2003; Schwartz *et al*., 2003). In particular, the relative and absolute stabilities of the two 5′ ends of the siRNA strands determined which strand was capable of entering RISC, with the strand with the less thermodynamically stable 5′ end predominating in RISC and the other strand being destroyed.

It is always advisable to choose and test several different siRNAs against the same mRNA to determine the sequences that give the highest level of silencing. A BLAST search should be performed on all the selected sequences against sequence databases [e.g., EST or Unigene libraries from the National Center for Biotechnology Information (www.ncbi.nlm.gov)] to ensure that the siRNA sequence targets a single gene, thereby minimizing the chances of off-target effects. There are a number of Web sites that will predict potential siRNA sequences from a given mRNA sequence (see Table I).

B. Preparation of siRNA Strands

Solutions

1. *100% ethanol*
2. *95% ethanol*
3. *10 M ammonium acetate (pH 7.0)*: Dissolve 77.08 g ammonium acetate in distilled water, adjust pH to 7.0, and make up to 100 ml
4. *1 X annealing buffer (pH 7.4)*: 0.1 *M* potassium acetate, 2 m*M* magnesium acetate, 30 m*M* HEPES KOH (pH 7.4). Make a 1 *M* HEPES KOH solution by dissolving 238.3 g of HEPES in distilled water, adjust the pH to 7.4 by adding potassium hydroxide, and make up to 1 liter. Make 1 *M* potassium acetate and 1 *M* magnesium acetate as per Sambrook *et al*. (1989). For 10 ml of annealing buffer, add 0.3 ml 1 *M* HEPES KOH (pH 7.4), 1 ml 1 *M* potassium acetate, and 20 µl of 1 *M*

magnesium acetate; make up to 10 ml with distilled water.

Steps

Chemically synthesized siRNAs can be obtained from commercial RNA synthesis companies (see Table II). The siRNA strands are preferably synthesized using protected ribonucleoside phosphoramidites to increase their stability. If protected groups are used, siRNAs will require deprotection and desalting before use. For specific details regarding the preparation of siRNAs prior to their use in a gene-silencing experiment, see the protocols from the appropriate RNA synthesis company. These companies offer different synthesis options and degrees of purity.

1. siRNAs synthesized by Dharmacon Research (Boulder, CO) use the 2′-ACE protection chemistry. siRNAs are deprotected by resuspensing the lyophilized siRNA pellet in 400 µl of the 2′-deprotection buffer (100 m*M* TEMED-acetate, pH 3.8), mixing thoroughly by vortexing and incubating at 60°C for 45 min.
2. To desalt siRNAs, add 0.1 volume of 10 *M* ammonium acetate, pH 7.0 (40 µl), and 1500 µl of 100% ethanol to the deprotected siRNA solution and mix thoroughly by vortexing.
3. Incubate the siRNA solution at –20°C for 2 h.
4. Centrifuge the sample at 12,000 *g* for 30 min at 4°C to pellet the siRNA.
5. Carefully remove the supernatant without disturbing the pellet.
6. Wash the pellet by adding 200 µl of ice-cold 95% ethanol and centrifuging the sample at 12,000 *g* for 30 min.
7. Remove the supernatant and allow the pellet to completely dry in a Speed Vac.
8. Resuspend the pellet in water or in an appropriate buffer (e.g., 1 X annealing buffer).
9. Determine the concentration of the siRNA by UV spectroscopy.

C. Annealing siRNA Strands

Solutions

1. *0.5X TBE buffer*: For 1 liter, add 100 ml 5X TBE buffer and 900 ml distilled water
2. *10 mg/ml ethidium bromide*: Add 1 g of ethidium bromide to 100 ml of distilled water

Steps

1. Add equimolar amounts of the two siRNA strands to an Eppendorf tube. Typically, siRNA solutions that are between 20 and 100 µ*M* are used so the annealed siRNAs can be used directly in silencing experiments without further dilution.

2. Anneal the siRNA strands by heating to 95°C for 5 min. Slow cool the siRNA solution by reducing the temperature by 1°C every 30 s until 35°C and 1°C every minute until 5°C. This can be achieved with the use of a thermal cycler. Alternatively, the siRNA sample can be heated at 90°C for 1 min, followed by a 1-h incubation at 37°C. The duplexed siRNA should be stored at –20°C.

3. To test for complete annealing, single-stranded sense and antisense siRNAs and the annealed duplex siRNA can be run on a 4.0% Nusieve GTG agarose gel, stained with ethidium bromide, and visualized under UV light. Load 1 µl of a 20–100 µ*M* stock of each of the single strands and 0.5–1 µl of the duplex siRNA (20–100 µ*M* stock concentration) in 1× agarose gel loading buffer on a 4.0% Nusieve GTG agarose gel in 0.5× TBE buffer. The ethidium bromide can be added directly to the gel (0.5 µg/ml final concentration) when poured or the gel can be stained after electrophoresis by immersing the gel in 0.5X TBE containing ethidium bromide (0.5 µg/ml final concentration). The duplexed siRNAs should migrate more slowly in the gel than the single strands of the siRNA.

D. Parameters for the Efficient Transfection of siRNAs into Mammalian Cells

A variety of transfection reagents have been developed specifically for the transfection of siRNAs (see Table III). These different transfection reagents have been optimized for the transfection of different cell lines and have different protocols and requirements for optimal use. To achieve maximal levels of silencing, the transfection conditions for any particular cell line must be optimized. This includes optimizing the number of cells used in the transfection, the amount of siRNAs, and transfection reagent needed for optimal transfection. In addition the degree of silencing of any particular gene will be dependent on the abundance and half-life of that protein. Typically a knockdown phenotype can be seen between 24 and 72 h posttransfection; however, proteins with a longer half-life will only be decreased after extended periods of time. If the rate at which the siRNAs are diluted by the doubling of the cells is shorter than the half-life of the protein, it maybe necessary to retransfect the cells with the siRNAs. Alternatively, siRNAs can be expressed from a DNA vector to achieve a stable, long-lived silencing.

TABLE III Transfection Reagents Optimized for siRNA Transduction

Transfection reagent	Company

iFECT	Molecula www.molecula.com

Although there are a variety of reagents available for siRNA transfection, we have predominately used Oligofectamine for the transfection of siRNAs into mammalian cells. In addition, Lipofectamine 2000 has been used effectively for the cotransfection of a plasmid and an siRNA. Oligofectamine is an excellent choice for the transfection of siRNAs due to the low level of toxicity that this lipid has on the cells; however, Oligofectamine is inefficient at transfecting plasmids. Unlike Oligofectamine, Lipofectamine 2000 is very effective at transfecting plasmids, but due to its toxicity to the cells, transfections should be performed on cells at higher cell densities and media containing the transfection media need to be removed 4 to 6 h after the start of the transfection and replaced with fresh media.

E. Transfection of siRNAs into Mammalian Cells with Oligofectamine

Solutions

1. *Oligofectamine*
2. *Dulbecco's modified Eagles media*
3. *Opti MEM I reduced serum medium*
4. Fetal bovine serum

Steps

1. Plate HeLa cells at 5×10^4 to 1×10^5 cells per well in a 6-well plate 16–24 h before the transfection. The cells should be plated in DMEM supplemented with 10% FBS but without antibiotics. For transfections with Lipofectamine 2000, plate the cells at a higher density (e.g., 4×10^5 cells/well) to combat some of its cytotoxic effects. Incubate the cells overnight at 37°C in a CO_2 incubator.
2. Prepare the siRNA–lipid complexes. For each well of the transfection:
   a. Add the annealed, double-stranded siRNA to serum-free, antibiotic-free DMEM or OptiMEM I reduced serum medium to give a final siRNA concentration of 10–100 pmol/transfection (100 pmol would be 1 µl of a 100 µ*M* siRNA solution in 1 ml final volume of the transfection reaction) in a 50-µl final volume. It is important to note that not all serum-free medium formulations [e.g., 293 SFM II (Invitrogen)] are compatible with cationic lipid transfection reagents and should be tested prior to use.
   b. Prepare the Oligofectamine by diluting 3 µl of Oligofectamine in serum-free, antibiotic-free DMEM or OptiMEM I reduced serum medium to a final volume of 50 µl. Mix the contents of the tube gently and let it incubate at room temperature for 5 to 10 min.
   c. Combine the diluted siRNA solution and the diluted Oligofectamine solution and mix gently. Incubate for 15–20 min at room temperature to allow for the siRNA–lipid complexes to form.
3. Remove growth media from the cells and wash once with serum-free, antibiotic-free DMEM. Add 900 µl of the serum-free, antibiotic-free medium on the cells. The transfection can be performed in OptiMEM I reduced serum medium without affecting the transfection efficiency. *Note*: If the health of the cells is compromised, transfection with Oligofectamine can be performed in the presence of serum.
4. Add 100 µl of the siRNA–lipid complexes to each well of the cells in serum-free medium and incubate the cells for 4 h at 37°C in a CO_2 incubator.
5. After the 4 h of incubation, add 1 ml of DMEM containing 20% serum to each well. For most cell types there is no need to remove the medium containing the siRNA–lipid complex due to the low degree of toxicity of Oligofectamine; however, the medium containing siRNA–lipid complexes can be removed and DMEM containing 10% serum can be add to the cells. Some cell types can be grown for extended periods of time in OptiMEM I reduced serum medium. For these cells, the siRNA–lipid complexes in OptiMEM can be grown for longer periods of time (e.g., overnight) without having to change the transfection medium.
6. Grown cells at 37°C in a CO_2 incubator until they are ready to be analyzed for the silencing phenotype. This is typically between 24 and 72 h posttransfection, but a time course experiment should be performed to determine the time of maximal gene silencing for each particular protein.

F. Cloning of shRNA into an U6 Promoter Containing Vector

Preparing Vectors That Have a Blunt end at the 5′ End

This protocol is for vectors that have an *Apa*I site directly at the start site of transcript on the U6 promoter (Fig. 3). The *Apa*I site (GGGCCC) is the first restriction site of the poly linker, with the first G of the recognition site being the +1 position of the transcript. Digesting with *Apa*I and creating a blunt end by treatment with T4 DNA polymerase will provide the necessary guanosine residue at the +1 position and will leave no additional residues at the 5′ end of the transcript. Vectors with this design include the pBS/U6 plasmid from Sui and colleagues (2002), which lacks a selectable marker but can be used in transient transfections and the pSHARP series of plasmids (available from the author), versions of which have hygromycin or zeocin selectable markers or dsRed fluorescent protein.

Solutions

1. *Phenol:chloroform:isoamyl alcohol (25:24:1)*
2. *Chloroform:isoamyl alcohol (24:1)*: For 25 ml, add 24 ml of chloroform and 1 ml of isoamyl alcohol
3. *3 M sodium acetate (pH 5.2)*: For 1 liter, dissolve 408.1 g of sodium acetate in distilled water, adjust the pH to 5.2 with glacial acetic acid, and bring the volume to 1 liter with distilled water
4. *100% ethanol*
5. *70% ethanol*: For 100 ml, combine 70 ml of 100% ethanol and 30 ml of distilled water
6. *0.5X TBE buffer*: For 1 liter, add 100 ml 5X TBE buffer and 900 ml distilled water
7. *10 mg/ml ethidium bromide*: Add 1 g of ethidium bromide to 100 ml of distilled water

Steps

1. Digest the vector with *Apa*I at 25°C for 1–3 h. Heat inactivate the enzyme by incubating the reaction at 75°C for 20 min.

◀ **FIGURE 3** Cloning of a short hairpin RNA expression cassette into a pol III promoter-based expression system. (A) Structure of the pSHARP-zeo plasmid. shRNAs are expressed from the U6 promoter. The plasmid also contains a zeocin resistance gene that allows for the selection of stable siRNA-expressing cell lines. (B) The multiple cloning site (MCS) of pSHARP vectors. The *Apa*I restriction site (GGGCĈC) has been cloned directly next to the U6 promoter. When the vector is cut with *Apa*I and blunted by T4 DNA polymerase, the first G of the *Apa*I recognition site forms the +1 G of the transcript. All of the sites listed are found uniquely in the MCS. (C) An example of oligo nucleotides that will be ligated together to form the DNA insert, which when expressed will produce the shRNA. This pair of oligo nucleotides encode for an shRNA that is active against the green fluorescent protein (GFP) (Stewart *et al*., 2003). The shRNA encodes a 19 nucleotide stem and a 9 nucleotide loop (TTCAAGAGA) (in the gray box) and a run of five thymidine residues for the termination of transcription (Brummelkamp *et al*., 2002). When the strands are annealed, they will form a blunt end at the 5′ end (relative to the forward oligo nucleotide) and the overhang of the *Eco*RI restriction site at the 3′ end. Each of the strands has been synthesized with a phosphate group at the 5′ end so the oligo nucleotide can be cloned directly into the vector after annealing. (D) Cloning strategy for the insertion of oligo nucleotides for the shRNA into the pSHARP vector. See the cloning protocol for cloning of shRNA into an U6 promoter-containing vector. The shRNA against GFP was produced by transcription from the U6 promoter. The shRNA is cleaved by Dicer, leading to the production of the active siRNA against GFP.

2. Purify the DNA. Add an equal volume of phenol:chloroform:isoamyl alcohol (25:24:1) to the DNA solution. Vortex the solution briefly (1 min) and centrifuge for 10 min at 12,000 *g* (~13,000 rpm in a microcentrifgue). Carefully remove the upper aqueous phase and place in a new tube.

3. Add an equal volume of chloroform:isoamyl alcohol (24:1), vortex briefly, and centrifuge for 10 min at 12,000 *g*. Remove the upper aqueous phase and place in a new tube.

4. Precipitate the DNA by adding 0.1 volume of 3 *M* sodium acetate (pH 5.2) and 2.5 volumes of 100% ethanol. Incubate at –20°C for 30 min. Centrifuge the sample at 12,000 *g* for 10 min at 4°C. Be careful to avoid the pelleted DNA and remove the supernatant.

5. Wash the DNA pellet by adding 200 µl of ice-cold 70% ethanol. Centrifuge the sample at 12,000 *g* for 10 min at 4°C. Remove the supernatant and air dry the pellet.

6. Blunt the *Apa*I site. Resuspend the DNA in distilled H_2O and add 0.1 volume of T4 DNA polymerase buffer, dNTP (100 µ*M* final concentration of each dNTP), and BSA (0.1 mg/ml final concentration). Add 5 units of T4 DNA polymerase/µg of DNA. Incubate at 37°C for 5 min. Heat inactivate by incubating at 75°C for 20 min. The 3′→5′ exonuclease activity of T4 DNA polymerase will chew back the 3′ overhang, which the 5′→3′ polymerase activity of T4 DNA polymerase will fill in, in the presence of excess dNTPs, leaving a blunt end on the vector and maintaining the +1 G residue.

7. Clean up the T4 DNA polymerase by repeating steps 2–5.

8. Digest the vector with *Eco*RI at 37°C for 1–3 h. Heat inactivate the enzyme by incubating at 75°C for 20 min.

9. Load the digested DNA on a 1.0% agarose gel made with 0.5 X TBE buffer. Add agarose gel loading buffer at 1 X final concentration to the DNA sample before loading on the gel.

10. To visualize the DNA, immerse the gel in 0.5 X TBE containing ethidium bromide to a final concentration of 0.5 µg/ml. Alternatively, the ethidium bromide can be incorporated into the agarose gel prior to pouring the gel (0.5 µg/ml final concentration). Visualize the DNA using UV light.

11. Purify the DNA from the gel. DNA embedded in the agarose is cut out of the gel and extracted from the agarose using the QIAquick DNA extraction kit (Qiagen).

Alternatively, some vectors have restriction enzyme sites that allow for cloning using sticky ends at both the 5′ and the 3′ ends of the inserted DNA oligo nucleotide. This would allow for cloning without the need for blunting one end by T4 DNA polymerase treatment after the first restriction endonuclease digestion. However, additional sequences would be present at the 5′ end of the resulting transcript.

G. Annealing the DNA Oligo Nucleotides

Solution

1. *STE buffer*: 10 m*M* Tris (pH 8.0), 50 m*M* NaCl, 1 m*M* EDTA. For 100 ml, add 1 ml 1 *M* Tris (pH 8.0), 5.0 ml 1 *M* NaCl, and 0.2 ml 0.5 *M* EDTA, making up to 100 ml with distilled water.

Steps

1. Resuspend the DNA oligo nucleotides in STE buffer at as high a concentration as possible (~1–10 OD_{260} units/100 µl).

2. Add equimolar amounts of each of the DNA oligo nucleotides to an Eppendorf tube.

3. Incubate the tube at 95°C for 10 min followed by a gradual cooling to room temperature. This can be

achieved by placing the samples in a heat block set to 95°C, incubating the sample for 10 min, and turning off the heating block and allowing it to cool to room temperature. The annealed oligo nucleotides can be stored at –20°C or used immediately for ligating into the prepared vector.

H. Ligating the Annealed DNA Oligo Nucleotides into the Prepared Vector

Solutions

1. *T4 DNA ligase*
2. *10X T4 DNA ligase buffer containing ATP*
3. *LB (Luria–Bertani) agar*: Dissolve 40 g of Difco LB agar and Miller powder in 1 liter of distilled water with heating. When fully dissolved, autoclave at 121°C for 15 min.
4. *Ampicillin*: Ampicillin can be prepared as a 50-mg/ml stock solution in distilled water and sterilized by filtration through a 0.22 µm filter. Store at –20°C.

Steps

1. Add the restriction enzyme digested and purified DNA vector and the annealed DNA oligo nucleotides at a molar ratio of 1:4 (vector:insert) using ~50–200 ng of vector DNA. Add T4 DNA ligase buffer containing ATP (1 m*M* final concentration) to a 1X final concentration. Add 1–2 µl of T4 DNA ligase (400 units/µl).
2. Incubate the ligation at 16°C for 16 h (overnight).
3. Transform the ligated DNA into chemically competent *Escherichia coli* cells (e.g., TOP 10 cells, Stratagene) and plate on LB agar medium supplemented with ampicillin (50 µg/ml final concentration).
4. Screen the individual clones by DNA sequencing to ensure that the DNA oligo nucleotide has been properly ligated into the vector.

I. Generation of Stable Silencing Cell Lines

Transfection of HeLa cells with the plasmid encoding the siRNA expression cassette using cationinc lipids (e.g., Lipofectamine 2000).

Solutions

1. *Lipofectamine 2000*
2. *Dulbecco's modified Eagles media*
3. *Opti MEM I reduced serum medium*
4. *Fetal bovine serum*

Steps

1. Prior to the transfection, it is important to perform a dosage curve to determine the best concentration of the antibiotic to use for the selection of stable siRNA expressing cell lines. This should be performed for every cell line that is going to be used and every drug that will be used.
2. The day before the transfection, plate HeLa cells at 4×10^5 cells/well in DMEM containing 10% fetal calf serum but without antibiotics. Incubate at 37°C in a CO_2 incubator. Plate an additional well that will not be transfected but will be treated with the antibiotic to control for the efficiency of drug selection.
3. Preparing the plasmid DNA–lipid complexes:
   a. Add 2–4 µg of plasmid DNA to serum-free, antibiotic-free DMEM or Opti-MEM I reduced serum medium (Invitrogen) in a 100 µl final volume. It is important to note that not all serum-free medium formulations [e.g., 293 SFM II (Invitrogen)] are compatible with cationic lipid transfection reagents and should be tested prior to use.
   b. Prepare the Lipofectamine 2000 by diluting 1–10 µl of Lipofectamine 2000 in serum-free, antibiotic-free DMEM or OptiMEM I reduced serum medium to a final volume of 100 µl. Mix the contents of the tube gently and let it incubate at room temperature for 5 min. To optimize the efficiency of transfection and minimize the cytotoxic effects of the Lipofectamine 2000, vary the ratio of DNA (µg):Lipofectamine 2000 between 1:0.5 and 1:5. To further reduce the likehood of cytotoxic effects, perform the transfection at high cell densities (~90% confluent for HeLa cells).
   c. Combine the diluted DNA solution and the diluted Lipofectamine 2000 solution and mix gently. Incubate for 15–20 min at room temperature to allow for the DNA–lipid complexes to form.
4. Remove growth media from the cells and wash with serum-free, antibiotic-free DMEM. Add 800 µl of serum-free, antibiotic-free medium or OptiMEM I reduced serum medium to the cells.
5. Add 200 µl of the DNA–lipid complexes to each well of the cells in serum-free medium or OptiMEM.
6. Incubate the cells for 4–5 h at 37°C in a CO_2 incubator. Due to the toxicity of Lipofectamine 2000, it is a good idea to monitor the health of the cells during the course of the transfection.
7. After 4–5 h of incubation, remove the transfection medium and wash the cells with DMEM containing 10% fetal calf serum. Add 2 ml of serum containing DMEM to the cells.
8. Incubate the cells at 37°C in a CO_2 incubator for 48 h posttransfection.

J. Selection of Stable siRNA Expressing Clones

Steps

1. Add the appropriate concentration of the antibiotic, as determined by the dosage curve, to each of the wells, including the control untransfected well. It may be necessary to split the cells prior to the addition of the antibiotic. In this case the cells can be directly split into medium that contains the antibiotic.

2. Grow the cells in the presence of the antibiotics, monitoring the effectiveness of the drug selection on the untransfected control cells. Continue to replace the medium containing the antibiotic on the cells every 2–3 days to ensure that appropriate levels of the antibiotic persist to maintain selection.

3. Single cell clones can be picked when all the cells in the control untransfected plate have died and visible colonies appear in the transfected plates. This can take 1 to 2 weeks after the start of selection. It is important to pick single colonies, as even with a very effective siRNA sequence, there will be a large degree of variability regarding the amount of silencing seen in different stable cell lines. The degree of silencing will be influenced by the site of plasmid integration and the number of plasmids integrated in any particular cell.

4. Single cell clones can be obtained by either directly picking isolated single colonies or by limited dilution and plating in 96-well plates at 0.3 cells/well.

K. Analysis of the Silencing Phenotype

Because siRNAs act by targeting homologous mRNA, the most direct measure of the efficiency of siRNAs is the analysis of mRNA levels. This can be achieved by Northern blot analysis or reverse transcriptase–polymerase chain reaction (RT-PCR) analysis. The analysis of the function of the silenced gene requires that there be a decrease in the level of the targeted protein and that this decrease has a recognizable phenotype. The protein levels in siRNA-treated cells can be assessed by Western blot analysis. This analysis requires that there be antibodies present against the target protein. The ultimate aim of the siRNA-mediated silencing would be to determine the phenotypic consequences of the decreased protein levels. This would require assays that are specific to the protein of interest.

IV. Comments

The most important aspects of a successful siRNA-based gene silencing experiment are the identification of siRNA sequences that effectively target the mRNA for degradation and the efficiency of transduction of the cell type of interest. If cell lines are used that are difficult to transfect, the lack of an observable silencing phenotype may be due to the limits of transfection and not the efficiency of the siRNA sequence. To standardize siRNA transfections, many companies sell siRNAs that are known to work effectively against a target gene. Once transfection conditions have been established that work for the control siRNAs, they can easily be carried over to testing the siRNAs of interest. Once an effective sequence has been identified, it can be used directly to transfect cells or it can be cloned into a DNA vector for stable gene silencing.

Antisense Oligonucleotides

Erich Koller and Nicholas M. Dean

I. INTRODUCTION

Although the Human Genome Project revealed myriad gene sequences, the function of these new genes remains unknown. Few traditional approaches for studying gene function offer acceptable specificity in a time- and cost-effective manner. Therefore, progress has been slow in determining the function of these genes. Experimental approaches have become essential for determining the biological functions of cellular gene products. Antisense oligonucleotides (ASO) offer significant advantages over traditional methods in terms of specificity and versatility (Koller *et al*., 2000). ASOs validate the function of genes *in vitro* and *in vivo*. In addition, antisense oligonucleotides are developed as drugs with many products currently being tested in clinical trials (Monia *et al*., 2000).

ASOs are short stretches of synthetic, chemically modified nucleic acids that use Watson–Crick base pairing to specifically hybridize to mRNA sequences. For optimal activity, oligonucleotides must first be taken up by the cell or the targeted organ, and the targeted mRNA sequence must then be accessible to the oligonucleotide. *In vivo*, injected oligonucleotides are distributed mainly to the liver and kidneys before they become available to other tissues (Sands *et al*., 1994). *In vitro*, an uptake enhancer is generally, although not entirely, required. A large number of these are available. Antisense oligonucleotides inhibit protein expression by a variety of mechanisms. The best characterized mechanism involves RNase H-mediated cleavage of target mRNA. RNase H is an endonuclease that recognizes RNA–DNA duplexes and selectively cleaves the RNA strand (Dash *et al*., 1987; Kanaya and Ikehara, 1995). Several chemical modifications to antisense oligonucleotides that are designed to increase the affinity of oligonucleotides to RNA or enhance their nuclease resistance do not support RNase H-mediated cleavage (Baker *et al*., 1997). Therefore, additional mechanisms of action exist, including inhibition of translation, modulation of pre-mRNA splicing and modulation of poly(A) adenylation sites, steric blockage for ribosomal subunit attachment to mRNA at the 5′ cap site, and interference with proper mRNA splicing through antisense binding to splice donor or splice acceptor sites (Baker and Monia, 1999; Taylor *et al*., 1999).

Small interfering RNA has been used successfully to inhibit gene expression in mammalian cells. Comparison of siRNAs to RNase H-dependent oligonucleotides showed that they exhibit similar degrees of inhibition of gene expression (Vickers *et al*., 2002). This article focuses on RNase H-dependent oligonucleotides.

II. MATERIALS AND INSTRUMENTATION

Opti-MEM (Invitrogen, Cat. No. 31985070)
Lipofectin (Invitrogen, Cat. No. 18292011)
Oligofectamine (Invitrogen, Cat. No. 12252011)
Lipofectamine (Invitrogen, Cat. No. 18324012)
Cytofectin (Isis Pharmaceuticals, Inc.)
Ribogreen (Molecular Probes, Cat. No. R-11490)
Electroporator (BTX, T-820)
Real time RT-PCR machine (ABI PRISM, 7700 sequence detector)
Fugene 6 Roche (Biosciences, Cat. No. 1 814 443)
Superfect (Qiagen, Cat. No. 301305)

III. PROCEDURES

A. Oligonucleotide Design

Before ASOs are designed, the following questions need to be answered.

1. Is the sequence information for the gene of interest available? Sequence information for certain species can be limited.
2. Is the gene expressed in the targeted cells to be studied? A robust detection method will make it easier to test the effect of the ASO treatment.
3. Can these cells be transfected easily with ASOs (Table I)? Adherent cells are usually easier to transfect.
4. Are antibodies available to detect the protein?
5. What is the half-life of the protein to be inhibited? The treatment might not result in efficient target reduction if the half-life of the protein is longer than the half-life of the ASO. However, this is usually not a concern.
6. Is the mRNA accessible to a given ASO sequence? Inaccessibility is probably caused by the secondary structure of the mRNA or by proteins bound to mRNA. Therefore, several ASOs are generally designed to identify an oligonucleotide that displays robust inhibition of target expression. Generally, 5–10 different ASOs are evaluated to find a few sequences that are active in inhibiting RNA expression (Branch, 1998). The success rate varies from gene to gene target, but can be as high as 80%. The chance to see phenotypic changes increases with more potent oligonucleotides. These phenotypic effects have to be seen with more than one ASO to be specifically target related. Computer programs used for designing polymerase chain reaction (PCR) primers are useful in identifying potential antisense sequences. In addition to selecting sequences with a high T_m for target mRNA, these programs can be used to identify areas of oligonucleotide self-complementation that might interfere with antisense activity. A few other motifs should be avoided in antisense design. Four contiguous G residues generate ASOs that can prevent Watson–Crick hybridization (Wyatt *et al*., 1994). Furthermore, palindromes of six or more bases have been reported to induce interferon, and unmethylated CG can induce other immunostimulatory effects (Krieg *et al*., 1995; Monteith *et al*., 1997). Methylation of the 5′ position of the cytosine minimizes these effects.

B. Experimental Design

Using appropriate controls is crucial when performing experiments with ASOs. Oligonucleotides at high concentrations can be toxic for cells and complicate experimental interpretation Therefore, control ASOs should be included in your experiment. No single optimal control ASO exists, and we suggest evaluating multiple controls. These can be mismatched sequences, scrambled sequences (that have the same base composition but a different order of bases), or oligonucleotides in the sense orientation. They should have the same length and chemistry as the antisense oligonucleotide. A specific ASO should reduce target mRNA or protein in a dose-dependent manner. If you test oligonucleotides that utilize a non RNase H-dependent mechanism, you must measure protein reduction, as RNA levels might not be affected. In any case, always test the ability of the ASO to reduce target levels first before measuring any other phenotypic end points. Kinetic studies are necessary to determine when to perform phenotypic end point experiments. It is ideal to have more than one active ASO against a given target when phenotypic end points are measured to ensure specific effects. Some proteins with a long half-life time might require repeated transfections with the oligonucleotide before a decrease is observed.

C. Chemistry

Historical experiments with ASO utilized phosphodiester DNA with the disadvantage that it got metabolized rapidly (Thierry and Dritschilo, 1992). Since then, several chemical modifications have been introduced that increased nuclease resistance. Two such chemically modified oligonucleotides that are available commercially are phosphorothioate oligodeoxynucleotides and 2′-*O*-methyl oligonucleotides. Phosphorothioate oligodeoxynucleotides in which one of the nonbridging oxygen atoms in the nucleotide backbone is replaced with sulfur fully support RNase H activity and increase nuclease resistance dramatically (Akhtar *et al*., 1991; Campbell *et al*., 1990). Although binding affinity to mRNA is reduced, phosphorothioate ASOs are probably the most practical and effective choice for researchers performing antisense experiments. The addition of a methoxy group to the C2′ position of the sugar, in combination with a phosphorothioate backbone, provides further enhancement of nuclease resistance and increases the affinity of an oligomer for mRNA (Altmann *et al*., 1996). However, the 2′-*O*-methyl modification does not support RNase H-mediated cleavage of mRNA. If degradation of target mRNA is required as a mechanism of action, this modification must be incorporated into a gapped or chimeric structure with methyl modifications in the wings of the molecule and

oligodeoxynucleotides in the central portion (McKay *et al*., 1999).

D. Oligonucleotide Treatment

Transfection reagents, such us polycations, liposomes, peptides, and dendrimers, facilitate the uptake of oligonucleotides into cells (Kang *et al*., 1999). These reagents are more or less effective in adherent cells, but they generally do not work well for suspension cells. An alternative method for cells in suspension is electroporation. We have found that some primary cell types will effectively take up oligonucleotides in the absence of transfection reagents. However, higher ASO concentrations are required to achieve this uptake compared to transfections using transfection reagents. For example, in primary hepatocytes, efficient target reduction is achieved at 300 n*M* ASO.

Whatever method you use, each cell type must be optimized for transfection method and conditions. Table I will help in choosing the right experimental conditions. Because each method can lead to cell toxicity, it is important to normalize for cell number when target reduction is determined. In addition to observing apparent changes in phenotype under the microscope, it is useful to use ribogreen or some other method to ensure that the amount of RNA between treatment groups is comparable. For adherent cells, it is important that cells are spread and adhere to plastic. The delivery of oligonucleotides with cationic lipids is dependent on the interaction between the positively charged lipid and the negatively charged oligonucleotide.

1. Lipofectin

The cationic lipid called lipofectin is used frequently to transfect oligonucleotides into cells. Depending on cell type, a concentration range between 1 and 300 n*M* should be tested. Typically, IC_{50} values for target mRNA reduction range between 100 and 200 n*M*.

Solutions

1. *Opti-MEM*
2. *Lipofectin*
3. *Phosphate-buffered saline (PBS)*

Steps

1. Plate out cells the day before treatment so that they reach 60–80% confluency the next day. Plate 5000–15,000 cells/well for a 96-well plate or 0.4–1.4 × 10^6 cells/plate for a 100-mm plate.
2. The next day, gently wash plated cells with 5 ml sterile PBS (for 100-mm plate).
3. Aspirate off PBS and replace with Opti-MEM (GibcoBRL) containing 3 µl lipofectin/ml Opti-MEM per 100 n*M* oligo nucleotide used. *Note*: We do not use below 3 µl Lipofectin/ml Opti-MEM or above 15 µl Lipofectin/ml Opti-MEM (e.g., the same concentrations of lipid would be used for 50 and 100 n*M* treatments).
4. Incubate cells with oligo nucleotide/Lipofectin for 4–6 h at 37°C/5% CO_2.
5. Aspirate off oligo nucleotide/Lipofectin mixture and replace with complete growth media.
6. Harvest cells to analyze activity of oligonucleotides by method of choice (Northern blot, Western blot, RT-PCR, ribonucleotide protection assay or arrays).

2. Electroporation

Electroporation is used for cell lines that are not amenable to transfection with currently available transfection reagents, e.g., suspension cell lines (Bergan *et al*., 1993). Oligonucleotides that are neutral or partially charged, e.g., morpholinos, are not compatible with charged lipids either. Therefore, electroporation is the method of choice for suspension cells and transfection of neutral oligonucleotides into any cell type. Each cell line must be optimized for electroporation prior to experimental assays. The electric field strength (EFS) is defined as the voltage applied divided by the distance between the electrodes (V/cm). In general, as the EFS increases, the amount of DNA transfected is increased while cell viability decreases. The pulse length is determined by a number a variables, including buffer type, resistance, and capacitance (microfaradays), selection, and sample volume. Typically, a voltage titration is performed for each cell line (0–350 V, depending on cuvette) at constant capacitance and resistance and constant pulse length (6–9 ms) using a single pulse. It is very helpful to test the conditions with a highly expressed target using a well-characterized oligonucleotide. After determining the optimal voltage, it is recommended to do a dose–response curve with an ASO concentration between 1 and 20 µ*M*. Further optimization can be performed by adjusting the capacitance or pulse length. Typically, IC_{50} values for target mRNA reduction range between 1 and 10 µ*M*.

Steps

1. Resuspended cells (1 × 10^7 cells/ml) in 90 µl (1-mm cuvette) or 360 µl complete medium (2-mm cuvette).
2. Add cells to microcentrifuge tube containing 10 and 40 µl oligonucleotides, respectively.

TABLE I

Cell Name	Species	Cell type	Transfection method
Adherent tumor lines			
A549	hu	Lung	Lipofectin
C6	Rat	Glioma	Electroporation
EMT6	mu	Breast	Lipofectin

3. Pipetted the cell oligonucleotide mix into the cuvette and electroporate immediately so that cells will not settle.
4. After electroporation, transfer the cell oligonucleotide mix into a 100-mm culture dish containing complete medium.
5. Incubate cells for 24 h until harvest for mRNA or protein. Protein reduction might require longer, depending on the half-life time of the protein of interest.

Acknowledgments

The authors thank Namir Sioufi for providing cell transfection protocols and Jon Bodnar for critical comments during the preparation of this manuscript.

Contents of Volume 4

Contents of other Volumes

VOLUME 1

PART A. CELL AND TISSUE CULTURE: ASSOCIATED TECHNIQUES

Section 1. General Techniques

Section 2. Culture of Specific Cell Types: Stem Cells

Section 3. Culture of Specific Cell Types: Haemopoietic, Mesenchymal, and Epithelial

Section 7. Cell Separation Techniques

Section 8. Cell Cycle Analysis

Section 9. Cytotoxic and Cell Growth Assays

Section 10. Apoptosis

Section 11. Assays of Cell Transformation, Tumorigenesis, Invasion, and Wound Healing

PART E. TISSUE ARRAYS

Section 13. Tissue Arrays

PART F. CYTOGENETICS AND *IN SITU* HYBRIDIZATION

Section 14. Cytogenetics

Section 15. *In Situ* Hybridization

PART G. GENOMICS

Section 16. Genomics

PART H. TRANSGENIC, KNOCKOUTS, AND KNOCKDOWN METHODS

Section 17. Transgenic, Knockouts and Knockdown Methods

Contributors

Numbers in parenthesis indicate the volume (bold face) and page on which the authors' contribution begins.

Mads Aaboe (**4**: 83) Clinical Biochemical Department, Molecular Diagnostic Laboratory, Aarhus University Hospital, Skejby, Brendstrupgaardvej, Aarhus N, DK-8200, DENMARK

Tanja Aarvak (**1**: 239) Dynal Biotech ASA, PO Box 114, Smestad, N-0309, NORWAY

Harindra R. Abeysinghe (**3**: 345) Department of Pathology and Laboratory Medicine, University of Rochester School of Medicine, 601 Elmwood Ave., Rm 1-6337, Rochester, NY 14642

Ruedi Aebersold (**4**: 437) The Institute for Systems Biology, 1441 North 34th Street, Seattle, WA 98103-8904

Ueli Aebi (**3**: 233, 241) ME Muller Institute for Microscopy, Biozentrum, University of Basel, Klingelbergstr. 50/70, Basel, CH-4056, SWITZERLAND

Cheol-Hee Ahn (**4**: 29) School of Materials Science and Engineering, Seoul National University, Seoul, 151-744, SOUTH KOREA

Natalie G. Ahn (**4**: 443) Department of Chemistry & Biochemistry, University of Colorado, 215 UCB, Boulder, CO 80309

Ramiro Alberio (**4**: 45) School of Biosciences, University of Nottingham, Sutton Bonington, Loughborough, Leics, LE12 5RD, UNITED KINGDOM

Donna G. Albertson (**3**: 445) Cancer Research Institute, Department of Laboratory Medicine, The University of California, San Francisco, Box 0808, San Francisco, CA 94143-0808

Heiner Albiez (**1**: 291) Department of Biology II, Ludwig-Maximilians University of Munich, Munich, GERMANY

Terence Allen (**3**: 325) CRC Structural Cell Biology Group, Paterson Institute for Cancer Research, Christie Hospital NHS Trust, Wilmslow Road, Withington, Manchester, M20 4BX, UNITED KINGDOM

Noona Ambartsumian (**1**: 363) Department of Molecular Cancer Biology, Danish Cancer Society, Institute of Cancer Biology, Strandboulevarden 49, Copenhagen, DK-2100, DENMARK

Øystein Åmellem (**1**: 239) Immunosystems, Dynal Biotech ASA, PO Box 114, Smestad, N-0309, NORWAY

Patrick Amstutz (**1**: 497) Department of Biochemistry, University of Zürich, Winterthurerstr. 190, Zurich, CH-8057, SWITZERLAND

Jens S. Andersen (**4**: 427) Protein Interaction Laboratory, University of Southern Denmark—Odense, Campusvej 55, Odense M, DK-5230, DENMARK

Mads Hald Andersen (**1**: 97) Tumor Immunology Group, Institute of Cancer Biology, Danish Cancer Society, Strandboulevarden 49, Copenhagen, DK-2100, DENMARK

Helena Andersson (**4**: 63) Bioscience at Novum, Karolinska Institutet, Halsovagen 7-9, Huddinge, SE-141 57, SWEDEN

Peter W. Andrews (**1**: 183) Department of Biomedical Science, The University of Sheffield, Rm B2 238, Sheffield, S10 2TN, UNITED KINGDOM

Preface

Scientific progress often takes place when new technologies are developed, or when old procedures are improved. Today, more than ever, we are in need of complementary technology platforms to tackle complex biological problems, as we are rapidly moving from the analysis of single molecules to the study of multifaceted biological problems. The third edition of *Cell Biology: A Laboratory Handbook* brings together 236 articles covering novel techniques and procedures in cell and molecular biology, proteomics, genomics, and functional genomics. It contains 165 new articles, many of which were commissioned in response to the extraordinary feedback we received from the scientific community at large.

As in the case of the second edition, the *Handbook* has been divided in four volumes. The first volume covers tissue culture and associated techniques, viruses, antibodies, and immunohistochemistry. Volume 2 covers organelles and cellular structures as well as assays in cell biology. Volume 3 includes imaging techniques, electron microscopy, scanning probe and scanning electron microscopy, microdissection, tissue arrays, cytogenetics and in situ hybridization, genomics, transgenic, knockouts, and knockdown methods. The last volume includes transfer of macromolecules, expression systems, and gene expression profiling in addition to various proteomic technologies. Appendices include representative cultured cell lines and their characteristics, Internet resources in cell biology, and bioinformatic resources for in silico proteome analysis. The Handbook provides in a single source most of the classical and emerging technologies that are essential for research in the life sciences. Short of having an expert at your side, the protocols enable researchers at all stages of their career to embark on the study of biological problems using a variety of technologies and model systems. Techniques are presented in a friendly, step-by-step fashion, and gives useful tips as to potential pitfalls of the methodology.

I would like to extend my gratitude to the Associate Editors for their hard work, support, and vision in selecting new techniques. I would also like to thank the staff at Elsevier for their constant support and dedication to the project. Many people participated in the realization of the *Handbook* and I would like to thank in particular Lisa Tickner, Karen Dempsey, Angela Dooley, and Tari Paschall for coordinating and organizing the preparation of the volumes. My gratitude is also extended to all the authors for the time and energy they dedicated to the project.

Julio E. Celis

CHAPTER

1

Impact-Mediated Cytoplasmic Loading of Macromolecules into Adherent Cells

Mark S. F. Clarke, Daniel L. Feeback, and Charles R. Vanderburg

I. INTRODUCTION

The advent of modern molecular biology, including the development of gene array technologies, has resulted in an explosion of information concerning the specific genes activated during normal cellular development, as well as those associated with a variety of pathological conditions. These techniques have provided a highly efficient, broad-based screening approach for those specific genes involved in regulating normal cellular physiology and identifying candidate genes directly associated with the etiology of specific disease states. However, this approach provides information at the transcriptional level only and does not necessarily indicate that the gene in question is in fact translated into a protein or whether posttranslational modification of the protein occurs.

The critical importance of posttranslational modification (i.e., phosphorylation, glycosylation, sialylation) to protein function has been recognized with regard to a number of proteins involved in a variety of important disease states. For example, altered glycosylation of the β-amyloid precursor protein results in an increase in the amount of β-amyloid peptide generated and hence secreted as insoluble extracellular amyloid deposits (Georgopoulou *et al.*, 2001; Walter *et al.*, 2001), a pathological hallmark of Alzheimer's disease. Abnormal phosphorylation of synapsin I has been linked to alterations in synaptic vesicle trafficking, leading to defective neurotransmission in Huntington's disease (Lievens *et al.*, 2002). Altered phosphorylation of the TAU protein involved in microtubule function has been linked to a number of neurodegenative diseases, such as Alzheimer's disease (Billingsley and Kincaid, 1997; Sanchez *et al.*, 2001). Aberrant sialylation of cell surface antigens has been detected in a number of different tumor cell types and has been linked to the acquisition of a neoplastic phenotype (Sell, 1990), whereas improper sialylation of sodium channels in cardiac tissue has been linked to heart failure (Ufret-Vincenty *et al.*, 2001; Fozzard and Kyle, 2002). In addition to the limitations associated with the total lack of information provided regarding posttranslational modification of the encoded protein, gene analysis cannot provide information on the role of protein–protein interactions within the cellular milieu. For example, a combination of gene and protein analysis may indicate that a particular protein is unregulated at both mRNA and protein levels, respectively. However, the presence of a regulatory protein(s) in the cellular milieu may result in this overexpression being of no physiological importance. For example, cytokine stimulation leading to an elicited cellular response is not only associated with the action of a particular cytokine at its specific receptor, but also with a cascade of downstream signal transduction events that are under the control of a variety of negative regulatory proteins (Carra *et al.*, 2000; Murphy *et al.*, 2000). Such protein–protein interactions underscore the complexity of the interplay between proteins in modulating cell function and are an excellent example of the limitations of gene analysis techniques in probing "cause-and-effect" relationships between gene expression and cellular response. It is the study of the interaction among gene expression, modified transcript splicing, and posttranslational modification on protein function as it impacts cellular/tissue phenotype, which is now the modern research field of proteomics.

One approach to overcoming the limitations of genetic analysis is to insert a protein of interest into a

Copyright 2006, Elsevier Science (USA).
All rights reserved.

cell and directly observe the effects on cell function. The direct "insertion" of a protein (in contrast to transfection of a genetic construct followed by protein expression) allows investigation of the functional role of the inserted molecule in determining cell phenotype in a fashion that also considers the role of protein–protein interactions in the cellular milieu. Insertion of individual or mixtures of purified proteins prepared in the ***native*** state also increases the possibility that any observed effects of the protein on cell phenotype/response are of true physiological relevance. As yet, such functional proteomic studies are limited by the availability of technologies that allow efficient insertion of native proteins directly into cells.

Microinjection (Bloom *et al*., 2003; Bubb *et al*., 2003), electroporation (Chow and Gawler, 1999; Ponsaerts *et al*., 2002), and lipid vesicle-mediated protein loading (Chen *et al*., 1993) all have been demonstrated to achieve protein insertion into cultured cells. Mechanical-based loading techniques such as biolistics (Maddelein *et al*., 2002), syringe loading (Clarke and McNeil, 1992), and scrape loading (McNeil *et al*., 1989) can also be used to load a variety of cell types with a range of proteins. However, apart from microinjection, which requires expensive equipment and skilled personnel to produce relatively few loaded cells, none of the aforementioned techniques have wide applicability to loading of either individual or mixtures of purified proteins into adherent primary cells in tissue culture. This article describes a technique, known as impact-mediated loading, that is capable of simultaneously loading a large number of adherent primary cells (>10,000 cells during a single procedure) with a variety of proteins at high efficiency. This approach is based on the production of transient plasma membrane wounds by particle impact with the cell membrane. We have used this technique previously in order to load dyes, antibodies, and plasmid constructs into the cytoplasm of a number of primary and established cell lines utilizing a crude, relatively uncontrolled experimental apparatus (Clarke *et al*., 1994). In addition, we have used a more refined version of this technique to study the effects of altered gravitational conditions on the membrane-wounding response of human primary myoblasts (Clarke *et al*., 2002). Based on observations made during these latter studies, we have developed a novel technology, known as the G-Loader (Fig. 1), which utilizes the effects of hypergravity at 200 *g* to enhance macromolecular loading into the cytoplasm of adherent cells via impact-mediated plasma membrane wounding (Clarke *et al*., 2001). The protocol described here specifically details the experimental approach used to load primary human skeletal myocytes with FITC-labeled IgG immunoglobulin as an example of the suitability of G-Loader technology for loading biologically active proteins into primary adherent cells.

II. MATERIALS AND INSTRUMENTATION

Dulbecco's modified Eagle's medium–F12 medium (X1 concentration) (DMEM/F12, Cat. No. 320-1885AG), bovine fetal calf serum (CS) (Cat. No. 200-6170AG), and penicillin–streptomycin solution (Cat. No. 600-5140AG) are obtained ready to use from Gibco BRL (Grand Island, NY). Alexa Fluor 488-labeled goat anti-mouse IgG (M_r 150,000 kDa) (Cat. No. A-11001) is obtained from Molecular Probes (Eugene, OR). Tissue culture flasks (T-75, T25, and 35-mm diameter plates) (Cat. Nos. 10-126-41, 10-126-26, and 25050-35) and sterile polypropylene conical centrifuge tubes (50 ml capacity) (Cat. No. 05-538-55A) are from Fisher Scientific (Pittsburgh, PA). The G-Loader technology and associated consumables are from Peilear Technologies (Houston, TX). Living cells loaded with fluorescently labeled IgG are examined utilizing an Zeiss Axiophot inverted microscope in order to view them in the 35-mm tissue culture plate directly.

III. PROCEDURES

A. Preparation of Tissue-Cultured Cells for Impact-Mediated Loading Using the G-Loader

Stock Solutions and Media Preparation

1. *Stock IgG solution*: Stock Alexa Fluor 488 goat anti-mouse IgG (2 mg/ml) can be stored at 4°C in the dark for up to a month or aliquoted and frozen in the dark at –80°C for storage up to a year. Prior to use on living cells, it is important to remove any preservative (e.g., sodium azide) from the immunoglobulin solution, as exposure of living cells to such contaminants can result in rapid cell death. Removal of such preservatives can be carried out using either a miniature dialysis device or buffer exchange using a 30,000 MW cutoff centrifugal miniature concentrator. One milliliter of stock IgG (2 mg/ml) solution should be dialyzed against a minimum of three changes of 100 ml of sterile DMEM/F12 medium over a period of 24 h prior to use. The total volume of dialyzed IgG solution should be adjusted to original volume prior to dialysis to maintain the overall IgG concentration. Buffer exchange using a centrifugal concentrator should

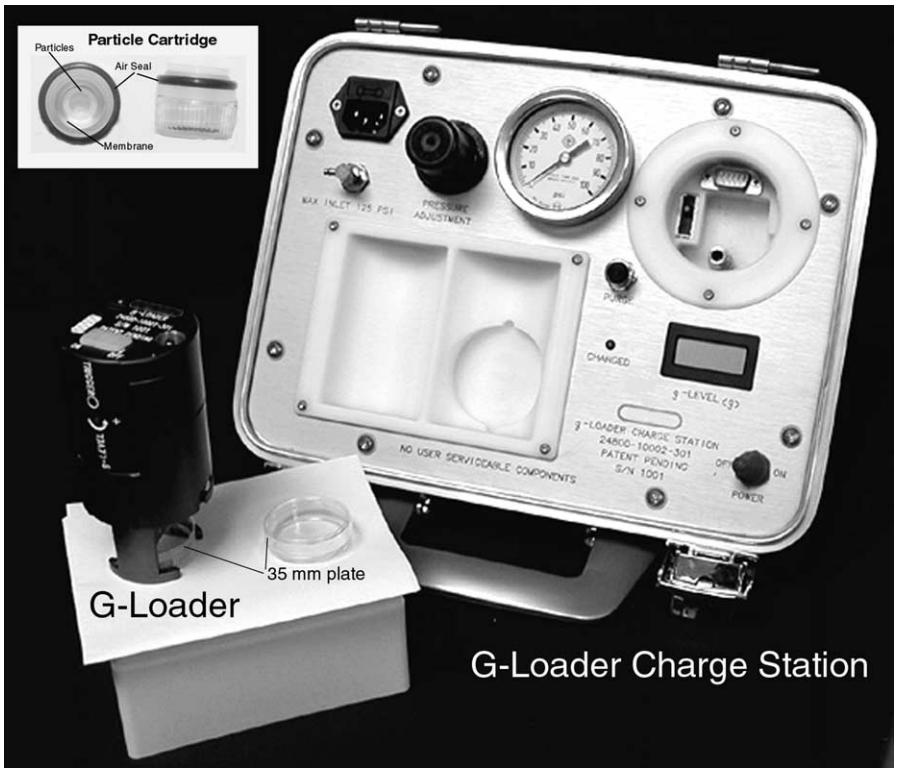

FIGURE 1 Impact-mediated loading apparatus known as the G-Loader. The G-Loader device itself is approximately 25 cm tall and 10 cm in diameter. A 35-mm tissue culture plate containing a monolayer of adherent cells is placed in the base of the G-Loader after being incubated with loading medium containing the macromolecule of interest. Prior to placing the cell sample into the G-Loader, a particle cartridge is inserted into the device consisting of a circular cartridge that supports a rupturable membrane on which is located a layer of 10-μm particles arranged in a specific pattern (see insert). In addition, the device has been charged with air to the required pressure and the on-board *g*-load accelerometer trigger has been set to the required *g* value using the G-Loader charging station (for benchtop operation there is a manual trigger button located on the side wall of the device). When the G-Loader is activated, either manually or by reaching a set *g* load, a metered volume of pressurized air is directed into the particle cartridge and the membrane ruptures and disperses particles into the airstream. The particles then impact the cell layer, inducing membrane wounding in a highly controllable and reproducible fashion.

involve a minimum of three complete exchanges of the original volume of stock IgG solution with serum-free DMEM/F12 medium.

2. *IgG loading solution*: Add 125 μl of stock IgG solution to 0.875 ml of serum-free DMEM/F12 to obtain final concentrations of 250 μg IgG/ml. Equilibrate this loading solution to the correct temperature and pH by incubating in a standard 5% CO_2 tissue culture incubator maintained at 37°C for a period of 30 min prior to loading cells with the IgG.

3. *10% FCS.DMEM/F12 tissue culture medium*: Add 5 ml of sterile penicillin/streptomycin solution and 50 ml of sterile fetal calf serum to 445 ml of sterile (X1) DMEM/F12 solution to obtain DMEM/F12 culture medium containing 10% FCS, 100 IU/ml penicillin, and 100 μg/ml streptomycin (10% FCS.DMEM). Store at 4°C for up to 21 days.

B. Culture of Human Primary Myoblasts

1. Obtain primary human myoblasts from the Clonetics Corporation (Walkersville, MD) and culture to confluence in T-75 (75 cm^2) culture flasks using 15 ml of 10% FCS.DMEM/F12 maintained at 37°C in a 5% CO_2 humidified atmosphere with subculture every fourth day.

2. The day prior to the loading procedure, trypsinize, collect by centrifugation, and resuspend cells in 5 ml of 10% FCS.DMEM/F12 as a single cell suspension. Determine the number of cells in the suspension using a hemacytometer and adjust cell density in the solution to 50,000 cells/ml using 10% FCS.DMEM/F12. Place 2 ml of this cell suspension into a 35-mm tissue culture plate and incubate cells overnight to allow formation of a monolayer. Under

these culture conditions the center of the 35-mm plate is between 60 and 80% confluent after 24 h of culture prior to loading.

3. Prior to loading, wash cells three times over a period of 5 min with warm, serum-free DMEM/F12 *containing no antibiotics* to remove any unattached cells and to wash away serum components that may interact with the IgG molecules being loaded.

C. Impact-Mediated Loading of IgG Using G-Loader Technology

1. Remove serum-free medium from the cell monolayer, replace with 400 µl of loading solution, and agitate the 35-mm plate gently so that the loading solution covers all of the culture surface. Agitate the loading solution for a minimum of 30 s to ensure that the dissolved macromolecule is in contact with the surface of the cells.

2. Remove the loading solution from the 35-mm plate by tilting the plate to one side and removing the loading solution with a 1-ml sterile pipette. *Note*: The loading solution can be reused on up to five additional 35-mm plates if used immediately after first centrifuging at 10,000 *g* for 1 min to remove any particulate/cellular material.

3. The cells are now ready to be loaded using the G-Loader technology. Place the 35-mm plate in the G-Loader and operate the firing mechanism in the tissue culture hood. Alternatively, the device and cells can be placed into the centrifuge and loading performed under hypergravity conditions (i.e., 200 *g*) (Fig. 1). In the case of human primary skeletal myoblasts and IgG loading, highly efficient cytoplasmic loading of IgG can be achieved without the need for the use of hypergravity conditions during impact-mediated loading.

4. Remove the 35-mm plate from the G-Loader and immediately place 2 ml of warm serum-free DMEM/F12 medium (without antibiotics) into the 35-mm plate to prevent drying of the cells. Gently wash the cell layer three times over 2 min with three changes of serum-free DMEM/F12 medium to remove both excess IgG and particles impacted with the cell surface.

5. Replace washing medium with 10% FCS.DME/F12 tissue culture medium and incubate for the required time period. After this time (0–24 h depending on the goal of the project), wash once with warm D-PBS (pH 7.2), replace with fresh D-PBS, and view the living cell monolayer by inverted fluorescent microscopy using UV excitation and emission at 488 nm.

IV. COMMENTS

This technology provides a highly efficient means of loading large macromolecules into living adherent cells with little or no disruption of the adherent monolayer. As can be seen in Fig. 2, there is little or no visually discernible damage to the cell monolayer 1 h after impact-mediated cytoplasmic loading of a 2×10^6-Da-sized fluorescent dextran. The protocol detailed here describes the procedure required to load fluorescently labeled IgG into cultured primary skeletal muscle cells (Fig. 3). In addition, this technique has been applied to a large number of different cell types and a wide variety of different macromolecules, including

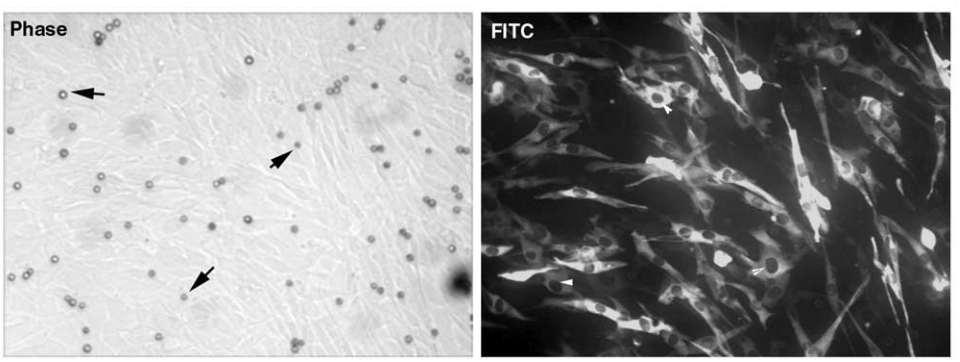

FIGURE 2 Paired phase-contrast and FITC-fluorescent micrographs of a Swiss 3T3 fibroblast monolayer 1 h after impact-mediated cytoplasmic loading of 2×10^6-Da fluorescent dextran (FDx). The monolayer was washed three times with warm serum-free DMEM to remove excess FDx (200 kDa) and to remove the majority of the particles (arrows). Note the clear exclusion of the 200-kDa dextran from the nuclear region of the cells (arrowheads) and little or no visual damage to the cell monolayer (left). Complete bead removal can be achieved by washing the monolayer multiple times with medium over a period of 4 h.

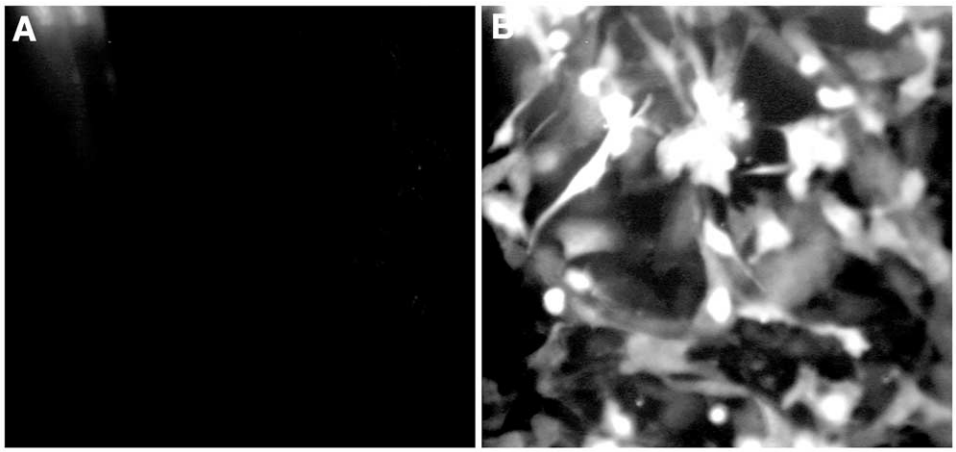

FIGURE 3 Fluorescent micrographs of (A) control and (B) Alexa Fluor 488 goat anti-mouse IgG-loaded primary human myoblasts. Control monolayers are treated in an identical fashion to loaded cells (including incubation with IgG loading solution) except that they are not subjected to impact-mediated loading. Micrographs were photographed under identical conditions immediately after loading and washing of monolayers. Note the somewhat "perturbed" appearance of the cells, an appearance that disappears after 20 to 60 min of additional culture in serum-containing medium (see Fig. 6).

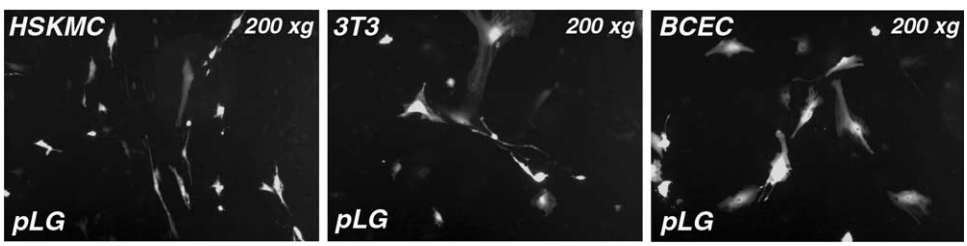

FIGURE 4 Fluorescent micrographs of primary human skeletal myoblasts (HSKMC), Swiss 3T3 cells (3T3), and primary bovine capillary endothelial cells (BCEC) 24 h after impact-mediated loading of a plasmid construct encoding for a green fluorescent protein, Lantern Green (pLG).

plasmid DNA constructs as a means of transfecting both primary and established cell lines (Fig. 4). Furthermore, this technique has the ability to simultaneously load two or more macromolecules directly into the cell cytoplasm of living cells, which are then localized to specific cellular compartments within the living cell based on size exclusion (Fig. 5). In addition, the use of hypergravity conditions during impact-mediated loading significantly increases the amount of fluorescently labeled IgG protein loaded into the cell cytoplasm (Fig. 6).

V. PITFALLS

The impact-mediated loading technology described here (i.e., The G-Loader) is a highly efficient means of simultaneously loading large numbers of living cells with large macromolecules. Under the conditions required for loading of macromolecules below 1×10^6 Da in size, the number of cells that are wounded, loaded, and survive the procedure is extremely high (approximately 70–80% of the starting population) (Fig. 1). One of the disadvantages of the technique described in this article for loading IgG is that not all cells in the 35-mm tissue culture dish are loaded. This is due to a limited particle impact area (approximately one-half of the culture area radiating from the center of the plate) generated by the device. This drawback can be overcome by growing cells only in the center region of the 35-mm plates utilizing a 20-mm-diameter cloning ring or plating cells on 20-mm-diameter glass coverslips located in the center of the 35-mm plates and removing the coverslips after loading. This approach yields a cell population in

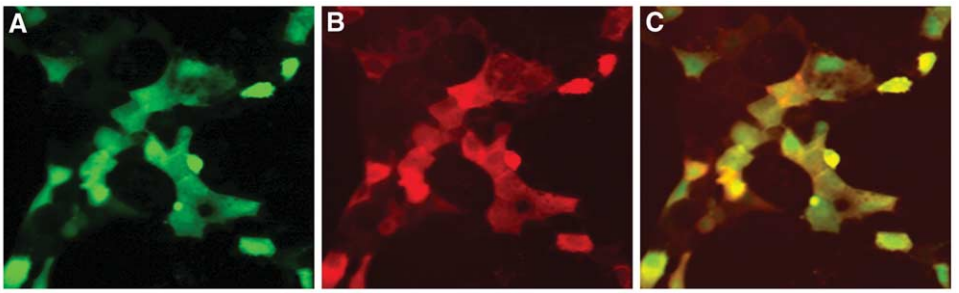

FIGURE 5 Matched fluorescent micrographs of NGF-differentiated PC-12 cells 20 min after impact-mediated loading of a mixture of fluorescently labeled dextrans. Two different-sized, different-colored dextran molecules (***green, FDx–10 kDa; red, TRITC–30 kDa***) were loaded simultaneously into monolayers of PC-12 cells using impact-mediated loading. Note exclusion of the larger dextran (red signal) from the nucleus of the cells (B), whereas the smaller dextran (green signal) is found in both the cytoplasm and the nucleus of the loaded cells (A). When a digital overlay of the images is generated, cells are colored predominantly orange in their cytoplasm (i.e., mixed red and green signal), whereas cell nuclei are green (C).

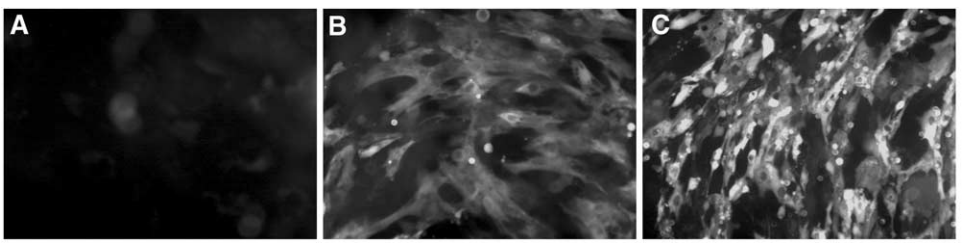

FIGURE 6 Fluorescent micrographs of Swiss 3T3 cell monolayers loaded cytoplasmically with Fluor 488 goat antimouse IgG employing impact-mediated loading at 1 *g* (B) and (C) 200 *g* in a benchtop centrifuge. Control cells (A) were exposed to IgG for the same period of time but were not impact loaded. Micrographs were taken at the same photographic conditions. Note the larger amount of IgG present in the cytoplasm of cells loaded at 200 *g* as compared to those loaded at 1 *g* and that IgG is excluded from the nuclear regions of the loaded cells.

which approximately 70–80% of the starting population is loaded. However, in those experiments where direct localization by microscopic techniques is utilized, the presence of unloaded cells in the region closest to the edge of the plate serves as an excellent internal negative control.

A second area of concern is the purity of the macromolecule that is being loaded. In initial experiments using commercially produced, fluorescently labeled IgG, IgM, and plant lectins, impact-mediated loading was observed at high efficiencies immediately after loading as determined by direct inspection of the cell layer by fluorescent microscopy. Subsequently, however, the majority of the cells died within 2 h of loading. After investigation, it was found that most commercially produced products had some form of preservative in the storage buffer that needed to be removed prior to contact with living cells during the loading procedure.

The G-Loader technology utilizes a combination of particle impact-induced membrane wounding and hypergravity conditions to load macromolecules directly into the cell cytoplasm. This technology appears to have utility for loading in a wide range of cell types, both established cell lines (e.g., COS, 3T3, C2C12 cells) and primary cell types (e.g., human myoblasts, bovine endothelial cells, chick corneal fibroblasts, rat gut epithelium), as well as multicellular microorganisms (e.g., hydra, nematodes, *Xenopus* ova). However, in order to achieve optimal loading efficiency, a mechanistic approach to determining impact pressure, macromolecular concentration in the loading solution, and whether or not hypergravity conditions are required for efficient loading is suggested. In addition, the nature of the macromolecule being loaded is also important. Those compounds that are highly charged or may interact with cell surface components may need longer contact with the

cells prior to loading, a higher loading solution concentration, or higher *g* load (i.e., 200 *g*) (Fig. 5) in order to achieve the most efficient cytoplasmic loading possible.

CHAPTER

2

A Peptide Carrier for the Delivery of Biologically Active Proteins into Mammalian Cells: Application to the Delivery of Antibodies and Therapeutic Proteins

May C. Morris, Julien Depollier, Frederic Heitz, and Gilles Divita

I. INTRODUCTION

In order to circumvent the technological problems of gene delivery, an increasing interest is being taken in designing novel strategies to deliver full-length proteins into a large number of cells (Ford *et al*., 2001; Wadia and Dowdy, 2002). However, the development of peptide drugs and therapeutic proteins remains limited by the poor permeability and the selectivity of the cell membrane. Substantial progress has been made in the development of cell-penetrating peptide-based drug delivery systems that are able overcome both extracellular and intracellular limitations (Morris *et al*., 2000; Gariepy *et al*., 2001; Langel *et al*., 2002). A series of small protein domains, termed protein transduction domains (PTDs), have been shown to cross biological membranes efficiently, independently of transporters or specific receptors, and to promote the delivery of peptides and proteins into cells (for review see, Langel *et al*., 2002). The use of PTD-mediated transfection has proven that "protein therapy" can have a major impact on the future of therapies in a variety of viral diseases and cancers. TAT protein from immunodeficiency virus (HIV-1) (Schwarze *et al*., 1999; Schwarze and Dowdy, 2000), the third α helix of Antennapedia homeodomain (Derossi *et al*., 1994), VP22 protein from herpes simplex virus (Elliott and O'Hare, 1997), and transportan (Pooga *et al*., 2001), as well as polyarginine sequences (Futaki *et al*., 2000), have been used successfully to improve the delivery of covalently linked peptides or proteins into cells. However, PTDs display a certain number of limitations in that they all require cross-linking to the target peptide or protein. Moreover, protein transduction using the PTD-TAT-fusion protein system may require denaturation of the protein prior to delivery, introducing an additional delay between time of delivery and intracellular activation of the protein.

We have described a new strategy for the delivery of full-length proteins and peptides into mammalian cells based on a short amphipathic peptide carrier, Pep-1. This peptide carrier allows the delivery of several distinct proteins and peptides into different cell lines in a fully biologically active form, without the need for prior chemical covalent coupling or denaturation steps (Morris *et al*., 2001). Pep-1 is a 21 residue peptide (KETWWETWWTEWSQPKKKRKV) consisting of three domains with specific functions: a hydrophobic tryptophan-rich motif (KETWWETWWTEW), involved in the main interactions with macromolecules and required for efficient targeting to the cell membrane; a hydrophilic lysine-rich domain (KKKRKV) derived from the nuclear localization sequence (NLS) of simian virus 40 (SV-40) large T antigen, required to improve intracellular

delivery and solubility of the peptide vector; and a spacer domain (SQP), which improves the flexibility and the integrity of both hydrophobic and hydrophilic domains (Morris *et al*., 2001). Given that the mechanism through which Pep-1 delivers macromolecules does not involve the endosomal pathway, the degradation of macromolecules delivered is significantly limited and rapid dissociation of the Pep-1/macromolecule particle is favoured as soon as it has crossed the cell membrane. This peptide-based protein delivery strategy presents several advantages, including rapid delivery of proteins into cells with very high efficiency, stability in physiological buffers, lack of toxicity, and lack of sensitivity to serum. Pep-1 technology constitutes a powerful tool for basic research, and several studies have demonstrated that Pep-1 technology is extremely powerful for studying the role of proteins and for targeting specific protein/protein interactions *in vitro* as well as *in vivo* (Morris *et al*., 2001; Gallo *et al*., 2002; Wu *et al*., 2002, Pratt and Kurch, 2002, Aoshiba *et al*., 2003).

This article describes several protocols for the use of noncovalent Pep-1 technology for the delivery of biologically active proteins into mammalian cells *in vitro*.

II. MATERIALS AND INSTRUMENTATIONS

A. Products

β-Galactosidase is from the Chariot kit (Cat. No. 30025) or the β-galactosidase staining kit (Cat. No. 35001) from Active Motif (Carsbad-USA). Phosphate-buffered saline (PBS) (Cat. No. 14190-169), cell culture reagents Dulbecco's modified Eagle's medium (DMEM) (Cat. No. 41965-062), glutamine, and streptomycin/penicillin (Cat. No. 15140-130) are from Invitrogen Life Technologies (Carsbad, CA). Foetal bovine serum (FBS) is from PERBIO (Lot 3264EHJ, Cat. No. CH30160-03). Potassium ferricyanide (Cat. No. P3667), potassium ferrocyanide (Cat. No. P9387), magnesium chloride (Cat. No. M2670), 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside (X-gal; Cat. No. B4252), *N, N*-dimethylformamide (DMF) (Cat. No. D4551), formaldehyde (Cat. No. F8775), and glutaraldehyde (Cat. No. G5882) are from Sigma (St. Louis, MO).

B. Peptide Carrier Pep-1/Chariot

Pep-1 is 21 residue peptide KETWWETW WTEWSQPKKKRKV (molecular mass 2907 Da). The peptide is acetylated at it N terminus and carries a cysteamide group at its C terminus, both of which are essential for the stability of the peptide and the transduction mechanism (Morris *et al*., 2001). Pep-1 can be synthesized in house or obtained from commercial sources. Protocol for the synthesis and purification of Pep-1 and derivatives are described in Mery *et al*. (1993) and Morris *et al*. (1999, 2001). Also, Pep-1 is manufactured under the name of Chariot by Active Motif Inc. (Carlsbad, CA; http://www.activemotif.com, Cat. No. 30025). The protein transduction kit contains lyophilized Chariot and additional reagents required for the transduction protocol, including a positive transduction control (β-galactosidase Cat. No. 35001). All the protocols described for Pep-1 are directly transposable to Chariot.

III. PROCEDURES

A. Preparation of Pep-1/Protein or Pep-1/Peptide Complexes

This procedure is modified according to Morris *et al*. (2001).

Solutions

1. *Storage of Pep-1 powder*: Pep-1 is stable at least one year when stored at –20°C in a lyophilized form
2. *Stock solution of Pep-1*: Take the vial containing the peptide powder out of the freezer and equilibrate for 30 min at room temperature without opening the vial. This step is essential to limit hydration of the peptide powder. Resuspend the peptide at a concentration of 2 mg/ml (concentration: 0.68 m*M*) in water or in PBS buffer. Mix gently by tapping the tube or by vortexing at low speed for 20 s.
3. *Storage of the Pep-1 solution*: Because repeated freeze/thaw cycles can induce peptide aggregation, is recommended to aliquot the Pep-1 stock solution into tubes containing the amount you expect to use in a typical experiment prior to freezing. The Pep-1 stock solution is stable for about 2 months when stored at –20°C.

Steps

1. Dilute the amount of protein or peptide in 100 µl of PBS for each reaction. Use 0.5–1 µg of protein or 0.1–0.5 µg of peptide or low molecular weight protein per transduction reaction. The protein or peptide can be used at concentrations varying from 50 n*M* up

to 1 μ*M* or higher depending on the biological response expected.

2. For peptide or low molecular weight protein (<10 kDa) transduction, the Pep-1 solution must be diluted 1 : 10 in sterile H_2O (concentration: 68 μ*M*). At this stage, sonication of the peptide solution is recommended, to limit aggregation, for 5 min in a water bath sonicator. A probe sonicator can also be used: place the tube in water and sonicate for 1 min at an amplitude of 30%. In a tube dilute the appropriate volume of Pep-1 into 100 μl of sterile water or PBS for each reaction. For optimal transduction the molar ratio between Pep-1 and protein or peptide is generally 15 : 1 to 20 : 1.

3. Add 100 μl of diluted protein to 100 μl diluted Pep-1. Mix gently by tapping the tube. It is necessary to make the Pep-1/protein complex in a concentrated solution, which will be added to the cells and then be diluted to the final transduction volume (600 μl for 35-mm culture plate).

4. Incubate at 37°C for 30 min to allow the Pep-1/protein complex to form and then proceed immediately to the transduction experiments. At this stage, Pep-1/protein complexes should not be stored.

B. Protein Transduction Protocol for Adherent Cell Lines

The protocol is modified for 35-mm culture plates according to Morris *et al*. (2001). The amount of protein, Pep-1, transduction volume, and number of cells should be adjusted accordingly to the size of the culture plate used.

Steps

1. In a 6-well or a 35-mm tissue culture plate, seed 0.3×10^6 cells per well in 2 ml of complete growth medium. Incubate the cells at 37°C in a humidified atmosphere containing 5% CO_2 until the cells are 50–70% confluent. It is recommended to pass the cells the day before treatment for a better response following transduction.

2. Aspirate the medium from the cells to be transfected.

3. Wash the cells with PBS.

4. Overlay the cells with the 200 μl Pep-1/protein complex. Add 400 μl of serum-free medium to the overlay to achieve the final transduction volume of 600 μl for a 35-mm plate.

5. Incubate at 37°C in a humidified atmosphere containing 5% CO_2 for 1 h.

6. Add 1 ml of complete growth medium to the cells. Do not remove the Pep-1/protein complex. Then incubate at 37°C in a humidified atmosphere containing 5% CO_2 for 30 min to 24 h, depending on the cellular response expected. Peptides and proteins are fully released in the cells 1 and 2 h later, respectively.

7. Process the cells for observation or detection assays. Cells may be fixed or observed directly using live imaging technology.

8. For a 6-well plate, dilute Pep-1 into 600 μl of water or PBS and the protein into 600 μl of PBS. Mix the two solutions and then proceed as described in steps 1–7. For multiple transductions, do not use a mix that exceeds the volume required for six transductions per tube, as this may cause aggregation.

C. Protein Transduction Protocol for Suspension Cells

These conditions were optimized using several cell lines for the delivery of protein of size ranging from 5 to 100 kDa. However, efficient transduction may require optimization of Pep-1 concentration, cell numbers, and exposure time of cells to the Pep-1/protein complex.

Steps

1. The same number of cells recommended for seeding adherent cells is recommended for suspension cells (confluency between 50 and 70%). Culture cells in standard medium in 35-mm dishes or 6-well plates.

2. Form the Pep-1/protein or Pep-1/peptide complexes as described for adherent cells steps 1–4 in section III,A.

3. Collect the suspension cells by centrifugation at 400 *g* for 5 min. Remove the supernatant.

4. Wash the cells twice with PBS.

5. Centrifuge at 400 *g* for 5 min to pellet the cells. Remove the supernatant.

6. Solubilize the cell pellet in the Pep-1/protein or peptide complex solution (200 μl). Add serum-free medium to achieve a final transduction volume of 600 μl.

7. Incubate at 37°C in a humidified atmosphere containing 5% CO_2 for 1 h.

8. Add complete growth medium to the cells. Do not remove the Pep-1/protein or peptide complex. Continue to incubate at 37°C in a humidified atmosphere containing 5% CO_2 for 1 to 24 h depending on the expected cellular response. As described for adherent cells, peptides and proteins are fully released in the cells 1 and 2 h later, respectively.

9. Process the cells for observation or detection assays. Cells may be fixed or observed directly using live imaging spectroscopy.

D. Application: Transduction of β-Galactosidase as a Control Protein

Solutions

1. *Preparation of β-galactosidase*: β-Galactosidase is provided in a lyophilized form and stored at –20°C. Make a stock solution at 0.25 mg/ml in water. Aliquot into several tubes to avoid repeated freeze/thaw cycles, taking into account that 0.5–1.0 µg of β-galactosidase is used per transduction reaction on 35-mm plates. Store the stock solution at –20°C.

2. *Staining solution*: Prepare stock solutions in water. Mix 400 m*M* potassium ferricyanide (13.2 g for 100 ml), 400 m*M* potassium ferrocyanide (16.9 g for 100 ml), 200 m*M* of magnesium chloride (4.6 g for 10 ml), and 20 mg/ml X-Gal resuspended in DMF. Store solutions at –20°C in the dark. The staining solution should be prepared freshly: 250 µl of 400 m*M* potassium ferricyanide (4 m*M* final), 250 µl of 400 m*M* potassium ferrocyanide (4 m*M* final), 250 µl ml of 200 m*M* magnesium chloride (2 m*M* final), 1.25 ml X-Gal (20 mg/ml in DMF) (1 mg/ml final), and 23 ml of PBS.

3. *Fixation solution*: Prepare a 10-fold concentrated solution in PBS (10X) containing 20% formaldehyde and 2% glutaraldehyde. Store at 20°C.

1. Transduction Protocol

Steps

1. Dilute 6 µl of Pep-1 stock solution (0.68 m*M*) in 100 µl of sterile water.
2. Dilute 0.5 µg of β-Gal in 100 µl of PBS.
3. Add the Pep-1 solution to the β-Gal solution and mix gently
4. Incubate at 37°C for 30 min to allow the Pep-1/β-Gal complex to form.
5. Use the transduction protocol described in Section III,B (steps 1–7) for adherent cell lines and in Section III,C (steps 1–8) for suspension cell lines.

2. Staining Protocol

Steps

1. After 2 to 3 h, remove the growth medium from the transfected cells.
2. Rinse the cells three times with PBS.
3. Add fixing Solution. (Dilute the 10X stock in sterile water to make a 1X solution.) Incubate at room temperature for 5 min and rinse extensively with PBS.
4. Add a freshly made staining solution to the cells.
5. Incubate the cells at 37°C for 30 min to 2 h. Cells can be kept overnight at room temperature before analysis.
6. Analyze the percentage of cells transfected with β-galactosidase under a microscope.

E. Application: Delivery of Fluorescently Labelled Antibodies

Pep-1 strategy has been used for the delivery of antibodies into living cells. The protocol was optimized according to Morris *et al*. (2001) and to the Chariot guideline manual (www.activemotif.com).

Steps

1. Detection of fluorescently labelled antibodies in cells requires a large amount of antibody to be delivered. Depending on the sensitivity required to detect your antibody, it may be necessary to increase the amount of Pep-1 and antibody used. Using fluorescently labelled antibodies, concentrations in the final transduction volume of 0.1 µ*M* for antibody and 5 µ*M* for Pep-1 are recommended.
2. Incubate Pep-1 and antibody solution for 30 min at 37°C.
3. Overlay onto cultured cells for 1 to 3 h as described in Section III,C or III,D.
4. Extensively wash and observe cells by fluorescence microscopy. There is no need to fix the cells for observation.

IV. COMMENTS

A large variety of proteins, antibodies, and peptides have been successfully introduced into different cell lines using Pep-1/Chariot strategy and have been shown to retain their biological activity (Morris *et al*., 2001; Buster *et al*., 2002, Jurney *et al*., 2002; Gallo *et al*., 2002; Wu *et al*., 2002; Pratt and Kinch, 2002; Aoshiba *et al*., 2003). An update of published work using Chariot strategy is available on the Web site of Active Motif.

The advantages of the Pep-1 technology are directly associated with the mechanism through which this carrier promotes the delivery of proteins and peptides into cells.

a. The fact that Pep-1-mediated protein transduction is independent of the endosomal pathway significantly limits degradation and preserves the biological activity of the internalized protein for prolonged time periods.

b. An important property of Pep-1-based protein delivery is that it allows for the relatively rapid introduction of proteins into cells. That there is no need of covalent coupling for the formation of Pep-1/macromolecule particles favours rapid release of peptides or proteins into the cytoplasm as soon as the cell

membrane has been crossed. Then the final localization of the macromolecule is determined by its inherent intracellular targeting properties. Entry of Pep-1/macromolecule complexes into the cell occurs in a short time (10 min), and release of macromolecules varies from 1 to 3 h, depending on the nature of the protein and on its affinity for the target (Morris *et al*., 2001).

c. It is important that the process of complex formation between the Pep-1/protein was performed in the absence of serum to limit interactions with serum proteins. However, the transduction process itself is not affected by the presence of serum, which is a considerable advantage for most biological applications (Morris *et al*., 2001).

V. PITFALLS

1. Although this protocol was tested on several cells lines, conditions for efficient protein transduction should also be optimized for each cell line, including reagent concentration, cell number, and exposure time of cells to the Pep1/macromolecule complexes. β-Galactosidase should always be used as a positive control of transduction.

2. Low protein transduction efficiency may be associated with several parameters.

   a. For adherent cells, the optimal confluence is about 50–60%; a higher confluence (90%) reduces the transduction efficiency dramatically.

   b. Conditions for the formation of Pep-1/macromolecule complexes are critical and should be respected. Special attention should be paid to the recommended volumes, incubation times for the formation of Pep-1/macromolecule complexes, and time of exposure of these complexes to cells.

   c. ***Transduced macromolecules may be cytotoxic.*** Transfect the macromolecule at a lower concentration. Compare untransfected cells, cells incubated with Pep-1 alone, and cells with macromolecule alone. Transfect the β-galactosidase control protein.

3. Pep-1 interacts via hydrophobic and hydrophilic interactions. Each peptide or protein will have a different hydrophobicity pattern and may require a different amount of Pep-1. The association of Pep-1 with proteins depends on the structure and biophysical properties of both components of the complex, and thus complex formation may vary between different combinations of Pep-1 and macromolecules (Morris *et al*., 2001). The size of the protein or peptide may also affect the decaging procedure, and low efficiency may be observed for peptides shorter than 15 residues.

4. Diluting Pep-1 in dimethyl sulfoxide (DMSO) may improve the delivery of high molecular weight proteins and antibodies. Pep-1 should first be diluted in 60% DMSO and then combined with the antibody or protein dilution. The final concentration of DMSO should not exceed 20%. However, as this amount of DMSO may be toxic, it may need to be lowered for certain cell lines.

Selective Permeabilization of the Cell-Surface Membrane by Streptolysin O

Jørgen Wesche and Sjur Olsnes

I. INTRODUCTION

Streptolysin O (SLO) is a bacterial exotoxin secreted by β-hemolytic streptococci. The toxin binds to cholesterol in the cell surface of mammalian cells where it oligomerises to form large pores in the plasma membrane (Bhakdi *et al*., 1985; Palmer *et al*., 1998). The pores can reach a diameter of 35 nm and allow the release of large proteins from the cytosol. Importantly, SLO binds to cholesterol on the plasma membrane at 4°C, while pore formation requires 37°C (Bhakdi *et al*., 1993). Thus, permeabilisation can be controlled easily by prebinding the toxin to cells at 4°C and then allowing permeabilisation to occur by incubating the cells at 37°C (Fig. 1).

SLO is used as a tool in cell biology to analyse the transport of toxins with intracellular targets (e.g., ricin and diphtheria toxin) and growth factors into the cytosol (Rapak *et al*., 1997; Wesche *et al*., 1999, 2000). In these experiments, labelled toxin or growth factor is added to intact cells and allowed to translocate into the cytosol before SLO is used to permeabilise the cells and allow the cytosolic proteins to leak out for analysis. In this way, only the protein that has reached the cytosol is obtained and not protein in intracellular membrane-bound compartments such as endosomes and the Golgi apparatus. This is very useful for studying the translocation of toxin mutants devoid of the enzymatic activity often used to assay translocation and for translocation of growth factors without defined cytosolic targets.

The toxin is also widely used in experiments involving semi-intact cells to follow cellular processes such as exocytosis and endocytosis. In these experiments, the plasma membrane is permeabilised selectively by SLO to release the cytosol without affecting intracellular membranes. Cytosol can then be added back either depleted for certain proteins or supplemented with antibodies or membrane-impermeable inhibitors and then cellular processes may be investigated under these conditions.

II. MATERIALS

Minimal essential medium with Earle's salts and without $NaHCO_3$ (Cat. No. 61100-087) is from GIBCO. HEPES (Cat. No. H-3375) and MESNA (2-mercaptoethanesulfonic acid sodium salt, Cat. No. M-1511) are from Sigma. SLO is from S. Bakhdi (for information on how to order SLO from Bhakdi's laboratory please consult http://www.mikrobiologie.medizin.uni-mainz.de/en/index.html). SLO can also be supplied by Sigma (Cat. No. S-5265).

III. PROCEDURES

A. Optimizing Permeabilisation

The concentration of toxin used to obtain optimal permeabilisation in the cells of interest must be determined experimentally. Increasing concentrations of the toxin should be tested for the optimal release of cytosolic components. An easy way to measure the degree of release is to measure the activity of the enzyme lactate dehydrogenase (LDH, 135 kDa). Commercial kits exist for the analysis of LDH activity (Sigma, Cat. No. TOX-7).

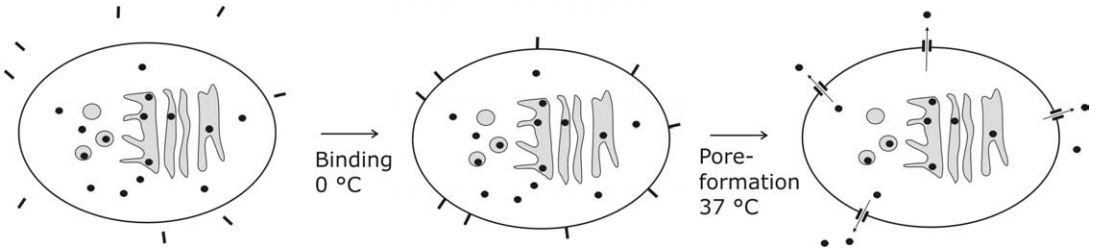

FIGURE 1 Selective permeabilisation using SLO. Radiolabelled ligand (black dots) may localise to intracellular membrane-bound compartments after endocytosis. Part of the ligand may also translocate to the cytosol. To discriminate between the different localisations, SLO is added (black lines) to selectively permeabilise the cell-surface membrane and allow the cytosolic proteins to leak out of the cell for analysis. SLO binds to the cell at 4°C, while insertion and pore formation require 37°C. Permeabilisation of the plasma membrane can therefore be controlled easily.

Solutions

1. *1 M MESNA*: To make 1 ml, dissolve 164.2 mg MESNA in 1 ml water
2. *HEPES medium*: Bicarbonate-free minimal essential medium with Earle's salts buffered with 20 m*M* HEPES to pH 7.4

Steps

1. Store SLO (~500 µg/ml) in aliquots at –80°C and thaw carefully on ice. To be active, SLO must be reduced by agents such as dithiothreitol or MESNA (MESNA is membrane impermeable and might be advantageous to avoid reduction of cellular components after addition of the toxin to cells).
2. Seed out cells growing in culture on tissue culture plates the day prior to the experiment. Before use, wash cells once in HEPES medium.
3. Dilute the toxin in HEPES medium to obtain the required concentrations (1–25 µg/ml) and add 10 m*M* MESNA to activate the toxin. After a 30-min incubation at 37°C with the reducing agent, add the toxin mixture to the cells and keep for 10 min at 4°C.
4. Remove nonbound toxin (and MESNA) by washing the cells once in HEPES medium.
5. Incubate the cells at 37°C for 10 min to allow permeabilisation to occur.
6. Transfer the cells to 4°C and keep for 30 min to let cytosolic proteins leak out into the medium.
7. The degree of permeabilisation can then be measured by analysing the release of the protein LDH into the medium. The optimal concentration of released LDH is normally between 60 and 80%. SLO concentrations that allow a higher release of LDH often affect intracellular membranes as well. To check if intracellular membranes have been affected, a Western blot analysis of organelle marker proteins may be used (Rapak *et al*., 1997). Ligands that are endocytosed by the cells, but not translocated to the cytosol (e.g., transferrin), can also be used to check if endosomes are affected by the treatment (Wesche *et al*., 2000).

B. Experiment

In the following experiment, translocation of the growth factor FGF-1 is used as an example of how SLO can be used to monitor translocation of an exogenously added protein to the cytosol.

Steps

1. Seed out NIH/3T3 cells on 6-wells tissue culture plates at a density of 2×10^5 cells per well. The next day, change the medium to medium containing 0.5% serum for starvation of the cells. After 24 h, add radiolabelled FGF-1 to the cells and incubate further for 6 h. Wash the cells once in HEPES medium and once in high salt/low pH medium (2 *M* NaCl, pH 4.0, in phosphate-buffered saline) to remove surface-bound FGF-1. (Pronase may also be used to remove surface-bound proteins.) Then wash the cells an additional time with HEPES medium.
2. Add SLO to the cells and keep for 10 min at 4°C.
3. Remove nonbound toxin by washing the cells in HEPES medium.
4. Incubate the cells at 37°C for 10 min to allow permeabilisation to occur.
5. Keep the cells at 4°C for 30 min to let cytosolic proteins leak out into the medium.
6. The content of the cytosol (released into the medium) can now be analysed by SDS–PAGE and fluorography (see Fig. 2). The remaining cell components can be lysed (1% Triton X-100 in HEPES buffer) and fractionated into a membrane and nuclear fraction by centrifugation (Fig. 2).

FGF-1 appears in the cytosol after 4 h and reaches a maximum after 6 h. FGF-1 is also found in the nuclear

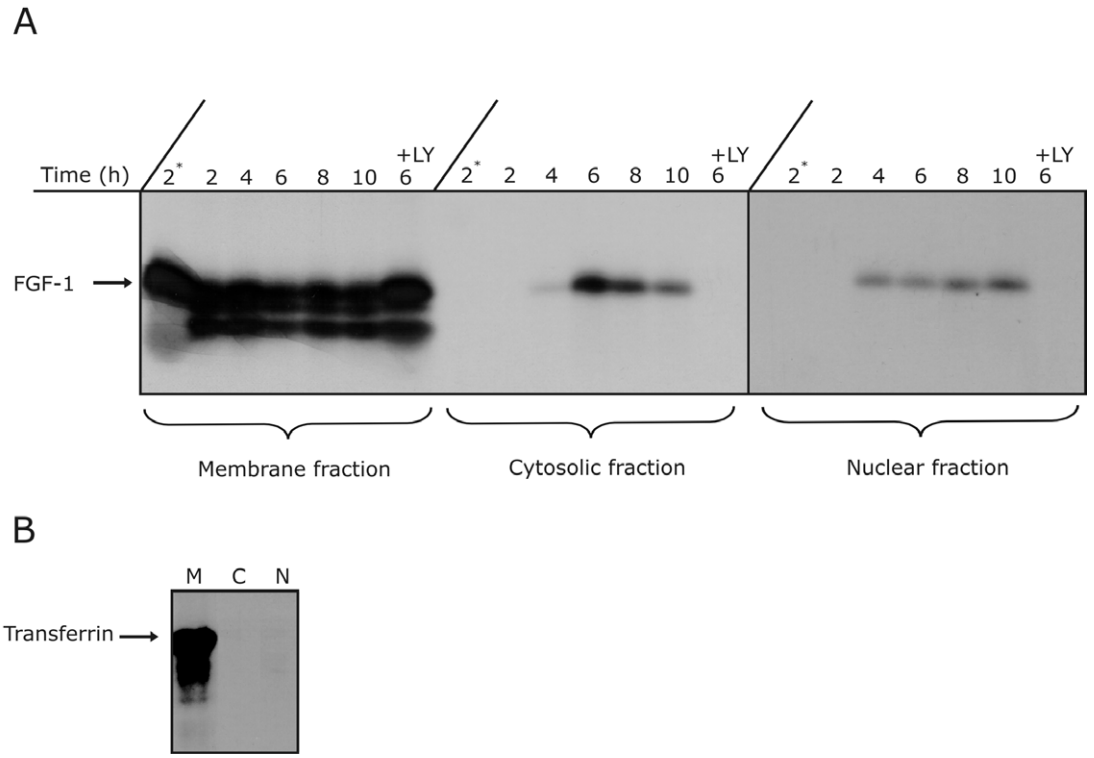

FIGURE 2 Transport of FGF-1 to the cytosol and the nucleus. Radiolabelled FGF-1 or transferrin was added to serum-starved NIH/3T3 cells and incubated for 6 h at 37°C. In lanes labelled +LY, the PI-3 kinase inhibitor LY294002 was added to block translocation to the cytosol and the nucleus. The time point labelled with an asterisk indicates that the incubation was performed at 4°C. The cells were then treated with SLO as described in the text. Cytosolic proteins were recovered from the medium and designated the cytosolic fraction. The remaining cell components were lysed with 1% Triton X-100 and fractionated into a nuclear fraction and a membrane fraction. FGF-1 was recovered from the different fractions by adsorption to heparin–Sepharose. The adsorbed material was analysed by SDS–PAGE and fluorography.

fraction. Transferrin that does not translocate to the cytosol or the nucleus is only found in the membrane fraction (Fig. 2).

IV. COMMENTS

The preparations of SLO vary a lot depending on the suppliers and there are also considerable batch variations. Each batch must therefore be tested for activity.

A mutant that does not require reduction has been constructed and has been reported to have the same activity as wild-type toxin (Pinkney *et al.*, 1989).

An alternative to SLO for plasma membrane permeabilisation is the mild nonionic detergent digitonin. As SLO, digitonin binds to cholesterol and therefore makes holes preferentially in the plasma membrane. A major difference, however, is that digitonin also permeabilises the cells at 4°C and is therefore more difficult to control.

Permeabilisation can also been done on cells in suspension by carefully centrifugating the cells between washes.

V. PITFALLS

SLO isolated from cultures of β-hemolytic streptococci may contain proteases that could cause cells growing on support to detach and may also attack intracellular proteins after permeabilisation (Bhakdi *et al.*, 1993).

4

New Cationic Liposomes for Gene Transfer

Nancy Smyth Templeton

I. INTRODUCTION

We developed improved liposomes that produce efficacy for the treatment of cancer (Ramesh *et al*., 2001; Shi *et al*., 2002; Tirone *et al*., 2001), cardiovascular diseases, and HIV-1 related diseases in small and large animal models. These liposomes condense nucleic acids, mixtures of nucleic acids and proteins, and viruses (Yotnda *et al*., 2002) on the interior of bilamellar invaginated vesicles (BIVs) produced by a novel extrusion procedure (Templeton *et al*., 1997). These nucleic acid : liposome complexes have extended half-life in the circulation, are stable in physiological concentrations of serum, have broad biodistribution, efficiently encapsulate various sizes of nucleic acids and other molecules, are targetable to specific organs and cell types, penetrate through tight barriers in several organs, are fusogenic with cell membranes, are optimized for nucleic acid : lipid ratio and colloidal suspension *in vivo*, can be size fractionated to produce a totally homogeneous population of complexes prior to injection, and can be administered repeatedly. We can add specific ligands either by ionic interactions or by covalent attachments to the surface of these nucleic acid–liposome complexes to accomplish targeted delivery to specific cell surface receptors. The ligands include monoclonal antibodies, Fab fragments, peptides, peptide mimetics, small molecules and drugs, proteins, and parts of proteins. In addition, the charge on the surface of these complexes can be modified in order to avoid uptake by nontarget cells using our novel technology called "reversible masking." We have also achieved high-dose systemic delivery of these complexes without toxicity *in vivo* by further purification of plasmid DNA. We have developed proprietary technologies for the detection and removal of contaminants found at high levels in clinical grade plasmid DNA preparations produced by several different companies. For instance, these DNA contaminants preclude high-dose delivery of complexes that may be required for the treatment of metastatic cancer. Our "Super Clean DNA" also provides for elevated levels of gene expression and prolonged transient expression *in vitro* and *in vivo*. Our complexes have been injected into mice, rats, rabbits, pigs, nonhuman primates, and humans. Currently, these complexes are injected intravenously into patients in clinical trials to treat lung cancer and will be used in upcoming trials to treat breast, pancreatic, head and neck cancers, hepatitis B and C, and restenosis. This article focuses on the production of these BIV liposomes and on mixing nucleic acid–liposome complexes. Because our processes are reproducible, we have standard operating procedures for the cGMP manufacture of these reagents that have been approved by the Food and Drug Administration for use in phase I/II clinical trials.

II. MATERIALS AND INSTRUMENTATION

The following materials are necessary: ethanol, paper towels, gloves, spatulas, 1-liter round-bottomed flask, cork ring to hold the round-bottomed flask, timer, small weigh boats, sterile 5% dextrose in water (D5W; Abbott Laboratories Inc. Part No. 1522-02), cGMP grade (Cat. No. 770890) or GLP grade (Cat. No. 890890) 18:1 dimethyldioctadecylammonium bromide (DOTAP) powder form (Avanti Polar Lipids), cGMP

grade synthetic cholesterol (Sigma Cat. No. C1231), ACS grade chloroform (Fisher Cat. No. C298-1), 0-grade argon gas, RBS pF detergent concentrate (Pierce Cat. No. 27960), sterile glass vials with screw tops, sterile 50-ml polypropylene conical tubes (Falcon Cat. No. 352098), sterile 15-ml polypropylene conical tubes (Falcon Cat. No. 352097), sterile polysulfone syringe filters 1.0 µm pore size 13 mm diameter (Whatman Cat. No. 6780-1310), sterile polysulfone syringe filters 0.45 µm pore size 13 mm diameter (Whatman Cat. No. 6780-1304), sterile ANOTOP syringe filters 0.2 µm pore size 10 mm diameter (Whatman Cat. No. 6809-1122), sterile ANOTOP syringe filters 0.1 µm pore size 10 mm diameter (Whatman Cat. No. 6809-1112), glass pipettes, sterile polystyrene pipettes, lens paper, parafilm, sterile 10-cc syringes (Becton Dickinson Cat. No. 309604), sterile water (Baxter Cat. No. 2F7114), sterile microfuge tubes, sterile pipette tips with no barriers, latex control particles (Beckman-Coulter Part No. 6602336), plastic cuvettes with caps (Beckman-Coulter Part No. 7800091), conductivity calibration standard (Beckman-Coulter Part No. 8301355), and EMPSL7 mobility standard (Beckman-Coulter Part No. 8304073).

The following instrumentation is necessary: Class II type A/B3 laminar flow biological safety cabinet (hood), vortex, analytical balance, rotary evaporator (Buchi Model R-114), vacuum aspirator (Brinkmann Model B-169), water baths, circulating water bath (Lauda Model E100), freeze dryer (Labconco Model Freezone 4.5), low-frequency sonicator (Lab-Line TansSonic Model 820/H), pipette aid, pipetmen, spectrophotometer (Beckman Model DU640B), spectrophotometer turbidity cell holder (Beckman Part No. 517151), UV silica-masked semimicrocell (Beckman Part No. 533041), submicron particle size analyzer with computer (Coulter Model N4 Plus), and zeta potential analyzer (Coulter Model Delsa 440SX).

III. PROCEDURES

A. Liposome Preparation

This procedure prepares 30 ml of BIV liposomes. The final yield is about 95%; therefore, approximately 28.5 ml of 5× stock liposomes is produced.

1. Clean all work surfaces and the hood with 70% ethanol.
2. Allow lipids, DOTAP, and synthetic cholesterol to come to room temperature.
3. Weigh 420 mg of DOTAP and place into a 1-liter round-bottomed flask.
4. Weigh 208 mg of synthetic cholesterol and place into the 1-liter round-bottomed flask.
5. Dissolve the lipids in 30 ml of chloroform.
6. Rotate on the rotary evaporator at 30°C for 30 min to make a thin film.
7. Dry the film in the flask under vacuum for 15 min.
8. Under the hood, add 30 ml of D5W to the film, cover with Parafilm, and make small holes in the Parafilm with a syringe needle.
9. Rotate the flask in a 50°C water bath for 45 min, rotating and swirling the flask until the film is in solution.
10. Place the flask in a 37°C water bath and continue to swirl for 10 min.
11. Cover the flask with more Parafilm (over the Parafilm with holes) and allow flask to sit overnight at room temperature.
12. The next day, remove the Parafilm with no holes and sonicate the flask at low frequency (35 kHz) for 5 min at 50°C.
13. Under the hood, place the contents from the flask into a sterile 50-ml tube and aliquot liposomes evenly into three sterile 15-ml tubes.
14. Place one 15-ml tube into a circulating water bath at 50°C (nearby the hood) for 10 min.
15. Under the hood, remove the plungers from four sterile 10-cc syringes and attach one of each pore size sterile filter (1.0, 0.45, 0.2, and 0.1 µm) to the syringes.
16. Under the hood, rapidly filter the liposomes through all four filters, starting with the largest pore size (1.0 µm) and ending with the smallest pore size (0.1 µm).
17. Under the hood, collect liposomes in a sterile 50-ml tube.
18. Repeat steps 14–16 for the remaining two 15-ml tubes and collect all liposomes in the same sterile 50-ml tube (listed in step 17) under the hood.
19. Under the hood, aliquot the liposomes into sterile glass tubes with screw caps, flush with argon or nitrogen gas through a 0.2-µm filter, and store at 4°C.
20. Rinse the round-bottomed flask with hot water, then with ethanol, and fill with 1× RBS and allow to sit overnight. The next day, rinse out the flask, then rinse with hot water, then with distilled water, and finally with ethanol. Seal the flask with Parafilm after it is dry.

B. Quality Assurance/Quality Control Testing for the Liposome Stock

1. Place 10 µl of liposomes into 190 µl of sterile water. Read the sample on the spectrophotometer at

OD_{400} using the turbidity holder and corresponding cuvette. The reading should be about 4.0, and the acceptable range is any reading lower than 4.5 OD_{400}.

2. Determine the size for the L100 and L200 standards using the particle size analyzer. If the standards are within range, proceed to assessing the liposome stock. Place 12 µl of liposomes into 4 ml of sterile water in the plastic cuvette. Determine the particle size, which should be about 200 nm, and the acceptable range is between 50 and 250 nm.

3. Access the mobility for the conductivity calibration standard and the mobility standard using the zeta potential analyzer. If the standard is within range, proceed to assessing the liposome stock. Place 120 µl of liposomes into 1880 µl of sterile water. Determine the zeta potential, which should be about 65 mV, and the acceptable range is between 50 and 80 mV.

4. Assays for residual chloroform in the liposome stock should not detect any chloroform. All sterility tests should show no observable growth or no contamination.

C. Complex Preparation

Using pipetmen and microfuge tubes, final volumes ranging from 50 to 1200 µl of complexes can be prepared.

1. Bring all reagents to room temperature.

2. Under the hood, dilute the 5× stock liposomes to 2× in D5W in a microfuge tube. For example, to mix a 300-µl final volume of complexes, dilute 60 µl of 5× stock liposomes in 90 µl of D5W.

3. Under the hood in a second microfuge tube, dilute the stock nucleic acid in D5W to 1 µg/ul. The volume of diluted nucleic acid must be identical to the volume of diluted stock liposomes in step 2. The final mixed complexes have a concentration of 0.5 µg of nucleic acid/ul. *Note*: The stock nucleic acid should be vortexed well prior to removing any aliquot for mixing complexes.

4. Under the hood, pipette the diluted nucleic acid into the diluted liposomes by rapid mixing at the surface of the liposomes. Rinse up and down about twice using the pipetman.

5. Read the sample (10 µl of the complexes in 190 µl of sterile water) on the spectrophotometer at OD_{400} using the turbidity holder and corresponding cuvette. The OD_{400} should be about 0.8, and the acceptable range is between 0.65 and 0.95 OD_{400}. If the complexes fall out of this range, then the amount of nucleic acid used for mixing must be adjusted. Specifically, if the OD_{400} is too low, then more nucleic acid must be used for mixing. If the OD_{400} is too high, then less nucleic acid must be used for mixing. If the nucleic acid is not adequately pure, then the appropriate OD_{400} of the complexes will not be obtained. *Note*: To avoid wasting material in order to establish the proper mixing conditions, we mix final volumes of complexes at 50 µl first before we begin large-scale mixing using new lots of nucleic acids.

6. When the proper mixing volumes have been established, more complexes can be mixed if needed following the steps given earlier. All complexes can be pooled after mixing, and the OD_{400} of the pooled complexes should be measured and should fall between 0.65 and 0.95 OD_{400}.

7. The particle size of the complexes can also be measured. Determine the size for the L300 and L500 standards using the particle size analyzer. If the standards are within range, proceed to assessing the complexes. Place 12 µl of complexes into 4 ml of sterile water in the plastic cuvette. Determine the particle size, which should be about 400 nm, and the acceptable range is between 200 and 500 nm.

8. Because the encapsulation of nucleic acids is spontaneous, the complexes can be administered after mixing. Complexes can also be stored in glass vials at 4°C and administered the following day.

IV. COMMENTS

The complexes can be administered and readministered into animals and humans by any delivery route. The dose and administration schedule will be determined by the specific nucleic acid therapeutic and disease model of the investigator and, therefore, must be optimized. Please also see Section V.

We have found that BIV DOTAP is best for transfection of cells in culture (Yotnda *et al*., 2002; N. S. Templeton, unpublished data). The same protocol is used to produce these liposomes; however, cholesterol is not added. Complexes made with BIV DOTAP are mixed using the procedure given earlier.

V. PITFALLS

1. Many investigators are not set up to produce liposomes in their laboratories. Therefore, the BIV liposomes and other custom services can be purchased from our nonviral core facility at the Baylor College of Medicine (contact Nancy Smyth Templeton at **NANCYT@bcm.tmc.edu** to place orders). The BIV DOTAP:Chol liposomes described here are also sold

by Qbiogene and are listed as the *In Vivo* GeneShuttle in their catalog.

2. Using the optimal liposomes for transfection is not necessarily enough to ensure success. Other reagents must be optimized, such as expression plasmid design (Lu *et al*., 2002) and plasmid DNA preparation (Templeton, 2002), for applications that use plasmid DNA.

Cationic Polymers for Gene Delivery: Formation of Polycation–DNA Complexes and *in vitro* Transfection

Yong Woo Cho, Jae Hyun Jeong, Cheol-Hee Ahn, Jong-Duk Kim, and Kinam Park

I. INTRODUCTION

Although nonviral gene delivery systems were first introduced with cationic lipids, cationic polymers (or polycations) have gained increasing attention in recent years as a nonviral vector for gene therapy due to their nonimmunogenicity and low acute toxicity. In both systems, DNA is incorporated into a complex by electrostatic interactions between anionic phosphate groups of DNA and cationic groups of lipids or polycations under physiological conditions. A large number of polycations have been studied as nonviral vectors, such as poly-L-lysine (Wu and Wu 1987), poly(ethylenimine) (Behr *et al*., 1999; Ahn *et al*., 2002), poly(amidoamine) dendrimers (Haensler and Szoka, 1993), poly(2-dimethylaminoethyl methacrylate) (Cherng *et al*., 1996), and chitosan (Lee *et al*., 1998). Cationic polymers have flexibility in designing a carrier with well-defined structural and chemical properties on a large scale as well as the ability to introduce functional moieties (e.g., targeting moieties). In general, the ability to vary and control the physicochemical properties in cationic lipid–based system is relatively limited. This article describes methods that are used commonly in characterizing polycation-based gene delivery systems in *in vitro* transfection, focusing on complex formation between polycations and DNA.

II. MATERIALS AND INSTRUMENTATION

HEPES (Cat. No. H4034), bicinchoninic acid (BCA) protein assay kit (Cat. No. BCA-1), fetal bovine serum (FBS, Cat. No. F3885), 100× penicillin–streptomycin (Cat. No. P0781), trypan blue (Cat. No. T0076), methylthiazoletetrazolium (MTT, Cat. No. M5655), and poly(L-aspartic acid) (Cat. No. P5387) are from Sigma (St. Louis, MO). Polyethylenimine (PEI, Cat. No. 40,872-7), glycerol (Cat. No. 19,161-2), and dimethyl sulfoxide (DMSO, Cat. No. 27,043-1) from Aldrich (Milwaukee, WI). Dulbecco's modified eagle's medium (DMEM, Cat. No. 12100-046) and 10× trypsin–EDTA (Cat. No. 15400-054) are from Gibco-BRL (Carlsbad, CA). Agarose (Cat. No. 161-3101), ethidium bromide (EtBr Cat. No. 161-0433), TBE (Tris/boric acid/EDTA, Cat. No. 161-0733), bromphenol blue (Cat. No. 161-0404), and xylene cyanole FF (Cat. No. 161-0423) are from Bio-Rad (Hercules, CA). The plasmid maxi kit (Cat. No. 12162) is from QIAgen (Valencia, CA). pSV-β-galactosidase (Cat. No. E1081), β-galactosidase enzyme assay system (Cat. No. E2000), pGL3 control containing the SV40 promoter-driven luciferase reporter gene (Cat. No. E1741), and Luciferase assay system (Cat. No. E1500) are from Promega (Madison, WI).

The spectrofluorometer (Spex FluoroMax-2) is from JY Horiba (Edison, NJ). The gel electrophoresis (Mini-PROTEAN 3 electrophoresis cell) system is from Bio-Rad. The microtiter plate reader (SOFTmax PRO) is from Molecular Device Corp. (Sunnyvale, CA). The luminometer (Lumat LB9507) is from Berthold Technologies (Oak Ridge, TN). The dynamic light scattering (90 plus) is from Brookhaven Instruments Corp. (Holtsville, NY).

III. PROCEDURES

A. Formation of Polycation/DNA Complexes (Polyplexes)

Solutions

1. *HEPES-buffered saline:* 15 m*M* HEPES, 150 m*M* NaCl, pH 7.4. To make 500 ml, add 1.787 g HEPES and 4.383 g NaCl to 480 ml water and adjust the pH to 7.4 with 1 *M* NaOH. Adjust the total volume to 500 ml with water. Sterilize the buffer by filtering through a filter with a 0.22-μm pore size.

2. *Plasmid stock solution:* Plasmid DNA (e.g., pSV-β-galactosidase or pGL3 control containing the SV40 promoter-driven luciferase reporter gene) is transformed into *Escherichia coli*. The transformed cells are grown in larger quantities (0.5–1.0 liter) of Luria and Bertan (LB) broth. The plasmid DNA is isolated using the plasmid maxi kit from QIAgen according to instructions of the manufacturer. The plasmid DNA is collected in HEPES-buffered saline and stored at 4°C. The purity is confirmed by 1% agarose gel electrophoresis, and DNA concentration can be measured by UV absorption at 260 nm.

3. *Polycation stock solution, 5 mg/ml in HEPES-buffered saline:* Dissolve 50 mg of a cationic polymer in 10 ml HEPES-buffered saline. Sterilize the polymer solution through a filter with a 0.22-μm pore size.

Steps

1. DNA: Dilute the plasmid DNA stock solution to a final concentration of 20 μg/ml in HEPES-buffered saline.

TABLE I Amount of Polyethylenimine (PEI) for Forming Polyplexes with Various N : P ratios[a]

N : P ratio	0.2	0.5	1.0	1.5	2.0	3.0	4.0	5.0	6.0
PEI (μl)[b]	0.10	0.26	0.52	0.77	1.03	1.55	2.06	2.58	3.10

[a] Twenty micrograms of DNA is used.
[b] PEI stock solution at 5 mg/ml in HEPES-buffered saline.

2. Cationic polymers: Make a series of dilutions in HEPES-buffered saline (see Table I). The N : P ratio is defined as the molar ratio of amino groups in polycations to phosphate groups in DNA.
3. Add polycation solutions to plasmid DNA solutions at different N : P ratios and vortex gently.
4. Incubate at room temperature for 30 min to allow complex formation.
5. Store at 4°C.

B. Analysis of Polycation/DNA Complexes

1. Ethidium Bromide Displacement Assay

The degree of DNA condensation by polycations can be determined by an EtBr displacement assay using a fluorometer (Wadhwa *et al*., 1995; Choi *et al*., 1998). Ethidium bromide intercalates between stacked base pairs of double-stranded DNA to give a significant increase of fluorescence intensity. Addition of a polycation causes a large drop in fluorescence intensity due to displacement of ethidium bromide molecules from DNA, which indicates the condensation of DNA to form complex particles.

Solutions

1. *Ethidium bromide at 10 mg/ml*: The stock solution should be stored in a bottle wrapped in aluminum foil at 4°C and in the dark.

2. *Plasmid DNA stock solution*: *(See solutions in Section III,A)*

3. *Stock solutions of polycations*: *(See solutions in Section III,A)*

Steps

1. The spectrofluorometer is operated with an excitation wavelength (λ_{ex}) of 510 nm and an emission wavelength (λ_{em}) of 590 nm. Use slit widths set at 10 nm and an integration time of 3 s. Perform all experiments in triplicate.
2. Dilute the DNA stock solution to a final concentration of 10 μg/ml, including 0.4 μg/ml EtBr in a test curvette (total volume of 2 ml).
3. Incubate the DNA solution for 15 min to ensure interactions between DNA and EtBr.
4. Measure the fluorescence and calibrate to 100%.
5. Measure the background fluorescence with EtBr alone and set to 0%.
6. Add aliquots of the polycation stock solution sequentially to the DNA solution at various N : P ratios, mix gently, and measure the fluorescence after each addition.
7. Plot the graph the relative fluorescence (%) *vs* N : P ratio.

8. Determine or compare the abilities of different polycations to condense DNA.

2. *Agarose Gel Retardation Assay*

The complex formation between polycations and DNA can be observed by a decrease of mobility of DNA in agarose gel electrophoresis (Ahn *et al*., 2002).

Solutions

1. *Ethidium bromide solution*: *See solutions in Section III,B*
2. *Loading buffer solution:* 0.25% (w/v) bromphenol blue, 0.25% (w/v) xylene cyanole FF, 5% glycerol
3. *Electrophoresis buffer solution*: The ionic strength and pH of the buffer can play major roles in complex stability. Standard electrophoresis buffers such as TBE (90 m*M* Tris–borate, 2 m*M* EDTA, pH 8.3) and TAE (40 m*M* Tris–acetate, 1 m*M* EDTA, pH 7.9) commonly prove satisfactory, but others such as TE (10 m*M* Tris, 1 m*M* EDTA) have been used.
4. *Dissociation buffer solution:* Dissolve 100 mg poly(L-aspartic acid) in 5 ml double distilled water.

Steps

1. Prepare polycation/DNA complexes at various N : P ratios in HEPES-buffered saline and incubate at room temperature for 30 min to allow the complexes to form properly.
2. Add aliquots of the polyplexes (20 µl) in Eppendorf tubes containing 2 µl gel-loading buffer and mix gently.
3. Load the complexes onto wells of the 0.8% agarose gel containing ethidium bromide (1 µg/ml). Also, apply the controls for free DNA and a free polycation to the gel.
4. Perform electrophoresis in 0.5× TBE buffer at 100 V until the bromphenol blue has migrated 5–7 cm through the gel.
5. Visualize and photograph the electrophoresed gel on an UV illuminator to show the location of DNA and complexes.
6. Incubate the gels in the dissociation buffer for 30 min to disturb polycation/DNA complexes and rephotograph the gel to show the presence of DNA dissociated from the polymer.

3. *Measurements of Particle Size*

Solutions

1. *Plasmid DNA stock solution in double-distilled water*: *See solutions in Section III,A*
2. *Stock solutions of polycations in double-distilled water*: *See solutions in Section III,A*

Steps

1. Turn on dynamic light-scattering equipped with a He–Ne laser at a scattering angle of 90°.
2. Set parameters for software. Set viscosity to 0.890 centipoise (cP), refractive index (RI) medium to 1.333 in water. However, if complexes are in 150 m*M* NaCl, set viscosity to 1.145 cP and RI medium to 1.340; if in HEPES, set viscosity to 1.546 cP and RI medium to 1.363. Set the temperature to 25°C for all the solutions.
3. Prepare 500-µl complexes at 20 µg/ml in test tubes and filter through a 0.45-µm filter. Cap the sample and allow it to equilibrate for 30 min before initiating measurements.
4. Calculate the particle size and size distribution using nonnegative least squares (NNLS) algorithms. When the difference between the measured and calculated baselines is less than 0.2%, accept the correlation function. If not, the concentration of complexes can be controlled to give a reasonable signal.
5. Measure the mean particle size, polydispersity factor using the Stokes–Einstein equation, and the cumulant method.

C. *In Vitro* Transfection

This procedure describes the *in vitro* transfection of 293T cells using cationic polymers, such as PEI and PLL, as a vector. The protocol can be used for all adherent cell types with slight modifications. For suspension type cells, cells need to be spun down before changing media.

Solutions

1. *HEPES-buffered saline*: *See solutions in Section III,A*
2. *Phosphate-buffered saline (PBS):* 137 m*M* NaCl, 2.7 m*M* KCl, 8.1 m*M* Na_2HPO_4, 1.47 m*M* KH_2PO_4, pH 7.4. To make 1 liter of 10× PBS, dissolve 80.06 g NaCl, 2.01 g KCl, 11.50 g of Na_2HPO_4, and 2.00 g KH_2PO_4 in 800 ml water. Adjust the pH to 7.4 with 1 *N* HCl. Adjust the total volume to 1 liter with water. To make 1 liter of 1× PBS, mix 100 ml 10× PBS (described earlier) with 900 ml of water. Sterilize the buffer through a filter with a 0.22-µm pore size.
3. *Tissue culture medium:* Tissue culture medium may vary, depending on the requirements of the cell line. Typically, Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum, 100 units/ml penicillin–streptomycin, and 2 m*M* L-glutamine are used to maintain cell lines.
4. *Plasmid stock solution: See solutions in Section III,A*
5. *Stock solutions of polycations: See solutions in Section III,A*

6. *0.05% trypsin–0.02% EDTA solution (1×):* Add 10 ml of 10× trypsin–EDTA to 90 ml of PBS and store at 4°C

7. *0.5% trypan blue solution:* Dissolve 0.5 g trypan blue in 100 ml PBS and filtrate through a filtration paper to remove possible crystals. Store at –20°C

Steps

1. Passage 293T cells 3–4 days before the transfection experiment.
2. Detach the cells with trypsin–EDTA solution and determine the cell number and cell viability using trypan blue. Mix 50 µl cell suspension and 50 µl of 0.5% trypan blue solution. Bring the mixture into a counting chamber and count the number of uncolored (vital) and blue (dead) cells in a number of squares using a microscope. When more than 10 cells are counted per square, dilute the cell suspension and count again.
3. Seed cells in a 6-well tissue culture plate at a density of ~2×10^5 cells/well in 2 ml completed DMEM and incubate overnight at 37°C in a humidified atmosphere under 5% CO_2.
4. Prepare polycations/DNA complexes at various N : P ratios in HEPES-buffered saline and incubate for 20 min at room temperature (see steps in Section III,A).
5. Remove culture media from the cells and replace with 2 ml of serum-free DMEM.
6. Introduce 400 µl polyplexes to each well and incubate for 4 h at 37°C in an incubator.
7. Aspirate transfection media, replace with 2 ml of completed DMEM, and culture the cells in an incubator for 48 h at 37°C.
8. Evaluate the transfection efficiency.

D. Determination of Transfection Efficiency

1. β-*Galactosidase Activity*

The β-galactosidase activity in transfected cell lysates can be determined using the substrate *O*-nitrophenyl-β-D-galactopyranoside (ONPG).

Solutions

1. *Phosphate-buffered saline: See solutions in Section III,C*
2. β-*Galactosidase enzyme assay system with reporter lysis buffer (Promega) including reporter lysis buffer (5×), assay 2× buffer,* β-*galactosidase, 1 M sodium carbonate*

Steps

1. Remove growth media from the cells and wash twice with 2 ml PBS.
2. Add 200 µl of a lysis buffer to cover the cells and rock the 6-well plate slowly several times to ensure complete coverage of the cells.
3. Incubate at room temperature for 15 min.
4. Transfer the cell lysate to a microcentrifuge tube.
5. Centrifuge at top speed in a microcentrifuge for 2 min and transfer the supernatant to a fresh tube.
6. Pipette 50 µl of the cell lysates into wells of a 96-well plate.
7. Meanwhile, make a series of dilutions for the standard curve of β-galactosidase in 1× lysis buffer between 0 and 5.0×10^{-3} units. Prepare 50 µl of each β-galactosidase standard per well.
8. Add 50 µl of assay 2× buffer to each well of the 96-well plate and mix by pipetting.
9. Incubate at 37°C until faint yellow color has developed or the highest standard shows an absorbance of 2 or more.
10. Stop the reaction by adding 150 µl of 1 *M* sodium carbonate.
11. Measure the absorbance of the samples at 420 nm in a microtiter plate reader and calculate the β-galactosidase amount of a sample by comparing with the linear standard curve.
12. The β-galactosidase amount in each sample is normalized to milligrams of protein. Protein concentrations in cell lysates can be measured using a BCA protein assay kit according to instructions of the manufacturer.

2. Luciferase Activity

Solutions

1. *Phosphate-buffered saline: See solutions in Section III,C*
2. *Luciferase assay system (Promega) including a lysis buffer and luciferase assay reagent*

Steps

1. Remove growth media from the cells and wash twice with 2 ml PBS.
2. Add 200 µl of a lysis buffer to cover the cells and rock the 6-well plate slowly several times to ensure complete coverage of the cells.
3. Incubate at room temperature for 15 min.
4. Transfer the cell lysate to a microcentrifuge tube.
5. Centrifuge at top speed in a microcentrifuge for 2 min and transfer the supernatant to a fresh tube.
6. Dispense 20 µl of the supernatant into a luminometer tube.
7. Set the read time to 10 s (the read time can be varied).

8. Initiate reading by injecting 100 µl of Luciferase assay reagent into the tube.
9. Luciferase activity in each sample is normalized to milligrams of protein. Protein concentrations in cell lysates can be measured using a BCA protein assay kit according to instructions of the manufacturer.

E. *In Vitro* Cytotoxicity Assay

Cytotoxicity of polycation/DNA complexes can be evaluated by the MTT assay. The assay is based on the cleavage of the yellow tetrazolium salt, MTT, to form dark blue formazan crystals by active mitochondria dehydrogenases. This conversion only occurs in living cells.

Solutions

1. *MTT stock solution, 5 mg/ml in PBS*
2. *Tissue culture medium:* DMEM
3. *Polyplexes solution*

Steps

1. Seed cells in 24-well microplates at a density of ~4 $\times 10^4$ cells/well in 1 ml of completed DMEM and incubate overnight at 37°C in a humidified atmosphere under 5% CO_2.
2. Remove culture media from the cells and replace with 1 ml of serum-free DMEM.
3. Introduce 40 µl of polyplexes to each well and incubate for 4 h at 37°C in an incubator.
4. Aspirate transfection media, replace with 1 ml of completed DMEM, and culture cells in an incubator for 48 h at 37°C.
5. Remove old media and replace with new completed DMEM.
6. Add 50 µl of 5 mg/ml MTT solution to each well and incubate for 4 h at 37°C.
7. Remove MTT-containing media and add 750 µl of dime to each well and pipette up and down to dissolve formazan crystals formed by live cells.
8. Measure the absorbance at 570 nm using a microtiter plate reader
9. Calculate the absorbance percentage relative to that of untreated control cells.

IV. COMMENTS

Complex formation between polycations and DNA can be affected by several factors, such as the nature of the cation, the molecular weight of the polycation, the molecular architecture of the polycation, and the N : P ratio. Full complexation to form stable nanoparticles between 20 and 100 nm is necessary for effective transfection. Generally, shorter polycations need a higher N : P ratio to achieve full condensation.

V. PITFALLS

1. Large aggregates or precipitated materials can be observed in some cases. They lower the transfection efficiency and may cause toxic effects to cells. They may occur when the N : P ratio is too low or the pH of the transfection medium is too high. Generally, small cationic particles can be formed at the excess of positive groups of polycations compared with negative groups of DNA.

2. The size of polycation/DNA complexes may vary in different buffers mainly due to their different ionic strengths.

3. In some cases, complex particles may not be spherical. Particles with any extended structures may be ignored with light scattering, which leads to inaccurate results. Therefore, the morphology of complex particles must be checked using transmission electron microscopy or atomic force microscopy, as well as characterizing their size and distribution using light scattering.

4. Cell transfection can be performed in the absence or presence of serum. The effect of serum in the transfection medium will vary depending on the nature of polycations.

5. Cells of high passage number are transfected inefficiently.

Electroporation of Living Embryos

Takayoshi Inoue, Kristen Correia, and Robb Krumlauf

I. INTRODUCTION

Gene transfer by electroporation (EP) has been widely used to introduce exogenous molecules into both prokaryotic and eukaryotic cells. In the process of EP, transient pores at the cellular membrane are generated by electric shocks, allowing charged macromolecules such as DNAs, RNAs, and proteins to actively penetrate into cells by means of electrophoresis (Fig. 1A). Noncharged molecules can also be incorporated into cells by molecular diffusion. It was Japanese physicians who initially tried to perform gene therapy with EP *in vivo* (Okino and Mohri, 1987; Nishi *et al.*, 1996). However, the main difficulty in applying this approach to living tissues or organisms in the past was that the electric shocks often damaged cells and resulted in substantial cell death. A key breakthrough was the discovery that a rapid series of controlled square wave pulses (Fig. 1B) reduces the level of cell death dramatically. Using this modification, Muramatsu and colleagues (1997) reported the first remarkable results of EP-mediated gene transfer into developing chicken embryos. Based on these observation, chick embryologists around the world are now routinely utilizing this convenient technology perfected in Japan and it is also being applied to many other living tissues and organisms, including mammals (Momose *et al.*, 1999; Akamatsu *et al.*, 1999; Hass *et al.*, 2001; Reviewed in Itasaki *et al.*, 1999; Yasugi and Nakamura, 2000; Shwartz *et al.*, 2001; Inoue and Krumlauf, 2001; Osumi and Inoue, 2001; Takahahi *et al.*, 2002). As EP-mediated gene transfer is relatively nontoxic to cells and/or tissues and it is possible to precisely control the area selected for transfection (Fig. 1A), the method could further provide a powerful tool for human gene therapy. This article summarizes optimal conditions for EP-mediated gene transfer into chicken and mouse embryos, particularly with respect to situations for controlling the area of transfection.

II. PROCEDURES

A. EP-Mediated Gene Transfer in Chicken Embryos at the Early Primitive Streak Stage (HH stage 3+/5–)

Materials and Instrumentation

A variety of methods to efficiently target restricted regions in chicken embryos by EP have been described previously (Muramatsu *et al.*, 1997; Momose *et al.*, 1999; Itasaki *et al.*, 1999; Yasugi and Nakamura, 2000; Schwarts *et al.*, 2001). Above all, Momose *et al.* (1999) reported the microelectroporation method in which they can precisely target a confined region using the various positioning of a needle type and a wire type electrode. Here we introduce a modified protocol to facilitate EP into relatively young chicken embryos (stages HH 3+/5–). The following materials are required for this protocol.

Tape (3M scotch tape 1 in. width, 3M, USA); needle/spatula (#18-568, Miltex Instruments, USA); blunt scissors (#18-1478, Miltex Instruments, USA); transfer pipette (#232-205, Samco, USA); capillary tubes (#GC150F-10, Harvard Apparatus, USA); electrophoresis pipette tips (#23 35 165-6, Eppendorf, Germany); electroporator (CUY21, Bex Co. Ltd., Japan); electronic leads and 0.5-mm-diameter platinum wire electrode (Computech, USA); and forceps (#17-305X, Miltex, USA).

Copyright 2006, Elsevier Science (USA).
All rights reserved.

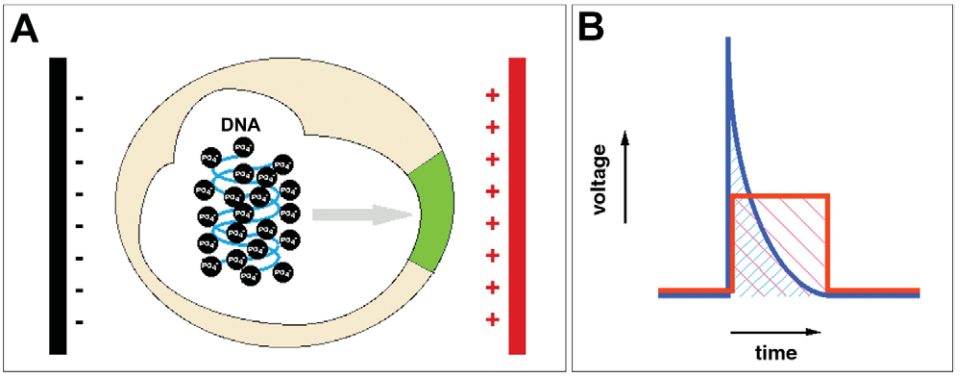

FIGURE 1 (A) The principle of electroporation (EP)-mediated gene transfer. As the DNA molecule includes negatively charged phosphate groups in its backbone (black circles), it naturally charges negative as a whole and will migrate toward the positive electrode (red) in the process of EP. As a result, a restricted area (green) can be targeted in the relevant tissue. (B) For living tissues or embryos, controlled square pulses (red) instead of canonical ones simply decay exponentially (blue) should be applied during EP. Note that the square pulse generates higher amount of energy at relatively lower voltages than the canonical one (the amount of energy is equal to the area with blue or red oblique).

Solutions

1. Plasmid DNA, Qiagen column purified and resuspended in sterile ddH_2O
2. 5% fast green (#EM-4510, VWR)
3. 10X phosphate-buffered saline (PBS): Add 8 g NaCl, 0.2 g KCl, 1.15 g Na_2HPO_4, and 0.2 g KH_2PO_4 to 100 ml of H_2O. Autoclave.

Steps

1. Preparing the DNA. On the day of EP, make 5 µl of solution containing 2 µg/µl plasmid DNA and 0.005% fast green in 1X PBS. It is possible to use two or more different plasmids (see comments later). Centrifuge the DNA solution for 30 s at 13,000 rpm to remove any particulates that might clog the capillary tip. Load 5 µl of the DNA solution into a pulled capillary tube using an electrophoresis pipette tip. Allow the DNA solution to reach the tip of the capillary tube and connect the capillary to a suction pipette.

2. Incubating the eggs. Incubate the eggs on their side until HH stage 3+/5–. This should be approximately 24 h in a humidified incubator at 35°C. Remove the eggs and set a timer for 2 h. Spray the top of the eggs with 70% ethanol and wipe off any debris. Put a piece of tape on the top of each egg, lengthwise. Adhere the tape to the eggshell, making sure that all creases are completely sealed to prevent leaking of egg white. The concave side of the spatula can be used to flatten the tape against the egg.

3. Opening the eggs. Set an egg horizontally on the egg holder. Use the point of the blunt scissors to put a hole in the top of the egg. Cut a long, 2 × 3-cm oval within the taped area of the egg, using short cuts to prevent cracking, leave the shell attached, and fold back. The embryo should be located in the center of the yolk. If the embryo is not at the center of the yolk, discard the egg. Remove any bubbles and 1–2 ml of thin egg white with a transfer pipette to lower the level of the embryo below the cut edge of the shell. Cover the embryo with a drop of thin egg white using the transfer pipette.

4. Staging the eggs. Place the egg under the microscope. Illuminate the egg from one side to view and stage the embryo (Hamburger and Hamilton 1951). Do **not** inject ink, as this will kill the embryo. Stage 3 embryos are round, whereas stage 4 to 5 embryos are pointed near the posterior end. The streak will be half the embryo length at stage 3 and three-quarters the embryo length at stage 4. At stage 5, the head process is visible anterior to the streak. If the embryo is abnormal in its development (if the shape is not symmetrical or if there is more than one streak), discard the egg. To optimize survival while electroporating the posterior mesoderm, choose embryos that are stage 4+/5–. To electroporate the most anterior mesoderm, such as head mesoderm and anterior somites, choose embryos that are stage 3+/4–.

5. Injecting DNA solution. To make a small hole in the vitelline membrane over the embryo, run the capillary tip over the membrane to create a small fold over the tip. Then lift the tip quickly, cutting a small hole in the fold. Insert the needle tip into the hole in the membrane and inject about 0.25 µl of DNA into the space

between the embryo and the membrane (Fig. 2A). Be careful not to scratch the surface of the embryo with the capillary tip. If the capillary tip becomes clogged, run the tip over the taped edge of the eggshell while expelling the DNA solution. After injection, the DNA should diffuse over the top of the embryo. If the yolk was injected, the DNA will be localized in a small area. If the DNA diffuses past the outside boundary of the embryo, then the DNA was injected on top of the vitelline membrane. In good injections, the primitive streak should be highlighted by the fast green tracer (Fig. 2A inset). Fast green can also highlight scratches in the surface of the embryo made by the capillary tip.

6. Performing electroporation. Set the electroporator to 7 V; 50 ms time length of the pulse (pON); 150 ms time length between pulses (pOFF); and three repetitions of pulses. Position the ends of the upper negative (black) and lower positive (red) wires parallel to one another and 4 mm apart (Fig. 2A). At about 20 mm from the ends, bend both wires up and back to help avoid contacting the eggshell when the electrode is positioned over the embryo. Dip electrode briefly in egg white. Pierce the yolk outside of the area opaca, about 25 mm posterior to the embryo with the forceps. Insert the lower wire and let the yolk settle back in place. Approximately 1 cm of the lower electrode should be contacting the egg white and yolk. Position the upper wire over the streak with the end at the node and the side covering the streak. Approximately 2 mm of the upper electrode should be contacting the surface of the egg white. This situation makes a radial electric field rather than a parallel one, enabling one to target a confined area giving rise to somites. While administering the pulses, small bubbles should form on the upper visible electrode tip. After administering the pulses, carefully remove the electrode and wipe it clean with a paper towel.

7. Reincubation of the egg. Replace the shell and tape up the window using two overlapping pieces of tape. Make sure that all creases are completely sealed to prevent leaking of egg white. Eggs should be returned to the incubator within 2 h of having been removed for maximum viability. After 24 h the electroporated DNA reporters should be expressed in the posterior somites and presomitic mesoderm if electroporated at stage 4+/5– (Figs. 2B–2E) and in the head mesoderm and anterior somites if electroporated at stage 3+/4– (Figs. 2F–2I).

Comments

1. **Promoters.** The expression plasmid pCA (see Section II,B) used in these experiments directs very strong and ubiquitous expression in most tissues of chick embryos. Other plasmids containing promoters

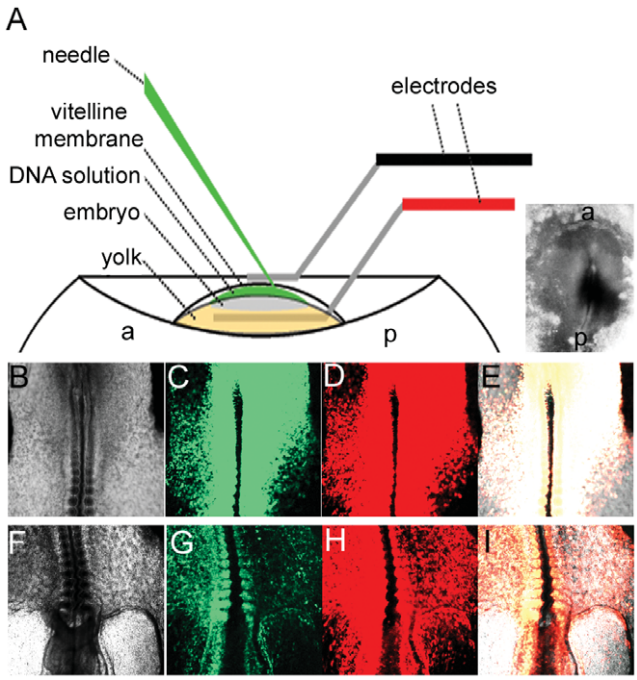

FIGURE 2 (A) Diagram of DNA injection and electroporation. To introduce the DNA solution, the tip of the injection needle is placed between the vitelline membrane and the embryo. To electroporate, the lower, red electrode is positioned within the yolk and the upper, black electrode is placed on top of the vitelline membrane overlying the embryo. The electrodes should be aligned with the anterior (a)/posterior (p) axis of the embryo as shown. (Inset) Stage 3+/4– chick embryo injected with DNA. Anterior is to the top. The DNA solution appears black, the embryo is gray, and the area opaca is white. The DNA solution collects within the streak and also diffuses over the surface of the embryo. (B–E) Stage 10 chick embryo electroporated at stage 4+/5– and incubated *in ovo*. Anterior is to the bottom. The plasmids pCA-dsRed express and pCA-GFP were combined at a concentration of 0.5 and 0.05 µg/µl, respectively. (B) Light microscope image of the posterior end of the embryo; anterior is to the bottom. (C) The CA promoter drives expression of GFP in all electroporated cells. GFP is expressed in somites, the presomitic mesoderm, and the lateral plate mesoderm. The neural tube of this embryo was not electroporated. (D) The same promoter drives expression of dsRED express in the same tissues. (E) Merged image of B, C, and D. Areas where strong GFP and dsRED expression overlap are yellow. (F–I) Stage 10 chick embryo electroporated at stage 3+/4– and incubated *in ovo*. Anterior is to the bottom. The plasmids pCA-dsRed express and cHoxb1 3′pGZ40-GFP were combined at a concentration of 0.25 and 0.75 µg/µl respectively. (F) Light microscope image of the head of the embryo; anterior is to the bottom. (G) The GFP protein driven by the Hoxb1 3′ enhancer is expressed strongly in somites and at a lower level in the head mesoderm. Its expression is driven by enhancers within region 3′ of chicken Hoxb1, which are linked to the chicken β-globin minimal promoter. (H) The dsRed express protein is driven by a ubiquitous promoter and marks the majority of electroporated cells. It is expressed in the head mesoderm, but not in the neural tube. Most embryos are also electroporated in the neural tube by this method, but this embryo clearly shows that expression in the mesoderm of this embryo is not due to the neural crest. (I) Merged image of F, G, and H. Areas where intense expression of both GFP and dsRed overlap are yellow.

that mediate widespread expression in chick embryos include pCAGGS (Niwa *et al*., 1991), MiwSV (Tomomura *et al*., 1990), pBK-CMV (Stratagene, USA), and pCS2 (Turner and Weintraub, 1994). For tissue-specific expression, a choice of unique enhancer sequences can be linked to the minimal β-globin promoter in pGZ40 (Itasaki *et al*., 1999).

2. **Stage and rate of survival.** The stage of the embryo at the time of EP affects the survival rate. At stage 3+, approximately 50–60% of embryos survive and develop normally. This mainly relates to a decrease in survival as a consequence of windowing of the egg and is not generally an affect of the EP itself. At stage 5–, approximately 80–90% of embryos develop normally.

3. **Multiple plasmids.** Depending on the strength of the promoters, it may be possible to use multiple plasmids. For example, a DNA concentration of 0.05 μg/μl is sufficient to visualize expression of pCA-GFP. Therefore, more DNA (2.45 μg/μl) from a plasmid with a weaker enhancer can be combined with the DNA of a stronger expressing plasmid. Mix both plasmids in the same tube before loading in the capillary tube for reproducibility. In the example shown, GFP is used as a positive control to determine how well the EP has worked (efficiency) and to determine what general area was electroporated.

Pitfalls

1. **Embryo drying.** A sign that the embryo is drying out during incubation is the presence of a hardened area of yolk adhering to the embryo. If the window is sealed well with tape and the embryos are still drying out, rotating the eggs at a 90° angle can help. This results in the uncut shell being positioned over the top of the embryo. Also, transient drying during embryo manipulation can affect the development of the embryo. Be sure to keep a drop of thin egg white on top of the embryo during the procedures.

2. **Positioning the electrode.** Inserting and removing the electrode can be difficult if the window is not large enough or if the embryo is oriented with its rostrocaudal axis along the short axis of the oval window. Keep the microscope on a low power so that the edge of the window can be seen. Rotate the top of the egg toward you so that the edge of the window is lower on the side facing the operator. If the bottom wire contacts the eggshell, pushing down may cause it to bend upward unexpectedly, poking into the embryo or narrowing the distance between the electrodes.

3. **Too much injectant.** If there is a large outpocketing of yolk sac, this is a sign that too much solution is being injected. If the opening of the capillary tip is too large, it will be difficult to inject the proper small volume of DNA solution. Too much fast green in the solution may also be toxic for embryos.

B. EP-Mediated Gene Transfer into Cultured Mouse Embryos

Materials and Instrumentation

For mouse whole embryo culture (WEC), we recommend a rotator bottle system with a continuous gas supply (from BTC engineering, UK, or Type10-0310 from Ikemoto Rika, Japan). The system allows mouse embryos at post-implantation stages (E7.0–E13.0) to develop normally for a few days *in vitro* culture. This time frame covers many of the dynamic events during mouse early organogenesis, permitting analysis of developmental processes over this period with EP (Fig. 3A). Embryo cultures may be initiated from E6.5, but it is hard to target a specific area with EP at this stage. Mouse embryos become more placenta dependent after E10.0 and the placenta does not grow well in the culture system. Hence it is very difficult to keep the *in vitro* embryo culture effective following this stage. To maintain embryos in good condition, the yolk sac and amnion must be opened to directly expose the embryo to culture media (Osumi and Inoue, 2001; Fig. 3L).

To obtain as many embryos as possible for EP, we use the CD-1/ICR mice strain (Charles River, USA). However, other mouse strains, including transgenic and/or mutant mice lines, are equally acceptable for the system. The morning when vaginal plugs are detected is designated as E0.5. Pregnant mice were sacrificed at the developmental stages of interest, as approved by the IACUC Review Committee for Animal Experimentation of the Stowers Institute for Medical Research.

An electroporator that can generate controlled square pulses is essential to EP of mouse embryos. We use CUY-21 (Bex Co. Ltd., Japan), which generates most stable pulses at lower voltages. For mouse experiments, other types of electroporators, such as the BTX-T820 (BTX, USA), are acceptable because relatively higher voltages compared with the chicken experiments are sufficient for efficient EP(see earlier discussion).

For mouse embryos, we used specially designed chamber type electrodes, where the distance between the electrodes is 2.5 cm (Fig. 3B). The electrodes and electric wires are now available commercially from TR Tech/Bex Co. Ltd., Japan. Electrodes made of platinum yield the best results because the metal is resistant to ionization during EP. For DNA injection, microcapillaries (#B100-58-10, Sutter Inc.) are pulled and the solutions are filled by suction with mouth pipette.

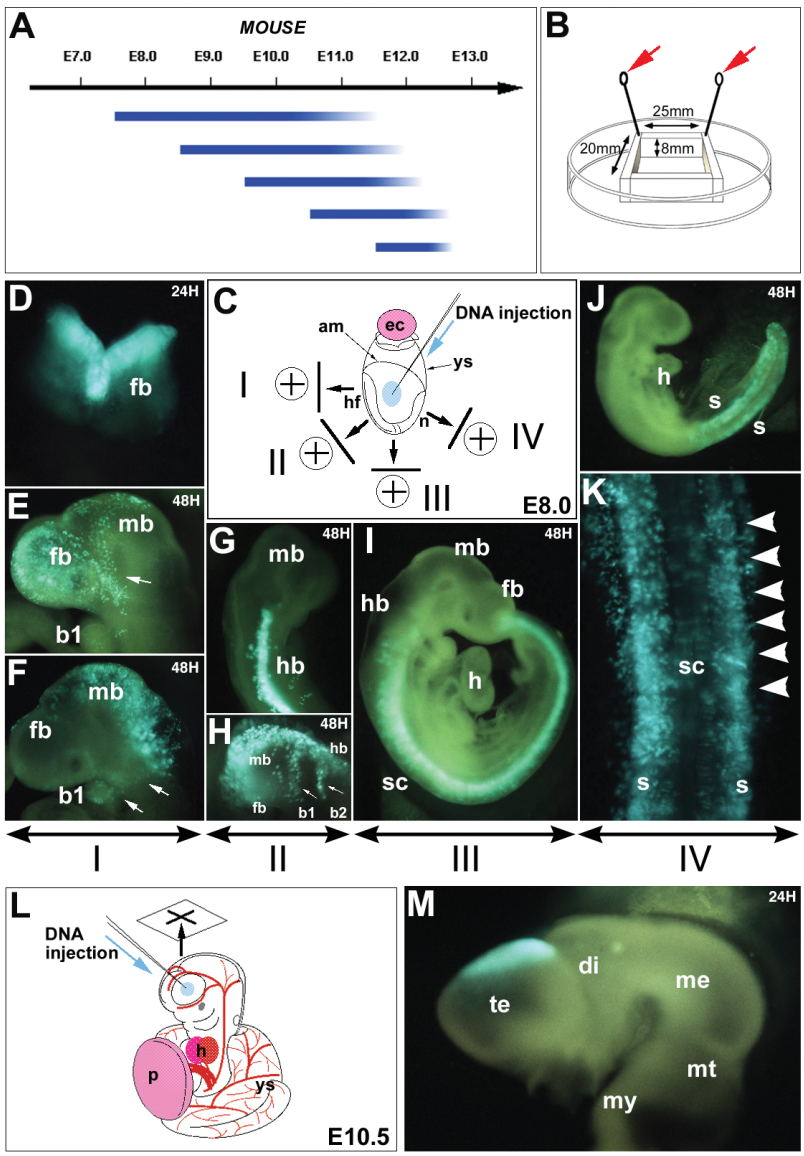

FIGURE 3 (A) Possible time schedules for mouse whole embryo culture after electroporarion (EP). The left edge of a blue bar indicates the start point of culture with EP, and the solid blue area represents the duration in which more than 75% of embryos can grow normally *in vitro*. (B) The electrode chamber designed for mouse embryos at any developmental stages. We made the chamber with silicone blocks on the 100-mm glass dish to be able to set two thin platinum plates (20 × 8 mm each) apart in a 25-mm distance. A lead wire is connected to each electrode and the end is bent to attach to the alligator clips from the electroporator (red arrows). (C) Schematic drawing of a mouse embryo at E8.0 ready for *in vitro* culture. DNA able to direct ubiquitous GFP expression (light blue oval) was microinjected into the amniotic cavity. By rotating the embryo in the electrode chamber filled with Tyrode's solution, various regions (I–IV) facing the positive (+) electrode were targeted by EP. (D–F) Results of EP in targeting region I of C. Embryos cultured *in vitro* for 24 or 48 h (24H/48H) showed a restricted pattern of GFP expression in anterior brain neuroepithelial cells. Neural crest cells emigrated from the forebrain, midbrain, and/or anterior hindbrain were also positive for GFP (white arrows in E and F). (G and H) Results of EP in targeting region II of C. Cells in the hindbrain and neural crest cells migrated out from the hindbrain to branchial arches (white arrows in H) harbored the exogenous GFP expression after 48 h of culture (48H). (I) Results of EP in targeting region III of C. The ventral part of the spinal cord strongly expressed GFP after 48 h of culture (48H). (J) Results of EP in targeting region IV of C. Pairs of posterior somite blocks express the exogenous GFP after 48 h of culture (48H) because cells just posterior to the node give rise to the somitic mesoderm. (K) A higher magnification of J. (L) Schematic drawing of a mouse embryo at E10.5 ready for *in vitro* culture. DNA able to direct GFP expression (light blue circle) was microinjected into the telencephalic vesicle, and the dorsal telencephalon was placed to face the positive (+) electrode in the electrode chamber. (M) After 24 h of culture (24H), strong GFP expression was found only in the dorsal part of the telencephalon. am, amnion; b, branchial arch, di, diencephalon; E, embryonic day; ec, ectoplacental cone; fb, forebrain; h, heart; hb, hindbrain; hf, head fold; mb, midbrain; me, mesencephalon; mt, metencephalon; my, myelencephalon; n, node; p, placenta; s, somite; sc, spinal cord; ys, yolk sac.

All embryo manipulations are performed under the binocular microscope ($MZ9_5$, Leica), and photographs are taken under a fluorescent microscope (MZ FLIII, Leica) fitted with a filter suitable for GFP.

The procedure described here is partly according to Akamatsu *et al*. (1999), Inoue *et al*. (2001), and Osumi and Inoue (2001).

Solutions

1. *Tyrode's solution, pH 7.4 (TS)*: Perform dissections and EP in TS to keep embryos in the best condition. Five liters of TS contains NaCl, 40.0 g; KCl, 1.0 g; $CaCl_2$, 1.0 g; $MgCl_2{\cdot}6H_2O$, 1.05 g; $NaH_2PO_4{\cdot}2H_2O$, 0.285 g; $NaHCO_3$, 5.0 g; and glucose, 5.0 g. To avoid possible precipitation of salts, we add these reagents in this order and sterilize by filtration. TS stored at 4°C should be prewarmed up to room temperature prior to use.

2. *Culture medium*: Prepare a 1 : 1 mixture of the rat serum and DMEM (#D5546, Sigma) containing L-glutamine and penicillin–streptomycin (100× solutions are available commercially from Gibco-BRL). The method used to collect rat serum was described previously (Hogan *et al*., 1994).

3. *DNA solutions*: Plasmid DNA solutions with high concentration (~5 μg/μl) are required for mouse EP protocol. The following experiments used the GFP expression vector driven by the cytomegalovirus enhancer and β-actin promoter (pCA-GFP; Inoue *et al*., 2001). After the Qiagen column and/or CsCl-based DNA purification, dissolve DNA into PBS (see earlier discussion) and add fast green (see earlier discussion) by 0.005% to be able to visualize the solution during the injection/EP processes.

Steps

1. Harvesting mouse embryos. Dissect the mouse embryos in the TS and preincubate them for more than 2 h in the culture system. Mice dissection procedures for WEC were described previously in details (Osumi and Inoue, 2001).

2. Preparations of electrode. Sterilize the electrode chamber briefly with 70% ethanol and then wash with TS three times.

3. Measure resistance. Transfer the embryo(s) from the culture bottle to the chamber and measure the resistance between electrodes. The resistance should be less than or equal to 120 Ω for optimal results. If not, add more TS to reduce the resistance.

4. Injection of DNA. DNA solutions may be injected into the region of interest while manually holding the embryo with forceps. For example, we inject DNA into the amniotic cavity for embryos at the 0–3 somite stages to direct ubiquitous GFP expression or into the lumen of the neural tube/brain ventricles at E9.0–12.0 to obtain region-specific expression in the nervous system (Figs. 3D–3I and 3M). A mouth pipette can control injections, and the volume of injectant may vary according to the developmental stages, but should be less than 0.5 μl.

5. Positioning embryos. Immediately after injection, center the embryo(s) in the chamber and arrange the embryo(s) so as to face the target region against the positive electrode (Figs. 3C and 3L). Negatively charged DNA molecules will migrate toward the positive electrode during EP. If a stable position cannot be obtained for the embryo(s), a block of agarose gel with a hollowed-out space can be used to hold them.

6. Electroporation. Send electric pulses. While the pON, pOFF, and the number of pulses can be fixed at 50 ms, 950 ms, and five repeats, respectively, the voltage should be changed depending on the embryonic stages. For optimal results we have found that application of 65 V for the 0–3 somite stage mouse embryos, 75 V for E9.5 mouse embryos, and 85 V for E10.5 mouse embryos with the 2.5-cm gap electrode chamber are best. For rat embryos, 1.1 times higher voltages are set than for mouse embryos (also see later for optimization of the EP parameters).

7. Embryo culture. Carefully transfer the embryo(s) into the fresh TS to get rid of any possible contamination of free radicals and/or ionized materials produced around the electrodes by EP. Then the embryo(s) can be put back into the WEC apparatus. The first evidence of exogenous gene expression can normally be detected after 6–8 h of EP, and 24–48 h culture is generally sufficient to see the maximum expression of reporter genes following the EP (Figs. 3D–3K and 3M).

8. Avoiding contamination. The chamber must be washed thoroughly with TS before trying the next round of EP. Repeat steps 3–7 until finishing up all embryos.

Comments

For efficient gene transfer, further optimization of the parameters of EP can be very helpful. The following are critical points in optimization.

i. Generally, a higher voltage is toxic for the cells, but it can yield better results. First try 25 V/cm with five pulses (pON 50 ms/pOFF 950 ms). This is a maximum voltage for any fragile tissues (e.g., early stage embryos).

ii. Keep in mind that the EP energy is proportional to total pulse length and square voltages. Doubling the

voltage results in the energy quadrupling, creating heat and damage to cells.

iii. The pulse length can be shortened to increase the voltage and the efficiency as well. For example, while a 2-ms pulse with 300 V generates exactly the same energy as a 50-ms pulse with 60 V, the former condition works much better than the latter condition with respect to the efficiency of gene transfer. It should be noted, however, that too high a voltage damages more cells. Hence this may not be effective for fragile early embryos and/or tissues.

iv. Time length between pulses (pOFF) can affect the EP efficiency. If the electroporator can control this parameter, shorter bursts are better, but it should not be too short to generate a continuous series of pulses.

A disadvantage of WEC is that the method is limited to events between E7.0 and 13.0, as it is difficult for the placenta to develop *in vitro*. However, there are established methods for *in utero* manipulations that could equally be applicable to EP, and several groups have indeed reported elegant results (Fukuchi-Shimogori and Grove, 2001; Saito and Nakatsuji, 2001). The ultrasound backscatter microscope has also been found to be effective at visualizing developing embryos and actually helps in perfecting the transfer genes *in utero* through EP (Takahashi *et al*., 2002). EP could further be extended to slice cultures of adult tissues or organ culture to investigate questions dealing with events after embryogenesis.

Pitfalls

We use highly concentrated DNA solutions for EP in mouse embryos because we found that solutions less than 1 μg/μl did not yield robust uniform patterns of expression. However, if mosaic expression is useful, then lower DNA concentration, as well as voltage, can be effective. It can be very difficult to load highly concentrated DNA into a capillary, but preheating of the solution for 10 min at 62°C can facilitate the process. Furthermore, the preheating process enhances the efficiency of EP, probably because DNA molecules in the solution stored at 4°C make aggregates, which could influence DNA transportation through cell membranes.

EP generates free radicals and/or ionized materials toxic enough to kill almost all of the cells around the electrodes. Therefore, the electrodes should not touch the embryo and/or tissues during EP and the length between electrodes should be set as distant as possible. It is hard to achieve normal growth of mouse embryo following EP at the somite stage between 4 and 9. The abnormality seen most frequently is a defect in the turning of embryos, so it is possible to examine other events during this period of development.

III. FUTURE PROSPECTIVE

Systems for EP-mediated gene transfer, as described here, are easily set up and EP is indeed an efficient way to evaluate gene function. Most current studies have utilized plasmid DNA. However, dyes, chemical reagents, antibodies, antisense morpholino oligonucleotides, double-strand RNAs, ribozymes, or bacterial artificial chromosomes could be mixed together in any combinations. These might be transferred into specific groups of cells or tissues for which there are not good cell culture models, as any charged macromolecules can be targeted using EP. Several research groups have actually reported excellent results of gene attenuation by dsRNA or morpholino oligonucleotides with EP (Takahashi *et al*., 2002; Mellitzer *et al*., 2002; Calegari *et al*., 2002). In the future, such broad accessibility should drastically change experimental designs in cell and developmental biology. EP will also offer a relatively high-throughput means of assaying or evaluating gene function and regulation, which must be important in light of the flood of information coming from the human genome project.

Somatic Cell Nuclear Transfer

CHAPTER

7

Somatic Cell Nuclear Transplantation

Keith H. S. Campbell, Ramiro Alberio, Chris Denning, and Joon-Hee Lee

I. INTRODUCTION

The production of live offspring by nuclear transfer using a cultured cell population as nuclear donors was first reported in sheep (Campbell *et al.*, 1996). Since that time, offspring have been reported in a range of species, including sheep (Wilmut *et al.*, 1997), cattle (Cibelli *et al.*, 1998), mice (Wakayama *et al.*, 1998), pigs (Polejaeva *et al.*, 2000), cats (Shin *et al.*, 2002), rabbits (Chesne *et al.*, 2002), horses (Galli *et al.*, 2003), and rats (Zhou *et al.*, 2003), and from a variety of cell types derived from embryos, fetuses, juvenile, and adult animals (for review, see Campbell *et al.*, 2003). The ability to culture large numbers of cells *in vitro*, which can be used as successful nuclear donors, provides unique opportunities for the preservation and genetic modification of defined genomes. Primary cell populations have been used for the production of transgenic animals by gene addition (Schnieke *et al.*, 1997) and also by gene knockout (McCreath *et al.*, 2000; Denning *et al.*, 2001) and knockin strategies (McCreath *et al.*, 2000), producing animals for agricultural, medical, and research applications. Genotype preservation from both live (Wells *et al.*, 1998) and dead (Loi *et al.*, 2001) animals has been demonstrated. Many factors affect the development of embryos reconstructed by nuclear transfer (for review see, Campbell *et al.*, 2003). The methodology described here is based on the production of ovine embryos; with differences in timings, the methods are similar to those used in other species that have been produced by nuclear transfer.

II. MATERIALS AND INSTRUMENTATION

Embryo manipulations are carried out under a Leica MZ12.5 stereomicroscope and under a Leica DMIRBE inverted microscope fitted with differential interference contrast and epifluorescence. Both microscopes are fitted with Linkam M60 warmed stages. A MMO-202ND Narishige three-axis hanging joystick micromanipulator, one IM-5B Narishige injector for oocyte holding, and one Eppendorf Celltram Oil/Vario for cell transfer are fitted to the inverted microscope (Fig. 1A). The oocyte holding system is filled with Fuorinert FC77 (Sigma F-4758). Alternatively, the Narishige IM-9C injector can be used for oocyte holding. This system works properly with air.

Glass pipettes are prepared after pulling borosilicate capillaries (thin wall 1 mm o.d. × 0.8 mm i.d., Intrafil) on a P-97 Sutter Instruments Co. puller. For grinding the pipettes, the EG-400 (Narishige) micropipette grinder is used in conjunction with a microforge MF-830 (Narishige).

Cell fusion is performed with an Eppendorf multiporator fitted with a fusion chamber (electrodes 200 or 500 μm apart; Fig. 1B). For the fusion of somatic cells (15–18 μm) with a MII oocyte, a combination of an AC pulse and DC pulses give a fusion rate of more than 75% on sheep and cattle couplets.

Reagents are from Sigma unless specified. For isolation, culture, and assessment of donor cells, Glasgow MEM (G-5154), 200 m*M* glutamine (G-7513), 100 m*M* sodium pyruvate (S-8636), MEM nonessential amino

acids (M-7145), trypsin (T-4044), Giemsa solution (G-3032), glycine (G-7126), phosphate-buffered saline (PBS) tablets (P-4417), gelatin (G-1890), trisodium citrate (C-3434), and dimethyl sulfoxide (DMSO) (D-5879) are used. Gentamycin (15750-037) is from Invitrogen/Gibco. Methanol (M/4000/17) and glacial acetic acid (A/0400/PB17) are from Fissons. Fetal calf serum (FCS) (SH-30088) is from HyClone. Vectashield mountant (H-1200) is from Vector Labs. Chamber slides (TKT-210-430L) are from Fisher Scientific. Monoclonal mouse antihuman Ki-67 antigen (clone MIB-1) (M-7240) and FITC-conjugated rabbit antimouse immunoglobulin (F-0261) are from Dako.

III. PROCEDURES

A. Preparation of Tools for Micromanipulation

Tools are prepared differently according to individual preferences relating to the position of the pipettes on the microscope. We will provide the technique used in our laboratory for performing NT with pipettes aligned horizontally to the oocyte (Fig. 2A), although it is also possible to conduct the manipulation at a 45°C angle (Fig. 2B).

1. Holding Pipette

Steps

1. Pull glass capillaries (GC10–100, Intrafil) by hand over a small flame to give a 100- to 150-μm diameter.
2. Mount capillaries with straight end onto the microforge and apply heat until the open tip is almost closed, ensuring an internal diameter of approximately 20 μm.

2. Enucleation Pipette

Steps

1. Pull glass capillaries using the microcapillary puller to give an initial taper, which reduces the diameter of the capillary to slightly greater than the diameter required, with the second taper being almost parallel.

2. Mount a drawn capillary on the microforge. Measure the diameter of the pipette using an eyepiece graticule and break at the required size, between 20 and 25 µm. The break is made by fusing the capillary onto a bead of glass, which is heated using the minimum temperature needed to stick the glass onto the capillary. The power is turned off and the capillary breaks by retraction of the cooled glass bead. Care should be taken to ensure that the capillary is not overheated, as this may cause distortion and thickening of the glass. The tip area must be straight so that it can be properly ground to a point.

3. Mount the pipette in the microforge at a 45° angle and ground it at medium speed ensuring a continuous water flow over the surface where the pipette is being ground.

4. Pipettes with thick walls can be made thin by dipping into 20% hydrofluoric acid for 30–60 s while continuously blowing air through (this prevents acid entering the inside of the pipette). If thin wall capillaries are used, there is no need for hydrofluoric acid dipping.

5. Wash with distilled water to remove acid.

6. Mount the pipette on the microforge with the tip hole in view. Heat the forge to the minimum temperature required to melt the glass bed. Touch the tip of the pipette against the glass bead and pull the tip of the pipette out to a sharp point.

3. Manipulation Chamber

Materials

1. Silicon vacuum grease (Beckman), coverlips, and plastic spacers of 2.5 cm.
2. Siliconized glass slides: Cover clean glass slides with Sigmacote (Sigma SL-2), drain, and let air dry.

Steps

1. Apply a line of wax 2 cm in length along both edges of the upper surface of a siliconized glass slide.
2. Apply silicon vacuum grease to both sides of two plexiglass spacers (2 cm), attach them parallel to the long axis of the slide, and press down firmly.
3. Pipette 60 µl of manipulation medium into the center of the chamber between the spacers. Place a clean coverslip (cleaned in 70% ethanol) on top of the spacers and push down firmly.
4. Turn the chamber upside down and fill with silicon oil until the drop of manipulation medium is enclosed in oil. This seals the ends, preventing evaporation of the manipulation medium.
5. Turn the chamber to the upright position.

B. Preparation of Equipment for Manipulation

Steps

1. Place a prepared manipulation chamber onto the stage of the microscope.
2. Put a small volume of manipulation medium into the holding pipette.
3. Attach the holding pipette to the left-hand side tool holder, ensuring that all air is removed from the hydraulic system.
4. Move the holding pipette into the manipulation chamber.
5. Coat the inside of the injection pipette with sigmacote by aspirating the solution through the pipette several times. Wash with water and mount onto the pipette holder.
6. Mount the pipette on the right side of the chamber and ensure that the system is free from air bubbles. A slight angle of approximately 5° from horizontal allows the pipette to pick up cells from the bottom of the chamber.

C. Enucleation of Oocytes

Solutions and Equipment

1. Manipulation chamber and microtools: *See Section III,A*
2. MII oocytes
3. *Hyaluronidase stock solution*: Dissolve hyaluronidase in PBS to give 750–1500 IU/mg (H-4272). Dispense into 1-ml (300 IU/ml) aliquots. Store at –20°C.
4. *Cytochalasin B (C-6762) stock solution*: 10 mg/ml in DMSO stored at –20°C
5. *Bisbenzimide (Hoechst 33342) stock solution*: 1 mg/ml in PBS. Prepare 10-µl aliquots and store at –20°C.

Steps

1. Select oocytes surrounded by at last three layers of cumulus cells.

2. Incubate the matured oocytes in a Falcon tube containing 400 µl of hyaluronidase (300 IU/ml) for 2 min at 37°C and then vortex for 4 min.

3. Wash denuded oocytes in modified HEPES-buffered SOF medium (supplemented with 4 mg/ml BSA) and return to maturation medium.

4. At regular intervals, place batches of 10–15 oocytes with extruded polar bodies into mHSOFaac/4 mg/ml BSA containing 50 µg/ml bisbenzimide (Hoechst 33342) and incubate for 15 min at 35°C on the heated stage.

5. After incubation, transfer each batch of treated oocytes to the manipulation chamber.

6. Using 20× magnification, pick up and attach a single oocyte to the holding pipette using negative pressure.

7. Change the magnification to 40× DIC and focus on the oocyte held by the pipette.

8. Bring the enucleation pipette into focus. Using the enucleation pipette, rotate the oocyte into a position where the polar body and the area of cytoplasm adjacent to it can be aspirated into the pipette (Fig. 3A).

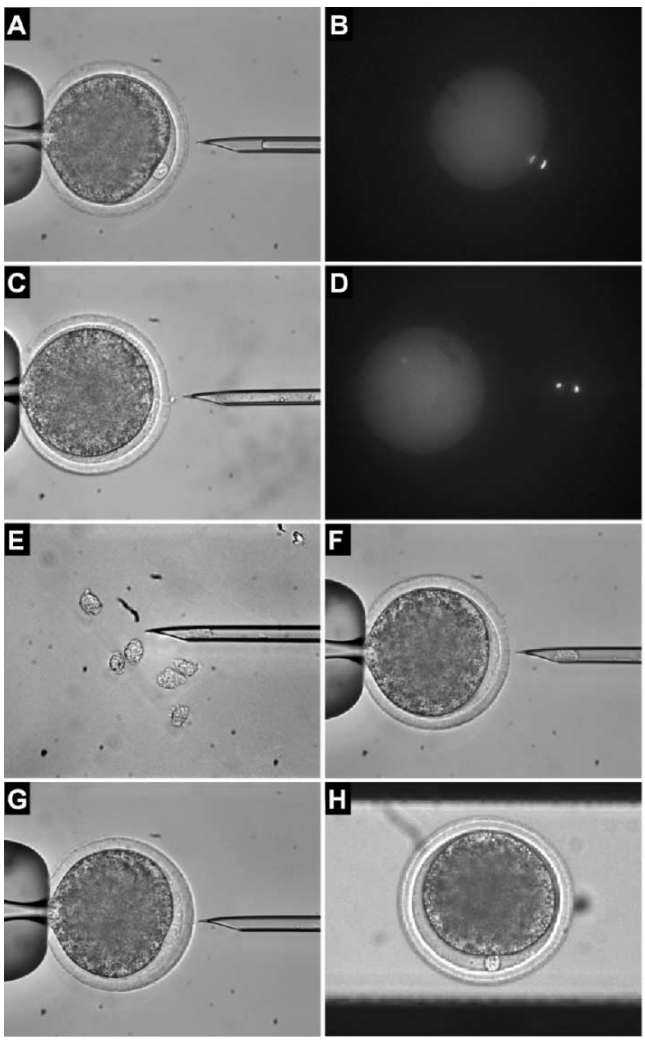

FIGURE 3 Oocyte enucleation and reconstruction of oocyte somatic cell couplets (A) holding the oocyte prior to enucleation (note position of the polar body). (B) Localisation of the polar body (PB) and metaphase plate (MP) by epifluorescence. (C) Enucleated oocyte (D) confirmed by epifluorescence (note PB and MP in the pipette). (E) Somatic cells in suspension. (F) Transfer into enucleated oocyte. (G) Cells after transfer should be in close contact with the oolema. (H) The couplet is positioned between the electrodes for fusion (note perpendicular orientation of the couplet to the electrodes).

9. Insert the enucleation pipette through the zona pelucida at a point opposite the holding pipette.

10. Manipulate the enucleation pipette into a position next to the polar body, apply a small amount of negative pressure, and aspirate the polar body and a small amount of cytoplasm from directly beneath it into the pipette (Fig. 3C).

11. Withdraw the pipette from the oocyte and remove the oocyte from the field of view.

12. Turn off the transmitted light source, change to UV illumination (blue light), and examine the aspirated karyoplast (while inside the pipette) for fluorescence using filter block UV-2A. If the metaphase has been removed, it will fluoresce with a blue color; the polar body will also be visible. The metaphase plate fluoresces with a lower intensity than the polar body (Figs. 3B and 3D).

13. Move the enucleated oocyte to the right-hand side of the chamber and discard the aspirated karyoplast form the pipette. If the enucleation was unsuccessful, it is possible to repeat the procedure a second time.

14. Remove completed batches of oocytes from the manipulation chamber and place into a microdrop or dish containing HEPES-SOF (4 mg/ml). Maintain at 37°C until the required number of oocytes have been enucleated.

D. Embryo Reconstruction

Solution and Equipment

1. Manipulation chamber and microtools
2. Cumulus-free enucleated MII oocytes
3. Serum-starved quiescent donor cells
4. *Calcium-free fusion medium*: 0.3 *M* manitol with addition 0.1 m*M* $MgSO_4$ in distilled H_2O with an osmolarity of 280 mOsm

Steps

1. Prepare a manipulation chamber, as for the enucleation procedure, containing HEPES-buffered SOF 4 mg/ml BSA.
2. Using a hand-drawn mouth pipette attached to aspirator tube (Sigma; A5177), place the nuclear donor cells into the upper left-hand corner of the chamber and a group of enucleated oocytes into the right hand corner of the chamber.
3. Pick up an enucleated oocyte with the holding pipette.
4. Move the holding pipette to the top.
5. Focus the microscope onto the bottom of the chamber.

6. Move the enucleation pipette to the chamber, maneuver it to the cells, and gently aspirate two to three suitable cells into the pipette (Fig. 3E).
7. Refocus on the enucleated oocyte and move the enucleation pipette until it is in focus.
8. Insert the enucleation pipette through the hole made previously in the zona pelucida. While holding the pipette against the cytoplasm, expel one donor cell into the perivitelline space (Fig. 3F). Ensure contact between the two cells of the couplet (Fig. 3G).
9. Transfer donor cells to groups of 10 oocytes. Upon completion of each batch, wash couplets in washing medium.
10. Place 100 µl of warm (35°C) fusion medium, spanning the electrodes, into the fusion chamber.
11. Pipette the reconstructed oocytes into the fusion medium but outside the electrodes and allow them to settle down for 15–30 s.
12. Using a hand-drawn capillary mouth pipette, place two to three couplets between the electrodes, moving them until the plane of contact between cytoplast and karyoplast is parallel to the electrodes. Precise orientation is necessary for fusion to occur (Fig. 3H).
13. Apply the fusion pulse, which consists of a 5-s AC pulse of 5 V/cm followed by one or two DC pulses of 35 V/cm for 30 µs (for electrodes 200 µm apart).
14. Remove the reconstructed oocytes from the chamber and wash each batch with washing medium.
15. Transfer them into a 50 µl drop of mSOFaaci/4 mg/ml BSA (Holm *et al.*, 1999). Incubate at 39°C for 15–20 min and then examine for cell fusion.
16. Refuse unfused couplets by two DC pulses of 35 V/cm for 30 µs.
17. Incubate fused couplets for 1 h in mSOFaaci and then activate.
18. Activate fused couplets in H-SOF plus 5 µ*M* calcium ionophore (A23187) for 5 min at 35°C and culture subsequently in mSOFaaci with 10 µg/ml of cycloheximide and 7.5 µg/ml cytochalasin B for 5 h.
19. Following activation, wash the reconstructed embryos and culture under oil in 50-µl droplets of mSOFaaci supplemented with 2%(v/v) BME, 1%(v/v) MEM, and 4 mg/ml BSA (fatty acids free) in a humidified atmosphere of 5% CO_2, 5% O_2, and 90% N_2 at 39°C.
20. At day 3 of culture, transfer cleaved embyos into mSOFaaci supplemented with 5% heat-inactivated FBS.
21. At days 7 to 8 transfer embryos surgically into naturally cycling, foster mother ewes, 7 days after estrus.

E. Isolation, Culture, and Preparation of Cells Used as Nuclear Donors

Solutions

1. *Culture medium:* To 500 ml of Glasgow MEM (GMEM) add 56 ml (10%) of FCS, 5.6 ml of L-glutamine, 5.6 ml of sodium pyruvate, and 5.6 ml of nonessential amino acids. Warm to 37°C before use.
2. *Low serum medium:* As in solution 1 but containing 0.5% FCS.
3. *Trypsin solution:* Aliquot and store at –20°C. Thaw and warm to 37°C before use.
4. *Gelatin solution*: Add 1 g of gelatin to 1000 ml Milli-Q water. Autoclave, allow to cool, and filter.
5. *Hypotonic solution:* Add 4 g of trisodium citrate to 1000 ml Milli-Q water. Filter sterilise.
6. *Karyotyping fixative:* Add 3 parts methanol to 1 part acetic acid.

Isolation of a Primary Culture

Steps

1. Add 20 ml of gelatin solution to a T175 flask. Place flask in tissue culture hood until cells have been prepared.
2. Remove the uterus from a 30- to 35-day-old pregnant ewe and immediately remove the fetus.
3. Eviscerate and decapitate the fetus and transfer the carcass to 10 ml PBS supplemented with 100 µg/ml gentamycin. Wash the carcass twice with 10 ml PBS–gentamycin.
4. Place the carcass in a 10-cm tissue culture dish and add 3 ml of trypsin solution. Use scissors to cut cubes of 1 mm. Incubate at 37°C for 10 min.
5. Add 10 ml of culture medium to the dissociating cells and transfer to a 15-ml tube.
6. Dissociate clumps by pipetting.
7. Stand tube for 1 min to allow larger clumps to settle.
8. Aspirate gelatin solution from T175 flask.
9. Avoiding the pelleted cells, transfer the cells in suspension to the gelatinised T175 flask.
10. Resuspend the remaining clumps in the tube in 10 ml culture medium. Repeat steps 6 and 7. Add the cell suspension to the same flask as before.
11. Discard the tube containing the remaining cell clumps.

12. Add culture medium to the T175 flask to a total volume of 50 ml.
13. Add gentamycin to a final concentration of 50 µg/ml and incubate cells for 24 h at 37°C in an atmosphere composed of 5% CO_2, 20% O_2, and 75% N_2.
14. Replace medium with fresh medium containing no antibiotic. Culture cells at 37°C.
15. Record time required for culture to reach confluence. Trypsinise, pellet, and cryopreserve aliquots of 1×10^6 cells in a mixture of 90% growth medium: 10% DMSO.
16. Subsequent passages and culture of cells do not require gelatinized flasks or antibiotics.

F. Preparation of Mitotic Spreads

Steps

1. Culture cells in a T25 flask to subconfluency.
2. Aspirate growth medium and wash once with warm (37°C) PBS.
3. Add 1 ml of trypsin solution. Incubate at 37°C and monitor the culture for detachment of cells.
4. When cells are detached, add 10 ml of culture medium.
5. Decant cells into a 15-ml tube and pellet at 300 *g* for 5 min.
6. Aspirate medium and resuspend cell pellet in 10 ml fresh growth medium.
7. Add 2 ml of the cell suspension and 8 ml of growth medium to a T25 flask.
8. Incubate for 24 h.
9. Trypsinise cells as described previously and resuspend in 10 ml culture medium.
10. Transfer the cell suspension to a 15-ml tube and pellet the cells at 300 *g* for 5 min.
11. To resuspend the cells, add 10 ml of hypotonic solution gradually while vortexing.
12. Incubate at room temperature for 15 min to allow cells to swell.
13. Pellet the cells at 300 *g* for 5 min. Discard supernatant.
14. Resuspend the cells by adding 6 ml of karytyoping fixative dropwise while vortexing.
15. Pellet the cells at 300 *g* for 5 min. Discard supernatant.
16. Repeat steps 13 and 14 twice more.
17. After the final spin, resuspend the pellet in 0.5 ml karytoping fixative.
18. Prepare spreads by dropping fixed cell suspension onto clean glass slide.
19. Air dry.
20. Stain with 3% Giemsa for 15 min at room temperature.

G. Induction and Assessment of Quiescence in Donor Cells

Solutions

1. *Fixative*: Prepare a 70% : 30% of mixture of methanol : 50 m*M* glycine. Store at –20°C. (Add 0.38 g glycine to 100 ml Milli-Q water.)
2. *Humidified chamber*: Place a sheet of filter paper into a 10-cm petri dish. Dampen with distilled water.
3. *PBS/1% FCS*: Add 1 ml of FCS to 100 ml sterile PBS
4. *1° antibody working solution*: Dilute Ki-67 antibody (clone MIB-1) 1:150 with PBS/1% FCS.
5. *2° antibody working solution*: Dilute FITC-conjugated rabbit antimouse antibody 1:20 with PBS/1% FCS.
6. Nail varnish.
7. Mountant (Vecta shield) containing 1 µg/ml DAPI.

Steps

1. Trypsinise an 80% confluent monolayer of donor cells and resuspend in growth medium.
2. Replate cells at one-fifteenth the original density in growth medium in 1-well glass chamber slides and continue to culture for 48 h.
3. Wash the monolayer three times with low serum medium and then continue culture in this medium.
4. Exit from the growth cycle; survival in the quiescent state must be established for each cell line. At the time of serum reduction and at 24-h intervals, process one slide for Ki-67 staining as detailed later.
5. Remove culture chamber and rubber gasket from one chamber slide.
6. Rinse in PBS at 4°C and fix in methanol: 50 m*M* glycine for 20 min at –20°C.
7. Wash in PBS.
8. Block in PBS/1% BSA for 30–45 min at room temperature.
9. Wash in PBS and transfer slide to humidified chamber.
10. Add 500 µl of 1° antibody solution to each slide. Incubate for 1 h at 37°C.
11. Wash three times with PBS/1% FCS.
12. Add 500 µl of 2° antibody solution. Incubate for 1 h at 37°C.
13. Wash three times with PBS/1% FCS.
14. Remove excess liquid. Add two drops of mounting and overlay with a coverslip. Seal edges with nail varnish.
15. Store at 4°C in darkness.
16. Examine using epifluorescence.

17. Record the percentage of Ki-67-positive nuclei. Ki-67 is a nuclear antigen expressed at all active stages of the cell cycle but absent in resting (G0 phase).

IV. PITFALLS

1. Ensure that enucleated oocytes are at MII at the time of enucleation. Oocytes that have activated spontaneously as a result of handling will resume meiosis; this will be visible as a third fluorescent area corresponding to the anaphase/telophase.

2. It is recommended to perform enucleation in early matured oocytes (17–19 h after onset of maturation) to guarantee close contact of the metaphase plate and the polar body. Metaphase plates from matured oocytes tend to move away from the polar body after they have reached the MII stage.

3. Avoid temperature oscillations during manipulation as these can cause spontaneous oocyte activation.

CHAPTER

8

Expression of cDNA in Yeast

Caterina Holz and Christine Lang

I. INTRODUCTION

The ability to express heterologous genes in yeast has become a powerful tool for many biological research techniques. Yeast combines the advantage of eukaryotic posttranslational modifications, such as phosphorylation, glycosylation, disulfide cross-linking, and subcellular targeting, with the expression of soluble proteins in large amounts. The yeast system is also very attractive as both the culture and the protocols for expression are easy to handle. The first species to be employed for the production of heterologous proteins was *Saccharomyces cerevisiae*. The host-vector systems for this organism are now well developed and a wealth of knowledge on its genetics and its physiology has been accumulated. This has led to its frequent use as a model eukaryote to understand the function and properties of many mammalian proteins in recent years (Romanos *et al*., 1992). Suitable *S. cerevisiae* host strains are available (or can be generated easily) that bear alterations to enhance protein production, such as the elimination of major proteases or the increase of transcription and expression level (Harashima, 1994). Both homologous and heterologous proteins may be produced in the cytoplasm or directed through the secretory pathway. The first approach, the intracellular expression of cDNAs by the yeast *S. cerevisiae*, is the focus of this article.

The most widely used expression vectors are *Escherichia coli*/yeast shuttle plasmids (Bonneaud *et al*., 1991) that are stabilized mitotically by autonomously replicating sequences (ARS/CEN region, 2-µm origin) or by integration into the yeast genome. Foreign genes, which are inserted in 2-µm-based plasmids, are maintained in high copy numbers; however, selection is required for growth and protein expression (Rose and Broach, 1990). This article describes the use of such an episomal expression plasmid that is easily introduced into yeast cells by lithium–acetate transformation into competent cells (Gietz *et al*., 1992) or by electroporation (Becker and Guarente, 1991).

Various strategies are available to induce the expression of the recombinant protein; the specific method chosen depends on the physiological characteristics of the yeast strain used. The use of inducible promoters is advisable when the product itself or its synthesis is deleterious to the cells or, as in cell biology studies, when the impact of the recombinant protein on cellular physiology is to be investigated. This article describes a method based on the expression vector pYEXTHS-BN (Holz *et al*., 2002), where the transcription of cDNAs is controlled by the Cu^{2+}-induced *CUP*1 promoter from the yeast metallothionein gene. This strong promoter is induced rapidly by copper sulfate (0.01 to 1 m*M*, depending on the copper resistance of the host strain) (Etcheverry, 1990; Ward *et al*., 1994). The cloned gene is fused to small antigenic epitopes. These epitope tags, the N-terminal His_6 tag (Porath, 1992) and the C-terminal StrepII tag (Schmidt *et al*., 1996), facilitate the subsequent immunological identification and purification of the gene product by two-step affinity chromatography. The intracellular double-tagged protein is released from the cells by disrupting the cell walls by enzymatic, chemical, or mechanical procedures as described here.

II. MATERIALS AND INSTRUMENTATION

The pYEXTHS-BN expression plasmid was constructed in the Protein Structure Factory laboratory (Berlin, Germany). The strain *S. cerevisiae* AH22*ura*3 (MATa, ura3Δ, leu2-23, 112, his4-519, can1) was provided by Berlin University of Technology, Department of Microbiology and Genetics (Germany). NaCl (Cat. No. 1.06404), $NH_4H_2PO_4$ (Cat. No. 1.01126), NH_4Cl (Cat. No. 1.01145), $Na_2HPO_4{\cdot}2H_2O$ (Cat. No. 1.06580), $NaH_2PO_4{\cdot}H_2O$ (Cat. No. 1.06346), $MgCl_2{\cdot}6H_2O$ (Cat. No. 1.05833), $CaCl_2{\cdot}H_2O$ (Cat. No. 1.02380), KH_2PO_4 (Cat. No. 1.04873), $MgSO_4{\cdot}7H_2O$ (Cat. No. 1.05886), sodium L-glutamate monohydrate (Cat. No. 1.06445), $ZnSO_4{\cdot}7H_2O$ (Cat. No. 1.08883), $FeSO_4{\cdot}7H_2O$ (Cat. No. 1.03965), $CuSO_4{\cdot}5H_2O$ (Cat. No. 1.02790), $MnCl_2{\cdot}4H_2O$ (Cat. No. 1.05927), $Na_2MoO_4{\cdot}2H_2O$ (Cat. No. 1.06521), nicotinic acid (Cat. No. 8.18714), L-histidine HCl (Cat. No. 1.04350), imidazole (Cat. No. 1.047169), isopropanol (Cat. No. 1.09634), 2-mercaptoethanol (Cat. No. 1.15433), glycine (Cat. No. 1.04169), and Tween 20 (Cat. No. 1.00731) are from Merck. *myo*-Inositol (Cat. No. 26310), pyridoxine (Cat. No. 33990), biotin (Cat. No. 15060), sucrose (Cat. No. 35580), dodecylsulfate-Na-salt (SDS) (Cat. No. 20783), Triton X-100 (Cat. No. 37240), and Ponceau S (Cat. No. 33429) are from Serva. Thiamine (Cat. No. T4625), calcium *d*-pantothenate (Cat. No. C8731), bovine serum albumin (BSA) (A-3912), phenylmethylsulfonyl-fluoride (PMSF) (Cat. No. 78830/Fluka), bromphenol blue (Cat. No. B-6131), EDTA sodium salt (Cat. No. E-5134), avidin (Cat. No. A-9275), and desthiobiotin (Cat. No. D-1411) are from Sigma. Tris base (Cat. No. 155004-038) is from Gibco/LifeTechnologies. Concentrated HCl (Cat. No. P074.1), glycerol (Cat. No. 3783.2), methanol (4627.2), milk powder (blotting grade) (Cat. No. T145.1), and glass beads (0.5 mm) (Cat. No. A553.1) are from Roth. Ni-NTA agarose (Cat. No. 30210), penta-His antibody (Cat. No. 34660), and polypropylene columns (1 ml, unpacked columns) (Cat. No. 34924) are from Qiagen. Rabbit antimouse IgG/HRP conjugate (Cat. No. P0260) is from Dako (Denmark), and Strep-Tactin HRP conjugate (Cat. No. 2-1502-001) and Strep-Tactin sepharose (50% suspension) (Cat. No. 2-1201-005) are from IBA GmbH (Göttingen, Germany). The ECL substrate western lightning chemiluminescence reagent plus (Cat. No. NEL 105) is from PerkinElmer Life Science, the polyvenylidene difluoride (PVDF) membrane (Cat. No. IPVH00010) is from Millipore, and the 3 MM chromatography paper (Cat. No. 3030-690) is from Whatman.

The incubator shaker (Innova 4430) is from New Brunswick Scientific. The centrifuge is from Heraeus Instruments (Megafuge 1.0R). The vortex (Vortex-2 genie, Model G-560) is from Scientific Industries Inc., the semidry blotter (Cat. No. 24200) is from H. Hölzel GmbH (Germany), and power supplies are from Bio-Rad (Power Pac 200/300). The imaging system (LAS-1000 luminescent image analyzer, Fujifilm) is from Raytest. The Thermomix Comfort (Cat. No. 5355000.011) is from Eppendorf. The micropipettes are from Gilson.

III. PROCEDURES

A. Copper-Inducible Expression of Proteins (Standard Scale)

The expression plasmid pYEXTHS-BN used here is a pYEXbx (Clontech) derivative, which was constructed to subclone cDNAs carrying a N-terminal *Bam*HI site and C-terminal *Not*I site overhang as polymerase chain reaction fragments (Holz *et al*., 2002). The expression of cDNAs is induced by adding $CuSO_4$. The strain *S. cerevisiae* AH22*ura*3 (Polakowski *et al*., 1998) is used as the expression strain. The plasmid DNA containing the cloned cDNA insert is transformed in *S. cerevisiae*, and the selected transformants are transferred to WMVIII medium for protein expression.

Solutions

1. *WM VIII medium*: See Table I
2. *0.5 M $CuSO_4$ stock*: Dissolve 6.2 g in 50 ml distilled water
3. *10× PBS stock*: 100 m*M* phosphate and 1.5 *M* NaCl. To make 2 liter, weigh 29.9 g of $Na_2HPO_4{\cdot}2H_2O$, 4.16 g of KH_2PO_4, and 175.32 g of NaCl and adjust to 2 liter with distilled water.
4. *1× PBS*: 8.4 m*M* Na_2HPO_4, 1.6 m*M* KH_2PO_4, and 150 m*M* NaCl. To make 500 ml, take 50 ml of 10× PBS and add distilled water to 500 ml.
5. *1 M Na_2HPO_4 stock*: To make 1 liter, weigh 177.99 g of $Na_2HPO_4{\cdot}2H_2O$ and bring up to 1 liter with distilled water
6. *1 M NaH_2PO_4 stock*: To make 1 liter, weigh 137.99 g of $NaH_2PO_4{\cdot}H_2O$ and top up to 1 liter with distilled water
7. *3 M NaCl*: To make 500 ml, weigh 87.66 g of NaCl and adjust to 500 ml with distilled water
8. *100 mM phenylmethylsulfonyl fluoride*: Dissolve 174 mg PMSF in 10 ml isopropanol. Divide the solution into 1-ml aliquots and store at –20°C.

TABLE I Components of WM VIII Protein Production Medium[a]

Ingredient	Amount
Component I: Autoclaved in 990 ml distilled water	
Sucrose	50 g
$NH_4H_2PO_4$	0.25 g
NH_4Cl	2.8 g
$MgCl_2 \cdot 6H_2O$	0.25 g
$CaCl_2 \cdot 2H_2O$	0.1 g
KH_2PO_4	2.0 g
$MgSO_4 \cdot 7H_2O$	0.55 g
myo-Inositol	0.075 g
Sodium L-glutamate monohydrate	10.0 g
Component II (microelements): Dissolved in 100 ml 10 m*M* EDTA, pH 8.0, and filter sterilized	
$ZnSO_4 \cdot 7H_2O$	43.7 mg
$FeSO_4 \cdot 7H_2O$	12.5 mg
$CuSO_4 \cdot 5H_2O$	2.5 mg
$MnCl_2 \cdot 4H_2O$	2.5 mg
$Na_2MoO_4 \cdot 2H_2O$	2.5 mg
Component III (vitamin stock solution): Dissolved in 200 ml H_2O, and filter sterilized	
Nicotinic acid (vitamin B)	0.5 g
Pyridoxine (vitamin B_6)	1.25 g
Thiamine (vitamin B_1)	0.5 g
Biotin	0.125 g
Calcium *d*-pantothenate	2.5 g
Component IV: Filter sterilized in 20 ml distilled water	
L-Histidine HCl	0.4 g

[a] Component I is mixed after autoclaving with 4 ml of component II, 4 ml of component III, and 2 ml of component IV. The pH will be approximately 6.

9. *Lysis buffer*: 100 m*M* NaPO4, pH 8.0, 300 m*M* NaC1, and 1% Triton X. To make 100 ml, add 9.3 ml of a 1 *M* stock solution of Na_2HPO_4, pH 8.0, 680 µl of a 1 *M* stock solution of NaH_2PO_4, 10 ml of a 3 *M* stock solution of NaCl, and 1 ml Triton X-100 (100%, Serva). Fill up to 100 ml with distilled water.

10. *1 M Tris–HCl (pH 6.8) stock*: Dissolve 121.1 g Tris base in 800 ml of H_2O. Adjust pH to 6.8 by adding concentrated HCl (about 80 ml), complete to 1 liter with distilled water, and sterilize by autoclaving.

11. *4× SDS PAGE sample buffer*: 0.2 *M* Tris–HCl, pH 6.8, 8% (w/v) SDS, 40% (v/v) glycerol, 5% (v/v) 2-mercaptoethanol, and 0.4% (w/v) bromphenol blue. To make 50 ml, add 10 ml of a 1 *M* stock of Tris–HCl, pH 6.8, 4 g of SDS, 20 ml of glycerol, 2.5 ml of β-mercaptoethanol, and 0.2 g bromphenol blue. Top up to 50 ml with distilled water.

Steps

1. Inoculate 20 ml WM VIII medium containing 40 mg/liter histidine in a 100-ml shake flask with a single colony of *S. cerevisiae* AH22*ura*3 bearing the pYEXbx derivative with target CDNA insert as preculture and grow overnight with shaking (200 rpm) at 28°C.

2. Inoculate 100 ml WM VIII medium containing 40 mg/liter histidine in a 500-ml shake flask with 1 ml from the preculture. Grow with shaking (200 rpm) at 28°C for 16–24 h to an OD_{600} of 7–10.

3. Induce the protein expression of the culture by adding 100 µl of a 0.5 *M* stock of $CuSO_4$ (0.5 m*M* final concentration) and incubate the culture with shaking for another 3–4 h at 28°C.

4. Collect an aliquot of 7–10 ml of the cell culture (corresponding to OD_{600} = 70) by centrifugation (10 min, 2500 *g*, 4°C).

5. Resuspend the cell pellet in 5 ml cold PBS. Repeat the spin and discard supernatant.

6. Freeze the washed cells in dry ice-ethanol or liquid nitrogen or store cell pellet at –70°C.

7. Thaw cells at room temperature and resuspend the cells in 300 µl ice-cold lysis buffer and add 3 µl of 100 m*M* stock solution of PMSF (1 m*M* final concentration).

8. Add 1 volume of sterile, acid-washed glass beads (0.5 mm) and disrupt the cells by seven cycles of 1 min full-speed vortexing/1 min cooling on ice.

9. Centrifuge the lysate for 15–20 min at 10,000 *g* at 4°C to remove cellular debris and transfer the supernatant to a fresh tube.

10. Take a 15-µl sample and add 5 µl 4× SDS–PAGE sample buffer, heat the sample at 95°C for 5 min, and store at –20°C for SDS–PAGE and Western blot analysis. *Note:* You cannot detect the recombinant target gene product directly from the total yeast protein after electrophoresis of proteins by staining the gel due to the low proportion of recombinant protein. This requires purifying the recombinant protein from crude extract or detecting the target protein by immunoblotting (Section III,D).

11. Proceed to protocols for purification (Sections III,B and III,C).

B. Affinity Purification of His_6-Tagged Proteins via Ni-NTA Agarose

Solutions

1. *1 M imidazole stock*: To make 100 ml, weigh 6.81 g of imidazole and complete to 100 ml with distilled water

2. *Wash buffer*: 50 m*M* $NaPO_4$, pH 8.0, 300 m*M* NaC1, and 5 m*M* imidazole. To prepare 500 ml, add 23.3 ml of a 1 *M* stock solution of Na_2HPO_4, pH 8.0, 1.7 ml of a 1 *M* stock solution of NaH_2PO_4, 50 ml of a

3 *M* stock solution of NaCl, and 2.5 ml of a 1 *M* stock solution of imidazole. Adjust pH to 8.0 with HCl and adjust volume to 500 ml with distilled water.

3. *Elution buffer*: 50 m*M* $NaPO_4$, pH 8.0, 300 m*M* NaCl, and 250 m*M* imidazole. To prepare 100 ml, add 4.66 ml of a 1 *M* stock solution of Na_2HPO_4, pH 8.0, 340 µl of a 1 *M* stock solution of NaH_2PO_4, 10 ml of a 3 *M* stock solution of NaCl, and 25 ml of a 1 *M* stock solution of imidazole. Adjust pH to 8.0 with HCl and adjust volume to 100 ml with distilled water.

Steps

1. Add 100 µl of a 50% slurry of Ni-NTA resin (100 µl resin has a capacity for 500 µg–1 mg His_6-tagged protein) to 300 µl cleared lysate that contains whole cell proteins (Section III,A, step 8) and mix gently by shaking for 60 min at 4°C.
2. Load the lysate Ni-NTA mixture into an unpacked column.
3. Collect the column flow through. Save flow through for SDS–PAGE analysis.
4. Wash three times with 400 µl wash buffer and collect wash fractions. Save wash fractions for SDS–PAGE analysis.
5. Elute the protein three times with 100 µl elution buffer. Collect the elution fractions and analyze by SDS–PAGE.

C. Affinity Purification via StrepTactin

The affinity purification is carried out according to Voss and Skerra (1997) with some modifications.

Solutions

1. *1 M Tris–HCl (pH 8.0) stock*: Dissolve 121.1 g Tris base in 800 ml of H_2O. Adjust pH to 8.0 by adding concentrated HCl (about 40 ml), top up to 1 liter with distilled water, and sterilize by autoclaving.
2. *250 mM EDTA stock*: Weigh 9.3 g of EDTA, top up to 100 ml with distilled water, and sterilize by autoclaving
3. *Buffer W*: 100 m*M* Tris–HCl, pH 8.0, 1 m*M* EDTA. To make 100 ml, take 10 ml of a 1 *M* stock solution of Tris–HCl, pH 8.0, and 400 µl of a 250 m*M* EDTA stock solution. Top up to 100 ml with distilled water.
4. *25 mM Desthiobiotin solution*: 25 m*M* Desthiobiotin and 100 m*M* Tris–HCl, pH 8.0. To make 100 ml, add 0.536 g Desthiobiotin, 10 ml of 1 *M* stock solution of Tris–HCl, pH 8.0, and top up to 100 ml with distilled water.
5. *Buffer E*: 100 m*M* Tris–HCl pH 8.0, 1 m*M* EDTA, and 2.5 m*M* Desthiobiotin. To make 100 ml, add 10 ml of a 1 *M* stock solution of Tris–HCl, pH 8.0, 400 µl of a 250 m*M* EDTA stock solution, and 10 ml of a 25 m*M* stock solution of Desthiobiotin. Adjust to 100 ml with distilled water.
6. *Avidin solution (2 mg/ml)*: Dissolve 5 mg avidin (65 units) in 2.5 ml buffer W.

Steps

1. Transfer 200 µl of 50% StrepTactin sepharose (IBA GmbH) into an unpacked column and wash twice with 600 µl buffer W.
2. Load 200 µl of the eluate from the Ni-NTA resin (Section III,B step 5) onto the equilibrated column to perform the second step of the two-step affinity chromatography purification or take 200 µl cleared lysate (Section III,A step 8), pretreat this lysate with 1 µl of avidin solution (2 mg/ml) to mask inhibiting biotinylated proteins for 30 min at 4°C, spin down the aggregates formed by centrifugation (15 min, 10,000 *g*, 4°C), and load the cleared supernatant onto the column.
3. Collect the column flow through. Save flow through for SDS–PAGE analysis.
4. Wash five times with 200 µl buffer W and collect wash fractions. Save wash fractions for SDS–PAGE analysis.
5. Elute protein with 5× 100 µl buffer E. Collect the elution fractions and analyze by SDS–PAGE.

D. Protein Analysis by Western Blot and Immunodetection with Anti-His Antibody or StrepTactin HRP Conjugate (Chemiluminescent Method)

The proteins are separated by 12.5% SDS–PAGE according to Laemmli (1970). Following electrophoresis, proteins in polyacrylamide gel are transferred to polyvinylidene difluoride (PVDF) membranes by semidry electroblotting as described later and characterized by immunodetection (Fig. 1).

Solutions

1. *Transfer buffer*: 25 m*M* Tris base, 192 m*M* glycine, and 10% methanol. To make 1 liter, weigh 3.03 g Tris base, 14.4 g glycine, add 100 ml methanol, and adjust to 1 liter with distilled water.
2. *PBST*: 8.4 m*M* Na_2HPO_4, 1.6 m*M* KH_2PO_4, 150 m*M* NaCl, and 0.1% (v/v) Tween 20. To make 1 liter, take 100 ml of 10× PBS, 1 ml Tween 20, and top up to 1 liter with distilled water.
3. *Blocking solution*: 2% (w/v) BSA in PBST. To make 100 ml, weigh 2 g of BSA and top up to 100 ml with PBST. Prepare fresh or keep at –20°C.
4. *Secondary antibody dilution buffer*: 5% (w/v) nonfat dried milk (milk powder) in PBST. To make

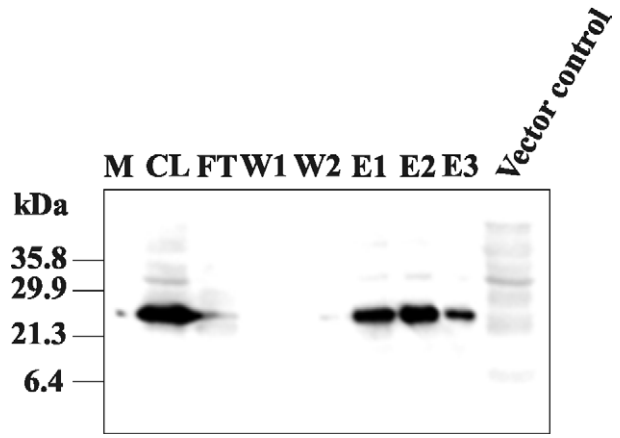

FIGURE 1 Expression and purification of the His_6/StrepII-tagged human G-substrate protein (21 kDa) from *S. cerevisiae* as an example. Cleared cell lysate (CL) was prepared and expressed protein purified via Ni-NTA. A clone carrying an empty expression vector was used as the negative control (vector control). The proteins were separated by SDS–PAGE and detected by immunoblotting with StrepTactin HRP conjugate. M, prestained Bio-Rad broad range marker; FT, flow through from Ni-NTA column; W1, wash fraction 1; W2, wash fraction 2; E1–E3, eluates 1–3.

100 ml, weigh 5 g of milk powder and top up to 100 ml with PBST.

Steps

1. Cut eight pieces of Whatman 3 MM paper and a piece of membrane to the same size as the gel. To avoid contamination, always handle the filter paper and membrane with gloves.
2. Wet the PVDF membrane in 100% methanol (or ethanol) for 15 s. Then transfer it to a container of distilled (or Milli-QR) water for 2 min.
3. Equilibrate the membrane for at least 5 min in the transfer buffer.
4. Soak the filter paper in transfer buffer.
5. Immerse the gel in the transfer buffer.
6. Place four sheets of filter paper in the center of the anode electrode plate (positive, usually red), avoiding air bubbles, and place the membrane on top of the filter paper.
7. Place the gel on top of the membrane and place four sheets of filter paper on top of the gel. Air bubbles can be removed by gently rolling a Pasteur pipette over each layer in the sandwich.
8. Place the cathode plate cover (negative, usually black) on the top of the assembled transfer stack.
9. Connect the anode and the cathode lead to their corresponding power supply outputs. Follow the manufacturer's instructions regarding current, voltage, and transfer times. The current density required is determined by the size of the gel: 1 mA/cm^2 is recommended (1-h transfer).
10. After transferring, mark the orientation of the membrane and the position of bands of the prestained protein standard. You can stain the blot to assess the quality of transfer with Ponceau-S red (reversible stain). Incubate membrane in staining solution (0.5% Ponceau S, 1% acetic acid) with gentle agitation for 2 min. The blot will be destained in distilled water or during the following immunological detection procedure.
11. Incubate the membrane for at least 1 h in blocking solution at room temperature. If using StrepTactin HRP conjugate for detection, subsequently pretreat the membrane in PBST containing 2 µg/ml avidin for 30 min to block biotinylated proteins.
12. Incubate with primary antibody (penta-His antibody, Qiagen) diluted at 1 : 1000/1 : 2000 or StrepTactin HRP conjugate diluted at 1 : 4000 in blocking solution at room temperature for 1 h. *Note:* Do not use dilution buffer containing milk powder for anti-His antibody. This will reduce sensitivity. Do not use milk powder for StrepTactin HRP conjugate either as it contains large amounts of cross-reacting biotin.
13. Wash membrane three times for 10 min each time in PBST at room temperature. When using StrepTactin HRP conjugate, proceed directly to step 16.
14. Incubate with secondary antibody solution for 1 h at room temperature. Either alkaline phosphatase or horseradish peroxidase (HRP)-conjugated antimouse IgG may be used. The rabbit antimouse IgG/HRP conjugate from DAKO yields good results. Dilute according to manufacturer's recommendations. Use 5% nonfat dried milk in PBST for incubation with the secondary antibody when using the chemiluminescent detection method.
15. Wash filter four times for 10 min each time in PBST at room temperature.
16. Perform detection reaction with AP or HRP chemiluminescence reagent and expose to X-ray film or detect by a luminescent imaging system according to the manufacturer's recommendations. Western lightning chemiluminescence reagent plus (PerkinElmer) yields good results.

Semliki Forest Virus Expression System

Maria Ekström, Henrik Garoff, and Helena Andersson

I. INTRODUCTION

The Semliki forest virus (SFV) is a positive-stranded RNA virus belonging to the alphaviruses (Schlesinger and Schlesinger, 1986). The SFV expression system is based on a cDNA copy of the viral genome. The cDNA has been cloned into an SP6-based transcription vector in such a way that exact copies of the alphavirus RNA genome can be transcribed *in vitro* (Liljeström and Garoff, 1991). In the SFV1 vector, genes coding for the viral structural proteins have been replaced with a polylinker region into which heterologous genes can be cloned. The recombinant plasmid then serves as a template for *in vitro* synthesis of recombinant RNA. When introduced into cells, the recombinant RNA self-replicates, as it codes for its own replicase, leading to high synthesis of the heterologous protein while competing out the host protein synthesis.

In the SFVC vector the viral capsid gene is retained and the heterologous gene is cloned directly downstream of the capsid gene by polymerase chain reaction (PCR) (Horton *et al*., 1989). Due to the presence of a translation-enhancing region in the capsid gene, the expression level reached using the SFVC vector is about 10 times higher than when using the SFV1 vector (Sjöberg *et al*., 1994).

The recombinant RNA can be either directly introduced into cells by electroporation or packaged *in vitro* by cotransfecting cells with the recombinant RNA and a packaging-deficient helper RNA (SFV/Helper 1 or SFV/Helper 2) encoding the structural proteins of SFV needed for the assembly of new virus particles (Liljeström and Garoff, 1991; Berglund *et al*., 1993). The virus stock obtained is then used to introduce the recombinant RNA into cells by way of infection. This article describes optimized protocols for the production of heterologous proteins in baby hamster kidney (BHK 21) cells using this system.

II. MATERIALS AND INSTRUMENTATION

Culture medium Glasgow MEM (BHK 21) (Cat. No. 21710), fetal bovine serum (FBS) (Cat. No. 10106), tryptose phosphate broth (Cat. No. 18050), 1 *M* HEPES (Cat. No. 15630), 200 m*M* L-glutamine (100×) (Cat. No. 25030), penicillin–streptomycin (Cat. No. 15140), trypsin–EDTA (10×) (Cat. No. 35400), phosphate-buffered saline (PBS) Dulbecco's without Ca^{2+} and Mg^{2+} (Cat. No. 14190), minimum essential medium (MEM) (Cat. No. 21090-022), bovine albumin fraction V solution 7.5% (BSA) (Cat. No. 15260-037), unlabeled methionine (Cat. No. 11086), and PBS Dulbecco's with Ca^{2+} and Mg^{2+} (Cat. No. 14040) are from Invitrogen. Corning/Life Sciences provided 75-cm^2 flasks (Cat. No. 3375), 15-ml centrifuge tubes (Cat. No. 430789), 50-ml centrifuge tubes (Cat. No. 430828), and 35-mm tissue culture plates (Cat. No. 430165). HEPES (Cat. No. 223778) and chymotrypsin (Cat. No. 1418467) are from Roche. Magnesium acetate (MgOAc) (Cat. No. 105819), sodium acetate (NaOAc) (Cat. No. 106268), potassium hydroxide (KOH) (Cat. No. 105033), TitriplexIII, EDTA (Cat. No. 108418), sodium dihydrogen phosphate monohydrate ($NaH_2PO_4 \cdot H_2O$) (Cat. No. 106346), disodium hydrogen phosphate dihydrate ($Na_2HPO_4 \cdot 2H_2O$) (Cat. No. 106580), sodium chloride (NaCl) (Cat. No. 106404), methanol (Cat. No. 106009), sodium hydroxide (NaOH) (Cat. No. 106469), glacial acetic acid (Cat. No. 100066), and isopropanol (Cat. No.

No. M-3911), and Ficoll 400 (Cat. No. F-4375) are from Sigma-Aldrich. Diguanosine triphosphate sodium (Cat. No. 27-4643-01), SP6 RNA polymerase (Cat. No. E2520Y), ATP (Cat. No. 27-2056-01), CTP (Cat. No. 27-2066-01), GTP (Cat. No. 27-2076-01), and UTP (Cat. No. 27-2086-01) are from Amersham Pharmacia Biotech. *SpeI* (Cat. No. R6591) and RNasin (Cat. No. N2511) are from Promega. Sea-plaque agarose (Cat. No. 50100) is from FMC Bio Products. Ether (Cat. No. 32203) and boric acid (Cat. No. 31146) are from Riedel-de-Haën. Xylene cyanol FF (Cat. No. 44306 2B) and Nonidet P-40 (NP-40) (Cat. No. 56009 2L) are from BDH Laboratory supplies. Electroporation cuvettes (Cat. No. ECU-104) are from EquiBio. The gene pulser is from Bio-Rad. Tris (Cat. No. 146861) is from Angus buffersbiochemicals. FluorSave Reagent (Cat. No. 345789) is from Calbiochem. Coverslips (18 × 18 mm) (Cat. No. 1.0) are from Menzel-Glaser. [^{35}S]Methionine (Cat. No. AG1094) is from Amersham Biosciences. BHK 21 cells C-13 (Cat. No. CRL 8544) are from American Type Culture Collection.

III. PROCEDURES

A. Preparation of mRNA *in vitro*

Solutions

1. *DEPC-H_2O*: To make 1 liter, add 1 ml of diethyl pyrocarbonate to distilled water and mix hard overnight at 37°C with a stirring magnet. Pour into RNase-free bottles and autoclave. Store at room temperature.
2. *3 M NaOAc, pH 6.0*: To make 10 ml, add 2.46 g of NaOAc, adjust pH with glacial acetic acid, and complete the volume with distilled water. Store at room temperature.
3. *1 M HEPES–KOH, pH 7.4, stock solution*: To make 10 ml, add 2.38 g of HEPES to DEPC-H_2O, adjust pH to 7.4 with 3 *M* KOH, and complete the volume to 10 ml with DEPC-H_2O. Store at 4°C.
4. *1 M MgOAc stock solution*: To make 10 ml, add 2.14 g of MgOAc to DEPC-H_2O. Store at 4°C.
5. *200 mM spermidine–HCl stock solution*: To make 3 ml, add 153 mg of spermidine to DEPC-H_2O. Store as aliquots at –20°C.
6. *10x SP6 buffer*: 400 m*M* HEPES–KOH, pH 7.4, 60 m*M* MgOAc, 20 m*M* spermidine–HCl. To make 10 ml, add 4 ml of 1 *M* HEPES–KOH, pH 7.4, stock solution, 600 µl of 1 *M* MgOAc stock solution, 1 ml of 200 m*M* spermidine–HCl stock solution, and complete the volume to 10 ml with DEPC-H_2O. Store as aliquots at –20°C.
7. *50 mM DTT*: To make 10 ml, add 77.1 mg of DTT to DEPC-H_2O. Store as aliquots at –20°C.
8. *rNTPmix*: 10 m*M* ATP, 10 m*M* CTP, 10 m*M* UTP, 5 m*M* GTP. To make 200 µl, add 20 µl of 100 m*M* ATP stock solution, 20 µl of 100 m*M* CTP stock solution, 20 µl of 100 m*M* UTP stock solution, 10 µl of 100 m*M* GTP stock solution, and complete the volume to 200 µl with DEPC-H_2O. Store as aliquots at –20°C.
9. *0.5 M EDTA, pH 8.0, stock solution*: To make 10 ml, add 1.86 g of Titriplex III to DEPC-H_2O, adjust pH to 8.0 with NaOH, and complete the volume to 10 ml with DEPC-H_2O. Store at room temperature.
10. *5x TD*: 20% Ficoll 400, 25 m*M* EDTA, pH 8.0, 0.05% bromphenol blue, 0.03% xylene cyanol. To make 10 ml, add 2 g of Ficoll 400, 0.5 ml of 0.5 *M* EDTA pH 8.0 stock solution, 5 mg of bromphenol blue, 3 mg of xylene cyanol, and complete the volume to 10 ml with DEPC-H_2O. Store as aliquots at –20°C.
11. *10x TBE*: To make 1 liter, add 60.55 g of Tris base, 30.9 g of boric acid, and 9.3 g of EDTA to distilled water. Store at room temperature.

Steps

1. Linearise 3 µg of plasmid DNA with 3 U *Spe*I at 37°C for 60 min in a total volume of 50 µl. Verify complete linearisation by gel electrophoresis.
2. Add H_2O to a final volume of 100 µl and add 10 µl 3 *M* sodium acetate, pH 6.0.
3. Add 100 µl phenol : chloroform : isoamylalcohol and mix.
4. Centrifuge at 16,000 *g* for 1 min at room temperature.
5. Transfer the water phase to a fresh tube.
6. Add 500 µl water saturated ether and mix.
7. Centrifuge at 16,000 *g* for 20 s at room temperature.
8. Remove the ether phase with a water jet pump.
9. Repeat steps 6–8.
10. Add 250 µl ethanol and incubate for 10 min at –70°C to precipitate the DNA. Centrifuge for 20 min at 12,000 *g* in a microcentrifuge at 4°C. Wash the pellet with 800 µl 75% ethanol. Centrifuge for 20 min at 12,000 *g*. Remove ethanol. Dry the pellet in a Speed Vac for 10 min or at room temperature for about 20 min. Resuspend the DNA pellet in 5 µl DEPC-H_2O.
11. Mix the following in a 1.5-ml tube at room temperature: 23 µl H_2O, 5 µl 10 × SP6 buffer, 5 µl 10 m*M*

diguanosine triphosphate sodium, 5 µl 50 m*M* DTT, and 5 µl rNTP mix. Centrifuge at 16,000 *g* for 10 s at room temperature to remove precipitates.Transfer to a fresh tube: 1.5 µl RNasin (50 units), 5 µl linearised DNA, and 60 U SP6 RNA polymerase

12. Incubate at 37°C for 1 h.
13. Take a 1-µl aliquot into 7 µl DEPC-H_2O, add 2 µl of 5 × TD loading buffer, and run the RNA mix on a 0.7% agarose TBE gel containing 0.02% ethidium bromide to check RNA production.
14. Freeze the rest of the RNA mix on dry ice and then transfer it to –70°C.

B. *In vivo* Packaging of Recombinant RNA into SFV Particles

Solution

BHK 21 medium: 500 ml of BHK medium G-MEM,
25 ml of fetal bovine serum,
50 ml of tryptose phosphate broth,
5 ml of 1 *M* HEPES,
5 ml of 200 m*M* glutamine, and
5 ml of 10,000 U/ml penicillin/10,000 µg/ml streptomycin.
Store at 4°C.

Steps

1. Grow BHK 21 cells in a 75-cm^2 bottle to late log phase in complete BHK medium.
2. Wash cells with 10 ml PBS (without Ca^{2+} and Mg^{2+}).
3. Wash cells with 2 ml of 1x trypsin–EDTA (0.5/0.2 mg/ml, respectively) in PBS (without Ca^{2+} and Mg^{2+}) and incubate the cells at 37°C for 10 min.
4. Add 2 ml of complete medium and pipette the solution back and forth to detach cells and to remove clumps, add 8 ml of complete BHK medium, and again pipette to remove aggregates.
5. Transfer cells to a 15-ml centrifuge tube and harvest cells by centrifugation for 5 min, 400 *g* at room temperature.
6. Resuspend cells in 5 ml of PBS (without Ca^{2+} and Mg^{2+}).
7. Harvest cells as in step 5.
8. Resuspend cells in 0.8 ml of PBS (without Ca^{2+} and Mg^{2+}).
9. Add 20 µl of SFV/Helper 1 or SFV/Helper 2 RNA and 20 µl of SFV recombinant RNA.
10. Transfer the mixture to a 0.4-cm electroporation cuvette.
11. Pulse twice at 850 V/25 µF. The time constant should show 0.4 after each pulse.
12. Transfer cells to 16 ml of complete BHK medium and rinse the cuvette with the same medium to collect all cells. Then transfer the medium to a 75-cm^2 bottle.
13. Incubate cells for 24 h at 37°C.
14. Clarify the growth medium by centrifugation in a 50-ml centrifuge tube at 1800 *g* 10 min, 4°C.
15. Aliquot into 1.5-ml Eppendorf tubes and freeze rapidly on dry ice pellets. Store at –70°C.

C. Titer Determination of Helper 1-Packaged Virus by Immunofluorescence

Solutions

1. *Supplemented MEM*: 500 ml of MEM, 5 ml of 1 *M* HEPES, 5 ml of 200 m*M* glutamine 5 ml of 10,000 U/ml penicillin/10,000 µg/ml streptomycin, and 14.1 ml of 7.5% BSA. Store at 4°C.
2. *2% PBS–gelatine stock solution*: To make 100 ml, add 2 g of gelatine to PBS. Autoclave. Store at room temperature.
3. *0.2% PBS–gelatine*: To make 100 ml, add 10 ml of 2% PBS–gelatine stock solution and complete the volume to 100 ml with PBS. Store at room temperature.

Steps

1. Grow BHK 21 cells on 18 × 18-mm glasscoverslips to about 80% confluency in complete BHK medium.
2. Pipette 50, 5, and 0.5 µl of recombinant virus stock to Eppendorf tubes and complete the volume to 500 µl with supplemented MEM (dilutions 1 : 10, 1 : 100, 1 : 1000).
3. Remove the medium and wash cells with 2 ml PBS (with Ca^{2+} and Mg^{2+}).
4. Add the total virus solution (500 µl) to the cells.
5. Incubate for 60 min at 37°C. Tilt the dishes every 20 min to ensure even distribution of virus particles.
6. Remove virus solution and add 3 ml complete BHK 21 medium and continue incubation for 5 h at 37°C.
7. Rinse coverslips twice with 2 ml PBS (with Ca^{2+} and Mg^{2+}). Fix cells in –20°C methanol for 6 min at –20°C.
8. Remove methanol and wash coverslips three times with 2 ml PBS.
9. Add 2 ml of 0.2% PBS–gelatine and incubate for 5 min at room temperature to block nonspecific binding.
10. Replace blocking buffer with the same containing primary antibody and incubate at room temperature for 30 min.
11. Wash cells twice with 2 ml of 0.2% PBS–gelatine and twice with 2 ml of PBS. Incubate for 5 min at

room temperature between each wash (total of 20 min).
12. Dilute secondary antibody in blocking buffer and incubate with cells at room temperature for 30 min.
13. Wash cells twice with 2 ml of 0.2% PBS–gelatine for 5 min and twice with 2 ml of PBS for 5 min.
14. Rinse coverslips in distilled water, dry, and mount in FluorSave reagent.
15. Count positive cells in a fluorescence microscope.

D. Titer Determination of Helper 2-Packaged Virus by Immunofluorescence

Solutions

1. *See solutions in Section III,C*
2. *10 mg/ml chymotrypsin A4 stock solution*: To make 1 ml, add 10 mg of chymotrypsin A4 to PBS with Ca^{2+} and Mg^{2+}. Store as aliquots at –20°C.

Steps

1. Grow BHK 21 cells on 18 × 18-mm glasscoverslips to about 80% confluency in complete BHK medium.
2. Activate virus stock by taking 55.5 µl virus stock solution and add 2.8 µl 10 mg/ml chymotrypsin and incubate for 30 min at room temperature.
3. Inactivate chymotrypsin by adding 29.1 µl aprotinin.
4. Pipette 78.7, 7.9, and 0.8 µl of activated virus to Eppendorf tubes and complete the volume to 500 µl with supplemented MEM (dilutions 1 : 10, 1 : 100, 1 : 1000).
5. Continue from step 3, Section III,C.

E. Metabolic Labeling of Infected Cells

Solutions

1. *Starvation medium*: 100 ml of methionine-free MEM, 1 ml of 200 m*M* glutamine, 1 ml of 1 *M* HEPES, and 1 ml of 10,000 U/ml penicillin/10,000 µg/ml streptomycin. Store at 4°C.
2. *15 mg/ml unlabelled methionine stock solution*: To make 100 ml, add 1.5 g of methionine to distilled water. Sterile filter. Store as aliquots at –20°C.
3. *Chase medium*: 500 ml of MEM, 5 ml of 200 m*M* glutamine, 5 ml of 1 *M* HEPES, and 5 ml of 10,000 U/ml penicillin/10,000 µg/ml streptomycin. Store at 4°C. Add 150 µg/ml of unlabelled methionine just before use from the stock solution.
4. *10% NP40 stock solution*: To make 100 ml, add 10 g of NP-40 to distilled water. Sterile filter. Store at room temperature.
5. *1 M Tris–HCl, pH 7.6, stock solution*: To make 100 ml, add 12.1 g of Tris and adjust pH with HCl. Complete the volume with distilled water. Autoclave. Store at 4°C.
6. *4 M NaCl stock solution*: To make 100 ml, add 23.4 g of NaCl to distilled water. Autoclave. Store at room temperature.
7. *0.2 M EDTA stock solution*: To make 100 ml, add 7.45 g of Titriplex III to distilled water and warm it to dissolve the EDTA. Sterile filter. Store at room temperature.
8. *10 mg/ml PMSF stock solution*: To make 1 ml, add 10 mg of PMSF to isopropanol. Store dark at room temperature. *Note:* Very toxic.
9. *1x lysis buffer*: 1% NP-40, 50 m*M* Tris–HCl, pH 7.6, 150 m*M* NaCl, 2 m*M* EDTA, 10 µg/ml PMSF. To make 100 ml, add 10 ml of 10% NP-40 stock solution, 5 ml of 1 *M* Tris–HCl, pH 7.6 stock solution, 3.75 ml of 4 *M* NaCl stock solution, 1 ml of 0.2 *M* EDTA stock solution, and complete the volume to 100 ml with distilled water. Store at 4°C. Add 10 µg/ml of PMSF just before use from the stock solution.

Steps

1. Grow BHK 21 cells to 80–100% confluency on a 35-mm tissue culture plate in complete BHK medium.
2. Dilute virus in supplemented MEM using a multiplicity of infection of 5.
3. Remove the medium and wash cells with 2 ml of PBS (with Ca^{2+} and Mg^{2+}).
4. Add 500 µl of the virus solution to the cells.
5. Incubate for 60 min at 37°C. Tilt every 20 min.
6. Remove virus solution and add 3 ml of complete BHK 21 medium and continue incubation for 6 h at 37°C.
7. Aspirate growth medium and wash cells twice with 2 ml of PBS (with Ca^{2+} and Mg^{2+}) prewarmed to 37°C.
8. Overlay cells with 2 ml of starvation medium prewarmed to 37°C and incubate plates at 37°C for 30 min.
9. Aspirate medium and replace with 500 µl of the same containing 100 µCi/ml of [^{35}S]methionine and incubate for appropriate pulse time at 37°C.
10. Aspirate pulse medium and wash cells twice with 2 ml of chase medium prewarmed to 37°C.
11. Overlay cells with 2 ml of chase medium and incubate for required chase time at 37°C.
12. Remove medium and wash cells with 2 ml of ice-cold PBS (with Ca^{2+} and Mg^{2+}).
13. Add 300 µl of ice-cold lysis buffer and incubate for 10 min on ice. Resuspend cells and transfer into an Eppendorf tube.

14. Centrifuge for 5 min at 3000 *g* at 4°C to pellet nuclei. Transfer supernatant to a fresh tube. Store at –70°C.
15. Assay for protein expression by SDS–PAGE and autoradiography.

F. Metabolic Labeling of Transfected Cells

Solutions

See solutions in Section III,E

Steps

See Section III,B, steps 1–8.

9. Add 20 µl of recombinant RNA.
10. Transfer the mixture to a 0.4-cm electroporation cuvette.
11. Pulse twice at 850 V/25 µF. The time constant should show 0.4 after each pulse.
12. Transfer cells to 16 ml of complete BHK medium, rinse the cuvette with the same medium to collect all cells, and transfer 3 ml to a 35-mm tissue culture plate.
13. Incubate cells for 7 h at 37°C.
14. Continue from step 7 Section III,E.

IV. COMMENTS

The cloning of recombinant DNA into the SFVC vector has been done by PCR (Horton *et al*., 1989). The capsid protein has autoproteolytic activity and will cleave itself from the heterologous protein, provided that the cleavage site is preserved (Melancon and Garoff, 1987). Systematic probing of tolerated amino acid residues round the cleavage site has not been done, but a proline residue in position +2 relative to the cleavage site will inhibit cleavage. Both signal sequence-bearing proteins, as well as myristoylated proteins, have been expressed from the SFVC vector and they are processed normally.

When using SFV/Helper 1 for the production of recombinant virus stocks, a replicative form of the SFV genome may form (Berglund *et al*., 1993). This probably occurs through recombination promoted by the viral replicase, switching from recombinant to helper RNA in the cotransfected cells (Weiss and Schlesinger, 1991). In nature, SFV can infect humans and care must therefore be taken when using SFV/Helper 1. According to the commission of the European Communities directive 95/30/EC, SFV is classified as a class 2 agent (Official Journal of the European Communities, No. L 155, 6. 7. 1995, pp. 41–42). A corresponding level of containment is recommended for work with SFV (workplace with restricted access, an observation window, and surfaces that are easy to clean).

Therefore, SFV/Helper 2 was designed for use in producing conditionally infectious particles (Berglund *et al*., 1993). These particles must be activated by chymotrypsin treatment. Using this helper, no replication-proficient virus has been found (Berglund *et al*., 1993).

SFV has a very broad host range and the recombinant virus stocks can therefore infect many kinds of eukaryotic cells. For transfecting cells using electroporation, the electroporation parameters must be optimized for every cell type. For BHK cells, as many as 10^8 to 10^9 infectious particles can be obtained when cotransfecting 10^7 cells with recombinant and SFV/Helper 2 RNA and incubating for 24 h.

V. PITFALLS

1. Avoid repeated freezing and thawing of the virus stock. This will reduce virus infectivity.
2. For use in electroporation, the cells should not have been passaged more than about 30 times.
3. When amplifying the vector, rearrangments of the DNA may occur. Therefore the vector should be checked thoroughly after amplification by different restriction enzyme digestions.

Transient Expression of cDNAs in COS-1 Cells: Protein Analysis by Two-Dimensional Gel Electrophoresis

Pavel Gromov, Julio E. Celis, and Peder Madsen

I. INTRODUCTION

Transient and stable expression of exogenous cDNAs in eukaryotic cells provides a powerful approach for studying the corresponding gene products (see also related articles in this volume). Expression of a given protein is achieved by introducing an expression vector, harboring the cDNA of interest downstream an appropriate promoter, into eukaryotic cells. Several techniques are available for introducing DNA into eukaryotic cells (Ravid and Freshney, 1998; Thompson *et al*., 1999; Schenborn, 2000; Gromov and Celis, 2002): (i) electroporation (Chu *et al*., 1987; Shigekawa and Dower, 1988; Gehl, 2003), (ii) DEAE-dextran-mediated transfection (Sussman and Milman, 1984; Lopata *et al*., 1984; Schenborn and Goiffon, 2000a), (iii) calcium phosphate-mediated transfection (Wigler *et al*., 1978; Chen and Okayama, 1988; Schenborn and Goiffon, 2000b), and (iv) lipofection (Felgner *et al*., 1987; Whitt *et al*., 1990; Schenborn and Oler, 2000; Nicolazzi *et al*., 2003). All four techniques just mentioned can be used for transient transfection, although the method of choice usually depends on target cells, transfection efficiency, cytotoxity, cost, etc. Despite the relative high cost of liposome-mediated transfection, the method enjoys widespread use because of its reproducibility and high transfection rates.

This article describes a protocol for the effective transient transfection of COS-1 cells (Gluzman, 1981) using LipofectAMINE (Gibco, BRL) as a vehicle agent. The technique is carried out essentially according to the manufacturer's recommendation (Gibco, BRL) and is illustrated with the transient overexpression of three small GTP-binding proteins, arf, rab11, and p21-ras, using the pMT21 expression vector (Kaufman *et al*., 1991). The procedure offers an effective mean to produce considerable amounts of a given protein and, in addition, to faithfully reproduce some posttranslational modifications. In addition, the overexpressed protein can be used for antibody production as well as biochemical studies.

II. MATERIALS AND INSTRUMENTATION

A. Plasmid

Plasmid pMT21 (Kaufman *et al*., 1991) is used as an expression vector utilizing the adenovirus major late promoter for transcription initiation. The full-length cDNA of interest is subcloned into the pMT21 plasmid according to standard protocols (see, e.g., Sambrook *et al*., 1990).

B. COS-1 Cells

COS-1 monkey kidney cells (Gluzman, 1981) are grown in complete Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal calf serum (FCS). General procedures for cultured cells are described in details elsewhere (see, e.g., Celis and Celis, 1997; see also article by Mcleady and O'Eonnor in volume 1).

Copyright 2006, Elsevier Science (USA).
All rights reserved.

C. Reagents

DMEM (Cat. No. 31966-021) is from GIBCO. Penicillin/streptomycin (Cat. No. A2213) are from Biocrom KG. FCS (Cat. No. 04-001-1A) is from Biological Industries. Tissue culture plates (24-well) (Cat. No. 662 160) are from Greiner. All other reagents and general tissue culture facilities are as described elsewhere (Celis and Celis, 1997).

III. PROCEDURES

The protocol has been slightly modified from the original guidelines provided by Gibco BRL Life Technology.

Solutions

1. *Complete Dulbecco's modified Eagle's medium*: Prepare as described by Celis and Celis (1997). To make 500 ml, mix 445 ml of DMEM medium, 5 ml of 10x stock penicillin/streptomycin, and 50 ml of FCS.
2. *Hank's buffered saline solution*: To make 1 liter, dissolve 0.4 g of KCl, 0.06 g of KH_2PO_4, 0.0621 g of $NaHPO_4{\cdot}2H_2O$, and 8 g of NaCl in 800 ml of distilled water. After dissolving, complete to 1 liter with distilled water.
3. *Lysis solution*: 9.8 *M* urea, 2% (w/v) Nonidet P-40 (NP-40), 2% ampholytes, pH 7–9, and 100 m*M* dithiothreitol. Prepare as described by Celis *et al*. in this volume.

Steps

The volumes given are for tranfections carried out in a single well of a 24-well tissue culture plate. For larger tissue culture dishes or multiwell labeling, adjust all amounts accordingly.

1. Seed COS-1 cells in a 24-well tissue culture plate (approximately 3×10^4 cells per well) in 0.3 ml of complete DMEM medium containing 10% of calf serum, 2 m*M* of glutamine, and antibiotics.

2. Grow the cells at 37°C in a humidified, 5% CO_2 incubator for approximately 24 h or until the cells reach about 80% confluence.

3. For each transfection (single well), prepare the following solutions in sterile plastic conical tubes.
   a. *DNA solution*: Prepare 20 µl of the pMT21 plasmid solution in DMEM medium lacking serum and antibiotics at a concentration of 0.01 mg/ml. Mix gently.
   b. *LipofectAMINE solution:* Add 1.5 µl of the commercial LipofectAMINE reagent stock solution (mix gently prior to use) to 20 µl of DMEM medium lacking serum and antibiotics. Mix gently.

4. To make the transfection mixture, combine the two solutions, mix gently, and incubate at room temperature for 30 min to allow DNA–liposome complexes to form.

5. In the meantime, wash COS-1 cells twice with 0.4 ml of serum-free DMEM medium.

6. For each transfection (single well), add 160 µl of serum-free DMEM medium to the tube containing the transfection mixture. Mix gently and overlay the diluted transfection mixture onto the washed cells.

7. Incubate the cells with DNA–liposome complexes for 8 h at 37°C in a humidified 5%, CO_2 incubator.

8. Following incubation, carefully aspirate the transfection mixture and replace it with 0.3 ml of complete DMEM solution. Incubate the cells for an additional 8–10 h.

9. Label the cells with [^{35}S]methionine for 14 h as described in the article by Celis *et al*. in this volume.

10. Aspirate the labeling medium from the plate and wash cells gently with 1 ml of Hank's buffered saline solution. Repeat the washing step once more. Carefully remove excess Hank's buffered saline solution from the plate. Aspirate as much of the solution as possible using an elongated Pasteur pipette.

11. Resuspend the cells in 40 µl of lysis solution and run two-dimensional (2D) gels as described in the article by Celis *et al*. or by Görg and Weiss in this volume. Alternatively, the cells can be harvested for Northern blotting or prepared for immunostaining.

12. Following 2D gel electrophoresis, dry the gels and subject them to autoradiography.

IV. COMMENTS

In average, about 15–30% transfection efficiency can be achieved as estimated by immunofluorescence. Transcription of the construct starts approximately 10 h after the addition of the transfection mixture to the cells as determined by Northen hybridization. Given the high pMT21 promoter activity, it is possible to harvest the cells for gene activity assays about 24 h after starting transfection. Transfection times may vary depending on the cell type and/or promoter activity.

Representative 2D gel autoradiographs (IEF) of [^{35}S]methionine-labeled proteins from transiently transfected COS-1 cells [ADP-ribosylation factor (Arf), rab11a, and p21-ras] are shown in Fig. 1. Arf is overexpressed as a single polypeptide, whereas the human rab11a and p21-ras constructs yield a set of spots that

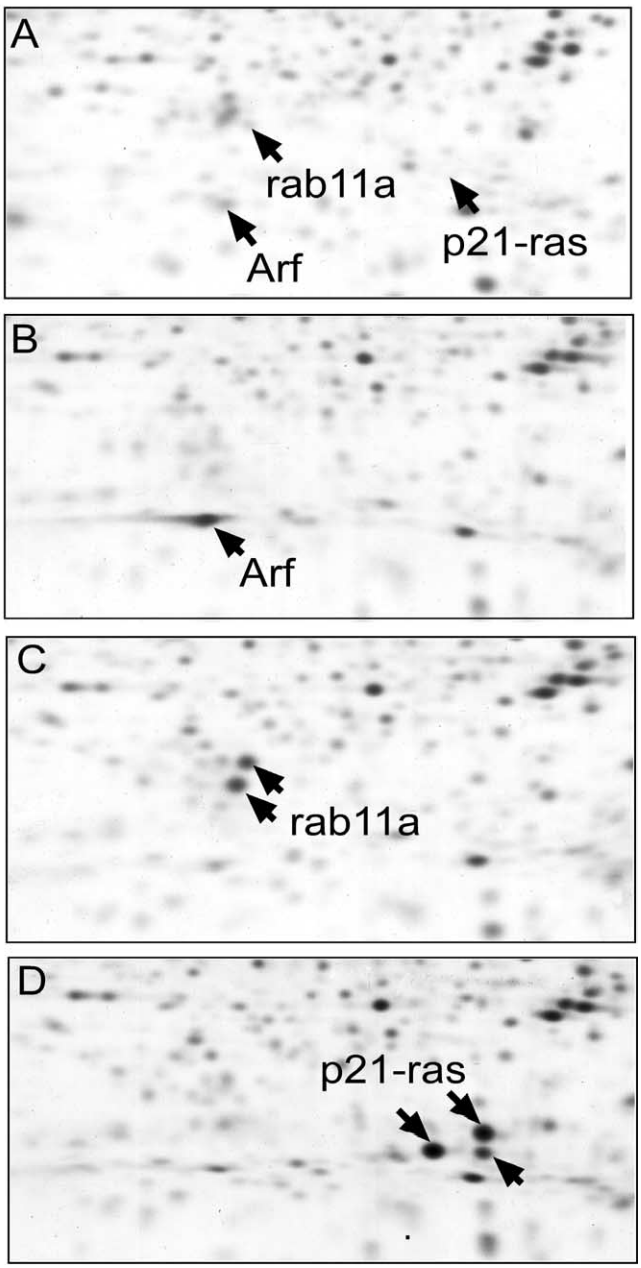

FIGURE 1 Two-dimensional gel (IEF) autoradiographs of [^{35}S]methionine-labeled proteins from COS-1 cells transfected transiently with pMT21 constructs: (A) control, nontransfected cells, (B) ADP-ribosylation factor (Arf), (C) rab11a, and (D) p21-ras.

reflect their posttranslational processing *via* geranylgeranylation and farnesylation, respectively. The COS-1 transfection system seems to reproduce a broad spectrum of posttranslational alterations of proteins and may represent an appropriate model system for the study of many posttranslational modifications.

To obtain significant amounts of the overexpressed protein, the protocol should be scaled up using six-well tissue culture plates. Resuspend the cells from one well in 60 µl of lysis solution, run 2D gels, and detect the overexpressed protein by Coomassie brilliant blue staining. Protein spots can then be electroeluted from the gel and used for immunization.

V. PITFALLS

1. Avoid growing the cells for more than 24 h prior to transfection. Always use the same conditions for cell culturing, as the transfection efficiency is sensitive to cell passage and confluence.
2. Avoid repeated freezing/defrosting of the plasmid DNA stock solution as it may induce one and double strain nicks in plasmid DNA, leading to linearization of supercoiled DNA. Linearized DNA is generally not as efficient a substrate for transient expression as supercoiled DNA. Aliquot the plasmid stock in several tubes (5–10 µl) and store at –70°C.
3. The LipofectAMINE commercial stock solution should be mixed gently before using.
4. Do not add antibacterial agents to transfection media.

CHAPTER

11

High-Throughput Purification of Proteins from *Escherichia coli*

Pascal Braun and Joshua LaBaer

I. INTRODUCTION

The preparation of purified protein provides a powerful tool enabling the study of the biophysical characteristics, structure, biochemistry, and functional activity of proteins. With the increased focus on proteomics approaches, there is a growing demand for high-throughput (HT) methods to study protein function. The recent development of protein microarrays and multiwell solution biochemistry enables the study of hundreds or more proteins at a time (Martzen *et al*., 1999; MacBeath and Schreiber, 2000; Zhu *et al*., 2001). These advances offer the possibility to help systematically analyze protein–protein interactions, delineate enzyme–substrate networks, and investigate the effects of posttranslational modifications and small molecules on protein interactions or activities (MacBeath, 2002; Zhu *et al*., 2001).

The use of these new technologies requires access to large numbers of purified proteins. The following protocols describe the expression and purification of proteins from *Escherichia coli* in an automatable 96-well format. The procedure has been shown to give yields in the range of 300 ng to 1 µg per 1 ml bacterial culture for ~50–80% of proteins up to 75 kDa (Braun *et al*., 2002).

II. MATERIALS AND INSTRUMENTATION

Refrigerated incubator shaker with adjustable temperature (20–37°C) with plate holders (alternatively, two standard incubator shakers: one in the cold room and one at room temperature will also work)
Collection plates (e.g., Corning costar # 3896)
96-deep well blocks 2.2 ml (Marsh Bioproducts, Cat. No. AB0600)
Gas-permeable seals (e.g., Abgene, Cat. No. AB-0718)
96-well filter plate 350 µl, GF/C (Whatman Unifilter, Cat. No. 7700-3301)
Eppendorf Thermoshaker R with 96-well plate holder (S534-41 and S534-46)
(Recommended): A 96-pin inoculator with pin length >2 in. that can reach the bottom of a 96-deep well block
Thermo Finnigen Multidrop 96 DW (MTX Labs, Cat. No. P97115)
Electronic 8-channel pipettes
96-well plate spectrophotometer
Centrifuge with plate holders (best is digital rpm indicator)
SDS–PAGE system that maximizes lane number to handle many samples (e.g., Bio-Rad criterion system—gels with 26 wells)
Aluminum sealing tape (Beckman Reorder# 538619)

III. PROCEDURES

The first step in high-throughput expression and purification of proteins is obtaining the corresponding protein expression constructs. The expression of proteins often requires that the gene sequences of interest be placed (1) under the control of a specific transcriptional promoter (regulated, strong/weak, etc.), (2) near specific translational signals (ribosome binding sites, etc.), (3) in association with a particular selectable marker (ampicillin, tetracycline, etc.) and, in many

Copyright 2006, Elsevier Science (USA).
All rights reserved.

cases (and nearly all conceivable HT screening scenarios), (4) linked at one or both ends to sequences encoding polypeptide tags to facilitate HT manipulations, such as purification (His_6, GST), detection (GFP), or functional readout (Gal4-AD) of the test proteins. The addition of peptide tags requires that the untranslated regions flanking the coding sequences be removed. Finally, the importance of ensuring that the expression clone sequences accurately reflect the natural gene sequence cannot be overemphasized. Even subtle changes in the amino acid sequences of proteins can have profound effects on protein function. The configuration of the clones should be determined in advance for each experiment and all of the clones should have the same configuration.

There is an increasing number of clone collections under construction or already available through both public and private sources that can provide useful starting material for protein expression experiments (Brizuela *et al*., 2001, 2002; Kikuchi *et al*., 2003; Reboul *et al*., 2003; Seki *et al*., 2002; Strausberg *et al*., 1999). Some of these clone collections contain full-length cDNAs, requiring that the user extract the coding sequences and place them into the appropriate vectors that support protein expression (Strausberg *et al*., 1999). Other clone collections have already configured the coding sequences into expression vectors, and their usefulness depends on whether the specific configuration suits the users needs (Martzen *et al*., 1999). The most flexible approach for protein expression utilizes recombinational cloning vectors, which enable the simultaneous and rapid transfer of the coding sequences into other plasmid vectors—in frame, without mutations (Hartley *et al*., 2000). These transfers occur in a single-step benchtop reaction that can be automated readily and nearly all vectors can be adapted (with a single fragment blunt ligation) to become recipient vectors. Thus clone collections that employ this approach can support a broad variety of experiments.

For bacterial transformation, several vendors provide competent cells in a 96-well format. The following protocol has been optimized for BL21pLys^S cells.

A. HT Protein Expression

Solutions

1. *TB media*: To prepare 1 liter of Terrific broth, mix 12 g Bacto-tryptone, 24 g yeast extract, and 4 ml glycerol and dissolve in 900 ml ddH_2O final volume. In a separate container, prepare a phosphate solution by mixing 2.31 g KH_2PO_4 with 12.54 g K_2HPO_4 and bring the final volume to 100 ml. Autoclave both solutions independently. Mix after solutions have cooled down.

2. *Ampicillin*: Dissolve 300 mg ampicillin in 3 ml H_2O. Store at –20°C. Make fresh weekly.

3. *Chloramphenicol*: Dissolve 340 mg chloramphenicol in 10 ml ethanol, store at –20°C.

4. *40% glucose*: Add 200 g L-glucose to 300 ml H_2O while stirring. Warm the solution to accelerate sugar dissolution. Once the glucose is in solution, bring the final volume to 500 ml to compensate for any evaporative loss. Filter sterilize and store at room temperature.

5. *1 M IPTG*: Dissolve 2.38 g IPTG in 10 ml H_2O. Aliquot and store at –80°C.

Steps

1. Aliquot 1 ml media into each well of a 96-deep well block. This is conveniently done using repetitive dispenser such as the Thermo Finnigen Multidrop. Alternatively, a repeat pipetting device (e.g., Eppendorf) can be used.

2. Inoculate cultures with bacteria containing the expression constructs. It is convenient to work with bacteria that are arranged in 96-well footprints. Dipping a sterilized 96-pin inoculation device into 96-well glycerol stocks and then softly pressing on agar will create such a footprint. After the colonies are grown, the same 96-pin device can be used to inoculate 96 O/N cultures simultaneously. Standard inoculation using sterile toothpicks will work, but careful attention must be paid to avoid mixing samples.

3. Grow cultures O/N at 37°C, 375 rpm for 14 h. Some experimentation with growth conditions may be necessary depending on the bacterial strain used. The cells should grow to early plateau, allowing slower growing colonies to catch up. However, avoid late plateau because different samples will reenter growth phase differentially. To avoid day-to-day variation, it is crucial to avoid growing the bacteria longer than 16 h.

4. Prepare a second culture block with 1.5 ml media containing appropriate antibiotics and 2% glucose.

5. After the O/N growth, check OD_{600} of the cultures using a 1:10 dilution. It is advisable to check the OD of the entire plate using a 96-well plate compatible spectrophotometer. However, when many blocks are processed in parallel or if only a standard spectrophotometer is available, sampling at least 24 wells of every plate to ensure even growth is acceptable. The overall variability should be <25%.

Bacteria settle quickly in the 96-well blocks. Whenever transferring bacteria, make sure that the O/N culture block is thoroughly mixed all the time. This can

be achieved by maintaining the culture block on a constantly rotating Eppendorf Thermoshaker.

6. Dilute the O/N cultures into the second block to achieve an average final OD_{600} = 0.1 Bacterial settling can also cause problems at this step. If possible, pipette all cultures simultaneously or mix the block with the O/N cultures constantly. Otherwise, the samples will get uneven starting densities.
7. Grow at 25°C until average OD_{600} of the culture is ~0.6 (~3.5 h).
8. Induce protein expression (with IPTG, etc.). We use IPTG at 1 m*M* final concentrations.
9. Express protein for 3 h at 25°C. We have found that cultures at 25°C grow more evenly and tend to have less protein degradation than at higher temperatures. Actual induction temperature and time may need adjustment depending on constructs and conditions.
10. *Optional:* Measure and record the OD_{600} of final culture while maintaining good mixing of the cultures.
11. *Optional:* Take an aliquot for Western blot analysis while maintaining good mixing of the cultures.
12. Harvest the cultures by centrifugation for 10–15 min, 4°C, 5000 *g*.
13. Decant media.
14. Freeze pellets to –20°C.

B. HT Protein Purification under Denaturing Conditions

Solutions

1. *Guanidine lysis buffer (GLB)*: 100 m*M* NaH_2PO_4, 10 m*M* Tris–HCl pH 8.0, 6 *M* guanidine hydrochloride, and 10 m*M* β-mercaptoethanol
2. *Ni-NTA matrix:* Ni-NTA can be obtained from Qiagen (Cat. No. 30210). Wash beads several times in GLB. After last wash, resuspend the beads in 10 volumes of GLB, forming a 10% slurry.
3. *Urea wash buffer (UWB):* 100 m*M* NaH_2PO_4, 10 m*M* Tris–HCl, and 8 *M* urea, adjust to pH 8.0
4. *Elution buffer (EB):* 100 m*M* NaH_2PO_4, 10 m*M* Tris–HCl, 8 *M* urea, and 500 m*M* imidazole, adjust to pH 8.0

Steps

1. Thaw the deep well block containing the bacterial pellets for 5–10 min at room temperature.
2. Pipette 100 µl GLB into each well. This step is conveniently done using a repeating device such as a Multidrop.
3. Resuspend pellets by shaking the plate on a Beckman Thermoshaker for 30–60 min at 750 rpm at room temperature. The use of a stationary-inverted 96-pin device will create enough turbulence to get a better resuspension (Fig. 1). This Swizzler improves lysis under both denaturing and nondenaturing conditions. If the goal is to recover functional protein by renaturation, the shaking speed should be reduced to 300 rpm after 5 min to minimize harmful oxidation of proteins.

FIGURE 1 A stationary-inverted 96-pin device.

4. Prepare two GF/C fiber plates.
   a. Filtration plate (to remove cell debris): Pipette 10 µl GLB into each well of the filtration plate.
   b. Binding plate (to capture the protein): Pipette 5 µl of 10% Ni-NTA slurry equilibrated in GLB buffer (0.5 µl bed volume) into the binding plate. Too much affinity matrix will increase nonspecific binding and lead to more impurities. Add 200 µl lysis buffer. Spin for 1.5 min at 16 *g*. Seal bottom with aluminum tape. Seal every well thoroughly!
5. Place the filtration plate on top of the binding plate, ensuring that well A1 is above well A1.
6. Transfer lysates from step 3 into filtration plate.
7. Spin the stacked plates at 2000 *g*, 2 min, 4°C.
8. Seal the top of the binding plate.
9. Rotate plate end over end for 45 min at room temperature.
10. Remove both seals. Remove the bottom seal first.

11. Spin at 50 *g* for 1.5 min into a waste vessel.
12. Wash the binding plate three times with UWB by adding 250 µl UWB followed by a 50 *g* spin for 90 s into a waste vessel at room temperature.
13. Place the binding plate on top of a 96-well collection plate.
14. Add 15 µl elution buffer to the binding plate.
15. Incubate at room temperature for 5 min.
16. Spin at 16 *g* for 1.5 min.
17. Repeat elution (steps 14–16) three more times (60 µl final volume).
18. After the final addition of elution buffer, spin once at 2000 *g* for 5 min. This hard spin will collect all remaining protein.

C. HT Protein Purification under Nondenaturing Conditions

Solutions

1. *10x phosphate-buffered saline (PBS):* Mix 80 g NaCl, 2.0 g KCl, 14.4 g Na_2PO_4, and 2.4 g KH_2PO_4 and dissolve in 900 ml ddH_2O. Adjust pH to 7.2 and bring volume to 1 liter.
2. *1x PBS:* Dilute 100 ml 10x PBS with 900 ml ddH_2O
3. *0.5 M EDTA, pH 8.0:* Dissolve 95 g EDTA in 450 ml ddH_2O. Start adjusting the pH with NaOH before the powder is dissolved to accelerate the dissolution process. Adjust pH to 8.0 and bring volume to 500 ml.
4. *DNase:* Dissolve 100 mg DNase (Sigma D-4527) in 10 ml H_2O. Aliquot in 0.5-ml aliquots and store at –80°C.
5. *Lysozyme:* Dissolve 300 mg lysozyme (enzyme grade) in 6 ml H_2O. Aliquot and store at –80°C.
6. *10% Triton X-100*: Slowly pipette 5 ml Triton X-100 in 45 ml H_2O. Rotate for a few hours or heat in a water bath until all flakes disappear. Store at room temperature.
7. *40x DNase buffer:* 900 m*M* $MgCl_2$, and 100 m*M* $MnCl_2$
8. *Wash buffer 1*: PBS, 2 m*M* EDTA; and 10% glycerol
9. *Wash buffer 2*: Tris–HCl, 100 m*M*, pH 8.0; NaCl, 500 m*M*; EDTA, 2 m*M*; 0.1% Triton X-100; and 10% glycerol
11. *Glutathione beads (Sigma G4510)*: Wash the beads three to six times in wash buffer 1 containing 5 m*M* dithiothreitol (DTT) (confirm the absence of ethanol smell) and store at 4°C
12. *Lysis buffer*: PBS, 2 m*M* EDTA; 10% glycerol; 5 m*M* DTT (*add fresh*), and protease Inhibitors (*add fresh*)
13. *Elution buffer*: Wash buffer 2 + 10 m*M* reduced glutathione. Verify and readjust the pH to 8.0, if necessary.
14. *Lysozyme mix*: Mix 64 µl lysozyme (50 µg/µl), 320 µl 10% Triton X-100, and 1016 µl lysis buffer. Pipette 8 × 150 µl into one column of a plate. From this reservoir, you can conveniently pipette the mix with an 8-channel pipette in step 4.
15. *DNase mix:* 80 µl DNase (10 mg/ml), 720 µl 40x DNase buffer, and 800 µl lysis buffer. Pipette 8 × 150 µl of this mix into 8 wells of one column of a plate. From this reservoir, one can conveniently pipette the mix with an 8-channel pipette in step 6.

Steps

1. Thaw the deep well block containing the bacterial pellets for 5–10 min at room temperature.
2. Pipette 100 µl lysis buffer into each well. This step is conveniently done using a repeating device such as a Multidrop.
3. Resuspend pellets by shaking the plate on a Beckman Thermoshaker for 30–60 min at 750 rpm, 4°C. The use of a stationary-inverted 96-pin device will create enough turbulence to improve resuspension (Fig. 1). This Swizzler improves lysis under both denaturing and nondenaturing conditions.
4. Add 10 µl lysozyme using an 8-channel pipetting device to transfer the mix from a column of wells of a 96-well plate.
5. Mix for 30 min at 300 rpm, 4°C. The lower speed reduces harmful oxidation of proteins. Preferably use a stationary 96-pin device to increase mixing.
6. Add 10 µl of DNase mix. An 8-channel electronic pipette is adequate.
7. Mix for 15 min at 300 rpm, 4°C.
8. Prepare two GF/C fiber plates.
   a. Filtration plate (to remove cell debris): Pipette 10 µl lysis buffer into each well of the filtration plate to wet the filters.
   b. Binding plate (to capture the protein): Pipette 50 µl of 50% slurry of GSH agarose beads in lysis buffer (25 µl bed volume) into the binding plate.
9. Add 200 µl lysis buffer.
10. Spin for 1.5 min at 16 *g*.
11. Seal bottom with aluminum tape. Seal every well thoroughly!
12. Place the filtration plate on top of the binding plate, making sure that well A1 is above well A1.
13. Transfer lysates from step 5 into filtration plate.
14. Spin the stacked plates at 2000 *g*, 2 min, 4°C.

15. Seal the top of the binding plate.

16. Rotate the sealed binding plate end over end for 45 min, 4°C.

17. Remove both seals. Remove the bottom seal first.

18. Spin at 16 *g* for 1.5 min into a waste vessel. Avoid higher speeds, which can dehydrate the matrix and denature the proteins, reducing yields and increasing nonspecific binding.

19. Wash the binding plate three times with wash buffer I by adding 250 µl wash buffer I followed by a 16 *g* spin for 90 s into a waste vessel at 4°C.

20. Wash the binding plate two times with wash buffer II by adding 250 µl wash buffer II followed by a 16 *g* spin for 90 s into a waste vessel at 4°C.

21. Place the binding plate on top of a 96-well collection plate.

22. Add 20 µl elution buffer to the binding plate.

23. Incubate at 4°C for 5 min.

24. Spin at 16 *g* for 1.5 min.

25. Repeat elution (steps 18–20) three more times (80 µl final volume).

26. After the final addition of elution buffer, spin once at 2000 *g* for 5 min. This hard spin will collect all remaining protein.

27. Analyze 10-µl eluate by SDS–PAGE and colloidal Coomassie blue staining

Microarrays for Gene Expression Profiling: Fabrication of Oligonucleotide Microarrays, Isolation of RNA, Fluorescent Labeling of cRNA, Hybridization, and Scanning

Mogens Kruhøffer, Nils E. Magnusson, Mads Aaboe, Lars Dyrskjøt, and Torben F. Ørntoft

I. INTRODUCTION

In less than a decade DNA microarray technology has become an indispensable part of functional genomics (Celis *et al.*, 2000). Functional gene expression studies provide insight into changes in the transcription profile resulting from disease, developmental processes, or physiological stimuli. DNA microarrays have especially demonstrated their great potential in human tumour classification and prediction (Thykjaer *et al.*, 2001; Dyrskjot *et al.*, 2003; van de Vijver *et al.*, 2002) but also within drug target discovery, drug action, and toxicity (for an overview and further references, see Heller *et al.*, 1999). Microarrays are not limited to any specific organism but its usefulness increases with increasing availability of sequence information.

A DNA microarray is an orderly arrangement of usually thousands of DNA spots typically less than 150 μm in diameter that provides a medium for hybridisation of labelled nucleic acids extracted from biological samples. The immobilised DNA samples on the array are called the probes and the sample that is labelled and hybridised to the probes is the target (Phimister, 1999). There are several steps in the design and implementation of a DNA microarray experiment and they require specialized robotics, imaging equipment, and software, which are all available commercially.

Since the first complete microarray protocols were published (Schena *et al.*, 1995; Shalon *et al.*, 1996), a wide variety of designs have developed that are mirrored in the numerous different DNA microarray protocols available. Common for them all are the four essential stages: (1) microarray fabrication, (2) target preparation, (3) hybridisation, and (4) data collection, normalisation, and bioinformatic analysis. In this chapter, protocols are outlined for the fabrication of oligonucleotide microarrays, preparation of amplified cRNA target, and the combination of these in the hybridisation procedure (Fig. 1).

For reviews of different aspects of the technology, please see Eisen and Brown (1999), Kricka (1998), Lemieux *et al.* (1998), Marshall and Hodgson (1998), and Schena and Davis (1999).

II. CHEMICALS

The following chemicals are from Sigma: sodium phosphate monobasic (Cat. No. S-0751), sodium phosphate dibasic (Cat. No. S-0876), Betaine monohydrate (Cat. No. B-2754), EDTA (Cat. No. E-5134), phenol (Cat. No. P-4557), $NaHCO_3$ (Cat. No. S-5761), $ZnCl_2$ (Cat.

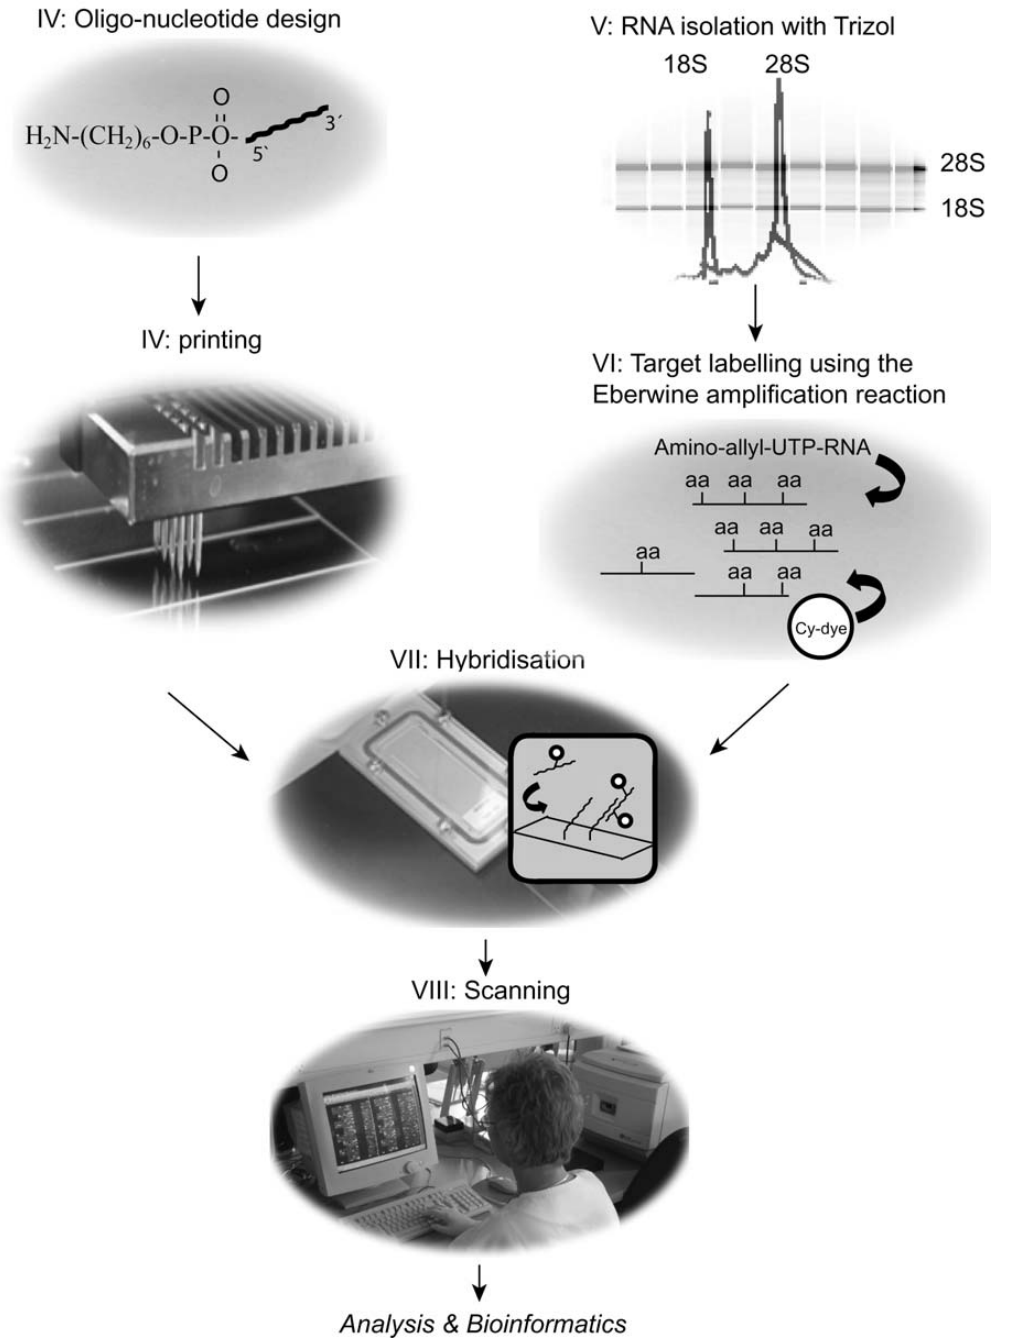

FIGURE 1 Flowchart of protocols outlined in this article for a complete microarray experiment where roman numbers refer to the relevant sections in the text. Upper left corner shows the two main fabrication steps of oligonucleotide microarrays: probe design and printing (Section IV). In the upper right corner, target preparation consisting of RNA isolation and labelling (Sections V and VI). In the middle, the combination of probes and target in the hybridisation reaction (Section VII) (Bottom) Data collection by scanning (Section VIII). Analysis and bioinformatics are beyond the scope of this chapter.

No. Z-4875), 7.5 *M* ammonium acetate (Cat. No. A-2706), 2-mercaptoethanol (Cat. No. M-3148), dimethyl sulfoxide (DMSO) (Cat. No. D-8779), 5-(3-aminoallyl)-2′-oxyuridine 5′-triphosphate (aa-UTP) 50 mg custom made (1-mg portions, Cat. No. A-5660), and Orange G (Cat. No. O-1625).

The following products are from Calbiochem: NaCl (Cat. No. 567441), Tris base (Cat. No. 648311), Tween 20 (Cat. No. 655204), sodium citrate (Cat. No. 567444), bovine serum albumin (Cat. No. 126575), SDS (Cat. No. 428023), formamide (Cat. No. 69189), and NaOH (Cat. No. 567530).

Glycerol (Cat. No. 818709), chloroform (Cat. No. 1.02445.1000), and isoamylalcohol (Cat. No. 748K 00555679) are from Merck. The tRNA is from Roche (Cat. No. 109495), and SeaKem GTG agarose (Cat. No. 50074) is from BMA products. Fish sperm DNA is from Serva (Cat. No. 18580.01), and ethidium bromide (Cat. No. U532813) is from Amersham Biosciences.

III. PREPARATION OF STOCK SOLUTIONS

1. *1 M Tris*: Add 121.1 g of Tris base in 800 ml of H_2O. Adjust the pH to 9.0 by adding 42 ml of concentrated HCl and bring the volume to 1 liter.
2. *TE* (*10 mM Tris–Cl, 1 mM EDTA*): To prepare 1 liter, mix 100 ml of 1 *M* Tris and 20 ml of 0.5 *M* EDTA and bring the volume to 1 liter.
3. *10 M NaCl*: Dissolve 399.7 g of NaCl in 800 ml of H_2O and bring the volume to 1 liter.
4. *0.5 M EDTA*: Add 186.1 g of EDTA·2 H_2O to 800 ml of H_2O. Stir on a magnetic stirrer. Adjust the pH to 8.0 with NaOH (~20 g of solid NaOH).
5. *20× SSC*: To make 1 liter, dissolve 175.3 g of NaCl and 88.2 g of sodium citrate in 800 ml of H_2O. Adjust the pH to 7.0 with a 10 *M* solution of NaOH and bring the volume to 1 liter.
6. *20× SSPE*: To make 1 liter, dissolve 175.3 g of NaCl and 27.6 g of $NaH_2PO_4{\cdot}H_2O$ and 7.4 g of EDTA in 800 ml of H_2O. Adjust the pH to 7.4 with a 10 *M* solution of NaOH and bring the volume to 1 liter.
7. *0.1 M carbonate buffer, pH 9.3*: To prepare 100 ml, dissolve 1.06 g of $NaHCO_3$ in 80 ml of H_2O. Adjust the pH with 10 *M* NaOH and bring the volume to 100 ml. Store frozen at –20°C in 1-ml aliqouts.
8. *10 M NaOH*: To prepare 1 liter, dissolve 40.0 g of NaOH in 800 ml of H_2O and adjust the volume to 1 liter.
9. *H_2O*: Molecular Biology Water (AccuGene, BMA products Cat. No. 51200), unless otherwise indicated in the text.

IV. FABRICATION OF OLIGONUCLEOTIDE MICROARRAYS

A. Introduction

Oligonucleotide microarrays are usually printed on slides with an activated surface that allows end-point attachment of 5′- or 3′-chemically modified DNA. The common theme is that the glass surface of the microarray slide is coated with active chemical groups, which facilitate the binding of end-modified DNA, typically amino modified. In this way, backbone binding is reduced and most of the immobilized DNA should be available for hybridisation. In the oligonucleotide microarray format, each gene is represented by one or more oligonucleotides that are designed solely on the basis of sequence information. This allows the user to design the probes avoiding cross-hybridisation with repetitive regions or regions that share similarity to other genes (Li and Stormo, 2001; Kane *et al*., 2000; Hudges *et al*., 2001). Oligonucleotide arrays have several advantages over cDNA microarrays. Gene-specific oligonucleotides can easily be designed and synthesised so there is no need for verification of bacterial clones and high-throughput production of polymerase chain reaction (PCR) products. In addition, oligonucleotide libraries covering large parts of the transcriptome are available from several companies.

B. Materials and Instrumentation

5′-modified 60-mer oligonucleotides dehydrated in a 96-well format are from DNA-Technology A/S, Denmark. CodeLink microarray slides are from Amersham Biosciences. The VersArray ChipWriter Pro System is from Bio-Rad Laboratories. The Biomek 2000 automated workstation is from Coultier Beckman inc. 384-well plates are from Genetix (Cat. No. x6003). The Array Designer 2.0 software is from Premier Biosoft International. The Hettich Rotina 35 R centrifuge is from Integrated Services TCP Inc. Humid chamber and container with rack are custom made at the Aarhus University workshop. Container and rack for blocking of 25 × 75-mm slides (Cat. No. 115067-0 and Cat. No. 115068-0) are from VWR international.

C. Procedures

1. Oligonucleotide Design

Several programs exist for oligonucleotide design. In Array Designer software, begin with the following criteria:

1. Length = 55–60
2. Distance from 3′ end < 999 bp
3. GC content 35–50%
4. $T_m = 75 \pm 5°C$
5. Hairpin $\Delta G_{max} = 3.0$ Kcal/mol
6. Self dimer $\Delta G_{max} = 6.0$ Kcal/mol
7. Maximum length of repeats ≤ 5 bp
8. Least cross-reactivity (Blast, http://www.ncbi.nlm.nih.gov/blast/)

If no probes are returned, reduce the stringency of one or more parameters in the software.

2. *Printing of Microarrays*

Solutions

1. 2× *printing buffer*: (300 m*M* sodium phosphate and 2 m*M* Betaine, pH 8.5. To prepare 100 ml, mix dissolve 0.41 g sodium phosphate monobasic, 3.785 g sodium phosphate dibasic, and 9 mg Betaine in 90 ml H_2O. Adjust pH to 8.5 using 1 *M* NaOH or 1 *M* HCl. Bring final volume to 100 ml with H_2O.
2. *Blocking Solution*: 0.1 *M* Tris, 50 m*M* ethanolamine, 0.1% SDS, pH 9.0. To prepare a 1-liter solution, dissolve 12.1 g Trizma base in 900 ml H_2O. Stir in 3.05 g ethanolamine and mix thoroughly. Adjust pH to 9.0 using 1 *M* NaOH or 1 *M* HCl. Bring final volume to 1 liter with H_2O. Add SDS to blocking solution to a final concentration of 0.1% prior to use.
3. *4× SSC, 0.1% SDS*

Steps

Steps 1–3 can be done manually or automated. We have implemented an automated workstation for all oligonucleotide dilutions and for preparation of source plates for printing.

1. Dissolve the 5′ amino-modified oligonucleotides in H_2O to a concentration of 120 µ*M*.
2. To prepare the source plate for printing, transfer 12.5 µl 2× spotting solution into each well of the source plate and then add 12.5 µl of 120 µ*M* oligonucleotide in a predetermined pattern. The final volume is 25 µl with an oligonucleotide concentration of 60 µ*M*.
3. Prepare the microarrayer for printing. This includes equilibrating to 30–35% relative humidity, design of a suitable program for printing, cleaning, and preconditioning of quilted pins. Clean the pins in 20% ethanol and dry them completely. Precondition the quill pins for 30 min to 1 h by printing on ordinary microscope slide with printing solution.
4. Place the slides and the source plate in the microarrayer and run the printing program.
5. Prepare a humid chamber by adding as much solid sodium chloride to H_2O as needed to form a 1-cm-deep slurry in the bottom of a plastic container with an airtight lid.
6. For DNA immobilisation, place slides in a humid chamber with approximately 75% relative humidity for 16–24 h at room temperature.
7. After immobilization, residual reactive groups are blocked. Place the slides in a rack (up to 20 slides) and submerge the slides in 300 ml blocking solution prewarmed to 50°C. Agitate gently for 15 min.
8. Discard the blocking solution and rinse the slides twice with H_2O at room temperature.
9. Wash the slides with 4× SSC, 0.1% SDS prewarmed to 50°C for 15 min with gentle agitation.
10. Rinse the slides twice by submerging in distilled water. This step removes residual salt and SDS.
11. Dry slides by centrifugation (800 rpm for 3 min).
12. Store the slides dark and desiccated until use.

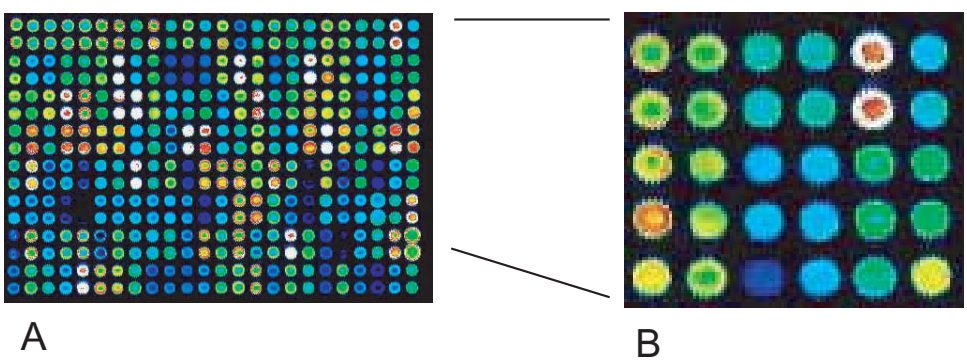

FIGURE 2 Control hybridisation of printed CodeLink slide for verification of spot presence and morphology. (A) Image of a slide with 5′ amine-modified oligonucleotides (60-mer) probes hybridised with a random 25-mer Cy5-labelled oligonucleotide and scanned at 633 nm with laser and PMT settings of 100 and 50%, respectively. (B) Magnified image.

3. *Quality Control of Printed Microarrays*

During printing of slides, one or more pins may be clogged for a longer or shorter period of time. This can result in abnormal or missing spots on a part of the microarray batch. We recommend performing quality control to evaluate printing errors and probe coupling efficiency for each 20th spotted slide in a batch (Fig. 2).

Solution

5′-Cy5-labelled 25-mer random oligonucleotide from DNA Technology A/S, DK

Steps

1. Dissolve the oligonucleotide in the hybridisation buffer (see Section VII) to a final Concentration of 5 µ*M*
2. Apply 25 µl of the hybridisation mix to the slide as described in Section VII and incubate for 30 min at room temperature.
3. Wash and dry the slide as described in Section VII.
4. Scan the slide with the 633-nm (Cy5) laser at a power setting of 100% and with the PMT setting at 50%.

V. ISOLATION OF TOTAL RNA WITH TRIZOL

A. Introduction

The quality of RNA for microarray experiments must be of high quality. It should be intact and contain no genomic DNA or enzyme inhibiting substances. Several extraction methods have been tested with a wide variety of biological samples. TRIzol has become our method of choice because it gives consistent, reliable results and is considerably less expensive than kit-based products. The outlined protocol is suitable for up to 100 mg of tissue, which should give you an abundant amount of total RNA compared to the 5 µg required per labelling reaction.

All materials should be RNase free and only handled using gloves. Keep a separate set of pipettes solely for RNA work. Glassware should be baked at 180°C for 6 h. The work area can be cleaned using RNase Zap to limit the risk of RNase contamination.

B. Materials and Instrumentation

RNAlater and RNase Zap are from Ambion. Lysing Matrix D (Cat. No. 6913-100) and Q-Bio gene are from Bio101 Systems. The Trizol reagent is from Invitrogen. Bio101 Fastprep, FP120, Savant Instruments Inc.

C. Procedures

Steps

1. After excision of a tissue sample, transfer it as fast as possible to a 1.5-ml microcentrifuge tube. Submerge the tube into a container with liquid nitrogen and then store in a –80°C freezer. Alternatively, add 5 (tissue) volumes of RNAlater and store at 25°C for a couple of days, at 4°C for up to a week, or at –20° or –80°C for long-time storage. Remove RNAlater before continuing with step 2.
2. Transfer the tissue to a lysing matrix placed on ice and add 1 ml TRIzol.
3. Place the matrix in the Fastprep homogeniser. Depending on how tenacious the tissue is, run the homogeniser one to three times for 25 s at 6.0 m/s^2. Cool the sample on ice between each treatment.
4. Spin the samples at 4°C for 10 min at max speed in microcentrifuge tubes or at 3000 *g* for 30 min in 15-ml conical tubes.
5. Transfer the homogenate to a microcentrifuge tube.
6. Add 0.2 ml of chloroform/isoamylalcohol (24:1) and shake vigorously for 15 s.
7. Incubate for 5 min on ice and then spin at max speed for 15 min at 4°C.
8. Transfer top (aqueous) layer to a new microcentrifuge tube, being careful not to pick up any of the white interphase layer (the lower phases may be saved for DNA and protein extractions).
9. If double extractions are needed, repeat steps 6–8, except that only 0.1 ml chloroform is added.
10. Precipitate RNA by adding 0.5 ml isopropanol, vortex, and leave on ice for 15 min.
11. Spin at max speed for 30 min at 4°C.
12. Pour off supernatant, add 1 ml cold 70% ethanol, and invert tube to loosen pellet.
13. Spin at max speed for 5 min at 4°C.
14. Pour off supernatant, spin briefly, and remove the remaining ethanol with a pipette.
15. Dry the pellet under a ventilated hood until the RNA is just dry.
16. Dissolve the RNA in 50 µl RNase-free H_2O by vortexing.
17. Measure the optical density at 260 and 280 nm to estimate the RNA concentration and purity. An OD_{260}/OD_{280} ratio of 2.0 indicates that the RNA is pure, but any value down to 1.7 is acceptable. The RNA concentration is calculated by the following equation: Concentration (µg/ml) = $OD_{260} \times 40 \times$ dilution factor. Verify RNA integrity by running 0.5 µg on a 1% agarose gel. The intensity of the 28S to 18S should have a ratio of approximately 2 : 1. Some species (e.g., drosophila) have 28S and 18S RNA that only move

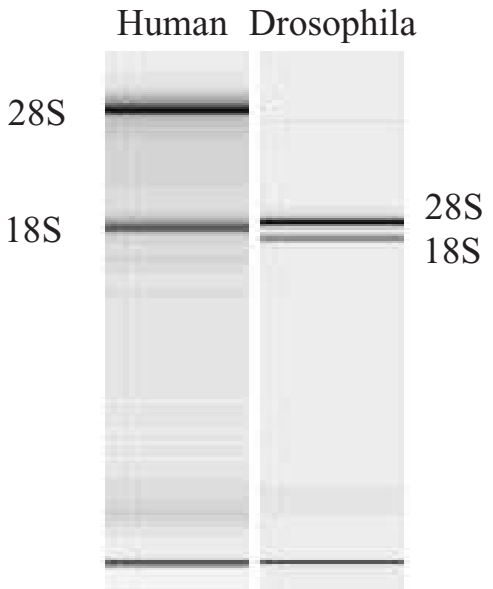

FIGURE 3 Total RNA from human and drosophila separated on a 4% Metaphor agarose gel for 90 min. High-quality RNA will have a 28S to 18S ratio of intensity of approximately 2 : 1.

with slightly different velocities (Fig. 3). In these cases, use a 4% Metaphor agarose gel (FMC Bio Products) and let it run for 90 min.

VI. SYNTHESIS OF LABELLED TARGET USING A MODIFIED EBERWINE AMPLIFICATION PROTOCOL

A. Introduction

We routinely use 5 µg of total RNA per labeling reaction using a modified Eberwine amplification protocol (Eberwine *et al*., 1992; 't Hoen *et al*., 2003) but any amount in the range of 200 ng–10 µg of total RNA will work fine. The procedures consist of several steps, starting with the conversion of messenger RNA into first strand cDNA through reverse transcription primed with a T7-tagged oligo(dT). Synthesis of the second-strand cDNA results in a T7-tagged double strand DNA that acts as template in the subsequent *in vitro* transcription (IVT). The incorporation of aminoallyl-UTP during IVT allows the conjugation of reactive-esterified flurophores to the cRNA. There are two clear advantages of this protocol compared to the synthesis of labelled cDNA by incorporation of fluorophore conjugated nucleotides during the reverse transcription: (1) a small amount of RNA down to 200 ng can be used instead of the otherwise recommended 20–50 µg and (2) there is no incorporation bias during incorporation of aminoallyl nucleotides as opposed to the incorporation of nucleotides coupled to two different sized Cy dyes.

B. Materials and Instrumentation

SuperScript double-stranded cDNA synthesis kit, Invitrogen; oligo$(dT)_{24}$-T7 reverse transcription primer with the sequence 5'-GGCCAGTGAATTGTAATAC GACTCACTATAGGGAGGCGGT_{24}), HPLC purified, DNA Technology, DK; gel electrophoresis equipment; PCR machine; MegaScript T7, Ambion; RNeasy kit, Qiagen; Cy dye PostLabelling reactive Dye Pack, Cat. No. RPN-5661, Amersham Biosciences.

C. Procedures

1. Preparation of Double-Stranded DNA

Solutions

1. *Hydrolysis buffer* (*1 ml*): 1 *M* NaOH, 2 m*M* EDTA Prepare by mixing 1 ml of 1 *M* NaOH and 4 µl of 0.5 *M* EDTA.
2. *Phenol* : *chloroform* : *isoamylalcohol solution* (*25* : *24* : *1*)
3. *7.5 M ammonium acetate*
4. *loading buffer* (*10 ml*): 0.4 ml of 50 mg/ml Orange G, 5 ml glycerol, and 4.6 ml H_2O

Steps

1. Mix total RNA (5 µg) with 100 pmol of oligo(dT)-T7 primer and add H_2O to a volume of 9.5 µl. Incubate the tube at 70°C for 10 min and immediately place on ice.

2. Thaw the following kit reagents on ice and then add to the RNA as follows: 2 µl H_2O, 4 µl 5× first strand buffer, 2 µl 0.1 *M* DTT, and 1 µl 10 m*M* dNTP. Mix gently and incubate at 37°C for 2 min before adding 1.5 µl SuperScript II. Mix gently by stirring with the pipette tip (final volume of 20 µl) and incubate at 42°C for 1 h.

3. Thaw the following reagents on ice and add 90 µl H_2O, 30 µl 5× second strand buffer, 3 µl 10 m*M* dNTP, 1 µl *E.coli* RNase H, 1 µl *E.coli* ligase, and 4 µl *E.coli* DNA polymerase I. Mix gently and incubate at 16°C for 2 h (at this point the reaction may be stored for later handling at –20°C).

4. Purify the cDNA product (total volume of 156.5 µl) by adding 156.5 µl phenol : chloroform : isoamylalcohol solution (25 : 24 : 1), mix carefully, and spin the tube for 10 min at max speed at 4°C.

5. Carefully transfer the water phase to a new tube.
6. Precipitate the cDNA by adding 80 µl of 7.5 *M* ammonium acetate, 400 µl 96% ethanol (–20°C), and mix carefully. Spin the tube for 30 min at max speed at 4°C.
7. Discard the supernatant and wash the DNA pellet with 200 µl of ice-cold 70% ethanol. Mix carefully and spin the tube for 10 min at max speed at 4°C.
8. Discard the ethanol and let the pellet air dry and then dissolve in 7 µl H_2O.
9. Check the quality of cDNA by gel electrophoresis by adding 3 µl loading buffer to 1 µl of cDNA and load it onto a 1% agarose gel (100 V for 25 min) (Fig. 4).

2. *Preparation of Aminoallyl-Labeled cRNA*

Place the RNA polymerase mix on ice, it is stored in glycerol and is not frozen at –20°C. Vortex the 10× reaction buffer and the ribonucleotide solutions (ATP, CTP, GTP, and UTP) until they are completely in solution. Once they are thawed, store the ribonucleotides on ice, but keep the reaction buffer at room temperature. Spin all reagents briefly before opening to prevent loss or contamination of material that may be present around the rim of the tube. The spermidine in the 10× reaction buffer can coprecipitate the template DNA if the reaction is assembled on ice. Add the 10× reaction buffer after the water and template DNA are already in the tube.

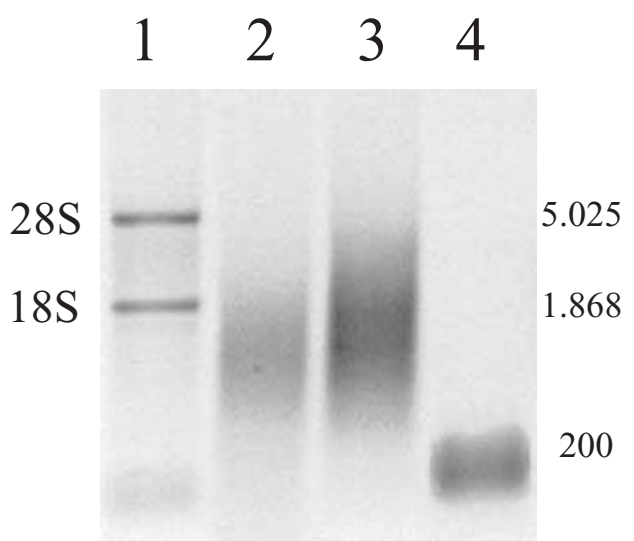

FIGURE 4 Control gel of products from the single steps in the probe preparation procedure. (1) Total RNA; (2) double-stranded cDNA will shown a smear with the highest intensity around 1500 bases; (3) cRNA from IVT should reflect the double-stranded cDNA in terms of size distribution; and (4) fragmented cRNA should be in a narrow range around 100 to 200 bases.

Solution

Prepare a 40 m*M* aminoallyl-UTP solution (stored at –80°C)

Steps

1. For each reaction (20 µl): 6 µl double-stranded cDNA, 1.1 µl H_2O, and 2 µl 10× reaction buffer. Mix and spin down. Keep the solution at room temperature.
2. Thaw the following reagents on ice and add 2 µl ATP, GTP, CTP (75 m*M*), 1.0 µl UTP (75 m*M*), 1.9 µl aa-UTP (40 m*M*) (the aa-UTP/UTP ratio is 1 : 1), and 2 µl of 10× RNA polymerase mix. Mix thoroughly by gently flicking the tube and then spin tube briefly to collect the reaction mixture at the bottom of the tube. Incubate at 37°C for 6 h or overnight.
3. Check the quality of aa-cRNA by gel electrophoresis: Add 3 µl loading buffer to 1 µl of aa-cRNA and load it onto a 1% agarose gel (100 V for 25 min).
4. Purify the aa-cRNA product using the RNeasy kit as follows: add 350 µl RLT buffer and 3.5 µl 2-mercaptoethanol. Mix and add 250 µl of 96% ethanol.
5. Transfer the sample to an RNeasy spin column and spin at max speed for 15 s.
6. Collect the run through and transfer it to the spin column again. Spin at max speed for 15 s.
7. Add 500 µl RPE and spin at max speed for 15 s.
8. Repeat step 7.
9. Transfer the spin column to a new tube and spin at max speed for 2 min to dry the filter in the column.
10. Elute the cRNA product with 50 µl H_2O. Place the column in a heating block (65°C) for 5 min.
11. Spin the column at the lowest possible speed for 1 min and continue at max speed for 1 min.
12. Repeat step 11.
13. Measure the absorbance at 260 and 280 nm (1 µl sample + 59 µl H_2O) and calculate the RNA concentration (1 OD = 40 µg/ml).
14. Aliquots (5 µg) of RNA may be stored at –80°C.

3. *cRNA Conjugation with Cy Dyes*

As the dyes are susceptible to photobleaching, all steps involving the labelled sample should be performed with as little light exposure as possible.

Solutions

1. *0.1 M carbonate buffer, pH 9.3*: To prepare 100 ml, dissolve 0.84 g of $NaHCO_3$ in 80 ml of H_2O. Adjust the pH with 10 *M* NaOH and bring the volume to 100 ml. Store frozen at –20°C in 1-ml aliqouts.
2. *1 M Tris (pH 9)*
3. *50 mM $ZnCl_2$*: To prepare 100 ml, dissolve 0.68 g of $ZnCl_2$ in 100 ml in H_2O. Store at room temperature.

4. *7.5 M ammonium acetate*
5. *70 and 96% ethanol*
6. *DMSO*

Steps

1. Speed-Vac 5 µg aa-cRNA to dryness. Resuspend in 4.5 µl 0.1 M carbonate buffer.
2. Add 9 µl DMSO to the Cy-dye vial and mix until the dye is completely dissolved. Add 4.5 µl of this mixture to the aa-cRNA solution.
3. Incubate at room temperature for 2.5 h.
4. To quench the remaining free Cy dyes, add 9 µl 1 *M* Tris (from –20°C) to the tube. Incubate at room temperature for 15 min.
5. Fragment the labelled RNA by adding 4.5 µl of 50 m*M* $ZnCl_2$ to the tube. It is important to mix the $ZnCl_2$ solution carefully before use. Incubate at 60°C for 30 min.
6. Precipitate the labelled RNA by first adding 2.25 µl of 7.5 M ammonium acetate to the tube. Then add 56.25 µl of 96% ethanol (4°C). Mix carefully.
7. Incubate at –20°C for 30 min or overnight.
8. Spin for 30 min at max speed (4°C).
9. Wash pellet with 70% ethanol (–20°C) and spin for 10 min at max speed (4°C).
10. Repeat step 9.
11. Remove the supernatant and dry the pellet for 5 min. This can be done in a Speed-Vac without heating.
12. Resolve the pellet in 60 µl H_2O and measure the absorbance at 260, 280, 550, and 650 nm.
13. Calculate the frequency of incorporation (FOI), which is the number of dye molecules per 1000 nucleotides. The optimal incorporation is 20–50 FOI.

FOI (dyes/1000 nucleotides): pmol dye × 340 per ng of cRNA

ng cRNA = $A_{260} \times 40 \times$ volume (µl)

pmol dye = **Cy3:** $A_{550} \times$ volume (µl)/0.15

Cy5: $A_{650} \times$ volume (µl)/0.25

VII. HYBRIDISATION

A. Introduction

The protocol outlined here is optimised for hybridisation of cRNA target to 60-mer oligonucleotide probes on CodeLink-activated slides. Other systems may benefit from different temperatures and hybridisation times and a different composition of the hybridisation buffer.

B. Materials and Instrumentation

Hybridisation chambers were custom made in John Kreitler's laboratory at Washington University School of Medicine (St. Louis, MO). LifterSlips are from Erie Scientific Company (Cat. No. 221x25-2-4635). The hybridisation oven is from Promega. The DNA 120 Speed-Vac is from Thermo Savant. The Plactronic rectangular hot plate (Cat. No. 6156100) is from J.P Selecta s.a.

C. Procedures

Solutions

1. The volume of hybridisation mix for one hybridisation (using LifterSlips) is 20 µl hybridisation buffer. To prepare 100 µl of hybridisation mix, combine 30 µl formamide [final concentration 30% formamide], 25 µl 20× SSC [final concentration 5× SSC], 1 µl 10% SDS [final concentration 0.1% SDS], 5 µl fish sperm DNA (0.66 mg/ml) [final concentration 0.033 mg/ml FS DNA], 5 µl tRNA (0.66 mg/ml tRNA) [final concentration 0.033 mg/ml tRNA], 10 µl 0.5% BSA [final concentration 0.05% BSA], and 24 µl H_2O. *Note: Formamide, SSC, and SDS should be filtered through a 0.22-µm syringe filter.*

2. *Nonstringent wash buffer* (*400 ml*): Mix 120 ml 20× SSPE, 0.2 ml 10% Tween 20, and 279.8 ml H_2O

3. *Stringent wash buffer* (*400 ml*): Mix 1.2 ml 20× SSPE and 398.8 ml H_2O

Steps

1. Combine 1 µg of each labelled cRNA (both Cy3 and Cy5, 1 : 1 ratio) and dry the combined target sample in a Speed-Vac for 30 min until the volume is only a few microliters (~2 µl). Avoid drying the sample completely.

2. Resuspend the sample in 20 µl hybridisation mix. Vortex slightly and incubate for 10 min at room temperature.

3. Place the slide and the LifterSlip on the heating plate (42°C) for a few minutes (array side up!). The LifterSlip should be cleaned with 96% ethanol and dried before use.

4. Denature the sample at 95°C for 2 min and let cool to 42°C in the prewarmed hybridisation oven until use.

5. Spin the sample for 5 min at 12,000 *g* and apply it onto the LifterSlip, avoiding air bubbles (Fig. 5A) and attach the slide (array side down!) to the liquid (Fig. 5B)—the LifterSlip should stick to the slide. Place the slide with the LifterSlip in the hybridisation chamber. To avoid drying out, add 70 µl 3× SSC to the reservoirs in the hybridisation chamber (Fig. 5C) and

FIGURE 5 Overview of the hybridisation procedure. (A) Applying the target sample to the LifterSlip. (B) Attaching the LifterSlip to the slide. (C) Humidifying the hybridisation chamber. See text for details.

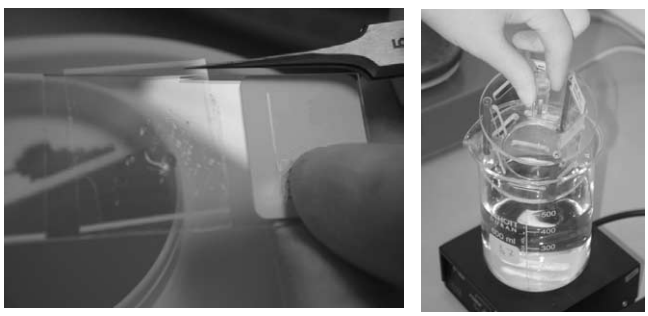

FIGURE 6 Overview of washing procedure. (A) Removing the LifterSlip from the slide. (B) Washing the slides. Slides have been placed in the rack.

make sure that the hybridisation chamber is closed tightly. Place it in the hybridisation oven at 42°C and incubate for 16 h. *These steps should be performed in a clean environment, as dust particles trapped within the hybridisation area will show on the scanning and hamper the results.*

Steps

1. Take out the hybridisation chamber with the slide from the hybridisation oven.
2. Remove the LifterSlip carefully with *a pair of tweezers* (Fig. 6A). Do not touch the array area. Try to remove it *vertically*, not horizontally.
3. Quickly transfer the slide into the slide rack and immediately submerge the slide rack into the nonstringent wash buffer (Fig. 6B). It is essential that the time used for these first steps (2–3) be minimised to ensure that the array area does not dry out.
4. Wash the slide for 30 s with gentle agitation in the nonstringent wash buffer.
5. Transfer the slide rack to the stringent wash buffer and wash for 10 s with gentle agitation.
6. Dry the slide by centrifugation (800 rpm for 3 min).

VIII. SCANNING

A. Introduction

Many different laser scanner and CCD camera imaging systems are available. This section outlines a few principles in the laser scanning imaging process, but it is recommended to read the manufactures instructions carefully for a detailed description.

B. Materials and Instrumentation

ScanArray 4000 laser scanner (Perkin Elmer)

Steps

After the slides have been dried they are ready to be scanned. For optimal fluorescence it is advisable to scan the slides immediately after they have been dried. If the slides cannot be scanned at this time, store them dark and desiccated.

1. Turn on the laser scanner and allow the 543-nm (Cy3) and 633-nm (Cy5) lasers to warm up. Set the desired parameters on the scanner, e.g., laser power and PMT gain and resolution. We recommend fixing the laser power at 100% and automatically adjust PMT settings. Otherwise, we recommend the following settings: 100% laser power and 55% PMT for the Cy5 fluorophore and 100% power and 70% PMT for the Cy3 fluorophore.
2. Select the area to be scanned. The (X, Y) values defining the position of the grid on the slide are set in the printing procedure.

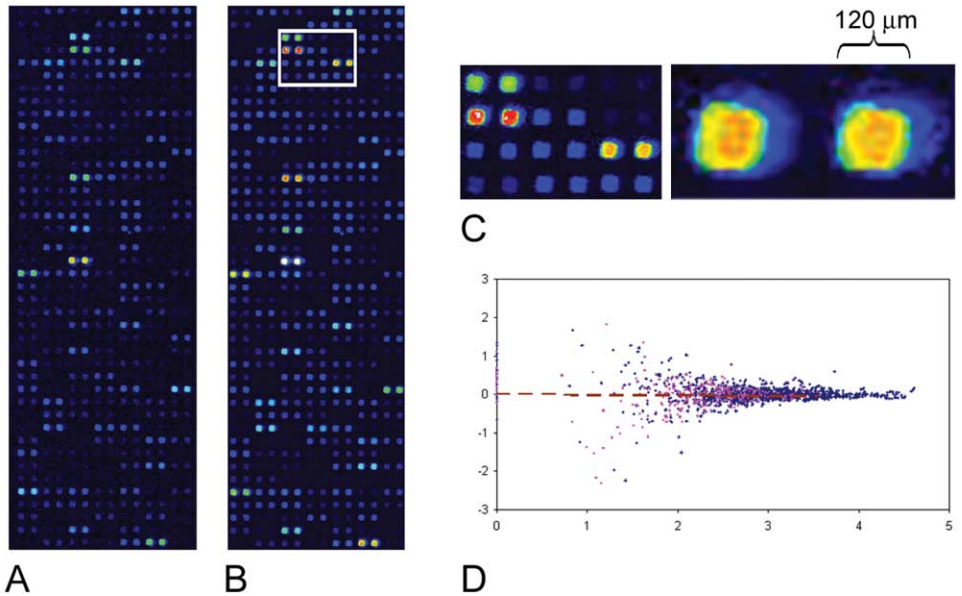

FIGURE 7 Two colour hybridisation. Scanned image of a Cy3- (A) and Cy5-labelled (B) cRNA hybridised overnight at 42°C. The same cRNA was labelled with the two dyes in order to measure the degree of variation between the two channels. (B) Enlarged view of spots. (C) MA plot of data generated from the two images. Data were normalised using a Lowess nonlinear normalisation and background corrected. The dotted line illustrates the regression line through the points. The correlation coefficient is 0.96 and indicates a low variation in a self versus self-hybridisation experiment.

3. Clean the backside of the slide to be scanned with a soft paper towel wetted with 96% ethanol. Allow the ethanol to evaporate.

4. Load the microarray (face up) into the scanner and scan the slide.

5. Save the Cy3 and Cy5 data images in an appropriate format for data analysis (Fig. 7).

IX. PITFALLS

1. Irregular spot morphology: Check the printing pins. Make sure that the temperature and humidity are kept constant when printing the slides.

2. The spotting solution should not contain aliphatic amino groups (e.g., Tris buffer) or nucleophiles (e.g., ethanolamine, lysine, and free ammonium), as these substances will compete for the active groups on the slide and inhibit the covalent coupling of the DNA to the slide. Detergents (e.g., Tween 20, SDS) should not be included in the printing solution, as they will decrease the binding efficiency on the CodeLink slides.

3. Uneven or high background after blocking: Make sure not to extend the time of blocking. Always use clean and freshly prepared solutions. Always clean glassware thoroughly after use.

4. Uneven or high background after hybridisation: Make sure that the target sample is washed properly after precipitation and does not contain free dye molecules. Be sure to use clean washing solutions and lab ware. Even trace amounts of dyes in lab ware may lead to increased background. Check that the labelling efficiency is in the desired range (20–50 dye molecules per 1000 nucleotides). Be sure the target has not dried out during incubation. If needed the sample volume may be increased.

5. Low signals after hybridisation: Check the labelling efficiency. Scan the slide again with increased laser power or PMT.

6. The spots are overlapping: Check that the relative humidity is below 35% during spotting.

ArrayExpress: A Public Repository for Microarray Data

Helen Parkinson, Susanna-Assunta Sansone, Ugis Sarkans, Philippe Rocca-Serra, and Alvis Brazma

I. INTRODUCTION

ArrayExpress is a public repository for microarray data developed and maintained at the European Bioinformatics Institute. ArrayExpress has three major goals: (1) to serve as an archive for microarray data associated with scientific publications and other research, (2) to provide easy access to microarray data in a standard format for the research community, and (3) to facilitate the sharing of microarray designs and experimental protocols. ArrayExpress has been online since 2002 (Brazma *et al.*, 2003). ArrayExpress contains data from over 3400 hybridisations from 10 different organisms, including human and all major model organisms (as of January 2004). ArrayExpress accepts data from all microarray platforms and supports the following experiment types: gene expression experiments, CHG, and chromatin IP.

ArrayExpress supports two standards developed by the Microarray Gene Expression Data (MGED) Society (http://www.mged.org): minimum information about a microarray experiment (MIAME) (Brazma *et al.*, 2001), a content standard, and microarray expression data mark-up language (MAGE-ML), a format standard (Spellman *et al.*, 2002). MIAME specifies the minimum information that has to be provided about a microarray experiment to enable its unambiguous interpretation and potential reproducibility. According to MIAME conventions, a microarray *experiment* is defined as a set of related hybridisations (often related to a publication). To satisfy MIAME requirements, the description of the overall experiment structure-sample, hybridisation, array design, and protocol(s) used in the experiment, alongside raw and normalised data files-should be provided (Fig. 1). MIAME compliant data are loaded into ArrayExpress in MAGE-ML format and the ArrayExpress implementation is based on the MAGE-OM.

Since December 2002, many of the major scientific journals, including *The Lancet*, the *EMBO Journal* and journals from the *Nature* group require MIAME compliant data submissions to public repositories such as ArrayExpress and GEO (Edgar *et al.*, 2002). A third public repository, CIBEX, is currently under development at DDBJ, Japan. As a result of journal requirements, both the number of submissions and the amount of data in ArrayExpress are growing rapidly.

Data in ArrayExpress can be accessed via the Web interface at http://www.ebi.ac.uk/arrayexpress. Users requiring programmatic access should contact arrayexpress@ebi.ac.uk for advice.

ArrayExpress is organised into three sections: *arrays*, *protocols*, and *experiments*. Each experiment, array, and protocol in ArrayExpress is given a unique accession number (see Section III for format information). ArrayExpress provides a password-protected log-in service for private submissions—this option can be used for anonymous reviewing of microarray experiment-based publications or for submitters to access their data before release. When data are released, this facility is withdrawn.

This article describes how to submit and access data in ArrayExpress.

II. DATA SUBMISSION

Data can be submitted to ArrayExpress either online using the microarray experiment submission and annotation tool MIAMExpress (http://www.ebi.

Copyright 2006, Elsevier Science (USA).
All rights reserved.

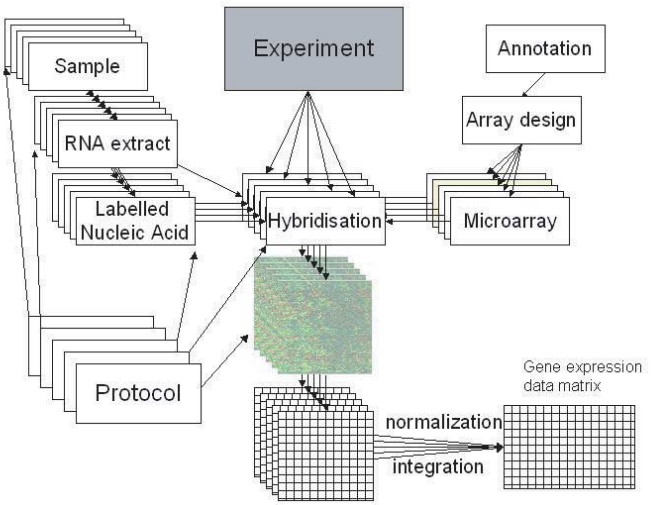

FIGURE 1 A schematic diagram of MIAME requirements showing relationships among the sections, including experiment structure, sample(s) description, hybridisation(s), array design(s), and protocols used.

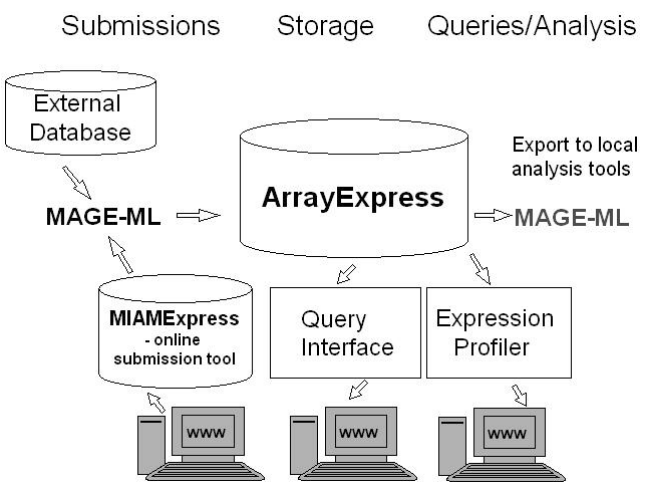

FIGURE 2 A schematic diagram of the ArrayExpress components, including data submission routes, data query, and data analysis.

ac.uk/miamexpress) or as a MAGE-ML-formatted file (Fig. 2). The second route is discussed briefly at the end of this section. The user opens an account, enters the experimental annotation, links the data files (normally stored on the user's local PC or file server accessible to the browser), and completes data submission. A typical submission of an experiment consisting of about 20 hybridisations will usually take 1 h (assuming that the submitter has read the basic instructions provided in the online help page). This section describes submission via MIAMExpress in detail.

To start a submission, users are required to create an account and provide contact details. They receive an email with their log-in details and can log-in again at any time whilst the submission is incomplete. A schematic diagram of a MIAMExpress submission is shown in Fig. 3. We suggest that users submit in the order: *arrays*, *protocols*, and *experiment(s)*. This is because the *arrays* and *protocols* are used within an *experiment* submission and observing this order speeds up the submission process. Users can try out MIAMExpress by clicking on the "Try me" option.

MIAMExpress is based on the MIAME checklist (Ball *et al.*, 2002) and the required fields appear as a series of text boxes, each of which has links to contextual help.

Whenever possible MIAMExpress uses drop-down lists of controlled vocabularies, helping the user select the appropriate term for the required field, and free text boxes are provided to add new terms. MIAMExpress is a generic tool, which is suitable for any species or domain, and is suitable for single and dual channel experiments and gene expression and CGH data submissions. MIAMExpress has been developed further for the toxicogenomics community (see Section II,C,6) and an Arabidopsis version is under development; both these versions have added domain-specific information and use specific vocabularies.

In MIAMExpress, as in MIAME, an *experiment* is defined as a group of related hybridizations. A completed submission consists of three parts: *arrays*, *protocols*, and *experiments*. The same *protocols* and *arrays* can be reused in many experiments, thereby making subsequent submissions quicker, especially if commercial arrays are used. MIAMExpress allows users to log back in to a submission at any time until it is completed. Once a submission is complete, data are exported from the MIAMExpress database (as MAGE-ML) and curated by the ArrayExpress curation team.

A. Arrays

Users need to submit details of the design of the array only if they are using a self-made array. The manufacturers normally provide details of commercial arrays. Users can check if their arrays are already present in the database using the "Browse existing arrays" link. If a particular commercial array is not present, the user should contact the ArrayExpress curation team (arrayexpress@ebi.ac.uk). ArrayExpress contains x commercial array designs from suppliers such as Agilent, Affymetrix, and Incyte and x user-supplied array designs, including many from academic facilities (figures from January 2004).

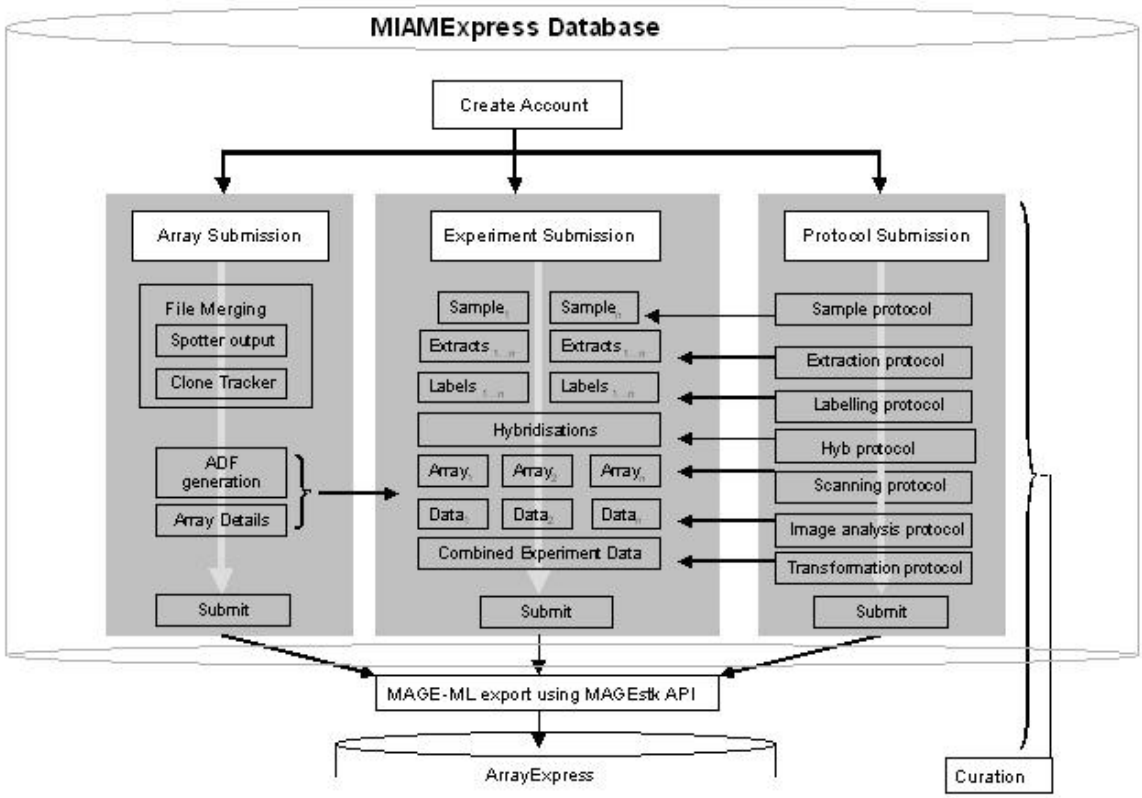

FIGURE 3 A schematic representation of the MIAMExpress submission process showing the branching tree structure of submissions.

Array designs are submitted in Array Design File (ADF) format; a simple tab delimited format, which is generated by merging a spotter output file and a clone tracker file. The ADF provides information layout (from the spotter output file) and the biological annotation for each spot (from the clone tracker file) in a single file. To allow users to access up-to-date annotation for their arrays, the ADF converter tool has been developed. It consists of a web form through which users submit a series of database identifiers, which describe the sequences on the array. These are submitted to EnsMart (Kasprzyk *et al.*, 2004), the output of the query is current sequence annotation (gene names, chromosomal location, and GO terms) in the form of database identifiers preformatted as an ADF-compatible file. Full help on the ADF is provided (http://www.ebi.ac.uk/miamexpress/help/adf/ADF_Help.htm) and the ArrayExpress curation team provides assistance in helping users generate ADF files for their arrays. MIAMExpress also allows submission of MIAME required information: species represented on the array, the surface/substrate type, a text description of the array, and finally the protocol used to manufacture the array. On submission of the array, users can use it immediately in an experiment submission and the ArrayExpress curation team will perform curation.

B. Protocols

All protocols (except those that relate to array design) are entered from a single protocol submission page. The different protocol types are sample growth, sample treatment, sample pooling, nucleic acid extraction, labelling, hybridisation, scanning, and data transformation (normalization). Different protocol types have different (MIAME) required parameters, e.g., when describing the labelling process, users must select which nucleic acid was labelled from a drop-down list of defined terms. Unchanged protocols can be reused in subsequent submissions.

C. Experiments

MIAMExpress employs a top-down annotation approach starting from the general information about the experiment, describing each sample and the extract(s) prepared from it, to a hybridisation(s)

process [linking labelled extract(s) to arrays], and the files (Fig. 3). Thus the user generates a branching tree structure as they enter information.

1. General Information

At the beginning of a submission, users are required to provide general information about the experiment, including a brief description and selecting an experiment design type and experimental factors from drop-down lists. For example, in an experiment where a sample is treated with a compound, the design type is "compound treatment" and factors could be the name of the compound. In cases where the supplied terms are not useful, users are encouraged to submit their own via the "other" text box present on all drop-downs. Information on publications and quality control methods can be provided. Users are asked to indicate the date for the experiment to be made public. Finally, in this section the total number of samples used in the experiment is provided and these are created for annotation. Samples can be added or deleted at any time during the submission process simply by returning to this experiment page and using the "Create" or "Delete" option.

2. Samples

Each sample is given a default name; we suggest that this is changed to one meaningful to the user. Species, sample type, and disease state information is supplied in boxes and the user decides which information is relevant for their experiment. This information can be copied across all samples for ease of submission. MIAME requires that sample-related protocols should be supplied and these are linked on this page. These can also be copied and pasted across multiple samples to limit the time needed for submission. It is also possible to navigate between samples by using the "Next" or "Previous" link; alternatively, these can be navigated by the list provided on the experiment page.

3. Extracts and Labelled Extracts

Each sample has one or more extracts—in single channel experiments usually there will be only one per sample. Users proceed from defining and describing a sample to creating a relationship between samples and extracts (Screenshot 1). Users define how many extracts they need and a drop-down list appears. Relevant samples are selected from this list. Pooling is supported as multiple samples can be linked to a single extract. For example, several organs from different mice may need to be pooled to provide sufficient nucleic acid for labelling. A "View/Edit" button opens the page for each extract. All extracts require an extraction protocol to be linked and where pooling is performed the pooling protocol can also be linked from this page. Protocol information can be propagated to all subsequent extracts, meaning users need only define this for the first sample. Users should complete all the extract annotation before proceeding to providing information about labelling.

Users are required to create labelled extracts for each extract. For a two-channel experiment with a dye swap, there will typically be two labelled extracts per extract: cy3 and cy5. For a single-channel system (like Affymetrix) the labelled extract-to-extract relationship is one to one. Once the labelled extracts are created, the labelling protocol is linked and this information can be propagated to all subsequent labelled extracts. The relationships among the samples, extracts, and labelled extracts are shown in Fig. 3.

4. Hybridizations

Hybridizations are created after the samples, extracts, and labeled extracts are annotated completely. If there are unannotated objects in the sample extract-labeled extract hierarchy (Fig. 3), an error page appears with hyperlinks to each object so they can be completed.

Users must select the number of hybridizations they want to create. Hybridizations can be added or deleted using the "Create" or "Delete" option. Each hybridization can be linked to the appropriate label by selecting them from a drop-down list. Array designs are selected from a list of the users own and publicly available designs.

5. Data Files

Data files are linked to hybridizations by uploading them from a local machine via a browse button. There is normally one raw and one normalized per hybridization. At least one data file per hybridization must be provided. MIAMExpress accepts data files in meta row, meta column data format, and block, row, and column data format (e.g., GenePix), which covers the majority of scanners. Full information and guidance on formatting cDNA and Affymetrix data files can be found in the contextual help (http://www.ebi.ac.uk/miamexpress/help/data_files.html). Relevant protocols must also be provided at this point (hybridization, scanning, normalization) and, as before, can be copied across all hybridizations after the first one has been annotated. Finally, a summary data file—the "Final Gene Expression Matrix" (FGEM)—may be provided. Typically this file will be generated from some transformation of the normalized data files and may be

averaged across replicates. For example, for a four-point time course experiment (0, 1, 2, 3), with two replicates per time point, the following data files may be submitted: eight raw data files (two per time point, one per hybridization), eight normalized files (two per time point, one per hybridization), and a FGEM file. Each column represents a single time point, where values have been averaged across the two replicates. Users can specify which hybridizations contributed to each column in the FGEM by providing the hybridization identifiers in the header row. Multiple quantitation types can also be provided in the same way. Rows in the FGEM typically correspond to genes and are matched with gene information provided in the ADF. On completion of submission, the experiment submission is locked; it can be released by curators, for example, to add additional information. The submission is exported from MIAMExpress in MAGE-ML format, an accession number is assigned, and it is loaded into ArrayExpress. All submissions are held confidential until the release date specified by the user.

6. Tox-MIAMExpress

Tox-MIAMExpress (http://www.ebi.ac.uk/toxmiamexpress/) is a specific version of the annotation and submission tool that links microarray data with biological end points (e.g., clinical observations, clinical chemistry, and histopathology evaluation) (Mattes *et al.*, 2004). While maintaining the general functionality of MIAMExpress, Tox-MIAMExpress provides the users with additional fields to describe toxicogenomics or pharmacogenomics specific details, such as treatment with a compound. Tox-MIAMExpress also allows submission of additional detail at the sample level. Users can provide the usual information on species and detail complex treatments such as compound/drug, dose, and delivery method. Details of blood/urine analysis commonly needed in toxicogenomics or pharmacogenomics experiments are provided via drop-down lists of terms and units. Pathological findings related to samples are entered onto a downloadable Excel spreadsheet (http://www.ebi.ac.uk/tox-miamexpress/pics/Pathology-Observation.xls). Protocols are linked to these sample treatments, in addition to the usual protocols required by MIAMExpress. Users provide information, including sample biometrics (e.g., body weight, organ weight), the target organ, and select nominal measurements, to describe any pathological changes of the organ (morphologies). This is then uploaded to Tox-MIAMExpress; the information is stored in the database and exported on completion of submission.

D. Direct MAGE-ML Submissions

Preparing MAGE-ML files is usually not a practical option for small laboratories. This direct submission route is used by laboratories with their own local microarray database systems or LIMS. In this case, a MAGE-ML export pipeline can be established from the source database directly to ArrayExpress. As of January 2004, MAGE-ML pipelines have been established from a number of local databases, including the Stanford Microarray Database (SMD) (Gollub 2003), TIGR microarray database (Saeed 2003), and German Genome Resource Centre (RZPD). Several microarray informatics tools, such as GeneSpring 6.1 (http://www.silicongenetics.com/), J-Express (http://www.ii.uib.no/~bjarted/jexpress/), and BioConductor (http://www.ebi.ac.uk/~ele/ext/submitter.html) are currently implementing MAGE-ML export and import. These developments will simplify data submission for many submitters and illustrate the utility of MAGE-ML as a data exchange format. Development of the pipeline from the SMD is described in an article available from the ArrayExpress Web site, which describes mapping a database to the MAGE-OM and implementing export using open source tools. If you wish to establish such a pipeline, please check the documentation on the ArrayExpress Web site (http://www.ebi.ac.uk/~ele/ext/submitter.html) or contact ArrayExpress at arraysubs@ebi.ac.uk for detailed advice.

III. ACCESSING DATA IN ARRAYEXPRESS

Querying data in ArrayExpress requires a web browser. Accession numbers in ArrayExpress are of the form E-XXXX-N, A-XXXX-N, or P-XXXX-N for experiments, array designs, and protocols respectively, where XXXX denotes an abbreviation of data source or data processing software and N is a number. For instance, an experiment submitted via a pipeline from the Stanford Microarray Database has accession numbers E-SMDB-N. All experiments submitted via MIAMExpress have accession numbers E-MEXP-N.

All routes to access and retrieve data from ArrayExpress consist of two basic steps.

1. Select the submission, i.e., experiment, array, or protocol, of interest by browsing or querying the database.
2. Explore the required information from the chosen submission and retrieve data.

Browsing or querying returns a brief description of the selected experiment, array, or protocol, which we will refer to as a *top-level* description. The top-level description consists of a brief summary of the submission and provides hyperlinks, which the users follow to explore data in detail or to perform specific tasks, such as retrieving raw or normalised data.

A. Retrieving the Top-Level Description

There are four ways to retrieve top-level descriptions.

1. Click on "View" experiments, arrays, or protocols.
2. Click on "Browse database."
3. Click on "Query database."
4. Click on "Log-in" (to access for submitters to non-public password-protected data).

The first two options are used to get an overview of the database. Query and log-in are described in detail in the following sections.

1. Query Database: Accessing Publicly Available Data

Clicking on "Query database" brings up the standard query interface page, which is organised into three separate sections: experiments, arrays, and protocols. The user is logged into the database as a "guest" by default and can only query public datasets. Experiments, arrays, or protocols can be retrieved quickly by their respective accession numbers or by their attributes, such as species, laboratory, or array type used in the experiment. For example, to retrieve all experiments from a single species *C. elegans*, select *Caenorhabiditis elegans* from the drop-down menu in the "organism" field of experiment menu and click on "query." This will retrieve all experiments that used samples of this species.

Combined queries are possible (for instance, by species and array type). If no query fields are completed, the query will retrieve all experiments, arrays, or protocols, respectively. Queries are case insensitive and wild cards are permitted. A query can be revised by going back to the query page (using the browser back button) and revising the selection criteria. For example, to retrieve all experiments involving human samples, you can select *Homo sapiens* from the drop-down list in the organism field and query for experiments. The user then can go back to the main query page and additionally choose *Affymetrix* from the array field to retrieve only experiments annotated as *Homo sapiens* and using Affymetrix arrays. If the query does not retrieve any results, this means that query criteria are too stringent and that there are no submissions in the database satisfying this particular combination of parameters. In this case the user should check the selected query parameters and relax them or use the browse options to explore data at a higher level.

2. Log-in: Accessing Password-Protected Data

Clicking on "Log-in" brings up the log-in page, where the user has to type in a user name and password. Passwords are only provided to the data submitter and authorised persons (with the permission of the submitter), such as journal editors and reviewers. Passwords are used to protect unreleased datasets until the specified release date. Once logged in, the query interface is identical to the query page described in Section IIIA.

B. Exploring the Experiment and Retrieving Data

Once an experiment, array, or protocol is selected, users can retrieve further details. For instance, experiments may contain raw and normalised data consisting of different quantitation types. The interface allows the user to select and export data from specific quantitation types from raw and/or normalised data. Users can also compare array designs or view protocols. This section describes data retrieval and exploration of experiments and protocols in detail.

Top-level information for experiments provides a brief free text description supplied by the submitter and an autogenerated experiment description, which indicates the number of samples and arrays used, hybridizations, and data files produced, as well as information on sample attributes, e.g., species. Hyperlinks help the user navigate to complete information on authors, laboratory, and type of experiment. By clicking on "Retrieve data," users retrieve a summary page of data associated with the particular experiment. The information is organized in two or more columns.

Column 1: Lists available data files and their type (raw or normalised). Raw data files are displayed first.
Column 2: List of quantitation types, with links to descriptions.
Column 3: List of sequence annotation, such as "Database accessions" and "Gene names" (only for arrays submitted after July 2003).

Any (or all) of the items in the columns can be exported to a tab-delimited data file. By clicking on "Export data," users can export the selected information and view them in tab-delimited format by clicking "View data matrix." The data matrix will appear in a new browser window and can be saved locally for future use. Alternatively, selected data can be imported

directly into Expression Profiler for analysis online (Vilo *et al.*, 2003).

Users can export data from several hybridisations/normalisations in a single file if the same array has been used, if data are about the same set of features (spots), reporters, or composite sequences (genes), and the same quantitation types are provided. In other cases, where, for example, only a subset of genes have expression values, data are exported as multiple files as the file will have different numbers of rows and/or columns.

C. Arrays

Users can query array designs by name, provider, and species. Details of the array layout and annotation are provided either as a spreadsheet (the ADF used to submit the array design through MIAMExpress) or as a simple tab-delimited file, both containing active hyperlinks to respective databases used for annotation. Both formats contain a single line for every feature (spot) on the array, except for Affymetrix arrays, where each line corresponds to a probe set due to the large number of rows in Affymetrix raw data files. Users can request complete Affymetrix data files by emailing arrayexpress@ebi.ac.uk and stating the accession number.

D. Protocols

When querying the protocols, users retrieve a list, including basic information (name, type, description) and protocol parameters.

IV. FUTURE PLANS

ArrayExpress repository can currently be queried by a number of parameters, including species, array design provider, and experiment type, as described earlier, returning a set of experiments, array designs, or protocols. However, querying the repository, users cannot retrieve, for example, all experiments where expression of a certain gene has been tested or the expression values of genes from a certain GO category and for samples treated under certain conditions.

To enable such granular queries, a data warehouse is under development. Users will be able to query parameters, including gene names, gene properties, ranges of expression values, and sample properties. The resulting query will return lists of genes, samples, or matrices of expression values (across many experiments). The database schema is very different from that of the ArrayExpress repository: whereas the repository has to be able to store all experimental details (MIAME and beyond) and import all well-formed MAGE-ML submissions, the main issue of the data warehouse is how well it can support queries of many different types.

The data warehouse will only contain a subset of the good quality experiments deposited in the database. Data from the repository to the data warehouse cannot be transferred automatically. It will require curation and selection of specific experimental properties important from the data mining perspective. For example, in the repository there is no distinction made among experiments on which measurements are the best estimates of gene expression levels and which specific sample properties (apart from experimental factors) are important from the data mining perspective.

A unique interface will allow users to query the repository and the data warehouse. Links from the data warehouse to the repository will be implemented to allow users to navigate from gene expression data to the experiment context.

Acknowledgments

The ArrayExpress design and software development is coordinated by Ugis Sarkans, with a major contribution from Gonzalo Garcia Lara. Mohammad Shojatalab coordinates MIAMExpress development, with major contributions from Niran Abeygunawardena and Sergio Contrino. The has been largely developed by the ArrayExpress curation team: Helen Parkinson, Ele Holloway, and Gaurab Mukherjee and Philippe Rocca-Serra and Susanna-Assunta Sansone. Susanna-Assunta Sansone developed the specification for Tox-MIAMExpress and implementation has been largely the work of Sergio Contrino. Helen Parkinson has coordinated the data curation and construction of MAGE-ML pipelines to ArrayExpress, with major contributions from Philippe Rocca-Serra, Ele Holloway, and the software development team. Anjan Sharma has developed a data management tool allowing curators to manage the growing number of data submissions. Ahmet Oezcimen is the ArrayExpress database administrator. Jaak Vilo, Misha Kapushesky, and Patrick Kemmeren developed expression Profiler. ArrayExpress is largely funded by the TEMBLOR grant from the European Commission, with contributions from International Life Sciences Institute, Health and Environmental Safety Institute (ILSI-HESI) and from CAGE grant from the European Commission. Incyte Genomics provided the initial funding. We also thank the MGED community, particularly Catherine

A. Ball, Gavin Sherlock, Pall Spellman, John Quackenbush, and Chris Stoeckert.

Serial Analysis of Gene Expression (SAGE): Detailed Protocol for Generating SAGE Catalogs of Mammalian Cell Transcriptomes

Sergey V. Anisimov, Kirill V. Tarasov, and Kenneth R. Boheler

I. INTRODUCTION

Serial analysis of gene expression (SAGE) is a sequencing-based technique that permits the simultaneous evaluation of thousands of transcripts in a single assay. SAGE relies on two major principles: (1) short DNA sequences are sufficient for identifying individual gene products and (2) concatenation (linking together) of short DNA sequences or tags increases the efficiency of identifying expressed mRNAs in a sequence-based assay. The transcript profile generated by SAGE currently relies on 14 to 21 base nucleotide sequences (SAGE tags) for gene identification (Velculescu, 1995; Saha, 2002). The technique generates large numbers of short tags, originating from the last (most 3′) unique location of a restriction enzyme recognition site in a cDNA generated from a single transcript. When the tags are sequenced, the technique can theoretically identify up to 4^{10} (1,048,576) unique transcripts; however, the newer LongSAGE method can distinguish 4^{17} different tags, a number sufficient to be virtually unique even within the whole genome.

II. MATERIALS AND INSTRUMENTATION

Kits: Messagemaker kit (Cat. No. 10298-016) and cDNA synthesis kit (Cat. No. 18267-013) are from Invitrogen. Deoxynucleotide triphosphates (dNTP) (Cat. No. US77100) are from Amersham.

Enzymes: T4 DNA Ligase (1 and 5 U/µl; Cat. Nos. 15224-017 and 15224-041) is from Invitrogen. Restriction enzymes *NlaIII* (Cat. No. 125S), *BsmFI* (Cat. No. 572S), *SphI* (Cat. No. 182S), and T4 polynucleotide kinase (PNK, Cat. No. 201S) with corresponding buffers are from New England Biolabs. DNA polymerase I Klenow fragment (Cat. No. M2201) is from Promega. AmpliTaq Gold polymerase (Cat. No. 4311814) is from Applied Biosystems.

DNA molecular weight markers: 25 bp (Cat. No. 10597-011), 100 bp (Cat. No. 15628-050), and 1 kb (Cat. No. 15615-016) are from Invitrogen.

Reagents: Dimethyl sulphoxide (DMSO, Cat. No. D2650), ammonium sulfate [$(NH_4)_2SO_4$, Cat. No. A5132], magnesium chloride ($MgCl_2$, Cat. No. M8266), potassium phosphate, monobasic (KH_2PO_4, Cat. No. P5379), potassium phosphate, dibasic (K_2HPO_4, Cat. No. P2222), sodium perchlorate ($NaClO_4$, Cat. No. S1513), and β-mercaptoethanol (Cat. No. M7522) are from Sigma. Agarose (Cat. No. 15510-027) is from Invitrogen, ATP (Cat. No. 27-1006.01) is from Amersham, and NaCl (Cat. No. 7581) is from Mallinckrodt.

Electrophoresis reagents: Polyacrylamide solutions (acrylamide : bisacrylamide, 19 : 1 (Cat. No. 161-0144) and 37.5:1 (Cat. No. 161-0148)), *N,N,N′,N′*-tetramethylenediamine (TEMED, Cat. No. 161-0800), and ammonium persulfate (Cat. No. 161-0700) are from Bio-Rad. TBE polyacrylamide precast gels (20%, Cat. No. EC6315) are from Novex.

All rights reserved.

Solutions: Ethylenediaminetetraacetic acid, disodium (Na_2EDTA, 0.5 *M*, pH 8.0, Cat. No. 3400-1003, Digene), phenol–chlorophorm–isoamyl alcohol mix (PC8, 25:24:1, pH 8.0, Cat. No. 0883, Amresco), isopropanol (Cat. No. 9084-01, J.T. Baker Inc.), and absolute ethanol (Cat. No. 201096, Warner-Graham Co.) are from commercial vendors. Tris/acetate/EDTA (TAE, 50×, Cat. No. 330-008-161), Tris–HCl (1 *M*, pH 7.5; Cat. No. 351-006-100; 1 *M*, pH 8.0 Cat. No. 351-007-100), sodium acetate ($C_2H_3NaO_2$, 3 *M*, pH 5.2, Cat. No. 351-035-060), NaCl (5 *M*, Cat. No. 351-036-100), and EDTA (0.25 *M*, pH 7.0, Cat. No. 118-090-060) are from Quality Biological. Diethylpyrocarbonate (DEPC, 0.1%)-treated water (Cat. 395-000), Tris/borate/EDTA buffer (TBE, 10×, pH 8.3, Cat. No. 336-000), and SOC media (Cat. No. 396-110) are from BioSource.

Other materials: Tryptone (Cat. No. 0123-17), yeast extract (Cat. No. 0127-01-7) and Bacto–agar (Cat. No. 0140-01) are from Difco. ElectroMAX DH10B cells (Cat. No. 18290-015), pZErO-1 (Cat. No. 2500-01), and zeocin (Cat. No. R250-01) are from Invitrogen. SYBR green I (Cat. No. S-7567) is from Molecular Probes, and glycogen (Cat. No. 901 393) is from Boehringer. Dynabeads M-280 (Cat. No. 112.05) are from Dynal.

Oligo-DNA linkers and primers are synthesized by Invitrogen. ***Linker 1A*** (gel purified): TTTGGATTTGCTGGTGCAGTACAACTAGGCTTAATAGGGACATG; ***linker 1B*** (gel purified): TCCCTATTAAGCCTAGTTGTACTGCACCAGCAAATCC[amino mod. C7]; ***linker 2A*** (gel purified): TTTCTGCTCGAATTCAAGCTTCTAACGATGTACGGGGACATG; ***linker 2B*** (gel purified): TCCCCGTACATCGTTAGAAGCTTGAATTCGAGCAG[amino mod. C7]; ***primer 1***: GGATTTGCTGGTGCAGTACA; ***primer 2***: CTGCTCGAATTCAAGCTTCT; ***5′-biotinylated oligo(dT)*** (gel purified): [biotin]T_{18}; ***M13 forward***: GTAAAACGACGGCCAGT; ***M13 reverse***: GGAAACAGCTATGACCATG.

Equipment: GeneAmp PCR systems 9600 and 9700 are from Perkin-Elmer. For polyacrylamide electrophoresis, use a protean II electrophoresis unit (Bio-Rad) or similar. For agarose electrophoresis, use Hoefer HE33 (Pharmacia) or similar. For precast polyacrylamide gels, use XCell II (Novex). Power supply: Power PAC 3000 (Bio-Rad) or similar. Electroporation is performed on Gene-Pulser II/Pulse Controller II system (Bio-Rad) in 0.2-cm cuvettes (Bio-Rad, Cat. No. 16086). The magnetic particle concentrator is of MPC-E type from Dynal; RT6000 centrifuge and H1000B rotor are from Sorvall.

Required standard laboratory equipment: Millipore H_2O system, bacterial incubator, orbital shaker, autoclave, imaging system with UV light, sequencer, and microfuge.

Plastics: SpinX microcentrifuge tubes (Cat. No. 8160) are from Costar, Hot Start 50 tubes (Cat. No. 6002) are from Molecular Bio Products, Nunc sterile 96-well plates with lids, U-shape (Cat. No. 81-6668-03) and SealPlates, sterile (Cat. No. 05-6125-12) are from PGC Scientific. Thermo-Fast 96-well detection plate Cat. No. AB-1100) and adhesive sealing sheets (Cat. No. AB-0558) are from Marsh Bioproducts. MicroAmp reaction tubes (Cat. No. 801-0580) and MicroAmp caps (Cat. No. 801-0535) are from Applied Biosystems.

Software: SAGE sequence analysis: SAGE 2000 V4.13 or better is recommended (available at http://www.sagenet.org); Database download: CuteFTP (GlobalSCAPE, Inc.), DOS to UNIX Text Converter (Streamline Solutions), WinRAR for Windows (any manufacturer); MS Access and MS Excel (Microsoft).

III. PROCEDURES

A. SAGE Protocol

This protocol is modified from those of Velculescu *et al.* (1995), Kenzelmann and Muhlemann (1999), and Anisimov *et al.* (2002). The whole protocol takes about 5–6 days, but this time will vary depending on the experience of the investigator.

Solutions

1. *2× binding and washing buffer (B + W):* 10 m*M* Tris–HCl (pH 7.5), 1 m*M* EDTA, 2.0 *M* NaCl. For 100 ml final, add 1 ml of 1 *M* Tris–HCl (pH 7.5), 1 ml 0.1 *M* EDTA, and 11.69 *g* of NaCl, adjust the volume with sterile H_2O, and store at room temperature.

2. *LoTE:* 3 m*M* Tris–HCl (pH 7.5), 0.2 m*M* EDTA (pH 7.5). For 50 ml final, add 150 µl 1 *M* stock solution of Tris–HCl and 100 µl 0.1 *M* stock solution of EDTA, adjust the volume with sterile H_2O, and store at 4°C

3. *10× PCR Buffer:* 166 m*M* $(NH_4)_2SO_4$, 670 m*M* Tris, pH 8.8, 67 m*M* $MgCl_2$, 100 m*M* β-mercaptoethanol. For 50 ml final, add 1.1 *g* of ammonium sulfate, 16.75 ml of Tris 2 *M* stock solution, 0.32 *g* of magnesium chloride, and 390 µl of β-mercaptoethanol, adjust the volume with sterile H_2O, distribute into 0.5-ml aliquots, and store at –20°C.

4. *Low salt LB agar plates with zeocin:* 1% tryptone, 0.5% yeast extract, 0.5% NaCl, 1.5% bacto-agar, 50 µg/ml zeocin. For 500 ml final, add 5 *g* of tryptone, 2.5 *g* of yeast extract, and 2.5 *g* of NaCl to 450 ml of dH_2O, stir, adjust pH of the solution to 7.5 with NaOH, add 7.5 *g* of Bacto-agar, and adjust the volume to 500 ml. Autoclave, cool to 55°C, add 250 µl of zeocin

100 µg/µl stock, and pour plates. Seal with Parafilm and foil and store at 4° for up to 1 month in the dark.

5. *TB medium base:* Add 12 *g* of tryptone, 24 *g* of yeast extract, 4 ml of glycerol to 900 ml dH_2O final volume and autoclave

6. *Phosphate buffer:* Add 2.3 *g* of KH_2PO_4 and 12.5 *g* of K_2HPO_4 to 100 ml dH_2O final volume and filter sterilize

7. *TB medium/zeocin:* For 1 liter, add 900 ml of TB medium base, 100 ml of phosphate buffer, and add 500 µl of zeocin (100 µg/µl). Store in dark room at 4° for up to 2 weeks.

8. *12% polyacrylamide solution:* For a 20 × 16 × 0.1-cm gel, add 29.4 ml of dH_2O, 13.1 ml of 40% PAAG mix (acrylamide : bisacrylamide, 19 : 1), 875 µl of 50× TAE, 438 µl of 10% ammonium persulfate, and 37.5 µl of TEMED

9. *8% polyacrylamide solution:* For a 20 × 16 × 0.1-cm gel, add 33.75 ml of dH_2O, 8.75 ml of 40% PAAG mix (Acrylamide : bisacrylamide, 37.5 : 1), 875 µl of 50× TAE, 438 µl of 10% ammonium persulfate, and 37.5 µl of TEMED

Preliminary and Routine Procedures

All incubations are performed in a water bath.

1. *Kinasing (phosphorylation) reaction for linkers:* In each of two Eppendorf tubes labeled "linker 1" and "linker 2," add 6 µl of LoTE, 2 µl of 10× kinase buffer, 2 µl of 10 m*M* ATP, and 1 µl of PNK (10 U/µl). Add 9 µl of linker 1B (350 ng/µl) to "linker 1" and 9 µl of linker 2B (350 ng/µl) to "linker 2". Incubate both tubes at 37°C for 30 min and then at 65°C for 10 min. Add 9 µl of linker 1A to "linker 1" and 9 µl of linker 2A to "linker 2." Incubate at 95°C for 2 min, transfer to 65°C for 10 min, then to 37°C for 10 min, and finally to room temperature for 20 min. Kinased linkers are stable at –20°C for up to a year.

2. *Control reaction for linkers:* Prepare four Eppendorf tubes marked as "1+," "1–," "2+," and "2–." Add 20 µl of LoTE, 8 µl of 5× ligation buffer, and 1 µl of kinased linker (linker 1 to tubes marked "1" and linker 2 to tubes marked "2") to each tube. Incubate all four tubes at 50°C for 2 min and then at room temperature for 15 min. Add 2 µl of T4 ligase (1 U/µl) to tubes marked "+" and 2 µl of LoTE to tubes marked "–" and incubate at 16°C for 2 h. Run 1 µl of each sample on 20% precast TBE polyacrylamide gel at 120 V for 3 h and stain with SYBR green I (20 µl/200 ml of 1× TBE buffer) for 15 min while shaking. Observe linkers on the gel under UV light. Only linkers dimerized with >70% efficiency (based on band fluorescence intensity) are acceptable.

3. *Prepare pZeRO-1:* To 4 µl of dH_2O, add 1 µl of restriction enzyme (RE) buffer 2, 2.5 µl of pZeRO-1 (1 µg/µl), 2.5 µl of *SphI* (5 U/µl), and incubate at 37°C for 25 min. Add 90 µl of TE (final concentration is 25 ng/µl) and heat inactivate enzyme at 68°C for 15 min. Quench on ice and use immediately. Linearized pZeRO-1 plasmid can be stored at –20°C, but its cloning efficiency decreases with time.

4. *Phenol–chloroform extraction:* Bring sample volume to 200 µl with LoTE and add an equal volume (200 µl) of PC8 and vortex. Separate the aqueous phase, which contains the DNA, from the organic phase by centrifugation in a microfuge at 7800 *g* for 2 min at room temperature. Transfer the aqueous phase into a fresh Eppendorf tube, while ensuring that no organic solution is included. Reextract if necessary.

5. *Ethanol (EtOH) precipitation:* DNA in aqueous solution can be precipitated by EtOH in the presence of sodium or ammonium acetate. Because of the small amount of DNA and small fragment sizes, glycogen is added as a career. For a 200-µl sample volume in LoTE, add 3 µl of glycogen (20 mg/ml), one-half volume 10 *M* ammonium acetate, and 2.2 volumes ice-cold (–20°C) 100% ethanol and vortex. Pellet the precipitated DNA by centrifugation in a microfuge at 15,300 *g* for 10 min. Remove the ethanol with care and always wash with 75% EtOH to remove any traces of salt. Centrifuge at 7800 *g* for 10 min, discard supernatant, dry the pellet, and resuspend in LoTE. In certain cases, an increased volume of ethanol or 10 min dry ice/ethanol incubation is required on the precipitation step, as indicated in the text.

6. *Isopropanol precipitation:* Bring sample volume to 450 µl with LoTE, add 3 µl of glycogen, 150 µl of 2 *M* sodium perchlorate and 330 µl of isopropanol. Vortex and spin at 15,300 *g* for 10 min at room temperature. Aspirate supernatant, dry the pellet, and resuspend in LoTE.

Steps

1. Prepare poly(A)$^+$ (mRNA) from total RNA with the Messagemaker kit according to the manufacturer's instructions (see Comment 1 and Pitfalls 1 and 2). A total quantity of 0.5–1.0 mg of total RNA gives the best mRNA yield and is convenient for handling.

2. Prepare cDNA from 5 µg of mRNA using a cDNA synthesis kit following the manufacturer's instructions. A 5′-biotinylated oligo$(dT)_{18}$ (500 ng/µl) is, however, suggested for first strand synthesis (see Comment 2). After the second strand reaction is terminated by the addition of 25 µl of 0.25 *M* Na_2EDTA (pH 7.5), extract cDNA sample with PC8, EtOH precipitate, and resuspend the pellet in 20 µl of LoTE.

3. To half the cDNA sample (10 µl), add 163 µl of LoTE, 2 µl of BSA (100×), and 5 µl of *Nla*III (anchoring enzyme, 10 U/µl) (see Pitfall 3). Incubate at 37°C for

1 h, extract with PC8, EtOH precipitate, and resuspend in 20 µl of LoTE. Use the second half of the cDNA sample as a backup.

4. Add 100 µl of resuspended M-280 streptavidin magnetic beads (Dynabeads) to two Eppendorf tubes marked "1" and "2". Use the magnetic particle concentrator to immobilize the beads and discard the storage buffer. Wash beads once with 200 µl 1×B+W buffer and discard the buffer. Add 100 µl of 2×B+W buffer, resuspend, and add 90 µl of dH_2O and 10 µl of cDNA digestion products to each Eppendorf tube. Incubate at room temperature in suspension for 15 min. Wash beads three times with 200 µl 1×B+W and then once with 200 µl LoTE, removing the wash each time after immobilizing the beads using the magnetic particle concentrator. Proceed immediately to step 5.

5. Resuspend the Dynabeads in 25 µl of LoTE and 8 µl of 5× ligase buffer. Add 5 µl of kinased linker 1 to the tube marked "1" and 5 µl of kinased linker 2 to the tube marked "2". Incubate both tubes at 50°C for 2 min and then at room temperature for 15 min. Add 2 µl of T4 ligase (high concentration, 5 U/µl) to each tube and incubate at 16°C for 2 h. Afterward, wash the beads four times with 200 µl 1×B+W and then two times with 1× RE buffer 4. Proceed immediately to step 6.

6. Resuspend the contents of tubes "1" and "2" in 84 µl of LoTE and then add 10 µl of 10× RE buffer 4, 2 µl of 100× BSA, and 2 µl of *Bsm*FI (2 U/µl, tagging enzyme). Incubate at 65°C for 1 h, mixing intermittently, immobilize Dynabeads using magnetic particle concentrator, and collect supernatants. Extract samples with PC8, EtOH precipitate, and resuspend pellets in 10-µl volumes of LoTE.

7. To each of these tagging enzyme digestion products, add 32.4 µl of dH_2O, 5 µl of 10× second strand buffer (from cDNA synthesis kit), 1 µl of 100× BSA, 1 µl of dNTPs (25 m*M*), and 0.6 µl of Klenow (5 U/µl) to fill in the 5′ DNA overhangs. Incubate at 37°C for 30 min, add 150 µl of LoTE, extract samples with PC8, and precipitate with a high concentration of EtOH [add 3 µl of glycogen, 100 µl of 10 *M* ammonium acetate, and 900 µl of ice cold (–20°C) 100% EtOH]. Vortex and pellet the precipitated DNA by centrifugation in a microfuge at 15,300 *g* for 10 min; remove the EtOH with care and wash with 75% EtOH. Centrifuge at 7800 *g* for 10 min, discard supernatant, and dry the pellets. Resuspend pellets in 6 µl of LoTE.

8. For ditag ligations, mix 2 µl of blunt-ended samples from the previous step, add 1.2 µl of 5× ligase buffer, and 0.8 µl of high concentration T4 ligase (5 U/µl). For negative control reactions, mix 2 µl volumes of blunt-ended samples from the previous step, 1.2 µl of 5× Ligase buffer, and 0.8 µl of dH_2O. Incubate at 16°C overnight, followed by the addition of 14 µl of LoTE. Proceed directly to PCR step.

9. Take 1-µl aliquots to make serial LoTE dilutions: 1/10, 1/25, 1/50, and 1/100 for ditag ligation reactions, 1/10 and 1/25 for negative control reactions, and one LoTE sample as an additional negative control. Prepare a PCR mix using 31.0 µl of sterile water, 1 µl of selected ligation reaction or control dilution, 5 µl of 10×PCR Gold buffer, 3 µl of $MgCl_2$ (25 m*M*), 3 µl of DMSO, 4 µl of dNTPs (25 m*M*), 1 µl each of primers (350 ng/µl each), and 1.0 µl of AmpliTaq Gold polymerase (5 U/µl). Use one strip (8 tubes) of MicroAmp reaction tubes for PCR. Cycling conditions (optimized for Gene Amp PCR system 9700) are as follows: 10 min at 95°C, followed by 28 cycles (30 s at 95°C, 1 min at 55°C, 1 min at 72°C), final extension at 72°C for 5 min, and a hold at 4°C.

10. Mix 20 µl of each PCR product with 4 µl of 6× loading buffer. Load the samples and 100-bp DNA ladder (one lane) to the wells of a 10-well 20% precast Novex TBE polyacrylamide gel. Use 1× TBE as a running buffer. Set voltage to 30 V until the entire sample has entered the gel and then increase the voltage to 120 V. Terminate the reaction when the bromphenol blue stain in the loading buffer migrates to the bottom of the gel. Stain gel with SYBR green I (20 µl/200 ml of 1× TBE buffer) for 15 min while shaking. Visualize by UV. Ligated ditags are located at ~102 bp. Another bright band is present at ~80 bp (linker–linker ligation), and the remaining bands are considerably less bright. The negative control reaction should lack the 102-bp band, and PCR with LoTE as a template (negative control) should not produce any bands (Fig. 1). The optimal dilution of the ditag ligation reaction products for large-scale PCR is considered based on 102-bp band brightness to background ratio and highest dilution ratio. Usually, 1/50–1/100 dilutions produce best results with comparatively low background and a large number of possible PCR reactions. If little or no ditags are visualized, the backup volume of blunt-ended cDNA tags (2 µl for each of the linkers) could be used to repeat steps 8–10 (without negative control); alternatively, backup cDNA could be used to repeat the protocol starting from step 3.

11. Once the conditions have been optimized, perform a large-scale PCR with a fresh LoTE dilution of the selected ditag ligation product as a template. Perform the reaction as described in step 10, except use a Thermo-Fast 96-well detection plate. Cover plate with adhesive sealing sheets and spin for 3 min at 600 *g* on a RT6000 centrifuge using a H1000B rotor (Sorvall) and adapters for 96-well plates. Run about 110–120 50-µl reactions in the GeneAmp 9700.

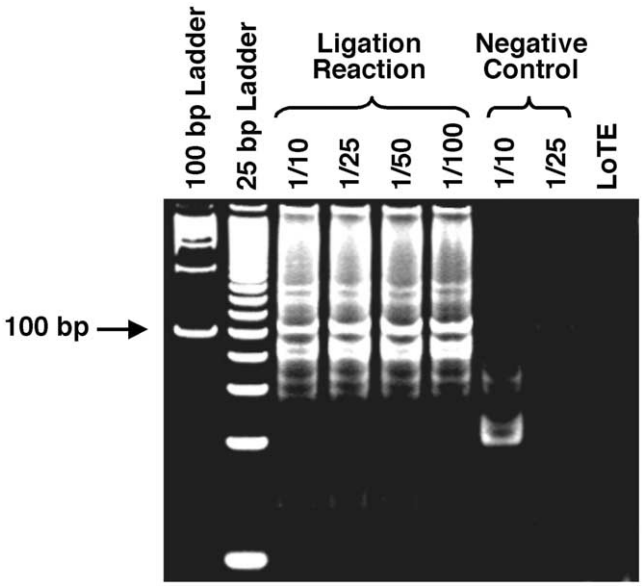

FIGURE 1 PCR amplification of ditags. PCR products of the serial LoTE dilution of ditag ligation reactions (1/10 to 1/100), negative control reaction (1/10 to 1/25), and LoTE-template reaction resolved on a 20% TBE polyacrylamide gel (Novex). Ditag ligation reaction products are represented by a major 102-bp band, whereas other bands represent products of linker–linker ligation (~80 bp) and unspecific products.

12. Combine the PCR products into 12 Eppendorf tubes (~450 µl in each), extract with PC8, EtOH precipitate (using 1 ml of absolute ethanol), and resuspend the pellets in 18 µl of LoTE (288 µl total). Add 57.6 µl of 6× loading buffer and load the entire volume into 8 wells of a 12% polyacrylamide gel (acrylamide : bisacrylamide, 19 : 1). Load a 100-bp DNA ladder to both end wells of the gel. Use 1× TAE as a running buffer. Electrophorese at 30 V until all the samples have fully entered the gel and then increase the voltage to 130 V. Terminate the reaction when bromphenol blue in the loading buffer migrates to the bottom of the gel. Stain gel with SYBR green I (20 µl/200 ml of 1× TAE buffer) for 15 min while shaking. Pierce the bottoms of eight 0.5-ml test tubes with a needle or surgical blade to form a hole with a diameter of about 0.8–1.0 mm and place them in 1.5-ml Eppendorf tubes. Visualize the gel by UV, and using a surgical blade, cut off the 102-bp bands and put the DNA into individual pierced tubes. Spin tubes at 15,300 *g* for 2 min at room temperature and then discard 0.5-ml tubes. Add 300 µl of LoTE to each Eppendorf and vortex. Incubate at 65°C for 15 min, mixing intermittently. Transfer the contents of each tube to individual SpinX tubes and spin at 15,300 *g* for 2 min at room temperature. Discard SpinX cartridges with a solid phase, EtOH precipitate the samples (aqueous phase) using 940 µl of absolute ethanol, and resuspend pellets in 14.8 µl volumes of LoTE (118.5 µl total).

13. Combine the entire contents into a one Eppendorf tube, add 15 µl of 10× RE buffer 4, 1.5 µl of 100× BSA, and 15 µl of *Nla*III (10 U/µl). Incubate at 37°C for 1 h and 15 min, extract sample with PC8, and add 50 µl of LoTE to bring the sample volume to 200 µl. EtOH precipitate on dry ice/ethanol bath [add 3 µl of glycogen (20 mg/ml), 67 µl of 10 *M* ammonium acetate and 733 µl of ice-cold (–20°C) 100% EtOH] and vortex. Place the sample in a dry ice/100% EtOH bath for 10 min. Pellet the precipitated DNA by centrifugation in a microfuge at 15,300 *g* for 15 min at 4°C. Remove the EtOH with care and wash with 75% EtOH. Centrifuge at 7800 *g* for 10 min at room temperature, discard supernatant, dry the pellet, and resuspend in 32 µl of LoTE (see Comments 3 and 4).

14. Add 6.4 µl of 6× loading buffer and load onto two wells of 12% polyacrylamide gel (acrylamide: bisacrylamide, 19:1). Two lanes are reserved for 100- and 25-bp DNA ladders. Run and stain the gel as described in step 12. Using a surgical blade, cut 24 to 26-bp bands from the gel (Fig.2) and place in individual bottom-pierced 0.5-ml tubes. Spin tubes at 15,300 *g* for 2 min at room temperature and then discard 0.5-ml tubes. Add 300 µl of LoTE to each Eppendorf and vortex. Incubate at 37°C for 15 min, mixing intermittently, transfer the contents of each Eppendorf tube to individual SpinX tubes, and spin at 15,300 *g* for 2 min at room temperature. Discard SpinX cartridges with a solid phase and distribute the aqueous contents to three Eppendorf tubes. EtOH precipitate on dry ice/ethanol bath (as described in step 13). Resuspend and combine the pellets in 7 µl of LoTE.

15. To the pooled purified ditags (7 µl total), add 2 µl of 5× ligation buffer and 1 µl of high concentration T4 ligase (5 U/µl). Ligate ditags to form concatemers by incubation at 16°C for 3 h (see Comment 5), add 90 µl of LoTE, and continue to incubate at 60°C for 5 min. Extract the sample with PC8, EtOH precipitate, and resuspend the pellet in 10 µl of LoTE.

16. Incubate the concatemers at 60°C for 5 min, add 190 µl of LoTE, extract with PC8, EtOH precipitate, and resuspend the pellet in 10 µl of dH_2O. Incubate at 60°C for 5 min and immediately load onto one well of an 8% polyacrylamide gel (acrylamide:bisacrylamide, 37.5:1) (see Comment 6). Employ the 100-bp DNA ladder and 1-kb DNA ladder as markers. Run and stain the gel as described in step 12. Using a surgical blade, cut and separate concatemers of 600–1100 ("light" cluster) and 1100–2500 bp ("heavy" cluster) (Fig.3) and place each into two labeled bottom-pierced 0.5-ml tubes. Spin at 15,300 *g* for 2 min at room

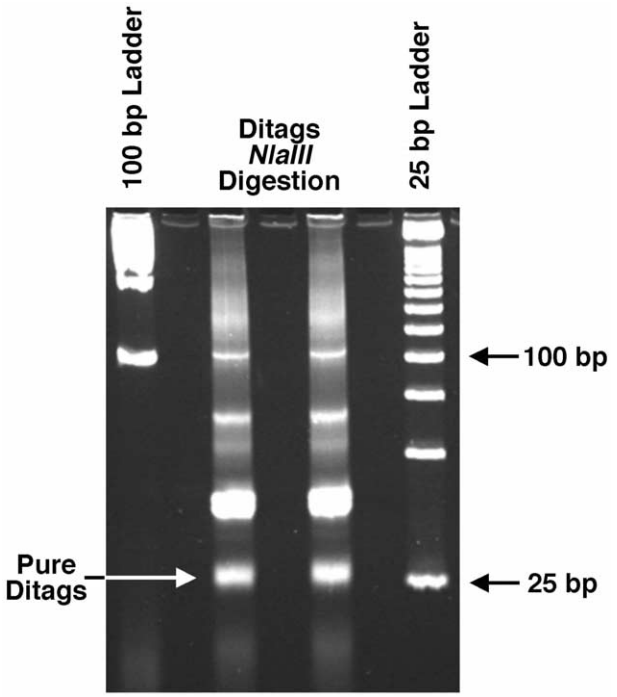

FIGURE 2 Pure ditags resolved on a 12% polyacrylamide gel. Bands represent (starting from the top) undigested linker–ditag–linker structures, products of incomplete anchoring enzyme digestion (one linker–ditag structures), pool of linkers, and pure ditags.

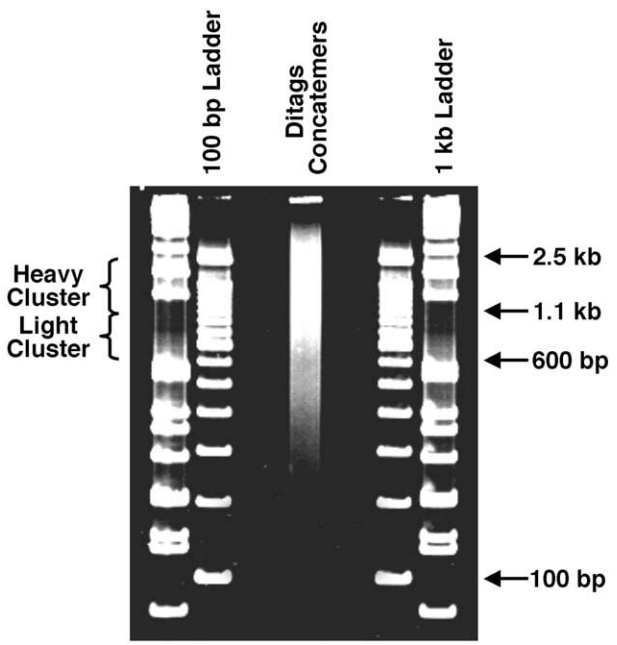

FIGURE 3 Ditag concatemers resolved on an 8% polyacrylamide gel using the "hot" variation of the original protocol (see Comment 6). Recommended "heavy" and "light" concatemer cluster sizes are 1100–2500 and 600–1100 bp, respectively.

temperature and discard 0.5-ml tubes. Add 300 µl of LoTE to each Eppendorf and vortex. Incubate at 65°C for 15 min, mixing intermittently. Transfer the contents of each Eppendorf tube to two SpinX tubes and spin at 15,300 *g* for 2 min at room temperature. Discard SpinX cartridges and transfer the aqueous phase from two SpinX tubes to one Eppendorf tube. EtOH precipitate using 933 µl of absolute ethanol and resuspend pellets in 5 µl total volume of LoTE for each "light" and "heavy" cluster of the sample.

17. To 5 µl of purified concatemers, add 2 µl of 5× ligase buffer, 1 µl of pZeRO-1 cut with *Sph*I (25 ng/µl), and 1 µl of T4 ligase (1 U/µl). Incubate at 16°C overnight, add 191 µl of LoTE to the samples, extract with PC8, EtOH precipitate, wash pellets three times with 70% ethanol, and resuspend pellets in 6 µl of LoTE. Use self-ligated pZeRO-1 vector as a negative control.

18. Electroporate bacteria with concatenated DNA by adding 2 µl of each sample to 40 µl of freshly thawed ElectroMAX DH10B cells on ice. Mix the contents gently by rotating a pipette tip in a test tube, rather than by trituration. On ice, transfer the mixture to the bottom of 0.2-cm electroporation cuvettes (avoiding bubbles) and electroporate: Voltage setting, 2.5 kV; capacitor, 25 µF; and resistance, 200 Ω. After the electric pulse, immediately transfer the cells to a 15-ml bacterial tube with 1 ml of prewarmed SOC media (no zeocin). Place in a bacterial shaker and incubate at 37°C for 40 min at 200 rpm.

19. Plate 80-µl aliquots of the cell/SOC solution onto 10-cm petri dishes with low salt LB agar plates supplemented with zeocin (50 ng/µl) (see Comment 7 and Pitfall 4). Incubate plates for about 20 h at 37°C.

20. Identify ~15–20 individual colonies from each "light" and "heavy" fraction to run a PCR control to determine cloning efficiency and the presence of concatemers in the clones (see Pitfall 5). For this purpose, prepare a 25-µl PCR reaction containing 18 µl of dH_2O, 2.5 µl of custom-made 10× PCR buffer (see *Solutions*), 1.5 µl of DMSO, 1.5 µl of dNTPs (25 m*M*), 0.5 µl of each M13 forward and reverse primer (both 350 ng/µl), and 0.1 µl of *Taq* polymerase (0.5 U), inoculated with a single bacterial colony picked with a sterile toothpick. Cycling conditions are: 2 min at 95°C, followed by 25 cycles (30 s at 95°C, 1 min 30 s at 56°C, 1 min 30 s at 70°C), final extension 70°C for 5 min, and hold at 4°C.

21. To the 5-µl aliquots of control PCR reactions, add 1 µl of 6× loading buffer and load onto an 1.2% agarose gel containing 1 µg/ml ethidium bromide and a 100-bp DNA ladder. Use 0.5× TBE as the running buffer, and electrophorese at 120 V. Estimate cloning

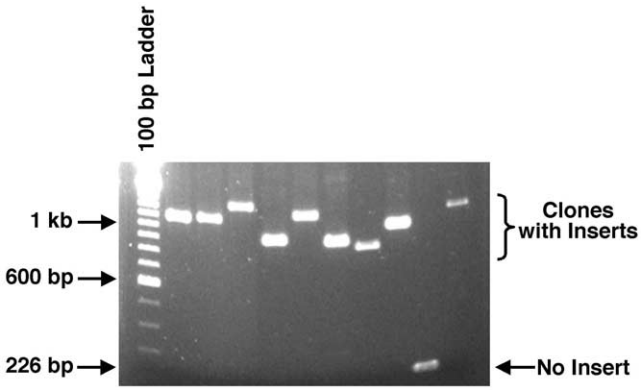

FIGURE 4 PCR control of cloning efficiency. A minor portion of the clones may lack inserts (PCR product will be of 226 bp size), whereas the majority should contain inserts with a size that varies as a function of concatemer length.

efficiency by calculating the ratio of clones with inserts to the total number of clones amplified with PCR. Background clones without inserts will appear on the gel as 226-bp bands (Fig.4).

22. For those clones with inserts, add 180 µl of LoTE to the remaining PCR volume (20 µl), extract with PC8, add 250 µl of LoTE, and precipitate samples with isopropanol. Resuspend each pellet in 10 µl of LoTE.

23. For test sequencing, use forward and/or reverse M13 primers to ensure appropriate ditag formation. If inserts of the test clones demonstrate correct concatemer structure (Fig.5) and the cloning efficiency is satisfactory, the SAGE library should be sequenced until a sufficient number of tags (i.e., 40,000) can be identified. We recommend using a commercial vendor for sequencing (e.g., Agencourt Bioscience Corp.).

24. Many commercial sequencing services require libraries to be submitted as frozen glycerol stocks. For this, inoculate the wells of a 96-well plate containing 100 µl of TB/zeocin media with bacterial colonies using sterile toothpicks. We recommend that 1 well in each plate (H12) be filled with sterile LoTE to serve as a negative control for the sequencing reactions. Incubate plates for about 20 h at 37°C.

25. Copy the "master plates" by transferring 15 µl of the bacterial cultures to the corresponding wells of another set of 96-well plates containing 100 µl of TB/zeocin media. Stop further bacterial growth in the "master plates" by adding 40 µl of sterile 50% glycerol to the wells. Seal plates with adhesive SealPlate film and store at –80°C until the project is completed successfully.

26. Incubate the "copy plates" for about 18 h at 37°C. Stop the bacterial growth in the "copy plates" by adding 60 µl of sterile 50% glycerol to the wells. Seal plates with adhesive SealPlate film, freeze at –80°C, and ship for sequencing on dry ice (see Comment 8).

B. SAGE Analysis

This analysis protocol is based on the original SAGE 2000 software (Kinzler, 2000) and a separate SAGE analysis software protocol is available online from Invitrogen (I-SAGE kit; http://www.invitrogen.com/downloads/sagesoftware_man.pdf; Invitrogen Corp., 2001).

Steps

1. Database Creation

The aim is to create a complete, up-to-date data set to match with the SAGE tags generated in your library.

1. Download a current release of a GenBank database (e.g., rodent, primate) from the National Center of Biotechnology Information (NCBI) Web site using ftp software (e.g., CuteFTP) from ftp.ncbi.nlm.nih.gov/Genbank/.

2. Extract GenBank sequence files from the archives using WinRAR or comparable software.

3. Convert the GenBank sequence file format from UNIX to DOS using Streamline Solutions or other appropriate software. Raw sequence files should be marked with the suffix *.seq.

4. Open SAGE 2000 software. Go to "Database, Create" to generate a new database [suggested name should include species identification (e.g., Mm, mouse; Hs, human), nonredundant (NR) and/or EST affiliation, and numeric index of the dataset release].

Individual databases are recommended for NR and EST data sets. "Add Files" to the database using GenBank under "File Format" and in the cDNA mode under "Method."

2. SAGE Project Creation and Analysis

The aim is to create and analyze a gene expression profile based on SAGE library sequence data (SAGE catalog).

5. To create a new project, hit "Project/New Project" and use the following settings: anchoring enzyme, *Nla*III; tag length, 10 bp; and ditag length, 24 bp. Copy raw sequence files (see Comment 9) to a folder, where a new project has been created.

6. Extract SAGE tags from the sequences with the "Project/Add Tags" option. Reset "Stop position" constant to 2000 bp (this also depends on the sequencer type used for large-scale sequencing, producing reliable readings of various length). For preliminary analysis (preprocessing), we recommend performing the analysis on each individually selected file (i.e., select file, and hit "Analyze" until all the files have been analyzed). Record the output (i.e., number of "Good Tags" and "Duplicate Dimers") on a spreadsheet.

7. Once the preliminary analysis is complete, use spreadsheets to remove files associated with background clones (no SAGE tags detected) and clones that produced a minor number of "Good Tags" and/or "Duplicate Dimers" (≤4 tags or ≤2 duplicate dimers; tags derived from such clones may contain sequencing errors).

8. Create a new project as in step 5 and reanalyze sequence files that passed preprocessing criteria only, but this time use the "Auto Analyze" option.

9. We recommend that $(A)_{10}$ be excluded from the list of tags (accessible via "Analyze/Report/Exclude Tags Manager" path: hit "Add", type "1" and hit "OK"). An $(A)_{10}$ SAGE tag is generally uninformative, gives multiple matches to databases entries, and may originate from an anchoring enzyme recognition site located immediately before the poly(A) tail.

10. We recommend that the expression profile of your sequence data be created using the "Analyze/Report" path. For primary analysis, "Minimum tag count for report" should be reset to 1 (via "Settings/Minimum tag count for report" path) and "Options/Exclude Tags" checked. Using additional features, the expression profile (identified tags and absolute tag count) could be saved in MS Access database format (by having "Options/Save Output as MS Access File" option checked), and tags could be linked to selected SAGE database [by opening a selected database (see steps 1–4) and having "Options/Link to Database" option checked]. The latter permits direct matching of tags to the GenBank database. Also, more than one SAGE catalog can be analyzed simultaneously using the "All open projects" option.

11. The analysis of SAGE catalogs by linking them sequentially to NR and EST GenBank databases is recommended. To supplement GenBank data with UniGene data (which has a different structure) we recommend direct one-by-one online analysis via SAGEmap applet (http://www.ncbi.nlm.nih.gov/SAGE/) due to the notable presence of false positives in the "downloadable" "SAGEmap_tag_ug" data sets (available for human, mouse, rat, and a few other species at ftp://ftp.ncbi.nih.gov/pub/sage/map/).

12. For the comparison of multiple SAGE catalogs, we recommend MS Excel and MS Access statistical functions, not the SAGE 2000 function (accessible via "Analyze/Compare" path, with selected normalization value). MS Access files can be easily reformatted to MS Excel.

3. Outside Comparisons

The aim is to include publicly available SAGE data in the analysis. We encourage investigators to submit their SAGE data to the Gene Expression Omnibus (GEO) database.

13. Interlibrary comparisons among SAGE data are available via public databases, most importantly Entrez ProbeSet (http://www.ncbi.nlm.nih.gov/SAGE/index.cgi?cmd=libsearch). Individual SAGE catalogs of interest (use keywords such as "mouse," "cancer," and "brain") can be accessed and downloaded (using "Full table view" option). These are then converted from plain text to MS Excel table, tag abundance normalized to tags per million (tpm) value, and comparisons performed in convenient MS Excel or MS Access formats.

IV. COMMENTS

1. This protocol is optimized for "standard" SAGE using the *Nla*III/*Bsm*FI enzyme pair. Other anchoring and restriction enzymes could be used to generate longer tags (LongSAGE; Saha *et al.*, 2002) or to generate SAGE tags from genes lacking the *Nla*III recognition site (*Sau*3A is suggested and is recognized by SAGEmap; Lash *et al.*, 2000). Certain modifications of the SAGE protocol are also available for SAGE applications with a limited amount of starting material (microSAGE, Datson *et al.*, 1999; miniSAGE, Ye *et al.*, 2000; SAR-SAGE, Vilain *et al.*, 2003).

2. For cDNA synthesis, we recommend using α^{32}P dCTP labeling only to test the protocol and skip it

for the generation of most SAGE libraries. If used to calculate cDNA yield, isotope labeling allows tracing of the cDNA up to the tagging enzyme digestion step.

3. A modification of the ditag purification step, based on the employment of 5′-biotinylated linkers for PCR, followed by the magnetic separation of anchoring enzyme digestion products, has also been suggested (Powell, 1998). Although this modification shortens the ditag purification stage, it does not always result in good yields of ditags.

4. A few modifications of the original SAGE protocol are suggested to improve the yield of anchoring enzyme digestion of ditags (Angelastro *et al*., 2000; Damgaard Nielsen *et al*., 2003). We find that complete *Nla*III digestion is readily ensured by increasing the amount of enzyme, the overall reaction volume, and the digestion time (150 U, 150 µl, 1 h and 15 min, recommended).

5. Although concatenation time can vary from 45 min to overnight, which depends on the volume of ditags purified, we find that a 3-h concatenation produces good results.

6. A modification of the original SAGE protocol allows better resolution of concatemers in polyacrylamide gels, improving the overall yield of SAGE libraries (Kenzelmann and Muhlemann, 1999): 65°C, 15 min, chill on ice, 10 min; and then load onto the gel. We recommend using the "hot" variation of the same modification: 60°C, 5 min; PC8 extract; EtOH precipitate, 60°C, 5 min; and load immediately.

7. A X-Gal/IPTG blue/white selection can be employed to distinguish between bacterial colonies containing or lacking inserts (Angelastro *et al*., 2002) This technique is most useful when the number of bacteria without inserts is high.

8. With pZeRO-1, we recommend the M13 forward primer for sequencing. For clones originated from the "heavy" cluster of concatemers, an additional M13 reverse-primed sequence could be beneficial, yielding more tags from long inserts, but it leads to rapid accumulation of duplicate dimers due to the partial overlapping of sequences.

9. We recommend that each individual clone be designated by a nomenclature that contains a project script, plate number, and clone position in a 96-well plate. For example, file "EX15A08.seq" indicates association with experiment X, plate #15, well A8. All *.seq files generated in this manner represent individual SAGE library raw sequence files.

V. PITFALLS

1. The quality of the mRNA and the purity of oligo-DNA linkers and primers are of a great importance. We recommend the technique of Chirgwin *et al*. (1979) for the preparation of total RNA. Test linker kinasing efficiency before proceeding with the protocol.

2. Preciseness and RNase- or DNase-free conditions are important at most steps. Use DEPC-treated glassware and plasticware on the early steps of the work and aerosol barrier pipette tips throughout the whole experiment.

3. The commonly used anchoring enzyme *Nla*III has a half-life of only about 3 months at –20°C; therefore, use only fresh batches of enzyme for each SAGE project.

4. Zeocin is light sensitive and comparatively unstable. TB/zeocin media can be kept in the dark for up to 2 weeks. Low salt LB agar/zeocin plates should be protected from light immediately after pouring.

5. Cloning efficiency (ratio of clones with inserts to the total number of clones) is the major concern of researchers employing the SAGE method. Reasons for the appearance of background clones with the pZeRO-1/zeocin system are not completely clear. Suggested strategies rely on specific concatemer cluster sizes to achieve an acceptable range of cloning efficiency (i.e., >80%). While small concatemers routinely have high cloning efficiency, the number of SAGE tags extracted from each single clone is low. Extremely long concatemers (>2500 bp) have a tendency to circularize, preventing effective cloning. The suggested concatemer cluster sizes (600–1100 bp for "light" and 1100–2500 for "heavy") seem to have the best tag yield/clones sequenced ratio, allowing direct large-scale sequencing. In other cases, an additional PCR step or X-Gal/IPTG selection could be required to select clones with insert before sequencing.

Representational Difference Analysis: A Methodology to Study Differential Gene Expression

Marcus Frohme and Jörg D. Hoheisel

I. INTRODUCTION

Representational difference analysis (RDA) was originally developed for the identification of differences between two complex genomes (Lisitsyn *et al.*, 1993). Adapted slightly, cDNA-RDA was established by Hubank and Schatz in 1994. It aims at the detection of differentially expressed genes, comparing two sources of RNA, e.g., tumour and normal tissue, by means of a polymerase chain reaction (PCR)-coupled subtractive and kinetic enrichment procedure (Fig. 1). First, the two complex mRNA populations are reverse transcribed into cDNA. An initial digest with a restriction enzyme is followed by the addition of PCR adapters and subsequent amplification, thereby reducing the complexity of each sample. The resulting mixtures of gene fragments are named "representations" (Fig. 2). Differences in transcript levels in the tissues analysed are imaged in the representations by relative differences in the abundance of the respective cDNA fragments. In a subtractive hybridisation reaction with a strong kinetic component, one representation (#2)—named "driver"—serves as a competitor during the reannealing of the other (#1), which is called "tester" (Fig. 1). Due to an earlier change of adapters, only double-stranded tester molecules and therefore predominantly fragments unique to or overrepresented in the tester are exponentially amplified. The product is named "difference product" and may need further enrichment, acting as a tester in a subsequent round of RDA with an increased ratio of driver to tester, for example. Swapping the role of the two representations reverses the analysis mode, then identifying transcripts that are more abundant in representation #2 compared to #1.

cDNA-RDA has been proven to be a powerful tool for the identification of differentially expressed genes in many screens in both eukaryotic and prokaryotic systems. RDA is less prone to produce false positives than differential display and is easier to perform. The possibility of modifying the driver's composition, e.g., by spiking with certain fragments, offers an option of suppressing unwanted products. In comparison to microarray techniques, RDA has the advantage that there is no preselection in the set of analysed genes. Thus, unknown genes and unexpected splice variants are found. Moreover, difference products may serve as highly informative probe molecules on DNA arrays or be used as hybridisation samples. The protocols described here are similar to the originals of Hubank and Schatz (1994) but contain modifications found to be useful.

II. MATERIALS AND INSTRUMENTATION

Because the technique is very prone to pick up DNA contaminations, always use allocated (aliquots of) chemicals, buffers, plasticware, and so on and avoid common stocks. Take all precautions for RNA work but remember that DNA contaminations are a problem too that does not disappear by autoclaving. The preparation of most chemicals and buffers follows standard protocols using chemicals from various suppliers. However, always use high-quality grade products (p.a.

Copyright 2006, Elsevier Science (USA).
All rights reserved.

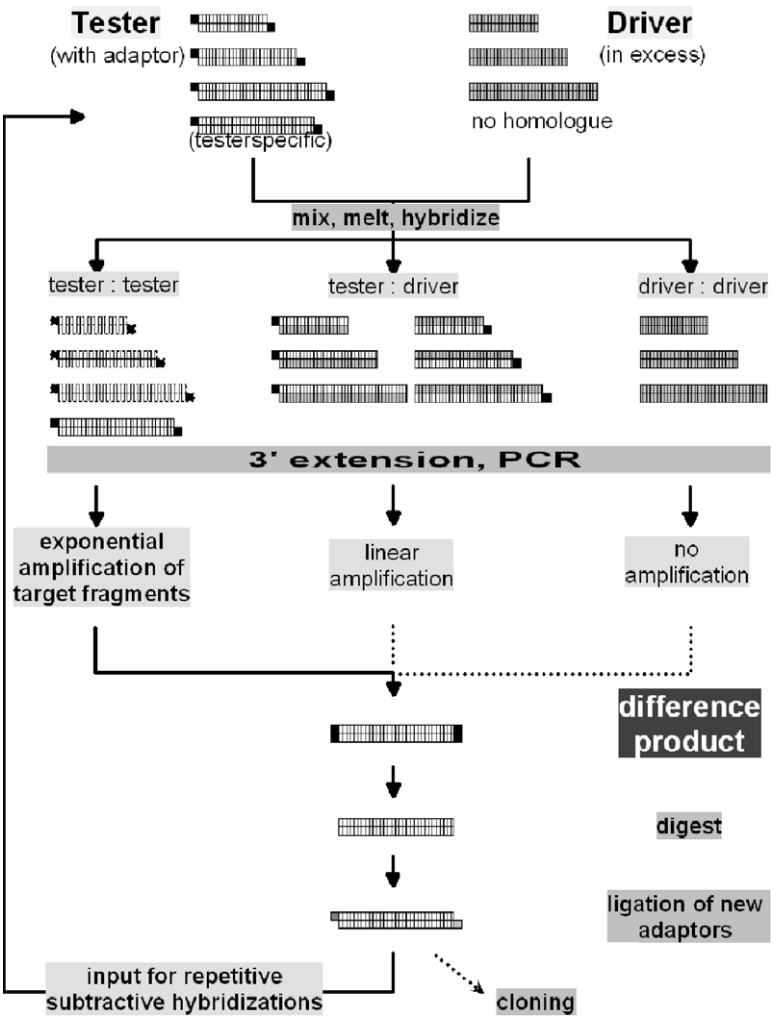

FIGURE 1 Schematic representation of the RDA procedure. Two cDNA populations are cut with a restriction enzyme. Subsequently, adapter molecules are added to the ends. The material is then PCR amplified to produce representations. The adapter of the tester sample is removed and replaced by a new molecule of different sequence (not shown). Tester and driver are mixed, denatured, and reannealed. During this process, the majority of tester molecules form duplexes with fitting driver molecules. Only fragments overrepresented in the tester or even lacking a homologue in the driver population will be amplified exponentially. The resulting difference product is either processed further or acts as a tester in another round of RDA.

or molecular biology grade) and prepare aliquots from freshly opened supplies.

Diethylpyrocarbonate (DEPC) is from Roth, Germany (Cat. No. K028.2), is diluted 1 : 1000 in water and autoclaved twice before being added to buffers. Low melting point (LMP) agarose is from Serva (Cat. No. 11408). The 50 × TAE stock solution for electrophoresis buffer consists of 2 *M* Tris–acetate (pH 8.2) and 50 m*M* EDTA. Various types of agarose are used for analytical gels as well as standard molecular weight markers with bands between 0.1 and 1 kb (100-bp ladders, pUC19/*Sau*IIIa digest, etc.); never use these markers on preparative tester gels, however. The ethidium bromide (Roth, Germany, Cat. No. 2218.1) stock solution (10 mg/ml) for gel staining is diluted 1 : 10,000 prior to use. Phenol/chloroform/isoamylalcohol (25 : 24 : 1) is equilibrated with Tris to a pH of 7.5 to 8.0 (Roth, Germany, Cat. No. UN2821); glycogen (1 µg/µl for molecular biology) is from Ambion (Cat. No. 9510); alternatively, linear acrylamide (Cat. No. 9520) may be used in precipitation.

Other chemicals are ethanol and 2-propanol (isopropanol); 1 *M* HCl for cleaning the gel chamber; 3 *M* sodium acetate (pH 5.3) (adjust pH with acetic acid, but use aliquots when checking the pH); 10 *M* ammonium acetate (sterile filter only, do not autoclave); 1 *M* Tris–HCl (pH 8.8) (8.5); 0.5 *M* EDTA stock (pH 8); TE: 10 m*M* Tris–HCl (pH 8.5); 1 m*M* EDTA; T1: 1 m*M* Tris–HCl (pH 8.5); T10: 10 m*M* Tris–HCl (pH 8.5); T50: 50 m*M* Tris–HCl (pH 8.8); 1 *M* $MgCl_2$; 1 *M* ammonium sulfate; 5x PCR buffer: 335 m*M* Tris–HCl (pH 8.8), 20 m*M* $MgCl_2$, 80 m*M* ammonium sulfate, 166 µg/ml

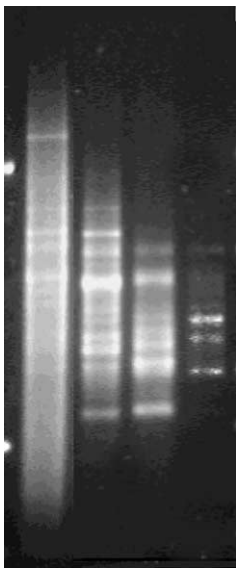

FIGURE 2 Difference products on an agarose gel. The four lanes of a 2.5% TAE agarose gel are shown. (Left to right) A tester representation and the three difference products resulting from iterative RDA are presented. The reduction in complexity is apparent. The white dots on the left margin indicate fragment sizes of 955 and 258 bp, respectively.

bovine serum albumm (BSA) (New England Biolabs, Cat. No. B9001S); nucleotides: dATP, dCTP, dGTP, and dTTP, each at 100 m*M* (Fermentas, Cat. No. R0181); dNTP mix containing 4 m*M* of each nucleotide; mineral oil (filtered) from Sigma (Cat. No. M 8662); alternatively, chill-out liquid wax from MJ Research is used; 10x ligase buffer: use buffer supplied with enzyme from New England Biolabs—if not available, prepare 500 m*M* Tris–HCl (pH 7.8), 100 m*M* $MgCl_2$, 100 m*M* dithiothreitot (DTT), 10 m*M* ATP—store frozen, mix vigorously before use; 300 m*M* EPPS (*N*-[2-hydroxyethyl]-piperazine-*N*′-[3-propanesulfonic acid] (pH 8.0) from Sigma (Cat. No. E-9502); 3x EE: 30 m*M* EPPS (pH 8.0), 3 m*M* EDTA; 5 *M* NaCl; yeast tRNA (Roche, Cat. No. 109495): set up as stock solution of 10 mg/ml; 0.5xTE/tRNA: mix tRNA stock with 1 volume TE; Qiaquick PCR purification kit (Cat. No. 28104); Qiaquick buffer QG (Cat. No. 19063); *Dpn*II: 10 U/µl from New England Biolabs (Cat. No. R0543L); T4 DNA ligase: 400 U/µl from New England Biolabs (Cat. No. M0202S) (if using ligase from another supplier, check the unit definition); mung bean nuclease: 10 U/µl from New England Biolabs (Cat. No. M0250S); *Taq* polymerase (5 U/µl) is purchased from different suppliers.

All oligonucleotides (final concentration 1 mg/ml) are purchased as HPLC-purified material.

Reagents for fluorescence measurements include TNE buffer: 100 m*M* Tris–HCl (pH 7.4), 10 m*M* EDTA, 2 *M* NaCl; Hoechst-dye 33258 (BisBenzimide H33258; Sigma, Cat. No. B 2883); DNA standard: calf thymus DNA from Sigma (Cat. No. D 4764).

Plasticware should be resistant to phenol and chloroform and amicable to centrifugation at high speed. PCR plasticware is from ABgene: 96-well PCR plates with disposable covers; 8-well PCR strips with additional lid strips; and individual PCR tubes. Also 1.5 and 2-ml reaction tubes are required, as well as larger reaction vessels of up to 30 ml volume. For all pipetting steps, use filter tips in order to avoid contamination.

All technical equipment necessary is conventional and standard in molecular biology laboratories. However, it should be set aside for RDA experiments in order to avoid contamination. Required are the following: a minigel chamber and a power supply to run agarose gels at about 100 V; a set of pipettes; a small centrifuge for 2-ml reaction tubes; a centrifuge for spinning 30-ml tubes at 12,000 *g*; a UV transilluminator with camera; a vortex shaker; a timer; incubation blocks to keep reactions at precise temperatures between 37 and 100°C, preferably with a mixer function (e.g., Eppendorff Thermomixer comfort); a water bath or other equipment to keep reaction vessels at 14°C; and a refrigerator or cold room for storage. In principle, all incubation steps can be done in a thermocycler. The PCR machine should have a hot-lid function and hold 96-well plates (e.g., MJ Research PTC 200). For fluorescence measurements, we use a DyNAquant 200 device (Hoefer Scientific).

III. PROCEDURES

A. RNA Extraction and cDNA Synthesis

For RNA preparation, we recommend using a protocol that is well established for the particular biological system. Generally, our experiences with phenol/guanidinium-thiocyanate protocols (Trizol reagent from Invitrogen, Cat. No. 15596-026) are better than with column-based methods. In some experiments, we performed DNase treatments of total RNA preparations. However, we cannot generally recommend this because RNA degradation was observed several times. If required, however, use RQi RNase free DNase from Promega (Cat. No. M6101) with the

RNasin ribonuclease inhibitor (Cat. No. N2111) according to the supplier's recommendations. For mRNA isolation, magnetic beads are highly recommended (Dynal Dynabeads mRNA purification kit, Cat. No. 610.06). An estimation of the mRNA amount may be done by adsorption measurements. Make sure that the sample can be recovered from the cuvette.

Synthesis of double-stranded cDNA is preferably done following the protocol provided by Invitrogen with the Superscript double-stranded cDNA synthesis kit (Cat. No. 11917-010). Primer is $dT_{(15)}$ or $dT_{(13)}$ with an anchor of two random bases at the 5′ terminus. Radioactive label, used frequently for quantification and quality control, should only be added to an aliquot rather than to the whole cDNA preparation. The final yield of double-stranded cDNA should be similar to the initial amount of mRNA.

B. Generation of Representations; Preparation of Driver and Tester

1. For a digest, use 1–1.5 µg cDNA of good quality. If less than 1 µg is cleaved, the eventual number of cycling reactions may have to be increased.

2. Mix 10 µl 10x *Dpn*II buffer, 5 µl *Dpn*II, cDNA, and water to a total of 100 µl, incubate at 37°C for at least 2 h, inactivate the enzyme at 65°C for 10 min, and add 500 µl PB buffer of the Qiaquick kit.

3. Place a Qiaquick spin column in a collection tube (without lid), apply sample to column, and centrifuge 60 s to bind the cDNA. Discard the flow through and put the column back into the tube. To wash, add 750 µl of the supplied PE buffer, incubate 5 min, and spin for about 60 s. Discard flow through, put the column back into the tube, and spin for 1 min to remove residual buffer. Place column into fresh tube to elute the cDNA. Add 42 µl EB buffer to the centre of the membrane, incubate for 1 min, and spin for 1 min. Continue with the next step immediately.

4. Mix 8 µl *R-Bam-24*, 4 µl *R-Bam-12*, 6 µl 10x ligase buffer, and 39 µl of the Qiaquick column eluate. Place sample in a heating block of 50°C and let the block cool down for more than 1 h in a cold room until the block temperature is below 14°C. Place tube on ice and add 3 µl T4 DNA ligase for an overnight incubation at 14°C. Subsequently, dilute the ligation by the addition of 140 µl TE.

5. Prepare a PCR reaction to check whether digest and ligation worked. Mix 69 µl water, 20 µl 5x PCR buffer, 8.5 µl dNTP, 1 µl *R-Bam-24*, and 1 µl ligation product. Incubate at 72°C for 3 min to melt off the 12-mer oligomer and add 0.5 µl *Taq* polymerase. Incubate for 5 min at 72°C to fill in the ends. Cycle 20 times: 1 min at 95°C and 3 min at 72°C. Finally, keep the sample at 72°C for 10 min. Check 5 µl on a 2.5% gel. A DNA smear between 0.1 and 1 Kb should be visible.

It is highly recommended to perform a negative and a positive control. Both representations should have a similar yield in quality and quantity. If not, and especially if the input amount of cDNA is low, the cycle numbers have to be adjusted. Perform the PCR with additional cycles and remove 5 µl every second or third cycle during the 72°C incubation, starting at cycle 17. Check the products on a gel. With an increase in cycle number the faint DNA smear will grow in intensity, finally reaching a plateau. The plateau is characterised by a smear toward the slot or a shift of the product to smaller sizes—going along with a decrease in quality. Pick an optimal number of cycles for each representation, avoiding the plateau phase, but with a good yield. Both representations used in an RDA reaction must look similar on a gel.

6. Perform PCR for the production of more material, following the protocol established earlier. For a driver preparation, perform identical 100-µl reactions in all wells of a 96-well microtiter plate. Eight reactions are sufficient for preparing a tester, as less material is needed. Mix enzyme, reaction buffer, and DNA first before distributing the mix into the wells. Always include a negative control without DNA. For most analyses, reciprocal experiments are recommended: each cDNA serves as both driver and tester. In this case, a total of one 96-well plate worth of DNA is sufficient. After PCR, check a representative number of products on a 2.5% gel.

7. Combine the 96 driver reactions (or the 8 tester reactions) in one tube, add an equal volume of phenol/chloroform, and vortex vigorously. Spin briefly for phase separation and transfer the supernatant into a new tube. Warming the sample slightly may clear the phases if cloudy. Repeat the extraction, add one volume of chloroform, and vortex again. Spin and recover the supernatant. Do avoid the interphase. If necessary, repeat the extraction. Add 0.1 volume sodium acetate, 1 volume cold isopropanol, mix, and precipitate for 20 min at –20°C; longer incubation may result in salt precipitation. Spin for 15–30 min at high speed (>10,000 *g*). Remove the supernatant carefully and wash pellet with 70% ethanol. Spin again a few minutes, remove the ethanol, and dry the pellet (preferably at 37°C and not in a vacuum). Resuspend a driver in 200 µl T10 and a tester in 20 µl. Determine the concentration with a fluorometer.

8. ***For the preparation of a driver***, mix 300 µg DNA, 140 µl *Dpn*II buffer, 75 µl *Dpn*II, and water to a final volume of 1400 µl. Incubate at 37°C for 4 h and stop the reaction at 65°C for 15 min. Extract twice with phenol/chloroform and once with chloroform and precipitate with cold isopropanol as described earlier.

Resuspend the DNA in 200 µl T10 and determine its concentration. Dilute the digested driver to about 600 ng/µl and determine the concentration again before diluting the driver to precisely 500 ng/µl.

9. ***For the preparation of a tester***, mix 10 µg DNA, 10 µl *Dpn*II buffer, 5 µl *Dpn*II, and water to a final volume of 100 µl. Incubate at 37°C for 2 h, incubate at 65°C for 15 min, and add 500 µl PB buffer. Alternatively, take 10 µg *Dpn*II-digested driver (= 20 µl) and add 100 µl PB buffer. Purify the DNA with a Qiaquick spin column as described in Section III, B, **step 3**. Elute the DNA finally with 50 µl EB buffer.

10. Clean one minigel chamber for each tester; do not run different testers in one gel. Wash the chamber with detergent and rinse with water extensively; incubate all tools (combs, spacer, etc.) for 30 min in 1 *M* HCl and wash with plenty of water.

11. Load 10 µg tester DNA on a 1.3% LMP-agarose gel in TAE buffer without any other DNA (no marker!). Use only a small amount of loading buffer; even better, add glycerol (up to 10%) only and run bromphenol blue in a separate lane. Electrophoresis is at 100 V for a short time. The bromphenol blue should have migrated about 2 cm. Stain the gel in a fresh ethidium bromide solution (use once only). Check on a clean long wavelength UV transilluminator at low (preparative) intensity. There should be a smear of DNA and, directly below, a band from the adapter molecules. Cut out the smear portion (up to the slot), transfer with a clean scalpel to a tube, of which you know the weight, and determine the weight of the agarose plug.

12. For DNA extraction, use Qiaex spin colums with the Qiaex protocol. Melt the agarose plug at 50 to 55°C in three gel volumes QG buffer for 10 min. The buffer has a pH indicator. If the mixture is orange or purple, add sodium acetate (about 10 µl) until the colour turns yellow. Add one gel volume of isopropanol and mix. Place a Qiaquick spin column in a collection tube (without lid), apply the sample to the column, and centrifuge for 60 s to bind DNA. Proceed as in Section III, B, **step 3**. Elute the DNA with 30 µl EB buffer. Check the concentration fluorometrically.
