Cells are coccoid, approximately 0.6–0.8 μ m in diameter, and grow in short chains. Facultatively anaerobic. α -hemolysis is produced on Columbia blood (sheep) agar with pin-point colonies being formed at 37°C under aerobic conditions for 1 d and approximately 0.3–0.8 mm diameter colonies after 3 d incubation. Strains produce acid from lactose, maltose, and sucrose. Acid is not produced from amygdalin, L-arabinose, D-arabinose, arabitol, arbutin, cyclodextrine, glycogen, inulin, mannitol, methyl β -D-glucopyranoside, melibiose, melezitose, pullulane, raffinose, ribose, sorbitol, tagatose, or trehalose. Strains produce β -galactosidase (*p*-nitrophenyl β -D-galactopyranoside substrate) and alanyl-phenylalanyl-proline arylamidase, but do not produce α -galactosidase, β -galactosidase (2-naphthyl β -D-galactopyranoside substrate), β -glucosidase, β -mannosidase, β -D-fucosidase, β -glucuronidase, glycine-tryptophan arylamidase, N-acetyl- β -glucosaminidase, pyrrolidonyl arylamidase, or urease. Alkaline phosphatase is a variable characteristic of this species. Arginine, esculin, and hippurate are not hydrolyzed. Acetoin is not produced (Voges–Proskauer reaction).

Strains have been isolated from the human tooth surface and pharynx.

16S rRNA gene sequence analysis places this species within the Mitis species group.

DNA G+C content (mol%): 39.8–40.5 (HPLC).

Type strain: O-66, ATCC 700780, CCUG 39814, CIP 105950, DSM 12493, GTC 848, JCM 10158, LMG 18719.

GenBank accession number (16S rRNA gene): AB008314.

41. ***Streptococcus phocae*** Skaar, Gaustad, Tønjum, Holm and Stenwig 1994, 649^{VP}

pho'cae. L. gen. n. *phocae* of a seal.

Cells are coccoid, 1 μ m in diameter, growing singly, in pairs, or chains. Colonies range from pinpoint up to 0.8 mm in diameter after aerobic incubation for 24 h at 37°C. β -Hemolysis is produced on blood agar plates. No growth is obtained at 10°C, at 45°C or in the presence of 40% bile or 6.5% NaCl. Acid is produced from N-acetylglucosamine, D-fructose, glucose, maltose, D-mannose, and ribose. Acid is not produced from inulin, lactose, mannitol, D-raffinose, salicin, sorbitol, or trehalose. Acid from glycogen and starch are variable characteristics of this species. A minority of strains (i.e., < 10%) produce acid from galactose, glycerol, melezitose, sucrose, and D-turanose. Alkaline phosphatase is produced by the majority of strains. Pyrrolidonyl arylamidase is not produced in the majority of strains. Acetoin is not produced (Voges–Proskauer reaction). Hyaluronidase is not produced. Arginine, esculin, and hippurate are not hydrolyzed. Starch is hydrolyzed by < 10% of strains. Strains

are sensitive to bacitracin (0.04 IU) but not to optochin. Lancefield group C, F, or non-groupable. Isolated from the organs (lungs, liver, spleen, and kidneys) of septicemic seals.

16S rRNA gene sequence analysis places this species within the Pyogenic group.

DNA G+C content (mol%): 38.6 (type strain) (T_m).

Type strain: 8399 H1, ATCC 51973, CCUG 35103, CIP 104665, LMG 16735, NCTC 12719.

GenBank accession number (16S rRNA gene): AF235052, AJ621053.

42. **Streptococcus pluranimalium** Devriese, Vandamme, Col-lins, Alvarez, Pot, Hommez, Butaye and Haesebrouck 1997, 1225^{VP}

plur.an.im.al'i.um. L. adj. *pluris* many; L. gen. pl. n. *animalium* from animals; N.L. gen. n. *pluranimalium* from many animals.

Cells are coccoid, forming chains or arranged in groups. Growth occurs equally well at 37°C and 42°C. Growth in broth culture produces precipitated cells with a clear supernatant. Colonies produce greening (α -hemolysis) on blood agar and are less than 1 mm in diameter. May grow in 6.5% NaCl broth. Acetoin is not produced (Voges-Proskauer reaction). Acid is produced from glucose, fructose, and trehalose, while other carbohydrate reactions may be weak and slow to develop in some strains. Acid is not produced from adonitol, D- and L-arabitol, D- and L-arabinose, D-cyclodextrin, dulcitol, erythritol, D- and L-fucose, gluconate, glycogen, inositol, inulin, 2- and 5-ketogluconate, D-lyxose, methyl α -D-glucoside, methyl α -D-mannoside, pullulan, rhamnose, starch, L-sorbose, D-turanose, D- and L-xylose, xylitol, and methyl β -xyloside. Variable carbohydrate reactions are obtained for N-acetylglucosamine, amygdalin, arbutin, cellobiose, galactose, β -gentiobiose, lactose, D-mannose, mannitol, maltose, melezitose, melibiose, methyl β -glucopyranoside, raffinose, ribose, sucrose, salicin, sorbitol, and D-tagatose. All strains produce leucine arylamidase, alanine-phenylalanine-proline arylamidase, and are able to hydrolyze 4-methylumbelliferyl (MU)-phosphate, L-phenylalanine 7-amido-4-methyl-coumarin (AMC), and L-tryptophan AMC. The following are variable characteristics of this species: arginine dihydrolase, pyrrolidonyl arylamidase, α -galactosidase, β -galactosidase, β -glucuronidase, β -glucosidase, alkaline phosphatase, and N-acetyl- β -glucosaminidase activities, hydrolysis of 4-MU β -glucoside, L-valine AMC, 4-MU α -D-glucoside, L-pyroglytamic acid AMC, L-arginine AMC, 4-MU N-acetyl- β -D-glucosaminide, 4-MU β -D-glucuronide, L-isoleucine AMC, *p*-nitrophenyl β -D-glucoside, *p*-nitrophenyl β -D-cellobioside, proline, and leucine *p*-nitroanilide. Strains do not have β -mannosidase or urease activities and are unable to hydrolyze *p*-nitrophenyl α -D-maltoside. Hippurate is hydrolyzed. Esculin hydrolysis is a variable reaction of this species with the majority of strains hydrolyzing this substrate on Edwards agar and giving a brown discoloration of this medium. Amongst strains of bovine origin those from the genital tract differ from other strains in being unable to grow in 6.5% NaCl broth, produce acid from amygdalin, arbutin, cellobiose, β -gentiobiose, melezitose, raffinose, ribose, or

sorbitol, in less frequently producing acid from mannitol or having β -glucosidase activity and in more frequently having β -glucuronidase activity. Strains are isolated from a relatively wide range of animal hosts and sites including the genital tract, udder, and tonsils of cattle, tonsils of the cat and goat, and the lung, crop, and a pox lesion of the canary.

16S rRNA gene sequence analysis has not shown this species to be associated with the main recognized species groups within the genus but is associated with *Streptococcus hyovaginalis* and *Streptococcus thoraltensis*.

Strains of *Streptococcus pluranimalium* resemble *Streptococcus acidominimus* and some reference strains of the latter have been re-identified as *Streptococcus pluranimalium* (Devriese et al., 1999; Facklam, 2002).

DNA G+C content (mol%): 38.5 (HPLC).

Type strain: T70, ATCC 700864, LMG 14177, CCUG 43803, CIP 106120.

GenBank accession number (16S rRNA gene): not available from type strain; Y18026 for strain LMG 14257.

43. **Streptococcus pneumoniae** (Klein 1884) Chester 1901, 63^{AL} (*Micrococcus pneumoniae* Klein 1884, 329) *pneu.mo'ni.ae*. Gr. n. *pneumon* the lungs; M.L. fem. n. *pneumonia* pneumonia. M.L. gen. n. *pneumoniae* of pneumonia.

Cells are oval or spherical, coccus-like forms, 0.5–1.25 μ m in diameter, typically in pairs, occasionally singly or in short chains. The distal end of each pair of cells tends to be pointed or lance-shaped. On primary isolation, generally heavily encapsulated with polysaccharide (termed SSS, specific soluble substance). Continued growth in laboratory media promotes chain formation. Gram-positive reaction of young cells may be lost as culture ages and subsequently stains Gram-negative.

Strong α -hemolysis on blood agar when cultures are incubated aerobically. Anaerobic incubation results in β -hemolysis due to pneumolysin O (identical to streptolysin O) activity. The addition of blood, serum, or ascitic fluid to media enhances growth especially on primary isolation. Muroid colonies result from copious capsular polysaccharide synthesis. Smooth colonies are glistening and dome-shaped, and reflect decreased capsular polysaccharide. Rough colonies occur rarely and have a wrinkled, mycelium-like appearance. "Phantom" colonies reflect early and rapid partial autolysis of a muroid colony which is suppressed by incubation under increased CO₂ tension.

Metabolism is fermentative, yielding primarily low levels of lactic acid. Final pH in glucose broth is approximately 5.0. Aerobically a significant quantity of H₂O₂ accumulates as well as acetic and formic acids. Acid is produced from glucose, galactose, fructose, sucrose, lactose, maltose, raffinose, glycogen, trehalose, and inulin. Strains frequently ferment N-acetylglucosamine and salicin. Slow acid production occurs from glycerol (aerobic incubation), xylose, arabinose, and erythritol. Some strains may ferment mannitol. Acid is not produced from amygdalin, arbutin, ribose, tagatose, dulcitol, or sorbitol.

Strains produce α -galactosidase, β -galactosidase, glycyl-tryptophan arylamidase, α -glucosidase, N-acetyl- β -galactosaminidase, sialidase (neuraminidase), and hyaluronidase. A minority of strains produce leucine

arylamidase, pyrrolidonyl arylamidase, α -fucosidase, β -fucosidase, and β -glucosidase.

Strains do not produce alkaline phosphatase, urease, or β -glucuronidase.

Hydrogen peroxide is produced. Acetoin is not produced (Voges-Proskauer reaction).

Esculin and arginine hydrolysis have been reported variously in the literature with the majority listing esculin hydrolysis as a variable characteristic and arginine hydrolysis as a positive characteristic. These tests are listed as "+" for arginine and "d" for esculin as in the previous edition of the *Manual*.

Pneumococci are inhibited by approximately 1:400 ethylhydrocupreine HCl (optochin); this sensitivity test and the bile-solubility test can be used to differentiate pneumococci from other streptococci (Bowers and Jeffries, 1955).

The cell-wall peptidoglycan type is Lys-Ala₂ (Ser). Major constituents of the cell-wall polysaccharides are glucose, N-acetylgalactosamine, and ribitol with trace amounts of galactose. The C-polysaccharide antigen (phosphorylcholine-containing teichoic acid) is covalently attached to the N-acetylmuramic acid of the peptidoglycan backbone and is uniformly distributed over the cell surface. C-Polysaccharide is responsible for pneumococcal reaction with C-reactive protein, an acute-phase human serum protein, and also for the bacterium's susceptibility to pneumococcal autolysin (an N-acetylmuramic acid-L-alanine amidase) where autolysin release from C-polysaccharide linked to a lipid moiety (i.e., the Forssman antigen) during cessation of growth due to starvation or treatment with detergents or penicillin, results in cellular autolysis.

Pneumococcal capsules. Ninety antigenically distinct capsular serotypes are recognized differing in component sugars and/or linkages (Henrichsen, 1995) and the structures of approximately half have been determined (Henrichsen, 1995; van Dam et al., 1990). Together these serotypes form the basis of pneumococcal serological typing (Kauffmann et al., 1960) in which capsular serotypes are designated numerically (serotype 1, etc.), and antigenically related serotypes form serogroups designated a common serogroup number within which all member serotypes are designated a different letter e.g., 7A, 7B, etc. Pneumococcal capsules are generally composed of repeating oligosaccharide units consisting of 2–10 monosaccharides which may be substituted with other organic and inorganic molecules (van Dam et al., 1990). Genes encoding the enzymes essential for the synthesis of a specific capsular polysaccharide are linked within the chromosome and are flanked by genes, common to all capsular serotypes, which are involved in regulation and polysaccharide transport (Hardy et al., 2000).

Virulence factors. Several factors, most found at the cell surface, contribute to the pathogenicity of *Streptococcus pneumoniae*. These include factors that aid the pathogen in escaping the host immune system and involved in the inflammation resulting from infection (Alonso DeVelasco et al., 1995).

Capsules. Capsules of *Streptococcus pneumoniae* are regarded as being essential for virulence and serve to protect from phagocytosis (Alonso DeVelasco et al., 1995). Encapsulated strains have been found to be at least five times as virulent as non-encapsulated strains (Avery and Dubos, 1931; Watson and Musher, 1990). Of the 90 known capsular serotypes, those associated more often with invasive disease in children include sero-

types 1, 5, 6B, 7F, 9V, 14, 18C, 19F, and 23F, with the spectrum of serotypes being less restricted in adult disease (Butler, 1997; Hausdorff et al., 2000; Sniadack et al., 1995).

Cell-wall polysaccharide. This induces inflammatory responses in the host by activation of the alternative complement pathway and stimulation of interleukin-1 production by monocytes (Riesenfeld-Orn et al., 1989; Winkelstein and Tomasz, 1977, 1978).

IgA₁ protease. This is produced and probably acts as a defence against the host immune system at mucosal surfaces.

Pneumolysin. This thiol-activated cytotoxin is released under the influence of autolysin. At high concentrations pneumolysin causes transmembrane ring formation on host cells resulting in lysis and at lower concentrations has several effects, including stimulating inflammatory cytokine (interleukin-1 and tumour necrosis factor) production by monocytes, slowing the beating of cilia and disrupting the integrity of human respiratory epithelium in culture, decreasing the migration and bactericidal activity of neutrophils, and inhibiting lymphocyte proliferation and antibody synthesis. Pneumolysin is able to activate complement via antibody binding of the Fc region. Pneumolysin has some sequence homology with C-reactive protein (CRP), an acute-phase protein that protects mice against pneumococci.

Autolysin. This is a cell-wall-degrading enzyme which, when activated during cell starvation or penicillin treatment, causes autolysis of the pneumococcus and release of inflammatory mediators such as peptidoglycan and teichoic acid and the release of pneumolysin from the cytoplasm.

Pneumococcal proteins studied in relation to virulence include neuraminidase (Berry et al., 1988), hyaluronidase (Berry et al., 1994), pneumococcal surface proteins PspA (Briles et al., 1988; Yother and Briles, 1992), PsaA (Sampson et al., 1994), SpsA (Hammerschmidt et al., 1997), and IgA₁ protease (Male, 1979; Poulsen et al., 1996).

Pathogenicity. The clinical patterns of pneumococcal infections in man are numerous. They include pneumonia, meningitis, otitis media, and some less frequent conditions such as abscesses, conjunctivitis, pericarditis, and arthritis. In animals pneumococci may occasionally cause mastitis and septicemia in cows, sheep and goats, and respiratory tract infections in monkeys.

Strains are isolated from the upper respiratory tract, inflammatory exudates and various body fluids of diseased humans and, rarely, domestic animals. The normal habitat in humans is the nasopharynx with an estimate of as high as 60% of the population colonized at any one time (Austrian, 1986).

DNA G+C content (mol%): 38.5 (chemical analysis) to 30 (T_m) and 42 (Bd). Genome sequencing of strain R6 gave an overall G+C content of 40.0 mol%.

Type strain: SV 1, ATCC 33400, CCUG 28588, CIP 102911, DSM 20566, LMG 14545, NCTC 7465.

GenBank accession number (16S rRNA gene): AF003930, AY485600, X58312.

Additional comments: *Streptococcus pneumoniae* is naturally competent for transformation with competence under the regulation of the *com* operon (Pestova et al., 1996). The process of horizontal gene transfer, often between *Streptococcus pneumoniae* and commensal oral streptococci including *Streptococcus mitis* and *Streptococcus oralis*, has been shown to

be important in the evolution of penicillin resistance and virulence determinants (Dowson et al., 1997). Low-affinity PBPs arising in resistant strains are encoded by mosaic genes, with oral commensal species *Streptococcus mitis* and *Streptococcus oralis* as gene donors for PBP2B (Dowson et al., 1993) and PBP2X (Sibold et al., 1994), respectively. Recombination events at the capsular polysaccharide synthesis locus give rise to serotype changes among natural populations (Coffey et al., 1998). Other virulence determinants displaying evidence for gene transfer include autolysin (*lytA*), neuraminidase (*nanA*) and IgA₁ protease (*iga*). It has been postulated that atypical *Streptococcus pneumoniae* strains lacking one or more of the defining phenotypic characteristics of the species, i.e., optochin susceptibility, bile solubility, and agglutination with antipneumococcal polysaccharide capsule antibodies, and “*Streptococcus mitis*-like” strains harboring pneumococcal virulence factor genes may act as reservoirs of DNA for recombination events (Whatmore et al., 2000).

The genomes of three strains of *Streptococcus pneumoniae* have been sequenced. These include serotype 4 strain TIGR4 (Tettelin et al., 2001), avirulent (non-encapsulated) strain R6 (Hoskins et al., 2001), and >90% of the genome of serotype 19 clinical isolate G54 (Dopazo et al., 2001).

16S rRNA gene sequence analysis places *Streptococcus pneumoniae* within the *Mitis* species group.

44. ***Streptococcus porcinus*** Collins, Farrow, Katic and Kandler 1985, 224^{VP} (Effective publication: Collins, Farrow, Katic and Kandler 1984a, 409.)

por.cí'nus. L. adj. *porcinus* of pigs, pertaining to pigs.

Cells are spherical to ovoid cocci in chains of small to medium length. Colonies on blood agar are normally small, elevated, and entire. β-Hemolysis is produced on blood agar. Growth does not occur at 10°C or at 45°C. Does not survive heating at 60°C for 30 min. Chemo-organotroph: metabolism fermentative. Acid is produced from glucose, N-acetylglucosamine, fructose, galactose, mannose, ribose, sorbitol, and trehalose. Most strains produce acid from cellobiose, glycerol, mannitol, maltose, salicin, and sucrose. Acid from amygdalin, lactose, and starch are variable characteristics of this species. Acid is not produced from D- and L-arabinose, D- and L-arabitol, adonitol, dulcitol, erythritol, D- and L-fucose, gluconate, glycogen, inositol, inulin, 2-ketogluconate, 5-ketogluconate, lyxose, melezitose, melibiose, methyl α-D-glucoside, methyl α-D-mannoside, raffinose, rhamnose, L-sorbose, tagatose, D-turanose, xylitol, D-xylose, and L-xylose. Acid production from arbutin, gentiobiose and starch are variable characteristics.

Strains produce alkaline phosphatase and leucine arylamidase. α-Galactosidase, β-galactosidase, and pyrrolidonyl arylamidase are not produced. β-Glucuronidase production is a variable characteristic. Arginine is hydrolyzed, some strains hydrolyze esculin and most hydrolyze gelatin if incubated anaerobically. Hippurate is not hydrolyzed. Acetoin production (Voges–Proskauer reaction) is a variable characteristic of this species. Strains may react with Lancefield group E,P,U, or V antiserum. The peptidoglycan contains lysine as the diamino acid (type: Lys–Ala₂₋₄). Menaquinones are absent. Major nonhydroxylated long-

chain fatty acids are hexadecanoic (C_{16:0}) and octadecenoic (*cis*-vaccenic acid); cyclopropane fatty acids are absent.

Collins et al. (1984a) describe the type strain, NCTC 10999, as producing acetoin and β-glucuronidase, reacting with Lancefield group V antisera, hydrolyzing esculin, and producing acid from arbutin, amygdalin, cellobiose, glycerol, lactose, salicin, and sucrose, with all other characteristics being as given above.

Strains are commonly associated with abscesses in the cervical lymph nodes of pigs; also isolated from other diseases of pigs (pneumonia and septicemia) and from milk.

16S rRNA gene sequence analysis places this species within the *Pyogenic* species group.

DNA G+C content (mol%): 37.1–37.7 (T_m).

Type strain: ATCC 43138, CCUG 27628, CIP 103218, DSM 20725, LMG 15980, NCTC 10999.

GenBank accession number (16S rRNA gene): AB002523, X58315.

45. ***Streptococcus rattii*** corrig. Coykendall 1977, 28^{VP}

rat'ti. L. gen. n. *rattii* of a rat.

Cells are coccoid, 0.5 μm in diameter and are in pairs or form chains. Growth occurs in air but is generally improved by an atmosphere of reduced O₂ content, with added CO₂. An adhesive extracellular glucan is produced from sucrose. Colonies on sucrose agar are often rough, heaped, and with beads or puddles of liquid (containing glucan) or some in the case of some strains, firm, “rubbery” colonies are formed. Strains are non-hemolytic on blood agar. The terminal pH in glucose broths is 4.2–4.4. Acid is produced from amygdalin, arbutin, cellobiose, methyl D-glucoside, N-acetylglucosamine, galactose, glucose, maltose, mannitol, raffinose, salicin, sorbitol, trehalose, sucrose, lactose, and inulin. The majority of strains produce acid from inulin, lactose, and melibiose. Acid is not produced from adonitol, arabinose, dulcitol, erythritol, glycerol, inositol, melezitose, methyl D-mannoside, methyl D-xyloside, rhamnose, ribose, sorbose, or xylose. Arginine and esculin are hydrolyzed but starch is not. Acetoin is produced (Voges–Proskauer reaction). Hydrogen peroxide is not produced. Strains can grow in the presence of 20 μg/ml bacitracin.

Strains of *Streptococcus rattii* were originally described (Coykendall, 1977) as a distinct serovar of *Streptococcus mutans*, designated *type b* (Bratthall, 1970). Two polysaccharide antigens, apparently with identical immunodeterminants, have been purified from this serovar (Mukasa and Slade, 1973) and a glycerol teichoic acid substituted with a galactosyl moiety has also been described (Vaught and Bleiweis, 1974). *Streptococcus rattii* was first obtained from a laboratory rat, but has also been isolated from the human mouth. However, this species is less commonly isolated from humans than other species belonging to the “mutans group” of streptococci.

16S rRNA gene sequence analysis places this species within the *Mutans* species group.

DNA G+C content (mol%): 41–43 (T_m).

Type strain: FAI, ATCC 19645 CCUG 27502, CCUG 27642, CIP 102509, DSM 20564, HAMBI 1518, LMG 14650.

GenBank accession number (16S rRNA gene): AJ420201.

Additional comments: *Streptococcus rattii* is the corrected name for strains previously called *Streptococcus rattus* by Coykendall (1977) (Trüper and de Clari, 1997).

46. ***Streptococcus salivarius*** Andrewes and Horder 1906, 712^{AL}

sa.li.va'ri.us. L. adj. *salivarius* salivary, slimy.

Cells are spherical to ovoid, 0.8–1.0 μm in diameter, forming chains of varying length from short to very long. Grows readily on suitable media in the presence of O₂. Growth occurs at 45°C but not at 10°C. The majority of strains are non-hemolytic on blood agar with occasional α-hemolytic and β-hemolytic strains found. Smooth and rough variants occur, with the rough variant often reverting after subculture in broth. On sucrose-containing agar most isolates produce soluble fructan (levan) which results in the development of large mucoid colonies. Some strains also produce insoluble glucans (dextrans). Colonies on sucrose agar vary from smooth to rough depending upon the relative proportions of the different polysaccharides synthesized. Acid is produced from amygdalin, arbutin, cellobiose, esculin, fructose, glucose, sucrose, maltose, mannose, *N*-acetylglucosamine, pullulan, and salicin. Acid is not produced from arabinose, arabitol, adonitol, cyclodextrin, dulcitol, gluconate, glycogen, glycerol, mannitol, melibiose, rhamnose, ribose, sorbitol, L (-) sorbose, starch, tagatose, or xylose. The production of acid from galactose, lactose, methyl *D*-glucoside, inulin, raffinose, and trehalose are variable characteristics. The final pH produced in glucose broth is 4.0–4.4. Strains produce α-arabinosidase, acid- and alkaline phosphatases, alanyl-phenylalanyl-proline arylamidase, chymotrypsin, α-*D*- and glucosidases, leucine aminopeptidase, leucine arylamidase, α-maltosidase phosphoamidase, and valine aminopeptidase but not α-*L*- and β-*D*-fucosidase, α-*D*-galactosidase, glucosaminidase, *N*-acetyl-α-*D*-glucosaminidase, β-*N*-acetylgalactosidase, β-*N*-acetylglucosaminidase, β-*D*-glucuronidase, glycyL-tryptophan arylamidase, hyaluronidase, α- and β-mannosidase, pyroglutamic acid arylamidase, pyrrolidonyl arylamidase, phosphor-β-galactosidase, β-sialidase (neuraminidase), or α- and β-xylosidase. β-*D*-Fucosidase, β-*D*-galactosidase, β-maltosidase, β-lactosidase, and urease are variable characteristics of this species. However, it should be noted that the proportion of strains reported to be positive in these tests varies within the literature. Esculin and starch are hydrolyzed. Urea is hydrolyzed by some strains. Arginine and hippurate are not hydrolyzed. Acetoin is produced (Voges–Proskauer reaction) by the majority of strains. Hydrogen peroxide and IgA₁ protease are not produced. Approximately 50% of strains react with Lancefield group K antiserum. Two types of peptidoglycan have been found in *Streptococcus salivarius* (Lys–Ala₂₋₃ and Lys–Thr–Gly) (Schleifer and Kilpper-Bälz, 1987).

Strains are isolated from the oral cavities of man and animals, being associated particularly with the tongue and saliva, and in feces. It is occasionally isolated from the blood of patients with infective endocarditis. Some strains have been shown to be cariogenic in gnotobiotic rats.

16S rRNA gene sequence analysis places this species within the *Salivarius* species group.

DNA *G+C* content (mol%): 39–42 (*T_m*).

Type strain: ATCC 7073, CCUG 11878, CCUG 17825, CIP 102503, DSM 20560, HAMBI 1716, JCM 5707, LMG 11489, NCIMB 701779, NCTC 8618.

GenBank accession number (16S rRNA gene): AY188352.

47. ***Streptococcus sanguinis*** corrig. White and Niven 1946, 722^{AL} emend. Kilian, Mikkelsen and Henrichsen 1989b, 482

san'gui.nis. L. n. *sanguis* blood; L. gen. n. *sanguinis* of the blood.

Cells are coccoid and occur in short chains in serum broth. α-Hemolysis is produced on blood (horse) agar and pronounced greening is seen on chocolate agar. The majority of strains are inhibited in the presence of 4% (w/v) NaCl and no growth occurs in 6.5% NaCl. Acid is produced from galactose, *N*-acetylglucosamine, fructose, glucose, maltose, mannose, lactose, salicin, sucrose, and trehalose. Acid is not produced from adonitol, arabinose, arabitol, cyclodextrin, dulcitol, glycerol, gluconate, glycogen, mannitol, *D*-melezitose, rhamnose, ribose, sorbose, tagatose, or xylose. Acid from amygdalin, arbutin, *D*-cellobiose, esculin, inulin, melibiose, methyl *D*-glucoside, pullulan, raffinose, sorbitol, and starch. Starch is weakly fermented producing a final pH of around 5.6–6.2. Reports of the proportion of strains able to ferment inulin vary in the literature.

Strains produce leucine aminopeptidase, α-maltosidase, and alanyl-phenylalanyl-proline arylamidase. Production of acid phosphatase, chymotrypsin, β-*D*-fucosidase, glycyL-tryptophan arylamidase, β-*D*-lactosidase, *N*-acetyl-β-*D*-glucosaminidase, phospho-β-galactosidase, phosphoamidase, and valine aminopeptidase are variable characteristics of this species. Strains do not produce alkaline phosphatase, α-*L*-arabinosidase, α-*L*-fucosidase, α-*D*-glucosidase, β-maltosidase, α- and β-mannosidases, β-*L*-fucosidase, β-glucuronidase, β-glucosaminidase, *N*-acetyl-α-*D*-glucosaminidase, *N*-acetyl-β-*D*-galactosaminidase, ornithine and lysine decarboxylases, sialidase (neuraminidase), urease, or α- and β-xylosidases. Detection of β-*D*-glucosidase, α-*D*-galactosidase, β-*D*-galactosidase, and *N*-acetyl-β-*D*-glucosaminidase activities are dependent on the substrate used and the percentage of strains reported as positive for these properties may vary considerably between studies.

Arginine is hydrolyzed. Esculin and starch are variable characteristics, being hydrolyzed by the majority of strains. Urea and hippurate are not hydrolyzed. Hydrogen peroxide and IgA₁ protease are produced. Acetoin is not produced (Voges–Proskauer reaction). Dextran is produced from sucrose-containing media by the majority of strains. Hyaluronidase is not produced and strains do not bind salivary amylase. Some strains react to Lancefield group H antiserum raised against strain “Blackburn” (Kilian et al., 1989b).

The cell wall contains glycerol teichoic acid and rhamnose, and the peptidoglycan type is Lys–Ala₁₋₃.

Streptococcus sanguinis has been separated into biovars (Kilian et al., 1989b), or biotypes (Beighton et al., 1991), on the basis of several biochemical and serological characteristics.

Strains are isolated from the human mouth. *Streptococcus sanguinis* is one of the commonest streptococci isolated from infective endocarditis (Douglas et al., 1993) and is a primary colonizer of dental plaque (Fransen et al., 1991).

16S rRNA gene sequence analysis places this species within the Mitis species group.

DNA G+C content (mol%): 43–46% (T_m).

Type strain: SK 1, ATCC 10556, CCUG 17826, CCUG 35770, CIP 55.128, DSM 20567, JCM 5708, LMG 14702, NCTC 7863.

GenBank accession number (16S rRNA gene): AB002524, AF003928, X53653.

Additional comments: *Streptococcus sanguinis* is the corrected name for strains previously called *Streptococcus sanguis* (Trüper and de Clari, 1997).

48. **Streptococcus sinensis** Woo, Tan, Leung, Lau, Teng, Wong and Yuen 2002, 1438^{VP} (Effective publication: Woo, Tan, Leung, Lau, Teng, Wong and Yuen 2002, 810.)

si.nen.sis. L. gen. n. *sinae* of China; N.L. masc. adj. *sinensis* pertaining to China, the country where the bacterium was isolated.

Cells are coccoid, 0.82–0.98 µm in diameter, occurring in chains. Facultatively anaerobic. Growth for 24 h incubation at 37°C in ambient air sheep blood agar produces α-hemolytic, gray colonies of 0.5–1 mm diameter. No enhancement of growth is seen in 5% CO₂. Growth occurs in 10 and 40% bile and on bile-esculin agar but not in 6% NaCl.

Acid is produced from glucose, lactose, salicin, sucrose, pullulan, trehalose, cellobiose, hemicellulase, mannose, maltose, and starch. Acid is not produced from inulin, mannitol, ribose, raffinose, or sorbitol. Strain HKU4 produces leucine arylamidase and β-glucosidase but not urease, lysine decarboxylase or ornithine decarboxylase. Esculin and arginine are hydrolyzed. Acetoin is produced (Voges–Proskauer reaction).

Non-groupable with Lancefield groups A, B, C, D, F, and G antisera. Resistant to optochin and bacitracin.

Strain HKU4, on which the species description is based, was isolated from the blood culture of a patient with infective endocarditis.

16S rRNA gene sequence analysis indicates that this species is affiliated with the Mitis and Anginosus species groups with 3.6, 3.7, 4.3, 4.7, and 5.9% base differences between it and *Streptococcus gordonii*, *Streptococcus intermedius*, *Streptococcus constellatus*, *Streptococcus sanguinis*, and *Streptococcus anginosus*, respectively. It is listed within the Mitis group in Table 133.

DNA G+C content (mol%): 53±2.9 (T_m).

Type strain: HKU4, DSM 14990, LMG 21517.

GenBank accession number (16S rRNA gene): AF432856.

49. **Streptococcus sobrinus** Coykendall 1983, 883^{VP}

so.bri'nus. L. masc. n. *sobrinus* male cousin on mother's side (referring to the "distant relationship" between this species and *Streptococcus mutans*).

Cells are coccoid, 0.5 µm in diameter, and occur in pairs or chains, often long chains. Colonies on sucrose agar are about 1 mm in diameter, rough, heaped, often showing

drops of glucan-containing liquid on or around the colony. Some strains are α-hemolytic on blood agar, others non-hemolytic. Acid is produced from glucose, maltose, mannose, sucrose, tagatose, and trehalose. Acid production is detectable from cellobiose and mannitol after extended incubation (96 and 48 h, respectively). Acid is not produced from adonitol, amygdalin, arabinose, arbutin, dulcitol, erythritol, esculin, gluconate, glycerol, glycogen, inositol, melibiose, methyl D-glucoside, methyl D-mannoside, methyl D-xyloside, N-acetylglucosamine, melibiose, melizitose, pullulan, raffinose, rhamnose, salicin, sorbose, starch, or xylose. Acid production from galactose, lactose, and sorbitol are variable characteristics of this species. Strains produce α-glucosidase. Alkaline phosphatase, α-arabinosidase, α-galactosidase, β-galactosidase, α-fucosidase, β-fucosidase, β-glucosidase, β-glucuronidase, N-acetylgalactosaminidase, N-acetylglucosaminidase, pyrrolidonyl arylamidase, glycyl tryptophan arylamidase, hyaluronidase, sialidase, and urease are not produced. Ammonia is not produced from arginine. Esculin is not hydrolyzed. Acetoin is produced (Voges–Proskauer reaction). Most strains produce hydrogen peroxide. Significant amounts of intra-cellular polysaccharide (IPS) are not produced. The peptidoglycan type is Lys–Thr–Ala. Strains usually belong to the serological type d or g of Bratthall (1970). However, the type strain SL-1 (ATCC 33478) does not belong to these serological types.

The habitat of *Streptococcus sobrinus* is the human tooth surface. Strains have been shown to be cariogenic in experimental animals and may be associated with human dental caries.

16S rRNA gene sequence analysis places this species within the Mutans species group.

The genome of strain 6715 is currently being sequenced (<http://www.tigr.org/tdb/mdb/mdbinprogress.html>).

DNA G+C content (mol%): 44–46 (T_m).

Type strain: SL1, NCTC 12279, ATCC 33478, CCUG 25735, CIP 103230, DSM 20742, HAMB1 1516, LMG 14641.

GenBank accession number (16S rRNA gene): AJ243966, AY188349, X58307.

50. **Streptococcus suis** (ex Elliott 1966) Kilpper-Bälz and Schleifer 1987, 160^{VP}

su'is. L. n. *sus* a pig; L. gen. n. *suis* of a pig.

Cells are coccoid, < 2 µm in diameter and occur singly, in pairs, or (rarely) in short chains. There is some tendency towards rod formation. Many strains produce β-hemolysis on horse blood agar and all are α-hemolytic on sheep blood agar. No growth occurs at 10 or 45°C, in 6.5% NaCl or 0.04% tellurite. Some strains are resistant to bile. All are resistant to optochin. Chemo-organotroph with fermentative metabolism. Acid is produced from D-glucose, sucrose, lactose, maltose, salicin, trehalose, and inulin. Acid production from raffinose and melibiose are variable characteristics of this species. Acid is not produced from L-arabinose, D-mannitol, D-sorbitol, glycerol, melezitose, or D-ribose. Strains produce L-ornithine decarboxylase, β-acetylglucosaminidase, α-galactosidase, β-glucuronidase, and leucine arylamidase. β-Galactosidase and hyaluronidase production are variable characteristics. Strains do

not produce acid or alkaline phosphatases or pyrrolidonyl arylamidase. Strains hydrolyze L-arginine, esculin, salicin, starch, and glycogen but not hippurate. Acetoin is not produced. Strains do not produce extracellular polysaccharide on sucrose-containing medium.

Type of peptidoglycan is usually lysine direct and, in a few cases, Lys-Ala₁₋₂. Cell-wall polysaccharides contain rhamnose, glucose, galactose, and glucosamine.

Strains assigned to *Streptococcus suis* by Kilpper-Bälz and Schleifer (1987) belonged to Lancefield groups R, S, RS, and T, or were ungroupable, and also included morphologically and biochemically similar strains described previously as serovars (1–8) of “*Streptococcus suis*” (Perch et al., 1983; Windsor and Elliott, 1975). Additional serotypes have been described (Gottschalk et al., 1991) and 35 different antigenic carbohydrate types of this species are described. The most common strains identified are Lancefield group R (type 2) and these are the only serotype identified from humans (Facklam, 2002). Lancefield group S strains are type 1.

Streptococcus suis is an important pig pathogen and has been isolated from cases of bacteremias and meningitis in piglets and from respiratory disease. Human infections are often associated with patients having worked in contact with pigs (Luttiken et al., 1986). The great extent of genetic diversity within this species has been noted by the demonstration of 60 pulsotypes by PFGE from a collection of 302 isolates from swine (Vela et al., 2003). 16S rRNA sequencing has shown a higher degree of diversity for serotypes 32, 33, and 34 (Chatellier et al., 1998).

16S rRNA gene sequence analysis places this species outside the main recognized species groups in most studies although it joined the Pyogenic species group in one study (Flint et al., 1999).

The genome of strain P1/7 is currently being sequenced and is approximately 1.7 Mb in size with a mol% G+C content of around 40.

DNA G+C content (mol%): 38–42 (T_m).

Type strain: Henrichsen S735, ATCC 43765, CCUG 7984, CIP 103217, DSM 9682, LMG 14181, NCTC 10234.

GenBank accession number (16S rRNA gene): AB002525 AF009477.

51. ***Streptococcus thermophilus*** (ex Orla-Jensen 1919) Schleifer, Ehrmann, Krusch and Neve 1995, 619^{VP} (Effective publication: Schleifer, Ehrmann, Krusch and Neve 1991, 387.) ther.mo'phil.us. Gr. n. *therme* heat; Gr. adj. *philos* loving. N.L. adj. *thermophilus* heat-loving.

Cells are spherical or ovoid, 0.7–1.0 μm in diameter, occurring in pairs to long chains. Irregular segments and cells can occur at 45°C. α-Hemolysis is formed on blood agar. Chemo-organotrophic, facultatively anaerobic. Able to grow at 45°C and most strains will survive heating to 65°C for 30 min. No growth at 15°C. No growth at pH 9.6 or in the presence of 0.1% methylene blue. Variable growth is observed in broth containing 2% NaCl, no growth at 3% NaCl. B-Vitamins and some amino acids are required. Acid is produced from fructose, glucose, lactose, mannose, and sucrose. Acid is not produced from N-acetylgalactosamine,

N-acetylglucosamine, adonitol, amygdalin, arabinose, cellobiose, cyclodextrin, dulcitol, erythritol, gluconate, glycerol, glycogen, inulin, maltose, mannitol, methyl D-glucoside, methyl D-mannoside, methyl D-xyloside, rhamnose, salicin, sorbitol, tagatose, trehalose, and xylose. Variable reactions are observed for arbutin, galactose, melizitose, melibiose, raffinose, and ribose. Acetoin is produced (Voges-Proskauer reaction). Strains do not hydrolyze esculin, casein, gelatin, or hippurate. Ammonia is not produced from arginine, which is in accordance with Teuber and Geis (1981) but in contrast to Hardie (1986a). Starch hydrolysis is a variable characteristic of this species. β-Galactosidase and leucine arylamidase are produced. Acid- and alkaline-phosphatase, α-fucosidase, α-galactosidase, α-glucosidase, β-glucosidase, β-glucuronidase, cysteine arylamidase, N-acetyl-β-glucoaminidase, pyrrolidonyl arylamidase, and valine arylamidase are not produced. DNase and urease are not produced. The peptidoglycan type is Lys-Ala₂₋₃. No group-specific antigen has been demonstrated.

Streptococcus thermophilus is found in dairy sources including heated and pasteurized milk.

16S rRNA gene sequence analysis places this species within the Salivarius group.

The genome sequencing of *Streptococcus thermophilus* strain LMG 18311 is currently under way.

DNA G+C content (mol%): 37–40 (T_m).

Type strain: ATCC 19258, CCUG 21957, CIP 102303, DSM 20617, LMG 6896, NCIMB 8510.

GenBank accession number (16S rRNA gene): AY188354, X68418.

52. ***Streptococcus thoraltensis*** Devriese, Pot, Vandamme, Kersters, Collins, Alvarez, Haesebrouck and Hommez 1997, 1077^{VP}

thor.al.ten'sis. L. masc. adj. *thoraltensis* from Thoraltum, L. name of Torhout, the town where the strains were isolated.

Cells are coccoid, arranged as short chains, pairs or groups. Colonies on blood (bovine) agar incubated in 5% CO₂ are approximately 1 mm in diameter, regular, opaque, and are α-hemolytic. Aerobic growth produces pinpoint colonies. Growth occurs at 25–37°C but is strongly inhibited at 42°C. Culture in broth produces sediment with clear supernatant. Growth occurs in the presence of 6.5% NaCl after 2 d. Strains will grow on Slanetz-Bartley medium without the reduction of triphenyltetrazolium chloride when incubated in the presence of 5% CO₂. Growth is strongly inhibited on bile-esculin medium. Strains produce acid from L-arabinose, arbutin, cellobiose, fructose, galactose, β-gentiobiose, methyl β-D-glucopyranoside, glucose, N-acetylglucosamine, inulin, lactose, maltose, mannose, mannitol, ribose, salicin, starch, sucrose, trehalose, and pullulan. Acid is not produced from adonitol, D-arabinose, D- and L-arabitol, cyclodextrin, dulcitol, erythritol, D- and L-fucose, glycerol, glycogen, gluconate, 2- and 5-ketogluconate, inositol, D-lyxose, methyl α-D-mannoside, rhamnose, L-sorbose, xylitol, L-xylose, or methyl β-xyloside. Strains produce leucine arylamidase, arginine dihydrolase, alanine phenylalanine proline arylamidase, β-glucuronidase, alkaline phosphatase (often weak), and β-glucosidase. Acetoin is produced (Voges-Proskauer reaction). Strains do not

produce pyrrolidonyl arylamidase, β -mannosidase, urease, and *N*-acetyl- β -D-glucosaminidase. α -Galactosidase, alkaline phosphatase, and hippurate hydrolysis are variable characteristics of this species. β -Galactosidase test results may vary depending on the substrate used. Sorbitol, amygdalin, melibiose, melezitose, raffinose, D-turanose, tagatose, D-xylose, and methyl α -D-glucoside are variable characteristics of this species. Strains are ungroupable by Lancefield grouping reaction.

16S rRNA gene sequence analysis has shown *Streptococcus thoraltensis* to form a distinct subline within the streptococci in association with, but distinct from, *Streptococcus hyovaginalis*.

Strains are associated with pigs, occurring most frequently in vaginal fluids and in the intestine. Involvement with pathological processes in these animals is unclear.

DNA G+C content (mol%): 40 (T_m).

Type strain: S69, ATCC 700865, CCUG 32906, CCUG 37868, CIP 105518, LMG 13593.

GenBank accession number (16S rRNA gene): Y09007.

53. **Streptococcus uberis** Diernhofer 1932, 370^{AL}

u'ber.is. L. n. *uber* udder, teat; L. gen. n. *uberis* of an udder.

Cells are coccoid, occurring as pairs to chains of moderate length. α -Hemolysis is produced on blood agar but β -hemolysis is not. Growth occurs in the presence of 4% but not 6.5% NaCl. Growth does not occur at pH 9.6. Growth is slow or does not occur at 10°C and does not occur at 45°C. Does not survive heating at 65°C for 30 min.

Acid is produced from amygdalin, arbutin, cellobiose, β -gentiobiose, inulin, lactose, maltose, mannitol, ribose, salicin, sorbitol, sucrose, *N*-acetylglucosamine, fructose, galactose, glucose, mannose, and trehalose. The majority of strains produce acid from tagatose. A minority of strains produce acid from glycogen, methyl α -D-glucoside and starch. Acid is not produced from adonitol, D-arabinose, L-arabinose, D-arabitol, L-arabitol, erythritol, D-fucose, L-fucose, dulcitol, glycerol, gluconate, 2-ketogluconate, 5-ketogluconate, inositol, lyxose, melibiose, melizitose, methyl α -mannoside, methyl α -xyloside, raffinose, rhamnose, sorbose, turanose, xylitol, D-xylose, or L-xylose. Strains produce leucine arylamidase, pyrrolidonyl arylamidase, and β -glucuronidase. A few strains produce alkaline phosphatase. Strains do not produce α - or β -galactosidase.

Arginine, esculin, and hippurate are hydrolyzed. Acetoin is produced (Voges-Proskauer reaction). Strains reduce tetrazolium, but do not decarboxylate tyrosine or produce DNase. The peptidoglycan type is Lys-Ala₁₋₃.

Strains are isolated from lips and skin of cows, raw milk, and udder tissue. All isolates previously reported from humans have been reidentified as *Globicatella sanguinis* (Facklam, 1977, 2002)

16S rRNA gene sequence analysis places this species within the Pyogenic species group.

DNA G+C content (mol%): 36–37.5 (T_m).

Type strain: ATCC 19436, CCUG 17930, CCUG 27579, CIP 103219, DSM 20569, JCM 5709, LMG 9465, NCTC 3858.

GenBank accession number (16S rRNA gene): AB002526, AB023573.

Additional comments: Strains of *Streptococcus uberis* and *Streptococcus parauberis* were previously referred to as *Streptococcus uberis* types I and II, respectively on the basis of DNA–DNA similarity data (Collins et al., 1984a; Garvie and Bramley, 1979b). These two species are physiologically and biochemically indistinguishable, and species-specific probes have been designed to differentiate them (Bentley et al., 1993).

The genome of *Streptococcus uberis* strain 0140J is currently being completed. The genome is approximately 1.7 Mb in size with a mol% G+C content of around 40.

54. **Streptococcus urinalis** Collins, Hutson, Falsen, Nikolaitchouk, LaClaire and Facklam 2000, 1177^{VP}

u.ri.na'lis. M.L. adj. *urinalis* pertaining to urine.

Cells are ovoid and occur singly, in pairs or short chains. Facultatively anaerobic. Non-hemolytic on blood agar. Growth occurs in 6.5% NaCl but not at 10°C. Gas is not produced in MRS broth. Acid and clot are formed in litmus milk. Strains produce acid from glucose, lactose, ribose, sucrose, maltose, and trehalose, although lactose fermentation has been reported as a negative characteristic when testing strains using a commercial test system (API) (Collins et al., 2000). Acid is not produced from L-arabinose, D-arabitol, cyclodextrin, glycogen, glycerol, inulin, mannitol, melibiose, melezitose, methyl β -D-glucopyranoside, *N*-acetylglucosamine, pullulan, sorbitol, sorbose, raffinose, or tagatose. Strains are positive for leucine aminopeptidase, pyrrolidonyl arylamidase, acid phosphatase, alkaline phosphatase, α -glucosidase, β -glucosidase, pyroglutamic acid arylamidase, and leucine arylamidase. Strains are negative for alanine-phenylalanine-proline arylamidase, chymotrypsin, esterase C4, ester lipase C8, α -fucosidase, α -galactosidase, β -galactosidase, β -galacturonidase, β -glucuronidase, glycyl-tryptophan arylamidase, lipase C14, α -mannosidase, β -mannosidase, trypsin, and valine arylamidase. Hippurate, urea, starch, and arginine are not hydrolyzed. Pyruvate is not utilized. Extracellular polysaccharide is not produced. Acetoin is produced (Voges-Proskauer reaction). Strains are vancomycin-sensitive and bacitracin-resistant. Bile-esculin-positive. Strains are not grouped with Lancefield antisera for groups A, B, C, D, E, F, and G.

Strains have been isolated from the urine of patients suffering from cystitis.

16S rRNA gene sequence analysis places this species within the Pyogenic species group.

DNA G+C content (mol%): 39 (T_m).

Type strain: 2285-97, CCUG 41590, CIP 106463.

GenBank accession number (16S rRNA gene): AJ131965.

55. **Streptococcus vestibularis** Whiley and Hardie 1988, 338^{VP}

ves.tib.u.lar'is. L. n. *vestibulum* entrance hall or forecourt; N.L. adj. *vestibularis* pertaining to the vestibule of the mouth where the organism was originally isolated.

Cells are coccoid, approximately 1 μ m in diameter growing in chains. α -hemolysis is produced on blood (horse) agar. Colonies growing anaerobically for 3 d on sucrose-containing (Mitis Salivarius) agar are 1–2 mm in diameter, dark blue, matte, and umbonate with undulate edges. Colonies grown aerobically on Mitis Salivarius agar are

1–2 mm in diameter, dark blue, convex, glossy with entire edges. Both aerobic and anaerobic growth on 5% sucrose containing agar (TYC) produce 1–2 mm diameter colonies, white, convex and glossy with entire edges. Growth does not occur at 10°C or at 45°C, in the presence of 4% NaCl or 0.0004% (w/v) crystal violet. The majority of strains grow in the presence of 10% (w/v) bile but not 40% (w/v). The type strain does not grow in 10% bile. Extracellular polysaccharide is not produced on sucrose agar. Acid is produced from *N*-acetylglucosamine, fructose, galactose, glucose, lactose, maltose, mannose, salicin and sucrose. Acid is not produced from adonitol, arabinose, dextrin, dulcitol, fucose, glycerol, glycogen, inositol, inulin, mannitol, melezitose, melibiose, raffinose, ribitol, ribose, sorbitol, starch, or xylose. The majority of strains produce acid from cellobiose and amygdalin. Few strains produce acid from trehalose or *D*-glucosamine hydrochloride. Arbutin fermentation is a variable characteristic of *Streptococcus vestibularis*. Strains which ferment trehalose but not cellobiose and amygdalin constitute a separate biotype from the majority of the strains.

β -Galactosidase is produced. Alkaline phosphatase, α -galactosidase, α -fucosidase, β -glucosidase, glucuronidase, β -fucosidase, *N*-acetylglucosaminidase, *N*-acetylgalactosaminidase, hyaluronidase, neuraminidase, and pyrrolidonyl arylamidase are not produced. Urease and hydrogen peroxide are produced. α -Glucosidase is a variable characteristic of this species. Esculin and starch are hydrolyzed. Acetoin is produced (Voges–Proskauer reaction). Arginine is not hydrolyzed to produce ammonia. Cellular long-chain fatty acids consist of major amounts of hexadecanoic (C_{16:0}⁷, palmitoleic), octadecenoic (C_{18:1}^{6,7}, *cis*-vaccenic) acids together with tetradecanoic (C_{14:0}⁷, myristic), hexadecenoic (C_{16:1}⁷, palmitoleic), octadecanoic (C_{18:0}⁷, stearic), octadecenoic (C_{18:1}^{6,9}, oleic), and eicosenoic (C_{20:1}) acids.

Strains are isolated mainly from the oral vestibular mucosa of the human oral cavity.

16S rRNA gene sequence analysis places this species within the *Salivarius* species group.

DNA G+C content (mol%): 38–40 (T_m).

Type strain: MM1, ATCC 49124, CCUG 24893, CIP 103363, DSM 5636, LMG 13516, NCTC 12166.

GenBank accession number (16S rRNA gene): AY188353, X58321.

Species *Incertae Sedis*

56. *Streptococcus pleomorphus* Barnes, Impey, Stevens and Peel 1977, 52^{AL}

ple.o.mor'phus. N.L. adj. *pleomorphus* many forms.

Obligatory anaerobic. Cells are pleomorphic and occur singly, in pairs or short chains. Variations in size and shape of cells occur depending on the media and growth conditions. Cells may stain Gram-negative within 24 h of culture. Colonies after 3 d of incubation on growth media such as RCM, supplemented BGP agar (Barnes et al., 1978), or VL agar (Barnes and Impey, 1970; Beerens et al., 1963) are 2–3 mm in diameter, circular, convex with irregular edge. Some strains are weakly β -hemolytic on VL agar. Growth

in broth is flocculent. Good growth occurs at 37°C and at 45°C but none occurs at 20°C. No growth occurs in air or in air plus 10% CO₂. Carbohydrates are required for growth. Glucose is fermented to *L*-lactic acid; no gas production occurs. Traces of butyric, formic, and sometimes acetic and succinic acids are also found. The terminal pH is 4.4–5.0. Acid is produced from glucose, fructose, and, usually, mannose. No acid is produced from arabinose, cellobiose, dextrin, galactose, inositol, lactose, maltose, mannitol, salicin, starch, sucrose, or xylose. No change in cysteine milk, gelatin is not liquefied, indole is not produced and nitrates are not reduced. Small amounts of H₂S are detected in media containing ferrous sulfate and sodium thiosulfate. Growth occurs in the presence of polymyxin B (10 µg/ml), neomycin (100 µg/ml), and kanamycin (100 µg/ml), and most strains are resistant to brilliant green (1/100,000).

The peptidoglycan type is Lys–Thr–Ala (Ser).

Strains have been isolated from the intestines of chickens and occasionally from human feces.

DNA G+C content (mol%): 39 (type strain) (T_m).

Type strain: EBF 61/60B, ATCC 29734, CCUG 11733, DSM 20574, JCM 10414, NCTC 11087.

GenBank accession number (16S rRNA gene): M23730.

Additional comments: Previously listed in *Bergey's Manual of Systematic Bacteriology* within the “anaerobic streptococci” (Hardie, 1986c), subsequent 16S rRNA gene sequence cataloging (Ludwig et al., 1988) and 16S rRNA sequencing (Kawamura et al., 1995a) place this species outside the genus *Streptococcus* and most closely related to *Clostridium innocuum*. Recent analysis has placed this species within the family *Erysipelotrichaceae* together with *Eubacterium bifforme* and *Eubacterium cylindroides* (W. Wade, personal communication. See *Eubacterium* section of this volume).

“Lancefield group M *Streptococcus*”

In the previous edition of the *Manual* (Rotta, 1986) streptococci of Lancefield group M were also listed under *Species Incertae Sedis*. The description given included three biovars:

All three biovars produce acid from glucose, lactose, maltose, and sucrose but not from adonitol, dulcitol, melibiose, melezitose, inositol, rhamnose, or xylitol. Strains are unable to grow in the presence of 40% bile, 6.5% NaCl, or 0.04% tellurite.

Biovar I. α -Hemolytic, from humans, do not hydrolyze arginine, give a final pH in glucose broth of 4.6–5.2. Strains of this biovar also contain a heat-stable “group” antigen that is resistant to pepsin. Isolated from cases of endocarditis, abscesses, and the nasopharynx and vagina.

Biovar II. β -Hemolytic, from animals, are able to hydrolyze arginine, attain a final pH of 6.3–7.2 in glucose broth. Strains also contain both of the additional “group” antigens found in biovar I and III strains. Isolated from the urethra, vagina, and tonsillar area of dogs.

Biovar III. β -Hemolytic, also from animals, hydrolyze arginine, produce a lower final pH of 5.9–6.7 in glucose broth. Strains also contain a heat-labile “group” antigen that is pepsin-sensitive.

The study by Colman (1968) demonstrated that streptococci of Lancefield group M clustered on the one hand with

strains designated “*Streptococcus mitior*” as well as including distinct, β -hemolytic strains, on the other. During the DNA–DNA reassociation studies of Kilpper-Bälz and Schleifer (1984), a Lancefield group M strain was shown to belong to *Streptococcus agalactiae*. These data indicate that Lancefield group M streptococci belong to disparate taxa where possession of this antigen can be considered a variable characteristic.

Recently described species

Arbique et al. (2004) have recently described the new species *Streptococcus pseudopneumoniae* (type strain ATCC BAA-960), to which they have assigned unusual viridans streptococci resembling *Streptococcus pneumoniae* (R.R. Facklam, personal communication). *Streptococcus pseudopneumoniae* strains were characterized as resistant to optochin under increased CO₂ content, but susceptible when under an “ambient” atmosphere, not soluble in bile, and as being indistinguishable from *Streptococcus pneumoniae* when tested using the AccuProbe Pneumococcus test kit (based on 16S rRNA gene sequence), on the basis of PCR detection of the pneumolysin (*ply*) gene and by sequencing the superoxide dismutase (*sodA*) gene. However these strains formed a DNA similarity group distinct from all other streptococcal species tested, including *Streptococcus pneumoniae*, by DNA–DNA reassociation.

Between completion of this chapter and publication several new species and a subspecies have been described and are listed below.

Streptococcus caballi, isolated from the hindgut of horses with oligofructose-induced laminitis (Milinovich et al., 2008).

Streptococcus castoreus, isolated from a beaver (*Castor fiber*) (Lawson et al., 2005b).

Streptococcus dentirousetti, isolated from the oral cavities of bats (Takada and Hirasawa, 2008).

Streptococcus equi subsp. *ruminatorum*, isolated from mastitis in small ruminants (Fernandez et al., 2004)

Streptococcus halichoeri, isolated from gray seals (*Halichoerus grypus*) (Lawson et al., 2004).

Streptococcus henryi, isolated from the hindgut of horses with oligofructose-induced laminitis (Milinovich et al., 2008).

Streptococcus ictaluri, isolated from channel catfish (*Ictalurus punctatus*) (Shewmaker et al., 2007).

Streptococcus marimammalium, isolated from seals (Lawson et al., 2005a).

Streptococcus massiliensis, isolated from a human blood culture (Glazunova et al., 2006).

Streptococcus orisuis, isolated from the oral cavity of a pig (Takada and Hirasawa, 2007).

Streptococcus pseudoporcinus, isolated from the human female genitourinary tract (Bekal et al., 2006).

Acknowledgements

The authors would like to thank Professor William Wade for help and guidance with the construction of the phylogenetic tree of the genus *Streptococcus* (Figure 123).

Genus II. **Lactococcus** Schleifer, Kraus, Dvorak, Kilpper-Bälz, Collins and Fischer 1986, 354^{VP}
(Effective publication: Schleifer, Kraus, Dvorak, Kilpper-Bälz, Collins and Fischer 1985, 189.)

MICHAEL TEUBER

Lac.to.coc'cus. L. n. *lac* milk, L. gen. n. *lactis* of milk, Gr. n. *coccus* (*kokkos*) a grain or berry; N.L. masc. n.
Lactococcus milk coccus

Spheres or ovoid cells occur singly, in pairs, or in chains, and are often elongated in the direction of the chain. Gram-stain-positive. Endospores are not formed. Nonmotile. Not β -hemolytic. Facultatively anaerobic; catalase-negative. Growth at 10°C but not at 45°C. Usually grows in 4% (w/v) NaCl with the exception of *Lactococcus lactis* subsp. *cremoris* which only tolerates 2% (w/v) NaCl. Chemo-organotroph. Metabolism fermentative. The predominant end product of glucose fermentation is L(+)-lactic acid. May contain menaquinones. Most strains react with group N antisera (Lancefield, 1933). Nutritional requirements are complex and variable. The peptidoglycan is of group A with L-lysine as diamino acid in position 3 of the peptide subunit. Typical inhabitants of plants, animals, and their products.

DNA G+C content (mol%): 34–43 (*T_m*).

(*Bacterium lactis* Lister 1873, 408; *Streptococcus lactis* Löhnis 1909, 554.)

Further descriptive information

Phylogenetic treatment. The phylogenetic position of the lactococci within the *Firmicutes* was established by comparison of the 16S rRNA sequences (Schleifer and Ludwig, 1995) and in

the current analysis used in the roadmap to Volume 3 (Ludwig et al., this volume) *Lactococcus* is a member of the family *Streptococcaceae*, along with *Streptococcus* and *Lactovum*, in the order *Lactobacillales* (Figure 1 and Figure 3). The lactococci are clearly separated from pathogenic genera of streptococci (Stackebrandt and Teuber, 1988). A phylogenetic tree reflecting the close relationships within the genus *Lactococcus* is shown in Figure 124. The five accepted species *Lactococcus garvieae*, *Lactococcus lactis*, *Lactococcus raffinolactis*, *Lactococcus piscium*, and *Lactococcus plantarum* are clearly separated.

Based on this phylogeny, Tailliez (2001) proposed that the lactic acid bacteria including the lactococci appeared before the photosynthetic cyanobacteria. As these were found in sediments dated 2.75 billion years ago, lactic acid bacteria may have emerged 3 billion years ago, before the atmosphere contained appreciable amounts of oxygen, which is consistent with their poor adaptation to aerobic environments.

Cell morphology. A typical scanning electron micrograph of *Lactococcus lactis* is presented in Figure 125. The elongated shape of the ovoid cells is evident.

Cell-wall composition. The peptidoglycan type (Schleifer and Kandler, 1972) was an important early feature that enabled differentiation of the five species: Lys–D–Asp in *Lactococcus lactis*

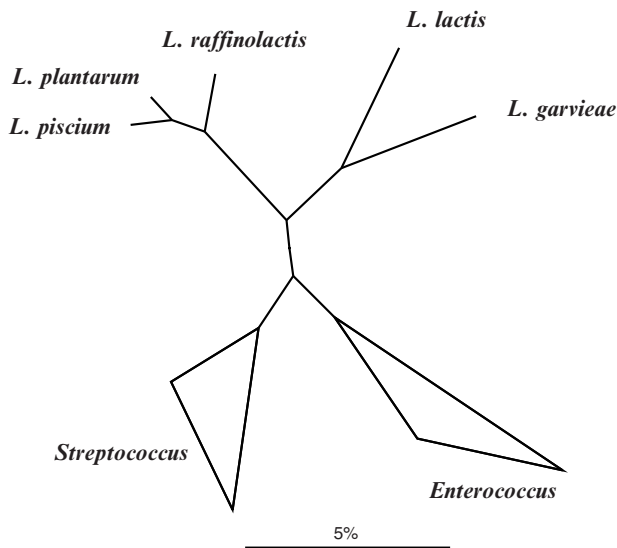

FIGURE 124. Phylogenetic tree of the species of the genus *Lactococcus*. The tree was constructed by a maximum-likelihood analysis of more than 50,000 full 16S rRNA sequences. The bar indicates 5% estimated sequence differences (courtesy of Wolfgang Ludwig, TU Munich, Germany).

FIGURE 125. Scanning electronmicrograph of *Lactococcus lactis* subsp. *lactis* Bu2 (Neve et al., 1987).

and its subspecies, Lys–Ala–Gly–Ala in *Lactococcus garvieae*, Lys–Ser–Ala in *Lactococcus plantarum*, and Lys–Thr–Ala in *Lactococcus raffinolactis* (Schleifer et al., 1985); the peptidoglycan type of *Lactococcus piscium* has not been reported.

The group N antigen previously important for classification, differentiation, and identification within the large group of morphologically very similar streptococci (Lancefield, 1933) is a cell-wall-associated glycerol teichoic acid containing galactose phosphate (Smith and Shattock, 1964). Commercially available antibodies for its determination are no longer on the market.

Colonial and cultural characteristics. Lactococci produce small, translucent to whitish colonies that are circular, smooth, and entire within 1–2 d of incubation on semisolid complex media like blood agar, Elliker agar (Elliker et al., 1956), or

M17 medium (Terzaghi and Sandine, 1975). Incubation under reduced oxygen pressure is not necessary.

Nutrition and growth conditions. Lactococci, like lactobacilli, are typical inhabitants of plants and animals and products derived from these organisms (see *Ecology* section). As a consequence they are nutritionally fastidious because they have adapted to being supplied by their host environment with carbohydrates, amino acids, vitamins, nucleic acid derivatives, fatty acids, and other compounds. The sum of these requirements is obvious from the composition of a defined medium that was developed to achieve exponential growth of *Lactococcus lactis* (Jensen and Hammer, 1993): the amino acids L-alanine, L-arginine, L-asparagine, L-cysteine, L-glutamate, L-glutamine, glycine, L-histidine, L-isoleucine, L-leucine, L-lysine, L-methionine, L-phenylalanine, L-proline, L-serine, L-threonine, L-tryptophan, L-tyrosine, and L-valine, glucose as carbohydrate, the short-chain fatty acid acetate, the vitamins biotin, pyridoxal-HCl, folic acid, riboflavin, niacinamide, thiamine, and pantothenate, and the micronutrients Mo, B, Co, Cu, Mn, and Zn, in addition to Mg and Ca.

Lactococci are mesophilic (grow in the range of 10–40°C) but some may grow at as low as at 7°C upon prolonged incubation for 10–14 d (Sakala et al., 2002b).

Lactococci are microaerophilic and growth is not severely affected by aeration. Under aerobic growth conditions, however, highly toxic oxygen compounds such as superoxide, hydrogen peroxide, and hydroxyl radicals are generated by *Lactococcus lactis*. Although lactococci are catalase-negative, they possess NADH oxidases/peroxidases, and superoxide dismutases which are up-regulated under aerobic stress conditions (Hansson and Häggström, 1984). In the presence of a heme source in a complex medium, *Lactococcus lactis* has been demonstrated to exhibit respiration due to the presence of a terminal cytochrome oxidase (*bd*) (Gaudu et al., 2002). This leads to increased survival and growth yield, decreased lactate production, and increased acetate and diacetyl in the medium. So lactococci may be on their way from a fermentative to an oxidative route of living.

Lactococci grow best at near neutral pH values in buffered media but cease to grow at about pH 4.5.

Metabolism, metabolic pathways, and genetics. The metabolism of lactococci in an unstirred culture such as in milk fermentations is fermentative; it means energy for growth is produced by substrate-level phosphorylation. The study of metabolism and metabolic pathways is tremendously advanced due to the application of *Lactococcus lactis* strains of the subspecies *cremoris* and *lactis* as starter cultures for the manufacture of fermented dairy products like hard, semihard, soft, and fresh cheeses, sour milk, and sour cream (Teuber, 2000) as compiled in Table 136.

Lactose metabolism. Lactococci are homofermentative lactic acid bacteria. During growth in milk, lactose is converted to lactic acid. Lactose is taken up by a PEP-dependent phosphotransferase system. During transport, lactose is phosphorylated to lactose 6-phosphate which is subsequently hydrolyzed by a phospho-β-galactosidase into glucose and galactose 6-phosphate (gal-6-P). Glucose is phosphorylated by glucokinase and metabolized to lactate by the glycolytic pathway. Gal-6-P is converted to the glycolytic intermediates glyceraldehyde 3-phos-

TABLE 136. Lactococci as components of starter cultures for fermented dairy products^a

Type of product	Composition of starter culture
Cheese type without eye formation (Cheddar, Camembert, Tilsit)	<i>Lactococcus lactis</i> subsp. <i>cremoris</i> , 95–98%; <i>Lactococcus lactis</i> subsp. <i>lactis</i> , 2–5%
Cottage cheese, quarg, fermented milk, cheese types with few or small eyes (e.g., Edam)	<i>Lactococcus lactis</i> subsp. <i>cremoris</i> , 95% and <i>Leuconostoc mesenteroides</i> subsp. <i>cremoris</i> , 5% or <i>Lactococcus lactis</i> subsp. <i>cremoris</i> , 85–90%, <i>Lactococcus lactis</i> subsp. <i>lactis</i> , 3%, <i>Leuconostoc mesenteroides</i> subsp. <i>cremoris</i> , 5%
Cultured butter, fermented milk, buttermilk, cheese types with round eyes (e.g., Gouda)	<i>Lactococcus lactis</i> subsp. <i>cremoris</i> , 70–75%, <i>Lactococcus lactis</i> subsp. <i>lactis</i> biovar diacetylactis, 15–20%, and <i>Leuconostoc mesenteroides</i> subsp. <i>cremoris</i> , 2–5%
Taette (Scandinavian ropy milk)	<i>Lactococcus lactis</i> subsp. <i>cremoris</i> (ropy strain producing extracellular polysaccharides)
Viili (Finnish ropy milk)	<i>Oidium lactis</i> (yeast covering surface); <i>Lactococcus lactis</i> subsp. <i>cremoris</i> (ropy strain)
Casein	<i>Lactococcus lactis</i> subsp. <i>cremoris</i>
Kefir	Kefir grains containing lactose-fermenting yeasts (e.g., <i>Candida kefir</i>), <i>Lactobacillus kefir</i> , <i>Lactobacillus kefiranofaciens</i> , <i>Lactococcus lactis</i> subsp. <i>lactis</i>

^aThe quantitative composition has been taken from the culture catalogue of a major worldwide supplier.

phate and dihydroxyacetone-phosphate by enzymes of the tagatose pathway including galactose-6-P isomerase, tagatose-6-phosphate kinase, and tagatose-1,6-diphosphate aldolase. So far the *lac*-phenotype has always been found to be correlated to the presence of specific plasmids in different strains. In *Lactococcus lactis* subsp. *cremoris* NCDO712, the structural genes for the *lac*-specific PTS-system, the phospho- β -galactosidase, and the enzymes of the tagatose pathway are organized in a 7.8 kb *lac*-operon located on a 56.6 kb conjugative plasmids. A specific repressor (*lacR*) is located at the start of the operon. This gene is expressed in the presence of glucose and repressed during growth in milk. Transcription of the *lac*-operon into two polycistronic transcripts (*lacA–E*, *lacA–X*) is regulated by the repressor *LacR* and tagatose 6-phosphate as the inducer (van Rooijen and de Vos, 1990).

Exopolysaccharides. The production of significant amounts of exopolysaccharides (EPS) is quite common among lactococci and an important technological trait for the produced sour milk or cheese (von Wight and Tynkkynen, 1987). The strains can be assigned to three major groups: group I contains strains that produce EPS containing galactose, glucose, and rhamnose; the EPSs of group II strains consist only of galactose, and those of group III contain galactose and glucose. Additional strains show unique EPS sugar composition. The genes for EPS synthesis are found on plasmids larger than 20 kb and clustered in large operons of up to fourteen coordinately expressed genes; one of these plasmids, the 42,180-bp pNZ4000, has been completely sequenced (van Kranenburg et al., 2000).

Amino acid and protein metabolism. Dairy lactococci are dependent upon the presence of some essential amino acids for growth (Anderson and Elliker, 1953; Jensen and Hammer, 1993), whereas some *Lactococcus lactis* subsp. *lactis* strains isolated from nondairy environments are prototrophic for amino acids. The analysis of the genome sequence of *Lactococcus lactis* IL1403 revealed the genetic potential (95 putative genes) to synthesize all 20 standard amino acids. Mutational inactivation of some amino acid biosynthetic pathways, a possible consequence of the adaptation to growth in milk, can explain the auxotrophic phenotype of dairy lactococci. Several operons involved in the synthesis of amino acids have been characterized in detail in lactococci from dairy and nondairy origins. These include those for the biosynthesis of aromatic amino acids, histidine, threonine, and the branched-chain amino acids.

Due to this amino acid auxotrophy and the lack of sufficient amounts of free amino acids in milk, dairy lactococci need a proteolytic system for growth in milk. This system consists of a cell-wall-bound protease (PrpP), three peptide transporter (Opp, DtpT, DtpP), and a variety of peptidases (Pep). The genes for the majority, if not all, of the enzymes necessary for casein degradation and transport of the degradation products were cloned, sequenced, and analyzed in detail. From these data, the following picture emerges. Caseins of the milk are partially degraded by the cell-wall-bound protease into a large number of oligopeptides; some of these oligopeptides (≤ 10 amino acid residues) are taken up by the oligo- and the di/tripeptide transport systems and subsequently hydrolyzed to amino acids by a plethora of peptidases. Mutants missing transporter or/and peptidase genes have been constructed by targeting deletion or disruption of the corresponding genes. Those missing the Opp system but still having di/tripeptide transport activity are unable to grow in milk. Mutants with an increasing number of peptidase mutations showed decreasing growth rates in milk; a five-fold peptidase mutant grew 10 times slower than the wild-type. The genes for the peptide transport systems and the peptidase are located on the chromosome; those for the proteases are located exclusively on plasmids.

Genetics. Sophisticated and efficient transformation and special vector systems have been developed which aid analysis of gene regulation and the cloning and expression of homologous and heterologous genes. Transformation of lactococci is best performed by electroporation (Harlander, 1987). Several protocols allow successful transformation even of strains that were resistant to the formerly used method of polyethylene glycol-induced protoplast transformation. Cloning and expression of genes from different sources, random and targeted inactivation of genes, selection for promoter-, terminator-, and signal-sequences, and anchoring of proteins to the surface of lactococci are state of the art techniques.

A homologous *Lactococcus* system makes use of the autoregulatory properties of the nisin gene cluster. Nisin, at concentrations far below the minimal inhibitory concentration, acts as an inducer from outside via a two component signal transduction system consisting of a histidine protein kinase (NisK), and a response repressor (NisR). The two genes, *nisK* and *nisR* (under the control of a constitutive promoter), were delivered by recombinant plasmids or are integrated into the chromo-

some of the expression strain. The gene to be expressed is fused to the *nisA* promoter that is part of the expression vectors. Vectors for transcriptional and translational fusions have been constructed. Homologous as well as heterologous proteins can make up to 47% of the total cell protein with increasing amounts of the inducer.

Several systems to anchor and display heterologous (poly) peptides at the cell surface of lactococci have been developed (Leenhouts et al., 1999). This allowed changes of the outside composition of the cells which may help in the understanding of the mechanisms of protein targeting. Changes in the surface composition may also influence interactions between the bacteria and the environment and allow potentially important biotechnological applications such as immobilization of enzymes at the bacterial surface, fixing of cells to special carrier surfaces, and display of entire peptide libraries. *Lactococcus lactis* presenting proper antigens may in the future be used as live bacterial vaccine delivery systems (Steidler et al., 1998).

A variety of peptides and proteins could be anchored and at least partially presented at the cell surface of lactococci (Wells and Mercenier, 2003). These includes enzymes like β -lactamase, α -amylase, and nucleases, and epitopes of the human cytomegalovirus of the human immunodeficiency virus, the *Plasmodium falciparum* merocoin stage surface antigen, and the *Clostridium tetani* toxin C fragment.

Genome analysis. Discovery of extrachromosomal elements (plasmids) in dairy lactococci (Cords et al., 1974) and the elucidation of the complete genome sequence of *Lactococcus lactis* subsp. *lactis* IL1403 (Bolotin et al., 1999, 2001) are two milestones in the genetics of these bacteria.

Lactococcus lactis is an AT-rich Gram-positive bacterium; its genome consists of 2345 ± 5 kb with a mean G+C content of 35.4 mol%. The sequencing data allowed the prediction of some very interesting features of the lactococcal genome. The presence of 42 copies of the five different IS-elements – two of the five were previously unknown – indicate the importance of these elements for genetic exchange. The genome of IL1403 also carries six potential or rudimentary prophages (Chopin et al., 2001). The genome sequencing data confirmed the presence of six rRNA operons.

A total of 62 tRNA genes were detected, the majority organized in four large operons, and 1495 protein-encoding genes were identified, mostly oriented collinear to the direction of replication. The total number of lactococcal genes is estimated to be about 2300, approximately one gene per kilobase of DNA.

16S rDNA sequence analysis. This technique is now the gold standard for the assignment of an unknown, newly isolated strain to the genus *Lactococcus* and its species. It is also the basis for the phylogenetic positioning as presented in Figure 124. In addition, appropriate 16S rDNA and 16S rRNA sequences have been used to construct genus- and species-specific nucleotide probes (fluorescent or radioactively labeled) for the identification and differentiation of lactococci *in situ* and in single colonies (Bauer et al., 2000; Betzl et al., 1990).

DNA–DNA similarity. DNA–DNA hybridization studies were an essential milestone for the clustering of the genus *Lactococcus* and its species and subspecies (Schleifer et al., 1985). DNA/DNA similarities between the different *Lactococcus* species are about 15–20%, whereas within the *Lactococcus lactis*

subspecies (*Lactococcus lactis* subsp. *cremoris*, *Lactococcus lactis* subsp. *lactis*, and *Lactococcus lactis* subsp. *hordniae*) the similarity is more than 80%.

Plasmids, phages, and bacteriocins

Plasmids. Dairy lactococci possess an unusually large complement of plasmids, ranging in molecular size from about 2 to more than 100 kb (Gasson and Shearman, 2003; Teuber, 1995). The number of plasmids from different strains isolated from dairy cultures varies from 1 to 12. Up to 10% or more of the coding capacity of lactococci consists of extrachromosomal DNA. In the natural habitat, plasmids can be transferred among lactococci and even into other bacterial species of other genera like *Lactobacillus*, *Bacillus*, *Leuconostoc*, *Pediococcus*, *Listeria*, and *Streptococcus* by conjugation and mobilization (Gasson and Davies, 1980; McKay et al., 1973; Neve et al., 1984, 1987; Walsh and McKay, 1981). Transfer of plasmid DNA by transduction is also possible in experimental systems.

Plasmid curing performed by treatment with acridine dyes, ethidium bromide, nalidixic acid, growth at elevated temperature, or protoplast regeneration provided evidence for plasmid linkage of a variety of functions important in fermentation technology (Gasson, 1983). These include lactose transport and metabolism, casein degradation by cell-wall protease, citrate and oligopeptide transport (permeases), bacteriophage protection by restriction/modification and abortive infection, formation of extracellular polysaccharides, bacteriocin production and immunity, insertion (IS) element-dependent recombination and cointegrate formation, group II-intron based lactococcal sex factor, conjugal transfer and mobilization, antibiotic resistance, UV- and metal-resistance, and plasmid replication (Teuber, 1995).

Antibiotic resistance. The molecular analysis of an antibiotic resistant strain of *Lactococcus lactis* subsp. *lactis* isolated from a raw milk soft cheese revealed a 29,815-bp multiresistance plasmid pK214 (Perreten et al., 1997). It assembles resistance genes like *tetS*, *str* (streptomycin adenylase), *cat* (chloramphenicol acetyltransferase), and a new multiple drug transporter (*mdtA*) which had previously been detected in *Listeria monocytogenes* and *Staphylococcus aureus*. *mdtA* encodes a new efflux protein. This observation proves that lactococci are able to pick up multiple antibiotic resistance elements in an antibiotic-challenged habitat (Teuber et al., 1999) from other members of the microbial gene exchange community (Gram-positive and Gram-negative) that share genetic pieces (Baquero, 2004).

Bacteriophages in dairy fermentations. Because sour milk and cheese are normally not made from sterilized milk and because most cheese fermentations are open systems (open vats, control of fermentation by direct and open inspection with hands, tools, etc.), bacteriophages are a common threat. Even pasteurized milk may still contain virulent bacteriophages and residual lactic acid bacteria (Neve and Teuber, 1991).

The phages of the mesophilic dairy lactococci have been investigated in detail. At least 11 genetically distinct phage types have been described (Jarvis et al., 1991). They may be lytic or temperate. Many starter culture strains of lactococci carry prophages that may be released during sour milk and cheese fermentations. The microbiology and genetics of these phages have been investigated thoroughly, leading to clear information

on phage adsorption, injection, replication, and release. The host specificities have been found to vary substantially. Bacteriophage-resistant mechanisms have been characterized as being due to inhibition of adsorption, DNA injection, restriction/modification, or abortive infection. Many of these traits are coded for on plasmids and are therefore amenable to genetic engineering and transfers from cell to cell. In cheese factories, high bacteriophage levels in whey and curds are found under conditions that may also lead to contamination with undesirable bacteria.

In addition to the use of phage-resistant strains developed by genetic engineering (Walker and Klaenhammer, 2003) or selected by challenge with bacteriophage cocktails (Möller and Teuber, 1988), there are many generally accepted technological measures that reduce or avoid the bacteriophage problem. These include use of starters containing phage-unrelated or phage-insensitive strains, production of phage-free bulk starter, aseptic propagation systems, use of phage-inhibitory media, reduction of phage contamination of processing plants, starter culture rotations, air conditioning and free air flow, avoidance of aerosol generation, cleaning/chlorination of vats between refills, use of cleaning-in-place (CIP) systems, segregation of starter room and cheese process equipment, removal of deposits on bulk starter vessels, good factory design (suitable location of whey storage tanks, whey-handling systems and wastewater treatment plants), regular use of an aerosol containing an agent such as chlorine to reduce contamination in the atmosphere, and other measures such as use of cultures for direct setting of the milk, inspection of jacket/agitators for pin-holing, and early renneting.

Slow acidification due to bacteriophage attack of the starter culture may lead to good proliferation conditions for undesirable contaminant bacteria such as staphylococci, enterococci, listeria, enteric bacteria, and others. The use of strains resistant to specific phages may induce the selection of new, less virulent phages not encountered previously (Moineau et al., 1993). The proper handling of the bacteriophage issue still remains a major challenge for proper dairy fermentations.

Bacteriocins. Bacteriocins, proteinaceous compounds that kill closely related bacteria, are produced by a variety of lactococcal strains (Skaugen et al., 2003). In a survey of 280 strains isolated from dairy environments, 5% were found to produce such substances. On the basis of biochemical and physical properties, host range, and cross-reactivity, eight bacteriocin types were predicted (Geis et al., 1983; Klaenhammer, 1993; Skaugen et al., 2003). Many of these bacteriocins have been characterized by genetic and biochemical methods. These belong mainly to two defined classes: lantibiotics class I, and small, heat-stable nonlantibiotics class II (Nes et al., 1996).

Nisin, a class I bacteriocin, is a small peptide (34 amino acid residues) produced by several *Lactococcus lactis* subsp. *lactis* strains (Hirsch, 1953). It strongly inhibits the growth of a wide range of Gram-positive bacteria. Two natural variants, nisin A and nisin Z, were found. Nisin is ribosomally synthesized as a 57-amino acid precursor peptide which is subjected to various modifications. The mature peptide (34 amino acids) shows some unusual features including the dehydrated amino acids dehydroalanine and -butyrine and lanthionine and β -methylanthionine residues which form five intracellular thioester bridges. Nisin is able to form pores in the membrane of Gram-positive bacteria mediating the efflux of ions, amino acids, and ATP from cells

(Sahl et al., 1987). The structural genes for nisin A and Z were cloned and sequenced. The structural genes are part of a large gene cluster of eleven genes that are involved in all aspects of the nisin biosynthesis. An autoregulated pathway for nisin has been proposed; via a two-component signal system nisin activates the *nisA* promoter. This results in the production of pre-nisin, which is modified by a membrane-bound enzyme system. Subsequently, the precursor nisin is translocated by an ABC transporter and activated by proteolytic cleavage by an extracellular proteinase.

Nisin production is always linked to the ability to ferment sucrose (Rauch and De Vos, 1992). This linkage was confirmed by curing experiments and conjugal transfer. It was shown that the nisin-sucrose element is part of a conjugative transposon that integrates in several different sites of the lactococcal chromosome by a mechanism of transposition similar to that of the *Tn916* family. Nisin is a legal food preservative/additive in many countries and is used to protect high-moisture food commodities against the pathogenic *Listeria monocytogenes* or *Clostridium botulinum*, but also against spoilage by clostridia and other Gram-positive bacteria.

Pathogenicity

Lactococcus garvieae must be regarded as a fish pathogen and responsible for mastitis in cows and buffalos. It has been denoted as an emerging pathogen of increased clinical significance in both veterinary and human medicine (Facklam and Elliott, 1995; Teixeira et al., 1996; Vela et al., 2000). Although not very common, *Lactococcus garvieae* was recently isolated in Switzerland from 4.5% of 150 milk samples collected from cows with either chronic or subclinical mastitis (Thomann and Perreten, Institute of Veterinary Bacteriology, University of Berne, Switzerland; personal communication, 2003/2004). *Lactococcus garvieae* is the etiologic agent of hemorrhagic septicemia in farmed trout and is characterized by bilateral exophthalmos, darkening of the skin, congestion of the intestine, liver, kidney, spleen, and brain, and a characteristic hemorrhagic enteritis (Domenech et al., 1993). The disease has been termed lactococcosis to distinguish it from streptococcosis. It is a worldwide bacterial disease affecting different fish species such as eels, yellowtails, farmed trout, and prawns. *Enterococcus seriolicida* is a junior synonym of *Lactococcus garvieae* (Eldar et al., 1999). Pathogenicity and virulence factors have not yet been identified.

In contrast, *Lactococcus piscium* seems to be a meat spoilage bacterium encountered in vacuum-packed, chilled meat (Sakala et al., 2002b). The isolation of the type strain from a diseased rainbow trout (Williams et al., 1990b) cannot be taken as evidence for its pathogenicity because no other cases have been reported since.

In rare instances, *Lactococcus lactis* has been isolated from human cases of urinary tract and wound infections, and from patients with endocarditis (Aguirre and Collins, 1993). In this behavior it resembles other lactic acid bacteria.

Ecology

The most important habitats for lactococci are in the dairy industry and are shown in Table 136.

The lactococci comprise the species *Lactococcus lactis*, *Lactococcus garvieae*, *Lactococcus plantarum*, *Lactococcus piscium*, and *Lactococcus raffinolactis* (Table 137).

Silage	(+)				

^a+, Detected by direct plating; (+), detected by plating after enrichment.

Lactococcus lactis subsp. *lactis* and *Lactococcus lactis* biovar “diacetylactis” (according to Schleifer et al., (1985), the subspecific status *Lactococcus lactis* subsp. “diacetylactis” is no longer valid; because of the importance of diacetyl-forming lactococci, especially in dairy fermentations, we still distinguish, for practical reasons, between *Lactococcus lactis* subsp. *lactis* and *Lactococcus lactis* biovar “diacetylactis”, instead) have commonly been detected directly or following enrichment in plant material, including fresh and frozen corn, corn silks, navy beans, cabbage, lettuce, peas, wheat middlings, grass, clover, potatoes, cucumbers, and cantaloupe (Sandine et al., 1972). Lactococci are usually not found in fecal material or soil. Survival of *Lactococcus lactis* MG1363 ingested by human volunteers disappeared within 4 h from their ileal fluids (Vesa et al., 2000). Only small numbers occur on the surface of the cow and in its saliva. This was ascertained by an environmental screening. *Lactococcus lactis* and its subspecies *Lactococcus lactis* subsp. *lactis* and *Lactococcus lactis* subsp. *cremoris* were detected without enrichment in raw milk, milking machines, and the udders at 10^3 – 10^4 c.f.u. per gram or cm^2 , respectively, after enrichment in addition in the saliva and on the skin of cows and bulls, on grass and in soil and silage (Klijn et al., 1995). In a dairy environment, lactococci were abundant in cheese milk, cheese whey, waste whey, and the waste water tank. After enrichment, *Lactococcus lactis* was also found in the waste water disposal site soil and on grass. *Lactococcus garvieae* and *Lactococcus raffinolactis* were also consistently detected in raw milk, the skin and saliva of cows, and on grass (see Table 137). Since raw cow’s milk consistently contains *Lactococcus lactis* subsp. *lactis*, *Lactococcus lactis* subsp. *lactis* biovar “diacetylactis” and *Lactococcus lactis* subsp. *cremoris*, it is tempting to suggest that lactococci enter the milk from the exterior of the udder during milking and from the feed, which may be the primary source of inoculation. *Lactococcus lactis* subsp. *cremoris* seems to have its main habitat in milk, fermented milk, cheese, and starter cultures.

A study of lactococci isolated from animal material in Belgium revealed the following habitats (Pot et al., 1996): *Lactococcus lactis* subsp. *lactis*, from bovine intestine, milk from healthy

cows and cows with mastitis, tonsils of cats, dogs and goats; *Lactococcus garvieae* from bovine milk and tonsils, tonsils of dogs, feces of cats and horses, conjunctiva of a turtle; *Lactococcus raffinolactis*, from bovine tonsils, goat intestine; and *Lactococcus piscium* was consistently detected in vacuum-packed, refrigerated beef in Japan, when incubation of the plated samples was at 7°C for 10–14 d (Sakala et al., 2002b). The type strain of *Lactococcus piscium* was isolated from a diseased rainbow trout (Williams et al., 1990b).

New, undefined *Lactococcus* species. The results of screening of a dairy environment have shown that new, not yet differentiated *Lactococcus* species can be shown to exist in nature if modern molecular methods such as 16S RNA gene sequencing are employed (Klijn et al., 1995). Another, interesting habitat seems to be the microflora of the gut of wood-feeding termites like *Reticulitermes flaviceps*. The Gram-positive cocci comprising about 50% of the culturable microflora contained new species closely related to *Enterococcus faecalis*. Three other studied strains cluster closely with *Lactococcus garvieae*, but definitely represent a new species (Bauer et al., 2000).

In summary, animal and plant environments are the main habitats of the investigated lactococci. To what extent the lactococci used by the dairy industry have gone through recent phases of evolutionary changes due to their deliberate use as starter cultures, remains to be established. Their original habitat is and was the dairy cow and the raw milk extracted from it. In a recent attempt to reisolate *Lactococcus lactis* subsp. *cremoris*, it was found in samples of Chinese and Moroccan raw milk, and one corn (*Zea mays*) sample, but not in *Rubus discolor* (Himalayan blackberry), *Hypericum calycinum* (gold flower), *Prunus* sp. (plum), *Hedera helix* (English ivy), *Acer platanoides* (green lace tree), and *Ginkgo biloba* (maidenhair tree) (Salama et al., 1993).

Industrial application. The present-day significance is in the large-scale use of the lactococci for industrial fermentations, especially dairy products (Cogan and Accolas, 1996; Teuber, 2000). The species *Lactococcus lactis* and its subspecies used on

a large scale by the dairy industry are generally recognized as safe (GRAS) for human consumption. The world cheese production based on starter cultures of lactic acid bacteria was more than 16 million metric tonnes in 2000 (Food and Agriculture Organization of the United Nations, 2001), most of it made with lactococci. No similar data are available for the other lactococcal products such as cultured butter, sour milk, and casein. The deliberate use of the lactococci in the dairy industry as starter cultures for many different products is documented in Table 136. This development was initiated at the turn of the century when Weigmann, Storch, and Conn identified lactococci as the essential components of the mesophilic microflora in spontaneously fermented cream and milk. This finding led to the introduction of pure starter cultures of lactic acid bacteria to the dairy field for use in the fermentation and ripening of milk, cream, and cheese (Weigmann, 1905-1908).

In recent years, the physiology, biochemistry, genetics, and molecular biology of the lactococci have gained much attention due to the great economic importance of these organisms (see above). Lactococci are employed in single and mixed cultures for the production of different kinds of cheeses, fermented milks, cultured butter, and casein (see Table 136).

The biochemical and technological functions of lactococci necessary for milk fermentation and cheese production can be summarized as follows:

1. Formation of lactic acid from lactose (early function in fermentation). The resulting lowered pH values (4.0–5.6) as compared with milk (6.6–6.7) prevent or retard growth of spoilage bacteria, especially clostridia, staphylococci, *Enterobacteriaceae*, and psychrotolerant proteobacteria like *Pseudomonas*. If the isoelectric point of casein at pH 4.6–4.8 is approached, casein is precipitated and the milk curdles. This effect is used in the production of cottage cheese, quarg, sour milk, yogurt, and casein. Starter bacteria for this purpose are *Lactococcus lactis* subsp. *lactis* and *Lactococcus lactis* subsp. *cremoris* (besides lactobacilli and *Streptococcus thermophilus*).

2. Formation of diacetyl from citrate (early to medium function in fermentation). Diacetyl is the most characteristic aroma compound provided by *Lactococcus lactis* subsp. *lactis* biovar “diacetyl-lactis”. It is derived from the citrate of milk (about 0.1%) that is present in solution and in the casein micelles as a casein-citrate-calcium-phosphate complex. The pathway goes through oxaloacetate, pyruvate, and α -acetolactate with a coupled release of carbon dioxide, which induces eye formation in cheese but also unwanted floating of the curd in the manufacture of cottage cheese or quark if an unbalanced mixed starter is used (see Table 136).

3. Limited proteolysis during cheese ripening (medium to late function in cheese fermentation). Many strains of all lactococcal species possess a β -casein-specific, cell-wall-associated protease, together with a complement of peptidases including an aminopeptidase, an X-prolyl-dipeptidyl aminopeptidase, and a dipeptidase, which are necessary for growth in milk but also function during cheese ripening.

Propagation and preservation of starter cultures. Starter cultures are needed and applied by the industry producing food and feed as indicated in Table 136. Dairy products are almost always made with commercial cultures. Liquid, dried, and frozen starter cultures are in use. Starter cultures must have

a high survival rate of micro-organisms coupled with optimum activity for the desired technological performance, e.g., the fermentation of lactose to lactate, controlled proteolysis of casein, and production of aroma compounds like diacetyl. Because the genes for lactose and citrate fermentation and those for certain proteases are located on plasmids, continuous culture has not been successful because fermentation-defective variants develop easily. In most instances, pasteurized or sterilized skim milk is the basic nutrient medium for the large-scale production of starter cultures because it ensures that only lactococci fully adapted to the complex substrate, milk, will develop. For liquid starter cultures, the basic milk medium may be supplemented with yeast extract, glucose, lactose, and calcium carbonate. To obtain optimum activity and survival, it may be necessary to neutralize the lactic acid that is produced by addition of sodium or ammonium hydroxide. Because many strains of dairy lactococci produce hydrogen peroxide during growth under microaerophilic conditions, it has been beneficial to add catalase to the growth medium, thus leading to cell densities of more than 10^{10} viable units per ml of culture.

For the preparation of concentrated starters, the media are clarified by proteolytic digestion of skim milk with papain or bacterial enzymes to avoid precipitation of casein in the separator used to collect the lactococcal biomass. The available self-cleaning clarifiers, e.g., bactofuges, concentrate the fermentation broth to cell concentrations of about 10^{12} c.f.u./ml. These concentrates can either be lyophilized or are preferentially transferred drop-wise into liquid nitrogen. The formed pellets are packed in metal cans or cartons and are kept and shipped at -70°C (dry ice). These modern starter preparations allow the direct inoculation of cheese vats because the bacteria immediately resume exponential growth if harvested in the late exponential growth phase. This modern technology shifts most of the microbiological work and responsibility from the cheese factory to the starter producer.

The classical liquid starter culture with about 10^9 c.f.u./ml and traditional lyophilized cultures containing about 10^{11} c.f.u./gram must be further propagated in the factory. However, lyophilized cultures can be transported easily and kept at ambient temperature for several months. Concentrated lyophilized starters are also suited for direct vat inoculation having a short lag phase, however, before growth is resumed. Direct vat inoculation may have a certain advantage regarding protection against bacteriophages which are common in the open dairy fermentation systems (see above).

Enrichment and isolation procedures

Enrichment and isolation. Lactococci are nutritionally fastidious. They all require complex media for optimal growth. In synthetic media, all strains require amino acids such as isoleucine, valine, leucine, histidine, methionine, arginine, and proline, and the vitamins niacin, Ca-pantothenate, and biotin (Anderson and Elliker, 1953; Jensen and Hammer, 1993).

Isolation from plant material. Plant material such as grass and herbage is the natural source of lactic acid bacteria. Silage allows the enrichment of lactococci, leuconostocs, and pediococci. The isolation procedure takes advantage of the sequential growth of the above-mentioned genera. For this purpose, the procedure of Whittenbury (1965) is recommended.

Isolation from cheese. The main problem in isolating lactic acid bacteria including lactococci from dairy products is a proper dissolution or dispersion of the solid or semisolid fat containing material. An accepted method is the one by Olson et al. (1978), as follows.

Using aseptic technique, thoroughly comminute or mix each sample until representative portions can be removed. Heat 99-ml dilution blanks of sterile, freshly prepared (less than 7 d old), aqueous 2% sodium citrate to 40°C. Aseptically transfer 11 g of cheese to a sterile blender container previously warmed to 40°C and add the warmed sodium citrate blank. Mix for 2 min at a speed sufficient to emulsify the sample properly, invert the container to rinse particles from the interior walls, and remix for approximately 10 s. Inadvertent heating to temperatures in excess of 40°C from friction in agitation may occur with some mechanical blenders. This should be determined before use of the blender so corrective action can be taken if needed. If heating is unavoidable with equipment available, mixing periods of less than 2 min should be used provided that complete emulsification is obtained. The 1:10 dilution should be plated or further diluted immediately with great care being taken to avoid air bubbles or foam.

Isolation of lactic acid bacteria and lactococci from cultured milk, cultured cream, yogurt, acidophilus milk, Bulgarian buttermilk, and similar cultured or acidified semifluid products follows a similar technique (Olson et al., 1978).

No satisfactory selective medium is available for the isolation of lactococci. Two media, both commercially available, are generally accepted to give reliable growth of these organisms. The medium proposed by Elliker et al. (1956) is widely used for the isolation and enumeration of lactococci. Elliker Agar Medium for Isolation of Lactococci contains (per l): tryptone, 20.0 g; yeast extract, 5.0 g; gelatin, 2.5 g; glucose, 5.0 g; lactose, 5.0 g; sucrose, 5.0 g; sodium chloride, 4.0 g; sodium acetate, 1.5 g; ascorbic acid, 0.5 g; agar, 15.0 g. The medium has a pH of 6.8 before autoclaving. This medium is probably the most cited for the isolation and growth of lactococci, although it is unbuffered. This disadvantage can be overcome by the addition of suitable buffer substances. Addition of 0.4% (w/v) of diammonium phosphate improves the enumeration of lactic streptococci on Elliker agar. Colony counts were up to about eight times greater due to improved buffering capacity (Barach, 1979). M17 medium (Terzaghi and Sandine, 1975), a complex medium supplemented by 1.9% β -disodium glycerophosphate, results in improved growth of lactococci. M17 Medium for Isolation of Lactococci contains (per l): phytone peptone, 5.0 g; polypeptone, 5.0 g; yeast extract, 5.0 g; beef extract, 2.5 g; lactose, 5.0 g; ascorbic acid, 0.5 g; β -disodium glycerophosphate, 19 g; 1.0 M $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 1.0 ml; glass-distilled water, 1 l. The medium is sterilized at 121°C for 15 min. The pH of the broth is 7.1.

Solid medium contains 10 g agar/l of medium. This medium is useful for the isolation of all strains of *Lactococcus lactis* subsp. *cremoris*, *Lactococcus lactis* subsp. *lactis*, *Lactococcus lactis* biovar "diacetyllactis", and *Streptococcus thermophilus* and mutants of those strains lacking the ability to ferment lactose. Addition of a pH indicator dye (bromocresol purple) and reduction of β -disodium glycerophosphate (5 g/l) allows an easy differentiation between lactose-fermenting (large yellow colonies) and nonfermenting

(small white colonies) strains (Kondo and McKay, 1984). This medium has become the standard for genetic investigations of lactococci. Lactococcal bacteriophages can be efficiently demonstrated and distinguished on M17 agar. Plaques larger than 6 mm in diameter could be observed as could turbid plaques, indicating lysogeny (Terzaghi and Sandine, 1975).

Enumeration of citrate-fermenting bacteria in lactic starter cultures and dairy products. To control gas and aroma (diacetyl) production in the fermentation of various dairy products, it is important to know the quantitative composition of the starter cultures used. *Leuconostoc* species and *Lactococcus lactis* biovar "diacetyllactis" are components of many mesophilic starter cultures (Table 136). These organisms are able to ferment citrate with concomitant production of CO_2 and diacetyl. For the collective enumeration of leuconostocs and *Lactococcus lactis* biovar "diacetyllactis" in starters and fermented dairy products, a whey agar containing calcium lactate and Casamino acids (WACCA) has been introduced by Galesloot et al. (1961). A modified medium based on the different action on the lactose analog 5-bromo-4-chloro-3-indolyl- β -D-galactopyranoside (Xgal) has been suggested (Vogensen et al., 1987).

Maintenance procedures

Lactococci can conveniently be kept for several weeks at refrigeration temperature in the buffered M17 medium in stab cultures. Freeze drying in neutralized skimmed milk yields cultures that can be kept for several years when sealed *in vacuo*. Starter cultures keep well in freeze-dried preparations or when deep frozen in liquid nitrogen and stored at -70°C (Sandine, 1996).

Differentiation from closely related taxa

When isolating lactic acid bacteria and lactococci from plant and food sources, it is necessary to distinguish lactococcal colonies from pediococci and leuconostocs which often grow on the same media along with lactococci. The method of choice in the microbiological laboratory is to analyze the fermentation products from glucose: L(+)-lactic acid in *Lactococcus*, DL-lactic acid in *Pediococcus*, and D(-)-lactic acid, CO_2 , acetic acid, and ethanol in *Leuconostoc*.

Taxonomic comments

The first studies of the lactococci were those by Joseph Lister (1873), who was attempting to prove Pasteur's germ theory of fermentative changes. In experiments with boiled milk as a nutrient medium, he obtained, by chance, the first pure bacterial culture. It is worthwhile to recall his original discussion of this discovery, marking the start of bacterial taxonomy:

"Admitting then that we had here to deal with only one bacterium, it presents such peculiarities both morphologically and physiologically as to justify us, I think, in regarding it a definite and recognizable species for which I venture to suggest the name *Bacterium lactis*. This I do with diffidence, believing that up to this time no bacterium has been defined by reliable characters. Whether this is the only bacterium that can occasion the lactic acid fermentation, I am not prepared to say."

This bacterium was later renamed *Streptococcus lactis* (Löhnis, 1909). On the basis of exhaustive reinvestigations including cell-wall analysis, long-chain fatty acid composition, unsaturated

fatty acid patterns, menaquinone composition, immunological cross-reactions of purified superoxide dismutases, biochemical properties, and DNA/DNA hybridization, Schleifer et al. (1985) proposed that the N streptococci (Lancefield, 1933) be separated from the oral streptococci, the enterococci, and the hemolytic streptococci. They suggested the new genus name *Lactococcus*. The molecular taxonomy of the lactococci has yielded the detection and differentiation of new species besides *Lactococcus lactis*: *Lactococcus garviae*, *Lactococcus raffinolactis*, *Lactococcus plantarum*, and *Lactococcus piscium*.

^bLancefield (1933).

Colonies on blood agar or nutrient agar are circular, smooth, and entire. Nonpigmented. Nonhemolytic (some strains may produce a weak α -reaction). Ovoid cells elongated in the direction of the chain. Mostly in pairs or short chains. Gram-positive. Nonmotile. Facultatively anaerobic. Catalase-negative. Growth at 10°C but not at 45°C. Grows in 4% (w/v) NaCl and 0.1% methylene blue milk. Chemo-organotrophic; fermentative metabolism. All strains produced acid from galactose, glucose, fructose, lactose, maltose, mannose, *N*-acetylglucosamine, ribose, and trehalose. Most strains produced acid from arbutin, cellobiose, β -gentiobiose, and salicin. Acid not produced from *D*-arabinose, *L*-arabinose, *D*-arabitol, *L*-arabitol, adonitol, 2-ketogluconate, 5-ketogluconate, dulcitol, erythritol, *D*-fucose, *L*-fucose, gluconate, glycerol, glycogen, inositol, melibiose, melizitose, α -methyl-*D*-glucoside, α -methyl-*D*-mannoside, *D*-lyxose, raffinose, rhamnose, *L*-sorbose, sorbitol, *D*-tagatose, *D*-turanose, xylitol, and *L*-xylose. Variable results may be obtained from amygdalin, inulin, mannitol, sucrose, starch, and *D*-xylose. Esculin and hippurate hydrolyzed. Arginine dehydrolase and leucine arylamidase-positive. Alkaline phosphatase, α -galactosidase, β -galactosidase, and β -glucuronidase-negative. A few strains are pyrrolidonyl arylamidase-positive. Some strains can utilize citrate (in conjunction with a fermentable carbohydrate) with the production of CO₂, acetoin, and diacetyl (if they possess a proper plasmid encoding a citrate permease, CitP). Reacts with Lancefield serological group N antiserum.

The petidoglycan type is Lys-*D*-Asp. Low levels of menaquinones produced, with MK-9 predominating. Contains poly(glycerophosphate)-lipoteichoic acid partially substituted with α -galactosyl residues and *D*-alanine esters. The major glycolipid is Glc(α 1-2)Glc(α 1-3)acyl₂Gro. Aminophospholipids are not present. Major nonhydroxylated long-chain fatty acids are hexadecanoic, *cis*-11,12-oc-tadecenoic, and *cis*-11,12-methylenoctadecanoic acids.

The level of 16S rRNA similarity between the type strain of *Lactococcus lactis* subsp. *lactis* and the type strains of the other *Lactococcus lactis* subspecies is 98–99%. The level of 16S rRNA sequence similarity between *Lactococcus lactis* subsp. *lactis* and the type strains of the other *Lactococcus* species is 90–93%, and it is 98–99% between *Lactococcus lactis* subsp. *lactis* and other strains of the other subspecies of *Lactococcus lactis*.

DNA G+C content (mol%): 34.4–36.3 (*T_m*).

Type strain: ATCC 19435, CCUG 7980, CIP 70.56, DSM 20481, HAMBI 1591, JCM 5805, LMG 6890, NCIMB 6681, NCTC 6681, VKM B-1662.

GenBank accession number (16S rRNA gene): AB100803.

- 1b. ***Lactococcus lactis* subsp. *cremoris*** (Orla-Jensen 1919) Schleifer, Kraus, Dvorak, Kilpper-Bälz, Collins and Fischer 1986, 354^{VP} (Effective publication: Schleifer, Kraus, Dvorak, Kilpper-Bälz, Collins and Fischer 1985, 192.) (*Streptococcus cremoris* Orla-Jensen 1919) *cre'moris*. L. n. *cremor* cream; L. gen. n. *cremoris* of cream.

In most respects, the description of *Lactococcus lactis* subsp. *cremoris* corresponds to the description of *Lactococcus lactis* subsp. *lactis*. It differs in the following character-

istics. Grows in 2% but not 4% (w/v) NaCl. No growth at 40°C. Acid not produced from maltose and ribose. Most strains do not produce acid from β -gentiobiose, salicin, and trehalose. Arginine dehydrolase-negative. Produces detectable quantity of CO₂.

DNA G+C content (mol%): 34.8–36.3 (*T_m*).

Type strain: ATCC 19257, CCUG 21953, CIP 102301, DSM 20069, HAMBI 1588, BBRC 3427, LMG 6897, NCIMB 8662.

GenBank accession number (16S rRNA gene): AB100802, M58836.

- 1c. ***Lactococcus lactis* subsp. *hordniae*** (ex Latorre-Guzman, Kado and Kunkee 1977) Schleifer, Kraus, Dvorak, Kilpper-Bälz, Collins and Fischer 1986, 354^{VP} (Effective publication: Schleifer, Kraus, Dvorak, Kilpper-Bälz, Collins and Fischer 1985, 193.) (*Lactobacillus hordniae* Latorre-Guzman, Kado and Kunkee 1977, 365)

hord'ni.ae. N.L. fem. n. *Hordnia* generic name; N.L. gen. n. *hordniae* of *Hordnia circellata* (name of the leaf hopper from which the organism was isolated).

In most respects, the description of *Lactococcus lactis* subsp. *hordniae* corresponds to the description of *Lactococcus lactis* subsp. *lactis*. It differs in the following characteristics: Grows in 2% but not 4% (w/v) NaCl. No growth at 40°C. Acid not produced from galactose, lactose, maltose, or ribose. Hippurate is not hydrolyzed. *cis*-11,12-Methylenoctanoic acid is absent.

DNA G+C content (mol%): 35.2 (*T_m*).

Type strain: ATCC 29071, CCUG 32210, CIP 102973, DSM 20450, HAMBI 1590, JCM 1180, LMG 8520, NCIMB 702181.

GenBank accession number (16S rRNA gene): AB100804.

2. ***Lactococcus garvieae*** (Collins, Farrow, Phillips and Kandler 1983) Schleifer, Kraus, Dvorak, Kilpper-Bälz, Collins and Fischer 1986, 354^{VP} (Effective publication: Schleifer, Kraus, Dvorak, Kilpper-Bälz, Collins and Fischer 1985, 183.) (*Streptococcus garvieae* Collins, Farrow, Phillips and Kandler 1983, 3430)

gar'vie.ae. N.L. gen. n. *garvieae* of Garvie, named for E.I. Garvie, a British microbiologist.

Colonies on blood agar or nutrient agar are circular, smooth, and entire. Nonpigmented. Not β -hemolytic. Ovoid cells elongated in the direction of the chain; mostly in pairs or short chains. Gram-positive. Nonmotile. Facultatively anaerobic. Catalase-negative. Grows at 10°C and 40°C but not at 45°C. Grows in 4% (w/v) NaCl. Grows in and reduces 0.1% methylene blue milk. Chemo-organotrophic; fermentative metabolism. Acid produced from galactose, glucose, fructose, cellobiose, amygdalin, arbutin, mannose, ribose, trehalose, salicin, β -gentiobiose, and *N*-acetylglucosamine. Acid not produced from *D*-arabinose, *L*-arabinose, *D*-arabitol, *L*-arabitol, adonitol, 2-ketogluconate, 5-ketogluconate, dulcitol, erythritol, *D*-fucose, *L*-fucose, glycogen, inulin, inositol, melibiose, melizitose, β -methylxyloside, α -methyl-*D*-glucoside, α -methyl-*D*-mannoside, *D*-lyxose, raffinose, rhamnose, *L*-sorbose, sorbitol, *D*-turanose, xylitol, *D*-xylose, and *L*-xylose. Variable results may be obtained from malt-

ose, mannitol, sucrose, and D-tagatose. Esculin hydrolyzed. Hippurate hydrolysis variable. Starch hydrolysis negative. Arginine dehydrolase, leucine arylamidase, and pyrrolidonyl arylamidase-positive. α -Galactosidase, β -galactosidase, and alkaline phosphatase-negative. Some strains react with Lancefield group N antisera.

The peptidoglycan type is Lys-Ala-Gly-Ala. Low levels of menaquinones produced with MK-9 predominating. Contains poly[Gal(α 1-6)Gal(α 1-3)Gro-1-P(2 \leftarrow 1 α Gal)] lipoteichoic acid. The major glycolipid is Glc(α 1-2)Glc(α 1-3)acyl₂Gro. Aminophospholipids are not detected. Major nonhydroxylated long-chain fatty acids are hexadecanoic, *cis*-11,12-octadecenoic and *cis*-11,12-methylene-octadecanoic acids.

The level of 16S rRNA sequence similarity between *Lactococcus garvieae* and the type strains of the other *Lactococcus* species is 91–93%.

DNA G+C content (mol%): 38.3–38.7 (T_m).

Type strain: ATCC 43921, CCUG 32208, CIP 102507, DSM 20684, HAMBI 1592, JCM 10343, JCM 12256, LMG 8893, NCIMB 702155.

GenBank accession number (16S rRNA gene): X54262.

3. **Lactococcus piscium** Williams, Fryer and Collins 1990a, 320^{VP} (Effective publication: Williams, Fryer and Collins 1990b, 113.)
piscium. L. n. *piscis* fish; L. gen. pl. n. *piscium* of fishes.

Cells are short rods to ovoid in shape, mostly in pairs or short chains. Gram-positive. Nonmotile. Facultatively anaerobic. Catalase-negative. Grows at 5°C and 30°C; no growth at 40°C. Acid is produced from amygdalin, L-arabinose, arbutin, N-acetylglucosamine, cellobiose, D-fructose, galactose, β -gentiobiose, gluconate, glucose, lactose, maltose, D-mannose, mannitol, melibiose, melizitose, D-raffinose, ribose, salicin, sucrose, trehalose, D-turanose, and D-xylose. Acid is not produced from adonitol, D-arabinose, D-arabitol, L-arabitol, dulcitol, erythritol, D-fucose, L-fucose, glycogen, glycerol, inositol, inulin, 2-ketogluconate, 5-ketogluconate, D-lyxose, α -methyl-xyloside, rhamnose, L-sorbose, sorbitol, D-tagatose, xylitol, and L-xylose. Esculin is hydrolyzed. Starch hydrolysis is slow and weak. Arginine hydrolysis and urease-negative. H₂S is not produced.

The cell-wall type has not been determined. The long-chain fatty acids are of the straight-chain saturated, mono-unsaturated, and cyclopropanoic types. The major acids correspond to hexadecanoic acid, ω 7-octadecenoic acid, and ω 7-methylene-octadecenoic acid.

The level of 16S rRNA sequence similarity between *Lactococcus piscium* and the type strains of the other *Lactococcus* species is 92–93%.

DNA G+C content (mol%): 38.5 (T_m).

Type strain: HRIA 68, ATCC 700018, CCUG 32207, CCUG 32732, CIP 104371, DSM 6634, JCM 11055, NCIMB 13196.

GenBank accession number (16S rRNA gene): X53905.

4. **Lactococcus plantarum** (Collins, Farrow, Phillips and Kandler 1983) Schleifer, Kraus, Dvorak, Kilpper-Bälz, Collins and Fischer 1986, 354^{VP} (Effective publication: Schleifer, Kraus, Dvorak, Kilpper-Bälz, Collins and Fischer 1985, 193.)

(*Streptococcus plantarum* Collins, Farrow, Phillips and Kandler 1983, 3430)

plan.ta'rum. L. n. *planta* plant; N.L. gen. pl. n. *plantarum* of plants.

Colonies on blood agar or nutrient agar are circular, smooth, and entire. Nonpigmented. Not β -hemolytic. Spheres or ovoid cells elongated in the direction of the chain; mostly in pairs or short chains. Gram-positive. Nonmotile. Facultatively anaerobic. Catalase-negative. Grows at 10°C but not at 45°C. Grows in 4% (w/v) NaCl. Does not grow in 0.1% methylene blue milk. Chemo-organotrophic; fermentative metabolism. Acid produced from amygdalin, arbutin, cellobiose, dextrin, fructose, glucose, maltose, D-mannose, mannitol, melizitose, N-acetylglucosamine, salicin, sorbitol, sucrose, and trehalose. Acid not produced from adonitol, D-arabinose, L-arabinose, arabitol, 2-ketogluconate, 5-ketogluconate, dulcitol, erythritol, D-fucose, L-fucose, galactose, gluconate, glycogen, glycerol, inositol, inulin, lactose, D-xylose, melibiose, α -methyl-D-glucoside, α -methyl-D-mannoside, β -methylxyloside, raffinose, ribose, rhamnose, L-sorbose, D-tagatose, D-xylose, L-xylose, and xylitol. Variable results may be obtained from β -gentiobiose and turanose. Esculin hydrolyzed. Starch, hippurate, and gelatin not hydrolyzed. Leucine arylamidase-positive. β -Galactosidase, β -glucuronidase, alkaline phosphatase, arginine dehydrolase, and pyrrolidonyl arylamidase-negative. Some strains are α -galactosidase-positive. Reacts with Lancefield group N antisera.

The peptidoglycan type is Lys-Ser-Ala. Menaquinones are absent. Contains poly(glycerophosphate)-lipoteichoic acid substituted solely with D-alanine esters. The major glycolipid is Glc(α 1-2)Glc(α 1-3)acyl₂Gro. Contains D-alanyl- and L-lysylphosphatidylglycerol. Major nonhydroxylated long-chain fatty acids are hexadecanoic, *cis*-11,12-octadecenoic acids, and *cis*-11,12-methyleneoctadecanoic acid.

The level of 16S rRNA sequence similarity between *Lactococcus plantarum* and the type strains of the other *Lactococcus* species is 90–93%.

DNA G+C content (mol%): 36.9–38.1 (T_m).

Type strain: ATCC 43199, CCUG 39180, CIP 102506, DSM 20686, HAMBI 1593, JCM 11056, LMG 8517, NCIMB 11945.

GenBank accession number (16S rRNA gene): X54259.

5. **Lactococcus raffinolactis** (Orla-Jensen 1932) Schleifer, Kraus, Dvorak, Kilpper-Bälz, Collins and Fischer 1988, 220^{VP} (Effective publication: Schleifer, Kraus, Dvorak, Kilpper-Bälz, Collins and Fischer 1985, 194.) (*Streptococcus raffinolactis* Orla-Jensen and Hansen 1932, 6)
 raf.fi.no.lac'tis. N.L. adj. *raffinoseum* raffinose; L. gen. n. *lactis* of milk; L. gen. n. *raffinolactis* raffinose fermenting bacterium from milk.

Colonies on blood agar are circular, smooth, and entire. Nonpigmented. Not β -hemolytic. Spheres or ovoid cells elongated in the direction of the chain; mostly in pairs or short chains. Gram-positive. Nonmotile. Facultatively anaerobic. Catalase-negative. Growth at 10°C, but not at 40°C. Does not grow in 4% (w/v) NaCl or 0.1% methylene blue milk. Chemo-organotrophic; fermentative metabolism.

Acid is usually produced from arbutin, D-fructose, galactose, lactose, maltose, D-mannose, melizitose, melibiose, N-acetylglucosamine, raffinose, salicin, starch, sucrose, and trehalose. Most strains produce acid from D-xylose. Acid not produced from adonitol, arabitol, D-arabinose, dulcitol, erythritol, D-fucose, gluconate, glycerol, glycogen, inositol, 2-keto-gluconate, D-lyxose, α -methyl-D-mannoside, β -methylxyloside, rhamnose, sorbitol, D-tagatose, L-xylose, and xylitol. Variable results may be obtained with amygdalin, L-arabinose, dextrin, β -gentiobiose, inulin, mannitol, melizitose, α -methyl-D-glucoside, ribose, L-sorbose, and turanose. Esculin hydrolyzed. Casein, hippurate, and gelatin not hydrolyzed. α -Galactosidase and leucine arylamidase-positive. Alkaline phosphatase, β -galactosidase, β -glucuronidase, and pyrrolidonyl arylamidase-negative. Most strains are arginine dehydrolase-negative. Reacts with Lancefield group N antisera.

The peptidoglycan type is Lys-Thr-Ala. Menaquinones are absent. Contains poly(glycerophosphate)-lipoteichoic acid substituted solely with D-alanine ester. The major glycolipid is Glc(α 1-2)Glc(α 1-3)acyl₂Gro. Contains D-alanyl- and L-lysylphosphatidylglycerol. Major nonhydroxylated long-chain fatty acids are hexadecanoic and *cis*-11,12-octadecenoic acids. *cis*-11,12-Methylenoctadecenoic acid is absent.

The level of 16S rRNA sequence similarity between *Lactococcus raffinolactis* and the type strains of the other *Lactococcus* species is 92–93%.

DNA G+C content (mol%): 40–43 (T_m).

Type strain: ATCC 43920, CCUG 32209, CIP 102300, DSM 20443, HAMBI 1589, JCM 5706, LMG 13095, NCIMB 13197.

GenBank accession number (16S rRNA gene): not available for type strain.

Additional remarks: X54261 is the GenBank accession number (16S rRNA) for strain NCIMB 702156.

Genus III. **Lactovum** Matthies, Gössner, Acker, Schramm and Drake 2005, 547^{VP}
(Effective publication: Matthies, Gössner, Acker, Schramm and Drake 2004, 853.)

HAROLD L. DRAKE

Lact.o'vum. L. n. *lac* (gen. *lactis*) milk. L. neut. n. *ovum* egg; N.L. neut. n. *Lactovum* egg from milk (to indicate that the capacity to form lactate yields egg-shaped cells).

Gram-stain-positive, **mesophilic**, **anaerobic** with an **aerotolerant**, **chemo-organotrophic**, fermentative metabolism. Cells are ovoid, do not form spores, and lack flagella (Figure 126).

DNA G+C content (mol%): 37.6 (HPLC).

Type species: **Lactovum miscens** Matthies, Gössner, Acker, Schramm and Drake 2005, 547^{VP} (Effective publication: Matthies, Gössner, Acker, Schramm and Drake 2004, 853.)

Further descriptive information

Members of the genus *Lactovum* are currently represented by a single species, i.e., the type species *Lactovum miscens*. *Lactovum miscens* is phylogenetically distantly related to the genera *Lactococcus* and *Streptococcus*. Sequence similarity of the 16S rRNA gene sequence of *Lactovum miscens* to that of its closest relatives, *Lactococcus garvieae* and *Lactococcus piscium*, is 89.3%. Sequence similarity of the 16S rRNA gene sequence of *Lactovum miscens* to

that of its closest streptococcal relative, *Streptococcus pyogenes*, is 88.2% (Matthies et al., 2004).

Enrichment and isolation procedures

The type species of *Lactovum* was isolated from an acidic forest floor (L horizon) solution obtained from a beech forest in east-central Germany (Matthies et al., 2004). Forest floor solution was supplemented with N-acetylglucosamine and incubated at 15°C. An N-acetylglucosamine enrichment was streaked onto solidified anoxic medium and incubated at 15°C in O₂-free gas jars. The type species was derived from an isolated colony.

Maintenance procedures

The type species is easily maintained in the phosphate-buffered, yeast extract medium described by Matthies et al. (2004). Stability under long-term storage conditions has not been determined.

List of species of the genus *Lactovum*

1. **Lactovum miscens** Matthies, Gössner, Acker, Schramm and Drake 2005, 547^{VP} (Effective publication: Matthies, Gössner, Acker, Schramm and Drake 2004, 853.)
mis.cens. L. part. adj. *miscens* mixing (to indicate a mixed fermentative metabolism).

Cells are 0.7 × 1.0 μm, contain multiple cell-wall layers and intracellular membranes. Cells often occur in pairs. Grows at 0–35°C and pH 3.5–7.5. Doubling time is 4.7 h at pH 6.3 and 25°C. Cell lysis is minimal in broth cultures. Grows on glucose, galactose, fructose, mannitol, glucosamine, N-acetylglucosamine, cellobiose, and maltose.

Displays a mixed fermentative metabolism (Figure 127). Certain sugars (e.g., glucose) are metabolized to lactate via homolactate fermentation, while other sugars (e.g., galactose) are metabolized to ethanol, formate, and acetate. O₂, nitrate, sulfate, and Fe(III) are not utilized as terminal electron acceptors. Cells are aerotolerant, do not contain membranous or cytoplasmic cytochromes, and lack catalase and NADH oxidase.

DNA G+C content (mol%): 37.6 (HPLC).

Type strain: anNAG3, ATCC BAA-490, DSM 14925.

GenBank accession number (16S rRNA gene): AJ439543.

FIGURE 126. Transmission electron micrograph of *Lactovum miscens* (DSM 14925). Arrow points identify regions of cells forming septa prior to division. Cells often occur in pairs; an amorphous cellular bridge (arrow) occurs between paired cells. Bar = 0.5 μm . (Taken from Matthies et al., 2004; used with permission.)

FIGURE 127. Metabolic transformations of *Lactovum miscens*. The route by which pyruvate is metabolized is dependent upon the sugar that is fermented. Abbreviations: [H], reductant; ATP, adenosine triphosphate; CoA, coenzyme A. (Taken from Matthies et al., 2004; used with permission.)

JUERGEN WIEGEL

Clos.tri.di.a'ce.ae. N.L. neut. n. *Clostridium* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Clostridiaceae* the *Clostridium* family.

Phylogenetic and taxonomic comments

The family *Clostridiaceae* is the first of 19 families within the order *Clostridiales* of the class “*Clostridia*” of the phylum *Firmicutes*. In the current volume, the family contains 13 recognized genera. However, in this volume the only species of the genus *Anaerobacter*, *Anaerobacter polyendosporus*, is reassigned to *Clostridium* as *Clostridium polyendosporum*, and the only species of the genus *Thermobrachium*, *Thermobrachium celere*, is reassigned in this volume to the genus *Calaromator* as *Calaromator celere*, thus reducing the number of genera to 11. The type genus of the *Clostridiaceae*, *Clostridium*, presently contains about 190 recognized species (Euzéby, 1997). However, some of these are not validly published, either because they lack a designated type strain or, if published after 2000, have not been deposited in two culture collections in two different countries. Furthermore, as indicated by the analysis of Collins et al. (1994) and discussed by Wiegel et al. (2006), probably more than half of the validly named clostridial species do not belong to the genus *Clostridium sensu stricto* (Collins' Group I) and should be reassigned to new genera and families. Thus, extensive modification of the systematics of *Clostridiaceae* is to be expected, and the reader should consult Jean Euzéby's List of Prokaryotic Names with

Standing in Nomenclature (<http://www.bacterio.cict.fr/>), which is updated monthly on publication of the *International Journal of Systematic and Evolutionary Microbiology*.

The systematics of *Clostridiaceae* used for this volume differs significantly from what has been published previously (Hippe et al., 1992). The new system relies heavily on phylogenetic analyses of the 16S rRNA gene and attempts to circumvent some of the problems of the previously ill-defined genus *Clostridium*. These problems have been evident for decades prior to 16S rRNA gene sequence analyzes, e.g., from the wide range of values for the G+C content of DNA (22–55 mol%) and the variability of sporulation and Gram staining. Thus, several of the species which were not in the radiation of the genus *Clostridium sensu stricto* have been transferred to novel genera and other families, in some cases even in different orders. Examples of well known species being transferred in this way include the transfer of *Clostridium thermosaccharolyticum* to *Thermoanaerobacterium* (Lee et al., 1993) and *Clostridium thermoaceticum* to *Moorella*, both in the family “*Thermoanaerobacteraceae*” of the order “*Thermoanaerobacterales*” (Collins et al., 1994; Ludwig et al., 2009; Stackebrandt et al., 1999a; Stackebrandt and Rainey, 1997). Even though many of the “clostridia-like” thermophiles

have been transferred to the *Thermoanaerobacterales*, the family *Clostridiaceae sensu stricto* and genus *Clostridium sensu stricto* still contains many thermophiles, such as *Caloramator* and *Thermohalobacter* spp. and *Clostridium thermobutyricum*, respectively. Thus, thermophily in itself is not a reliable phylogenetic marker.

All species of this genus *Clostridium sensu stricto* (previously called Group I of Collins et al., 1994) are obligately anaerobic, sporulating rod-shaped bacteria with a G+C content of their chromosomal DNA of around 22–35 mol%. Most, especially the mesophilic species, stain Gram-positive and contain meso-diaminopimelic acid in their cell walls. An exception is *Clostridium thermobutyricum*, which stains Gram-negative (Wiegel et al., 1989b). They are not capable of dissimilatory sulfate reduction. Thus, most properties are still consistent with the definition of *Clostridium* as given by Hippe et al. (1992). However, several of the other genera within the family *Clostridiaceae* have different properties. Some genera contain species that are asporogenic (but contain sporulation genes) or are even nonsporogenic or lack sporulation genes (Brill and Wiegel, 1997; Onyenwoke et al., 2004). Some species, especially many of the thermophilic taxa such as *Clostridium thermocellum*, stain Gram-negative at all growth phases even though they possess a Gram-type-positive cell wall without lipopolysaccharide (Wiegel, 1981).

Since the organization of the family *Clostridiaceae* is still in flux, it is expected to change in the near future. As discussed by Rainey et al. (2006), some of the genera included in this family were placed there in part because some members had been previously published as species of *Clostridium*. Likewise, many of the 13 genera in the present family *Clostridiaceae* are only represented by a single species. Thus, as further species are described, their systematic position will have to be adjusted accordingly. Current evidence suggests that this family contains three phylogenetic groups in addition to close relatives of *Clostridium sensu stricto*. These include the clusters of *Alkaliphilus*, *Anoxyratronum*, *Natronincola*, and *Tindallia*; *Caloranaerobacter* and *Thermohalobacter*; and *Caminicella*. If future investigations warrant it, some or all of these groups may be moved to separate families.

Morphological and physiological comments

The taxa presently placed into the *Clostridiaceae* are generally obligately anaerobic rods. Their cells usually stain Gram-positive, although a significant number, especially the thermophilic species, stain Gram-negative at all growth phases. The typical cell wall, especially for the species of the type genus *Clostridium sensu stricto*, contains meso-diaminopimelic acid and is of the A1 γ peptidoglycan type. Species such as *Clostridium thermoalkaliphilum*, which is not a member of the *Clostridium sensu stricto* and has the A4 β type of cell wall type that contains a L-ornithine-D-asparagine interpeptide bridge, will probably be reclassified into other families. Aside from species with rod-shaped morphologies, the family *Clostridiaceae sensu stricto* includes species or genera with coccoid or polymorphic morphologies. For instance, *Sarcina* species are characterized by their very distinct morphology, forming symmetrical packages of multiples of four cells and producing cellulose as a “glue-like” material outside of their cells. Most of the proposed species belonging to the *Clostridiaceae* form endospores or have been shown to contain sporulation-specific genes (Onyenwoke et al., 2004). Although *Anaerobacter* falls within the radiation of *Clostridiaceae sensu stricto*

(Stackebrandt et al., 1999a), it produces many spores within one cell instead of only one spore per cell, as most other clostridia.

Other physiological characteristics of the *Clostridiaceae* are highly variable. Nearly all members of the type genus *Clostridium sensu stricto* form butyrate as a major fermentation product. Exceptions include *Clostridium ljungdahlii*, *Tindallia*, and *Natronincola*, which produce acetate using the Wood–Ljungdahl homoacetogenic pathway. These bacteria produce acetate as the sole acid from fructose as well as autotrophically from H₂/CO₂ or CO. Most clostridial species are described as heterotrophs that depend upon substrate level phosphorylation for ATP generation, but exceptions are observed. *Clostridium ljungdahlii* and *Natronincola histidinovorans* use electron transport phosphorylation involving the Wood–Ljungdahl pathway. *Natronincola histidinovorans* also couples the oxidation of histidine to fumarate reduction via an electron transport chain and gains ATP by an anaerobic respiration. Thiosulfate can also function as an electron acceptor. Members of the *Clostridiaceae* are glycolytic, saccharolytic, peptolytic (including amino acid utilization), and/or chemolithoautotrophic. The fermentation products include various organic acids and alcohols, representing various pathways such as mixed acid, solvent, and homoacetogenic fermentation.

Although most species are neutrophiles, several alkaliphilic, alkalithermophilic, moderate halophilic, haloalkaliphilic, and slightly acidophilic species have been described.

Comments on habitats

Habitats from which members of the *Clostridiaceae* have been isolated are very diverse, various types of feces and manure piles, sewage sludge, freshwater and marine sediments, salt lakes, and various parts of the human body. Habitats also vary greatly with respect to temperature, i.e., from permafrost, common mesobiotic habitats, and geothermally and anthropogenically heated sources. Since many species of the *Clostridiaceae* form desiccation and heat-resistant spores, it is not surprising that members of the family can be generally regarded as ubiquitous. However, some species are more restricted in their habitats.

The family also includes clinically important and highly pathogenic species, many within the genus *Clostridium sensu stricto*, as well as biotechnologically important species such as the solvent-producer *Clostridium acetobutylicum* and related species.

 Genus X. *Sarcina*^{AL} (Goodsir, 1842)
Sarcina ventriculi^{AL(T)} (Goodsir, 1842)
Sarcina maxima^{AL} (Lindner, 1888)
 Genus XI. *Thermobrachium*^{VP} (Engle et al., 1996)
Thermobrachium celere^{VP(T)} (type and only species,
 reassigned to *Caloramator*) Wiegel, 2009
 Genus XII. *Thermohalobacter*^{VP} (Cayol et al., 2000a)
Thermohalobacter berrensis^{VP(T)} (presently not freely
 available; Euzéby, 2007)
 Genus XIII. *Tindallia*^{VP} (Kevbrin et al., 1998)
Tindallia magadiensis^{VP(T)} (Kevbrin et al., 1998)
Tindallia californiensis^{VP} (Pikuta et al., 2003a)
Tindallia texcoconensis^{VP} (Alazard et al., 2009)

Genus I. *Clostridium* Prazmowski 1880, 23^{AL}

FRED A. RAINEY, BECKY JO HOLLEN AND ALANNA SMALL

Clos.tri'di.um. Gr. n. *closter* a spindle; N.L. neut. dim. n. *Clostridium* a small spindle.

Rods, usually stain Gram-positive at least in very early stages of growth, although in some species Gram-stain-positive cells have not been seen. Motile or nonmotile. When motile, cells usually are peritrichous. The majority of species form oval or spherical **endospores** that usually distend the cell.

Usually chemoorganotrophic; some species are chemoautotrophic or chemolithotrophic as well. Usually produce mixtures of organic acids and alcohols from carbohydrates or peptones. **May be saccharolytic, proteolytic, neither, or both.** May metabolize carbohydrates, alcohols, amino acids, purines, steroids, or other organic compounds. Some species fix atmospheric nitrogen. **Do not carry out a dissimilatory sulfate reduction.** Usually catalase-negative, although trace amounts of catalase may be detected in some strains.

The cell wall usually contains *meso*-diaminopimelic acid (*meso*-DAP).

Most species are obligately **anaerobic**, although tolerance to oxygen varies widely; some species will grow but not sporulate in the presence of air at atmospheric pressure.

For most species, growth is most rapid at pH 6.5–7 and at temperatures between 30 and 37 °C.

DNA G+C content (mol%): 22–53.

Type species: Clostridium butyricum Prazmowski 1880, 24^{AL}.

Taxonomic comments

There are currently 168 validly published species of the genus *Clostridium*. Of these, 77 fall within the 16S rRNA gene sequence cluster I of the clostridia as defined by Collins et al. (1994) and are listed in Table 140. The remaining 81 species fall outside of cluster I (*Clostridium sensu stricto*) and so, although currently assigned to the genus *Clostridium*, their genus assignment is in many cases uncertain (Table 141). Many of these species fall within the radiation of other established genera. The phylogenetic relationships of the species falling within clusters I and II of the clostridia are shown in Figure 128. The characteristics of the species of clusters I and II falling with the family *Clostridiaceae* are given in the descriptions below and in Table 142. The polyphyletic nature of the genus *Clostridium* and possible solutions to the restructuring of the genus has been described and discussed at length previously (see Collins et al., 1994; Rainey et al., 1993; Stackebrandt et al., 1999a; Wiegel et al., 2005).

Since Collins et al. (1994) demonstrated the extensive phylogenetic diversity of the species then assigned to the genus *Clostridium*, a number of species have been reclassified to novel or existing genera. However, species (27 since 1995) continue to be added to the genus *Clostridium* even though they are not members of cluster I, the *Clostridium sensu stricto*, or the family *Clostridiaceae*. The addition of these new species to the genus *Clostridium* is adding to the taxonomic confusion associated with this taxon.

List of species of the genus *Clostridium*

Species designated with an asterisk (*) are descriptions taken from the previous edition of *Bergey's Manual* (Cato et al., 1986). Additional information on the phylogenetic position of these species has been added when available. In the previous edition of this volume (Cato et al., 1986), species were grouped together and compared on the basis of phenotypic characteristics. The main criteria for clustering the species for comparative purposes included the production of acid from glucose, gelatin hydrolysis, meat digestion, starch hydrolysis, and combinations thereof.

The characteristics of the species of the genus *Clostridium sensu stricto* and those within the family *Clostridiaceae* are given in the species description as well as in Table 142. The species are listed in Table 142 in the order in which they cluster in the 16S rRNA gene sequence based dendrogram Figure 128. The characteristics of other species that fall outside of the genus *Clostridium sensu stricto* for which Tables of characteristics were provided in the previous edition of this volume (Cato et al., 1986) are given in Table 143, Table 144, and Table 145.

1. *Clostridium butyricum** Prazmowski 1880, 24^{AL}

bu.ty ri.cum. Gr. n. *boutyron* butter; N.L. neut. adj. *butyricum* related to butter, butyric.

Type species of the genus *Clostridium*.

Cells in PYG broth are Gram-stain-positive straight rods with rounded ends, motile and peritrichous, 0.5–1.7 × 2.4–7.6 μm. Occur singly, in pairs, or in short chains and occasionally as long filaments. Cells are often granulose-positive. Spores are oval, central to subterminal, and usually do not swell the cell. No exosporium or appendages are present. Sporulation occurs readily both in broth and on solid media. Cell walls contain *meso*-DAP and glucose. Glutamic acid and alanine are present.

Surface colonies on blood agar plates are 1–6 mm in diameter, circular to irregular, lobate or slightly scalloped, raised to convex, translucent, gray-white, shiny or dull, smooth, with a granular or mottled internal structure.

Cultures in PYG broth are turbid with a smooth or flocculent sediment and have a pH of 4.6–5.0 after incubation for 5 d.

The optimum temperature range for growth is 30–37 °C; many strains grow equally well at 25 °C and growth can occur at 10 °C. Growth is stimulated by a fermentable carbohydrate and inhibited by 6.5% NaCl. Strains of *Clostridium butyricum* grow readily in glucose-mineral salts medium with biotin as the only required vitamin.

Pectin is strongly fermented by all strains tested. Pectin degradation has been implicated in the formation of wet-wood in living hardwood trees and in the anaerobic digestion of fruit and vegetable wastes, and strains of *Clostridium butyricum* which carry out these processes have been isolated from these sources. Chlorinated hydrocarbon pesticides can be degraded in the presence of glucose by strains of this species. Atmospheric N₂ is fixed.

Strains contain an iron-sulfur-thiamin pyrophosphate enzyme involved in the reduction of ferredoxin by pyruvate. DNase activity has been detected. Neutral red and resazurin are reduced.

Products in PYG broth are butyric, acetic, and formic acids; lactic and succinic acids; butanol and ethanol are

Additional <i>Clostridium</i> species
<i>Clostridium cylindrosporum</i>

sometimes produced. Pyruvate is converted to acetate, butyrate, and sometimes formate. Neither lactate nor threonine is utilized. Products from the fermentation of pectin are large amounts of methanol, acetate, H₂, and CO₂, and moderate amounts of butyrate and ethanol.

All strains tested are susceptible to clindamycin, chloramphenicol, erythromycin, and tetracycline; 9 of 37 strains are resistant to penicillin. Three clinical isolates, resistant to penicillin, produce a β-lactamase. Two clinical isolates tested are susceptible to cefoxitin (4 μg/ml), clindamycin (1 μg/ml), and metronidazole (1 μg/ml). Culture supernatants are not toxic to mice. A bacteriocin produced by the type strain is active against cell membrane functions of several species of clostridia, particularly those of *Clostridium pasteurianum*.

Other characteristics of the species are given in Table 142.

Source: soil, freshwater and marine sediments, cheese, rumen of healthy calves, animal and human feces (including feces of healthy infants), snake venom, and, although seldom in pure culture, from a wide variety of human and animal clinical specimens including those from blood, urine, lower respiratory tract, pleural cavity, abdomen, wounds, and abscesses.

DNA G+C content (mol %): 27–28 (T_m).

FIGURE 128. 16S rRNA gene sequence based phylogeny of clusters I and II of the genus *Clostridium* as defined by Collins et al. (1994).

Type strain: ATCC 19398, CCUG 4217, CIP 103309, DSM 10702, HAMBI 482, IAM 14194, NBRC 13949, JCM 1391, KCTC 1786, KCTC 1871, LMG 1217, NCCB 89156, NCIMB 7423, NCTC 7423, VKM B-1773.

GenBank accession number (16S rRNA gene): AB075768, M59085.

Further comments: 16S rRNA gene studies have established the phylogenetic position of *Clostridium butyricum* in relationship to other *Clostridium* species. As the type species of the genus, *Clostridium butyricum* is the core of the true genus *Clostridium* in cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives to the type species of the genus based on sequence similarity values are *Clostridium saccharoperbutylacetonicum* (97.6%), *Clostridium beijerinckii* (97.5%), *Clostridium diolis* (97.5%), *Clostridium puniceum* (97.3%), and *Clostridium saccharobutylicum* (97.1%).

DNA/DNA homology experiments established that *Clostridium butyricum* is a distinct species that includes strains previously identified as other species. In addition, many strains previously labeled *Clostridium butyricum* are now recognized as *Clostridium beijerinckii*. The two species are most easily differentiated by distinct electrophoretic patterns of cellular proteins and by nutritional requirements. *Clostridium butyricum* will grow well even in a third serial transfer in a medium containing only glucose, mineral salts, and biotin, while *Clostridium beijerinckii* requires other vitamins and growth factors such as are provided by yeast extract. The two species also differ in phospholipid composition. *Clostridium butyricum* has ethanolamine as its major nitrogenous phospholipid base, while *Clostridium beijerinckii* has *N*-methylethanolamine and ethanolamine.

Historically, "*Clostridium pseudotetanicum*" has been differentiated from *Clostridium butyricum* by spore location. However, both terminal and subterminal spores are seen in cultures of strains of the two species. The reference strain of "*Clostridium pseudotetanicum*" (Prévot, 1938) Smith and Hobbs 1974, 567 (ATCC 25779; NCIB 10630) is phenotypically indistinguishable from strains of *Clostridium butyricum*. Bulk RNA preparations from ATCC 25779 are 100% homologous with the 23S RNA from ATCC 19398, the type strain of *Clostridium butyricum* (Johnson and Francis, 1975). In addition, the electrophoretic patterns of soluble cellular proteins of the two strains are identical. Thus, "*Clostridium pseudotetanicum*" appears to be a later synonym of *Clostridium butyricum* pending confirmation by DNA-DNA homology determinations.

2. *Clostridium acetium** (ex Wieringa 1940) Gottschalk and Braun 1981, 476^{VP}

a.ce'ti.cum. L. n. *acetum* vinegar; L. adj. suff. *-icus* belonging to; N.L. neut. adj. *acetium* related to acetic acid, which it produces.

Cells in broth cultures in an atmosphere of 67% H₂ and 33% CO₂ are Gram-stain-negative rods, motile and peritrichous, 0.3–1.0µm × 4.0–8.0µm. With fructose as the substrate, cells may be up to 40µm in length. Spores are round, terminal, and swell the cell. Sporulation occurs most readily on fructose agar medium after 2 d incubation. Cell walls contain *meso*-DAP and are composed of at least two layers. Colonies are not readily formed. After prolonged incubation

^aSymbols: +, reaction positive for 90–100% of strains; -, reaction negative for 90–100% of strains; ±, 61–89% of strains positive, -/+, 11–39% of strains positive; d, 40–60% of strains positive; w, weak; numbers (hydrogen) represent abundant (4) to negative on a “-” to “4” scale; c (milk), curd; a (milk), acid; tr, trace; NT, not tested. Where two reactions are listed, the first is more usual and occurs in 60–90% of strains.

^bProducts (listed in the order of amounts usually detected): a, acetic acid; b, butyric acid; l, lactic acid; s, succinic acid; p, propionic acid; f, formic acid; iv, isovaleric acid; ib, isobutyric acid; v, valeric acid; c, caproic acid; ic, isocaproic acid; 2, ethanol; 3, propanol; 4, butanol; i4, isobutanol; i5, isopentanol. Capital letters indicate at least 1 meq/1000 ml of culture; small letters indicate less than 1 meq/1000 ml. Products in parentheses are not detected uniformly.

in roll tubes in an agar medium containing mud extract and a CO₂-H₂ (1:2) atmosphere, “a barely visible, light-brown tuft of cellular material” can be seen.

Growth occurs in the temperature range 25–37 °C with an optimum temperature for growth of 30 °C; growth is poor at 45 °C. Growth occurs in the pH range pH 7.5–9.5 with an optimum for autotrophic growth at 8.3. Strains of this species grow chemolithotrophically in an atmosphere of CO₂ and H₂ and converting these substrates to acetate. They also utilize the organic substrates fructose, ribose, glutamate, fumarate, malate, pyruvate, serine, formate, ethylene glycol, and ethanol, but, in the presence of organic substrates CO₂ and H₂, are not converted to acetate. Amygdalin, dulcitol, adonitol, citrate, succinate, glycine, threonine, lactate, maltose, sucrose, xylose, methanol, 2-propanol, and glycerol are not utilized. H₂ is produced only in the stationary growth phase and inhibits growth in fructose medium at pH 8.5 if the bicarbonate concentration is very low. Esculin, gelatin, and starch are not hydrolyzed. Atmospheric N₂ is fixed. Gluconate is fermented to pyruvate and glyceraldehyde-3-phosphate by a modified Entner–Doudoroff pathway.

Source: soil, lake sediment, and sewage sludge.

DNA G+C content (mol%): 33 (T_m).

Type strain: ATCC 35044, DSM 1496.

GenBank accession number (16S rRNA gene): Y18183.

Further comments: *Clostridium acetium* is not a member of the genus *Clostridium sensu stricto* and falls in the cluster XI as defined by Collins et al. (1994). The 16S rRNA gene sequence of the type strain DSM 1496^T shows highest similarity to the species *Clostridium felsenium* (97.7%) and *Clostridium formicaceticum* (97.6%). The closest non-clostridial species is *Anerovirgula multivorans* (96.8%) (Pikuta et al., 2006).

Clostridium acetium can be differentiated from *Clostridium felsenium* in that *Clostridium felsenium* produces acid from glucose, sucrose, and xylose; produces acetate, butyrate and H₂ as end products of fermentation; hydrolyzes esculin and gelatin (see description of *Clostridium felsenium* below).

The species is most easily differentiated from *Clostridium formicaceticum*, which it most closely resembles phenotypically, by its ability to form acetate from CO₂ and H₂ and to utilize formate, serine, or ethylene glycol, but not methanol, as substrates.

3. *Clostridium acetireducens* Örlygsson, Krooneman, Collins, Pascual and Gottschal 1996, 458^{VP}

a.ce.ti.re.du'cens. L. neut. n. *acetum* vinegar; L. pres. part. *reducens* reducing; L. neut. adj. *acetireducens* vinegar- or acetic acid-reducing.

Straight rods, $1.0 \times 6 \mu\text{m}$ in length. Gram-stain-positive cell wall with thin S-layer. Endospores and flagella are not observed. Nonmotile. Strict anaerobe. Growth occurs in the temperature range 30–45 °C and optimally at 39–43 °C. The pH range for growth is 6.0–8.2, with optimal growth at pH 6.4–7.6. Acetate is used as an electron acceptor when growing on leucine, valine, isoleucine, and alanine. The reduced end product of growth is butyrate. Growth on leucine, valine, isoleucine, and alanine only occurs when acetate is available. Yeast extract required for growth. Cannot degrade sugars. Peptone (pancreatic digest of casein), serine, threonine, α -ketobutyrate, α -ketoisocaproate, and α -keto-3-methylvalerate are utilized as growth substrates. Unable to grow on saccharides, citrate, succinate, propionate, H₂-acetate, ethanol, and other amino acids. Fumarate, sulfate, sulfite, nitrate, nitrite, and oxygen cannot be used as electron acceptors.

Source: samples of an anaerobic bioreactor at the AVEBE potato starch factory in De Krim, Netherlands.

DNA G+C content (mol%): 28.5 (T_m).

Type strain: 30A, DSM 10703.

GenBank accession number (16S rRNA gene): X79862.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium acetireducans* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The 16S rRNA gene sequence of *Clostridium acetireducans* shows ~94% similarity to those of the species *Clostridium pascui*, *Clostridium cochlearum*, and *Clostridium tetanomorphum*. In the original description of *Clostridium acetireducens* (Örlygsson et al., 1996), the type strain is incorrectly cited as DSM 7310 when it is, in fact, DSM 10703.

4. ***Clostridium acetobutylicum***^{*} McCoy, Fred, Peterson and Hastings 1926, 483^{AL} emend. Keis, Shaheen and Jones 2001, 2100.

a.ce.to.bu.ty.li.cum. En. n. *acetone*; N.L. adj. *butylicum* butylic; N.L. neut. adj. *acetobutylicum* referring to production of acetone and butyl alcohol.

This description includes that provided by Cato et al. (1986) and Keis et al. (2001).

Cells in PYG broth cultures are straight rods, motile and peritrichous, $0.5\text{--}0.9 \times 1.6\text{--}6.4 \mu\text{m}$. Granulose (a starch-like polymer) is often present. Gram-stain-positive, becoming Gram-stain-negative in older cultures. Spores are oval and subterminal, slightly swelling the cell.

Cell walls contain *meso*-DAP, glucose, rhamnose, galactose, and mannose. The wall is triple-layered. Surface colonies on blood agar plates are 1–5 mm, flat to raised, granular, translucent to semiopaque with irregular margins and occasionally with a mosaic internal structure.

Cultures in PYG broth are turbid with a smooth sediment, and have a pH of 4.5–5.0 after incubation for 5 d.

The optimum temperature for growth is 37 °C. A fermentable carbohydrate, biotin, and *p*-aminobenzoic acid are required. No growth in the presence of 6.5% NaCl or 20% bile. Acetyl methyl carbinol is produced. Neutral red is reduced. Abundant gas is produced in glucose agar deep cultures. H₂S is produced by one of nine strains tested. Fixes atmospheric N₂.

Strains produce an inducible carboxymethyl cellulase and cellobiase. NADH and NADPH-ferredoxin and rubredoxin oxidoreductases also are present. Superoxide dismutase and deoxyribonuclease are produced.

Fermentation products include acetic, butyric, and lactic acids; butanol; acetone; CO₂; and large amounts of H₂. Small amounts of succinic acid may be formed. Ethanol was detected with high pressure liquid chromatography. During exponential growth, products are acetate and butyrate. Production of butanol and acetone is highest after 18 h when the organisms are in their stationary growth phase and is associated with morphological changes in the cells. Pyruvate is converted to acetate, butyrate, and butanol. Neither lactate nor threonine is utilized.

The type strain produces the amino acids lysine, arginine, aspartic acid, threonine, serine, glutamic acid, alanine, valine, isoleucine, leucine, and tyrosine in broth.

Strains are susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Culture supernatants are nontoxic to mice. Other characteristics of the species are listed in Table 142.

Characteristics added in the emendation of the species by Keis et al. (2001) include fermentation of amygdalin and raffinose.

Source: soil, lake sediment, well water, clam gut, bovine feces, canine feces, human feces.

DNA G+C content (mol%): 28–29 (T_m).

Type strain: ATCC 824, BCRC 10639, CCUG 42182C, CECT 508, DSM 792, IFO (now NBRC) 13948, JCM 1419, KCTC 1790, LMG 5710, NCCB 84048, NCCB 29024, NCIMB 13357, NRRL B-527, VKM B-1787.

GenBank accession number (16S rRNA gene): U16166, X78070.

Further comments: 16S rRNA gene sequence comparison show *Clostridium acetobutylicum* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives of *Clostridium acetobutylicum* based on sequence similarity values are *Clostridium sardiniense* (94.8%) and *Clostridium collagenovorans* (94.1%).

5. ***Clostridium acidisoli*** Kuhner, Matthies, Acker, Schmittroth, Gößner and Drake 2000, 880^{VP}

a.ci.di.so'li. L. adj. *acidus* acidic; L. neut. n. *solum* soil; N.L. gen. neut. n. *acidisoli* of acidic soil.

Rod-shaped cells, $1.0 \times 3\text{--}7\ \mu\text{m}$, occur singly or in chains. Cells in chains do not separate after septum formation. Motile with 8–12 peritrichous flagella. Gram-stain-positive. Sporeforming. Anaerobe. Catalase-, oxidase-, tryptophanase-, and urease-negative. No cytochromes. Chemoorganotroph with fermentative metabolism. Growth occurs in the temperature range 5–37°C and optimally at 25–30°C. Acid tolerant. The pH range for growth is 3.6–6.9, with no defined pH optimal for growth between pH 3.6 and 6.6. Doubling time on glucose at 30°C and pH 4.0 is ~3.5 h. Glucose, cellobiose, xylose, arabinose, maltose, mannose, salicin, mannitol, lactose, sucrose, glycerol, melezitose, raffinose, and rhamnose support growth. Does not grow on sorbitol, trehalose, H₂/CO₂, CO/CO₂, vanillate, Casamino acids, peptone, or various purines and pyrimidines. Glucose is fermented to acetate, butyrate, lactate, H₂, and CO₂. Under certain conditions, formate is formed. Nitrate and sulfate are not reduced. Nitrogen is fixed at pH 3.7.

Source: an acidic peat bog.

DNA G+C content (mol%): 30.7 (HPLC).

Type strain: CK74, ATCC BAA-167, DSM 12555.

GenBank accession number (16S rRNA gene): AJ237756.

Further comments: 16S rRNA gene sequence comparison show *Clostridium acidisoli* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The 16S rRNA gene sequence of *Clostridium acidisoli* shows ~97% similarity to those of the species *Clostridium akagii* and *Clostridium pasteurianum*. *Clostridium acidisoli* differs from *Clostridium pasteurianum* in substrate utilization range, forming lactate but not ethanol, lacking a carbon monoxide dehydrogenase, growing at pH 3.6 and fixing nitrogen at low pH. *Clostridium acidisoli* shares the ability to fix nitrogen at pH 3.7 with its other close relative *Clostridium akagii* (see description below) but differs in range of substrates utilized and cellular morphology.

6. ***Clostridium aciditolerans*** Lee, Romanek and Wiegel 2007, 314^{VP}

a.ci.di.to'le.rans. N.L. n. *acidum* an acid; L. part. adj. *tolerans* tolerating; N.L. part. adj. *aciditolerans* acid-tolerating.

Straight to slightly curved rods, $0.5\text{--}1 \times 3.0\text{--}9.0\ \mu\text{m}$. Type strain stains Gram-stain-negative at all growth phases, but have Gram positive wall structure. Retarded peritrichous flagellation. Forms subterminal spores that are oval in shape and do not swell the cell. After 1–2 d, colonies are irregular, mostly translucent, and less than 1.5 mm in diameter. Anaerobic growth. Growth occurs in the temperature range 20–45°C with optimal growth around 35°C. No growth at or below 18°C or at or above 47°C. The pH^{25°C} range for growth is pH 3.8–8.9 with optimal growth at pH 7.0–7.5. Growth at pH 4.5–5.0 takes place at 52% of the optimal growth rate; no growth is observed at or below pH 3.5 or at or above pH 9.2. The salinity range for growth is from 0–1.5% NaCl (w/v). Methyl red test, indole production, and lecithinase are positive, but Voges–Proskauer reaction and lipase are negative. Gelatin is hydrolyzed, but casein is not. Hemolysis occurs on blood agar. Grows on peptone–yeast extract (PY), peptone–yeast extract–glucose (PYG), reinforced clostridial medium (RCM, Difco), and thioglycolate broth (Difco). The following substrates serve as carbon and energy source in the presence of 0.02% yeast extract: beef extract, Casamino acids, peptone, tryptone, cellobiose, fructose, galactose, glucose, lactose, maltose, mannose, raffinose, ribose, sucrose, xylose, pyruvate, glutamate, and inulin. Acetate, lactate, arabinose, trehalose, inositol, mannitol, sorbitol, xylitol, and cellulose do not support growth. No autotrophic growth on CO₂ and H₂ (80:20). Fe(III), nitrate, thiosulfate, elemental sulfur, sulfate, sulfite, MnO₄, and fumarate are not used as electron acceptors. The main end products from glucose fermentation are acetate, butyrate, and ethanol. Resistant to tetracycline (10 μM) and sensitive to ampicillin (10 μM), chloramphenicol (10 μM), erythromycin (10 μM), rifampin (10 μM), and streptomycin (10 μM).

Source: a constructed wetland system receiving acid sulfate water.

DNA G+C content (mol%): 30.8 (HPLC).

Type strain: JW/YJL-B3, ATCC BAA-1220, DSM 17425.

GenBank accession number (16S rRNA gene): DQ114945.

Further comments: 16S rRNA gene sequence comparison shows *Clostridium aciditolerans* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The 16S rRNA gene sequence of *Clostridium aciditolerans* shows 96.2% similarity to *Clostridium drakei*. *Clostridium aciditolerans* can be differentiated from *Clostridium drakei* (see description below) in its ability to grow at pH 3.8; its ability to utilize lactose, maltose, and raffinose; and lack of growth on cellulose, inositol, and mannitol.

7. ***Clostridium acidurici**** (corrig. Liebert 1909) Barker 1938, 323^{AL}

a.ci.du'ri.ci. N.L. n. *acidum uricum* uric acid; N.L. gen. n. *acidurici* of uric acid.

Cells in PY-0.3% uric acid broth stain Gram-variable to Gram-stain-negative, motile and peritrichous, $0.5\text{--}0.7 \times 2.5\text{--}4.0\ \mu\text{m}$, occurring singly. Spores are oval, terminal and subterminal, and swell the cell. Sporulation occurs most reliably on chopped-meat uric-acid agar slants incubated at

30 °C for 1 week in an atmosphere of N₂. Cell walls contain *meso*-DAP. Surface colonies on uric acid agar are spreading, rhizoid, transparent, colorless, and flat, clearing the agar. No growth in gelatin or milk, or on egg-yolk or blood agar.

Broth cultures supplemented with 0.3% uric acid have a smooth sediment with no turbidity and a pH of 7.4–7.7 after incubation under N₂ for 6 d. Most rapid growth occurs in media at an initial pH of 7.6–8.1; there is poor growth below pH 6.5 or above 9.0. Growth occurs between 19 °C and 37 °C. Uric acid, xanthine, guanine, or hypoxanthine is required as a carbon and energy source. Selenite and tungstate stimulate xanthine dehydrogenase and formate dehydrogenase activity.

Products in PY-urate broth are acetate, NH₃, and CO₂. No H₂ is produced. No carbohydrates are fermented. The type strain is resistant to erythromycin, penicillin, and tetracycline. It is moderately sensitive to chloramphenicol and clindamycin. Culture supernatants of the type strain are nontoxic to mice.

Other characteristics of the species are given in Table 143.

Source: soil, chicken droppings, wild birds.

DNA G+C content (mol%): 28 (T_m).

Type strain: ATCC 7906, CIP 104303, DSM 604, NCCB 46094.

GenBank accession number (16S rRNA gene): M59084.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium acidurici* to fall within the radiation of the cluster XII of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarity values are *Clostridium purinolyticum* (93.8%) and *Eubacterium angustum* (92.1%).

8. ***Clostridium aerotolerans*** van Gylswyk and van der Toorn 1987, 104^{VP} emend. Chamkha, Garcia and Labat 2001a, 2109.

ae.ro.to'le.rans. Gr. masc. n. *aer* air, gas; L. v. *tolerare* to endure, to'put up with, tolerate; L. neut. part. adj. *aerotolerans* air-tolerating.

Straight rods, 0.4–0.6 × 1.5–3.0 μm. Grow under strictly anaerobic conditions or in unreduced media. Gram-stain-negative. Motile by peritrichous flagella. Produces single, terminal endospores. Spores are slightly oval and measure 0.6–0.8 μm. Colonies are round, have smooth edges, convex, and 2.5 mm in diameter. Appear light brown at the center but become translucent around the edges. The temperature range for growth is 15–45 °C with an optimum at 38–39 °C. The pH range for growth is 5.2–7.0 with an optimum at pH 6.6–6.9.

Ferments xylan to produce formic, acetic, and lactic acid; ethanol; carbon dioxide; and hydrogen. Maximum growth occurs on glucose, yeast extract, cysteine hydrochloride·H₂O, and Na₂S·9H₂O without reducing agent. Reduces various cinnamic acids. Digests xylan. Does not reduce sulfate. Gelatin is not hydrolyzed. Strains cannot digest casein. Indole is not produced. Urease, catalase, and nitrate reducing enzymic activity not observed. Various cinnamic acids including cinnamic; *o*-, *m*-, *p*-coumaric; *o*-, *m*-, *p*-methoxycinnamic; *p*-methylcinnamic; caffeic; ferulic; isoferulic; and 3,4,5-trimethoxycinnamic acids are reduced to their corresponding phenylpropionic acids, i.e., 3-phenyl,

3-(2-hydroxyphenyl), 3-(3-hydroxyphenyl), 3-(4-hydroxyphenyl), 3-(2-methoxyphenyl), 3-(3-methoxyphenyl), 3-(4-methoxyphenyl), 3-(4-methylphenyl), 3-(3,4-dihydroxyphenyl), 3-(4-hydroxy-3-methoxyphenyl), 3-(3-hydroxy-4-methoxyphenyl), and 3-(3,4,5-trimethoxyphenyl) propionic acids. In addition to the reduction of *p*-coumaric acid to 3-(4-hydroxyphenyl) propionic acid, *Clostridium aerotolerans* involves another pathway, i.e., *p*-coumaric acid can be decarboxylated to yield 4-vinylphenol which is reduced to 4-ethylphenol. Supplementation of glucose markedly accelerates all these conversions. Cinnamyl alcohol and phenylpropionic acids, including 3-phenylpropionic acid and 3,4-dihydroxyphenylpropionic acid, are not transformed.

Source: rumen of a sheep.

DNA G+C content (mol%): 40 (T_m).

Type strain: X8A62 = ATCC 43524, DSM 5434.

GenBank accession number (16S rRNA gene): X76163.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium aerotolerans* to fall within the radiation of cluster XIV of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarity are *Clostridium xylanolyticum* (99.4%), *Clostridium saccharolyticum* (98.4%), *Clostridium algidixylanolyticum* (98.1%), and *Clostridium amygdalinum* (98.0%).

9. ***Clostridium aestuarii*** Kim, Jeong and Chun 2007, 1317^{VP} *aes.tu.a'ri.i*. L. gen. n. *aestuarii* of the tidal flat.

Rod-shaped cells, 0.7–0.8 × 2–4 μm. Motile with peritrichous flagella. Forms circular and yellowish colonies on MRCM. Gram-stain-negative. KOH-negative. Forms oval, terminal spores. Strictly anaerobic and chemoheterotrophic. Temperature range for growth is 15–30 °C with optimal growth at 30 °C. The optimum pH for growth on MRCM is 7.0 with a growth occurring in the range pH 5.5–8.5. Requires 1–10% (w/v) artificial sea salts (optimum 4%) for growth. Does not grow on reinforced clostridial medium containing 0–5% (w/v) NaCl alone. Glucose, maltose, and sucrose are utilized. Arabinose, cellobiose, fructose, galactose, glycerol, lactose, mannitol, mannose, melezitose, raffinose, rhamnose, ribose, salicin, sorbitol, trehalose, and xylose are not utilized. The fermentation end products from glucose are butyric acid, propionic acid, glycerol, and H₂. Nitrate is not reduce. Produces alkaline phosphatase, esterase (C4), esterase lipase (C8), valine arylamidase, acid phosphatase, and naphthol-ASBI-phosphohydrolase but not lipase (C14), leucine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, N-acetyl-β-glucosaminidase, α-mannosidase, or α-fucosidase. Indole is not produced and urease-negative. Cells are catalase-negative and lecithinase-negative. Esculin is hydrolyzed, but gelatin is not.

Source: a tidal flat sediment on Ganghwa Island, South Korea.

DNA G+C content (mol%): not determined.

Type strain: HY-45-18, IMSNU 40129, JCM 13194, KCTC 5147.

GenBank accession number (16S rRNA gene): DQ126679.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium aestuarii* to fall within the radiation

of cluster I of the clostridia as defined by Collins et al. (1994). The 16S rRNA gene sequence of *Clostridium aestuarii* (DQ126679) shows 96.5% 16S rRNA gene sequence similarity to that of *Clostridium ganghwense*. Other validly published species share less than 94% similarity in their 16S rRNA gene sequences with that of *Clostridium aestuarii*. Both *Clostridium aestuarii* and *Clostridium ganghwense* (see description below) were isolated from tidal flat sediments on Ganghwa Isand, South Korea and require sea salts for growth. *Clostridium aestuarii* can be differentiated from *Clostridium ganghwense* by its ability to utilize sucrose but not mannose, fructose, salicin, gelatin, and cellobiose. Differences are also observed in the end products of glucose fermentation with *Clostridium aestuarii* forming butyrate, propionate, glycerol, and H₂ while *Clostridium ganghwense* forms glycerol, ethanol, and CO₂.

10. ***Clostridium akagii*** Kuhner, Matthies, Acker, Schmittroth, Gößner and Drake 2000, 879^{VP}

a.ka'gi.i. L. gen. n. *akagii* named after James M. Akagi, who worked for more than three decades at the University of Kansas on the physiology of various anaerobic bacteria.

Rod-shaped cells, 1.0 × 2–11 μm, occur singly or in chains and linked by a connecting filament. Motile with 10–15 peritrichous flagella. Sporeforming. Gram-stain-negative and lack an outer membrane. Anaerobic, chemoorganotrophic, fermentative growth. Growth occurs in the temperature range 5–30 °C and optimally at 20–25 °C. The pH range for growth is 3.7–7.1 with no distinct optimum between 4.2 and 6.8. Ferments glucose, cellobiose, xylose, arabinose, maltose, mannose, and salicin. Does not utilize mannitol, lactose, sucrose, glycerol, melezitose, raffinose, rhamnose, sorbitol, trehalose, H₂/CO₂, CO/CO₂, vanillate, Casamino acids, peptone, purines, and pyrimidines. End products of glucose fermentation are acetate, butyrate, lactate, H₂, and CO₂. Under certain conditions, formate is also produced. Doubling time of ~11 h at pH 4.0, 25 °C growing on glucose. Nitrate and sulfate are not reduced. Nitrogen is fixed at pH 3.7. Does not contain cytochromes. Negative for catalase, oxidase, tryptophanase, and urease activity.

Source: acidic beech liter.

DNA G+C content (mol%): 31.4 (HPLC).

Type strain: CK 58, ATCC BAA-166, DSM 12554.

GenBank accession number (16S rRNA gene): AJ237755.

Further comments: The 16S rRNA gene sequence of *Clostridium akagii* shows ~97% similarity to those of the species *Clostridium acidisoli* and *Clostridium pasteurianum*, falling within cluster I of the clostridia as defined by Collins et al. (1994). These species are differentiated on the basis of morphology and substrate utilization. *Clostridium akagii* differs from *Clostridium pasteurianum* in morphology, substrate range, the formation of lactate but not ethanol, growth and N₂ fixation at pH 3.7, and the lack of carbon monoxide dehydrogenase.

11. ***Clostridium aldenense*** Warren, Tyrrell, Citron and Goldstein 2007, 893^{VP} (Effective publication: Warren, Tyrrell, Citron and Goldstein 2006, 2420.)

al.de.nen'se. N.L. neut. adj. *aldenense* pertaining to R. M. Alden Research Laboratory and its first patron, Rose M. Alden Goldstein.

Rod-shaped cells 2–5 × 0.8–1.1 μm. Colonies that are 1–2 mm in diameter, flat, opaque to white, and nonhemolytic on Brucella blood agar plates after 48 h incubation at 37 °C. Gram-stain-negative. Spores only rarely formed.

Positive indole reaction. Acid from glucose, maltose, mannose, raffinose, sucrose, and xylose but not from cellobiose, esculin, mannitol, melezitose, rhamnose, sorbitol, or starch. Urea, starch, and gelatin are not hydrolyzed, and nitrate is not reduced. Fermentation of arabinose, lactose, salicin, and trehalose, and esculin hydrolysis are variable. Enzymically, α-galactosidase and β-galactosidase are positive, but arginine dihydrolase, β-galactosidase-6-phosphate, α-glucosidase, β-glucosidase, β-glucuronidase, N-acetyl-β-glucosaminidase, arginine arylamidase, praline arylamidase, leucyl glycine arylamidase, phenylalanine arylamidase, leucine arylamidase, pyroglutamic acid arylamidase, tyrosine arylamidase, alanine arylamidase, and glycine arylamidase are negative. Variable reactions are produced for α-arabinosidase and alkaline phosphatase.

Source: human clinical infections.

DNA G+C content (mol%): not reported.

Type strain: RMA 9741, ATCC BAA-1318, CCUG 52204.

GenBank accession number (16S rRNA gene): DQ279736.

Further comments: Comparison of the 16S rRNA gene sequence of *Clostridium aldenense* shows it to cluster with the species of the *Clostridium clostridiforme* group. This group was designated cluster XIVa by Collins et al. (1994). 16S rRNA gene sequence similarities are in the range 95.8–96.7% to the species *Clostridium citroniae* (96.7%), *Clostridium clostridiforme* (96.2%), *Clostridium asparagiforme* (95.9%), and *Clostridium bolteae* (95.8%). This species differs from the other species of the *Clostridium clostridiforme* group in that it is indole-positive. *Clostridium aldenense* and *Clostridium citroniae* can be differentiated by their profile numbers obtained by Rapid ID 32A and individual phenotypic tests such as raffinose, rhamnose, α-galactosidase, and β-galactosidase (Warren et al., 2006).

12. ***Clostridium aldrichii*** Yang, Chynoweth, Williams and Li 1990, 270^{VP}

al.dri'chi.i. N.L. gen. n. *aldrichii* of Aldrich, named for Henry C. Aldrich, a professor of the University of Florida, Gainesville, for his contributions to ultrastructural research on the strictly anaerobic bacteria.

Cells are rods, 3–5 × 0.5–1.0 μm. Slightly rounded ends, pleomorphic, and occasionally swollen at the ends. Cells are found singly, in pairs, or short chains. Strict anaerobe. Gram-stain-positive. Motile with a bundle of flagella at one end. Oblong spores occur subterminally after 2 weeks, measuring 1–2 × 0.5–1.0 μm. Colonies are round, smooth, semitransparent to grayish white, and 1–2 mm in diameter. Cellulolytic activity creates clear zones around colonies 4–6 mm in diameter and 2–3 mm in width. Growth occurs in the temperature range 20–45 °C with an optimum for growth 35 °C. Growth occurs in the pH range 6.2–7.8 with optimal growth at pH 7.0.

Trypticase, yeast extract, and trace vitamins aid growth. Does not require rumen fluid. Grows on cellulose, xylan, and cellobiose. Ferments cellobiose to acetic, propionic, isobutyric, butyric, isovaleric, lactic, and succinic acids,

hydrogen, and carbon dioxide. Hydrolyzes esculin. Fructose, glucose, glycogen, inositol, lactose, maltose, mannitol, mannose, starch, sucrose, and xylose are not utilized. Milk is not clotted, and gelatin is not liquified. Does not produce indole or hydrogen sulfide. Tests negative for nitrate reduction and lecithinase A.

Source: a 3-month-old poplar wood-fed continuously stirred anaerobic digester.

DNA G+C content (mol%): 40 (T_m).

Type strain: P-1, ATCC 49358, DSM 6159, OGI (now OCM) 122.

GenBank accession number (16S rRNA gene): X71846.

Further comments: *Clostridium aldrichii* is not a member of the genus *Clostridium sensu stricto* and falls in the cluster III as defined by Collins et al. (1994). The 16S rRNA gene sequence of the type strain DSM 6159 shows highest similarity to the species *Acetivibrio cellulolyticus* (ATCC 33288) (98.8%), *Clostridium straminisolvens* (95.9%), *Clostridium alkallicellulosi* (95.5%), and *Clostridium thermocellum* (94.3%). *Clostridium aldrichii* can be differentiated from its closest relatives by its lower temperature range for growth as well as its extensive range of end products of fermentation including propionic, isobutyric, butyric, isovaleric, and succinic acids.

13. ***Clostridium algidicarnis*** Lawson, Dainty, Kristiansen, Berg and Collins 1995, 197^{VP} (Effective publication: Lawson, Dainty, Kristiansen, Berg and Collins 1994, 156.)

al.gid.i.carn'is. L. adj. *algidus* cold; L. gen. n. *carnis* of meat; N.L. gen. n. *algidicarnis* of cold meat

Rod-shaped cells, 0.5–1.0 × 2.5 μm, occur singly, in pairs, or in chains of 3–4 cells. Anaerobe. Gram-stain-positive. Non-motile. Colonies are creamy gray in color, raised, convex, and 2–3 mm in diameter. Cells form ovoid terminal spores. Growth occurs in the temperature range 4–40 °C with an optimum at 37 °C.

Ferments fructose, glucose, mannose, ribose, and N-acetylglucosamine to produce acetic acid, butyric acid, propionic acid, and gas. Arabinose, cellobiose, glycerol, lactose, maltose, mannitol, melezitose, melibiose, raffinose, rhamnose, salicin, sorbitol, starch, sucrose, and trehalose are not utilized. Cells do not hydrolyze esculin. Sulfite is reduced, but nitrate is not. Cells test negative for urease and lecithinase activity. Cells contain arylamidase activity. Cells digest casein weakly, but not gelatin, milk, or cooked meat. Indole is not produced

Source: spoiled, vacuum-packed cooked pork.

DNA G+C content (mol%): not reported.

Type strain: DSM 15099, NCIMB 702931 (formerly NCFB 2931).

GenBank accession number (16S rRNA gene): AF127023, X77676.

Further comments: Comparison of the 16S rRNA gene sequence of *Clostridium algidicarnis* shows it to share high similarity with that of *Clostridium putrefaciens* at ~99.0% within cluster I of the clostridia as defined by Collins et al. (1994). At the time of the original description of *Clostridium algidicarnis*, the 16S rRNA gene sequence of *Clostridium putrefaciens* was either not available or not included in the analysis. The comparisons made at the time were between *Clostridium algidicarnis* and *Clostridium tryobutyricum* (Lawson et al., 1994). Further phenotypic and genetic comparisons should

be made between the type strains of the species *Clostridium algidicarnis* and *Clostridium putrefaciens*.

14. ***Clostridium algidixylanolyticum*** Broda, Saul, Bell and Musgrave 2000a, 629^{VP}

al.gi.di.xy.la.no.ly'ti.cum. L. adj. *algidus* cold; Gr. derived N.L. n. *xylanum* xylan; Gr. adj. *lyticus* dissolving; N.L. gen. n. *algidixylanolyticum* cold xylan-dissolving.

Tapered rods, 0.5–0.8 × 1.8–2.8 μm, occurring singly. Motile. Colonies measure 0.8–2.5 mm in diameter. On sheep-blood agar colonies are circular with a grayish white to translucent color. β-Hemolytic. Spores are produced in the late stationary phase of growth and do not cause swelling of the paternal cells. Growth occurs in the temperature range 2.5–32.2 °C with an optimum at 25.5–30 °C. Growth occurs in the pH range 4.7–9.1 with an optimum at 6.8–7.0. Saccharoclastic. Ferments arabinose, cellobiose, fructose, galactose, glucose, inulin, lactose, maltose, mannose, raffinose, rhamnose, salicin, sucrose, and xylose. Fermentation products from growth on PYGS broth include acetate, formate, lactate, ethanol, butyrate, butanol, hydrogen, and carbon dioxide. Starch can be hydrolyzed and xylan degraded.

Source: vacuum-packed, temperature abused raw lamb.

DNA G+C content (mol%): 38.4 (T_m).

Type strain: SPL73, ATCC BAA-156, DSM 12273.

GenBank accession number (16S rRNA gene): AF092549.

Further comments: 16S rRNA gene sequence comparisons place *Clostridium algidixylanolyticum* within cluster XIVa as defined by Collins et al. (1994). It groups with the species *Clostridium aerotolerans* (98.1%), *Clostridium xylanolyticum* (97.8%), *Clostridium saccharolyticum* (97.5%), *Clostridium amygdalinum* (97.4%), and *Clostridium celerecrescens* (97.1%). In the paper describing this species, comparisons were made both to psychrotolerant species as well as these phylogenetically related xylanolytic species (Broda et al., 2000a). Differences in phenotype and fatty acid patterns were used to delineate this species from related species.

15. ***Clostridium alkallicellulosi*** corrig. Zhilina, Kevbrin, Tourova, Lysenko, Kostrikina and Zavarzin 2006, 925^{VP} (Effective publication: Zhilina, Kevbrin, Tourova, Lysenko, Kostrikina and Zavarzin 2005, 564.)

al.kal.i.cell.ulosi. Arabic article *al* the; Arabic n. *qaliy* ashes of saltwort, soda; N.L. n. *cellulosum* cellulose; N.L. gen. n. *alkallicellulosi* of alkaline cellulose, intended to mean that the bacterium utilizes cellulose under alkaline conditions.

Cells are straight or slightly curved rods 0.5–0.7 × 1.1–2.5 μm. Gram-stain-positive, sporeforming and non-motile. Some strains are motile due to presence of flagella. Spores are 0.7–1.0 μm in diameter, spherical and terminal; resistant to drying and moderately heat-resistant. Growth occurs after heating for 30 min at 80 °C but not 100 °C. On medium containing microcrystalline cellulose colonies are 0.5–1.0 mm in diameter, circular, and flat with a yellowish center and a denser granular edge. On cellobiose, colonies are 1–2 mm in diameter, white, dense, and flat with smooth edges. Mesophile, growing at 18–42 °C with an optimum temperature for growth at 35–45 °C. Obligate extreme alkaliphile growing at pH 8.0–10.2 with optimum pH for growth of 9.0. Sodium ions are obligately required. Weakly

halophilic growing at 0.017–0.4M Na⁺ with an optimum at 0.15–0.3M Na⁺.

Strict anaerobe with fermentative metabolism. Catalase-negative. Dinitrogen fixer. Chemoorganoheterotroph. Cellulolytic, utilizing a narrow range of polymers and sugars. Cellulose, cellobiose, and xylan are used as carbon and energy sources. No other mono-, di-, or poly saccharides are utilized. Capable of decomposing plant and algal debris. Yeast extract or vitamins are required for anabolism. Organic acids, alcohols, and protein substrates are not utilized. End products from fermentation of cellobiose and or cellulose are lactate, ethanol, acetate, hydrogen, and traces of formate. Tolerant of up to 48mM Na₂S in culture medium. Grows in the presence of kanamycin and neomycin. Growth is suppressed by chloramphenicol, streptomycin, penicillin, ampicillin, ampiclox, bacillin, novobiocin, and bacitracin. Inhabits steppe soda lakes with a moderate salt content and usually with coastal vegetation.

Source: the anaerobic cellulose degrading community of Verkhnee Beloe Lake (Buryatiya, Russia).

DNA G+C content (mol%): 29.9–30.2 (*T_m*).

Type strain: Z-7026, DSM 17461, VKM 2349.

GenBank accession number (16S rRNA gene): AY959944.

Further comments: Strain Z-7026^T was originally described as *Clostridium alkalicellum* (*sic*) (Zhilina et al., 2005). The original spelling of the specific epithet, *alkalicellum* (*sic*), has been corrected on validation according to Rule 61. *Clostridium alkalicellulosi* falls within the cluster III of the clostridia as defined by Collins et al. (1994). 16S rRNA gene sequence comparisons show the closest phylogenetic relatives of *Clostridium alkalicellulosi* to be *Clostridium straminisolvens* (96.2%), *Acetivibrio cellulolyticus* (95.7%), *Clostridium thermocellum* (95.4%), and *Clostridium aldrichii* (95.45). *Clostridium alkalicellulosi* can be further differentiated from these related species on the basis of its temperature and pH ranges and optima for growth, production of trace amounts of formate and the relatively low G+C content of its DNA at 29.9 mol%. In contrast to *Clostridium straminisolvens* which can tolerate oxygen, *Clostridium alkalicellulosi* is a strict anaerobe (Kato et al., 2004).

16. ***Clostridium aminophilum*** Paster, Russell, Yang, Chow, Wose and Tanner 1993, 109^{VP}

a.mi.no'phi.lum. chem. term *amino* amino; G. adj. *philos* loving; N.L. neut. adj. *aminophilum* loving amino acids.

Irregular Gram-stain-positive rods, 1.0 × 1.5 μm. Non-motile with occasional central or subterminal spores. Cells survive heating to 80 °C for 10 mins. Obligate anaerobe. Growth occurs in the temperature range 25–45 °C and at pH 5.3. Asaccharolytic. Utilizes amino acids or peptides. Preferred carbon sources are glutamine, glutamate, serine, and histidine. Some strains deaminate pyroglutamate. Ferments Casamino acids to ammonia, acetate, butyrate, and traces of lactate and succinate. Hydrogen is not produced. Sodium required for growth. Indole is produced. Sulfate is reduced. Gelatin is not hydrolyzed. Casein is not digested. Tests negative for urease, lipase, lecithinase, and esculinase activity.

Source: fistulated cattle.

DNA G+C content (mol%): 52.5 (*T_m*).

Type strain: F, ATCC 49906, DSM 10710.

GenBank accession number (16S rRNA gene): L04165.

Further comments: Phylogenetic analysis of the 16S rRNA gene shows *Clostridium aminophilum* to fall within the radiation of cluster XIVa of the clostridia as defined by Collins et al. (1994). *Clostridium aminophilum* represents a distinct lineage within this cluster and is not closely related to other taxa. The closest relatives are the species *Clostridium symbiosum* (92.1%), *Clostridium celerecrescens* (92.0%), *Clostridium spenoides* (91.9%), and *Clostridium amygdalinum* (91.9%).

17. ***Clostridium aminovalericum**** Hardman and Stadtman 1960, 552^{AL}

a.mi'no.va.ler'i.cum. N.L. n. *acidum aminovalericum* aminovaleric acid; L. adj. suff. *-icus* related to; N.L. neut. adj. *aminovalericum* referring to ability to ferment aminovaleric acid strongly.

Cells in PYG broth cultures are straight rods, motile and peritrichous, 0.3–0.5 × 1.5–5.2 μm, occurring singly and in pairs. Cells stain Gram-positive but rapidly become Gram-stain-negative as cultures reach maximum stationary phase. Spores are small, spherical, and terminal, swelling the cell. Sporulation occurs most reliably on chopped-meat agar slants incubated at 30 °C for 5 d. Cell walls contain meso-DAP.

Surface colonies on blood agar plates are 0.5–1 mm, circular, entire, flat to convex, translucent to opaque, granular, gray, dull, smooth, and weakly hemolytic.

Cultures in PYG broth are turbid with a smooth sediment and have a pH of 5.9–6.2 after incubation for 1 week. Optimum temperature for growth is 37 °C; grows at 25 °C and 30 °C; poor growth at 45 °C. Growth is inhibited by 6.5% NaCl and by 20% bile. Hippurate is hydrolyzed by the type strain. Neutral red and resazurin are reduced. Abundant gas is produced in PYG agar deep cultures. Deoxyribonuclease is present.

Products in PYG broth at a pH of 6.1 include major amounts of acetic acid and abundant H₂. At a pH of 7.4–7.7, acetate, ammonia, propionate, and valerate are produced from aminovalerate as the sole energy source. Phenylacetic acid has been detected in the one strain tested. Culture supernatants of the type strain are nontoxic to mice. The type strain is sensitive to chloramphenicol, erythromycin, penicillin G, and tetracycline. Resistance to clindamycin is variable. Other characteristics of the species are given in Table 143.

Source: sewage sludge, rumen contents of bloating calves, urine specimens from pregnant women with bacteriuria, hamster feces, and human feces.

DNA G+C content (mol%): 33 (*T_m*).

Type strain: ATCC 13725, CIP 104304, DSM 1283, JCM 11016, NCIB 10631.

GenBank accession number (16S rRNA gene): X73436.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium aminovalericum* to fall within the radiation of the cluster XVIa of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarity values include *Clostridium jejuense* (95.2%), *Clostridium xylanolyticum* (93.5%), and *Clostridium populeti* (93.2%). *Clostridium aminovalericum* is distinguished by its ability to grow with aminovalerate as its sole source of energy.

18. ***Clostridium amygdalinum*** Parshina, Kleerebezem, Sanz, Lettinga, Nozhevnikova, Kostrikin, Lysenko and Stama 2003, 1797^{VP}

a.myg.da.li'num. L. neut. adj. *amygdalinum* made from almonds, referring to the smell of benzaldehyde, which is reduced by the type strain.

Oval or straight rod-shaped cells, $0.5\text{--}1.0 \times 0.5\text{--}10\ \mu\text{m}$, occurring singly, in pairs, or in chains. Gram-stain-positive. Cells are motile by means of one terminal flagellum, however, older cells lose their motility. Cell chains, as well as swelling cells, are formed in the late-stationary phase of growth. Round, free spores are formed only in nitrogen-free medium. Colonies on agar are circular, approximately 1 mm in diameter, cream with a yellowish elevated center with a slightly undulated margin. Anaerobic, but aerotolerant up to 50% air in gas phase. N_2 not fixed. Moderately thermophilic. Temperature range for growth is $20\text{--}60\ ^\circ\text{C}$ with an optimum at $45\ ^\circ\text{C}$. Growth occurs in the pH range $6.5\text{--}8.0$ with an optimum at pH $7.0\text{--}7.5$. Substrates utilized as carbon and energy sources include yeast extract, glucose, sucrose, fructose, ribose, arabinose, xylose, melibiose, maltose, cellobiose, crotonate, casitone, pyruvate, lactate, ethanol, inositol, glycerol, mannitol, xylan, betaine, starch, casein, cysteine, serine, and threonine. Galactose, rhamnose, lactose, mannose, gelatin, cellulose, methanol, and $\text{CO}_2\cdot\text{H}_2$ are not utilized. Obligate requirement for yeast extract (1–2 g/l). Major end products formed from yeast extract are H_2 , CO_2 , and acetate. Minor amounts of propionate, butyrate, and valerate are formed. End products from glucose fermentation are ethanol, acetate, H_2 , and CO_2 . Benzaldehyde, sulfite, and thiosulfite are used as electron acceptors. Sulfate, dithionite, disulfite, sulfur, and nitrate are not used as electron acceptors. Catalase-negative. Produces indole. Does not liquefy gelatin.

Source: anaerobic-digester sludge.

DNA G+C content (mol%): 32 (HPLC).

Type strain: BR-10, ATCC BAA-501, DSM 12857.

GenBank accession number (16S rRNA gene): AY353957.

Further comments: *Clostridium amygdalinum* falls within the radiation of cluster XIVa (Collins et al., 1994) and shows highest 16S rRNA gene sequence similarity to the *Clostridium* species *Clostridium saccharolyticum* (98.9%), *Clostridium indolis* (98.4%), *Clostridium celerecrescens* (98.0%), and *Clostridium aerotolerans* (97.9%). Strain BR-10^T differs from *Clostridium saccharolyticum* in its inability to utilize galactose, rhamnose, lactose, and mannose. *Clostridium amygdalinum* degrades starch while *Clostridium saccharolyticum* does not. The species to which strain BR-10^T is most closely related are mesophiles while *Clostridium amygdalinum* is a moderate thermophile. Strain BR-10^T is also capable of using sulfite and thiosulfate as electron acceptors.

19. ***Clostridium arcticum**** (ex Jordan and McNicol (1979) Cato, George and Finegold 1988, 220^{VP} (Effective publication: Cato, George and Finegold 1986, 1154.)

arc'ti.cum. L. neut. adj. *arcticum* related to the Arctic.

This description is based on the description by Jordan and McNicol (1979) and on the study of Jordan and McNicol strain III, one of the strains included in the original description.

Cells in PYG broth are straight or slightly curved motile rods, Gram-stain-negative, and $0.5\text{--}0.7 \times 3.2\text{--}4.6\ \mu\text{m}$. They

occur singly or in pairs. Spores are round, terminal, and swell the cell. Cell wall content has not been determined.

There is no growth on blood agar or egg-yolk agar plates. On trypticase soy agar, colonies are pinpoint, circular, convex, and creamy or yellowish. On Jensen's N_2 -free medium, colonies are yellow. In PYG deep agar cultures, colonies are white balls with slime that adheres to the sides of the tube.

Cultures grow slowly in PYG broth, which becomes turbid with little sediment; the pH after 7 d is 5.4. The optimum temperature for growth is $22\text{--}25\ ^\circ\text{C}$. Strains grow at $5\ ^\circ\text{C}$ and $37\ ^\circ\text{C}$ but more slowly and not as well. Growth is stimulated by fermentable carbohydrate. Resazurin is reduced. Atmospheric N_2 is fixed. Products in PYG broth culture are propionic and acetic acids. Only traces of H_2 are detected. Lactate in chopped-meat carbohydrate is converted to propionate. Culture supernatants are nontoxic for mice.

Other characteristics of the species are given in Table 144.

Source: arctic soil where the species represented 19% of the anaerobic N_2 -fixing strains isolated.

DNA G+C content (mol%): not reported.

Type strain: Jordan and McNicol no. III.

GenBank accession number (16S rRNA gene): not reported.

20. ***Clostridium argentinense*** Suen, Hatheway, Steigerwalt and Brenner 1988, 380^{VP}

ar.gen.tin.en'se. N.L. neut. adj. *argentinense* coming from Argentina.

Straight to slightly curved rods, $0.5\text{--}2.0 \times 1.6\text{--}9.4\ \mu\text{m}$. Anaerobic. Motile with peritrichous flagella. Gram-stain-positive. Form spores. Both small, smooth colonies and large, rough colonies form on blood agar. Cells are β -hemolytic on rabbit blood and weakly to not hemolytic on sheep blood. Optimal growth occurs at $35\text{--}37\ ^\circ\text{C}$ and at a pH of 7.0.

Does not ferment sugars. Produces acetic, isobutyric, butyric, isovaleric, and phenylacetic acids. Tests negative for catalase, urease, lipase, deoxyribonuclease, and indole production. Cells are proteolytic and gelatinolytic. Strains may or may not produce a neuroparalytic toxin that causes botulism in laboratory animals. Toxin is neutralized with type G botulinum antitoxin.

Source: soil, amniotic fluid, autopsy specimens, blood, and wounds in Argentina, Switzerland, and the USA.

DNA G+C content (mol%): $28\text{--}30$ (T_m).

Type strain: ATCC 27322.

GenBank accession number (16S rRNA gene): X68316.

Further comments: The 16S rRNA gene sequence of *Clostridium argentinense* strain ATCC 27322 shows highest similarity to *Clostridium schirmacherense* (99.4%). *Clostridium argentinense* differs from *Clostridium schirmacherense* in its more mesophilic temperature range for growth; *Clostridium schirmacherense* grows at $5\text{--}35\ ^\circ\text{C}$. In addition, the end products on PYG medium differ in that *Clostridium argentinense* does not produce formate or propionate. *Clostridium schirmacherense* does hydrolyze esculin but is not β -hemolytic. *Clostridium argentinense* also has greater than 99% 16S rRNA gene sequence similarity with type G *Clostridium botulinum* strain ATCC 27322 (M59087).

21. ***Clostridium asparagiforme*** Mohan, Namsolleck, Lawson, Osterhoff, Collins, Alpert and Blaut 2007, 1933^{VP} (Effective

publication: Mohan, Namsolleck, Lawson, Osterhoff, Collins, Alpert and Blaut 2006, 297.)

as.pa.ra.gi.for'me. L. masc. n. *asparagus* asparagus, L. neut. suffix *-forme* having the shape of, N.L. neut. adj. *asparagi-forme* having the shape of asparagus stems.

Rod-shaped cells with tapered ends, 0.6–0.8 × 2.3–5.0 μm. Gram-stain-positive. Sporesforming. On Columbia blood agar, nonhemolytic, slightly raised, white, and irregular colonies with a diameter of 2–2.5 mm are formed after 48 h at 37 °C.

Anaerobe. Hydrolyzes glucose, L-tryptophan, and the *p*-nitrophenyl derivatives of β-D-galactopyranoside, α-D-galactopyranoside, β-D-glucuronide, α-D-glucopyranoside, and α-L-fucopyranoside but not D-mannose, arabinose, xylose, and D-raffinose. The major end products of glucose fermentation are acetate, lactate, and ethanol with minor amounts of hydrogen and formate. Using the API ZYM system, activity was detected for esterase, acid phosphatase, esterase lipase, naphthol-AS-BI-phosphohydrolase, β-glucuronidase, and α-glucuronidase. The major cellular fatty acids are C_{18:1 DMA 9c} (15.23%), C_{16:0} (14.84%), C_{16:1 DMA 9c} (13.76%), C_{16:0 DMA} (8.14%), C_{17:1 8c} (6.92%). Other minor components include: C_{14:0} (5.84%), C_{15:1 7c} (5.77%), C_{18:1 9c} (5.77%), C_{18:1 DMA 9c} (5.42%), C_{16:0 aldehyde} (3.46%), C_{16:1 9c} (3.04%), C_{18:1 11c} (2.69%), C_{17:1 8c} (2.11%), C_{14:0 DMA} (1.29%), and C_{16:1 DMA 7c} (1.2%).

Source: human fecal sample.

DNA G+C content (mol%): 53.0 (HPLC).

Type strain: N6, CCUG 48471, DSM 15981.

GenBank accession number (16S rRNA gene): AJ582080.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium asparagi-forme* to fall within the radiation of cluster XIVa of the clostridia as defined by Collins et al. (1994). The closest relatives of *Clostridium asparagi-forme* based on 16S rRNA gene sequence similarity values are *Clostridium bolteae* (98.5%) and *Clostridium clostridiforme* (97.2%).

22. *Clostridium aurantibutyricum*^{*} Hellinger 1944, 46^{AL}

au.ran.ti.bu.ty'ri.cum. N.L. adj. *aurantium* orange; N.L. n. *acidum butyricum* butyric acid; N.L. neut. adj. *aurantibutyricum* probably intended to mean the orange-colored organism producing butyric acid.

Cells in PYG broth cultures are motile and peritrichous, straight rods 0.5–0.8 × 2.8 to 6.3 μm, occurring singly and in pairs, Gram-stain-positive, rapidly becoming Gram-stain-negative in older cultures; often granulose positive. Spores are oval and subterminal, swelling the cell. Sporulation occurs most readily on chopped-meat agar slants incubated at 30 °C for 1 week. Cell walls contain *meso*-DAP; cell-wall sugars are rhamnose and traces of glucose, galactose, and mannose.

Surface colonies on blood agar plates are 1–2 mm in diameter, circular to slightly irregular, entire, raised to low convex, translucent, gray to pink-orange, dull, smooth, with a mosaic internal structure. PYG broth cultures are turbid with a heavy, ropy, or viscous sediment and have a pH of 5.4 after incubation for 6 d. The optimum temperature for growth is 37 °C. Moderate growth occurs at 30 °C but not at 25 °C or 45 °C. Growth is inhibited by 6.5% NaCl and by 20% bile. Abundant gas is detected in PYG deep agar cultures.

Neutral red and resazurin are reduced. On egg-yolk agar, lipase is produced with a zone of opacity extending beyond the area of lipase production. There is stormy fermentation in milk; a solid curd is formed with 50% digestion in 3 weeks.

Products of fermentation in PYG broth are acetate and lactate with small amounts of butyrate, propionate, and succinate. Large amounts of butyrate are produced in chopped-meat carbohydrate broth. Large amounts of butanol as well as acetone and 2-propanol are formed. Pectic lyase enzymes and pectinesterase, but no pectic hydrolase, are formed.

The type strain is susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Culture supernatants of the type strain are nontoxic to mice.

Other characteristics of the species are given in Table 142.

Source: rotting hibiscus stumps, flax, rotting potatoes, soil, sewage sludge; bovine, human infant, and adult feces.

DNA G+C content (mol%): 27 (T_m).

Type strain: ATCC 17777, CIP 104305, DSM 793, NCIB 10659.

GenBank accession number (16S rRNA gene): X68183.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium aurantibutyricum* to fall within the radiation of the cluster I of the clostridia as defined by Collins et al. (1994). 16S rRNA gene sequence comparison of the type strain of these species shows it to have highest similarity to the species *Clostridium chartatabidum* (97.9%), *Clostridium paraputrificum* (97.0%), and *Clostridium beijerinckii* (96.5%).

23. *Clostridium baratii*^{*} corrig. (Prévot 1938) Holdeman and Moore 1970, 60^{AL} (*Inflabilis barati* Prévot 1938, 77; *Clostridium perenne* (Prévot 1940), McClung and McCoy 1957, 673; *Clostridium paraperfringens* Nakamura, Tamai and Nishida 1970, 137.)

ba.ra'ti.i. N.L. gen. n. *baratii* in honor of Barat, French bacteriologist.

Cells in PYG broth are Gram-stain-positive, often granulose positive, nonmotile, straight rods, 0.5–1.9 × 1.6–10.2 μm and usually occur singly, occasionally in pairs. Spores are round to oval, subterminal to terminal, and swell the cell. Strains sporulate poorly and spores may be found more readily in chopped-meat carbohydrate broth or PY broth cultures than in cultures on agar slants or plates. Cell walls contain *meso*-DAP. Surface colonies on blood agar plates are 0.5–2 mm in diameter, circular to irregular, entire to lobate, flat to low convex, granular to mosaic, translucent to opaque, with a smooth, shiny surface. Most strains are β-hemolytic, but some show α- or no hemolysis.

Cultures in PYG broth are turbid with a heavy, sometimes ropy sediment, and have a pH of 4.5–4.8 after incubation for 5 d. Growth is equally abundant at 30 °C, 37 °C, and 45 °C, but less at 25 °C. Growth is inhibited by 6.5% NaCl and by 20% bile.

Abundant gas is produced in PYG deep agar cultures. Ammonia is produced. Neutral red and resazurin are reduced. Acetyl methyl carbinol is formed by four of eight strains tested.

Products of fermentation in PYG broth are butyric, acetic, and lactic acids; smaller amounts of formic, propionic,

and succinic acids are sometimes produced. Butanol is not detected. Abundant H₂ is produced. Pyruvate is converted to acetate and butyrate; most strains convert threonine to propionate. Lactate is not utilized. All strains tested are sensitive to chloramphenicol, penicillin G, and tetracycline; nearly all strains are resistant to clindamycin and erythromycin. Culture supernatants are nontoxic to mice.

Other characteristics of the species are given in Table 142.

Source: normal human and rat feces; war wounds; peritoneal fluid, infections of the eye, ear, and prostate; soil; sediments in Puget Sound; soil from Antarctica.

DNA G+C content (mol%): 28 (*T_m*).

Type strain: ATCC 27638, CCUG 24033, CIP 104306, BCRC 14541, DSM 601, JCM 1385.

GenBank accession number (16S rRNA gene): X68174.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium baratii* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994) and to be most closely related to a number of species of the genus *Eubacterium*, namely *Eubacterium budayi* (99.5%), *Eubacterium nitritogenes* (99.0%), *Eubacterium moniliforme* (98.2%), and *Eubacterium multiforme* (97.7%). These *Eubacterium* species are unrelated to the type species of the genus *Eubacterium*, and further phenotypic characterizations and comparisons of these species and *Clostridium baratii* are required.

24. ***Clostridium bartlettii*** Song, Liu, McTeague, Summanen and Finegold 2004a, 1425^{VP} (Effective publication: Song, Liu, McTeague, Summanen and Finegold 2004b, 182.)

bart.let'ti. i. N.L. gen. n. *bartlettii* to honor John G. Bartlett, for his contributions to the role of intestinal flora in disease and to our knowledge of infectious diseases in general.

Rod-shaped cells, 1.0–1.5 × 5.0–50 μm, forming yellowish, circular, umbonate, entire, dull, opaque colonies on Brucella blood agar plates which have a small zone of β-hemolysis and attain a diameter of 2–3 mm after 48 hours. Gram-stain-positive. Occasional free spores. Obligately anaerobic. In PY broth and PYG broth, major amounts of acetic acid, isovaleric acid, and isobutyric acid are produced by all isolates. The major nonvolatile fatty acid produced is phenylacetic acid; occasionally, lactic acid or methylmalonic acid are also detected. Esculin, gelatin, and urea are not hydrolyzed. Indole is not produced and nitrate is not reduced. Lecithinase, lipase, and catalase are absent. Sensitive to kanamycin (1000 μg) and vancomycin (5 μg) and resistant to colistin (10 μg) special potency identification disks. Resistant to 20% bile in PYG broth. Acid is produced from fructose, glucose, maltose, mannitol, ribose, and sucrose when grown in PRAS carbohydrate broths. Acid is not produced from lactose, mannose, melibiose, melezitose, salicin, or xylose. With the API ZYM system, acid phosphatase, galactosidase, and β-glucuronidase are detected. In the BIOLOG system, the type strain utilizes D-cellobiose, dextrin, D-fructose, gentiobiose, α-D-glucose, glucose-6-phosphate, maltose, maltotriose, D-mannitol, D-mannose, 3-methyl-D-glucose, β-methyl-D-glucoside, palatinose, sucrose, D-trehalose, and turanose. The type strain also utilizes glyoxylic acid, α-keto-butyric acid, pyruvic acid, pyruvic acid methyl ester, alaninamide, L-alanine, L-alanyl-L-glutamine, L-alanyl-L-histidine, L-alanyl-L-threonine,

glycyl-L-methionine, L-methionine, L-phenylalanine, L-serine, and L-threonine for growth. The predominant cellular fatty acid produced is C_{18:1 9c}. Intermediate susceptibility to ampicillin (MIC ≤ 1 μg/ml); susceptible to bacitracin (MIC ≤ 2 μg/ml), cefoxitin (MIC ≤ 2 μg/ml), clindamycin (MIC 0.25 μg/ml), imipenem (MIC ≤ 4 μg/ml), metronidazole (MIC ≤ 1 μg/ml), and vancomycin (MIC 4 μg/ml). Resistant to trimethoprim/sulfamethoxazole 2/1 (MIC ≥ 64 μg/ml trimethoprim).

Source: human fecal material, habitat most likely the human gut.

DNA G+C content (mol%): 29.8 (*T_m*)

Type strain: WAL 16138, ATCC BAA-827, CCUG 48940.

GenBank accession number (16S rRNA gene): AY438672.

Further comments: 16S rRNA gene sequence shows *Clostridium bartlettii* to fall within the radiation of the cluster XI as defined by Collins et al. (1994). The closest relatives are the *Clostridium* species *Clostridium mayombeii* (96.9%), *Clostridium glycolicum* (96.7%), *Clostridium lituseburense* (96.5%), *Clostridium irregulare* (96.2%), and *Clostridium sordellii* (96.0%).

25. ***Clostridium beijerinckii**** Donker 1926, 145^{AL} emend. Keis, Shaheen and Jones 2001, 2100.

beijer.inck'i. i. N.L. gen. n. *beijerinckii* named for M.W. Beijerinck, Dutch bacteriologist.

Cells in PYG broth culture are straight rods with rounded ends, motile and peritrichous, 0.5–1.7 × 1.7–8.0 μm, occurring singly, in pairs, or in short chains. They are Gram-stain-positive, becoming Gram-stain-negative in older cultures. Spores are oval, eccentric to subterminal, and swell the cell, with no exosporium or appendages. Sporulation occurs readily on chopped-meat agar slants incubated at 30 °C. Cell walls contain *meso*-DAP; cell-wall sugars are glucose and galactose. Surface colonies on blood agar plates are 1–5 mm, circular to irregular, entire to scalloped, flat to raised, translucent, gray, shiny, and smooth. Strains may be either α, β, or nonhemolytic.

Cultures in PYG broth are turbid with a smooth to flocculent sediment and have a pH of 4.6–5.4 after incubation for 5 d.

Optimum temperature for growth is 37 °C. Cultures grow well at 30 °C but poorly if at all at 25 °C or 45 °C. Growth is stimulated by a fermentable carbohydrate, inhibited by 6.5% NaCl or 20% bile. Strains are nutritionally fastidious, requiring a complex mixture of growth factors such as are supplied by yeast extract. Abundant gas is detected in deep cultures in PYG agar. Ammonia is produced by 10 of 40 strains tested. Neutral red is reduced; most strains reduce resazurin. Atmospheric N₂ is fixed. Ammonium salts are utilized as the sole N₂ source to produce a wide variety of amino acids including alanine, valine, aspartic acid, and threonine. A neuraminidase is produced by strains of this species. Two of three strains tested produce an extracellular β-glucuronidase. The activity of a ferro-flavoprotein hydrogenase isolated from one strain has been investigated. The emendation of Keis et al. (2001) included the ability to ferment sucrose and the ability of the majority of the strains to utilize the alcohol sugars D- and L-arabitol, dulcitol, and inositol, but glycerol only weakly. All of the strains of *Clostridium beijerinckii* were also able to ferment methylglucopyranoside, turanose, dextrin, and pectin.

Products in PYG broth are butyric and acetic, moderate amounts of succinic, lactic, and formic acids; traces of propionic acid may also be detected. Although not a stable trait, most strains produce substantial amounts of *n*-butanol, and some produce moderate amounts of acetone or 2-propanol. Pyruvate is converted to butyrate and acetate; neither threonine nor lactate is utilized. All strains tested are sensitive to erythromycin and tetracycline. Of 21 strains, one is resistant to clindamycin, one to chloramphenicol, and one to penicillin G. Culture supernatants are nontoxic to mice.

Other characteristics of the species are given in Table 142.

Source: soil, infected wounds, fermenting olives, spoiled candy, human feces.

DNA G+C content (mol%): 26–28 (T_m).

Type strain: ATCC 25752, CIP 104308, DSM 791, JCM 1390, LMG 5716, NCTC 13035.

GenBank accession number (16S rRNA gene): X68179.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium beijerinckii* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarities include *Clostridium diolis* (99.9%), *Clostridium saccharoperbutylacetonicum* (99.1%), *Clostridium puniceum* (98.6%), *Clostridium saccharobutylicum* (98.6%), and *Clostridium butyricum* (97.7%). This species is most easily differentiated from *Clostridium butyricum* which it resembles most closely phenotypically by its requirement for growth factors present in yeast extract. Patterns of soluble cellular proteins of these two species, as determined by polyacrylamide gel electrophoresis, are distinct. Differential fermentation patterns are helpful but not absolute. *Clostridium butyricum* usually ferments ribose and glycerol but not inositol; *Clostridium beijerinckii* usually ferments inositol but not ribose or glycerol.

26. ***Clostridium bifermentans***^{*} (Weinberg and Séguin 1918) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 323^{AL} emend. Chamkha, Bharat, Garcia and Labat 2001c, 195 (*Bacillus bifermentans* Weinberg and Séguin 1918, 128.)
bi.fer.men'tans. L. pref. *bis* twice; L. part. adj. *fermentans* leavening; N.L. adj. *bifermentans* fermenting both carbohydrates and amino acids.

Cells in PYG broth are Gram-stain-positive straight rods, 0.6–1.9 × 1.6–11.0 μm, motile and peritrichous, occurring singly, in pairs, or in short chains. Spores are oval, central to subterminal, and usually do not swell the cell. Sporulation occurs readily both in PY broth and on chopped-meat agar slants. The composition of sporulation medium can affect the chemical content of spores, their germination rate, and their resistance to heat and to chemical agents. Spores have an exosporium. Six different types of spores have been identified depending on the presence, type, or absence of spore appendages. The significance or functional role of these appendages is unknown.

Cell walls of most strains contain *meso*-DAP; in 9 of 32 strains tested, DAP was not detected. Cell-wall sugars of most strains are glucose, rhamnose, and mannose; walls of some strains contain galactose rather than mannose; in some strains only glucose was detected.

Surface colonies on blood agar plates are 0.5–4mm, circular with irregular margins, flat or raised, lobate or scalloped,

translucent or opaque, granular or slightly mottled, gray, shiny, and smooth. Individual colonies can often be seen best on 4% agar plates. Most strains are β-hemolytic. Addition of beef liver catalase to plating media increases the percentage recovery of the species. Cultures in PYG broth are turbid with a heavy, often ropy, sediment. The optimum temperature for growth is 30–37 °C. Most strains grow nearly as well at 25 °C and 45 °C. Growth is inhibited by 6.5% NaCl and by 20% bile. Abundant gas is detected in deep PYG agar cultures. Ammonia is produced. Neutral red is reduced; reduction of resazurin is variable. Fermentation products from PYG broth include large amounts of acetic and formic acids, smaller amounts of isobutyric, isovaleric, isocaproic, hydrocinnamic, benzoic, and propionic acids, and ethyl alcohol. Trace amounts of butyric and phenylacetic acids and propyl and isobutyl alcohols are produced by some strains. In young cultures only acetic and formic acids may be detected. Abundant H₂ is produced. The glucose analog 1,2-*O*-isopropylidene-β-glucopyranose (“monoacetone glucose”) is utilized as a carbon source with different proportions of volatile fatty acids produced from those detected from glucose; a larger percentage of propionic, butyric, isovaleric, and valeric acids, and a smaller percentage of isobutyric acid. Valine is converted to isobutyrate, leucine to isovalerate and isocaproate, isoleucine to isovalerate, and threonine to propionate. Pyruvate is converted by most strains to acetate and formate; excess isobutyrate, isovalerate, and isocaproate may be produced. Lactate is not converted to propionate. Proline, serine, threonine, arginine, and aspartate are utilized; δ-aminovalerate and α-aminobutyrate are produced. DNase is produced by 10 strains tested.

All strains tested are susceptible to chloramphenicol, erythromycin, and penicillin G. One of 72 strains is resistant to clindamycin; one strain (a different one) is resistant to tetracycline. Three strains tested are sensitive to 8 μg of nalidixic acid/ml. Culture supernatants are nontoxic to mice.

Other characteristics of the species are given in Table 144.

Source: soil; fresh water; marine sediments; human feces; normal cervical flora; snake venom; a goat stomach ulcer; wounds in horses and sheep; clinical specimens including wounds, abscesses, and blood; clam gut; cheese fondue; canned tomatoes; vacuum packed smoked fish.

DNA G+C content (mol%): 27 (T_m).

Type strain: ATCC 638, CCUG 36626, BCRC 14542, CIP 104309, DSM 14991, JCM 1386, NCIMB 10716, NCTC 13019.

GenBank accession number (16S rRNA gene): AB075769, X75906.

Further comments: 16S rRNA gene sequence shows *Clostridium bifermentans* to fall within the radiation of the cluster XI as defined by Collins et al. (1994). The closest relatives are *Clostridium ghonii*, *Eubacterium tenue*, and *Clostridium sordellii*, all sharing 97.7% 16S rRNA gene sequence similarity.

27. ***Clostridium bolteae*** Song, Liu, Molitoris, Tomzynski, Lawson, Collins and Finegold 2003a, 935^{VP} (Effective publication: Song, Liu, Molitoris, Tomzynski, Lawson, Collins and Finegold 2003b, 88.)

bol.te.ae. N.L. gen. n. *bolteae* to honor the American Ellen Bolte, who first proposed a bacterial role in late-onset autism and stimulated work in this area.

Rod-shaped cells, $1.0\text{--}1.2 \times 2.0\text{--}5.0\ \mu\text{m}$, that form occasional subterminal spores. Gram-stain-positive. Obligately anaerobic. Colonies are 2–3 mm in diameter, gray, waxy, circular with slightly scalloped edges, slightly raised, smooth, dull, and opaque after anaerobic incubation for 48 hours at 37 °C when grown on Brucella blood agar.

Saccharolytic. Glucose metabolism produces acetate and lactate as end products. Acid is produced from arabinose, fructose, glucose, glycerol, maltose, mannose, melezitose, sorbitol, sucrose, trehalose, and xylose. Acid is not produced from erythritol, inulin, lactose, mannitol, melibiose, ribose, or salicin. Esculin, gelatin, and urea are not hydrolyzed. Lecithinase- and lipase-negative. Indole-negative. Nitrate is not reduced. Using the API ZYM system, acid phosphatase, alkaline phosphatase (weak reaction), α -galactosidase, β -galactosidase, and α -glucosidase are detected. The predominant cellular fatty acids produced are $C_{16:0}$, $C_{14:0}$, and $C_{16:1\ \text{DMA}\ 9c}$. Susceptible to kanamycin (1000 μg) and colistin sulfate (10 μg) identification disks; susceptible or had intermediate susceptibility to bacitracin (MIC $\leq 2\ \mu\text{g}/\text{ml}$), cefoxitin (MIC 32 $\mu\text{g}/\text{ml}$), clindamycin (MIC $\leq 4\ \mu\text{g}/\text{ml}$), imipenem (MIC $\leq 4\ \mu\text{g}/\text{ml}$), metronidazole (MIC 0.25 $\mu\text{g}/\text{ml}$), ramoplanin (MIC $\leq 16\ \mu\text{g}/\text{ml}$), trimethoprim/sulfamethoxazole 2/1 (MIC $< 16\ \mu\text{g}/\text{ml}$ trimethoprim), and vancomycin (MIC 2 $\mu\text{g}/\text{ml}$). Resistant to ampicillin (MIC $> 2\ \mu\text{g}/\text{ml}$) and usually resistant to piperacillin and ticarcillin and to the vancomycin (5 μg) identification disk.

Source: human gut, human fecal material, blood, and intra-abdominal abscess.

DNA G+C content (mol%): 50.5 (HPLC).

Type strain: WAL 16351, ATCC BAA-613, CCUG 46953.

GenBank accession number (16S rRNA gene): AJ508452.

Further comments: 16S rRNA gene sequence shows *Clostridium bolteae* to fall within the radiation of the cluster XIVa as defined by Collins et al. (1994). *Clostridium bolteae* is most closely related to the species *Clostridium asparagiforme* (98.5%), *Clostridium clostridioforme* (98.2%), and *Clostridium citroniae* (96.9%). *Clostridium bolteae* was differentiated from *Clostridium clostridioforme* on the basis of its lack of acid production from lactose and salicin, its acid production from melezitose and sorbitol, and its lack of esculin hydrolysis and β -glucuronidase production.

28. *Clostridium botulinum** (van Ermengem 1896) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 328^{AL} (*Bacillus botulinus* van Ermengem 1896, 443.)

bo.tu.li'num. L. n. *botulus* sausage; N.L. adj. *botulinum* pertaining to sausage.

The species includes seven toxin types, A, B, C, D, E, F, and G, differentiated by the antigenic specificity of their individual toxins. All strains of the species produce neurotoxins with similar effects on an affected host, but the toxins of the different types are serologically distinct. These distinctions do not necessarily correlate with observed phenotypic differences. The species was divided into three metabolic groups by Holdeman and Brooks (1970). Strains of *Clostridium botulinum* type G, described by Gimenez and Ciccarelli (1970), are metabolically distinct and were placed in a separate group by Smith and Hobbs (1974). These groups and other species that are phenotypically similar are: (a) strains

of type A, proteolytic strains of types B and F, and *Clostridium sporogenes*; (b) strains of type E and saccharolytic strains of types B and F; (c) strains of types C and D and *Clostridium novyi* type A; and (d) strains of type G and *Clostridium subterminale*. The validity of this grouping has been confirmed by the data of Johnson and Francis (1975) in that the metabolic types correlate well with rRNA homology groups I-F, I-A, I-H, and I-K, respectively. The toxins of all types are pathogenic to laboratory animals through the action of a neurotoxin. Some toxins, particularly those of the nonproteolytic strains, require trypsin activation for effectiveness in laboratory toxin testing. Human disease (botulism) with similar symptoms is caused by toxins elaborated under anaerobic conditions usually by colonization of food, less often by colonization of wounds, or colonization of the intestinal tract as in infant botulism (Wilcke et al., 1980).

This description is based on those by Smith and Hobbs (1974), Holdeman et al. (1977a), and on the study of the type and 15 other strains of *Clostridium botulinum* type A, 14 proteolytic strains of type B, 2 saccharolytic strains of type B, 24 strains of type C, 5 strains of type D, 9 strains of type E, 3 proteolytic strains of type F, 4 saccharolytic strains of type F, and 6 strains of type G.

(a) Type A and proteolytic strains of types B and F. Cells in PYG broth are usually motile and peritrichous, straight to slightly curved rods, $0.6\text{--}1.4 \times 3.0\text{--}20.2\ \mu\text{m}$. Spores are oval and subterminal and swell the cell. Sporulation occurs most readily on egg-yolk agar plates incubated for 2 d or on chopped-meat agar slants incubated at 30 °C for 1 week.

Cell walls contain *meso*-DAP and glucose. A cell-wall protein with a common antigenic specificity has been isolated from each of these types. Surface colonies on blood agar plates are 2–6 mm in diameter, circular to irregular with a scalloped or rhizoid margin, flat to raised, translucent to semiopaque, gray, often with a mottled or crystalline internal structure, and are β -hemolytic.

Cultures in PYG broth are turbid with a smooth or flocculent sediment and have a pH of 5.6–6.2 after incubation for 1 week. Ammonia produced from the deamination of amino acids often masks acid production from carbohydrates.

Optimum temperature for growth is 30–40 °C. Some strains grow well at 25 °C and a few at 45 °C. Growth is inhibited by 6.5% NaCl, 20% bile, and at a pH of 8.5. The bile acids lithocholic and chenodeoxycholic are the most inhibitory. Strains of *Clostridium perfringens* and *Clostridium sporogenes* isolated from soil also can inhibit growth.

Toxin production is delayed in an atmosphere of 100% CO₂ and pressurized CO₂ is lethal to strains, depending on the amount of pressure and the length of exposure.

Gelatin, milk, and meat are digested. Ammonia and H₂S are produced.

Strains of *Clostridium botulinum* type A and type B reduce proline to δ -aminovalerate. Arginine, glycine, phenylalanine, serine, tyrosine, and tryptophan are also utilized for growth; valine, α -aminobutyrate, and γ -aminobutyrate are produced. The aromatic amino acids, phenylalanine, tyrosine, and tryptophan are reduced to phenylpropionic, *p*-hydroxyphenylpropionic, and indolepropionic acids, respectively. *Clostridium botulinum* type A and proteolytic types B and F convert valine to isobutyrate, and

isoleucine and leucine to isovalerate; types A and B, but not type F, produce isocaproate from leucine.

Fermentation products in PYG broth include large amounts of butyric and acetic acids with moderate amounts of isobutyric and isovaleric acids. Isocaproic, propionic, and valeric acids, and ethanol, propanol, and butanol may also be detected. Hydrocinnamic acid is produced in trypticase soy broth cultures by all strains of types A and (presumably proteolytic) strains of types B and F tested; abundant H₂ gas is produced. Pyruvate is converted to acetate, butyrate, ethanol, and butanol; excess amounts of isovalerate from those produced in basal medium may also be detected. Most strains convert threonine to propionate; lactate is not utilized.

All strains are sensitive to chloramphenicol, penicillin G, and tetracycline. One strain of proteolytic type B is resistant to clindamycin and erythromycin; all other strains are sensitive to these antibiotics. Types A and B are resistant to cycloserine, sulfamethoxazole, and trimethoprim. Sensitive *in vitro* to tetracycline (0.5 µg/ml), metronidazole (1 mg/ml), penicillin (4 µg/ml), rifampin (2 µg/ml), and erythromycin (4 µg/ml); more than 90% are sensitive to chloramphenicol (4 µg/ml), clindamycin (4 µg/ml), cefoxitin (1 µg/ml), and vancomycin (8 µg/ml); they are resistant to nalidixic acid and gentamicin.

Culture supernatants are toxic to mice. Culture supernatants of type A are toxic to chickens, turkeys, pheasants, and peafowl. Although bacteriophages have been demonstrated in all types and two phages have been isolated from a strain of type A, there has been no report of the mediation of toxin production by phage in these strains.

Other characteristics are given in Table 142.

Source: soil, marine and lake sediments; animal, bird, and fish intestines; food (particularly improperly preserved vegetables, meat, and fish). (The types isolated reflect those present in the soil or sediment of the area. *Clostridium botulinum* toxin type F has been implicated in one case of infant botulism, but otherwise only types A and B have been reported. These two types also are most frequently isolated in outbreaks of food poisoning and cases of wound botulism.)

DNA G+C content (mol%): 26–28 (*T_m*).

Type strain: Type A, ATCC 25763, CIP 104310, NCIB 10640.

GenBank accession number (16S rRNA gene): L37585.

Reference strains: Proteolytic type B, ATCC 7949 (NCIB 10657); proteolytic type F, ATCC 25764 (NCIB 10658) (GenBank accession number L37593).

Further comments: *Clostridium botulinum* type A and proteolytic strains of types B and F have high DNA–DNA homology with *Clostridium sporogenes* and cannot be distinguished metabolically or biochemically. Strains of these types are identified by toxin neutralization tests in mice. Although cellular protein electrophoretic patterns of the proteolytic *Clostridium botulinum* strains cannot be used to identify the toxin type, they are distinct from patterns given by strains of nontoxic *Clostridium sporogenes* as are gas chromatographic patterns of trimethylsilyl derivatives of whole-cell hydrolysates of strains of the two species. 16S rRNA gene sequence comparisons show these strains to cluster with the type strain of *Clostridium sporogenes* with greater than 99.5% sequence similarity (Hutson et al., 1993; Figure 128).

(b) Type E and saccharolytic strains of types B and F. Cells in PYG broth cultures are motile and peritrichous, straight rods, 0.8–1.6 × 1.7–15.7 µm, occurring singly and in pairs. Spores are oval, eccentric to subterminal, and usually swell the cell. Sporulation occurs readily in broth and on solid media. Cell walls contain *meso*-DAP.

Surface colonies on blood agar plates are β-hemolytic, 1–5 mm in diameter, irregular with lobate or scalloped margins, raised, translucent to opaque, gray-white, with a mottled or mosaic internal structure.

Cultures in PYG broth are turbid with a smooth sediment, and have a pH of 5.2–5.5 after incubation for 1–2 d.

Optimum temperature for growth ranges from 25–37°C. Little or no growth occurs at 45°C. Growth is stimulated by a fermentable carbohydrate and is inhibited by 6.5% NaCl, 20% bile, or a pH of 8.5. Nonproteolytic strains of types B and F and toxic strains of type E are inhibited by soil strains of *Clostridium perfringens*, while type E strains that have lost toxicity are unaffected. A boticin isolated from a nontoxic strain of *Clostridium botulinum* type E inhibited both vegetative growth and spore germination of 10 out of 12 toxic and 3 out of 6 nontoxic strains of *Clostridium botulinum* E, as well as 2 out of 2 strains of nonproteolytic *Clostridium botulinum* type B. Plasmids that may be related to production of “boticin E” have been demonstrated in both toxic type E and nontoxic type E-like strains. Gelatin is digested but milk and meat are not.

Fermentation products in PYG broth cultures are butyric and acetic acids. Large amounts of H₂ are detected in headspace gas. Most strains convert pyruvate to acetate and butyrate. Neither lactate nor threonine is utilized.

All strains tested are susceptible to chloramphenicol, clindamycin, erythromycin, penicillin, and tetracycline. They also are susceptible to metronidazole, rifampin, cefoxitin, and vancomycin, but are resistant to nalidixic acid and gentamicin (Swenson et al., 1980).

Culture supernatants are toxic to mice. Supernatants of strains of type E are toxic to gallinaceous birds. Other characteristics are given in Table 142.

Source: soil, marine and lake sediments, food, fish, birds, mammals.

DNA G+C content (mol%): 27–29 (*T_m*).

Reference strains: Nonproteolytic type B, ATCC 25765 (NCIB 10642) (GenBank accession number 16S rRNA: X68173); nonproteolytic type F, ATCC 27321 (NCIB 10641); and type E, ATCC 9564 (NCIB 10660).

Further comments: 16S rRNA gene sequence comparisons show these strains to form a distinct cluster unrelated to the type strain of this species (Hutson et al., 1993) and clustering with *Clostridium uliginosum* (Figure 128).

(c) Type C and type D. Cells in PYG broth are straight rods, motile and peritrichous, 0.5–2.4 × 3.0–22.0 µm, and occur singly or in pairs. Spores are oval, subterminal, and swell the cell. Sporulation of most strains occurs most readily on chopped-meat agar slants incubated at 30°C for 1 week. Cell walls contain *meso*-DAP.

Surface colonies on blood agar plates are β-hemolytic, 1–5 mm in diameter, circular to slightly irregular, slightly scalloped or lobate, flat to raised, translucent, gray-white, with a mottled or mosaic internal structure.

Cultures in PYG broth are turbid with a smooth or flocculent sediment and have a pH of 5.2–5.7 after incubation for 1–2 d.

Optimum temperature for growth is 30–37 °C; most strains grow well at 45 °C and poorly, if at all, at 25 °C. Growth is stimulated by a fermentable carbohydrate but is inhibited by 6.5% NaCl, 20% bile, or a pH of 8.5. There was no inhibition of growth by strains of *Clostridium perfringens* isolated from soil samples from the USA, but several species of *Bacillus* isolated from samples of mud from England, France, and Spain were inhibitory to growth of a strain of *Clostridium botulinum* type C.

Gelatin is digested; milk is acidified, curdled, and digested by 20 of 29 strains tested; meat is digested by 20 of 28 strains tested. Production of ammonia and H₂S varies among strains.

Strains of type C utilize glutamic acid, serine, glycine, arginine, and aspartic acid; δ-aminovalerate is not produced.

Products in PYG broth are butyric, propionic, and acetic acids; traces of valeric, succinic, and lactic acids may be detected. Abundant H₂ is formed. Lactate is converted to propionate. Pyruvate is converted to acetate and butyrate; propionate is formed from pyruvate by some strains. Five of 24 strains convert threonine to propionate.

All strains tested are susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. They also are susceptible to metronidazole, rifampin, cephalothin, and cefoxitin, but resistant to nalidixic acid and gentamicin.

Culture supernatants are toxic to mice; culture supernatants of strains of type C are toxic to gallinaceous birds; strains are pathogenic for laboratory animals. The toxin of *Clostridium botulinum* type C is inactivated by bacteria in the rumen of cattle and sheep, but the specific organisms involved are not known. Toxin production by *Clostridium botulinum* type C and type D is phage-mediated, and the specific type of toxin produced is determined by the specific phage with which the culture is infected. *Clostridium botulinum* type C can be cured of type C phage and of its toxin, then converted to *Clostridium novyi* type A following infection by a *Clostridium novyi* type A phage.

Other characteristics of these types are given in Table 142.

Source: feces and carcasses of animals and birds, soil, lake mud, rotting vegetation.

DNA G+C content (mol%): is: 26–28 (*T_m*).

Reference strains: Type C, ATCC 25766 (NCIB 10618); Type D, ATCC 25767 (NCIB 10619).

Further comments: These species can be identified by toxin neutralization testing. They are most easily differentiated from *Clostridium novyi* type A, which they resemble phenotypically, by distinct patterns of cellular proteins produced by polyacrylamide gel electrophoresis. 16S rRNA gene sequence comparisons show these strains to cluster with the type strain of *Clostridium novyi* with greater than 99.0% sequence similarity (Hutson et al., 1993; Figure 128).

Type G. Cells in PYG broth cultures are straight rods, motile and peritrichous, 1.3–1.9 × 1.6–9.4 μm, and occur singly and in pairs. Spores, though rarely seen, are oval, subterminal, and swell the cell. We have not detected spores from any medium. Cell-wall composition has not been reported.

Surface colonies on blood agar plates are β-hemolytic, 1–4 mm in diameter, circular to irregular, lobate to filamentous, raised, translucent, smooth, and shiny. A spreading film may cover the entire plate. Large, rough, fried-egg colonies may be formed.

Cultures in PYG broth are turbid with a smooth white sediment and have a pH of 6.2–6.3 after 5 d incubation.

Optimum temperature for growth is 30–37 °C. Cultures grow almost as well at 25 °C and 45 °C. Growth is inhibited by 6.5% NaCl and by 20% bile. The reference strain is inhibited by three strains of *Clostridium perfringens* isolated from soil. Moderate gas is detected in PYG deep agar cultures.

Products in PY broth are acetic, butyric, isovaleric, isobutyric, and phenylacetic acids and butyl and ethyl alcohols. When products are converted to butyl esters, hydroxyphenylacetic acid is also detected. Abundant H₂ is formed. Pyruvate is converted to acetate and ethyl alcohol; lactate and threonine are not utilized. Valine is converted to isobutyric acid and leucine to isovaleric acid. Indoleacetic acid is produced and lysine is utilized.

Gelatin and casein are digested rapidly; milk and meat are digested within 3 weeks. Ammonia and H₂S are produced.

The type strain is susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. It also is susceptible to metronidazole, rifampin, cephalothin, and cefoxitin, but is resistant to vancomycin, nalidixic acid, and gentamicin.

Culture supernatants are toxic to mice. Monkeys, chickens, guinea pigs, and mice are susceptible to the toxin; sheep and dogs are resistant.

Other characteristics are given in Table 142.

Source: soil, human autopsy specimens.

DNA G+C content (mol%): not reported.

Reference strains: ATCC 27322, NCIB 10714.

GenBank accession number (16S rRNA gene): M59087.

Further comments: Unlike all other types of *Clostridium botulinum*, strains of type G do not produce lipase on egg-yolk agar. They have been distinguished from strains of *Clostridium subterminale*, which they resemble most closely phenotypically, by their toxicity for mice, but they can be differentiated readily by their distinct patterns of soluble cellular protein shown by polyacrylamide gel electrophoresis.

In any other group of organisms, this species would have been divided into four separate species because of the distinct differences in metabolic activity exhibited by strains in the four groups and the lack of DNA homology among groups. However, because of the unique and similar action of the toxins produced by all strains and to facilitate communication between the microbiological and medical professions, they have been retained in one species. 16S rRNA gene sequence comparisons show these strains to cluster with the type strain of *Clostridium argentinense* with greater than 99.0% sequence similarity (Hutson et al., 1993).

29. *Clostridium bowmanii* Spring, Merkhoffer, Weiss, Kroppenstedt, Hippe and Stackebrandt 2003, 1027^{VP}

bow.ma'ni.i. N.L. gen. n. *bowmanii* referring to Bowman, in honor of the microbiologist

John P. Bowman, who has made important contributions to our knowledge of the diversity of psychrophilic bacteria.

Rod-shaped, 1.0–1.2 × 2.0–8.0 μm, occurring singly, in pairs or short chains. Gram-stain-positive. Motile by peritrichous flagella. Endospores are spherical and located in a terminal to subterminal position; sporangium is not swollen. When grown on solid media, cultures frequently produce filamentous cells. Colonies on sheep-blood agar are 1–2 mm in diameter, round with often coarsely granulated margins, smooth, slightly raised, cream-white to grayish, semi-transparent to opaque and nonhemolytic.

The optimum temperature range for growth is 12–16 °C with an upper limit is 20 °C. The pH range for growth is 5.6–7.4 with optimal growth occurring at pH 6.8–7.2. Under optimal conditions, the doubling time is 8.4 hours.

The following carbohydrates are utilized: fructose, galactose, glucose, inulin, maltose, mannose, ribose (weak), salicin, sucrose, trehalose, and xylose. The following carbohydrates are not utilized: amygdalin, arabinose, cellobiose, glycogen, inositol, lactose, mannitol, melezitose, melibiose, raffinose, rhamnose, sorbitol, and starch. Gelatin and starch are not hydrolyzed. The fermentation products formed are butyrate, acetate, formate, ethanol, lactate, 1-butanol, hydrogen, and carbon dioxide. The cell-wall peptidoglycan contains *meso*-diaminopimelic acid. The major cellular fatty acids are C_{16:1 ω9}, C_{14:0}, C_{16:1 DMA ω9}, C_{16:0}, C_{16:1 ω11}, and C_{16:1 ω7}.

Source: a microbial mat sample taken from a moated area around Lake Fryxell, Antarctica.

DNA G+C content (mol%): 32.0 (HPLC).

Type strain: A-1/C-an/Cl, ATCC BAA-581, DSM 14206.

GenBank accession number (16S rRNA gene): AJ506119 (clone 11), AJ506120 (clone 16).

Further comments: 16S rRNA gene sequence analysis shows *Clostridium bowmanii* to fall within cluster I of the clostridia as defined by Collins et al. (1994). Two 16S rRNA gene sequence clones were obtained for strain DSM 14206^T which shared >99.0% sequence similarity (Spring et al., 2003). Sequence similarity values in the range 98.2–98.8% are found between *Clostridium bowmanii* and the species *Clostridium lacusfryxellense*, *Clostridium estertheticum* subsp. *laramiense*, and *Clostridium estertheticum* subsp. *estertheticum*. *Clostridium bowmanii* can be differentiated from these related species based on substrate utilization patterns as well as end products of fermentation. Of these species *Clostridium bowmanii* also has a higher temperature optimum for growth (Spring et al., 2003). DNA–DNA reassociation studies demonstrated the distinct species status of *Clostridium bowmanii* with a values of 28–47% to the related species (Spring et al., 2003).

30. ***Clostridium cadaveris**** (Klein 1899) McClung and McCoy 1957, 672^{AL}. (*Bacillus cadaveris* Klein 1899, 280.)

ca.da'ver.is. L. n. *cadaver* dead body; L. gen. n. *cadaveris* of a corpse.

Cells in PYG broth are Gram-stain-positive straight rods, usually motile and peritrichous, 0.5–1.3 × 1.4–9.4 μm, and occur singly or in pairs. Spores are oval, terminal, and swell the cell. Subterminal spores are seen occasionally. Sporulation of most strains occurs most readily on chopped-meat agar slants incubated at 30 °C for 1 week.

Cell walls of most strains contain *meso*-DAP; no DAP was detected in 5 of 12 strains. Surface colonies on blood agar plates are 0.5–3 mm, circular, entire to slightly scalloped, convex, translucent to opaque, smooth, and shiny. Hemolysis is variable.

Cultures in PYG broth are turbid with a smooth sediment and have a pH of 4.9–5.4 after incubation for 5 d.

The optimum temperature for growth is 30–37 °C. Most strains grow nearly as well at 25 °C and 45 °C. Growth is stimulated by fermentable carbohydrate and inhibited by 6.5% NaCl. Most strains are inhibited by 20% bile.

Ammonia and H₂S are produced. Neutral red is reduced; most strains reduce resazurin. Hippurate is hydrolyzed by 5 of 30 strains tested. Abundant gas is detected in PYG deep agar cultures. Deoxyribonuclease is formed.

Fermentation products in PYG broth include large amounts of butyric and acetic acids along with ethyl and butyl alcohols. Traces of other alcohols and small amounts of lactic, formic, propionic, and succinic acids may be detected. Abundant H₂ is formed. In chopped-meat broth or PY broth cultures containing at least 2% peptone, large amounts of acetate and butyrate and moderate amounts of isobutyrate and isovalerate are produced. Lipid fatty acids of the type strain detected in a trypticase-yeast extract-thioglycolate medium without glucose have been identified. Major fatty acids formed are normal saturated C₁₆, C₁₄, C₁₈, and C₁₂ acids with smaller amounts of unsaturated C₆ acids with a double bond at the 7 or 9 position. Pyruvate is converted to acetate and butyrate; neither lactate nor threonine is converted to propionate. There is some increase in the amount of isobutyrate produced in valine broth without glucose but no utilization of leucine or isoleucine.

All strains tested are susceptible to penicillin G; of 37 strains, 4 are resistant to erythromycin and clindamycin, 5 are moderately resistant to clindamycin alone, 3 are resistant to tetracycline, and 2 are resistant to chloramphenicol. Three clinical isolates tested are susceptible to cefoxitin (1 μg/ml), moxalactam (4 μg/ml), cefoperazone (4 μg/ml), clindamycin (2 μg/ml), and metronidazole (0.25 μg/ml).

Culture supernatants are nontoxic to mice. Phage-like particles that inhibited growth of a strain of *Clostridium septicum* have been demonstrated in one strain.

Other characteristics of the species are given in Table 142.

Source: soil, marine sediment, animal and human feces, snake venom, human clinical specimens from abscesses, wounds, and blood.

DNA G+C content (mol%): 27 (T_m).

Type strain: ATCC 25783, CCUG 24035, CIP 104314, CNCIB 10676, DSM 1284, JCM 1392.

GenBank accession number (16S rRNA gene): M59086.

Further comments: Fermentation of glucose, production of indole, and lack of lecithinase activity phenotypically differentiate *Clostridium cadaveris* from other clostridial species. The formation of isobutyrate and isovalerate from PY broth but not from PYG broth is most helpful in identification. 16S rRNA gene sequence comparisons show *Clostridium cadaveris* to represent a distinct species within cluster I of the clostridia as defined by Collins et al. (1994). The species to which it shows highest 16S rRNA gene sequence similarity are *Clostridium frididicarnis* (93.6%), *Clostridium diolis* (92.7%), *Clostridium beijerinckii* (92.7%), and *Clostridium subterminale* (92.6%).

31. ***Clostridium caminithermale*** Brisbarre, Fardeau, Cuffey, Cayol, Barbier, Cilia, Ravot, Thomas, Garcia and Ollivier 2003, 1046^{VP}

ca.mi.ni.ther.ma'le. L. n. *caminus* chimney; L. pl. n. *thermae* hot springs; N.L. neut.adj. *caminithermale* of a thermal chimney, describing the site of sampling.

Strictly anaerobic rods, 0.4–0.5 × 5–9 μm, and occurring singly or in pairs. Gram-stain-positive. The cell wall is

composed of three dense layers with two thick layers and a middle thinner layer separated by two less dense spaces. Motile by a few laterally inserted flagella.

Optimum temperature range for growth is 20–58 °C with an optimum at 45 °C. Grows in the presence of sea salt at 12–55 g/l and optimally at 30 g/l. The optimum pH for growth is 6.6, with growth occurring at pH 5.8–8.2.

Heterotrophic. Yeast extract is required for growth on sugars. Ferments yeast extract, peptone, Bio-trypticase, and Casamino acids into a mixture of volatile fatty acids. Fructose, galactose, glucose, glycerol, maltose, mannose, and ribose are fermented primarily into acetate, butyrate, propionate, and H₂ + CO₂. Succinate, fumarate, and pyruvate are also fermented. The following substrates are not used: arabinose, cellobiose, lactose, mannitol, melibiose, raffinose, rhamnose, starch, sucrose, xylose, dulcitol, sorbitol, lactate, formate, acetate, propionate, and H₂ + CO₂. The following amino acids are used as energy sources in the presence of yeast extract and peptone (0.5 g/l): arginine, cysteine, glycine, proline, and tyrosine (oxidized to acetate); glutamic acid (to propionate); histidine (to propionate and formate); isoleucine (to methyl 2-butyrate); leucine (to isovalerate); lysine (to acetate and butyrate); and methionine (to propionate and acetate). The following amino acids are not used: alanine, asparagine, aspartic acid, glutamine, phenylalanine, serine, threonine, tryptophan, and valine. Performs the Stickland reaction, using isoleucine as electron donor and methionine or betaine as electron acceptors. Does not use elemental sulfur, sulfate, thiosulfate, sulfite, nitrate, or nitrite as an electron acceptors. The following tests were negative: β-galactosidase, arginine dihydrolase, lysine and ornithine decarboxylases, Simmons' citrate, H₂S production, urease, tryptophan deaminase, indole, and acetoin production (Voges–Proskauer reaction). Adverse effects on animals and humans are not known. Because of the ability to degrade amino acids and peptides, the possibility of harmful effects cannot be excluded. Cautious handling and autoclaving of cultures before disposal is recommended.

Source: an Atlantic Ocean hydrothermal chimney.

DNA G+C content (mol%): 33.1 (HPLC).

Type strain: DVird3, CIP 107654, DSM 15212.

GenBank accession number (16S rRNA gene): AF458779.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium caminithermale* to fall within the cluster XI of the clostridia as defined by Collins et al. (1994). Strain DVird3^T forms a distinct lineage with the closest related *Clostridium* species being *Clostridium halophilum* at on 92.8% sequence similarity. *Clostridium caminithermale* is related at the 91.7% and 91.4% to the species *Caminicella sporogenes* and *Anerovirgula multivorans*, respectively. The addition of this strain to the genus *Clostridium*, although it was not a member of cluster I as defined by Collins et al. (1994), was on the basis of its relatedness to *Clostridium halophilum*. Strain DVird^T is differentiated from *Clostridium halophilum* on the basis of differences in substrate utilization patterns, temperature, and NaCl range for growth (Brisbarre et al., 2003).

32. ***Clostridium carboxidivorans*** Liou, Balkwill, Drake and Tanner 2005, 2089^{VP}

car.bo.xi.di.vo'rans. N.L. neut. n. *carboxidum* carbon monoxide; L. part. adj. *vorans* devouring; N.L. part. adj. *carboxidiv- orans* carbon monoxide-devouring.

Rod-shaped cells, 0.5 × 3.0 μm, occurring singly and in pairs and motile. Gram-stain-positive. Cells rarely sporulate, but spores are subterminal to terminal with slight cell swelling. Obligate anaerobe. Optimum growth temperature is 38 °C and an optimum pH for growth of 6.2.

Grows autotrophically with H₂/CO₂ or CO and chemoorganotrophically with ribose, xylose, fructose, glucose, galactose, L-arabinose, mannose, rhamnose, sucrose, cellobiose, trehalose, melezitose, pectin, starch, cellulose, inositol, mannitol, glycerol, ethanol, propanol, 2-propanol, butanol, citrate, serine, alanine, histidine, glutamate, aspartate, asparagine, Casamino acids, betaine, choline, and syringate. Methanol, D-arabinose, fucose, maltose, lactose, raffinose, melibiose, amygdalin, sorbitol, gluconate, lactate, malate, succinate, and arginine do not support growth. The end products of metabolism are acetic acid, ethanol, butyrate, and butanol. Methyl red positive, but negative for the Voges–Proskauer reaction, esculin hydrolysis, gelatin hydrolysis, nitrate reduction, indole production, catalase, oxidase, and urease.

Source: an agricultural settling lagoon in Oklahoma, USA.

DNA G+C content (mol%): 31–32 (HPLC).

Type strain: P7, ATCC BAA-624, DSM 15243.

GenBank accession number (16S rRNA gene): AY170379.

Further comments: 16S rRNA gene sequence comparison shows *Clostridium carboxidivorans* to be a member of cluster I of the clostridia as defined by Collins et al. (1994). Strain P-7^T forms a tight cluster with *Clostridium scatologenes* and *Clostridium drakei* and shows highest 16S rRNA gene sequence similarity with these species: *Clostridium scatologenes* (99.7%) and *Clostridium drakei* (99.8%). DNA–DNA reassociation studies demonstrate the species status of strain P-7^T with reassociation values of 31.8% and 50.2% with *Clostridium drakei* and *Clostridium Scatologenes*, respectively (Liou et al., 2005). *Clostridium carboxidivorans*, *Clostridium Drakei*, and *Clostridium scatologenes* can also be differentiated on the basis of substrate utilization patterns and the fact that *Clostridium scatologenes* grows slowly on H₂/CO₂ (Liou et al., 2005).

33. ***Clostridium carnis**** (Klein 1904) Spray 1939, 750^{AL} (*Bacillus carnis* Klein 1904, 459)

car nis. L. gen. n. *carnis* of flesh.

Cells in PYG broth cultures are Gram-stain-positive, motile and peritrichous, straight to slightly curved rods, 0.5–1.1 × 1.6–9.9 μm, and occur singly or in pairs. Spores are oval, terminal or subterminal, and swell the cell. Sporulation occurs most readily in chopped-meat broth cultures incubated for 24 h. Cell walls contain LL-DAP and glycine.

Surface colonies on anaerobic blood agar plates are pinpoint–2 mm, circular, entire, convex to slightly peaked, translucent, smooth, grayish white, with a mottled or mosaic internal structure. They may be slightly β-hemolytic. Colonies will grow on blood agar plates incubated aerobically, but spores are not formed under aerobic conditions. Cultures in PYG broth are turbid with a smooth sediment and have a pH of 4.9–5.4 after incubation for 1 week. The optimum temperature for growth is 37 °C. Growth is moderate at 30 °C but little or no growth occurs at 25 °C or 45 °C. Growth is stimulated by fermentable carbohydrate,

but inhibited by 6.5% NaCl, by 20% bile, or by a pH of 8.5. Abundant gas is formed in deep agar cultures. Neutral red and resazurin are reduced. DNase activity has been demonstrated.

Products in PYG broth are butyric, acetic, and lactic acids, with small amounts of formic and usually succinic acids. Abundant H₂ is produced. Pyruvate is converted to acetate; neither lactate nor threonine is utilized.

Strains are susceptible to chloramphenicol (5 µg/ml), erythromycin (2 µg/ml), penicillin (2 U/ml), and tetracycline (5 µg/ml). Culture supernatants are toxic to mice.

Other characteristics of the species are given in Table 142.

Source: soil, putrefying meat, soft tissue infections and blood in humans, human feces, clinical specimens in animals.

DNA G+C content (mol%): 28 (T_m).

Type strain: ATCC 25777, CIP 104315, DSM 1293, JCM 1393, NCIB 10670, NCTC 13036.

GenBank accession number (16S rRNA gene): M59091.

Further comments: 16S rRNA gene sequence comparison shows *Clostridium carnis* to be a member of cluster I of the clostridia as defined by Collins et al. (1994). It shows highest 16S rRNA gene sequence similarity with the species *Clostridium tertium* (98.7%), *Clostridium septicum* (98.3%), and *Clostridium chauvoei* (98.2%). This species is most easily differentiated from *Clostridium tertium*, which it resembles most closely phenotypically, by its lack of fermentation of mannitol or melibiose.

34. ***Clostridium celatum**** Hauschild and Holdeman 1974, 479^{AL}

ce.la'tum. L. neut. part. adj. *celatum* hidden.

This description is based on that by Hauschild and Holdeman (1974) and on study of the type and three other strains received from A.H.W. Hauschild.

Cells in PYG broth are Gram-stain-positive rods, straight or curved, nonmotile, 0.8–3.0 × 6.3 µm, occur singly, in pairs, or in long chains. Long filaments up to 200 µm are common. Spores are oval, terminal, subterminal, or central, and usually do not swell the cell. Sporulation occurs most readily on solid media (blood agar or egg-yolk agar plates or chopped-meat slants). Cell-wall composition has not been reported. Surface colonies on blood agar plates are 2–7 mm in diameter, circular, lobate to erose, flat to low convex, translucent to opaque, white, with a granular or mottled internal structure. Two of four strains tested were α-hemolytic, two were nonhemolytic on rabbit blood.

The optimum temperature for growth is 37 °C. Strains grow nearly as well at 30 °C and poorly, if at all, at 25 °C or 45 °C. Cultures in PYG broth are turbid with a smooth or fluffy sediment and have a pH of 5.2–5.5 after incubation for 1 d. Growth is stimulated by fermentable carbohydrate, but inhibited by 6.5% NaCl or 20% bile. Slight to moderate gas is detected in PYG deep agar cultures. Milk is acidified and slightly curdled. H₂S is produced from the reduction of bisulfite, but not from sulfate, in SIM medium. Nitrate is reduced in Bacto-nitrate broth media supplemented with 0.3% agar, glycerol, and galactose, but two of the four strains did not reduce nitrate in indole-nitrite medium (BBL). Urease is produced. Neutral red is reduced; resazurin is not reduced.

Fermentation products in PYG broth are acetic and formic acids and ethanol, with small amounts of butyric and pyruvic acids; succinic and fumaric acids are sometimes produced. Abundant H₂ is formed. Pyruvate is converted to acetate and formate; neither threonine, lactate, nor gluconate is utilized. Other characteristics of the species are given in Table 142. All strains tested are susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Culture supernatants are nontoxic to mice.

Source: human feces.

DNA G+C content (mol%): not reported.

Type strain: ATCC 27791, CIP 104316, DSM 1785, JCM 1394, NCTC 12746.

GenBank accession number (16S rRNA gene): X77844.

Further comments: 16S rRNA gene sequence comparison shows *Clostridium celatum* to be a member of cluster I of the clostridia as defined by Collins et al. (1994). It shows highest 16S rRNA gene sequence similarity with the species *Clostridium disporicum* (99.4%), *Clostridium quinii* (98.3%), and *Clostridium isatidis* (97.3%). Distinctive characteristics of this species are production of acetic and formic acids and ethanol from glucose, production of urease, and lack of production of lecithinase. *Clostridium celatum* differs from *Clostridium disporicum* in that it produces acetic and formic acids and ethanol while the latter only produces acetate and lactate.

35. ***Clostridium celerecrescens*** Palop, Valles, Piñaga and Flors 1989, 70^{VP} (emend. Chamkha, Garcia and Labat 2001a, 2110.)

cel.er.e.cres'cens. L. adj. *celer* -eris -ere fast; L. v. *creocere* to grow; N.L. part. adj. *celerecrescens* fast-growing.

Straight to slightly curved rods, 0.5–0.8 × 2–4 µm. Anaerobic. Gram-stain-positive. Motile with peritrichous flagella. Form spherical and terminal spores which cause cell swelling. Colonies appear after 10–14 d and are cellulolytic. Deep colonies are smooth, circular, translucent, unpigmented, and 0.5 mm in diameter. The optimal temperature for growth is 30–37 °C at a pH of 7.0.

Ferments cellulose, cellobiose, glucose, fructose, galactose, mannitol, maltose, adonitol, rhamnose, xylose, ribose, mannose, raffinose, trehalose, arabinose, and esculin. Lactose, melezitose, melibiose, sorbose, and sucrose are weakly fermented. Does not ferment dulcitol, erythritol, glycerol, inulin, sorbitol, or starch. The end products of fermentation of cellulose and cellobiose are ethanol, acetate, formate, butyrate, isobutyrate, isovalerate, caproate, lactate, succinate, H₂, and CO₂. Reduces cinnamic acids. Negative for urease, catalase, lipase, and lecithinase activity. Does not reduce nitrate or hydrolyze casein. Digests milk and forms curd. Gelatin is hydrolyzed. Produces indole. Does not produce acetylmethylcarbinol. Reduces *m*-methoxycinnamic acid to 3-(3-methoxyphenyl) propionic acid, *p*-methoxycinnamic acid to 3-(4-methoxyphenyl) propionic acid, and *p*-methylcinnamic acid to 3-(4-methylphenyl) propionic acid. Addition of glucose markedly increases the yield of conversions. Cinnamic, *o*-, *m*-, *p*-coumaric, *o*-methoxycinnamic, caffeic, ferulic, isoferulic, 3,4,5-trimethoxycinnamic acids, cinnamyl alcohol, and phenylpropionic acids (including 3-phenylpropionic acid and 3,4-dihydroxyphenylpropionic

acid) are not metabolized after 2 weeks incubation, with or without addition of glucose.

Source: a methanogenic cellulolytic culture inoculated from cow manure.

DNA G+C content (mol%): 38 (T_m).

Type strain: 18A, ATCC 49205, CECT 954, DSM 5628.

GenBank accession number (16S rRNA gene): X71848.

Further comments: 16S rRNA gene sequence comparisons places *Clostridium celerecresens* in cluster XIVa of the clostridia as defined by Collins et al. (1994). The highest similarities are to the species *Clostridium sphenoides* (99.1%), *Clostridium saccharolyticum* (98.5%), *Clostridium indolis* (98.4%), *Clostridium methoxybenzovorans* (98.1%), *Clostridium aerotolerans* (97.5%), and *Clostridium xylanolyticum* (97.5%).

36. ***Clostridium cellobioparum**** Hungate 1944, 503^{AL}

cel.lo.bi.o'par.um. N.L. n. *cellobiosum* cellobiose; L. verb. adj. suff. *-parus* producing; N.L. neut. adj. *cellobioparum* (*sic*) cellobiose-producing.

Cells in PYG broth culture stain Gram-negative and are straight or slightly curved rods, motile and peritrichous, 0.5–0.6 × 1.4–3.3 μm, and occur singly or in pairs. Spores are spherical or oval, terminal, and swell the cell. Sporulation occurs most readily on cellulose agar or in 3-week-old rumen fluid broth cultures. Cell walls contain *meso*-DAP. Surface colonies on blood agar plates are 0.5–1.5 mm in diameter, circular, entire, convex to pulvinate, semiopaque, creamy white to yellowish, shiny, and smooth. On rumen fluid cellobiose agar, they may have a scalloped margin, raised elevation, and translucent appearance.

Cultures in PYG broth supplemented with rumen fluid are turbid with a stringy sediment and have a pH of 5.3–5.5 after incubation for 5 d.

The optimum temperature for growth is 30–37 °C. There is little or no growth at 25 °C and none at 45 °C. Growth is stimulated by rumen fluid, a fermentable carbohydrate, and a gaseous atmosphere of 90% N₂ and 10% CO₂ (rather than 100% CO₂ or 100% N₂). H₂ gas produced by this organism will limit growth unless removed either mechanically or by H₂-utilizing organisms growing concurrently. Neither neutral red nor resazurin is reduced. Cellulose is hydrolyzed to cellobiose; glucose is not formed.

Fermentation products in PYG broth are acetic, lactic, and formic acids, ethanol, CO₂ and large amounts of H₂. Pyruvate is converted to acetate; neither lactate nor threonine is utilized.

The type strain is susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Culture supernatants are nontoxic to mice.

Other characteristics of the species are given in Table 143.

Source: the bovine rumen, human feces.

DNA G+C content (mol%): 28 (T_m).

Type strain: ATCC 15832, NCIB 10669, DSM 1351, LMG 5589.

GenBank accession number (16S rRNA gene): X71856.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium cellobioparum* to fall with the cluster III of the clostridia as defined by Collins et al. (1994). It forms a

cluster with the species *Clostridium termitidis*, *Clostridium josui*, *Clostridium hungatei*, *Clostridium papyrosolvens*, and *Clostridium cellulolyticum*. The highest 16S rRNA gene sequence similarity is with *Clostridium termitidis* at 99.1%. *Clostridium cellobioparum* can be differentiated from *Clostridium termitidis* on the basis of arabinose utilization by *Clostridium cellobioparum* but not by *Clostridium termitidis* as well as *Clostridium cellobioparum* having a negative Gram stain reaction compared to a positive reaction for *Clostridium termitidis*.

37. ***Clostridium cellulofermentans*** He, Ding and Long 1991, 308^{VP}

cell.u.lo.fer.men'tans. N.L. n. *cellulosum* cellulose; L. part. adj. *fermentans* fermenting; N.L. adj. *cellulofermentans* cellulose-fermenting.

Straight or slightly curved rods, 0.4–0.7 × 1.5–7.0 μm; found singly, pairs, or in short or long chains. Motile with peritrichous flagella. Anaerobic. Gram-stain-negative. Form terminal endospores, which cause swelling of the cell. Mature spores are 0.8–1.2 μm in diameter. On cellulose agar clear zones appear within 48–72 hours. Surface colonies are white, opaque, circular, and flat to slightly convex.

Negative for catalase and gelatinase activity. Does not produce acetylmethylcarbinol or indole. Reduces nitrate. Curdles milk. Does not reduce sulfate. Ferments cellulose to hydrogen, carbon dioxide, ethanol, and acetic acid. Slight growth occurs on PY media with no fermentable carbohydrates.

The temperature range for growth is 20–45 °C with an optimum of 37–40 °C. pH Range for growth is 6.0–8.2, with an optimum of 7.0–7.2.

Source: soil at a dairy farm.

DNA G+C content (mol%): 34 (T_m).

Type strain: AS 1.1775 (China Committee for Culture Collection of Microorganisms).

GenBank accession number (16S rRNA gene): not reported.

38. ***Clostridium cellulolyticum*** Petitdemange, Caillet, Giallo and Gaudin 1984, 157^{VP}

cell.u.lo'sum. N.L. n. *cellulosum* cellulose; Gr. adj. *lutikos* loosening, dissolving; N.L. adj. *lyticus* *-a* *-um* dissolving; N.L. neut. adj. *cellulolyticum* cellulose-dissolving.

Straight to slightly curved rods, 0.6–1.0 × 3–6 μm. Motile with peritrichous flagella. Anaerobic. Gram-stain-positive. Produce spherical, terminal spores, which cause cell swelling. Spores are 1.5 μm in diameter, and appear on cellulose media that is 3 d or more old. Surface colonies are smooth, circular, translucent, unpigmented, 0.5 mm in diameter, have a butyrous texture, and have undulate margins. Clear zones of cellulose around colonies are 1–4 mm in diameter. The temperature range for growth is 25–45 °C with an optimum at 32–35 °C. Growth occurs in the pH range 5.2–7.0.

Cellulose is fermented to carbon dioxide, hydrogen, acetate, ethanol, lactate, and formate. Utilizes arabinose, cellobiose, cellulose, fructose, glucose, and xylose. Does not grow with adonitol, amygdalin, dulcitol, erythritol, glycerol, glycogen, inositol, inulin, lactose, maltose, mannitol, melezitose, raffinose, rhamnose, salicin, sorbitol, sorbose, sucrose, and trehalose. Tests negative for catalase, urease, lipase, and lecithinase activity. Hydrolyzes esculin. Does not digest milk or casein. Does not hydrolyze starch or gelatin.

Does not produce nitrite, indole, or acetylmethylcarbinol. Does reduce thiosulfate. Lactate and pyruvate are not utilized.

Source: a decayed grass compost that had been packed for 3–4 months.

DNA G+C content (mol%): 41 (T_m).

Type strain: H10, ATCC 35319, DSM 5812.

GenBank accession number (16S rRNA gene): X71847.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium cellulolyticum* to fall within the radiation of cluster III of the clostridia as defined by Collins et al. (1994). It forms a cluster with the species *Clostridium papyrosolvens* (98.1%), *Clostridium josui* (98.1%), *Clostridium termitidis* (97.4%), and *Clostridium hungatei* (97.1%). *Clostridium cellulolyticum* can be differentiated from *Clostridium papyrosolvens* on the basis of mannose and glycerol utilization. In addition, *Clostridium cellulolyticum* shows a Gram-stain-positive straining reaction and *Clostridium papyrosolvens* a Gram-stain-negative staining reaction. There is also a considerable difference in the G+C content of the DNA of these two species; *Clostridium cellulolyticum* has a G+C content of 41 mol% while that of *Clostridium papyrosolvens* is 30 mol%.

39. ***Clostridium cellulosi*** He, Ding and Long 1991, 309^{VP}
cell.u.lo'si. L. gen. n. *cellulosi* of cellulose.

Straight to slightly curved rods, 0.3–0.6 × 2.0–15.0 μm, occur singly, in pairs, or in chains. Motile with lophotrichous flagella. Strict anaerobe. Gram-stain-negative staining reaction. Form terminal, spherical endospores which cause cell swelling. Colonies show clear zones on cellulose agar after 48 hours, and continue expansion afterwards. Tiny colonies appear within centers of the clear zone. Colonies appear white. Surface colonies are watery, irregular, and spread. Deep colonies are round with entire margins.

The temperature range for growth is 40–65 °C with an optimum of 55–60 °C. The pH range for growth is 6.2–8.5 with an optimum of 7.3–7.5.

Ruminal fluid, vitamins, or tryptic peptone not required for growth. Grows on 2g of yeast per liter. No germination in media with O₂ present. Tests negative for catalase and gelatinase activity. Does not produce indole. Curdles milk. Produces acetylmethylcarbinol. Ferments cellulose into hydrogen, carbon dioxide, ethanol, and acetic acid.

Source: cow manure compost.

DNA G+C content (mol%): 35 (T_m).

Type strain: AS 1.1777 (available from CCCC but an accession number is not provided).

GenBank accession number (16S rRNA gene): L09177.

Further comments: 16S rRNA gene sequence analysis shows *Clostridium cellulosi* to fall in the cluster IV of the clostridia as defined by Collins et al. (1994). The strain represents a distinct lineage that is not closely related to any species of the genus *Clostridium*. A 16S rRNA gene sequence similarity of <89% is found to *Clostridium Thermocellum*, a thermophilic, cellulolytic species at the root of the cluster III clostridia. The highest 16S rRNA gene sequence similarity is to the species *Ethanoligenens harbinense* at 93.9% similarity.

40. ***Clostridium cellulovorans*** Sleat, Mah and Robinson 1985, 223^{VP}
(Effective publication: Sleat, Mah and Robinson 1984, 92.)

cell.u'lo.vor.ans. L. n. *cellula* small cell; L. v. *vorare* to devour; N.L. adj. *cellulovorans* cell-devouring.

Rod-shaped cells, 0.7–0.9 × 2.5–3.5 μm. Anaerobic. Nonmotile. Gram-stain-negative. Forms central to subterminal spores within a sporangium that measures 1.5–2.0 × 4–7 μm. Spores are oblong and measure 1–1.5 × 2–4 μm. Colonies are irregularly shaped with an opaque edge and an empty center. Colonies in cellobiose roll tubes are rhizoid. The temperature range for growth is 20–40 °C with an optimum at 37 °C. The pH range for growth is 6.0–7.8 with an optimum of 7.0.

Ferments cellulose, xylan, pectin, cellobiose, glucose, fructose, galactose, sucrose, lactose, and mannose to H₂, CO₂, acetate, butyrate, formate, and lactate. Gum Arabic, rhamnose, melezitose, sorbitol, trehalose, xylose, arbutol, glycerol, erythritol, lactate, and pyruvate are not fermented. Gelatin is not liquefied. Starch and casein are not hydrolyzed. Yeast extract is required for growth. Vitamins and rumen fluid are not growth requirements.

Source: a batch of methanogenic fermentation of fire divided hybrid poplar wood.

DNA G+C content (mol%): 26–27 (T_m).

Type strain: 743B, ATCC 35296, DSM 3052.

GenBank accession number (16S rRNA gene): X71849, X73438.

Further comments: 16S rRNA gene sequence analysis shows *Clostridium cellulovorans* to fall in the cluster I of the clostridia as defined by Collins et al. (1994). It represents a distinct species not closely related to other cellulolytic species of the genus. The closest relatives within cluster I are the species *Clostridium paraputrificum*, *Clostridium disoricum*, *Clostridium sartagoforme*, and *Clostridium tertium*, with sequence similarities in the range 94.4–94.8%.

41. ***Clostridium chartatabidum*** Kelly, Asmundson and Hopcroft 1996, 625^{VP} (Effective publication: Kelly, Asmundson and Hopcroft 1987, 173.)

char'ta'tab'id'um; L. n. *charta* paper; L. adj. *tabidus* dissolving; N.L. adj. *chartatabidum* paper-dissolving.

Rod-shaped cells 1.0 × 3–6 μm. Obligate anaerobe. Motile with peritrichous flagella. Gram-stain-positive. Central to subterminal rod-shaped spores that measure 0.7 × 2–3.5 μm. Cells lack color. Colonies have orange centers with colorless umbonate to undulated edges.

The temperature range for growth is 28–45 °C with an optimum at 39 °C. Growth occurs in the pH range 5.9–7.0.

Ferments cellulose, cellobiose, sucrose, fructose, glucose, salicin, and xylose to hydrogen, acetate, butyrate, and ethanol. Rumen fluid is required for growth. Cells are cellulolytic. Utilizes glucose, sucrose, cellobiose, cellulose, lactose, fructose, and xylose. Does not utilize amygdalin, galactose, maltose, mannitol, melibiose, rhamnose, starch trehalose, and xylan.

Source: the rumen of sheep and cattle.

DNA G+C content (mol%): 31 (T_m).

Type strain: 163, CIP 104882, DSM 5482.

GenBank accession number (16S rRNA gene): X71850.

Further comments: 16S rRNA gene sequence analysis shows *Clostridium chartatabidum* to fall in the cluster I of the clostridia as defined by Collins et al. (1994). *Clostridium*

chartatabidum shares 16S rRNA gene sequence similarities in the range 96.3–96.6% to the species *Clostridium diolis*, *Clostridium beijerinckii*, *Clostridium vicentii*, *Clostridium saccharoperbutylacetonicum*, and *Clostridium puniceum*.

42. ***Clostridium chauvoei**** (Arloing, Cornevin and Thomas 1887) Scott 1928, 260^{AL} (*Bacterium chauvoei* Arloing, Cornevin and Thomas 1887, 82)

chau'voe.i. N.L. gen. n. *chauvoei* of Chauveau, named after J.A.B. Chauveau, French bacteriologist.

Cells in PYG broth cultures are Gram-stain-positive rods, usually motile and peritrichous. They may be quite pleomorphic with irregular staining, particularly in older cultures. Citron forms are seen often. Cells are 0.5–1.7 × 1.6–9.7 μm and occur singly or in pairs. Spores are oval, central to subterminal, and swell the cell. Sporulation occurs readily both in broth and on solid media. Cell walls contain lysine.

Surface colonies on blood agar plates are β-hemolytic, 0.5–3 mm in diameter, circular, low convex or raised, translucent to opaque, granular, shiny or dull, smooth, and have entire to erose margins.

Cultures in PYG broth are turbid with a smooth sediment and have a pH of 5.0–5.4 after incubation for 4 d.

The optimum temperature for growth is 37 °C. There is poor growth at 25 °C and 30 °C, no growth at 45 °C. Growth is stimulated by fermentable carbohydrate, inhibited by 6.5% NaCl, 20% bile, or a pH of 8.5. Abundant gas is formed in PYG deep agar cultures. Neutral red is reduced; reduction of resazurin is variable.

Products in PYG broth are acetic, butyric, and formic acids, butanol, CO₂, and H₂. Small amounts of lactic, succinic, and pyruvic acids may be detected. Pyruvate is converted to acetate and butyrate; neither lactate nor threonine is utilized.

All strains tested are susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Culture supernatants are nontoxic to mice. Strains produce deoxyribonuclease (β-toxin) and hyaluronidase (γ-toxin). Neuraminidase is also produced. Strains are pathogenic through tissue invasion for mice, guinea pigs, and hamsters. Experimentally, CaCl₂ must be injected to provide some tissue destruction before infection can occur. Cattle, sheep, goats, swine, deer, mink, freshwater fish, whales, and frogs are susceptible; humans, birds, cats, dogs, and rabbits are resistant, although the organism has been isolated from wounds in dogs and cats. No well-documented strain of *Clostridium chauvoei* has been isolated from humans. The organism is best known as the cause of blackleg in cattle and sheep. Habitat is probably the soil, and outbreaks of the disease often follow soil excavation in areas where animals graze.

Other characteristics of the species are given in Table 142

Source: infections in cattle, sheep, and other animals; intestinal contents of cattle and dogs.

DNA G+C content (mol%): 27 (*T_m*).

Type strain: ATCC 10092, CIP 104317, DSM 7528, NCIB 10665, NCTC 13023.

GenBank accession number (16S rRNA gene): U51843.

Further comments: 16S rRNA gene sequence analysis places *Clostridium chauvoei* in the cluster I of the clostridia as

defined by Collins et al. (1994). The type strain shares 99.2% 16S rRNA gene sequence similarity with *Clostridium septicum*. Other related species include *Clostridium carnis* (98.2%), and *Clostridium tertium* (98.0%). *Clostridium chauvoei* is most easily differentiated from *Clostridium septicum*, which it resembles most closely phenotypically, by its fermentation of sucrose and lack of fermentation of cellobiose or trehalose. Patterns of soluble cellular proteins are distinctive for each species (Cato et al., 1982) and specific fluorescent antibody is available commercially for identification.

43. ***Clostridium citroniae*** Warren, Tyrrell, Citron and Goldstein 2007, 893^{VP} (Effective publication: Warren, Tyrrell, Citron and Goldstein 2006, 2421.)

ci.tro'ni.i. N.L. gen. n. *citroniae* named after Diane M. Citron for numerous contributions to clinical anaerobic bacteriology as a clinical microbiologist and educator.

Rod-shaped cells, 0.8 to 1.1 × 2 to 5 μm. Gram-stain-negative staining reaction. Colonies are 1–2 mm in diameter, flat, opaque to white, and nonhemolytic on Brucella blood agar plates. Rarely a sporeformer. Optimal temperature for growth is 37 °C.

Produces acid from glucose, maltose, mannose, rhamnose, sucrose, trehalose, and xylose but not from cellobiose, esculin, lactose, mannitol, melezitose, raffinose, salicin, sorbitol, or starch. Does not hydrolyze urea, esculin, starch, or gelatin or reduce nitrate. Fermentations of arabinose are variable. Indole-positive. Alkaline phosphatase is positive, but arginine dihydrolase, α-galactosidase, β-galactosidase, β-galactosidase-6-phosphate, α-glucosidase, β-glucosidase, α-arabinosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, arginine arylamidase, praline arylamidase, leucyl glycine arylamidase, phenylalanine arylamidase, leucine arylamidase, pyroglutamic acid arylamidase, tyrosine arylamidase, alanine arylamidase, and glycine arylamidase are negative.

Source: human clinical infections.

DNA G+C content (mol%): not reported.

Type strain: RMA 16102, ATCC BAA-1317, CCUG 52203.

GenBank accession number (16S rRNA gene): DQ279737.

Further comments: *Clostridium citroniae* and *Clostridium aldenense* were described after the study of 158 strains previously identified as *Clostridium clostridioforme* strains (Warren et al., 2006). Comparison of the 16S rRNA gene sequence of *Clostridium citroniae* shows it to cluster with the species of the *Clostridium clostridioforme* group. This group was designated cluster XIVa by Collins et al. (1994). 16S rRNA gene sequence similarities are in the range 96.2–97.2% to the species *Clostridium clostridioforme* (97.2%), *Clostridium bolteae* (96.9%), *Clostridium aldenense* (96.7%), and *Clostridium asparagiforme* (96.2%).

Clostridium citroniae strains can be differentiated from the other species in this cluster by their profile numbers obtained by Rapid ID 32A and individual phenotypic tests such as raffinose utilization and indole production (Warren et al., 2006).

44. ***Clostridium clostridioforme**** corrig. (Burri and Ankersmit 1906) Kaneuchi, Watanabe, Terada, Benno and Mitsuoka 1976b, 202^{AL} (*Bacterium clostridioforme* Burri and Ankersmit 1906, 115)

clos.tri.di.o.for'me. Gr. n. *kloster* a spindle; Gr. dim. suff. *-idion*; N.L. neut. n. *clostridium* a small spindle; L. suff. *-formis* in the form of, N.L. neut. adj. *clostridioforme* in the form of a small spindle, spindle-shaped.

Cells in PYG broth culture are straight rods with pointed ends, $0.3\text{--}0.9 \times 1.4\text{--}9.0\ \mu\text{m}$. Gram-stain-negative. Cells usually occur in pairs but they also occur singly or in short chains. Spores are oval, central to subterminal, and swell the cell. They are often difficult to demonstrate, particularly in young cultures or from freshly isolated strains. Sporulation occurs most reliably on chopped-meat agar slants incubated at $30\text{ }^\circ\text{C}$ for 2–3 weeks or in 3-week-old chopped-meat broth cultures. All strains resist heating at $70\text{ }^\circ\text{C}$ for 10 min, but many do not survive heating at $80\text{ }^\circ\text{C}$. Motility is variable but sluggishly motile peritrichous cells or cells with a subpolar tuft of flagella can be detected in the majority of strains. Cell walls contain *meso*-DAP.

Surface colonies on blood agar plates are nonhemolytic, 0.5–2.0 mm in diameter, entire, slightly scalloped or erose, convex to slightly peaked, translucent to opaque, gray-white, usually with a mottled or mosaic internal structure.

Cultures in PYG broth are turbid with a heavy, sometimes viscous or ropy sediment and have a pH of 5.2–5.5 after incubation for 24 h.

Optimum temperature for growth is $37\text{ }^\circ\text{C}$; many strains grow equally well at $30\text{ }^\circ\text{C}$; growth is moderate at $25\text{ }^\circ\text{C}$, usually poor at $45\text{ }^\circ\text{C}$. Growth is inhibited by 6.5% NaCl or a pH of 8.5; strains vary in their reaction to 20% bile. Abundant gas is detected in PYG deep agar cultures. Ammonia is produced. H_2S is produced by 11 of 21 strains tested. Neutral red is reduced; reduction of resazurin is variable.

Low levels of superoxide dismutase have been reported from two clinical isolates. Deoxyribonuclease is formed by the one strain tested.

Fermentation products in PYG broth cultures are acetic acid, usually formic and lactic acids, and ethanol. Large amounts of H_2 are formed. Pyruvate is converted to acetate, usually with formate and ethanol. Some strains convert threonine to propionate; lactate is not utilized.

Susceptibility to antibiotics is variable. Of 42 strains tested, 28 are susceptible to chloramphenicol, 31 to clindamycin, 19 to erythromycin, 23 to penicillin G, and 27 to tetracycline. Clinical isolates most sensitive to metronidazole have been reported. An active β -lactamase has been demonstrated in one strain. Culture supernatants are nontoxic for mice.

Other characteristics of the species are given in Table 144.

Source: intestinal contents of birds, humans, and other animals; calf rumen contents; turkey liver lesions; abdominal, cervical, scrotal, pleural, and other infections; septicemias, peritonitis, and appendicitis.

DNA G+C content (mol%): 47–49 (T_m).

Type strain: ATCC 25537, BCRC 14545, CCUG 16791, CIP 104318, DSM 933, JCM 1291, NCIMB 11018, NCTC 11224, VIP 0316.

GenBank accession number (16S rRNA gene): M59089.

Further comments: Biochemical characteristics of strains in this species are quite variable, even those of a strain tested at different times. However, because of their morphologi-

cal similarity and the close agreement in high G+C ratios of DNA found in all strains tested, they have been retained in one species. When spores are not detected, they can be distinguished from other Gram-stain-negative anaerobes by their fermentation products. When spores are detected, the spindle-shaped cells are distinctive. 16S rRNA gene sequence comparisons have shown *Clostridium clostridioforme* to fall within the cluster XIVa of the clostridia as defined by Collins et al. (1994). The closest relatives are *Clostridium bolteae* (98.2%), *Clostridium asparagiforme* (97.3%), and *Clostridium citroniae* (97.2%). *Clostridium clostridioforme* can be differentiated from *Clostridium bolteae* on the basis of acid from lactose, melezitose, salicin, and sorbitol (Song et al., 2003b). In addition, differences are observed in β -glucouronidase production and esculin hydrolysis (Song et al., 2003b).

45. ***Clostridium coccoides**** Kaneuchi, Benno and Mitsuoka 1976a, 485^{AL}.

coc.coi'des. Gr. n. *coccus* a berry; Gr. n. *eidōs* shape; N.L. adj. *coccoides* berry-shaped.

Cells in PYG broth cultures are Gram-stain-positive, coccoid short rods, $0.6\text{--}1.0 \times 0.6\text{--}1.5\ \mu\text{m}$ and occur singly, in pairs, and in short chains. Nonmotile. Spores are round, central to subterminal, and slightly swell the cell. Sporulation occurs most readily on chopped-meat agar slants or on modified Eggerth–Gagnon agar plates after incubation at $37\text{ }^\circ\text{C}$ for 2–5 d. All strains survive heating at $70\text{ }^\circ\text{C}$ for 10 min but resistance is variable to $80\text{ }^\circ\text{C}$ for 10 min. Cell walls contain *meso*-DAP, lysine, and alanine.

Surface colonies on blood agar plates are punctiform–1 mm in diameter, circular, slightly irregular, slightly undulate, convex, gray-white, shiny, smooth, and nonhemolytic. On modified Eggerth–Gagnon agar plates, colonies are 1.5–2.5 mm in diameter, circular, convex, entire, translucent, yellowish gray, smooth, shiny, and nonhemolytic. Cultures in PYG broth are turbid with a smooth sediment and have a pH of 4.4 after incubation for 24 h. Growth is stimulated by fermentable carbohydrate.

The optimum temperature for growth is $37\text{ }^\circ\text{C}$. Strains grow well at $25\text{ }^\circ\text{C}$ and $45\text{ }^\circ\text{C}$ but poorly at $15\text{ }^\circ\text{C}$. Abundant gas is detected in PYG deep agar cultures. Resazurin is reduced. Acid is produced from inositol, dulcitol, β -methylglucoside, and α -methylmannoside. Orotic acid and tributyrin are not hydrolyzed. Small amounts of H_2S are produced.

Products in PYG broth culture after 5 d of incubation are acetic and succinic acids and abundant H_2 . Neither lactate nor threonine is utilized.

The type strain is susceptible to chloramphenicol, clindamycin, erythromycin, and tetracycline. It is resistant to penicillin G. Culture supernatants are nontoxic to mice.

Other characteristics of the species are given in Table 144.

Source: the cecum of mice fed high-lactose diets.

DNA G+C content (mol%): 43–45 (T_m).

Type strain: ATCC 29236, DSM 935, JCM 1395, NCTC 11035.

GenBank accession number (16S rRNA gene): not reported.

Further comments: This species is readily differentiated from other clostridial species by its morphology, by its pro-

duction of large amounts of succinic acid, by its fermentation of inositol and by its failure to produce indole. 16S rRNA gene sequence comparisons show *Clostridium coccooides* to fall within the radiation of cluster XIVa of the clostridia as defined by Collins et al. (1994). The highest similarity is to *Ruminococcus productus* at 99.1% and similarities in the range 93.4–95.2% to other *Ruminococcus* species.

46. ***Clostridium cochlearium**** (Douglas, Fleming and Colebrook 1919) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 333^{AL} (*Bacillus cochlearius* Douglas, Fleming and Colebrook in Bulloch et al., 1919, 40; *Clostridium lentopotrescens* Hartsell and Rettger 1934)

coch.le.a'ri.um. L. n. *cochlear* spoon; N.L. neut. adj. *cochlearium* resembling a spoon.

Cells in PYG broth are motile and peritrichous, straight to slightly curved rods with rounded ends, 0.5–1.3 × 1.6–14.1 μm, and occur singly or in pairs. Spores are round to oval, swelling the cell, usually terminal although subterminal spores are seen occasionally. Sporulation occurs readily both in broth media or on solid media (blood agar plates or chopped-meat slants). Three distinct spore coats and tubular appendages attached to one end of the spore have been demonstrated. Cell walls contain *meso*-DAP.

Surface colonies on blood agar plates are 0.5–2.0 mm, circular to irregular, slightly scalloped to lobate, flat to raised, translucent, gray-white, smooth, shiny, with a mottled or mosaic internal structure. Hemolysis is variable.

Cultures in PYG broth are turbid with a smooth sediment, and have a pH of 6.0–6.5 after 1 week of incubation.

Optimum temperature for growth is 37 °C. Most strains grow well at 30 °C and 45 °C but poorly if at all at 25 °C. Growth is inhibited by 6.5% NaCl, by 20% bile, or at a pH of 8.5.

Gelatin may be weakly and slowly digested; neither meat, casein, nor milk is digested. H₂S and ammonia are formed. Hippurate is hydrolyzed by three of eight strains tested. Neutral red is reduced.

One strain isolated from human subgingival plaque degrades fibrinogen, possibly contributing to periodontal disease.

Products in PYG broth are butyrate, acetate, and propionate; small amounts of lactate, formate, succinate, and butanol are sometimes formed; abundant H₂ is produced. Pyruvate is converted to acetate and butyrate; threonine is converted to propionate; lactate is not utilized. Glutamate is fermented to butyrate, acetate, CO₂, and ammonia by the methylaspartate pathway. Serine, aspartate, and histidine are utilized for growth. Phenylalanine is fermented to phenol. Major cellular fatty acids produced in trypticase-yeast extract medium are principally of the straight-chain saturated series including C₁₂, C₁₄, C₁₅, C₁₆, and C₁₈ acids; small amounts of straight-chain unsaturated acids, C₁₅ and C₁₈, each with one double bond, are also formed.

All strains tested are susceptible to clindamycin, erythromycin, penicillin G, and tetracycline. One of six strains is resistant to chloramphenicol. Culture supernatants are nontoxic to mice.

Other characteristics of the species are given in Table 142.

Source: soil, human oral cavity, human and horse feces, wounds, crabmeat.

DNA G+C content (mol%): 27–28 (T_m).

Type strain: ATCC 17787, CCUG 31665, BCRC 14471, CIP 104319, DSM 1285, NCCB 73036, NCIB 10633, NCTC 13027.

GenBank accession number (16S rRNA gene): M59093.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium cochlearium* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The highest 16S rRNA gene sequence similarity is to *Clostridium tetani* (98.1%). This species can be differentiated from *Clostridium tetani*, which it resembles most closely phenotypically, by its lack of toxicity for mice, by its weak to negative digestion of gelatin, and by distinct patterns of soluble cellular proteins of the two species.

47. ***Clostridium cocleatum**** Kaneuchi, Miyazato, Shinjo and Mitsuoka 1979, 10^{AL}

co.cle.a'tum. L. n. *coclea* a snail shell or whirlpool; L. neut. adj. *cocleatum* in the shape of a snail shell or whirlpool.

Cells in PYG broth cultures are Gram-stain-positive rods, nonmotile, 0.3–0.4 × 1.0–5 μm, semicircular, circular or spiral-shaped. They may grow in long chains, and be Gram-stain-negative with filaments or swollen forms. Spores are difficult to demonstrate but can be found most reliably on medium 10 agar or on chopped-meat agar slants incubated at 30 °C. Spores are round, terminal to subterminal, and swell the cell. Cell walls contain *meso*-DAP.

Surface colonies on blood agar plates are pinpoint–2 mm in diameter, circular, entire to erose, low convex to pulvinate, semiopaque to opaque, smooth, shiny, grayish white, and nonhemolytic.

Cultures in PYG broth are turbid with a smooth to mucoid sediment and have a pH of 4.9–5.4 after incubation for 4 d.

The optimum temperature for growth is 37–45 °C. Strains grow nearly as well at 30 °C, poorly at 25 °C and not at all at 15 °C. Growth is stimulated by fermentable carbohydrate and by rumen fluid, but inhibited by 6.5% NaCl or 20% bile. Abundant gas is detected in PYG deep agar cultures. Neutral red and resazurin are reduced. Dextrin, dulcitol, α-methylglucoside, and α-methylmannoside are not fermented.

Products in PYG broth are acetic and formic acids; lactic acid usually is produced. Abundant H₂ is formed. Pyruvate is converted to acetate and formate; neither threonine nor lactate is utilized.

All strains tested are susceptible to chloramphenicol, erythromycin, penicillin G, and tetracycline but resistant to clindamycin. Toxicity and pathogenicity have not been determined.

Other characteristics of the species are given in Table 144.

Source: feces of healthy humans; cecal contents of mice, rats, and chickens.

DNA G+C content (mol%): 28–29 (T_m).

Type strain: I50, ATCC 29902, DSM 1551, JCM 1397, NCTC 11210.

GenBank accession number (16S rRNA gene): Y18188.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium cocleatum* to fall within the radiation of cluster

XVIII. Sequence similarities in the range 96.6–96.9% are found to the species *Clostridium ramosum*, *Clostridium saccharogumia*, and *Clostridium spiroforme*. This species is closely related to *Clostridium spiroforme*, having 46–60% homology with strains of that species and being similar in morphology. *Clostridium cocleatum* ferments galactose, while *Clostridium spiroforme* does not. The patterns of soluble cellular protein as determined by polyacrylamide gel electrophoresis are also helpful in differentiating the two species.

48. ***Clostridium colicanis*** Greetham, Gibson, Giffard, Hippe, Merkhoffer, Steiner, Falsen and Collins 2003, 261^{VP}

co.li.can'is. L. n. *colum* colon, gut; L. gen. n. *canis* of the dog; N.L. gen. n. *colicanis* of the gut of a dog.

Rod-shaped cells, 0.9–1.0 × 3–10 μm. Gram-stain-negative. Oval to oblong shaped spores in PY-starch medium; position varies from subterminal to almost terminal or even central. Nonmotile. Colonies are 3–5 mm in diameter, round, with undulate margin and are slightly convex, opaque, glossy, and grayish-white. Nonhemolytic on Columbia sheep blood agar. Anaerobic.

Growth occurs in the range 30–45 °C, with no growth at 20 or 50 °C and optimum growth at 37–40 °C.

Produces acid from glucose (acidification of PY medium containing 1% glucose, pH 6.8; after 6 d the pH was 4.8). Acid is produced from cellobiose, esculin (weak), fructose, galactose, glucose, lactose, maltose, mannose, ribose, salicin (weak), starch (weak), and sucrose. Acid is not produced from amygdalin, L-arabinose, glycogen, inositol, mannitol, melezitose, melibiose, raffinose, rhamnose, sorbitol, trehalose, or xylose. Esculin and urea, but not gelatin, are hydrolyzed. Lecithinase- and lipase-negative. Indole is not produced. Nitrate is reduced to nitrite. Catalase-negative. Using API Rapid 32AN test system, activity is detected for alkaline phosphatase, arginine arylamidase, arginine dihydrolase, β-galactosidase, glycine arylamidase, histidine arylamidase, leucine arylamidase, leucyl glycine arylamidase, and N-acetyl-β-glucosaminidase. No activity is detected for alanine arylamidase, α-arabinosidase, α-fucosidase, α-glucosidase, β-glucosidase, β-glucuronidase, α-galactosidase, β-galactosidase-6-phosphate, glutamic acid decarboxylase, glutamyl glutamic acid arylamidase, phenylalanine arylamidase, proline arylamidase, pyroglutamic acid arylamidase, serine arylamidase, or tyrosine arylamidase.

Source: feces of a male Labrador dog.

DNA G+C content (mol%): 31.7 (HPLC).

Type strain: 3WC2, CCUG 44556, DSM 13634.

GenBank accession number(16S rRNA gene): AJ420008.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium colicanis* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives based on 16S rRNA gene sequence similarities are the *Eubacterium* species *Eubacterium moniliiforme* (96.2%), *Eubacterium multiforme* (95.9%), *Eubacterium budayi* (95.8%), *Eubacterium nitrogenes* (95.5%) as well as *Clostridium baratii* (95.9%) and *Clostridium diolis* (95.5%). The ~3–4% 16S rRNA gene sequence divergence along with some differences at the phenotypic level were used as justification for the description of the species *Clostridium colicanis* (Greetham et al., 2003).

49. ***Clostridium colinum**** (ex Berkhoff, Campbell, Naylor and Smith 1974) Berkhoff 1985, 157^{VP} (*Clostridium colinum* Berkhoff, Campbell, Naylor and Smith 1974, 203)

co.li'num. N.L. n. *Colinus* a zoological name; N.L. neut. adj. *colinum* referring to the most susceptible host, the quail (*Colinus virginianus*).

Cells in PYG broth culture are Gram-stain-positive rods that may rapidly become Gram-stain-negative. They are motile, peritrichous, 1 × 3–4 μm, and occur singly or in pairs. Spores are oval and subterminal. They are sparse in most media, but when transferred from chopped-meat glucose medium into PY-1% starch medium will survive heating at 70 °C for 10 min.

Cell-wall composition has not been reported.

Surface colonies on blood agar plates are pinpoint–0.5 mm, circular to slightly irregular, low convex, transparent, grayish white to colorless, shiny, and smooth. Most strains are α-hemolytic.

Cultures in PYG broth have a smooth white sediment without turbidity and a pH of 5.4 after incubation in an atmosphere of 100% CO₂ for 6 d. In brain heart infusion broth with glucose and an atmosphere of 100% N₂, the final pH is 5.2–5.5.

The optimum temperature for growth is 37 °C. Some strains grow equally well at 45 °C. There is little growth at 30 °C and none at 25 °C. Growth is stimulated by fermentable carbohydrate. Tryptose-phosphate-glucose agar with 8% horse plasma has been recommended for isolation. Although isolation may be difficult on other media (e.g., supplemented brain heart infusion agar or rumen fluid-glucose-cellobiose agar), stock cultures usually will grow on these media. Moderate gas is detected in PYG deep agar cultures.

Products in PYG broth are formic, acetic, and small amounts of lactic acids. Propionic acid usually is detected. Abundant H₂ is produced. Neither pyruvate, lactate, nor threonine is utilized.

All strains tested are susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline.

Strains are pathogenic to quail and chickens, causing ulcerative enteritis or liver necrosis and death in less than 18 h. Guinea pigs are not susceptible.

Other characteristics of the species are given in Table 144.

Source: intestinal tracts of quail, pheasants, grouse, partridge, chickens, and turkeys.

DNA G+C content (mol%): not reported.

Type strain: 72042, ATCC 27770, CCUG 21927, DSM 6011 and JCM 5831.

GenBank accession number (16S rRNA gene): X76748.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium colinum* to fall within the radiation of cluster XIVb of the clostridia as defined by Collins et al. (1994). The highest sequence similarity is found to *Clostridium piliiforme* at 95.2%. The next closest relative is *Clostridium lactatifermentans* with a similarity value of 89.9%.

50. ***Clostridium collagenovorans*** Jain and Zeikus 1988a, 328^{VP} (Effective publication: Jain and Zeikus 1988b, 140.)

col.ageno.vor'ans. Fr. n. *collagène* from Gr. n. *kolla* glue; L. v. *vorare* to devour; N.L. adj. *collagenovorans* collagen-devouring.

Rod-shaped cells, $0.8 \times 3.0 \mu\text{m}$. Obligate proteolytic anaerobe. Motile. Gram-stain-positive. Cells have a monolayer cell wall. Cells form subterminal spores. Colonies are white, circular, irregular in shape, and 1–3 mm in diameter.

The optimum temperature for growth is 30–37 °C with an optimum pH for growth of 6.0–8.0. Utilizes gelatin, collagen, azocoll, peptone, and meat. Slow growth on casein and bovine serum albumin. Does not grow on carbohydrates, and single or mixtures of amino acids. Cells are non-hemolytic. Ferments gelatin to acetate, CO_2 , H_2 , ethanol, isovalerate, and isobutyrate. No vitamins or growth factors are required for growth. Hydrogen is produced and consumed during growth. Cells produce collagenase. Cysteine inhibits growth. Catalase- and oxidase-negative. Growth is inhibited by penicillin and streptomycin (100 $\mu\text{g}/\text{ml}$)

Source: Nine Springs Sewage digester in Madison, WI, USA.

DNA G+C content (mol%): 24.22 (T_m).

Type strain: SG, ATCC 49001, DSM 3089.

GenBank accession number (16S rRNA gene): X73439.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium collagenovorans* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives are *Clostridium sardiniense* (95.1%), *Clostridium acetobutylicum* (94.1%), and *Clostridium lundense* (93.7%).

51. ***Clostridium cylindrosporum*** (*ex* Barker and Beck 1942) Andreesen, Zindal and Dürre 1985, 207^{VP} (“*Clostridium cylindrosporum*” Barker and Beck 1942)

cy.lin.dro.spo'rum. Gr. n. *kylin-dros* a cylinder; Gr. n. *sporos* a seed; N.L. adj. *cylindrosporum* cylinder-spored.

Cells are straight rods, $0.8 \times 3.3 \mu\text{m}$. Motile by peritrichous flagella. Colonies are unpigmented, flat, circular and up to 2 mm in diameter. Cylindrical to oval spores in terminal or subterminal position. Only actively growing cultures have a positive Gram-staining reaction.

Strictly anaerobic. The optimum temperature for growth is 40–45 °C, some growth at 19 °C. The pH optimum for growth is 6.7–8.5. This pH optimum varies with substrate utilized. Only uric acid, xanthine, guanine, 6,8-dihydroxypurine, and hypoxanthine are utilized as carbon and energy sources. Glycine is fermented when small amounts of uric acid or purines are present. Marginal growth with 4-aminimidazole-5-carboxamide. Thiamine and biotin required for growth of some strains. Selenite is required. The end products of fermentation of purines are acetate, formate, CO_2 , and ammonia. Glycine is detected in trace amounts under some growth conditions.

Acetoin, butanediol, butyrate, caproate, diacetyl, gas, indole, and sulfide are not produced. Nitrate is not reduced. Esculin, gelatin, and starch are not hydrolyzed. Catalase, lecithinase, and urease activities are not detected. Some strains produce lipase. Nonhemolytic on bovine blood cells. Bile extract (2%) inhibits growth but growth still occurs.

Source: soils and chicken intestines.

DNA G+C content (mol%): 27.2–30.4 (T_m).

Type strain: Barker and Beck HC-1, ATCC 7905, DSM 605, IFO (now NBRC) 13695, NCCB 46096.

GenBank accession number (16S rRNA gene): Y18179.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium cylindrosporum* to fall within the family *Clostridiaceae*. This species clusters with the species of the genus *Caloramator* at the 91–92% 16S rRNA gene sequence similarity level.

52. ***Clostridium difficile***^s (Hall and O'Toole 1935) Prévot 1938, 84^{AL} (*Bacillus difficile* Hall and O'Toole 1935, 390)

difficile. L. neut. adj. *difficile* difficult (referring to “the unusual difficulty that was encountered in its isolation and study”)

Cells are Gram-stain-positive, usually motile in broth cultures, peritrichous, and are $0.5\text{--}1.9 \times 3.0\text{--}16.9 \mu\text{m}$. Some strains produce chains consisting of two to six cells aligned end-to-end. Spores are oval, subterminal (rarely terminal), and swell the cell. Sporulation by most strains occurs on Brucella blood agar incubated for 2 d. Sporulation may be enhanced on solid media containing 0.1% sodium taurocholate.

Cell walls contain *meso*-DAP. Surface colonies on blood agar are 2–5 mm, circular, occasionally rhizoid, flat or low convex, opaque, grayish or whitish, and have a matt to glossy surface. All strains produce an evanescent pale green fluorescence under long wavelength ultraviolet light after 48 h incubation on Brucella blood agar supplemented with hemin and vitamin K_1 .

Cultures in PYG broth are turbid with a smooth sediment and have a pH of 5.0–5.5 after incubation for 5 d.

The optimum temperature for growth is 30–37 °C; growth also occurs at 25 °C and 45 °C. Proline, aspartic acid, serine, leucine, alanine, threonine, valine, phenylalanine, methionine, and isoleucine are utilized for growth; δ -aminovalerate and α -aminobutyrate are produced. A selective minimal medium described by Hubert et al. (1981), which contains selected amino acids as a source of carbon and energy, only a trace of fructose (0.1%), 2% bile as a growth stimulant, 16 $\mu\text{g}/\text{ml}$ cefoxitin, and 500 $\mu\text{g}/\text{ml}$ streptomycin for reduction of associated flora, has been found useful for isolation of these organisms from feces.

Abundant gas is produced in PYG deep agar cultures. Abundant H_2 is produced in PYG broth. Ammonia is produced. H_2S is produced by 8 of 17 strains tested.

The type strain metabolizes the bile acids cholic and chenodeoxycholic acids and splits the conjugate taurocholic acid. Hyaluronidase, chondroitin sulfatase, and collagenase are present in the one strain studied. One of two strains tested produces an extracellular β -glucuronidase. Uracil is not utilized.

Products in PYG broth include acetic, isobutyric, butyric, isovaleric, valeric, isocaproic, formic, and lactic acids. Pyruvate is converted to acetate and butyrate; threonine is converted to propionate; lactate is not utilized. Phenylacetic, phenylpropionic, hydroxyphenylacetic, indole acetic acids, and *p*-cresol are produced in trypticase medium supplemented with L-phenylalanine, L-tyrosine, and L-tryptophan. *p*-Hydroxyphenylacetic acid is converted to *p*-cresol. Iso-caproate is produced from leucine, isovalerate from leucine and isoleucine, and isobutyrate from valine.

All strains are susceptible to 8U penicillin G/ml, 4 μg ampicillin/ml, 4 μg vancomycin/ml, <1 μg rifampin/ml,

and 2 µg metronidazole/ml; susceptibility to clindamycin, cephalosporins, cephamycins, tetracyclines, chloramphenicol, and erythromycin is variable, whereas all strains are resistant to aminoglycosides. Tetracycline resistance has been demonstrated to be transferable from resistant to sensitive strains; the resistance determinant may be plasmid-mediated or chromosomal.

Pseudomembranous colitis in humans is caused by overgrowth of the organism in the colon, usually after the flora has been disturbed by antimicrobial therapy. A very similar disease can be produced in hamsters and several other rodents by administration of antibiotics, but rats and mice are not affected. Although *Clostridium difficile* has been reported to cause cecitis in rabbits and hares, *Clostridium spiroforme* appears to be a more common cause of the disease in these animals.

Clostridium difficile produces two large protein toxins (toxins A and B), and hamsters must be immunized against both toxins to survive *Clostridium difficile* cecitis. Toxin A is lethal when given orally to hamsters but toxin B is not; either toxin is lethal when injected intraperitoneally into these rodents. Toxins A and B are lethal for mice. 16,16-Dimethyl-prostaglandin E2 may inhibit production or release of cytopathic toxin(s) *in vitro*. Toxin A has been referred to as the enterotoxin because it causes fluid accumulation in the bowel, but the mechanism of action is not through stimulation of adenyl cyclase. Toxin B does not cause fluid accumulation, but is extremely cytopathic for all tissue-cultured cells tested. Exposure to less than a picogram of this toxin causes cells to become round, detach from supports, and slowly die. The mechanism of action is unknown. A motility altering factor also has been described that is different from the two known toxins, but the significance is unknown.

Other characteristics of the species are shown in Table 144.

Source: marine sediment, soil, sand, the hospital environment; camel, horse, and donkey dung; feces of dogs, cats, and domestic birds; the human genital tract; feces of humans without diarrhea; and rarely from blood and pyogenic infections in humans and animals.

DNA G+C content (mol%): 28.

Type strain: AS 1.2184, ATCC 9689, BCRC 10642, CCUG 4938, CIP 104282, DSM 1296, JCM 1296, LMG 15861, NCIB 10666, NCIMB 10666, NTCC 11209.

GenBank accession number (16S rRNA gene): AB075770.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium difficile* to fall within the radiation of cluster XI of the clostridia as defined by Collins et al. (1994). The closest relatives based on 16S rRNA gene sequence similarities are *Eubacterium tenue*, *Clostridium irregulare*, *Clostridium sordellii*, *Clostridium ghonii*, *Clostridium lituseburense*, *Clostridium mangentii*, and *Clostridium Bifermentans*, all having similarity values in the range 94.7–95.4%. This species is most easily distinguished from *Clostridium sporogenes*, which it resembles most closely phenotypically (although phylogenetically they are unrelated), by its ability to ferment mannitol and by its inability to digest meat or milk, or to produce lipase. *Clostridium difficile* is one of the few species that produces isocaproic and valeric acids.

53. ***Clostridium diolis*** Biebl and Spröer 2003, 627^{VP} (Effective publication: Biebl and Spröer 2002, 496.)

di.ó'lis. N.L. neut. gen. n. *diolis* of a diol (producing a diol).

Cells are 0.7–1.7 × 1.2–8 µm, occur singly or in pairs and occasionally in filaments. Gram-stain-positive becoming Gram-stain-negative in older cultures. Spores are oval, terminal or subterminal, and cause the cell to swell. Motile by peritrichous flagella.

The optimum temperature range for growth is 25–42 °C with an optimum of 37 °C. The pH range for growth is 5.5–8.5 with an optimum at 7.0. Glucose, fructose, cellobiose, lactose, galactose, trehalose, xylose, salicin, amygdalin, melibiose, glycogen, mannitol, and glycerol are fermented. Melizitose, arabinose, ribose, esculin, and sorbitol are weakly used. Raffinose, starch, and *m*-inositol are not used. Gelatin is not liquefied. Esculin is hydrolyzed. Milk is coagulated. Able to grow in a glucose-mineral medium with biotin as the only growth factor. Unable to grow in yeast extract-peptone medium without a fermentable carbon source. Fermentation products from glucose are butyrate and acetate, from glycerol 1,3-propanediol in addition to butyrate and acetate.

Source: decaying straw.

DNA G+C content (mol%): not reported.

Type strain: SH1, DSM 15410, ATCC BAA-557.

GenBank accession number: not reported.

Further comments: Strain SH1 was previously considered a *Clostridium butyricum* strain. Further characterization showed strain SH1 to be more closely related to *Clostridium beijerinckii* than *Clostridium butyricum* (Biebl and Spröer, 2002). Although strain SH1 has >99.0% 16S rRNA gene sequence similarity with that of the type strain of *Clostridium beijerinckii* (X81021) and a corresponding DNA–DNA reassociation value of 67.2%; the fact that strain SH1 and related glycerol fermenting strains did not require complex substances for growth, as well as the fact that these strains did not ferment starch, raffinose, and inositol was used as justification for the description of a new species, *Clostridium diolis*, by Biebl and Spröer (2002). High 16S rRNA gene sequence similarities are also found between *Clostridium diolis* and *Clostridium puniceum* (99.1%) and *Clostridium saccharobutylicum* (99.15%).

54. ***Clostridium disporicum*** Horn 1987, 400^{VP}

di.spor'í.cum. Gr. pref. *di* two; Gr. n. *sporos* seed; Gr. suff. *ikos* pertaining to; N.L. neut. adj. *disporicum* pertaining to two spores.

Rod-shaped cells, 1.5 × 2.5–10 µm. Obligate anaerobe. Gram-stain-positive. Nonmotile. Form subterminal oval spores. Some cells form two spores. The temperature range for growth is 22–44 °C with an optimum at 25–26 °C.

Fermentable carbohydrates required for growth. Ferments glucose to acetic and lactic acid with trace amounts of butyrate and succinate. Ethanol is also formed. Utilizes esculin, cellobiose, dulcitol, fructose, galactose, glucose, lactose, maltose, mannitol, mannose, melibiose, raffinose, ribose, salicin, starch, sucrose, trehalose, and xylose. Hydrolyzes esculin and starch. Does not utilize arabinose, inositol, melezitose, rhamnose, and sorbitol. Negative for lecithinase, lipase, and catalase activity. Does not hydrolyze

gelatin, digest cooked meat, or casein in milk. Indole is not produced.

Source: a slurry of rat cecal contents.

DNA G+C content (mol%): 40–41 (T_m).

Type strain: DS1, ATCC 43838, DSM 5521, NCIMB 12424.

GenBank accession number (16S rRNA gene): Y18176.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium disporicum* to fall within the radiation of the cluster I of the clostridia as defined by Collins et al. (1994). It shares 99.4% sequence similarity with *Clostridium celatum* and 97.8% with the next closest relative *Clostridium quinii*. *Clostridium celatum* differs from *Clostridium disporicum* in that it produces acetic and formic acids and ethanol while the latter only produces acetate and lactate.

55. ***Clostridium drakei*** Liou, Balkwill, Drake and Tanner 2005, 2089^{VP}

dra'ke.i. N.L. gen. n. *drakei* of Drake, in recognition of Harold L. Drake's contributions to our understanding of the physiology and ecology of acetogens.

Gram-stain-negative, motile rods, $0.6 \times 3\text{--}4\ \mu\text{m}$. Terminal spore former. Obligate anaerobe. Optimal growth temperature of 30–37 °C and optimum pH of 5.5–7.5. Grows autotrophically with H_2/CO_2 or CO and chemoorganotrophically with ribose, xylose, fructose, glucose, galactose, fucose, L-arabinose, mannose, rhamnose, sucrose, cellobiose, melezitose, starch, cellulose, inositol, mannitol, gluconate, glycerol, ethanol, propanol, 2-propanol, butanol, citrate, malate, fumarate, lactate, serine, alanine, histidine, glutamate, aspartate, asparagine, arginine, as amino acids, betaine, choline, and syringate. Methanol, D-arabinose, maltose, lactose, trehalose, raffinose, melibiose, amygdalin, sorbitol, and succinate do not support growth. Acetic acid, ethanol, butyrate, and butanol are the end products of metabolism. Cultures are methyl red-positive, but negative for the Voges–Proskauer reaction, esculin hydrolysis, gelatin hydrolysis, nitrate reduction, and indole production.

Source: sediment collected from an acidic coal-mine pond in east-central Germany.

DNA G+C content (mol%): 30–32 (HPLC).

Type strain: SL1, ATCC BAA-623, DSM 12750.

GenBank accession number (16S rRNA gene): Y18813.

Further comments: Strain SL1^T was originally described as a strain of *Clostridium scatologenes* (Kusel et al., 2000). Further characterization of this strain differentiated it from the type strain of *Clostridium scatologenes* and it was described as *Clostridium drakei* (Liou et al., 2005). 16S rRNA gene sequence comparison shows *Clostridium drakei* to be a member of cluster I of the clostridia as defined by Collins et al. (1994). Strain SL1^T forms a tight cluster with *Clostridium scatologenes* and *Clostridium carboxidivorans* and shows highest 16S rRNA gene sequence similarity with these species: *Clostridium scatologenes* (99.7%) and *Clostridium carboxidivorans* (99.8%). DNA–DNA reassociation studies demonstrated the species status of strain SL1^T with reassociation values of 31.8% and 50.2% with *Clostridium carboxidivorans* and *Clostridium Scatologenes*, respectively (Liou et al., 2005). *Clostridium carboxidivorans*, *Clostridium drakei*, and *Clostridium scatologenes* can also be differentiated on the basis of substrate utilization patterns and the fact that *Clostridium scatologenes* grows slowly on H_2/CO_2 (Liou et al., 2005).

56. ***Clostridium estertheticum*** Collins, Rodrigues, Dainty, Edwards and Roberts 1993, 188^{VP} (Effective publication: Collins, Rodrigues, Dainty, Edwards and Roberts 1992, 239.) emend. Spring, Merkhoffer, Weiss, Kroppenstedt, Hippe and Stackebrandt 2003, 1028.

est.er.thet'i.cum. N.L. neut. adj. *estertheticum* ester-producing

Cells are rod-shaped, $1.3\text{--}1.5 \times 2.4\text{--}6.0\ \mu\text{m}$, occur singly, in pairs or short chains. Motile by peritrichous flagella. Endospores are ellipsoidal and located mainly in a subterminal position, but sometimes also terminal or central; sporangium is slightly swollen. Gram-stain-positive. Colonies on sheep-blood agar are 1–2 mm in diameter, round with often coarsely granulated margins, smooth, slightly raised, cream-white to grayish, and semitransparent to opaque. Psychrophilic. The pH optimum is pH 6.5. Arabinose, cellobiose, fructose, galactose, glucose, inositol, inulin, maltose, mannitol, mannose, melibiose, raffinose, rhamnose, salicin, sorbitol, starch, sucrose, and xylose are utilized.

Amygdalin, lactose, melezitose, ribose, and trehalose are not utilized. Starch is hydrolyzed, but gelatin is not. The end products of fermentation are butyrate, acetate, lactate, formate, 1-butanol, ethanol, hydrogen, and carbon dioxide. The cell-wall peptidoglycan contains *meso*-diaminopimelic acid. The major cellular fatty acids are $\text{C}_{14:0}$, $\text{C}_{16:1\ \text{DMA}\ 69\text{e}}$, $\text{C}_{16:1\ 09\text{e}}$, $\text{C}_{16:0}$, $\text{C}_{16:1\ 011\text{e}}$ and an unknown compound with an equivalent chain-length of 14.777–14.783.

Source: chill-stored vacuum-packed beef.

DNA G+C content (mol%): 33.9 (HPLC).

Type strain: ATCC 51377, CIP 105093, DSM 8809, NCIMB 12511.

GenBank accession number (16S rRNA gene): S46734, X68181.

Further comments: 16S rRNA gene sequence analysis shows the species *Clostridium estertheticum* and both of its subspecies to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The subspecies of this species share 99.93% 16S rRNA gene sequence similarity and a DNA–DNA reassociation value of 79%. 16S rRNA gene sequence similarities are in the range of 98.7–99.6% to the species *Clostridium bowmanii*, *Clostridium frigioris*, and *Clostridium lacusfryxellense*. The type strains of the two subspecies can be differentiated on the basis of *Clostridium estertheticum* subsp. *laramiense* being β -hemolytic on blood agar (Spring et al., 2003) as well as some substrate utilization differences and physiological characteristics. It should be noted that the two subspecies of this species do not cluster together in the phylogenetic tree presented by (Spring et al., 2003) or in the analysis presented in Figure 128.

56a. ***Clostridium estertheticum* subsp. *estertheticum*** Collins, Rodrigues, Dainty, Edwards and Roberts 1993, 188^{VP} (Effective publication: Collins, Rodrigues, Dainty, Edwards and Roberts 1992, 239.) emend. Spring, Merkhoffer, Weiss, Kroppenstedt, Hippe and Stackebrandt 2003, 1028.

In addition to the characteristics mentioned in the description of *Clostridium estertheticum*, the following distinguishing properties allow identification of this subspecies: colonies on sheep-blood agar are nonhemolytic; temperature optimum for growth is 6–8 °C, the upper limit is 13 °C; pH range for growth is 5.5–7.8 with an optimum of 6.5–7.2;

glycogen cannot be utilized; and, in PYG broth, the most abundant nongaseous fermentation end products are volatile fatty acids including butyrate, acetate, and formate.

Source: chill-stored vacuum-packed beef.

DNA G+C content (mol%): 33.9 (HPLC).

Type strain: ATCC 51377, CIP 105093, DSM 8809, NCIMB 12511.

GenBank accession number (16S rRNA gene): S46734, X68181.

- 56b. ***Clostridium estertheticum* subsp. *laramiense*** Spring, Merkhoffer, Weiss, Kroppenstedt, Hippe and Stackebrandt 2003, 1028^{VP}

la.ra.mi.en'se. N.L. neut. adj. *laramiense* referring to the city of Laramie, WY, USA.

Basonym: *Clostridium laramiense* Kalchayanand et al. (1993). The original description was given by Kalchayanand et al. (1993).

Medium to thick rod-shaped cells, $0.5 \times 10 \mu\text{m}$). Gram-stain-positive. Oval, terminal endospores are formed. Straight and tumbling motion by peritrichous flagella.

Colonies on blood agar are small, grayish white, smooth, and convex. Good growth with gas formation in broth supplemented with L-cysteine (0.05%), hemin (0.1%), and vitamin K (0.001%).

Growth occurs in the temperature range -3 – 21°C with optimum growth at 15°C . No growth at 25°C or $<-3^\circ\text{C}$. The pH range for growth is 4.5–7.5 with optimum growth at pH 6.5.

Glucose, fructose, galactose, sucrose, maltose, melibiose, mannose, rhamnose, raffinose, mannitol, inositol, and gluconate are fermented. Arabinose, cellobiose, and xylose are also utilized. Lactose, ribose, trehalose, and inulin are not fermented. The end products of fermentation are butyric acid, butanol, acetate, formate, propionate, isobutyrate, and ethanol depending on the growth medium and substrate.

Catalase, lecithinase, and indole-negative. Lipase and β -hemolysin positive. Starch is hydrolyzed and meat digested. Gelatin and esculin are not hydrolyzed. Milk reaction negative. Nitrate is reduced. The following antibiotics inhibit growth: ampicillin (4 μg), cephalothin (6 μg), chloramphenicol (12 μg), erythromycin (3 μg), penicillin G (2U), and tetracycline (6 μg). Nontoxic to mice.

DNA G+C content (mol%): 32.4 (HPLC).

Type strain: NK1, ATCC 51254, DSM 14864.

GenBank accession number (16S rRNA gene): AJ506115.

Further comments: In contrast to the original description (Kalchayanand et al., 1993), Spring et al. (2003) reported that arabinose, cellobiose, and xylose can be utilized as substrates. In addition, Spring et al. (2003) reported the G+C content of the DNA of strain NK^T to be 32.4 mol% (HPLC method) in contrast to the value of 26 mol% (thermal denaturation method) reported by Kalchayanand et al. (1993) in the original description of *Clostridium laramiense*. Strain NK^T can be differentiation from *Clostridium estertheticum* subsp. *estertheticum* on the basis of the colonies on sheep-blood agar being β -hemolytic; having a temperature optimum for growth of 15°C , with an upper limit of 21°C ; the pH range for growth being 4.5–7.5 with an optimum of 6.5; glycogen

being utilized; and, in PYG broth, the end products of fermentation are butyrate, 1-butanol, and lactate.

57. ***Clostridium fallax**** (Weinberg and Séguin 1915) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 325^{AL} (*Bacillus fallax* Weinberg and Séguin 1915, 686.)

fal'lax. L. adj. *fallax* deceptive.

Cells in PYG broth cultures are Gram-stain-positive rods with rounded ends, 0.5 – 1.4×1.6 – $15.4 \mu\text{m}$ that occur singly or in pairs. In freshly isolated strains and young cultures, cells are motile and peritrichous, but both motility and flagella may be lost on subsequent transfer. Spores are oval, central to subterminal, and swell the cell. Sporulation of most strains occurs most readily in chopped-meat broth cultures. Cell walls contain LL-DAP and the sugars glucose, galactose, and rhamnose.

Surface colonies on blood agar plates are 1–5 mm in diameter, hemolytic, circular to slightly irregular, with entire to slightly erose margins, raised or convex, translucent, gray, shiny and smooth, often with a mottled or granular internal structure.

Cultures in PYG broth are turbid with a smooth sediment and have a pH of 4.8–5.3 after incubation for 1 week. The optimum temperature for growth is 37°C . Strains grow nearly as well at 30°C and 45°C but poorly if at all at 25°C . Growth is inhibited by 20% bile, 6.5 NaCl, or a pH of 8.5. Abundant gas is detected in PYG deep agar cultures. Deoxyribonuclease is present. Products in PYG broth are acetic, butyric, and lactic acids; pyruvic and succinic acids are usually detected. Abundant H_2 is produced. Pyruvate is converted to acetate; neither acetate nor threonine is utilized. Ammonia and H_2S are produced.

All strains tested are susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Culture supernatants are nontoxic to mice. The organism has been reported to be pathogenic for guinea pigs and mice, but pathogenicity is quickly lost.

Other characteristics of the species are given in Table 142.

Source: soil, marine sediments, animal wounds, clinical specimens from soft tissue infections in humans; human feces.

DNA G+C content (mol%): 26 (T_m).

Type strain: ATCC 19400, BCRC 14512, CCUG 4853, DSM 2631, JCM 1398, NCIMB 10634, NCTC 8380.

GenBank accession number (16S rRNA gene): M59088.

Further comments: 16S rRNA gene sequence analysis shows *Clostridium fallax* to fall within the radiation of the cluster I of the clostridia as defined by Collins et al. (1994). The highest sequence similarities are found to the species *Eubacterium tarantellae* (95.6%), *Clostridium polyendosporum* (95.6%), *Clostridium septicum* (95.1%), and *Clostridium chauvoei* (95.0%).

58. ***Clostridium felsineum**** (Carbone and Tombolato 1917) Spray 1939, 766^{AL} (*Bacillus felsineus* Carbone and Tombolato 1917, 563)

fel.si'ne.um. L. n. *Felsina* ancient Latin name for Bologna, Italy; N.L. neut. adj. *felsineum* pertaining to Bologna.

Cells in PYG broth cultures are Gram-stain-positive rods; Gram-stain-negative in older cultures, and 0.5 – $1.3 \times$

3.1–25.7 µm. They are motile and peritrichous although motility may be lost in cultures that have been maintained in the laboratory for many years. They are granulose positive in starch medium. Cells occur singly, in pairs, and in short or long chains. Spores are oval, subterminal, and swell the cell. There are no appendages and no exospore. Spores are difficult to detect, but usually can be found in PYG or PY-starch broth cultures incubated for 3–5 d. Cell walls contain *meso*-DAP, major amounts of galactose and rhamnose, with lesser amounts of glucose and mannose.

These organisms grow very poorly if at all on anaerobic blood agar or egg-yolk agar plates. Surface colonies on brain heart infusion agar roll streak tubes after incubation for 2–4 d are 1–4 mm in diameter, circular, flat to low convex, translucent to opaque, with a mottled or granular surface, a pebbled or mosaic internal structure, and an entire to slightly scalloped or lobate margin. They may be white, yellow, orange, or brownish. When slight growth occurs on anaerobic blood agar plates (3 of 13 strains), colonies are β-hemolytic.

Cultures in PYG broth are turbid with a heavy, ropy, or flocculent, often dark orange sediment, and have a pH of 4.7–5.4 after incubation for 24 h.

The optimum temperature for growth is 37 °C. Most strains grow nearly as well at 30 °C, but poorly if at all at 25 °C or 45 °C. Growth is markedly stimulated by fermentable carbohydrate but inhibited by 20% bile, 6.5% NaCl, or pH of 8.5. Abundant gas is detected in PYG deep agar cultures. Acetyl methyl carbinol is produced by 7 of 11 strains tested. Neutral red is reduced; resazurin is reduced by 4 of 13 strains tested.

Each of four strains tested, including the type strain, completely digests thin slices of carrot, turnip, and radish in PY-broth cultures within 3 d. PY-pectin is strongly fermented (pH 4.8–5.2), and has pectic lyase, pectic hydrolase, and polygalacturonase but no detectable pectinesterase activity in members of the species.

Spore suspensions of a strain of *Clostridium felsineum* will germinate in and lyse tumor tissue but not healthy tissue in mice. Destruction of the tumor tissue, however, is neither complete nor permanent. Atmospheric N₂ is fixed.

Products in PYG broth culture are butyric and acetic acids and butanol; lactic, formic and acetic acids may be detected. Pyruvate is converted to acetate, butyrate, and usually butanol. Neither lactate nor threonine is utilized. Abundant H₂ is detected. Acetone, CO₂, and ethanol may also be produced.

All strains tested are susceptible to clindamycin, erythromycin, penicillin G, and tetracycline. One of five strains is resistant to chloramphenicol. Culture supernatants are nontoxic to mice.

Other characteristics of the species are given in Table 144.

Source: rotting flax, soil in the USA and Antarctica, human feces.

DNA G+C content (mol%): 26 (T_m).

Type strain: ATCC 17788, DSM 794, JCM 1399.

GenBank accession number (16S rRNA gene): AF270502, X77851.

Further comments: Most of the strains available for study were isolated from enrichment cultures in 5% corn meal mash as described by McClung (1943). Pigmentation of colonies is most pronounced in this medium. Plating medium for purification of cultures was yeast infusion-starch agar and plates were incubated in an oat jar. Colonies of *Clostridium felsineum* under these conditions are yellow and, unlike colonies of *Clostridium roseum*, do not darken on exposure to air. *Clostridium felsineum* may be distinguished from *Clostridium aurantibutyricum* by failure to reduce nitrate and from *Clostridium puniceum* by fermentation of rhamnose, by lack of pectinesterase, and by colony pigmentation on corn meal agar. Although sharing some phenotypic characteristics with these species, 16S rRNA gene sequence comparisons show *Clostridium felsineum* to fall within the radiation of cluster XI of the clostridia as defined by Collins et al. (1994) and it shares highest sequence similarity with the species *Clostridium formicaceticum* (99.3%) and *Clostridium aceticum* (97.7%).

59. ***Clostridium fimetarium*** Kotsyurbenko, Nozhevnikova, Osipov, Kostrikin and Lysenko 1997, 242^{VP} (Effective publication: Kotsyurbenko, Nozhevnikova, Osipov, Kostrikin and Lysenko 1995, 810.)

fi.me.ta'ri.um. N.L. neut. adj. *fimetarium* inhabiting manure.

Rod-shaped cells 0.5–0.6 × 2.1–5.0 µm long. Gram-stain positive. Motile by peritrichous flagella. Oligosporous. Oval spores are 1.1 × 1.3 µm and terminal. Growth occurs in the temperature range 1–30 °C with an optimum temperature for growth of 20–25 °C. The pH range for growth is 5.5–8.3 with optimum growth at 6.8. Strict anaerobe.

Saccharolytic. Glucose, fructose, maltose, arabinose, xylose, cellobiose, galactose, and mannose are fermented. Raffinose, sorbose, ribose, lactose, rhamnose, trehalose, fucose, sucrose, melibiose, erythritol, inositol, dulcitol, adonite, mannitol, sorbitol, *N*-acetyl-D-glucosamine, D-glucosamine HCl, betaine, choline chloride, sarcosine HCl, glycogen, starch, cellulose (MCC), peptone, L-histidine HCl, DL-methionine, DL-serine, L-glutamate, L-glutamine, glycine, *N,N*-dimethylglycine, pyruvate, succinate, fumarate, malate, lactate, Casamino acids, glycerol, formate, acetate, propionate, butyrate, methanol, ethanol, propanol, butanol, mono-, di-, and trimethylamine, and H₂ + CO₂, and are not utilized. Polysaccharides are not hydrolyzed. The end products of fermentation are acetate, ethanol, lactate, formate, H₂, and CO₂. Formate, butyrate, and butanol are not produced. The main fatty acids are C_{16:0} and C_{18:1 09}.

Source: cattle manure digested at low temperature.

DNA G+C content (mol%): 35.6 (T_m).

Type strain: Z-2189, CIP 105360, DSM 9179.

GenBank accession number (16S rRNA gene): AF126687.

Further comments: When this species was described, the 16S rRNA gene sequence was not determined and the species was assigned to the genus *Clostridium* on the basis of the morphological and physiological characteristics observed. Subsequent determination and analysis of the 16S rRNA gene sequence of *Clostridium fimetarium* placed it outside cluster I of the clostridia as defined by Collins et al. (1994). *Clostridium fimetarium* falls within the radiation of cluster XIVa as defined by Collins et al. (1994).

60. *Clostridium formicaceticum** corrig. Andreesen, Gottschalk and Schlegel 1970, 155^{AL}.

for.mic.a.ce ti.cum. L. n. *formica* an ant, N.L. adj. *formicus* pertaining to ants, to formic acid; L. n. *acetum* wine-vinegar, N.L. adj. *aceticus* pertaining to vinegar, to acetic acid; N.L. neut. adj. *formicaceticum* pertaining to formic and acetic acids.

Cells in PY-fructose broth cultures are Gram-stain-negative, straight to slightly curved rods, motile and peritrichous, 1.2–2.0 × 5–12 μm, and occur singly or in pairs. Spores are round, terminal or subterminal, and swell the cell. Sporulation occurs readily both in broth media and on chopped-meat slants. Cell walls contain *meso*-DAP.

Surface colonies on brain heart infusion agar streak tubes incubated in an atmosphere of 100% N₂ are 1–3 mm in diameter, circular to slightly irregular, entire, flat to low convex, semiopaque, white, shiny, smooth, with a mosaic internal structure.

Cultures in PY-fructose broth are slightly turbid with a smooth sediment and have a pH of 6.3–6.7 (compared with a pH of 7.2 in PY broth) after incubation for 4 d in an atmosphere of 100% N₂. Ammonia is produced. Resazurin is not reduced.

The optimum temperature for growth is 37 °C. Moderate growth occurs at 28 °C, 32 °C, and 44 °C; there is no growth at 52 °C. Bicarbonate or formate and fermentable carbohydrate are required for growth. Substrates utilized for growth include fructose, ribose, gluconate, glucuronate, galacturonate, 2-keto-3-deoxygluconate, mannonate, galacturonate, glutamate, malate, mannitol, glycerol, lactate, pyruvate, fumarate, and pectin. An α-isopropylmalate synthase has been identified in extracts of *Clostridium formicaceticum* indicating that leucine is synthesized by the isopropylmalate pathway used by many aerobic organisms. Enzymes utilized in the degradation of glutamate and those required for the assimilation of N₂ and NH₄⁺ have been identified.

Carbon monoxide is oxidized to CO₂ by cell suspensions from cultures grown in fructose broth and this reaction is coupled with the reduction of CO₂ to acetate. During active growth in an atmosphere of either 100% N₂ or 90% N₂–10% CO₂, acetate is the major product detected in PY-fructose broth cultures; small amounts of succinate also may be formed. In the stationary phase of growth, both acetate and formate are produced. No H₂ is produced. L-malate is converted to acetate and CO₂; fumarate is reduced to succinate, acetate, and CO₂. The electron carriers cytochrome *b* and menaquinone are present in cultures and possibly involved in this reaction.

All strains tested are susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Culture supernatants are nontoxic to mice.

Other characteristics of the species are given in Table 143.

Source: sewage, pond and ditch mud, stagnant river water.

DNA G+C content (mol%): 34 (*T_m*).

Type strain: ATCC 27076, DSM 92.

GenBank accession number (16S rRNA gene): X77836.

Further comments: This species can be distinguished most readily from *Clostridium acetivum* by its production of formate in later stages of growth and by its inability to utilize

H₂ as a reducing agent in the conversion of CO₂ to acetate. *Clostridium formicaceticum* falls within the cluster XI of the clostridia as defined by Collins et al. (1994). It shows highest sequence similarity to *Clostridium felsineum* (99.3%) and *Clostridium acetivum* (97.7%).

61. *Clostridium frigidicarnis* Broda, Lawson, Bell and Musgrave 1999, 1549^{VP}

fri.gi.di.car'nis. L. adj. *frigidus* cool; L. n. *caro carnis* meat; N.L. gen. n. *frigidicarnis* of cool meat.

Rod-shaped cells, 1.3–1.6 × 4.5–9.4 μm, occur singly or in pairs. Motile. Gram-stain-positive. Form elliptical spores in early stationary growth phase. Colonies on sheep blood agar are 2.2–7.2 mm in diameter, circular to irregular shape, and creamy-gray to gray in color. Colonies are semi-opaque to translucent with circular or irregular with undulate, lobate, or erose margins. β-Hemolytic. Psychrotolerant growing in the temperature range 3.8–40.5 °C with an optimum of 30.0–38.5 °C. The pH range for growth is 4.7–9.5 with optimum growth at 6.4–7.2.

Ferments fructose, glucose, mannose, maltose, sorbitol, and trehalose. Cellobiose, galactose, lactose, mannitol, and xylose are not fermented. Ferments PYGS broth to produce acetate, ethanol, butyrate, isovalerate, butanol, isobutyrate, oxalacetate, lactate, hydrogen, and carbon dioxide. Indole is not produced. Lecithinase-positive and lipase-negative. Hydrolyzes gelatin. Esculin and starch are not hydrolyzed. Meat and milk are digested.

Source: temperature abused vacuum-packed beef.

DNA G+C content (mol%): 27.3–28.4 (*T_m*).

Type strain: SPL77A, ATCC BAA-154, DSM 12271.

GenBank accession number (16S rRNA gene): AF069742.

Further comments: 16S rRNA gene sequence analysis places *Clostridium frigidicarnis* in the cluster I of the clostridia as defined by Collins et al. (1994). It represents a distinct lineage within cluster I but shows highest sequence similarities to the species *Clostridium septicum* (95.9%), *Clostridium chauvoei* (95.2%), *Clostridium tertium* (94.7%), and *Clostridium carnis* (94.5%).

62. *Clostridium frigoris* Spring, Merkhoffer, Weiss, Kroppenstedt, Hippe and Stackebrandt 2003, 1026^{VP}

fri'go.ris. L. gen. n. *frigoris* of the cold.

Rod-shaped cells, 1.4–1.8 × 2.2–5.0 μm, occurring singly, in pairs or short chains. Filamentous cells are occasionally present, especially in cultures grown on agar plates. Motile by peritrichous flagella. Endospores are spherical and terminal in position; sporangium not swollen. Gram-stain-positive. Cell-wall peptidoglycan contains *meso*-diaminopimelic acid. Colonies on sheep-blood agar are 1–2 mm in diameter, round with often coarsely granulated margins, smooth, slightly raised, cream-white to grayish, semi-transparent to opaque and nonhemolytic. The major cellular fatty acids are C_{16:1 ω9c}, C_{14:0}, C_{16:1 DMA ω9c}, C_{16:0}, C_{16:1 ω11c}, and an unknown compound with an equivalent chain-length of 14.777–14.783. Optimal growth occurs at 5–7 °C with an upper limit of 11 °C. The pH range for growth is 5.5–7.5 with optimal growth in the range 6.8–7.2. Doubling time of 11 h under optimal growth conditions. Amygdalin, arabinose, cellobiose, fructose, galactose, glucose, glycogen, inositol (weak),

inulin, lactose, maltose, mannose, melibiose, raffinose, rhamnose, ribose (weak), salicin, starch, sucrose, trehalose, and xylose are utilized. Mannitol, melezitose and sorbitol are not utilized. Gelatin and starch are not hydrolyzed. The end products of fermentation are butyrate, formate, lactate, acetate, ethanol, hydrogen, and carbon dioxide.

Source: a microbial mat from a moated area around Lake Fryxell, Antarctica.

DNA G+C content (mol%): 31.9 (HPLC).

Type strain: D-1/D-an/II, ATCC BAA-579, DSM 14204.

GenBank accession number (16S rRNA gene): AJ506116 (clone 5), AJ506117 (clone 10).

Further comments: 16S rRNA gene sequence comparisons place *Clostridium frigoris* within cluster I of the clostridia as defined by Collins et al. (1994). Two 16S rRNA gene sequence clones of *Clostridium frigoris* were sequenced and found to share 99.4% sequence similarity. *Clostridium frigoris* shares highest sequence similarity with the species *Clostridium estertheticum* subsp. *laramiense* (99.7%), *Clostridium estertheticum* subsp. *estertheticum* (99.6%), *Clostridium lacusfryxellense* (99.2%), and *Clostridium bowmanii* (98.6%). DNA-DNA reassociation values in the range 16–62% between *Clostridium frigoris* and these related species helped define the individual species status of *Clostridium frigoris* (Spring et al., 2003). In addition, substrate utilization patterns and end products of fermentation can be used to differentiate this species.

63. ***Clostridium ganghwense*** Kim, Jeong, Kim and Chun 2006, 693^{VP}

gang.hwen'se. N.L. neut. adj. *ganghwense* named after Ganghwa Island in South Korea, the geographical origin of the type strain.

Rod-shaped cells, 0.7–0.8 × 4–8 μm. Motile with peritrichous flagella. Gram-stain-negative. KOH reaction negative. Colonies are circular and yellowish on RCM. Catalase-negative. Strictly anaerobic. Chemoheterotrophic. Requires 1–9% (w/v) artificial sea salts (optimum 3%). Does not grow on RCM containing 0–5% (w/v) NaCl alone. Growth occurs in the temperature range 15–40 °C with an optimal of 35 °C. Growth occurs in the pH range 5.5–10.0 with optimal growth at pH 7.5.

Glucose, maltose, salicin, cellobiose, and mannose are utilized. Mannitol, lactose, sucrose, xylose, arabinose, glycerol, melezitose, raffinose, sorbitol, rhamnose, and trehalose are not utilized. The end products of fermentation of glucose are glycerol, ethanol, and CO₂. Gelatin and esculin are hydrolyzed. Indole is produced urease is not.

Source: tidal flat sediment of Ganghwa Island, South Korea.

DNA G+C content (mol%): not reported.

Type strain: HY-42-06, IMSNU 40127, JCM 13193, KCTC 5146.

GenBank accession number (16S rRNA gene): AY903294.

Further comments: 16S rRNA gene sequence comparisons place *Clostridium ganghwense* within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives based on 16S rRNA gene sequence similarity values are *Clostridium aestuarii* (96.8%), *Clostridium homopropionicum* (95.0%), and *Clostridium hemolyticum* (94.9%).

Clostridium ganghwense can be differentiated from *Clostridium aestuarii* based on differences in substrate utilization patterns for sucrose, mannose, salicin, gelatin, and cellobiose. Differences also exist in end products formed from fermentation with *Clostridium aestuarii* forming butyrate, propionate, glycerol, and H₂ while *Clostridium ganghwense* forms glycerol, ethanol, and CO₂.

64. ***Clostridium gasigenes*** Broda, Saul, Lawson, Bell and Musgrave 2000b, 116^{VP}

ga.si'ge.nes. N.L. neut. n. *gasum* gas; Gr. v. *gennaio* to produce; N.L. gen. n. *gasigenes* gas-producing.

Rod-shaped cells, 0.4 × 2.0–7.5 μm. Motile. Gram-stain-positive. On blood sheep agar, colonies measure 0.7–3.0 mm in diameter. Colonies are gray-white to gray, with entire margins, circular, convex and shiny. β-Hemolytic. Produce elliptical subterminal spores in late-stationary growth phase. Psychrophilic with a temperature range for growth of 1.5–26 °C and an optimum of 20–22 °C. The pH range for growth is 5.4–8.9 with an optimum at 6.2–8.6.

Requires a fermentable carbohydrate for growth, even in PY broth. Ferments cellobiose, fructose, glucose, inositol, maltose, mannose, salicin, and trehalose. Lactose, xylose, arabinose, mannitol, raffinose, and sorbitol are not fermented. Hydrolyzes gelatin, esculin, and starch. Fermentation end products from PYGS broth are ethanol, acetate, butyrate, lactate, butanol, CO₂, and H₂.

Source: vacuum-packed, chilled lamb that showed “blown-pack” spoilage, which causes gas production and pack distension in vacuum-packed meat.

DNA G+C content (mol%): 28.3–29.4 (T_m).

Type strain: DB1A, ATCC BAA-158, CIP 106517, DSM 12272.

GenBank accession number (16S rRNA gene): AF092548.

Further comments: 16S rRNA gene sequence comparisons shows *Clostridium gasigenes* to fall within cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives based on 16S rRNA gene sequence comparisons are *Clostridium carnis* (96.7%), *Clostridium vincentii* (96.2%), and *Clostridium tertium* (96.1%). *Clostridium gasigenes* is differentiated from these related species on the basis of soluble protein patterns, fatty acid profiles, end products of fermentation, and substrate utilization patterns (Broda et al., 2000b).

65. ***Clostridium ghonii***^{*} corrig. Prévot 1938, 83^{AL}

gho'ni.i. N.L. gen. *ghonii* pertaining to Anton Ghon, Austrian bacteriologist.

Cells in PYG broth culture are Gram-stain-positive, straight rods, motile and peritrichous, and 0.5–1.4 × 1.6–6.3 μm. They usually occur singly, occasionally in pairs. Spores are central to subterminal, oval, and swell the cell. Sporulation occurs most readily on egg-yolk agar plates or in chopped-meat broth incubated for 2 d. Cell walls contain *meso*-DAP.

Surface colonies on blood agar plates are usually β-hemolytic, 0.5–2.0 mm in diameter, circular to slightly irregular, scalloped to lobate, translucent to semiopaque, flat to raised, white, shiny, and with a granular or mosaic internal structure.

Cultures in PYG broth are turbid with a smooth to ropy sediment and a pH of 6.2–6.4 after incubation for 4 d.

Growth is stimulated by carbohydrate even though no pH depression occurs. Good growth occurs at a pH of 8.5; growth is inhibited by 6.5% NaCl or 20% bile. Abundant gas is detected in PYG deep agar cultures. Gelatin, milk, meat, and casein are rapidly digested. H₂S and ammonia are formed. Neutral red is reduced; two of the five strains reduce resazurin.

The organism contains a wide variety of cellular C₁₂–C₁₈ fatty acids with unbranched, saturated fatty acids predominating, but with significant amounts of branched chain acids as well.

Products in PYG broth after 4 d of incubation include acetate, isobutyrate, butyrate, isovalerate, isocaproate, ethanol, butanol, and isobutanol; formate, propionate, and propanol may also be detected.

Moderate amounts of H₂ are formed. *Clostridium ghonii* has been reported to form significant amounts of methane and dithia-2,3 butane, and moderate amounts of propane and thiocyclopropane in sodium thioglycolate glucose broth cultures, but this finding requires confirmation. Pyruvate is converted to acetate, butyrate, and ethanol; threonine is converted to propionate; lactate is not utilized. Valine is converted to isobutyrate, leucine to isovalerate and isocaproate, isoleucine to isovalerate. Phenylpropionic and phenyllactic acids and indole are formed in trypticase-yeast extract-thioglycollate medium containing phenylalanine, tyrosine, and tryptophan.

All strains, tested are susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Culture supernatants are nontoxic to mice.

Other characteristics of the species are given in Table 145.

Source: soil and marine sediment, soft tissue infections in humans, human feces.

DNA G+C content (mol%): 27 (T_m).

Type strain: ATCC 25757, BCRC 14548, CCUG 9282, DSM 15049, JCM 1400, NCIMB 10636.

GenBank accession number (16S rRNA gene): X73451.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium ghonii* to fall within the cluster XI of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarities are *Eubacterium tenue* (99.0%), *Clostridium sordellii* (98.9%), and *Clostridium bifermentans* (97.2%).

66. ***Clostridium glycolicum**** Gaston and Stadtman 1963, 356^{AL} emend. Chamkha, Labat, Patel and Garcia 2001b, 2052.

gly.co'li.cum. L. adj. suff. *-icus* related to, belonging to; N.L. neut. adj. *glycolicum* referring to the ability to ferment ethylene glycol.

This description is based on that of Gaston and Stadtman (1963) and the emended description of Chamkha et al. (2001b).

Cells in PYG broth cultures are Gram-stain-positive, straight to slightly curved rods, motile and peritrichous, 0.3–1.3 × 1.8–15.4 μm, and occur singly or in pairs. Spores are oval and usually subterminal, occasionally terminal, often occurring as free spores. Sporulation occurs most readily in chopped-meat broth cultures or on chopped-meat agar slants. Cell walls do not contain DAP. They do contain lysine and iso-D-asparagine.

Surface colonies on blood agar plates are 1–4 mm, circular to irregular, raised to convex, translucent to semiopaque, grayish white, shiny, and smooth with a granular, mottled, or mosaic internal structure, and entire, scalloped, or erose margins.

Cultures in PYG broth are turbid with a smooth to stringy sediment and have a pH of 5.5–5.9 after incubation for 24 h. After 5 d of incubation, the pH is 5.2–5.6.

The optimum temperature for growth is 30–37 °C. Most strains grow moderately well at 25 °C, poorly if at all at 45 °C. Growth is inhibited by 6.5% NaCl, 20% bile, and a pH of 8.5. Abundant gas is detected in PYG deep agar cultures. Deoxyribonuclease is present. Ammonia is produced. H₂S is formed by 9 of 13 strains tested. Four of 13 strains hydrolyze hippurate. This organism can ferment ethylene glycol to acetate and ethanol, and propylene glycol to propionate, propanol, and small amounts of acetate and ethanol. A wide variety of both normal straight-chain saturated and iso-branched chain saturated and unsaturated fatty acids is present in strains of this species. *Clostridium glycolicum* degrades uracil to β-alanine, ammonia, and CO₂. Sugars fermented are glucose, fructose, sorbitol, xylose, maltose, and dulcitol, with acid and gas formation. Succinate is fermented into propionate and CO₂; glycerol is fermented into acetate, ethanol, H₂, and CO₂; yeast extract, Casamino acids, and Biotrypcase are fermented into acetate, isovalerate, ethanol, H₂, and CO₂; and peptone is fermented into acetate, isovalerate, and CO₂. Substrates not fermented include amygdalin, arabinose, cellobiose, galactose, glycogen, inulin, lactose, mannitol, mannose, melezitose, melibiose, raffinose, rhamnose, ribose, salicin, sucrose, and trehalose.

Products in PYG broth are acetic, isovaleric, and isobutyric acids, and ethyl, propyl, isobutyl, and isoamyl alcohols; propionic, formic, lactic, and succinic acids also may be detected. Abundant H₂ is produced. Threonine is converted to propionate; lactate is not utilized. Reduces the double bond of the side chain of a wide range of cinnamic acids: cinnamic, *o*-, *m*-, and *p*-coumaric, *o*-, *m*-, and *p*-methoxycinnamic, *p*-methylcinnamic, caffeic, ferulic, and isoferulic acids. The end products of metabolism of cinnamic acids are the corresponding phenylpropionic acids: 3-phenyl, 3-(2-hydroxyphenyl), 3-(3-hydroxyphenyl), 3-(4-hydroxyphenyl), 3-(2-methoxyphenyl), 3-(3-methoxyphenyl), 3-(4-methoxyphenyl), 3-(4-methylphenyl), 3-(3,4-dihydroxyphenyl), 3-(4-hydroxy-3-methoxyphenyl), and 3-(3-hydroxy-4-methoxyphenyl) propionic acids.

All strains are susceptible to penicillin G; of 30 strains tested, five are resistant to erythromycin, two to clindamycin, one to chloramphenicol, and one to tetracycline. Susceptibility to metronidazole is variable. Culture supernatants are nontoxic to mice.

Does not produce lecithinase, lipase, indole, caproic, or butyric acid. Does not hydrolyze starch or gelatin. Sulfate, thiosulfate, sulfite, elemental sulfur, nitrate, and fumarate are not reduced.

Source: soil, mud, snake venom, bovine intestine; human clinical specimens including wounds, abscesses, and peritoneal fluid; human feces.

DNA G+C content (mol%): 29 (T_m).

Type strain: ATCC 14880, DSM 1288, JCM 1401, NCIMB 10632, NCTC 13026.

GenBank accession number (16S rRNA gene): X76750.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium glycyrrhizinum* to fall within the radiation of cluster XI of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarity values are *Clostridium mayombeii* (98.9%), *Clostridium bartlettii* (96.7%), and *Clostridium irregulare* (96.3%). The production of large amounts of isovaleric acid is most helpful in distinguishing this species from other saccharolytic, non-proteolytic clostridia.

67. ***Clostridium glycyrrhizinilyticum*** Sakuma, Kitahara, Kibe, Sakamoto and Benno 2006b, 2057^{VP} (Effective publication: Sakuma, Kitahara, Kibe, Sakamoto and Benno 2006a, 484.) gly.cyr.rhi.zi.ni.ly'ti.cum. N.L. neut. n. *glycyrrhizinum* glycyrrhizin (a sugar from the roots of *Glycyrrhizinum* species); N.L. neut. adj. *lyticum* dissolving, able to dissolve; N.L. adj. *glycyrrhizinilyticum* glycyrrhizin-dissolving.

Short rods or rod-shaped cells, 0.5 × 1–2 µm. Colonies are <1mm in diameter, disc shaped, white-grayish color when grown on GAM blood agar plate for 48 hours. Obligate anaerobe. Nonsporeformer. Gram-stain-positive. Non-motile. Growth temperature 37 °C.

Acid is produced from L-arabinose, glucose, lactose, maltose, L-rhamnose, and D-xylose. Acid is not produced from glycerol, D-mannitol, sucrose, D-cellobiose, D-mannose, D-melezitose, D-raffinose, D-sorbitol, or D-trehalose. Esculin and gelatin are not hydrolyzed. Indole, catalase, and urease are not produced. Using Rapid ID 32A two strains had positive reactions for β-galactosidase, β-glucosidase, α-arabinosidase, β-glucuronidase and glutamic acid decarboxylase. Two strains had negative reactions on N-acetyl-β-glucosaminidase, alkaline phosphatase, leucylglycine arylamidase, alanine arylamidase, glycine arylamidase, glutamylglutamic acid arylamidase, α-galactosidase, β-galactosidasae-6-phosphate, α-glucosidase, α-fucosidase, urease, arginine dihydrorase, praline arylamidase, pyroglutamic acid arylamidase, tyrosine arylamidase, serine arylamidase, arginine arylamidase, phenylalanine arylamidase, leucine arylamidase, and histidine arylamidase.

Source: feces of a healthy human.

DNA G+C content (mol%): 45.7 (HPLC).

Type strain: ZM35, DSM 17593, JCM 13368.

GenBank accession number (16S rRNA gene): AB233029.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium glycyrrhizinilyticum* to fall within the cluster XIVa of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarity values in the range 95.7–96.8% are *Eubacterium contortum*, *Coprococcus comes*, *Clostridium oroticum*, and *Ruminococcus torques*. *Clostridium glycyrrhizinilyticum* can be differentiated from these related taxa on the basis of its negative result for esculin hydrolysis as well as acid production from a number of substrates.

68. ***Clostridium grantii*** Mountfort, Rainey, Burghardt and Stackebrandt 1996, 625^{VP} (Effective publication: Mountfort, Rainey, Burghardt and Stackebrandt 1994, 178.) grant.i'i. N.L. gen. n. *grantii* pertaining to William Donaldson Grant for his contribution to our understanding of marine polysaccharide degradation.

Slightly curved rod-shaped cells, 0.6 × 3.5–7.0 µm. Obligate anaerobe. Gram-stain-positive. Cell walls are composed of meso-diaminopimelic acid. Motile. Forms spores.

The temperature range for growth is 17–45 °C with an optimum at 30 °C. Growth occurs in the pH range 5.5–8.0 with an optimum at 6.5. The salinity range for growth is 1 to 10/10³. Ferments alginate, cellobiose, glucose, maltose, mannose, and fructose to produce acetate, ethanol, formate, and CO₂. Lactate, propionate, butyrate, succinate, and H₂ are not produced in fermentation. Does not utilize lactose, galactose, sucrose, dulcitol, carrageenan, agar, laminarin, cellulose, xylan, fucoidin, isoleucine, valine, esculin, fumarate, lactate, glycerol, malate, yeast extract, and Casamino acids. Nitrate and sulfate are not reduced.

Source: mullet gut contents.

DNA G+C content (mol%): 30.2 (T_m).

Type strain: A-1, CIP 105529, DSM 8605.

GenBank accession number (16S rRNA gene): X75272.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium grantii* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarity values are *Clostridium ganghwense* (94.4%), *Clostridium hemolyticum* (94.3%), *Clostridium aestuarii* (94.3%), and *Clostridium homopropionicum* (94.3%).

69. ***Clostridium haemolyticum**** (Hall 1929) Scott, Turner and Vawter 1935, 1972^{AL} (*Bacillus hemolyticus* Hall 1929, 156)

hae.mo.ly'ti.cum. Gr. n. *haema* blood; Gr. adj. *lutikos* dissolving; N.L. neut. adj. *hemolyticum* blood-dissolving, hemolytic.

Cells in PYG broth cultures are motile and peritrichous, 0.6–1.6 × 1.9–17.3 µm, and occur singly or in pairs. In very young cultures, they are Gram-stain-positive but they rapidly become Gram-stain-negative. Spores are oval, subterminal, and swell the cell. Sporulation occurs most readily in 2–3-week-old chopped-meat broth cultures or on chopped-meat slants incubated at 30 °C. Cell walls contain meso-DAP, alanine, and glutamic acid.

Surface colonies on blood agar plates are 1–3 mm in diameter, circular, raised to convex, translucent, gray, shiny, with a granular or mosaic surface, and an erose on slightly scalloped margin. Cultures in PYG broth are turbid, usually with a granular or flocculent sediment and have a pH of 5.0–5.5 after incubation for 24 h.

The optimum temperature for growth is 37 °C; growth is slight at 30 °C; there is little or no growth at 25 °C or 45 °C. The organisms are extremely sensitive to oxygen and require both pre-reduced media and stringent anaerobic conditions. Although they grow moderately well in carbohydrate-free media, growth is stimulated by fermentable carbohydrate. Growth is inhibited by 20% bile, 6.5% NaCl, or a pH of 8.5. Moderate gas is detected in PYG deep agar cultures. Small amounts of acid phosphatase are produced. Fermentation products in PYG broth are propionic, butyric, and acetic acids. Lactate is converted to propionate; threonine is converted to propionate by 9 of 12 strains tested; pyruvate is converted to acetate, propionate, and butyrate. Abundant H₂ is produced. All strains tested are susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline; the one strain tested is resistant to >100 µg/ml of metronidazole.

Culture supernatants are toxic to mice and cultures are pathogenic for cattle, sheep, and laboratory animals. The major lethal toxin is a phospholipase C (identical with *Clostridium novyi* beta toxin) which hydrolyzes lecithin and sphingomyelin and hemolyzes red blood cells. The organism produces the beta, eta, and theta toxins of *Clostridium novyi* B but not the alpha (necrotizing) toxin, the major lethal toxin of that species. In susceptible animals, *Clostridium haemolyticum* causes fatal bacillary hemoglobinuria. For a thorough review of the properties of *Clostridium haemolyticum*, its toxins, the disease it causes, and its relationship to *Clostridium novyi* B, see Smith (1975).

Other characteristics of the species are given in Table 142.

Source: liver infections, muscle of cattle and sheep, human feces.

DNA G+C content (mol%): 26–27 (T_m).

Type strain: ATCC 9650, DSM 5565, NCTC 13022.

GenBank accession number (16S rRNA gene): AB037910, Y18173.

Further comments: Based on 16S rRNA gene sequence comparisons, *Clostridium haemolyticum* falls within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarity values are *Clostridium thermobutyricum* (95.6%), *Clostridium thermopalmarium* (95.5%), and *Clostridium homopropionicum* (95.4%).

70. ***Clostridium halophilum*** corrig. Fendrich, Hippe and Gottschalk 1991, 580^{VP} (Effective publication: Fendrich, Hippe and Gottschalk 1990, 131.)

ha.lo'phi.lum. Gr. n. *halos* salt; Gr. adj. *philos* loving; N.L. adj. *halophilum* salt-loving.

Cells are rods, 0.8–1.0 × 2.5–7.0 μm. Strict anaerobe. Chemoorganotroph. Motile. Gram-stain-positive. Halophilic. Form spherical spores that measure 1.2 μm. Temperature range for growth is 18–49 °C with an optimum of 41 °C. Growth occurs in the pH range 6.0–8.0 with an optimum of 7.4.

Ferments D-cellobiose, dulcitol, D-fructose, D-glucose, inulin, D-mannitol, D-mannose, D-ribose, salicin, and D-sorbitol. When grown on pyruvate, cells produce propionate from threonine. Cells undergo the Stickland reaction cleaving betaine into trimethylamine and acetate. Fermentation of complex standard media produces acetate and ethanol. Tween 80 stimulates growth. Cells require 1.5% NaCl for growth, and grow best at 6.0% NaCl. Cells reduce resazurin and neutral red. Esculin is hydrolyzed. Gelatin and starch are not hydrolyzed. Tests negative for catalase, oxidase, lipase, lecithinase, and urease production. Nitrate, sulfate, thiosulfate, or sulfite is not reduced.

Source: anoxic hypersaline sediments of Maledive Islands and Solar Lake Egypt; marine sediments of the North Sea, Germany.

DNA G+C content (mol%): 26.9 (T_m).

Type strain: strain M1, ATCC 49637, DSM 5387.

GenBank accession number (16S rRNA gene): X77837.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium halophilum* to represent a distinct lineage within the cluster XI of the clostridia as defined by Col-

lins et al. (1994). The closest relatives based on sequence similarity values are *Clostridium caminitermale* (92.8%) and *Caminicella sporogenes* (92.7%).

71. ***Clostridium hathewayi*** Steer, Collins, Gibson, Hippe and Lawson 2002, 685^{VP} (Effective publication: Steer, Collins, Gibson, Hippe and Lawson 2001, 356.)

ha.the.way.i. N.L. gen. n. *hathewayi* of Hatheway, to honor the late American microbiologist Charles L. Hatheway in recognition of his outstanding contributions to the *Clostridium botulinum* group of organisms.

Rod-shaped cells with pointed ends, 0.7–1.0 × 2.0–5.0 μm, occurring in chains up to 30 cells. Strict anaerobe. Gram-stain-negative. May or may not be motile. Cells swell to form oval to round, subterminal spores. Some cells form slim capsules. Colonies are 2–3 mm in diameter, opaque, convex, round, and grayish-white in color. Growth occurs in the temperature range 15–45 °C with an optimum of 37 °C. Growth occurs in the pH range 5.0–8.5 with an optimum of 7.0. Growth occurs in the NaCl range 0–2.5%.

Ferments glucose to acetate, ethanol, CO₂, and H₂. Utilizes lactose, cellobiose, fructose, galactose, mannose, ribose, starch, sucrose, rhamnose, raffinose, melezitose, and xylose. Catalase-negative. Hydrolyzes starch and esculin, but not cellulose, gelatin, or urea. Negative for lipase and lecithinase, indole production, and nitrate reduction.

Source: human feces.

DNA G+C content (mol%): 50.7–50.9 (T_m).

Type strain: 1313, DSM 13479, CCUG 43506.

GenBank accession number (16S rRNA gene): AJ311620.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium hathewayi* to fall within cluster XIVa of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarity are *Clostridium celerecrescens* (95.8%), *Clostridium sphenoides* (95.7%), *Clostridium aertolerans* (95.3%), *Clostridium indolis* (95.3%), and *Clostridium saccharolyticum* (95.2%). *Clostridium hathewayi* can be differentiated from these related taxa on the basis of differences in end products of fermentation as well as substrate fermentation tests (Steer et al., 2001).

72. ***Clostridium herbivorans*** Varel, Tanner and Woese 1995, 493^{VP}

her.bi.vo'rans. L. fem. n. *herba* a green plant; L. v. *vorare* to devour; N.L. part. adj. *herbivorans* devouring plants.

Straight rods, 0.7–0.9 × 3.5–4.0 μm. Cells occur singly or in pairs. Motile with 15–20 peritrichous flagella. Gram-stain-positive. Obligate anaerobe. Subterminal to terminal spores are produced rarely. Spores are 1 × 2 μm long and cause the sporangium to swell. Cultures grown on insoluble substrates like cellulose or plant cell walls readily produce spores. The optimum temperature for growth is 39–42 °C and the optimum pH 6.8–7.2.

Fermentable carbohydrates like cellobiose, cellulose, maltose, starch, or glycogen are required for growth. Growth is not supported by amygdalin, arabinose, Casamino acids, erythritol, fructose, glucose, inositol, lactate, lactose, mannitol, mannose, melezitose, melibiose, pectin, pyruvate, raffinose, rhamnose, ribose, salicin, sorbitol, sucrose, trehalose, xylose, and xylan. Ruminant fluid (15%)

and yeast extract (1%) stimulate growth. Does not reduce nitrate or sulfate. Negative for catalase, oxidase, and urease activity. Cannot hydrolyze esculin, lecithin, and gelatin. Meat cannot be digested. Indole is not produced. Cellobiose is fermented to produce formate, butyrate, and little ethanol and hydrogen.

Source: pig intestine contents.

DNA G+C content (mol%): 38 (T_m).

Type strain: strain 54408, ATCC 49925, CIP 104610.

GenBank accession number (16S rRNA gene): L34418.

Further comments: 16S rRNA gene sequence analysis shows *Clostridium herivorans* to fall within cluster XIVa of the clostridia as defined by Collins et al. (1994). This species is phylogenetically distinct from the other cellulolytic species of the genus *Clostridium* and has as its closest relatives *Clostridium polysaccharolyticum* (96.7%) and *Clostridium populeti* (94.6%). *Clostridium herivorans* and *Clostridium polysaccharolyticum* both utilize cellulose, cellobiose, maltose, and starch but do not utilize glucose. They can be differentiated based on the fact that *Clostridium polysaccharolyticum* can utilize arabinose, xylan, and xylose but *Clostridium herivorans* cannot. In addition the DNA G+C content of the two species differs by 4 mol%.

73. ***Clostridium hiranonis*** Kitahara, Takamine, Imamura and Benno 2001, 43^{VP}

hi.ra.no'nis. N.L. masc. gen. n. *hiranonis* of Hirano, after the Japanese microbiologist Seiju Hirano for his contribution to the study of this bacterial isolate.

Straight to slightly curved rods, 0.8 × 1.6–10 μm. Cells occur singly or in pairs. Obligate anaerobe. Gram-stain-positive staining reaction. Colonies on EG blood agar are 1.0–2.0 mm in diameter, disc-shaped, and gray to grayish-white in color. The optimum temperature for growth is 37 °C and the pH 7.5–8.0.

Produces acid from glucose, fructose, mannose, and sucrose. Cannot not produce acid from adonitol, amygdalin, arabinose, cellobiose, dulcitol, erythritol, esculin, galactose, glycerol, glycogen, inositol, inulin, lactose, maltose, mannitol, melezitose, melibiose, raffinose, rhamnose, ribose, salicin, sorbitol, sorbose, starch, trehalose, or xylose. Does not reduce nitrate or sulfate. Cannot produce indole. Does not hydrolyze esculin, gelatin, and starch. Positive for N-acetyl-β-D-glucosamidase and proline aminopeptidase using the ANI-DENT test. Peptone-yeast-extract media produce acetic acid and iso-valeric acid, and small amounts of propionic and isobutyric acid.

Source: healthy human feces.

DNA G+C content (mol%): 31.1 (T_m).

Type strain: TO-931, JCM 10541, DSM 13275.

GenBank accession number (16S rRNA gene): AB023970.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium hiranonis* to fall within the radiation of cluster XI of the clostridia as defined by Collins et al. (1994). The closest relative in cluster XI is *Clostridium sordellii* with 94.8% sequence similarity. The lack of relationship between *Clostridium hiranonis* and *Clostridium sordellii* was demonstrated by DNA–DNA reassociation studies. All other species in cluster XI have <94.8% sequence similarity. *Clostridium hiranonis* and *Clostridium sordellii* both have

7α-dehydroxylating activity but that of *Clostridium sordellii* is low by comparison (Kitahara et al., 2001). The two species can be further differentiated based on indole formation, β-acetyl-β-D-glucosamidase, α-glucosidase, and alkaline phosphatase activities.

74. ***Clostridium histolyticum**** (Weinberg and Séguin 1916) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 328^{AL} (*Bacillus histolyticus* Weinberg and Séguin 1916, 449)

his.to.ly'ti.cum. Gr. n. *histos* tissue; Gr. adj. *lutikos* dissolving; N.L. neut. adj. *histolyticum* tissue-dissolving.

Cells in PYG broth culture usually are motile and peritrichous, straight rods, Gram-stain-positive, 0.5–0.9 × 1.3–9.2 μm, and occur singly, in pairs, or in short chains. Spores are oval, central to subterminal, and may slightly swell the cell. There are no exosporium or appendages. Sporulation of most strains occurs most readily in chopped-meat broth cultures. Cell walls contain meso-DAP, glutamic acid, and alanine.

Surface colonies on blood agar plates incubated anaerobically are β-hemolytic, 0.5–2 mm in diameter, circular to irregular, flat to low convex, translucent to semiopaque, gray-white, shiny, with a mosaic or granular surface, and an entire to undulate margin. Similar colonies are formed on blood agar plates incubated aerobically, but they are usually smaller and fewer in number. Spores are not formed during aerobic growth.

The optimum temperature for growth is 37 °C; most strains grow nearly as well at 30 °C; there is moderate growth at 25 °C but little or none at 45 °C. Although there is no pH depression, growth is stimulated by carbohydrate. Strains grow well at a pH of 8.5 but are inhibited by 6.5% NaCl or by 20% bile. Moderate amounts of gas are detected in PYG deep agar cultures.

Strains are strongly proteolytic, digesting gelatin, meat, milk, casein, collagen, hemoglobin, fibrin, elastin, egg white, coagulated serum, muscle, liver, brain, and Achilles tendon. Deoxyribonuclease is produced by the one strain tested.

The only major product detected in PYG broth is acetate; traces of formate, lactate or succinate are sometimes present. Small amounts of H₂ are produced; ammonia is produced; H₂S is produced by 4 of 12 strains tested. Pyruvate is converted to acetate; neither lactate nor threonine is converted to propionate. Threonine is utilized, but the product is acetate. Glycine, glutamate, serine, aspartate, and arginine are utilized as sources of energy; valine, leucine, isoleucine, lysine, proline, and alanine are produced. Glycine is fermented to acetate, CO₂, and NH₃.

Only straight-chain fatty acids, principally saturated C₁₄, C₁₂, C₁₆, and C₁₈ acids with small amounts of unsaturated acids of the same chain length are present in cells of this species. All strains tested are susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Under anaerobic conditions, strains are susceptible to 0.5–1.0 μg/ml of metronidazole. As the O₂ level increases, they are increasingly resistant.

Supernatant culture fluids are toxic to mice, although the degree of toxigenicity varies among strains and may be lost on subculture. In addition, as the culture ages, the

active proteases of the organism may destroy the toxins. *Clostridium histolyticum* is highly pathogenic to laboratory animals. Toxin found in fecal samples from guinea pigs with clindamycin-associated enterocolitis is neutralized by specific antitoxin to *Clostridium histolyticum*. Major lethal toxins are the α -toxin (necrotizing) and at least two collagenases (β -toxin). Collagenase from atoxic *Clostridium histolyticum* strains has been used to digest and remove necrotic tissue from burns. Other characteristics of the species are given in Table 142. Principal habitat is probably the soil.

Source: soil, war wounds, gas gangrene in humans and horses, human intestinal contents; gingival plaque of institutionalized and primitive populations.

DNA G+C content: not reported.

Type strain: ATCC 19401, BCRC 10644, CCUG 4854, CIP 103713, CN 1693, DSM 2158, JCM 1403, NCIMB 503, NCTC 503.

GenBank accession number (16S rRNA gene): M59094.

Further comments: 16S rRNA gene sequence comparisons show that *Clostridium histolyticum* clusters with *Clostridium limosum* (97.2%) and *Clostridium proteolyticum* (96.1%) in cluster II of the clostridia as defined by Collins et al. (1994). *Clostridium histolyticum* can be differentiated readily from *Clostridium limosum*, which it resembles most closely phenotypically, by its production of collagenase and lack of production of lecithinase. Unlike other aerotolerant clostridia, it is extremely proteolytic and does not ferment any carbohydrates tested. Unlike *Clostridium irregulare* it produces only acetic acid in broth cultures.

75. ***Clostridium homopropionicum*** Dörner and Schink 1991, 580^{VP} (Effective publication: Dörner and Schink 1990, 347.)

ho.mo.prop.ion'ic.um. Gr. adj. *homoios* similar; M.L. n. *acidum propionicum* prionic acid; *homopropionicum* referring to metabolic analogy to *Clostridium propionicum*.

Straight rods with rounded ends, 1.2–1.5 × 5.5–10 μ m; occur singly or in pairs. Motile with peritrichous flagella. Strict anaerobe. Chemorganotroph. Gram-stain-negative. KOH test negative. Form spherical terminal to subterminal spores, usually after growth with pyruvate, lactate, or in agar medium. Growth with lactate produces dark inclusions. Growth occurs in the temperature range 4–32 °C with an optimum at 28 °C. pH Range for growth is 6.0–8.5 with an optimum at 7.0.

Fermentation of fructose produces acetate, butyrate, butanol, and H₂. Ferments 2-, 3-, and 4-hydroxybutyrate, 4-chlorobutyrate, crotonate, vinylacetate, and pyruvate to acetate and butyrate. Acetate and propionate are fermentation products of lactate and acrylate. Does not utilize glucose, arabinose, xylose, ethanol, glycerol, 2-aminobutyrate, 4-aminobutyrate, α -alanine, β -alanine, β -hydroxypropionate, serine, aspartate, phenylalanine, malate, fumarate, succinate, mandelate, glycolate, ethylene glycol, trimethoxybenzoate, acetoin, and H₂/CO₂. Does not hydrolyze gelatin. Nitrogen is fixed. Cells do not reduce nitrate, nitrite, sulfite, sulfur, or thiosulfate. Fresh water media produce optimal growth. Cells contain no cytochromes.

Source: anoxic digester sludge.

DNA G+C content (mol%): 32 (*T_m*).

Type strain: LuHBu1, ATCC 51426, DSM 5847.

GenBank accession number (16S rRNA gene): X76744.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium homopropionicum* to fall within cluster I as defined by Collins et al. (1994). The closest relatives based on sequence similarity values are *Clostridium thermopalmarium* (95.5%), *Clostridium thermobutyricum* (95.3%), and *Clostridium hemolyticum* (95.3%).

76. ***Clostridium hungatei*** Monserrate, Leschine and Canale-Parola 2001, 130^{VP}

hun.gat'e.i. N.L. gen. n. *hungatei* of Hungate, named after R.E. Hungate, who pioneered the study of the ecology of cellulolytic bacteria.

Slightly curved rods, 0.5 × 2.0–6.0 μ m. Motile with sub-polar flagella. Obligately anaerobic. Gram-stain-negative. Form round terminal spores, 0.8–1.0 μ m. Surface colonies are circular, smooth, slightly raised, unpigmented, and measure 1–2mm in diameter. Optimum temperature for growth is 30–40 °C. Growth occurs at 45 °C but not at 15 or 50 °C. Optimum pH for growth is 7.2.

Cellulolytic. Fixes nitrogen. Utilizes carbohydrates as energy sources. Ferments cellulose, cellobiose, cellotriose, cellotetraose, cellopentaose, D-glucose, D-fructose, D-mannose, D-xylose, xylan, and gentiobiose. Does not ferment D-ribose, sucrose, maltose, lactose, glycerol, starch, pectin, and polygalacturonic acids. Ferments cellulose producing H₂, CO₂, acetate, ethanol, lactate, and formate. Cells produce an extracellular cellulase system producing a large protein. Vitamins or fatty acids are not required. Grows with rifampin, streptomycin, penicillin, erythromycin, and vancomycin. Growth is inhibited by tetracycline, ampicillin, kanamycin, neomycin, or chloramphenicol.

Source: moist rich soil in decaying plant material.

DNA G+C content (mol%): 40 (*T_m*).

Type strain: AD, ATCC 700212, DSM 14427.

GenBank accession number (16S rRNA gene): AF020429.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium hungatei* to fall within the radiation of cluster III of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarity are *Clostridium josui* (97.4%), *Clostridium termitidis* (97.1%), *Clostridium cellulolyticum* (97.1%), *Clostridium cellobioparum* (96.9%), and *Clostridium papyrosolvens* (96.4%). *Clostridium hungatei* can be differentiated from these related species based on phenotypic characteristics including Gram staining reaction, flagellar arrangement, and substrate utilization patterns.

77. ***Clostridium hylemonae*** Kitahara, Takamine, Imamura and Benno 2000, 977^{VP}

hai.le.mon'ae. N.L. gen. n. *hylemonae* of Hylemon, after the American microbiologist Phillip B. Hylemon, for his contributions to research on bile acid.

Straight to slightly curved rods, 0.2–0.5 × 1.0–5.3 μ m, occur singly or in pairs. Gram-stain-positive. Obligate anaerobe. Nonmotile. Form spores. Colonies are disc-shaped, gray, and 0.5–1.0mm in diameter. The optimum temperature for growth is 37 °C. Optimum pH for growth is 7.6.

Fermentation of peptone with yeast extract and glucose produces acetic, butyric, propionic, isobutyric, and iso-valeric

acids. Two strains ferment galactose to acid. Variable reactions with arabinose, fructose, maltose, ribose, and xylose. None of the strains produce acid from adonitol, amygdalin, cellobiose, dulcitol, erythritol, esculin, glycerol, glycogen, inositol, inulin, lactose, mannitol, mannose, melezitose, melibiose, rhamnose, salicin, sorbitol, sorbose, starch, or trehalose. H₂S and gas are produced. Does not reduce sulfate or nitrate. Does not hydrolyze gelatin, esculin, or starch. Indole not produced. *Source*: healthy adult human feces.

DNA G+C content (mol%): 48.6 (T_m).

Type strain: TN-271, CIP 106689, DSM 15053, JCM 10539.

GenBank accession number (16S rRNA gene): AB023972.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium hylemonae* to fall within the radiation of cluster XIVa as defined by Collins et al. (1994). Previous studies have concentrated on the comparison of *Clostridium hylemonae* and *Clostridium scindens* (Kitahara et al., 2000). However, the 16S rRNA gene sequence similarity between these two species is only 93.2%. Sequence similarities in the range 93.5–94.5% are found with a number of non-clostridial genera in this heterogeneous cluster.

78. *Clostridium indolis** McClung and McCoy 1957, 674^{AL}

in.do'lis. N.L. gen. n. *indolis* of indole.

Cells in PYG broth cultures are motile and peritrichous, straight to slightly curved rods, 0.5–0.9 × 1.3–10.2 μm, and occur singly and in pairs. They are Gram-stain-negative in 24 h. Spores are round to oval, swollen, and usually terminal, although subterminal spores are sometimes seen in the same preparation. Spores have no exosporium and no appendages. Sporulation occurs most readily on chopped-meat slants incubated at 30 °C.

Cell walls contain *meso*-DAP. Surface colonies on blood agar plates are nonhemolytic, 0.5–3.0 mm in diameter, circular to slightly irregular, convex, translucent to opaque, white, with a dull, granular surface and an entire to erose margin. Cultures in PYG broth are turbid with a smooth sediment and have a pH of 5.3–5.7 after incubation for 3 d.

Optimum temperature for growth is 37 °C; most strains grow nearly as well at 30 °C; growth is poor at 25 °C and there is little or no growth at 45 °C. Growth is stimulated by fermentable carbohydrate but inhibited by 20% bile or 6.5% NaCl. Abundant gas is detected in PYG deep agar cultures. More than 30% of strains tested can dehydrogenate the steroid nucleus. Polypectate is liquefied; pectin, pectate, and galacturonate are fermented. Citrate is not utilized.

Ammonia and H₂S are produced. Neutral red and resazurin are reduced. Of five strains tested, two produce acetyl methyl carbinol and hydrolyze hippurate.

Products in PYG broth include acetate, formate, and ethanol. Abundant H₂ is detected. Pyruvate is converted to acetate, formate, ethanol, and moderate amounts of butyrate; neither lactate nor threonine is utilized. Galacturonate is converted to acetate, butyrate, CO₂, and H₂. Of five strains tested, three are susceptible to chloramphenicol, four to clindamycin, four to erythromycin, four to tetracycline, and two to penicillin G. Culture supernatant fluids are nontoxic to mice.

Other characteristics of the species are given in Table 142.

Source: soil, human feces, and human clinical specimens from infections associated with the intestinal tract.

DNA G+C content (mol%): 44 (T_m).

Type strain: ATCC 25771, DSM 755, JCM 1380, NCTC 11811.

GenBank accession number (16S rRNA gene): Y18184.

Further comments: *Clostridium indolis* falls within the radiation of cluster XIVa of the clostridia as defined by Collins et al. (1994). The closest relative based on sequence similarity values is *Clostridium methoxybenzovorans* (99.4%). Other species showing similarity values in the range 98.4–98.5% include *Clostridium celerecrescens*, *Clostridium saccharolyticum*, *Clostridium amygdalium*, and *Clostridium sphenoides*.

Clostridium indolis can be differentiated from *Clostridium sphenoides*, which it resembles most closely phenotypically, by the terminal spores that are produced by all strains; spores of *Clostridium sphenoides* are subterminal. The electrophoretic patterns of soluble cellular proteins of the two species are distinctive. In addition, strains of *Clostridium sphenoides* can ferment citrate with the production of acetate and ethanol, while strains of *Clostridium indolis* do not utilize citrate.

79. *Clostridium innocuum** Smith and King 1962, 939^{AL}

in.noc'u.um. L. neut. adj. *innocuum* harmless.

Cells in PYG broth cultures are Gram-stain-positive, non-motile, straight rods with round or tapered ends, 0.4–1.6 × 1.6–9.4 μm. Sporulating cells tend to be among the larger ones. Cells occur singly or in pairs. Spores are oval, terminal, subterminal, or free and wider than the cell. Sporulation usually occurs readily in chopped-meat broth cultures incubated for 24 h or on egg-yolk agar plates incubated for 48–72 h.

Cell walls contain glucose and galactose but no DAP. They contain a lysine-alanine type of peptidoglycan.

Surface colonies on blood agar plates are 0.5–3 mm in diameter, circular, raised or convex, translucent, gray-white or yellowish, smooth, and shiny, with a mottled or mosaic internal structure and an entire or slightly scalloped margin. Hemolysis is variable between strains. Cultures in PYG broth are turbid with a smooth sediment and a pH of 4.7–5.2 after incubation for 24 h.

Optimum temperature for growth is 37 °C although many strains grow equally well at 25 °C, 30 °C, and 45 °C. Growth is stimulated by fermentable carbohydrate but inhibited by 6.5% NaCl. Abundant gas is detected in PYG deep agar cultures. Neither gelatin, milk, casein, nor meat is digested. Milk may be weakly acidified. Bacteriocin-like particles have been demonstrated in one strain of *Clostridium innocuum*, but no inhibitory activity was found against any strain tested.

Products in PYG broth are butyric, lactic, and acetic acids; small amounts of formic or succinic acids may be detected. Abundant H₂ is produced. Pyruvate is converted to acetate, butyrate, and sometimes formate. Neither lactate nor threonine is utilized. Ethanol has been detected by high performance liquid chromatography PYG broth cultures. Susceptibility to chloramphenicol, clindamycin, erythromycin,

penicillin G, and tetracycline is variable among strains; two strains tested were susceptible to 1.6 µg/ml of metronidazole. Supernatant culture fluids are not toxic to mice, and cultures are not pathogenic in laboratory animals.

Other characteristics of the species are given in Table 144.

Source: human infections, particularly those associated with the intestinal tract; empyema fluids; normal intestinal flora of human infants and adults.

DNA G+C content (mol%): 43–44 (T_m).

Type strain: ATCC 14501, CCUG 36763, BCRC (formerly CCRC) 14517, DSM 1286, JCM 1292, NCIMB 10674.

GenBank accession number (16S rRNA gene): M23732.

Further comments: 16S rRNA gene sequence analysis shows *Clostridium innocuum* to fall with cluster XVI of the clostridia as defined by Collins et al. (1994). This species shows sequence similarity value of 94.0 and 93.1% to two *Eubacterium* species, *Eubacterium dolichum* and *Eubacterium tortuosum*. All other taxa show less than 90.0% sequence similarity with *Clostridium innocuum*.

80. ***Clostridium intestinale*** corrig. Lee, Fujisawa, Kawamura, Itoh and Mitsuoka 1989, 335^{VP}

in.test.in.al'e. N.L. neut. adj. *intestinale* pertaining to the intestine.

Straight to slightly curved rods, 0.3–0.4 × 1.4–5.4 µm; occur singly, in pairs, or short chains. Aerotolerant, although cultures grow better anaerobically. Motile with peritrichous flagella. Gram-stain-positive. Form large, terminal, slightly oval spores under anaerobic conditions, measuring 0.1–1.1 × 1.5–2.0 µm. Colonies are circular, convex, rough, translucent, undulate, grayish-white in color, β-hemolytic, and 2–4 mm in diameter under anaerobic conditions. Under aerobic conditions, colonies are circular, convex, smooth, translucent, yellowish white in color, and 1 mm in diameter.

Optimum temperature for growth is 37 °C. Ferments glucose, mannose, fructose, galactose, sucrose, cellobiose, lactose, trehalose, mannitol, sorbitol, salicin, and amygdalin. Does not ferment arabinose, xylose, rhamnose, sorbose, ribose, maltose, melibiose, raffinose, melezitose, starch, glycogen, inulin, glycerol, erythritol, inositol, adonitol, dulcitol, and esculin. Cells produce gas. Fermentation products include acetic acid and butyric acid, with some lactic, formic, and succinic acid. Does not reduce sulfate or nitrate. Hydrolyzes esculin but not starch. Tests negative for catalase, lipase, and lecithinase activity. Does not produce indole.

Source: feces of cattle and pigs.

DNA G+C content (mol%): 26–28 (T_m).

Type strain: Catt39, ATCC 49213, DSM 6191, JCM 7506.

GenBank accession number (16S rRNA gene): X76740.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium intestinale* to fall within cluster I of the clostridia as defined by Collins et al. (1994). Sequence similarity values in the range 94.0–94.9 are found between *Clostridium intestinale* and the species *Anaerobacter polyendosporus*, *Eubacterium tarantellae*, *Clostridium fallax*, and *Clostridium sartagoforme*.

81. ***Clostridium irregulare**** corrig. (Choukévitch 1911) Prévot 1938, 85^{AL} (*Bacillus irregularis* Choukévitch 1911, 348)

ir.reg.u.lar'e. L. neut. adj. *irregulare* irregular, referring to pleomorphic, irregular cells.

Cells in PYG broth culture are Gram-stain-positive, straight to slightly curved rods, motile and peritrichous, and 0.8–1.6 × 3.5–12.6 µm. Cells in week-old cultures may be quite filamentous. They occur singly, in pairs, or in short chains. Spores are oval, central, or subterminal and swell the cell. Sporulation occurs most readily on chopped-meat agar slants incubated at 30 °C.

Surface colonies on blood agar plates are nonhemolytic, pinpoint–0.5 mm, circular to irregular, convex, transparent to translucent, colorless, with a granular or mottled surface and an entire or scalloped margin.

Cultures in PY-glucose broth are turbid with a smooth orropy sediment and have a pH of 6.0–6.3 after incubation for 4 d. The optimum temperature for growth is between 30 °C and 37 °C. There is little or no growth at 25 °C or 45 °C. Growth is inhibited by 6.5% NaCl and by 20% bile. No gas is detected in PYG deep agar cultures. H₂S is formed in SIM medium. Ammonia is produced. Gelatin is digested but not milk, casein, or meat. The type strain contains a 3-α-hydroxysteroid dehydrogenase. Products detected in PYG broth are acetate and isovalerate; formate, isobutyrate, and propionate also may be detected. H₂ is not formed. Pyruvate is converted to acetate and formate. Neither lactate nor threonine is utilized.

All strains are susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline.

Supernatant culture fluids are nontoxic for mice, and cultures are not pathogenic for laboratory animals.

Other characteristics of the species are given in Table 145.

Source: normal fecal flora of humans and horses, pond mud, pharmaceutical products prepared in a laboratory adjacent to a stable, human penile lesions, soil.

DNA G+C content (mol%): not reported.

Type strain: ATCC 25756, DSM 2635, JCM 1425.

GenBank accession number (16S rRNA gene): X73447.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium irregulare* to fall within the radiation of cluster XI of the clostridia as defined by Collins et al. (1994). The closest relatives are *Clostridium mayombei* (97.4%), *Clostridium lituseburense* (96.5%), *Clostridium glycolicum* (96.3%), and *Clostridium bartlettii* (96.2%).

82. ***Clostridium isatidis*** Padden, Dillion, Edmonds, Collins, Alvarez and John 1999, 1030^{VP}

i.sa'ti.dis. L. gen. n. *isatidis* of crucifer plant *Isatis*.

Rod-shaped cells, 0.3–0.6 × 1.8–9.1 µm. Cells occur singly, in pairs, or in chains. Gram-stain-positive. Motile. Anaerobic. Produce terminal oval endospores. Colonies are mucoid, white, circular, and convex or raised to a central point. The temperature range for growth is 30–55 °C with an optimum of 49–52 °C. The pH range for growth is 5.6–9.9 with an optimum of 7.2.

Produces acid from amygdalin, cellobiose, fructose, galactose, glucose, maltose, mannose, salicin, sorbitol, sucrose, starch, and trehalose. Arabinose, glycogen, inulin, lactose, mannitol, melezitose, raffinose, rhamnose, ribose, and xylose are not utilized. Nitrate is not reduced.

Growth on PYG produces acetic, lactic, and formic acids with ethanol, carbon dioxide, and hydrogen. Indole is not produced. Hydrolyze esculin. Lectinase-negative. Meat is not digested.

Source: a woad vat.

DNA G+C content (mol%): 27 (T_m).

Type strain: Wv6, CIP 107118, DSM 15098, NCIMB 703071.

GenBank accession number (16S rRNA gene): X98395.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium isatidis* to fall within the cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarity values are *Clostridium carnis* (97.6%), *Clostridium tertium* (97.4%), *Clostridium celatum* (97.4%), *Clostridium sartagoforme* (97.2%), and *Clostridium septicum* (97.1%). *Clostridium isatidis* can be differentiated from *Clostridium carnis* on the basis of differences in antibiotic resistances and substrate utilization patterns. In addition, *Clostridium carnis* produces butyrate as an end product of fermentation while *Clostridium isatidis* does not.

83. ***Clostridium jejuense*** Jeong, Yi, Sekiguchi, Muramatsu, Kamagata and Chun 2004, 1467^{VP}

je.ju.en'se. N.L. neut. adj. *jejuense* pertaining to Jeju Island, Korea, geographical origin of the type strain of the species.

Straight to slightly curved rods, 0.5 × 1.8–4.5 μm, with peritrichous flagella. Gram-stain-positive. Strictly anaerobic, mesophilic. Oval to almost spherical terminal endospores. Colonies on RC agar plates are 1.0–2.5 mm in diameter, circular, entire, flat, translucent to opaque, grayish, and smooth after 72 h.

The temperature range for growth is 10–40 °C with an optimum at 30 °C. The pH range for growth is 5.5–9.5 with an optimum at pH 7.0. Growth occurs at NaCl concentrations of 0–0.5% (w/v). Under optimum conditions, the doubling time is 10.5 hours. Utilizes D-cellobiose, D-glucose, lactose, D-maltose, D-mannose, sucrose, D-trehalose, D-fructose, D-galactose, D-ribose, L-arabinose, D-raffinose, D-xylose, and cellulose, but not D-sorbitol, D-mannitol, peptone (0.1%, w/v), or yeast extract (0.2%, w/v). Fermentation end products from glucose include pyruvate, lactate, acetate, formate, and H₂. Catalase- and indole-negative. Esculin is hydrolyzed, but gelatin and urea are not.

Source: soil in Jeju, Korea.

DNA G+C content (mol%): 41 (HPLC).

Type strain: HY-35-12, DSM 15929, IMSNU 40003, KCTC 5026.

GenBank accession number (16S rRNA gene): AY494606.

Further comments: 16S rRNA gene sequence comparison shows *Clostridium jejuense* to fall within the radiation of cluster XIVa as defined by Collins et al. (1994). The closest relatives based on sequence similarities are *Clostridium xylanovorans* (96.6%), *Clostridium aminovalericum* (95.4%), *Clostridium populeti* (93.8%), and *Clostridium amygdalinum* (93.6%). *Clostridium jejuense* can be differentiated from *Clostridium xylanovorans* on the basis of its catalase-negative reaction, utilization of arabinose and xylose but not mannitol. Differentiation of *Clostridium jejuense* from *Clostridium aminovalericum* can be made on the basis of utilization of lactose and D-raffinose but not D-sorbitol, D-mannitol, and yeast extract.

84. ***Clostridium josui*** Sukhumavasi, Ohmiya, Shimizu and Ueno 1988, 180^{VP}

jo.su'i. N.L. *josui* the first four letters were obtained by combining the initial letters of the names of the authors, and the last letter was added according to the requirements of the *International Code of Nomenclature of Bacteria*.

Rod-shaped cells slightly curved at the end, 0.2–0.3 × 3–5 μm, found singly, or long or short chains. Nonmotile. Anaerobic. Gram-stain-positive, but becomes Gram-stain-negative. Cells swell and form terminal oval spores 0.4–0.5 μm in diameter. Cultures show a clear zone of 10 mm around each colony within 3 d on BMC media. Deep colonies are yellow and spindle shaped. The temperature range for growth is 25–60 °C with an optimum of 45 °C. No growth below 20 °C or above 65 °C. The optimum pH for growth is 7.0. After 3 d of incubation the pH is changed from 7.0 to 5.5–5.1.

Cellulolytic. Does not grow on adonitol, amygdalin, bile, dulcitol, dextrin, erythritol, fructose, galactose, glycerol, glycogen, inositol, inulin, mannitol, mannose, melezitose, pectin, raffinose, rhamnose, salicin, sorbitol, sorbose, starch, sucrose, or trehalose. Esculin is hydrolyzed; starch is not. Tests indole- and nitrate-negative. Casein is not digested, and gelatin is not liquefied. Does not produce lecithinase and lipase. Growth on cellulose produces acetate, ethanol, CO₂, and H₂, with traces of propionate and butyrate.

Source: a compost in Thai.

DNA G+C content (mol%): 40 (T_m).

Type strain: strain III, FERM P-9684.

GenBank accession number (16S rRNA gene): AB011057.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium josui* to fall within the radiation of cluster III of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarity values are *Clostridium papyrosolvans* (98.5%) and *Clostridium cellulolyticum* (98.1%). Similarity values in the range 97.4–97.6% are found with the species *Clostridium termitidis*, *Clostridium hungatei*, and *Clostridium cellobioparum*. *Clostridium josui* can be differentiated from *Clostridium papyrosolvans* and *Clostridium cellulolyticum* on the basis of its higher optimum growth temperature as well as Gram-stain-positive staining in young cultures, lack of motility, and utilization of lactose and maltose. The end products of fermentation also differentiate *Clostridium josui* from its closest phylogenetic relatives.

85. ***Clostridium kluyveri***^{*} Barker and Taha 1942, 362^{AL}

kluy'ver.i. N.L. gen. n. *kluyveri* of Kluyver, named for A.J. Kluyver, Dutch microbiologist.

Cells in medium containing 20% yeast autolysate, 0.5% ethanol, and inorganic salts are motile and peritrichous, 0.9–1.1 × 3–11 μm, and usually occur singly, occasionally in pairs, or chains. They are weakly Gram-stain-positive, but quickly become Gram-stain-negative. Spores are oval, terminal, or subterminal and swell the cell.

Ultrastructural studies have demonstrated a five-layered cell wall and a three-layered plasma membrane. Cell walls contain meso-DAP.

Surface colonies on blood agar plates are nonhemolytic, pinpoint–0.5 mm in diameter, gray, with rhizoid margins. In laked blood streak tubes, colonies are low convex, gray-white, shiny, and smooth, with a scalloped margin and a

mosaic internal structure. There is no growth on egg-yolk agar plates. Cultures in PYG-1.5% ethanol broth have a stringy sediment and no turbidity after 5 d incubation in a 90% N₂-10% CO₂ atmosphere, and the pH is 6.8.

The optimum temperature for growth is 35 °C. Growth is slow and occurs between 19 °C and 37 °C. Strains require ethanol, CO₂, or sodium carbonate, and either a high concentration of yeast autolysate or acetate, propionate, or butyrate for growth. A synthetic medium containing inorganic salts, acetate, ethanol, biotin, and *p*-aminobenzoic acid will support growth. Small amounts of gas are detected in PYG deep agar cultures. Urease is produced; gelatin is not hydrolyzed; carbohydrates are not attacked.

In the presence of CO₂ or carbonate and acetate or propionate, ethanol is converted to butyrate, caproate, and H₂. H₂ gas is formed and small amounts of butyrate may be detected. Neither pyruvate, lactate, nor threonine is utilized. *Clostridium kluyveri* can be adapted to utilize crotonate and produce acetate, butyrate, and caproate.

The type strain is susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Other characteristics of the species are given in Table 142.

Source: fresh water, marine black mud, decaying plants, garden soil.

DNA G+C content (mol%): 30 (*T_m*).

Type strain: ATCC 8527, DSM 555, NBRC 12016, NCIMB 10680, NCCB 72061, NCCB 46095.

GenBank accession number (16S rRNA gene): M59092.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium kluyveri* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarities are *Clostridium ljungdahlii* (93.4%) and *Clostridium tyrobutyricum* (93.1%). This species is distinctive both in its nutritional requirements and in its ability to ferment ethanol to caproate.

86. ***Clostridium lactatifermentans*** van der Wielen, Rovers, Scheepens and Biesterveld 2002, 925^{VP}

lac.ta'ti.fer.men.tans. N.L. n. *lactas -atis* lactate; L. part. adj. *fermentans* fermenting; N.L. adj. *lactatifermentans* fermenting lactate.

Tapered rods, 2.8–10 × 1.1–1.3 μm wide. Gram-stain-negative, but Gram-positive cell-wall structure. Nonmotile. Nonsporeforming. Obligate anaerobe. Chemoorganoheterotroph. Temperature range for growth is 30–47 °C with an optimum of 41 °C. Growth occurs in the pH range 5.6–8.3 and optimally at pH 6.4–7.3.

Produces acetate, propionate, butyrate, and isovalerate from glucose and lactate. Utilizes glucose, xylose, pyruvate, DL-lactate, L-alanine, L-serine, L-cysteine, and L-threonine. Slow growth on L-valine, L-leucine, L-isoleucine, and L-aspartate. Does not utilize cellobiose, melibiose, raffinose, sorbitol, lactose, arabinose, starch, succinate, ethanol, acrylate, L-proline, L-lysine, L-arginine, or glycine. Hydrolyzes gelatin, but not esculin or urease. Negative for indole and catalase.

Source: ceca of a 31-d-old broiler chicken.

DNA G+C content (mol%): 44.6 (*T_m*).

Type strain: G17, DSM 14214, LMG 20954.

GenBank accession number (16S rRNA gene): AY033434.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium lactatifermentans* to fall within the radiation of cluster XIVb of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarities are *Clostridium neopropionicum* (94.8%) and *Clostridium propionicum* (94.7%). *Clostridium lactatifermentans* can be differentiated from its closest relatives on the basis of its ability to utilize glucose and xylose but not ethanol and acrylate. In addition, *Clostridium lactatifermentans* does not form spores, has a higher optimum growth temperature and DNA G+C content than its phylogenetic relatives.

87. ***Clostridium lacusfryxellense*** Spring, Merkhoffer, Weiss, Kroppenstedt, Hippe and Stackebrandt 2003, 1027^{VP}

la'cus.fry.xel.len'se. N.L. neut. adj. *lacusfryxellense* of Lake Fryxell, the lake in Antarctica from which the type strain was isolated.

Rod-shaped, 1.0–1.2 × 2.2–5.0 μm, occur singly, in pairs, or short chains. Gram-stain-positive. Motile by peritrichous flagella. Spherical to slightly ellipsoidal endospores, located at a terminal to subterminal position; sporangium is not swollen. Colonies on sheep-blood agar are 1–2 mm in diameter, round with often coarsely granulated margins, smooth, slightly raised, cream-white to grayish, semi-transparent to opaque, and nonhemolytic. The cell-wall peptidoglycan contains *meso*-diaminopimelic acid. The major cellular fatty acids are C_{16:1 ω9c}, C_{16:1 DMA ω9c}, C_{14:0}, C_{16:1 ω7c}, C_{16:0} and C_{16:1 ω11c}.

Temperature optimum for growth is in the range 8–12 °C with an upper limit of 15 °C. The pH range for growth is 6.0–7.3 with optimal grow at pH 6.6–7.1. Under optimal conditions, the doubling time is 10.7 hours.

Carbohydrates utilized include amygdalin, cellobiose, fructose, galactose, glucose, glycogen, inositol, inulin, lactose, mannitol, melezitose, melibiose, raffinose, ribose, salicin, starch, sucrose, trehalose, and xylose. Carbohydrates not utilized include arabinose, maltose, mannose, rhamnose, and sorbitol. Gelatin and starch are not hydrolyzed. End products of fermentation are butyrate, formate, acetate, lactate, ethanol, H₂, and CO₂.

Source: a microbial mat sample taken from a moated area around Lake Fryxell, Antarctica.

DNA G+C content (mol%): 32.1 (HPLC).

Type strain: C/C-an/B1, ATCC BAA-580, DSM 14205.

GenBank accession number (16S rRNA gene): AJ506118.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium lacusfryxellense* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives of *Clostridium lacusfryxellense* are the two subspecies of *Clostridium estertheticum* (99.7%), *Clostridium frigoris* (98.9%), *Clostridium bowmanii* (98.8%), and *Clostridium psychrophilum* (97.5%). DNA-DNA reassociation studies show *Clostridium lacusfryxellense* to represent a distinct species even though the 16S rRNA gene sequence similarity values are 99.7% with the subspecies of *Clostridium estertheticum*. At the phenotypic level *Clostridium lacusfryxellense* can be differentiated from the two subspecies of *Clostridium estertheticum* on the basis of having spherical spores and utilizing amygdalin, lactose, ribose, and trehalose but not starch.

88. **Clostridium lentocellum** Murray, Hofmann, Campbell and Madden 1987, 179^{VP} (Effective publication: Murray, Hofmann, Campbell and Madden 1986, 182.)

lent.to.cel'lum. L. adj. *lentus* slow; N.L. n. *cellulosum* cellulose; N.L. adj. *lentocellum*.

Slightly curved rods, 0.3–0.5 × 2.5–4.0 μm, found singly. Strict anaerobe. Gram-stain-negative. Motile, with fimbriae located at the cell end. Cells form round terminal spores. Colonies are flat, colorless, transparent, have undulate margins, and measure 7–10 mm in diameter. Colonies are cellulolytic.

The temperature range for growth is 15–46.5 °C with an optimum at 40 °C. Growth occurs in the pH range 5.7–9.13 with an optimum at 7.5–7.7.

Ferments cellulose to produce ethanol, acetic acid, hydrogen, and carbon dioxide. Utilizes arabinose, cellobiose, cellulose, esculin, fructose, galactose, glucose, glycogen, lactose, maltose, pyruvate, salicin, sucrose, trehalose, xylose, xylan, milk, starch, bile, and chopped meat for growth. Does not utilize adonitol, amygdalin, arginine, dulcitol, erythritol, glycerol, hippurate, inositol, inulin, lactate, mannitol, mannose, malezitose, melibiose, raffinose, rhamnose, ribose, sorbitol, sorbose, and threonine. Bile inhibits growth. Hemin, vitamin K, and rumen fluid stimulate growth. Cells weakly produce urease, but do not produce indole, catalase, or gelatinase. Sulfate and nitrate are not reduced. Acetylmethylcarbinol is produced.

Source: an estuarine mud bank or a river that was fed with paper-mill and domestic effluent.

DNA G+C content (mol%): 36 (T_m).

Type strain: RHM5, ATCC 49066, DSM 5427, NCIMB 11756.

GenBank accession number (16S rRNA gene): X71851, X76162.

Further comments: When first described, this species was compared at the phenotypic level with other cellulolytic species of the genus *Clostridium* described at that time. The availability of the 16S rRNA gene sequence of this strain showed it to be unrelated to other cellulolytic *Clostridium* species and to represent a distinct lineage within cluster XIVb of the clostridia as defined by Collins et al. (1994). The 16S rRNA gene sequence of *Clostridium lentocellum* shares less than 90% sequence similarity with any other described species.

89. **Clostridium leptum*** Moore, Johnson and Holdeman 1976, 250^{AL}

lep'tum. Gr. adj. *leptos* thin, delicate; N.L. neut. adj. *leptum* (referring to the morphological appearance of the cells).

Cells in PY-fructose broth cultures are nonmotile, slightly curved, Gram-stain-positive rods, 0.6–0.8 × 1.3–2.8 μm, that occur in pairs or short chains. Spores are oval, nearly terminal, and rarely seen. Heat-resistant cells can be demonstrated from chopped-meat slants incubated at 30 °C for 3 weeks, inoculated into PY-maltose broth, and heated at 80 °C for 10 min. Cell walls contain a lysine-serine-glycine type of peptidoglycan.

Surface colonies on supplemented brain heart infusion roll streak tubes are pinpoint–0.5 mm in diameter, circular, entire, low convex, tan, and translucent. Neither of the 2 of

8 strains tested that grew on the surface of anaerobic blood agar plates was hemolytic. Neither lecithinase, lipase, nor urease was detected from the 5 of 8 strains tested that grew on anaerobic egg-yolk agar plates.

Cultures in PY-maltose broth usually produce a smooth to stringy sediment with little or no turbidity and have a pH of 5.3–5.8 after incubation for 5 d. The optimum temperature for growth is 37 °C; some strains grow at 30 °C and 45 °C. Growth is markedly stimulated by some carbohydrates (glucose, cellobiose, mannitol, ribose) although there is little or no depression of pH of the medium. Growth is inhibited by 6.5% NaCl and by 20% bile. Traces of gas may be detected in PYG deep agar cultures. Glucose may be fermented weakly. A 7 α-dehydroxylase and a 12 α-hydroxysteroid dehydrogenase that may be significant in the breakdown of bile acids in the human colon have been isolated from a strain of this species. Products in PY-maltose broth are acetic acid and abundant H₂; ethanol also may be detected. Neither lactate nor pyruvate is utilized. Other characteristics of the species are given in Table 143.

Source: human feces and colonic contents.

DNA G+C content (mol%): 51–52 (T_m).

Type strain: ATCC 29065, CCUG 48287, DSM 753.

GenBank accession number (16S rRNA gene): AJ305238, M59095.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium leptum* to fall within the radiation of cluster IV of the clostridia as defined by Collins et al. (1994). The closest relative based on sequence similarity values is *Clostridium sporosphaeroides* (93.9%). The low 16S gene sequence similarity value is in correlation with the fact that these species differ extensively including different cell-wall types.

90. **Clostridium limosum*** André in Prévot 1948a, 165^{AL}

li.mo'sum. L. neut. adj. *limosum* muddy or slimy.

Cells in PYG broth cultures are Gram-stain-positive straight rods, 0.6–1.6 × 1.7–16 μm, and occur singly, in pairs, or in short chains. Motility is variable; motile cells are peritrichous. Spores are oval, central to subterminal, and usually swell the cell. Sporulation occurs most reliably on chopped-meat slants incubated at 30 °C or on egg-yolk agar plates incubated for 48–72 h.

Cell walls contain *meso*-DAP, alanine, and glutamic acid; cell-wall sugars are glucose, galactose, and small amounts of mannose and rhamnose.

Surface colonies on blood agar plates are β-hemolytic, 1–4 mm in diameter, circular to irregular, raised to convex, translucent, gray, shiny or dull, smooth, with a mosaic or granular internal structure and an entire, scalloped, or undulate edge.

Cultures in PYG broth are turbid with a smooth to ropy sediment and a pH of 6.1–6.5 after incubation for 1 week.

The optimum temperature for growth is 37 °C. Some strains grow as well at 30 °C or 45 °C; growth is poor at 25 °C. Growth is inhibited by 6.5% NaCl, 20% bile, or a pH of 8.5. Trace to moderate gas is produced in PYG deep agar cultures. Ammonia and H₂S are produced. Lecithinase, collagenase, ribonuclease, and deoxyribonuclease are produced. One of nine strains produces an extracellular β-glucuronidase.

Principal cellular lipid fatty acids are the saturated straight-chain C₁₆, C₁₄, and C₁₂ acids. The principal product in PYG broth is acetate; small amounts of formate, succinate, or lactate may be detected. Little or no H₂ is produced. Pyruvate is converted to acetate; neither lactate nor threonine is utilized. There is an increase in propionate in a threonine-trypticase-yeast extract-thioglycollate medium over that detected in the basal medium. β-Phenylethylamine, isoamylamine, and usually di-*n*-butylamine are produced. Glutamate is fermented by the methylaspartate pathway. Indole and phenol are produced from fermentation of tryptophan and tyrosine, respectively, although indole formation is repressed in usual laboratory test media. Glutamic acid and histidine are fermented.

All strains tested are susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline; the one strain tested was resistant to clindamycin.

Supernatant culture fluids of some strains are weakly toxic to mice; some strains are pathogenic for guinea pigs. Pathogenicity appears to be related to the action of the collagenase and the lecithinase. Toxicity and pathogenicity are readily lost in laboratory cultures. Other characteristics of the species are given in Table 142.

Source: mud, infections in cattle, water buffalo, alligators and chickens; snake venom; home-preserved meat; human feces; human clinical specimens including blood, peritoneal fluid, pleural fluids, and lung biopsy from pulmonary infections.

DNA G+C content (mol%): 24 (T_m).

Type strain: ATCC 25620, BCRC (formerly CCRC) 14513, CCUG 24037, DSM 1400, JCM 1427, NCIMB 10638, VPI 2700.

GenBank accession number (16S rRNA gene): M59096.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium limosum* to fall within the cluster II of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarity values are *Clostridium histolyticum* (97.2%) and *Clostridium proteolyticum* (96.9%). *Clostridium limosum* can be differentiated most easily from *Clostridium histolyticum*, which it resembles phenotypically, by its production of lecithinase.

91. ***Clostridium litorale*** Fendrich, Hippe and Gottschalk 1991, 580^{VP} (Effective publication: Fendrich, Hippe and Gottschalk 1990, 131.)

li.to.ra'le. L. adj. n. *litorale* at the beach or coast, referring to the source of samples, the seashore of northern Germany, from which the species was isolated.

Rods with rounded ends, 1.0–1.5 × 2.0–8.0 μm. Motile. Forms subterminal, ovoid spores, 1.5 × 2.0 μm in old cultures. Gram-stain-positive. Strict anaerobe. Chemooorganotroph. Temperature range for growth is 13–38.5 °C with an optimum of 28 °C. The pH range for growth is 6.5–8.4 with an optimum of pH 7.3. Growth occurs at 1.0% NaCl, and is inhibited by 6.0% NaCl.

No complex nutrients required for growth. Complex standard media is fermented to produce butyrate and acetate. Does not ferment carbohydrates. Betaine is reductively cleaved in the Stickland reaction to trimethylamine, acetate, H₂, glycine, L-alanine, L-leucine, L-isoleucine, L-valine, and L-phenylalanine. Sarcosine is fermented with

L-alanine and utilizes glycine with L-serine. Does not reduce nitrate, sulfate, thiosulfate, or sulfite. H₂S is not produced. Growth stimulated by Tween 80. Does not digest meat or milk. Starch and gelatin are not hydrolyzed. Does not produce gas, indole, ammonia, or hydrogen. Lipase, lecithinase, and urease are not produced. Tests negative for catalase and oxidase. Cells hydrolyze esculin, and reduce natural red and resazurin.

Source: anoxic marine sediments from the North Sea, Germany.

DNA G+C content (mol%): 26.1 (T_m).

Type strain: W6, ATCC 49638, DSM 5388.

GenBank accession number (16S rRNA gene): X77845.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium litorale* to fall within the radiation of cluster XI of the clostridia as defined by Collins et al. (1994). *Clostridium litorale* represents a distinct lineage within cluster XI and the closest relative based on sequence similarity values is *Eubacterium acidaminophilum* (94.2%).

92. ***Clostridium lituseburense**** (Laplanche and Saissac in Prévot 1948a) McClung and McCoy 1957, 664^{AL} (*Inflabilis lituseburense* Laplanche and Saissac in Prévot 1948a, 167.)

li.tus.e.bu.ren'se. L. n. *litus* coast; L. n. *ebur* ivory; N.L. adj. *lituseburense* pertaining to Côte d'Ivoire.

Cells in PYG broth cultures are Gram-stain-positive rods, straight or slightly curved, motile and peritrichous, 1.4–1.7 × 3.1–6.3 μm, and occur singly, in pairs, or in short chains. Spores are oval, central to subterminal, and may swell the cell or occur as free spores. Sporulation occurs readily in chopped-meat broth cultures incubated for 24 h. Cell walls contain L-lysine and aspartic acid.

Surface colonies on blood agar plates are β-hemolytic, 1–3 mm in diameter, circular, low convex, opaque with translucent margins, white, shiny, and smooth, with a coarse granular internal structure and an entire to scalloped margin. Cultures in PYG broth are turbid with a ropy sediment and a pH of 5.3 after incubation for 5 d.

Growth is equally profuse at 35 °C, 30 °C, and 37 °C, slightly less at 45 °C. Growth is inhibited by 6.5% NaCl and 20% bile but unaffected by a pH of 8.5. Traces of gas may be detected in PYG deep agar cultures. Ammonia is produced. Neutral red and resazurin are reduced. Gelatin, chopped meat, and casein are digested; milk is curdled and weakly digested in 3 weeks.

A complex mixture of straight and branched chain saturated and unsaturated cellular fatty acids is present with normal unsaturated C₁₆ acid predominating.

Products in PYG broth cultures include large amounts of butyric, acetic, and isovaleric acids and small amounts of formic, propionic, and isobutyric acids. Small amounts of ethyl, propyl, and isobutyl alcohols may be detected. In chopped-meat carbohydrate broth, butyric and isovaleric acids are greatly increased, and moderate isobutyric acid is detected. Little or no H₂ gas is formed. Threonine is converted to propionate; an increased amount of acetate is detected from pyruvate; lactate is not utilized. Phenylalanine, tyrosine, and tryptophan are converted to phenylacetic, hydroxyphenylacetic, and indole acetic acids. Valine is converted to isobutyric acid, leucine and isoleucine to

isovaleric acid. *Clostridium lituseburense* utilizes serine, threonine, and arginine, and produces 2-aminobutyric acid.

The type strain is susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Strains are not pathogenic for guinea pigs or mice. Other characteristics of the species are given in Table 144.

Source: soil and humus from Côte d'Ivoire.

DNA G+C content (mol%): 27 (T_m).

Type strain: ATCC 25759, BCRC (formerly CCRC) 14536, CCUG 18920, DSM 797, JCM 1404, NCIMB 10637.

GenBank accession number (16S rRNA gene): M59107.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium lituseburense* to fall within the radiation of cluster XI of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarities are *Clostridium bif fermentans* (96.8%), *Clostridium bartlettii* (96.5%), *Clostridium irregulare* (96.5%), *Eubacterium tenue* (96.3%), *Clostridium sordellii* (96.0%), and *Clostridium mayombi* (96.0%).

93. ***Clostridium ljungdahlii*** Tanner, Miller and Yang 1993, 235^{VP}

ljung.dahl'i.i. N.L. gen. n. *ljungdahlii* of Ljungdahl, in recognition of Lars G. Ljungdahl's research contributions in the study of both acetogens and clostridia.

Rod-shaped cells, $0.6 \times 2\text{--}3\ \mu\text{m}$. Cells occur singly. Anaerobe. Gram-stain-positive. Motile. Form spores rarely. The temperature range for growth is $30\text{--}40\ ^\circ\text{C}$ with an optimum of $37\ ^\circ\text{C}$. The pH range for growth is $4.0\text{--}7.0$ with an optimum at 6.0.

Utilizes $\text{H}_2\text{-CO}_2$ or CO autotrophically. Grows chemoorganotrophically with formate, ethanol, pyruvate, fumarate, erythrose, threose, arabinose, xylose, glucose, and fructose. Does not utilize methanol, ferulate, trimethoxybenzoate, lactate, glycerol, citrate, succinate, galactose, mannose, sorbitol, sucrose, lactose, maltose, and starch. Major metabolic end product of metabolism is acetic acid with trace amounts of ethanol.

Source: chicken yard waste.

DNA G+C content (mol%): 22–23 (T_m).

Type strain: PETC, ATCC 55383, DSM 13528.

GenBank accession number (16S rRNA gene): M59097.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium ljungdahlii* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarity are *Clostridium tyrobutyricum* (95.4%), *Clostridium aciditolerans* (93.7%), *Clostridium scatologenes* (93.6%), *Clostridium kluveri* (93.4%), *Clostridium drakei* (93.4%), and *Clostridium magnum* (93.4%). It should be noted that the type strain ATCC 49587, cited in the paper by Tanner et al. (1993), has been deaccessioned.

94. ***Clostridium lundense*** Cirne, Delgado, Marichamy and Mattiasson 2006, 627^{VP}

lund.en'se. N.L. neut. adj. *lundense* from Lund, relating to the city where the type strain was isolated.

Rod-shaped, $0.56 \times 2.8\text{--}4.5\ \mu\text{m}$ in size. Gram-stain-positive. Nonmotile. Spores are spherical, terminal, and deform the cell shape. Cells form associations of two or more cells in the stationary phase of growth. Colonies are circular, 1 mm in

diameter, convex, cream color with entire margins on peptone/yeast extract/glucose medium. Obligately anaerobic. Temperature range for growth is $25\text{--}47\ ^\circ\text{C}$ with optimum of $37\ ^\circ\text{C}$. Growth occurs between pH 5.0–8.5 with a broad optimal pH for growth between 5.5 and 7.0. Growth occurs with 0–3% (w/v) NaCl but is optimal in the absence of NaCl.

Catalase-negative, indole-positive, glucosidase positive, sulfide- production positive. Esculin is hydrolyzed. Gelatin is not hydrolyzed. The strain does not utilize glucose, xylose, maltose, sorbitol, salicin, mannitol, lactose, sucrose, arabinose, glycerol, mannose, melezitose, raffinose, rhamnose, or trehalose. The strain shows lipolytic activity and hydrolyzes olive, sesame, and corn oils.

Source: bovine rumen fluid.

DNA G+C content (mol%): 31.2 (HPLC).

Type strain: R1, CCUG 50446, DSM 17049.

GenBank accession number (16S rRNA gene): AY858804.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium lundense* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarities are *Clostridium tetanomorphum* (97.9%), *Clostridium pasculi* (95.4%), and *Clostridium peptidivorans* (95.2%). DNA–DNA reassociation studies confirm the species status of strain R1 with values of 61.9% and 54.3% to *Clostridium pasculi* and *Clostridium tetanomorphum*, respectively (Cirne et al., 2006). Strain R1 differs from *Clostridium tetanomorphum* in colony morphology, being able to hydrolyze esculin, and in not utilizing glucose, xylose, maltose, sorbitol, and salicin, which the later does.

95. ***Clostridium magnum*** Schink 1984b, 355^{VP} (Effective publication: Schink 1984a, 254.)

mag'num. L. neut. adj. *magnum* big, referring to cell size.

Rods with slightly pointed ends, $1.0\text{--}4.0 \times 4\text{--}16\ \mu\text{m}$. Gram-stain-negative. No outer membrane in thin sections. Motile with polar and subpolar flagella. Older cells form spindles with dark zones at each end. Cells form central to subterminal elliptical spores, $1.5 \times 2.5\ \mu\text{m}$, in ageing cultures, after growth on sugars. Strict anaerobe. Chemoorganotroph. Temperature range for growth is $15\text{--}45\ ^\circ\text{C}$ with an optimum of $30\text{--}32\ ^\circ\text{C}$. Growth occurs in the pH range 6.0–7.5 with optimal growth at 7.0.

Utilizes fructose, glucose, sucrose, xylose, malate, citrate, 2,3-butanediol, acetoin, and pyruvate. The only fermentation product is acetate. Does not utilize C_1 compounds, ethylene glycol, ethanol, acetate, glyoxylate, glycolate, serine, lactate, oxalate, malonate, fumarate, succinate, oxaloacetate, glutamate, glycerate, glycerol, diacetyl, orotate, maltose, ribose, arabinose, starch, peptone, Casamino acids, and yeast extract. Does not reduce nitrate, sulfate, thiosulfate, or fumarate. Gelatin and urea are not hydrolyzed. Mineral media with a reductant are required for growth. No growth factors or vitamins are required for growth. Cytochromes not detected.

Source: anoxic freshwater sediments, digester sludge.

DNA G+C content (mol%): 29.1 (T_m).

Type strain: Wo Bd P1, ATCC 49199, DSM 2767.

GenBank accession number (16S rRNA gene): X77835.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium magnum* to fall within the radiation of

cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarities are *Clostridium scatologenes* (96.0%), *Clostridium nitrophenolicum* (95.8%), *Clostridium drakei* (95.8%), *Clostridium aciditolerans* (95.7%), and *Clostridium pascui* (95.2%).

96. ***Clostridium malenominatum**** (Weinberg, Nativelle and Prévot 1937) Spray 1948, 786^{AL}. (*Bacillus malenominatus* Weinberg, Nativelle and Prévot 1937, 763.)

ma.le.nom.i.na'tum. L. adv. *male* ill; L. inf. *nominare* to name; N.L. part. adj. *malenominatum* poorly named.

Cells in PYG broth culture are Gram-stain-positive, although usually only Gram-stain-negative cells can be seen in 24-h cultures. Straight rods, 0.3–0.9 × 1.4–10.8 μm, usually motile and peritrichous, and occur singly or in pairs. Spores are oval or round, subterminal or terminal, and swell the cell. Sporulation occurs most readily on egg-yolk agar plates or on chopped-meat slants incubated at 30 °C for 1 week. Cell walls contain *meso*-diaminopimelic acid (Wilde et al., 1997).

Surface colonies on blood agar plates are pinpoint–2 mm, circular or slightly irregular, convex or raised, gray-white, and translucent, with a crystalline, mottled or granular internal structure, and an entire, erose or scalloped margin. The surface may be smooth or lumpy. Hemolysis is variable among strains.

Cultures in PYG broth are turbid with a smooth or ropy sediment and have a pH of 6.1–6.5 after incubation for 1 week. The optimum temperature for growth is 37 °C. Some strains grow equally well at 30 °C. Growth is moderate at 25 °C, poor at 45 °C. Growth is inhibited by 20% bile, 6.5% NaCl, or a pH of 8.5. Moderate amounts of gas are detected in PYG deep agar cultures. Ammonia is produced. Five of 27 strains tested weakly digest gelatin after incubation for 3 weeks. Neither casein, milk, nor meat is digested. H₂S is produced in SIM by 22 of the 27 strains. Uric acid, but not urea, is decomposed by one strain, an isolate from the chicken cecum.

Cellular fatty acids detected are straight-chain acids, principally saturated C₁₄ and C₁₆ and unsaturated C₁₆ acids.

Products in PYG broth include butyrate and acetate; propionate, lactate, and formate usually are detected; propyl and butyl alcohols may be present. Abundant H₂ is produced. Pyruvate is converted to acetate- and butyrate; 19 strains, including the type strain, convert threonine to propionate, and 5 strains convert lactate to butyrate. Glutamic acid and tyrosine are utilized. Glutamate is converted by the type strain to butyrate and acetate by the methylaspartate pathway. Traces of phenol and indole are formed from phenylalanine and tryptophan.

All strains tested are susceptible to chloramphenicol and erythromycin; susceptibility to clindamycin or tetracycline is variable among strains; one of seven strains tested is resistant to penicillin G. Supernatant fluids are not toxic to mice. Cultures have been reported pathogenic for the guinea pig and rabbit. Other characteristics of the species are given in Table 141.

Source: human feces, chicken cecal contents, soil, human and animal infections.

DNA G+C content (mol%): 28 (*T_m*).

Type strain: ATCC 25776, DSM 1127, JCM 1405.

GenBank accession number (16S rRNA gene): M59099.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium malenominatum* to fall within the radiation of the cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarities are *Clostridium lundense* (95.0%), *Clostridium tetanomorphum* (94.6%), *Clostridium pascui* (94.3%), *Clostridium coclearium* (94.3%), and *Clostridium peptidivorans* (94.2%).

97. ***Clostridium manganotii**** (Prévot and Zimmès-Chaverou 1947) McClung and McCoy 1957, 664^{AL}. (*Inflabilis manganoti* Prévot and Zimmès-Chaverou 1947, 603)

man.ge.no'ti.i. N.L. gen. n. *manganotii* pertaining to Professor G. Manganot, Italian bacteriologist.

Cells in PYG broth cultures are Gram-stain-positive, non-motile, 0.6–0.9 × 3.1–8.2 μm, and occur singly, in pairs, and in short chains. Spores are oval, subterminal, and swell the cell. Sporulation occurs most readily on egg-yolk agar plates incubated for 72 h. Cell walls contain *meso*-DAP.

Surface colonies on blood agar plates are pinpoint–0.5 mm, circular, low convex, translucent, granular, gray-white, and dull, with an entire margin and a grainy surface.

Cultures in PYG broth are turbid and have a stringy sediment and a pH of 6.2 after incubation for 1 week. The optimum temperature for growth is 30–37 °C. Strains grow moderately well at 25 °C but not at all at 45 °C. Growth is good at a pH of 8.5, but there is no growth with 6.5% NaCl or 20% bile. Moderate gas is detected in PYG deep agar cultures. Ammonia is produced in chopped-meat broth and H₂S is produced in SIM.

A wide variety of straight and branched chain saturated and unsaturated cellular fatty acids is produced with the straight-chain saturated C₁₆ acid predominating.

Products in PYG broth culture include acetate, formate, isocaproate, isovalerate, and isobutyrate; a small amount of propionate is present. A large amount of H₂ is formed. Pyruvate is converted to acetate; threonine is converted to propionate; lactate is not utilized. Valine is converted to isobutyrate; leucine to isovalerate and isocaproate; isoleucine to isovalerate. Phenyl propionic and phenyl lactic acids are produced from phenylalanine, tyrosine, and tryptophan. Proline is utilized and 5-aminovaleric acid and 2-aminobutyric acid are produced.

The type strain is susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Supernatant cultures are nontoxic to mice. Other characteristics of the species are given in Table 145.

Source: soil, marine sediments, human feces.

DNA G+C content (mol%): not reported.

Type strain: ATCC 25761, DSM 1289, JCM 1428.

GenBank accession number (16S rRNA gene): M59098.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium manganotii* to fall within the radiation of the cluster XI of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarities are *Clostridium difficile* (94.7%), *Clostridium irregulare* (94.2%), *Eubacterium tenue* (94.1%), *Clostridium ghonii* (94.0%), and *Clostridium sordellii* (94.0%).

98. **Clostridium mayombei** Kane, Brauman and Breznak 1992, 191^{VP} (Effective publication: Kane, Brauman and Breznak 1991, 103.)

may.omb'e.i. N.L. gen. n. *mayombei* of the Mayombe tropical rainforest, People's Republic of Congo, which is home to the termite (*Cubitermes speciosus*) from whose gut this bacterium was isolated.

Straight to slightly curved rods, $1 \times 2\text{--}6\ \mu\text{m}$, rounded ends, occurring singly or in pairs. Gram-stain-positive. Motile with peritrichous flagella. Form oval, terminal to sub-terminal heat-resistant spores $1\ \mu\text{m}$ in diameter. Colonies are oval, white to slightly yellow in color, 2 mm in diameter, and have smooth edges when grown on $\text{H}_2 + \text{CO}_2$. Strict anaerobe. Temperature range for growth is $15\text{--}45\ ^\circ\text{C}$ with an optimum of $33\ ^\circ\text{C}$. The pH range for growth is $5.5\text{--}9.3$ with an optimum of 7.3. Facultative chemolithotroph.

Ferments glucose, fructose, xylose, maltose, cellobiose, dextrin, starch, sorbitol, dulcitol, glycerol, formate, pyruvate, malate, syringate, alanine, glutamate, serine, salicin, and esculin to acetate as the major end product. Succinate is fermented to propionate and CO_2 . Valine is fermented to isobutyrate. No cytochromes detected. Does not reduce nitrate or sulfate. Tests negative for catalase and oxidase activity. Trypticase and yeast extract are required for good growth.

Source: the gut of the soil-feeding termite, *Cubitermes speciosus* found in the Mayombe tropical rainforest in the People's Republic of Congo.

DNA G+C content (mol%): 25.6 (T_m).

Type strain: SFC-5, ATCC 51428, DSM 6539.

GenBank accession number (16S rRNA gene): not reported.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium mayombei* to fall within the radiation of cluster XI of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarities are *Clostridium glycolicum* (98.9%), *Clostridium irregulare* (97.4%), *Clostridium bartlettii* (96.9%), and *Clostridium lituseburense* (96.0%).

99. **Clostridium methoxybenzovorans** Mechichi, Labat, Patel, Woo, Thomas and Garcia 1999b, 1207^{VP}

me.tho.xy.ben.zo'vo.rans. Fr. n. *methyl* the methyl radical; Gr. n. *oxys* acid, Fr. n. *benzoin* frankincense of Java; Ger. n. *benzoesaure* resin obtained from the tree *Styrax benzoin*; L. v. *vorare* to devour; N.L. neut. adj. *methoxybenzovorans* pertaining to the use of the organic acid methoxybenzoic acid as carbon and energy source, which is characteristic of this organism.

Rod-shaped cells, $3.0\text{--}5.0 \times 0.4\text{--}0.8\ \mu\text{m}$, occurring singly or in pairs. Gram-stain-positive. Nonmotile. Form terminal, spherical endospores that cause cell swelling. Strict anaerobe. Chemoorganoheterotroph. Optimal growth occurs at $37\ ^\circ\text{C}$ and pH 7.4, on a glucose medium.

Utilizes glucose, fructose, sorbose, galactose, *myo*-inositol, sucrose, lactose, cellobiose, lactate, betaine, sarcosine, dimethylglycine, methanethiol, dimethylsulfide, alcohols (methanol), and all methoxylated aromatic compounds as sole carbon and energy sources. Ferments carbohydrates to formate, acetate, and ethanol. Ferments lactate

to methanol. Ferments methoxylated aromatics to acetate and butyrate. Betaine, sarcosine, dimethyl-glycine, methanethiol, and dimethylsulfide are fermented to acetate.

Source: anaerobic methanogenic pilot-scale digester fed from olive mill wastewater.

DNA G+C content (mol%): 44 (T_m).

Type strain: SR3, ATCC 700855, DSM 12182.

GenBank accession number (16S rRNA gene): AF067965.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium methoxybenzovorans* to fall within the radiation of cluster XIVa of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarities are *Clostridium indolis* (99.4%), *Desulfotomaculum guttoideum* (98.1%), *Clostridium amygdalinum* (98.1%), *Clostridium sphenoides* (98.0%), and *Clostridium saccharolyticum* (98.0%).

100. **Clostridium methylpentosum** Himelbloom and Canale-Parola 1989, 495^{VP} (Effective publication: Himelbloom and Canale-Parola 1989, 291.)

me' thyl.pen.to'sum. N.L. neut. adj. *methylpentosum* pertaining to methylpentose.

Cells are rod-shaped, bent in the shape of rings with overlapping ends, $0.3 \times 2.0\ \mu\text{m}$; found singly or in the form of left-handed helical chains. Most chains are 3–4 cells, but can be up to 50 cells. Nonmotile. Terminal, spherical to oval spores form which distend the cells. Spores form on Sweet E agar supplemented with rhamnose. Gram-stain-positive. Surface colonies are 1–2 mm in diameter, white, opaque, smooth, mucoid, and circular. Obligate anaerobe. Chemoorganotroph. Growth occurs optimally at $45\ ^\circ\text{C}$ with no growth at 25 or $50\ ^\circ\text{C}$. Cultures in L-rhamnose broth are at pH range 4.5–5.0 after 16 h at $37\ ^\circ\text{C}$.

Ferments only L-rhamnose, L-fucose, L-lyxose, and D-arabinose. Does not ferment, N-acetylglucosamine, amino acids, L-arabitol, L-arabinose, L-ascorbate, cellobiose, D-fructose, fucoidan, D-fucose, D-galactose, D-galacturonate, D-gluconate, D-glucosamine, D-glucose, 2-deoxy-D-glucose, D-glucuronate, glycerol, lactate, lactose, D-lyxose, maltose, mannitol, D-mannose, pectin, polygalacturonate, 1,2-propanediol, pyruvate, raffinose, L-sorbose, starch, sucrose, D-xylose, and L-xylose. L-Rhamnose and L-fucose are fermented to propionate, *n*-propanol, acetate, CO_2 , and H_2 . L-Lyxose and D-arabinose are fermented to acetate, glycolaldehyde, CO_2 , and H_2 . Exogenous biotin, vitamin B₁₂, and bicarbonate are required for growth. Riboflavin and exogenous folic acid stimulate growth. Grows in 20% bile. Does not reduce sulfate.

Source: human feces.

DNA G+C content (mol%): 46 (T_m).

Type strain: R2, ATCC 43829, DSM 5476.

GenBank accession number (16S rRNA gene): Y18181.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium methylpentosum* to fall within the radiation of cluster IV as defined by Collins et al. (1994). This organism represents a distinct lineage that shares less than 90% with any other species of the genus *Clostridium*.

101. **Clostridium neopropionicum** Tholozan, Touzel, Samain, Grivet, Prensier and Albagnac 1995, 879^{VP} (Effective publication: Tholozan, Touzel, Samain, Grivet, Prensier and

Albagnac 1992, 256.)

ne.o.pro.pi.o.ni.cum. Gr. adj. *neos* new; N.L. n. *acidum propionicum* propionic acid; N.L. adj. *neopropionicum* a new propionic acid-producing *Clostridium*.

Straight rods with tapered ends, 0.5–0.6 × 1.4–3.0 μm; found singly, in pairs, or short chains. Strict anaerobe. Motile with one side-inserted flagellum. Gram-stain-negative. Large, oval, subterminal spores, measuring 0.7–0.9 μm. Temperature range for growth 15–40 °C with an optimum of 30 °C. Growth occurs in the pH range 6.1–8.2 with an optimum at 7.1–7.6.

Ferments ethanol to propionate, acetate, propanol, and butyrate. Threonine, glucose, and β-alanine are fermented to propionate, acetate, and butyrate. Ferments L-cysteine, L- and D-alanine, and L-serine to propionate and acetate. Growth occurs in freshwater selective media containing ethanol. No cytochromes detected.

Source: an anoxic digester sludge.

DNA G+C content (mol%): 34.5 (T_m).

Type strain: X4, DSM 3847.

GenBank accession number (16S rRNA gene): X76746.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium neopropionicum* to fall within the radiation of cluster XIVb of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarity values are *Clostridium propionicum* (98.1%) and *Clostridium lactatifermentans* (94.8%). DNA–DNA reassociation demonstrated the species status of *Clostridium neopropionicum* with a value of 18% when compared to *Clostridium propionicum* (Tholozan et al., 1992). Phenotypically *Clostridium neopropionicum* and *Clostridium propionicum* are very similar, only differing in the utilization of acrylate (30 mM), Gram staining reaction, and temperature range for growth. A larger number of characteristics exist for the differentiation of *Clostridium neopropionicum* and *Clostridium lactatifermentans* including utilization of glucose, xylose, ethanol, and acrylate (30 mM) as well as spore formation, optimum temperature for growth, and mol% G+C content of DNA (van der Wielen et al., 2002).

102. ***Clostridium nexile***^s Holdeman and Moore 1974, 276^{AL}

nek'si.le. L. neut. adj. *nexile* tied together (referring to its chain formation).

This description is based on that of Holdeman and Moore (1974) and on their study of the type and 10 other strains.

Cells in PYG broth cultures are Gram-stain-positive ovals or straight rods, nonmotile, 0.8–1.7 × 0.8–6.3 μm, and occur in pairs or chains. Spores are round or oval, subterminal or nearly terminal, but are rarely seen, even in cultures that resist heating at 80 °C for 10 min. Spores have been seen in 6-d-old cultures of PYG broth.

Surface colonies on blood agar plates are 0.5–1.0 mm in diameter, circular, convex to raised, semiopaque or with opaque centers and translucent edges, smooth, shiny, white to yellowish, nonhemolytic, and with entire margins.

Cultures in PYG broth have a smooth or ropy sediment, often with no turbidity, and a pH of 4.9–5.3 after incubation for 5 d. The optimum temperature for growth

is 30–37 °C. Most strains grow well at 45 °C but poorly at 25 °C. Growth is stimulated by fermentable carbohydrate, but is inhibited by 20% bile or 6.5% NaCl. Abundant gas is produced in PYG deep agar cultures. H₂S is produced by three of six strains tested. Neutral red and resazurin are reduced.

Products in PYG broth culture are acetic and formic acids and ethanol; moderate amounts of lactate and succinate are usually detected. Pyruvate is converted to acetate and ethanol; increased amounts of formate also are usually formed. Neither threonine nor lactate is utilized. Orotic acid is not hydrolyzed.

Of seven strains tested, all are susceptible to chloramphenicol and clindamycin, five are susceptible to penicillin G, three to erythromycin, and two to tetracycline. Other characteristics of the species are given in Table 144.

Source: human feces as part of the normal flora.

DNA G+C content (mol%): 40–41 (T_m).

Type strain: ATCC 27757, DSM 1787.

GenBank accession number (16S rRNA gene): X73443.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium nexile* to fall within the radiation of cluster XIVa of the clostridia as defined by Collins et al. (1994). Sequence similarities in the range 95.4–96.7% are found to the following taxa: *Coprococcus comes*, *Eubacterium contortum*, *Ruminococcus gnavus*, *Clostridium glycyrrhizinilyticum*, and *Hespellia porcina*. This species can be differentiated from *Clostridium oroticum*, which it resembles most closely phenotypically, by not hydrolyzing orotic acid, and by lack of fermentation of arabinose, maltose, and rhamnose as well as sharing 94.8% similarity in the 16S rRNA gene sequence.

103. ***Clostridium nitrophenolicum*** Suresh, Prakash, Rastogi and Jain 2007, 1889^{VP}

ni.tro.phen.o'li.cum. N.L. n. *nitrophenol* nitrophenol; L. suff. *-icus -a -um* suffix used with the sense of belonging to; N.L. neut. adj. *nitrophenolicum* referring to the substrate nitrophenol that can be utilized by the species.

Rod-shaped cells, 0.6–0.9 × 3.5–5.0 μm. Spores are oval and in a central position. Colonies grown on TSA are circular, smooth and convex with wavy margin. Strictly anaerobic.

Temperature range for growth is 20–45 °C. Does not grow at 15 or 50 °C. pH Range for growth is pH 6.5 and 8.0; no growth is observed below pH 6.5 and above 8.0. Optimum growth is observed at pH 7.2 and 30 °C. Growth occurs at 0–1% NaCl but not at 2.0% NaCl.

Negative for catalase and oxidase; positive for indole and methyl red test. Starch and urea are not hydrolyzed. Does not reduce nitrate to nitrite and is negative for Voges–Proskauer test, citrate utilization, and H₂S production. Using Biolog MicroPlates (AN), the strain showed a positive reaction for the assimilation of D-fructose, L-fucose, D-galactose, D-galacturonic acid, palatinose, and L-rhamnose and a negative reaction for acetic acid, N-acetyl-D-galactosamine, N-acetyl-D-glucosamine, N-acetyl-β-D-mannosamine adonitol, L-alaninamide, L-alanine, L-alanyl L-glutamine, L-alanyl L-histidine, L-alanyl

L-threonine, amygdalin, D-arabitol, arbutin, L-asparagine, D-cellobiose, α -cyclodextrin, β -cyclodextrin, dextrin, dulcitol, *i*-erythritol, formic acid, D-gluconic acid, α -D-glucose 1-phosphate, α -D-glucose 6-phosphate, L-glutamic acid, L-glutamine, glycerol, glyoxylic acid, α -hydroxybutyric acid, β -hydroxybutyric acid, inosine, *myo*-inositol, itaconic acid, α -ketobutyric acid, β -ketobutyric acid, lactic acid, lactulose, malic acid, maltose, maltotriose, D-mannitol, mannose, D-melibiose, L-methionine, methyl β -D-galactoside, methyl α -D-glucoside, methyl β -D-glucoside, 3-methyl-D-glucose, L-phenylalanine, propionic acid, pyruvic acid, D-raffinose, L-rhamnose, D-saccharic acid, salicin, L-serine, D-sorbitol, stachylose, succinic acid, sucrose, *m*-tartaric acid, L-threonine, thymidine, trehalose, turanose, uridine, urocanic acid, and L-valine. It produces acid from glucose, dulcitol, fructose, galactose, maltose, mannose, sucrose, and trehalose, but not from adonitol, arabinose, cellobiose, inositol, mannitol, melibiose, salicin, or sorbitol. Fermentation end products from glucose include acetate, formate, and pyruvate.

Menaquinone present is MK-7 and the cell-wall amino acid is *meso*-diaminopimelic acid. Polar lipids present are DPG, PG, PE, and two unknown phospholipids (UKP1 and UKP2). The major cellular fatty acids are (%); C_{16:0} (28.02), C_{17:1 iso} I/ante B (23.05), C_{16:1 ω7c}/C_{15:0 iso 20H} (10.82) and C_{14:0} (10.02).

Source: a subsurface soil sample from a depth of about 3–4 m.

DNA G+C content (mol %): 35.5 (HPLC).

Type strain: 1D, JCM 14030, MTCC 7832.

GenBank accession number (16S rRNA gene): AM261414.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium nitrophenolicum* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarities are *Clostridium aciditolerans* (98.7%), *Clostridium madnum* (95.8%), *Clostridium scatologenes* (95.7%), and *Clostridium drakei* (95.7%). DNA–DNA reassociation studies between *Clostridium aciditolerans* and *Clostridium nitrophenolicum* demonstrate their distinct species status with a value of 36.4% (Suresh et al., 2007). Differentiating characteristics include different fatty acid compositions, different Gram-staining reactions, the utilization of very few substrates by *Clostridium nitrophenolicum*, and different end products of fermentation of glucose (Suresh et al., 2007).

104. *Clostridium novyi** (Migula 1900) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 236^{AL} (*Bacillus novyi* Migula 1900, 672)

no'vyi. N.L. gen. n. *novyi* pertaining to F.G. Novy, American bacteriologist.

This description is based on those of Smith (1975) and of Holdeman et al. (1977a) and on the study of the type and 30 other strains of *Clostridium novyi* type A, 7 strains of type B, and the strain of type C ("*Clostridium bubalorum*") on which the description of this type was based.

Type A. Cells in PYG broth cultures are Gram-stain-positive rods, 0.6–1.4 × 1.6–17 μm, and occur singly or in pairs. They are usually motile and peritrichous. Motility may be difficult to detect in wet mounts, but peritrichous cells can usually be demonstrated. Spores are oval, central, or subterminal, and may swell the cell. There are no appendages or exosporium. Sporulation of most strains occurs most readily on blood agar plates incubated for 3 d. Cell walls contain meso-DAP, glutamic acid, and alanine.

Surface colonies on blood agar plates are β -hemolytic, 1–5 mm in diameter, circular or irregular, flat or raised, translucent or opaque, gray, dull or glistening, with a crystalline or mosaic internal structure, and a scalloped, undulate, lobate, or rhizoid margin. They may appear as a spreading film over the entire plate. Cultures in PYG broth are turbid with a smooth or flocculent sediment and have a pH of 5.1–5.8 after incubation for 1 week.

The optimum temperature for growth is 45 °C. Most strains grow nearly as well at 37 °C and moderately at 30 °C. There is little or no growth at 25 °C. Strains require strictly anaerobic conditions and will not grow in the presence of even traces of O₂. Fermentable carbohydrate greatly stimulates growth. There is no growth in 20% bile, 6.5% NaCl, or at a pH of 8.5. Moderate to abundant gas is produced in PYG deep agar cultures. Both lecithinase and lipase are produced on egg-yolk agar plates. Gelatin is digested by all strains; there is weak and slow digestion of chopped meat by 6 of 31 strains; milk is curdled but neither milk nor casein is digested. Deoxyribonuclease is produced by the type strain and by 16 of 25 other strains tested. One strain, isolated from marine mud, causes the breakdown of chitin to *N*-acetylglucosamine. Of 25 strains tested, 20 produced protease on casein agar, 4 produced ribonuclease, 3 produced amylase, and 8 produced hyaluronatylase.

Products in PYG broth culture include major amounts of butyric and propionic, and small amounts of acetic acids; small amounts of valeric acid and propanol may be detected. Abundant H₂ is produced. Pyruvate is converted to acetate, butyrate, and sometimes propionate; lactate is converted to propionate; threonine is not utilized. Large amounts of iso-amylamine and phenethylamine are produced in chopped-meat glucose broth cultures.

All strains tested are susceptible to chloramphenicol, clindamycin, erythromycin, and penicillin G. One of 15 strains is resistant to tetracycline. Cultures are pathogenic for guinea pigs, rabbits, mice, rats, and pigeons, and supernatant culture fluids of about one-half of the pathogenic strains are toxic to mice. The principal lethal toxin of both types A and B is the necrotizing alpha toxin. Type A strains also produce gamma (phospholipase C) and epsilon (lipase) toxins; some strains also produce delta (oxygen-labile hemolysin) toxin. The gamma toxin (lecithinase of type A) is active on horse red-blood cells. The epsilon toxin (lipase) produces a pearly layer on colonies on egg-yolk agar plates and is useful in differentiating between type A and type B strains. Also, the type A lecithinase (gamma toxin) is antigenically distinct from the lecithinase (beta toxin) of *Clostridium novyi* type B and *Clostridium hemolyticum*. Nontoxic strains can be converted to toxic strains through the mediation of specific bacteriophages. Plasmids have been found in both toxic and nontoxic variants

of the same strains and may be involved in this transfer of toxigenicity. Phage-like particles that inhibit the growth of strains of *Clostridium perfringens* and *Clostridium tertium* have been detected in one strain of *Clostridium novyi* type A; this strain of *Clostridium novyi* type A was inhibited by a strain of *Clostridium bifermentans*.

High levels of rRNA homology exist between *Clostridium botulinum* types C and D, *Clostridium hemolyticum*, and *Clostridium novyi* types A and B (Johnson and Francis, 1975). In addition, some strains of *Clostridium novyi* type A have been shown to share antigens with strains of *Clostridium botulinum* type C. For differentiation of these species, see *Further comments* following their descriptions. Other characteristics of the species are given in Table 142. The phylogenetic relationships are shown in Figure 128.

Source: soil, marine sediments, animal wounds, human wounds including gas gangrene.

DNA G+C content (mol %): 29 (T_m).

Type strain: ATCC 17861, DSM 14992, JCM 1406, NCTC 13029.

GenBank accession number (16S rRNA gene): AB045606, L37594.

Type B. Phenotypic characteristics that help to distinguish strains of type B from those of type A are: cells tend to be larger, 1.1–2.5 × 3.3–22.5 μm; mannose is fermented; milk and chopped meat are digested; lipase is not detected on egg-yolk agar; electrophoretic patterns of soluble cellular proteins are quite distinct. Like type A strains, *Clostridium novyi* type B strains produce the lethal, necrotizing *Clostridium novyi* alpha toxin. However, the lecithinase of type B strains is the beta toxin, which also is produced by strains of *Clostridium hemolyticum*. The beta toxin (lecithinase) can be identified by its hemolytic action on human red blood cells and can be neutralized by either *Clostridium novyi* type B or *Clostridium hemolyticum* antitoxin. Type B strains also produce zeta (hemolysin) and eta (tropomyosinase) toxins. Small amounts of theta toxin (lipase), commonly produced by strains of *Clostridium hemolyticum*, may be produced by some strains of *Clostridium novyi* type B. The lipase of the theta toxin does not produce a reaction on egg-yolk agar.

Type strain: ATCC 25758, NCIB 10626.

GenBank accession number (16S rRNA gene): AB035087.

Further comments: A nontoxigenic, nonpathogenic strain that is otherwise indistinguishable from *Clostridium novyi* type A was isolated from water buffalo with osteomyelitis. It was designated *Clostridium novyi* type C and *Clostridium "bubalorum"*. It produces only small amounts of lecithinase (gamma toxin) that are not detected on egg-yolk agar. Strains are quite commonly isolated that are phenotypically identical to *Clostridium novyi* type A or to *Clostridium botulinum* types C or D except that they are nontoxigenic, presumably through loss of their infecting phages. It has been shown that the heating process sometimes used in isolation of these strains can select for more actively sporulating strains and that there is an inverse relationship between sporulating potency and toxigenicity. For further discussion of the genetic relationships between these species, see below.

Reference strain: *Clostridium novyi* type C: ATCC 27323, NCIMB 9747.

GenBank accession number (16S rRNA gene): AB041865.

16S rRNA gene sequence comparisons show *Clostridium novyi* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). Representatives of each type A, B, and C fall within a cluster that comprises *Clostridium hemolyticum* and *Clostridium botulinum* type C and type D strains (Sasaki et al., 2001). *Clostridium novyi* types B and C share >99.9% 16S rRNA gene sequence similarity with *Clostridium hemolyticum*. The type A *Clostridium novyi*, the actual type strain of the species, shares 98.6% 16S rRNA gene sequence similarity with *Clostridium hemolyticum* and type B and C *Clostridium novyi* strains. It has been shown that strains of *Clostridium novyi* type B have 89–93% DNA–DNA homology to *Clostridium hemolyticum*, 28–37% homology to *Clostridium novyi* type A, and 68–70% homology to *Clostridium botulinum* type C (Nakamura et al., 1983).

105. *Clostridium oceanicum** Smith 1970, 811^{AL}

o.ce.an'i.cum. L. neut. adj. *oceanicum* belonging to the sea.

This description is based on that of Smith (1970), and on study of the type and 26 other strains.

Cells in PYG broth culture are Gram-stain-positive rods, 0.3–1.6 × 1.7–25.7 μm, and occur singly or in pairs. They are motile and peritrichous. Some strains are nonmotile when incubated at 37°C but motile at 25°C. Long filaments may be seen in older cultures. Spores are oval, terminal, or subterminal, and usually do not swell the cell. There may be two spores, one at each end, in a single cell. Sporulation of most strains occurs most readily in chopped-meat glucose broth incubated at 30°C. Cell walls contain *meso*-DAP.

Surface colonies on blood agar plates are β-hemolytic, 1–6 mm in diameter, circular to irregular, flat or raised, translucent, gray and shiny, with an undulate or scalloped margin and a crystalline mosaic internal structure.

Cultures in PYG broth are slightly turbid with a smooth or flocculent sediment and a pH of 5.0–5.7 after incubation for 1 week.

The optimum temperature for growth is 30–37°C. Strains grow poorly at 25°C and not at all at 45°C. Growth is stimulated by carbohydrate, by Tween 80, and by a N₂ rather than a CO₂ atmosphere. Strains will grow in media with a pH from 6.5–8.5; there is little or no growth initiation at a pH of 6.0. Growth is inhibited by 20% bile or by 6.5% NaCl; 4% NaCl is not inhibitory. Moderate to abundant gas is produced in PYG deep agar cultures. Ammonia is produced; H₂S is produced in SIM medium by 20 of 26 strains tested. Deoxyribonuclease and ribonuclease are produced.

Products in PYG broth include lactic, butyric, and acetic acids; small amounts of formic, propionic, isobutyric, isovaleric, isocaproic, and succinic acids; and ethanol, propanol, and butanol may be detected. Abundant H₂ is produced. Acid production, both in amount and variety, is enhanced in PY broth without fermentable carbohydrate; production of acetic, propionic, isobutyric, isovaleric, and isocaproic acids is stimulated, and valeric acid usually is detected. Pyruvate is converted to acetate and butyrate. Threonine is converted to propionate by 19 of 26 strains. Utilization of lactate is variable.

All strains tested are susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Culture supernatants are nontoxic to mice. Other characteristics of the species are given in Table 142.

Source: marine sediments, human feces.

DNA G+C content (mol %): 26–28 (T_m).

Type strain: ATCC 25647, DSM 1290, JCM 1407, LMG 3287.

GenBank accession number (16S rRNA gene): M59101.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium oceanicum* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarities are *Clostridium sporogenes* (96.2%), *Clostridium botulinum* (96.0%), and *Clostridium novyi* (95.9%). All other species of cluster I share less than 94% 16S rRNA gene sequence similarity.

106. ***Clostridium orbiscindens*** Winter, Popoff, Grimont and Bokkenheuser 1991, 356^{VP}

or.bi.scin'dens. N.L. adj. *orbiscindens* ring-cutting.

Straight rods, 0.9–1.0 × 2–7 μm, occurring singly or in pairs. Motile with peritrichous flagella. Gram-stain-variable. Form round, subterminal, unencapsulated spores, measuring 0.7 × 0.5 μm. Colonies on rabbit blood agar are 1 mm in diameter, circular, convex, slightly irregular, smooth, β-hemolytic, shiny, and gray or white in color. Colonies on sheep-blood agar are not hemolytic and slightly larger in size. Strict anaerobe. Optimal temperature 37 °C.

One of the four strains does not grow on bile. Good growth of all strains when grown anaerobically in broth of brain heart media. Does not ferment amygdalin, arabinose, cellobiose, erythritol, glucose, glycogen, mannitol, melzitose, raffinose, rhamnose, ribose, salicin, sorbitol, starch, sucrose, trehalose, xylan, and xylose. Produces indole (one of four strains) and H₂S (three of four strains). Utilizes fumarate (two of four strains) and pyruvate (three of four strains). Does not digest casein, meat, or gelatin. Does not produce urease, lipase, or lecithinase. Does not reduce nitrate. Produces acetic acid, butyric acid, and some propionic acid when grown on peptone-yeast-glucose broth.

Synthesizes a flavonoid molecule C-ring-cleaving enzyme. Susceptible to cephalothin (30 U), kanamycin (1,000 U), and metronidazole (80 U) but resistant to nalidixic acid (30 U), rifampin (15 U), and vancomycin (5 U). Susceptibility to penicillin is variable (two of four strains are susceptible). Apathogenic in mice.

Source: human feces.

DNA G+C content (mol %): 56–57 (T_m).

Type strain: 265, ATCC 49531, DSM 6740.

GenBank accession number (16S rRNA gene): Y18187.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium orbiscindens* to fall within the radiation of cluster IV of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarities are *Eubacterium plautii* (99.7%) and *Bacteroides capillosus* (97.4%); both of these taxa are clearly misclassified and unrelated to the type species of their respective genera.

107. ***Clostridium oroticum**** (Wachsman and Barker 1954) Cato, Moore and Holdeman 1968, 9^{AL} (*Zymobacterium oroticum* Wachsman and Barker 1954, 400)

o.ro'ti.cum. N.L. n. *acidum oroticum* orotic acid; N.L. neut. adj. *oroticum* pertaining to orotic acid.

Cells in PYG broth cultures are 0.6–1.6 × 1.3–3.9 μm, Gram-stain-positive rods or ovals with tapering ends. They

are nonmotile and occur in long tangled chains. Spores are round to ellipsoidal, central to subterminal, and do not swell the cell. Sporulation occurs most readily in PY broth cultures. Cell walls contain *meso*-DAP.

Surface colonies on blood agar plates are 1–2 mm in diameter, circular, convex, opaque, white or buff-colored, shiny, smooth, and nonhemolytic. No internal structure is visible.

Cultures in PYG broth are not turbid and have a heavy, smooth to mucoid sediment and a pH of 5.1 after incubation for 4 d. The optimum temperature for growth is 30–37 °C. Growth is nearly as good at 45 °C and moderate at 25 °C. Growth is only slightly inhibited by 20% bile or a pH of 8.5 but completely inhibited by 6.5% NaCl.

Abundant gas is detected in PYG deep agar cultures. Orotic acid is utilized with 90% of the substrate degraded in 4 d. The organism contains high levels of the iron-sulfur flavoprotein dihydroorotate dehydrogenase which catalyzes both the synthesis and degradation of pyrimidines. The organism also produces a zinc-containing metalloenzyme, dihydroorotase, which is active in pyrimidine degradation.

Products in PYG broth cultures are acetic and formic acids, ethanol, CO₂, and large amounts of H₂; trace amounts of lactic and succinic acids may be detected. Pyruvate is converted to acetate, formate, and ethanol; neither lactate nor threonine is utilized. Ammonia is produced in orotic acid medium. H₂S is not produced in SIM.

The two strains tested are susceptible to chloramphenicol, erythromycin, penicillin G, and tetracycline, but resistant to clindamycin. One clinical isolate of *Clostridium oroticum* is susceptible to amoxicillin (0.25 μg/ml), carbenicillin (2 μg/ml), cephalexin (0.063 μg/ml), tiberol (0.063 μg/ml), clindamycin (2 μg/ml), metronidazole (0.063 μg/ml), chloramphenicol (2 μg/ml), LY 99638 (0.25 μg/ml), and Searle 28538 (0.125 μg/ml); this strain is moderately resistant to moxalactam, cefoperazone, cefoxitin and doxycycline, and resistant to cefamandole, erythromycin, rosaramicin, and tetracycline. Culture supernatants are nontoxic to mice. Other characteristics of the species are given in Table 144.

Source: black mud from San Francisco Bay, human feces, suprapubic bladder aspirates, a rectal abscess.

DNA G+C content (mol %): 44 (T_m).

Type strain: ATCC 13619, DSM 1287, JCM 1429, LMG 3286, NCCB 73016.

GenBank accession number (16S rRNA gene): M59109.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium oroticum* to fall within the radiation of cluster XIVa of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarities are *Eubacterium contortum* (98.1%), *Clostridium glycyrrhizinilyticum* (95.8%), *Ruminococcus torques* (95.5%), and *Ruminococcus gnavus* (94.9%).

108. ***Clostridium papyrosolvens**** Madden, Bryder and Poole 1982, 90^{VP}

pa.py'ro.sol'vens. Gr. n. *papyros* paper; L. v. *soluere* to dissolve; N.L. part. adj. *papyrosolvens* paper-dissolving (intended to reflect the organisms' rapid fermentation of filter paper constituents).

This description is based on that of Madden et al. (1982) and on study of the type strain.

Cells in yeast extract-sea water-mineral solution-cellobiose broth are straight Gram-stain-negative rods with Gram-stain-positive cell-wall structure as shown by electron microscopy. They are motile and peritrichous, $0.5\text{--}0.8 \times 2.0\text{--}5.0\ \mu\text{m}$, and occur singly and in pairs. Spores are round, terminal, and swell the cell. Spores do not germinate unless they are heat shocked at 70°C for 15 min. After incubation for 3 weeks, deep colonies in cellulose agar roll tubes are 1–2 mm in diameter, circular, translucent, colorless and granular, surrounded by clear zones of cellulose hydrolysis 1–2 cm in diameter. Surface colonies in rumen fluid agar roll tubes are circular to slightly irregular, entire to erose, convex, translucent, colorless, shiny, and smooth. Cell-wall composition has not been reported.

Optimum temperature for growth is $25\text{--}30^\circ\text{C}$. The organism grows at 15°C and 37°C but only slightly at 45°C . Best growth occurs in an atmosphere of 90% $\text{N}_2\text{--}10\%$ CO_2 .

Cultures in PYG broth are slightly turbid with a granular sediment and have a pH of 5.0 after incubation for 5 d. Fermentable carbohydrate is required for growth. Abundant gas is detected in PYG deep agar cultures. Cellulose, glycerol, and esculin are fermented. Other characteristics of the species are given in Table 144. End products from growth in cellulose broth cultures are ethanol, acetate, lactate, H_2 , and CO_2 . Products in PYG broth are moderate amounts of lactic, formic, pyruvic, fumaric, and lactic acids, and abundant H_2 .

The type strain is susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline.

Source: estuarine sediments.

DNA G+C content (mol %): 30 (T_m).

Type strain: ATCC 35413, DSM 2782, NCIMB 11394.

GenBank accession number (16S rRNA gene): X71852.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium papyrosolvens* to fall within the radiation of cluster III of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarities are *Clostridium josui* (98.4%), *Clostridium cellulolyticum* (98.1%), *Clostridium termitidis* (97.1%), *Clostridium cellobioparum* (96.7%), and *Clostridium hungatei* (96.4%). *Clostridium papyrosolvens* can be differentiated from *Clostridium josui* and *Clostridium cellulolyticum* on the basis of differences in optimum temperature for growth, Gram staining reaction in young cultures, differences in motility and flagella arrangement, and substrate utilization patterns.

109. ***Clostridium paradoxum*** Li, Mandelco and Wiegel 1993, 454^{VP}

para.dox.um. Gr. adj. *paradoxon* fr. neut. of *paradoxos* contrary to expectation, incredible; N.L. adj. *paradoxum* referring to the unusual property of sporulated cells to be highly motile.

Rod-shaped cells, $0.7\text{--}1.1 \times 2\text{--}4.5\ \mu\text{m}$, two or more cells in chains in exponential phase. Pleiomorphic in stationary phase. Motile with 2–6 peritrichous flagella. Gram-stain-positive cell wall with Gram-stain-negative staining

reaction. Sporulation is pH dependent. Cells form round to oval terminal spores which distend and slightly enlarge cells. Sporulated cells are highly motile. Anaerobe. Growth occurs in the temperature range $30\text{--}63^\circ\text{C}$ with optimum at 56°C . Alkaliphilic. The pH range for growth 7.3–11.0 with optimal growth at pH 9.8–10.3. Cell wall contains *m*-diaminopimelic acid. Major fatty acid is $\text{C}_{15:0\text{iso}}$.

Growth requires prereduced medium with yeast extract or tryptone. Utilizes glucose, fructose, sucrose, maltose, and pyruvate. Does not utilize galactose, xylose, ribose, L-(+)-arabinose, mannose, mannitol, rhamnose, raffinose, salicin, sorbitol, malonate, glycerol, lactate, formate, pectin, starch, cellulose, ethanol, methanol, $\text{H}_2\text{--CO}_2$, and Casamino acids.

Major fermentation end products include acetate, CO_2 , and H_2 , with trace amounts of isovalerate, succinate, and butyrate. Negative for sulfate reduction. Strong positive results for An-Ident tests (API) incubated at 37 and 50°C , pH 8.5 and 10.5 include: α -glucosidase, indoxylacetate hydrolysis, arginine aminopeptidase, and arginine utilization. Weak positive results were obtained for indole production and catalase production. Negative results were obtained for *N*-acetylglucosaminidase, L-arabinosidase, β -glucosidase, α -fucosidase, α -galactosidase, β -galactosidase, leucineaminopeptidase, proline aminopeptidase, pyroglutamic acid arylamidase, tyrosine aminopeptidase, alanine aminopeptidase, histidine aminopeptidase, phenylalanine aminopeptidase, and glycine aminopeptidase.

Growth inhibited by chloramphenicol (25 $\mu\text{g}/\text{ml}$), erythromycin (25 $\mu\text{g}/\text{ml}$), tetracycline (25 $\mu\text{g}/\text{ml}$), monecin (25 $\mu\text{g}/\text{ml}$), gramicidin S (25 $\mu\text{g}/\text{ml}$), lasalocid (25 $\mu\text{g}/\text{ml}$), and gentamicin (50 $\mu\text{g}/\text{ml}$).

Source: a sewage plant in Athens, Georgia, USA; aeration pools, anaerobic digestors, digester effluent.

DNA G+C content (mol %): 30 (T_m).

Type strain: JW-YL-7, ATCC 51510, CIP 105527, DSM 7308.

GenBank accession number (16S rRNA gene): Z69939.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium paradoxum* to fall within the radiation of cluster XI of the clostridia as defined by Collins et al. (1994). The closest relative based on sequence similarities is *Clostridium thermoalcaliphilum* at 98.1% 16S rRNA gene sequence similarity. Other species are related at less than 93.0% similarity.

Multiple copies of the 16S rRNA gene that differ from each other are found in *Clostridium paradoxum* (Rainey et al., 1996). *Clostridium paradoxum* can be differentiated from *Clostridium thermoalcaliphilum* on the basis of differences in cell-wall type, *Clostridium paradoxum* having *m*-diaminopimelic acid while that of *Clostridium thermoalcaliphilum* contains L-Orn–D-Asp. In addition, viable heat-resistant spores have not been observed in *Clostridium thermoalcaliphilum*. While *Clostridium paradoxum* is a thermophile, *Clostridium thermoalcaliphilum* is considered a thermolerant organism.

110. ***Clostridium paraputrificum**** (Bienstock 1906) Snyder 1936, 402^{AL} (*Bacillus paraputrificus* Bienstock 1906, 413)

pa.ra.pu.tri.fi.cum. Gr. pref. *para* beside; N.L. n. *putrificum* a specific epithet; N.L. neut. adj. *paraputrificum* resembling (*Clostridium*) *putrificum*.

Cells in PYG broth cultures are straight or slightly curved rods, usually motile and peritrichous, $0.5\text{--}1.4 \times 1.9\text{--}17.0\ \mu\text{m}$, and occur singly or in pairs. They are Gram-stain-positive, but rapidly become Gram-stain-negative. Spores are oval, usually terminal, and swell the cells; subterminal and free spores may be seen in the same preparations. Sporulation occurs readily in chopped-meat or PY broth after incubation for 24 h.

Cell walls do not contain DAP; the peptidoglycan bridge is composed of lysine, serine, and glycine. Glutamic acid and alanine also are present. Traces of galactose are present in the wall of the type strain; other strains have been reported to contain glucose, rhamnose, and mannose as well.

Surface colonies on blood agar plates are nonhemolytic, 1–5 mm in diameter, circular, low convex or flat, translucent or semiopaque, smooth, dull, with a mottled or mosaic internal structure and a scalloped, erose, or undulate margin.

Cultures in PYG broth are turbid with a smooth, ropy, or flocculent sediment and a pH of 4.5–5.0 after incubation for 5 d.

Optimum temperature for growth is 30–37°C. Most strains grow nearly as well at 45°C but poorly at 25°C. Growth is markedly stimulated by fermentable carbohydrate; 20% bile is not inhibitory; there is little or no growth with 6.5% NaCl. Abundant gas is detected in PYG deep agar cultures. Acetyl methyl carbinol is produced by 8 of 16 strains tested.

Strains of this species are active in the metabolism of bile acids and steroids and produce compounds that have been implicated in the incidence of colon and breast cancer. One strain of this species is able to lyse Ehrlich ascites tumor tissue in mice. The lysis, however, is neither complete nor permanent. Other strains have been found to promote the formation of liver tumors in mice. Culture supernatants are not toxic to mice and strains are not pathogenic for guinea pigs or rabbits.

Products in PYG broth cultures include acetic, butyric, and lactic acids; formic, pyruvic, and succinic acids also may be detected. Abundant H_2 is produced. Of 39 strains tested, 1 is resistant to chloramphenicol, 3 are resistant to penicillin G, 3 are resistant to tetracycline, 13 are resistant to erythromycin, and 35 are resistant to clindamycin. Other characteristics of the species are given in Table 142.

Source: soil; marine sediments; avian; human infant feces; human adult feces; porcine and bovine feces; human clinical specimens including blood, peritoneal fluid, wounds, and appendicitis.

DNA G+C content (mol %): 26–27 (T_m).

Type strain: ATCC 25780, CCUG 32755, DSM 2630, JCM 1293, NCIB 10671, NCTC 11833.

GenBank accession number (16S rRNA gene): X73445, X75907.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium paraputrificum* to fall within the radiation of cluster I of the clostridia as defined by Collins et al.

(1994). The closest relative based on sequence similarities is *Clostridium vincentii* at 97.1%. *Clostridium paraputrificum* is a mesophile which grows optimally between 30 and 37°C, while *Clostridium vincentii* is a psychrophilic species growing optimally at 12°C.

111. ***Clostridium pascui*** Wilde, Collins and Hippe 1997, 169^{VP} pas'cu.i. L. gen. n. *pascui* of a pasture, referring to the habitat where the organism was isolated.

Rod-shaped cells, $0.75\text{--}1.0 \times 3.2\text{--}8.0\ \mu\text{m}$; found singly or in pairs. Gram-stain-negative. Motile. Form subterminal elliptical spores, which cause cell swelling. On blood sheep agar, colonies are nonhemolytic, round, opaque, white-gray in color, and 2 mm in diameter. Cell wall contains *meso*-diaminopimelic acid. The major cellular fatty acids are $\text{C}_{14:0}$, $\text{C}_{16:0}$, $\text{C}_{16:1\ 7\omega}$, and $\text{C}_{16:1\ 9\omega}$ acids and aldehydes.

Anaerobic. The temperature range for growth is 10–43°C with an optimum of 37–40°C. The pH range for growth is 5.5–9.0 with optimal growth at pH 6.4–7.8. Does not ferment carbohydrates. Ferments glutamate and histidine. Acid and gas produced. Fermentation end products include acetate, butyrate, ethanol, H_2 , and CO_2 . Positive for indole production. Negative for nitrate and sulfate reduction, lipase and lecithinase production, and the hydrolysis of gelatin.

DNA G+C content (mol %): 27 (T_m).

Type strain: Cm19, CIP 105172, DSM 10365, JCM 11012.

GenBank accession number (16S rRNA gene): X96736.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium pascui* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relative based on sequence similarities is *Clostridium peptidivorans* at 98.7%. Both of these species share the ability to degrade amino acids but not carbohydrates. *Clostridium pascui* stains Gram-negative while *Clostridium peptidivorans* has Gram-positive staining reaction. They also differ in that *Clostridium peptidivorans* is able to degrade proteinaceous compounds whereas *Clostridium pascui* is not. *Clostridium pascui* produces *n*-butyrate and ethanol in addition to acetate which along with formate are the end products of *Clostridium peptidivorans*.

112. ***Clostridium pasteurianum***^a Winogradsky 1895, 330^{AL}

pas.teu.ri.a'num. N.L. neut. adj. *pasteurianum* pertaining to Louis Pasteur, French microbiologist.

Cells in PYG broth culture are Gram-stain-positive, becoming Gram-stain-negative as old cultures, straight to slightly curved rods, $0.5\text{--}1.3 \times 2.7\text{--}13.2\ \mu\text{m}$, occurring singly or in pairs. Motility is variable and may be lost on subculture; motile cells are peritrichous. Granulose-positive. Spores are oval, subterminal, and swell the cell. Sporulation occurs most readily on chopped-meat slants incubated at 30°C for 1 week. There are no exosporium or appendages.

Cell walls contain *meso*-DAP; wall sugars are glucose, galactose, rhamnose, and mannose. Glutamic acid and alanine also are present. Squalene has been found in cell membranes, with greater amounts being present in spo-

relating than in vegetative cells. Activity of magnesium-dependent membrane ATP has been described.

Surface colonies on blood agar plates are nonhemolytic, 1–3 mm in diameter, circular to irregular, low convex or flat, translucent to semiopaque, gray, shiny, and smooth with an erose or rhizoid margin and a mosaic internal structure.

Cultures in PYG broth are turbid with a smooth sediment, and have a pH of 4.8–5.0 after incubation for 5 d. The optimum temperature for growth is 37 °C. Strains grow nearly as well at 30 °C, moderately well at 25 °C, and poorly if at all at 45 °C. Growth is stimulated by fermentable carbohydrate but inhibited by 20% bile, 6.5% NaCl, or a pH of 8.5. Growth occurs in synthetic medium. Abundant gas is detected in PYG deep agar cultures. Deoxyribonuclease is produced. Acetyl methyl carbinol is produced by the type strain.

Atmospheric N₂ is fixed; molybdenum is essential for biosynthesis and activity of the nitrogenase involved. There is an increase in cellular phospholipids with a high proportion of palmitic acid during N₂-fixing growth; during non-N₂-fixing growth, the proportion of palmitic acid decreases, accompanied by marked increases in shorter chain saturated fatty acids. Cellular fatty acids include mainly the C₁₆ straight-chain, monounsaturated straight-chain C₁₆, C₁₅ cyclopropane, and unsaturated cyclopropane. Leucine is synthesized by the α -iso-propylmalate pathway. The type strain of *Clostridium pasteurianum* can utilize crotonate slowly when the medium is supplemented with peptone and yeast extract. Chlorinated hydrocarbon pesticides can be degraded by this species. Has a nickel-requiring carbon monoxide dehydrogenase.

Products in PYG broth cultures include butyric and acetic acids and small amounts of formic acid; abundant CO₂ and H₂ are detected. Ethanol is produced. Neither ammonia nor H₂S is detected. Pyruvate is converted principally to acetate, CO₂, H₂, and small amounts of butyrate; neither lactate nor threonine is utilized. Gluconate is fermented by way of 2-keto-3-deoxygluconate. The amino acids formed by resting cells in synthetic medium with ammonium salts as sole nitrogen source are alanine, threonine, aspartic acid, arginine, glutamic acid, lysine, and valine, with traces of methionine, isoleucine, and serine.

Strains are susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Culture supernatants are not toxic to mice and strains are not pathogenic for laboratory animals. A bacteriocin produced by the type strain of *Clostridium butyricum* is bactericidal against growing cultures of the type strain of *Clostridium pasteurianum*. Other characteristics of the species are given in Table 142.

Source: soil.

DNA G+C content (mol %): 26–28 (T_m).

Type strain: ATCC 6013, BCRC (formerly CCRC) 10942, CCUG 31328, DSM 525, JCM 1408, KCTC 1674, LMG 3285, NCIB 9486, VKM B-1774.

GenBank accession number (16S rRNA gene): M23930.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium pasteurianum* to fall within the radiation of the cluster I of the clostridia as defined

by Collins et al. (1994). The closest relatives based on sequence similarities are *Clostridium acidisoli* (97.2%) and *Clostridium akagii* (96.4%). *Clostridium pasteurianum* differs from *Clostridium acidisoli* and *Clostridium akagii* in substrate range, in forming ethanol but not lactate, not growing or fixing N₂ at pH 3.7, and having a carbon monoxide dehydrogenase.

113. ***Clostridium peptidivorans*** Mechichi, Fardeau, Labat, Garcia, Verhé and Patel 2000a, 1263^{VP}

pep.ti.di.vo'rans. N.L. n. *peptidum* peptide; L. v. *vorare* to devour; N.L. part. adj. *peptidivorans* peptide-consuming.

Motile rods, 0.6–1.2 × 5–10 μ m. Gram-stain-positive. Form subterminal to terminal oval spores, which distend the cell.

Strictly anaerobic. Growth occurs in the temperature range 20–42 °C with optimal growth at 37 °C. The pH range for growth is 6–9 with an optimum at 7.0. Grows at concentrations less than 4% of NaCl. Grows on Biotrypcase, yeast extract, Casamino acids, gelatin, peptone, arginine, lysine, cysteine, methionine, histidine, serine, isoleucine, and crotonate. No growth on the following carbohydrates: glucose, fructose, xylose, ribose, sorbose, sorbitol, sucrose, melibiose, galactose, *myo*-inositol, sucrose, lactose, cellobiose, mannitol, mannose, arabinose, arabitol, raffinose, cellulose, xylan; organic acids: formate, acetate, propionate, *n*-butyrate, valerate, fumarate, malonate, malate, lactate, citrate, or succinate; or other amino acids: alanine, proline, aspartate, glycine, threonine, glutamate, glutamine, leucine, aspartate, asparagine, valine, tyrosine, phenylalanine, or tryptophan.

Reduces thiosulfate. Ferments lysine and crotonate to acetate and butyrate; biotrypcase, gelatin, and peptone to acetate, butyrate, H₂ and CO₂; cysteine to acetate, alanine, H₂, and CO₂; serine, cysteine, and yeast extract to H₂ and CO₂; histidine to acetate and formate; methionine to propionate; isoleucine to methyl 2-butyrate, H₂, and CO₂; arginine to acetate and ethanol; and Casamino acids to acetate, propionate, butyrate, methyl 2-butyrate, H₂, and CO₂. Cannot reduce sulfate, elemental sulfur, nitrate, and fumarate

Source: olive mill wastewater treatment digester.

DNA G+C content (mol %): 31 (T_m).

Type strain: TMC4, DSM 12505.

GenBank accession number (16S rRNA gene): AF156796.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium peptidivorans* to fall within the radiation of the cluster I of the clostridia as defined by Collins et al. (1994). The closest relative based on sequence similarities is *Clostridium pascui* (98.7%) with other species of this genus having <95.5% 16S rRNA gene sequence similarity. *Clostridium peptidivorans* and *Clostridium pascui* both ferment histidine but not carbohydrates. However, *Clostridium peptidivorans* utilizes proteinaceous substrates in contrast to *Clostridium pascui* which is not proteolytic and only grows on amino acids. They differ in Gram staining reaction as well as ability to ferment glutamate. *Clostridium peptidivorans* produces just acetate and formate from histidine while *Clostridium pascui* produces acetate, butyrate, ethanol, CO₂, and H₂.

114. ***Clostridium perfringens**** (Veillon and Zuber 1898) Hauduroy, Ehringer, Urbain, Guillot and Magrou 1937, 119^{AL} (*Bacillus perfringens* Veillon and Zuber 1898, 539; "*Bacterium welchii*" Migula 1900, 392)
per.frin'gens. L. part. adj. *perfringens* breaking through.

This species produces a number of soluble substances that cause a variety of toxic effects in *in vitro* or *in vivo* conditions, or both. *Clostridium perfringens* has been divided into five types (A, B, C, D, and E) on the basis of production of major lethal toxins. Type A produces alpha toxin; type B produces alpha, beta, and epsilon toxins; type C produces alpha and beta toxins; type D alpha and epsilon toxins; type E produces alpha and iota toxins. A sixth type (type F) was proposed, but it is now considered type C, and type F designation has been abandoned. The five types of *Clostridium perfringens* cannot be differentiated reliably on the basis of cellular or colonial morphology, biochemical reactions, or gas-liquid-chromatographic analyses of fatty and organic acid end products of metabolism.

This description, unless otherwise indicated, is based on study of strains representing the five types (A, B, C, D, and E) and 285 other strains.

Cells in PYG broth culture are Gram-stain-positive, atrichous, nonmotile, straight rods with blunt ends, that occur singly or in pairs and are 0.6–2.4 × 1.3–19.0 μm. Spores are rarely seen *in vivo* or in the usual *in vitro* conditions; when present they are large, oval, central, or subterminal, and distend the cell. There is no exosporium and spores lack appendages. A complex relationship exists between previous heat treatment, the ability to ferment certain sugars, and the ability to sporulate. Spore yield is markedly increased by addition of various methylxanthines to the medium. Spores from heat-resistant strains usually require heat activation to germinate, whereas those from heat-susceptible strains do not; spores from heat-resistant strains are also more resistant to the lethal effects of gamma radiation.

The cell wall contains LL-DAP; cell-wall sugars that may be present are galactose, glucose, and rhamnose; however, cell walls of different strains or types may not possess all three sugars. Approximately three-quarters of strains possess a capsule that is composed largely of polysaccharides; the composition of the capsular polysaccharide may vary among strains.

Colonies on the surface of sheep blood agar are usually 2–5 mm in diameter, circular, entire, dome-shaped, gray to grayish yellow, and translucent with a glossy surface. Several other colonial morphologies (dwarfs, rough colonies with lobate margins, and flat colonies with an irregular surface and filamentous margins) occur occasionally, even in the same culture. The kind and extent of hemolysis present depends on both the species of blood and the type of *Clostridium perfringens* being examined; the three types of hemolysins that may be produced in varying quantities are designated alpha, delta, and theta. On rabbit, sheep, cow, horse, or human blood, most strains produce a narrow zone of complete hemolysis due to the theta toxin and a surrounding zone of incomplete hemolysis due to the alpha toxin. Some type B and C strains may produce a very wide zone of hemolysis on sheep or cow blood due to

delta toxin. Synergistic hemolysis (CAMP phenomenon) between this species and *Streptococcus agalactiae* has been described. Colonies in agar are usually lenticular.

Cultures in PYG broth are turbid with a smooth or occasionally ropy sediment and have a pH of 4.8–5.6 after incubation for 1 week. The temperature for optimum growth of types A, D, and E is 45 °C; types B and C grow equally well at 37 °C and 45 °C. The range of temperatures that will support growth of most strains is 20–50 °C; occasional strains will grow at 6 °C for a limited number of passages, but they are not truly psychrophilic. Growth is stimulated by the presence of a fermentable carbohydrate and is not inhibited by 20% bile. Growth occurs readily from pH 5.5–8.0. Growth is not inhibited by NaCl concentrations up to 2%, but is markedly inhibited by 6.5% NaCl. Growth is not enhanced by addition of CO₂ to the atmosphere of incubation. Hyperbaric oxygen (100% oxygen at 3 atm) is bactericidal for this species; partial protection is conferred by addition of whole blood, presumably because of enzymic destruction of hydrogen peroxide by catalase. Abundant gas is produced in PYG deep agar cultures.

Occasional strains weakly ferment glycerol, inulin, and sorbose; ammonia is produced; acetyl methyl carbinol and H₂S are produced, and hippurate is hydrolyzed by some strains; neutral red is reduced; resazurin is reduced by most strains. Although more than 95% of strains ferment sucrose and produce lecithinase, an occasional isolate will be negative for one of these reactions.

Deoxyribonuclease, acid phosphatase, ribonuclease, elastase, hyaluronidase, amylase, neuraminidase, a hemoagglutinin that is distinct from neuraminidase, exo-β-D-galactosidase, ferredoxin-linked nitrate reductase, and superoxide dismutase are produced by some or all strains.

Bile acid metabolism includes deconjugation of taurocholic and glycocholic acids by types A, B, C, D, and E, degradation of chenodeoxycholic acid and cholic acid, and conversion of a number of 3-α-hydroxy bile acids to 3-β-hydroxy and 3-oxo-bile acids. Occasional strains are reported to possess a Δ⁴-steroid dehydrogenase and/or the ability to cause aromatization of the Δ-ring of 4-androsten-3,17-dione; these steps have been postulated to be important in converting steroids to colon carcinogens. Monoacetone glucose is fermented.

Most strains are susceptible to bacteriocins produced by enterococci, particularly *Streptococcus faecium*. Some soil isolates of *Clostridium perfringens* produce inhibitors that are active against some or all of *Clostridium botulinum* types A, B, E, and F. *Clostridium perfringens* also produces bacteriocins that are active against other strains of *Clostridium perfringens*. Bacteriocin produced by one strain has a single-chained polypeptide with a molecular weight of approximately 82,000. The mechanism of action of many bacteriocins involves inhibition of macromolecular synthesis (DNA, RNA, and proteins); an additional (but undefined) mechanism probably also exists. Bacteriocin production and resistance to that bacteriocin by several strains have been shown to be related to the presence of a plasmid. Caseinase activity appears to be related to the presence of a plasmid in the one strain tested.

Bacteriophages of this species have been recognized since 1949. Virulent bacteriophage has been recovered from sewage or river water below sewage discharge points. Some strains of types A, B, and C are lysogenic, whereas lysogeny has not been described for types D and E; in addition, smooth or rough strains usually are phage-susceptible whereas mucoid strains usually are resistant. The rapidity of sporulation and the percentage of spores that were heat-resistant decreased when one strain studied was cured of bacteriophage; these changes were reversed when the cured strain was reinfected with the temperate phage.

Cultures of all five types, when grown in PYG broth, produce large amounts of acetic, butyric, and lactic acids; sometimes smaller amounts of propionic, formic, and succinic acids are detected. Abundant H_2 is produced. Lactate occasionally is converted to butyrate; pyruvate is converted to acetate and butyrate and, occasionally, to formate; threonine is converted to propionate. The production of butyrate by one strain is abolished when nitrate was added to the medium. One strain of type E produces isovaleric acid and larger amounts of propionic acid in a medium containing monoacetone-glucose (rather than glucose). Two of four strains tested produce phenylacetic acid from a trypticase-yeast extract medium.

Most β -lactams, particularly penicillin G, are quite active against *Clostridium perfringens*, but relatively greater resistance of this species to penicillin G has been reported. Chloramphenicol, clindamycin, and metronidazole are active against most isolates, but less so on a weight basis than is penicillin G; erythromycin and tetracycline are generally less active than most of the penicillins, chloramphenicol, clindamycin, and metronidazole. A number of strains isolated from pig feces were reported to be resistant to tetracycline, erythromycin, lincomycin, and clindamycin; this degree of resistance appeared to correlate with the use of antimicrobial-containing animal feed. Aminoglycosides are inactive against *Clostridium perfringens*. Twelve of 25 strains were inhibited by 0.25 mg or less of nalidixic acid/ml whereas the remaining 13 strains required 4–64 μ g/ml for inhibition. Plasmid-mediated resistance of *Clostridium perfringens* to clindamycin-erythromycin, to tetracycline-chloramphenicol, and to tetracycline alone has been described.

Clostridium perfringens produces a variety of substances (often referred to as "exotoxins") that have been suggested as possible virulence factors. The four toxins alpha, beta, epsilon, and iota are often referred to as the major lethal toxins. The alpha toxin is a phospholipase C that hydrolyzes lecithin to phosphorylcholine and a diglyceride; it is produced by all five types of *Clostridium perfringens*. Alpha toxin exerts its lethal effects by lysing cell membranes, presumably as a consequence of hydrolysis of membrane lecithin. This toxin alone is the cause of muscle death in myonecrosis in cases of *Clostridium perfringens* gas gangrene in humans and other animals following trauma or abortion. The alpha toxin may also cause intravascular hemolysis. Several other diseases in animals are known or suspected to be caused by type A (presumably by the alpha toxin). These include a fatal enterotoxemia of

lambs, newborn alpacas, captive wild goats, reindeer, and possibly chickens, and delayed hypersensitivity to alpha toxin in swine that results in arthritis with eventual joint deformity, parakeratosis, and proliferative glomerulonephritis. In addition to causing myonecrosis and/or intravascular hemolysis in humans via the alpha toxin, type A strains may also produce an enterotoxin that causes a food-poisoning syndrome in humans (see below).

The beta toxin, produced by strains of types B and C, has not been completely characterized, but appears to be a highly trypsin-sensitive, single chain polypeptide with a molecular mass of approximately 30,000. It appears to exert its toxic effect by increasing capillary permeability. Intravenously administered beta toxin appears to induce release of endogenous catecholamines. Beta toxin production is thought possibly to be plasmid-mediated. The diseases produced by beta toxin involve the gastrointestinal tract. In humans a necrotic enteritis (pig-bel) develops soon after ingestion of roast pig that has been accidentally contaminated with feces containing *Clostridium perfringens* type C; it is not known whether toxin is ingested or produced in the gut following ingestion of the organism. A necessary antecedent of pig-bel appears to be ingestion of large quantities of sweet potatoes which contain a trypsin inhibitor. A similar form of necrotic enteritis in humans (Darmbrand) was seen in Europe in the mid- to late 1940s; in this setting the presence of starvation, which tends to produce low gastrointestinal levels of trypsin, was probably an important cofactor. Type C also causes enterotoxemia or necrotic enteritis in lambs, calves, piglets, and sheep, whereas type B causes enterotoxemia or necrotic enteritis in foals, lambs, sheep, and goats. An important cofactor for development of beta toxin-induced necrotic enteritis in newborn or very young animals may be the absence of trypsin in the gut.

Epsilon toxin is elaborated by types B and D in the form of a virtually nontoxic prototoxin that is converted to a potent heat-labile toxin by certain proteolytic enzymes such as trypsin. This toxin appears to increase vascular permeability, possibly by adenyl cyclase activation, that ultimately leads to tissue necrosis. Exposure of the gut to epsilon toxin (to which it is normally impervious) results in greater permeability to proteins, including epsilon toxin; this may be an important factor in pathogenesis of disease because oral administration of a single large dose of epsilon toxin may be without effect, whereas administration of the same total dose in several smaller portions may be lethal. The toxin probably produces an increase in vascular permeability of many organs, the most seriously affected of which is the brain; cerebral edema and necrosis of brain tissue is the most likely cause of death in afflicted animals. The toxin also is cytotoxic to guinea pig and rabbit peritoneal macrophages. Type D causes enterotoxemia of lambs, sheep, goats, cattle, possibly humans (very rarely), and chinchillas.

Iota toxin is produced only by type E. This toxin is elaborated as a prototoxin that is usually activated by proteolytic enzymes produced by the organism. Iota toxin markedly increases vascular permeability, produces necrosis on intradermal injection, and is lethal on intravenous

injection. The organism is sometimes carried by normal sheep and cattle, and is purported to be a rare cause of enterotoxemia in calves. Iota toxin has been implicated (by antitoxic neutralization) as a cause of antimicrobial-induced colitis in rabbits, the causative organism probably is *Clostridium spiroforme*; iota-like toxic activity is produced by strains tentatively identified as *Clostridium spiroforme*.

Type A strains and some type C and D strains produce an enterotoxin; *Clostridium perfringens* food poisoning in humans is produced by type A strains. Food poisoning can be caused by strains that produce only heat-sensitive spores, as well as by strains that produce heat-resistant spores. Spores that survive cooking may germinate and proliferate to high counts in food products (usually warm meats or meat products); when ingested, the vegetative cells sporulate in the gut and release enterotoxin. Enterotoxin is a product of the sporulation process and causes fluid accumulation in the small intestine of laboratory animals. Feeding of purified enterotoxin to volunteers reproduces the food poisoning syndrome. Type A enterotoxin as been implicated as the cause of a lethal enteritis in horses.

Clostridium perfringens also produces a variety of other substances that have been referred to as toxins. The role of these factors as regards virulence and pathogenicity either is not significant or is not known. Other possible "virulence factors" include sialidase and a non-alpha-delta-theta hemolysin.

Other characteristics of the species are given in Table 142. Some allegedly lecithinase-negative strains can be shown to produce lecithinase on a modified medium.

This species is more widely spread in nature than any other pathogenic microorganism. Although most investigators do not type their isolates, it has been stated that only type A strains are found as part of the microflora of both soil and intestinal tracts, and that types B, C, D, and E seem to be obligate parasites of animals and occasionally are found in humans. Sources yielding *Clostridium perfringens* include soil and marine sediment samples worldwide, clothing, raw milk, cheese, semipreserved meat products, and venison. *Clostridium perfringens* has been isolated from the intestinal contents of virtually every animal that has been investigated. It has also been isolated from pheasant small intestine and from rattlesnake venom.

In addition to causing specific toxin-induced diseases, *Clostridium perfringens* has also been isolated from a variety of mixed anaerobic/aerobic pyogenic infections of a number of different species of domesticated animals.

Humans frequently carry *Clostridium perfringens* as part of the normal endogenous flora. Although this species can be recovered in a small percentage of patients from the normal oral flora, the normal cervicovaginal flora, from urine (presumably reflecting the flora of the distal urethra), and from the skin of the antecubital fossae of approximately 20% of subjects, the main site of carriage is the distal gastrointestinal tract.

Approximately 80% of cases of gas gangrene (clostridial myonecrosis) involve *Clostridium perfringens*. In addition, this species has been reported to cause bacteremia (with and without intravascular hemolysis).

Clostridium perfringens is the species of *Clostridium* most commonly isolated from infections in humans; such infections are often polymicrobial. Although virtually every type of infection in humans has yielded *Clostridium perfringens* on one or more occasions, it is most commonly recovered from infections derived from the colonic flora (e.g., peritonitis, intra-abdominal abscess, and soft tissue infections below the waist).

Source: infections in humans, especially from colonic flora.

DNA G+C content (mol%): 24–27 (T_m).

Type strain: ATCC 13124, BCRC (formerly CCRC) 10913, CCUG 1795, CIP 103409, DSM 756, JCM 1290, LMG 11264, NCAIM B.01417, NCCB 89165, NCIMB 6125, NCTC 8237.

Reference strains: type B: ATCC 3626, NCIB 10691; type C: ATCC, 3628, NCIB 10662; type D: ATCC 3629, NCIB 10663; type E: ATCC 27324, NCIB 10748.

GenBank accession number (16S rRNA gene): M59103.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium perfringens* to fall within the radiation of the cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives based on sequence similarities include *Clostridium baratii* (95.0%), *Clostridium saccharobutylicum* (94.9%), and the *Eubacterium* species: *Eubacterium budayi*, *Eubacterium tarantellae*, and *Eubacterium moniliforme* (94.4–94.7%). Isolates previously identified as "*Clostridium plagarum*" possess a high degree of DNA homology (Nakamura et al., 1976) and 100% rRNA homology with *Clostridium perfringens*; such isolates should be considered lecithinase-negative, theta "toxin" negative variants of *Clostridium perfringens* (Nakamura et al., 1976).

115. ***Clostridium phytofermentans*** Warnick, Methé and Leshine 2002, 1158^{VP}

phy.to.ferm.men'tans. Gr. n. *phyton* plant; L. part. adj. *fermentans* fermenting; N.L. part. adj. *phytofermentans* plant-fermenting, referring to the wide range of plant polysaccharides that this organism is capable of utilizing as growth substrate.

Straight rods, 0.5–0.8 × 3–15 μm, singly or in pairs. Gram-stain-positive cell-wall type; Gram-stain-negative staining reaction. Motile with one or two flagella per cell. Form round, terminal spores, 0.9–1.5 μm in diameter, and cause sporangium swelling. Colonies are round, glossy, translucent, with slightly raised centers, and 2–5 mm in diameter.

Obligate anaerobe. Temperature range for growth is 15–42 °C with an optimum of 37 °C. The pH range for growth is 6.0–9.0 with optimal growth at pH 8.0. Ferments cellulose, pectin, polygalacturonic acid, starch, xylan, arabinose, cellobiose, fructose, galactose, gentiobiose, glucose, lactose, maltose, mannose, ribose, and xylose. Does not utilize glucose, pyruvate, sucrose, trehalose, and tryptone. Negative for urease, esculin hydrolysis, and nitrate and sulfate reduction. Ferments cellulose to ethanol, acetate, CO₂, H₂, and minor amounts of formate and lactate.

Source: forest soil in Massachusetts, USA.

DNA G+C content (mol%): 35.9 (T_m).

Type strain: ISDg, ATCC 700394, DSM 18823.

GenBank accession number (16S rRNA gene): AF020431.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium phytofermentans* to fall within the radiation of the cluster XIVa of the clostridia as defined by Collins et al. (1994). *Clostridium phytofermentans* forms a distinct lineage within this cluster and its closest relatives based on sequence similarities include *Anaerosporebacter mobilis* (93.8%) and *Clostridium jejuense* (93.0%); all other *Clostridium* species are related at less than 93% 16S rRNA gene sequence similarity.

116. ***Clostridium polyendosporum*** comb. nov. (Duda, Lebedinsky, Mushegian and Mitjushina 1996) Effective publication: Duda, Lebedinsky, Mushegian and Mitjushina 1987, 126 (*Anaerobacter polyendosporus* Duda, Lebedinsky, Mushegian and Mitjushin 1996, 625)

po.ly.en.do.spo'rum. Gr. pref. *poly* many; Gr. pref. *endo* within; Gr. n. *spora* spore; N.L. adj. *polyendosporum* (forming) several endospores.

The description is as given previously by Duda et al. (1987) and Siunov et al. (1999).

Cells are oval, 3–4 × 4–8 μm or spherical, 4–6 μm in diameter on solid media. In liquid media the cells are thick rods with rounded ends, 1.5–3 × 4–8 μm. Nonmotile. Surrounded by a polysaccharide capsule. The rod-shaped cells form one or two subterminal spores at the opposite poles. The oval and spherical cells form 1–5 round or oval spores. The endospores possess spore coats, exosporium, inner and outer membranes, cortex, and core. The cell wall consists of one layer and is sensitive to penicillin and lysozyme. Prosthecae-like appendages surrounded by the cytoplasmic membrane and the cell wall and containing cytoplasm are sometimes formed. Extensive lipid leaves form in the cytoplasmic membrane, located between the outer and internal lipid layers of the membrane. Colonies on the surface of solid media are large, up to 5 mm in diameter, round, smooth, opaque, brownish-white, viscous, navel-shaped, with entire margins.

Moderately aerotolerant anaerobe. Growth on solid media containing no reductants is possible at pO₂ ≤ 500 Pa. A weak catalase activity can sometimes be detected after growth at pO₂ of 500 Pa. Cytochromes are not present. Neutrophilic and mesophilic. Growth occurs in pH range 5.5–8.5 with an optimum at 6.5–7.5. The temperature range for growth is 15–45 °C with an optimum at 25–35 °C. Growth supported by cellobiose, fructose, galactose, glucose, inulin, maltose, mannitol, mannose, raffinose, salicin, sorbitol, sucrose, trehalose, xylose, and lactate. Starch is hydrolyzed but cannot support growth as the sole source of carbon and energy. Amino acids, alcohols, and organic acids other than lactate do not support growth. Gelatin is not liquefied. Lipase, lecithinase, and urease are not produced. Indol and sulfide are not formed. The end products of glucose fermentation include acetate, lactate, butyrate, ethanol, butanol, H₂, and CO₂. Sulfate and nitrate are not used as electron acceptors, but nitrite is reduced to ammonia in a dissimilatory process.

Source: meadow-gley soil under rice.

DNA G+C content (mol %): 29 (T_m).

Type strain: PS-1, DSM 5272, VKM B-1724.

GenBank accession number (16S rRNA gene): Y18189.

Further comments: 16S rRNA gene sequence comparisons show *Anaerobacter polyendosporus* to fall within the radiation of the cluster I of the clostridia as defined by Collins et al. (1994). The original description of this species as *Anaerobacter polyendosporus* did not include phylogenetic information for analysis (Duda et al., 1987). Subsequent studies demonstrated that based on 16S rRNA gene sequence analyses, *Anaerobacter polyendosporus* did, in fact group, within the cluster I of the clostridia as defined by Collins et al. (1994) (Siunov et al., 1999; Stackebrandt et al., 1999). The original justification for the creation of the genus *Anaerobacter* was based on the morphological characteristics of this organism as well as its ability to form numerous spores within a single cell (Duda et al., 1987). The study of Siunov et al. (1999) suggests that these morphological characteristics as well as the observation of lipid leaves in the cytoplasmic membrane, located between the outer and internal lipid layers of the membrane, justify the existence of the genus *Anaerobacter* even though it fell within the species of the genus *Clostridium sensu stricto*. Stackebrandt et al. (1999a) suggests that *Anaerobacter polyendosporus* should be reclassified as a species of the genus *Clostridium*. *Anaerobacter polyendosporus* shows highest 16S rRNA gene sequence similarity to the species *Clostridium fallax* (95.6%), *Eubacterium tarantellae* (95.1%), *Clostridium putrefaciens* (94.9%), *Clostridium intestinale* (94.8%), and *Clostridium chauvoei* (94.7%). In an attempt to further the reorganization of the genus *Clostridium*, the species *Anaerobacter polyendosporus* is transferred to the genus *Clostridium* as *Clostridium polyendosporum* comb. nov.

117. ***Clostridium polysaccharolyticum**** (van Gylswyk 1980) van Gylswyk, Morris and Els 1983, 438^{VP} (Effective publication: van Gylswyk, Morris and Els 1980, 492) (*Fusobacterium polysaccharolyticum* van Gylswyk 1980, 157)

po.ly.sac.ca.ro.ly'ti.cum. Gr. adj. *polys* many; Gr. n. *saccharon* sugar; Gr. adj. *lutikos* dissolving; N.L. neut. adj. *polysaccharolyticum* degrading polysaccharides.

This description is based on that of van Gylswyk (1980) and on study of the type strain.

Cells from cellobiose-rumen fluid agar medium are motile and peritrichous, Gram-stain-negative straight rods with rounded ends, 0.6–1.1 × 2–15 μm. In broth cellobiose-rumen fluid cultures, aseptate filaments may be more than 50 μm in length. Cells occur singly, in pairs, or in short chains. Spores are usually oval, occasionally spherical and subterminal, although terminal spores may be seen. They swell the cell. Sporulation occurs most readily on cellulose-rumen fluid-agar slants. Although the cells stain Gram-negative, cell walls have a peptidoglycan layer characteristic of Gram-stain-positive cells.

Surface colonies on rumen fluid-glucose-cellobiose agar plates are 1 mm in diameter, circular, low convex, semiopaque, buff colored, shiny, and smooth, with an entire edge and have no visible internal structure.

Cultures in PY-cellobiose broth with 30% rumen fluid are not turbid but have a smooth viscous sediment and a pH of 5.7 after incubation for 1 week. Optimum temperature for growth is 30–38 °C. There is no growth at 22 °C

and little or none at 45 °C. Fermentable carbohydrate and CO₂ in the gas phase are required for growth. Acetate stimulates growth. Rumen fluid (30%) is greatly stimulatory. Moderate gas is detected in cellobiose-rumen fluid deep agar cultures after incubation for 1 week. Cellulose, xylan, starch, and cellobiose are fermented consistently. Products in PY-cellobiose broth are formate, butyrate, acetate, propionate, H₂, and small amounts of ethanol. In media containing acetate and propionate, these compounds are utilized to form more butyrate or formate. Antibiotic susceptibility has not been determined.

Other characteristics of the species are given in Table 143.

Source: the sheep rumen.

DNA G+C content (mol%): 42 (*T_m*).

Type strain: strain B, ATCC 33142, DSM 1801.

GenBank accession number (16S rRNA gene): X71858, X77839.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium polysaccharolyticum* to fall within the radiation of the cluster XIVa of the clostridia as defined by Collins et al. (1994). The closest relatives of *Clostridium polysaccharolyticum* are *Clostridium herbivorans* (96.4%) and *Clostridium populeti* (92.9%). *Clostridium polysaccharolyticum*, like *Clostridium herbivorans*, utilizes cellulose, cellobiose, maltose, and starch but do not utilize glucose. They can be differentiated based on the fact that *Clostridium polysaccharolyticum* can utilize arabinose, xylan, and xylose but *Clostridium herbivorans* cannot. These two species differ in their DNA G+C content by 4 mol%.

118. ***Clostridium populeti*** Sleat and Mah 1985, 162^{VP}

po.pu'le.ti. L. n. *populetum* poplar wood; L. gen. n. *populeti* of poplar wood.

Motile rods, 1–1.5 × 1.7–3.0 μm; found singly or in pairs. Gram-stain-negative staining reaction. Form terminal spores which cause cell swelling and are 1.0–1.2 μm in diameter. Cells are resistant to sodium dodecyl sulfate, but are lysed by lysozyme and EDTA. Deep colonies are irregular, opaque, and yellow. Surface colonies are invisible except for a thin opaque edge. Clear zone of cellulolysis measures 20 mm in diameter.

Anaerobic growth. The temperature range for growth is 20–40 °C with an optimum at 35 °C. No growth at 15 °C. Growth occurs in the pH range 6.4–8.1 with optimum growth at pH 7.0.

Utilizes arabinose, xylose, fuctose, galactose, glucose, cellobiose, maltose, sucrose, cellulose, xylan, and pectin. Does not ferment rhamnose, glycerol, mannose, lactose, trehalose, melezitose, erythritol, arabitol, sorbitol, lactate, and pyruvate.

Ferments glucose and cellulose to produce H₂, CO₂, acetate, butyrate, and lactate. Trace amounts of ethanol and succinate are detected after glucose fermentation but no pyruvate or formate are produced. Produces butyrate and H₂ from cellulose fermentation. Yellow pigment is formed on the pebble-milled cellulose when the organism is growing on it. Hydrolyzes gelatin after extended incubation. Casein and starch are not hydrolyzed.

Source: a batch methanogenic fermentation of finely divided hybrid poplar wood.

DNA G+C content (mol%): 28 (*T_m*).

Type strain: 743A, ATCC 35295, DSM 5832.

GenBank accession number (16S rRNA gene): X71853.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium populeti* to fall within the radiation of the cluster XIVa of the clostridia as defined by Collins et al. (1994). The closest relatives of *Clostridium populeti* are *Clostridium herbivorans* (94.6%) and *Clostridium jejuense* (93.8%). *Clostridium populeti* can be differentiated from *Clostridium herbivorans* in that it does not produce formate and has a G+C value 10 mol% lower than *Clostridium herbivorans*.

119. ***Clostridium propionicum**** Cardon and Barker 1946, 631^{AL}

pro.pi.o'ni.cum. N.L. neut. adj. *propionicum* pertaining to propionic acid.

This description is based on that of Cardon and Barker (1946) and on study of the type strain.

Cells in PYG broth cultures are motile and peritrichous, Gram-stain-positive rods that rapidly become Gram-stain-negative, 0.5–0.8 × 1.3–5.0 μm. They are straight or slightly curved with tapered or rounded ends, and usually occur in pairs, occasionally singly or in short chains. Spores are oval, subterminal, and swell the cell. Sporulation occurs most readily on egg yolk agar plates or in PY broth. Cell walls contain *meso*-DAP.

Surface colonies on blood agar plates are pinpoint, circular, convex, translucent, gray, dull with a slightly shiny outer rim, smooth, with an entire to slightly scalloped margin and have no visible internal structure.

Cultures in PYG broth are turbid with a smooth sediment and have a pH of 6.0–6.2 after incubation for 1 week. *Clostridium propionicum* grows well between 25 °C and 30 °C. There is no growth at 45 °C. Alanine, serine, threonine, lactate, pyruvate, or acrylate is required for growth. Moderate amounts of gas are formed in PYG deep agar cultures; resazurin is reduced. Ammonia is produced. H₂S is formed in SIM medium.

A wide variety of lipid fatty acids, both straight and branched chain, saturated and unsaturated, is present in cells of the type strain of this species.

Products in PYG broth are propionate, isovalerate, isobutyrate, butyrate, small amounts of acetate, succinate, and sometimes lactate. Abundant H₂ is produced. Pyruvate is converted to propionate and acetate; threonine is converted to propionate and butyrate, CO₂, and ammonia. Lactate is converted to propionate by the acrylate pathway rather than by the more common fumarate pathway. Acrylate can accumulate in resting cell solutions when alternative electron acceptors are provided. Alanine is converted to propionate, acetate, NH₃, and CO₂. Valine is converted to isobutyrate; leucine and isoleucine are converted to isovalerate. Phenylalanine and tyrosine are oxidized to small amounts of phenylacetic and hydroxyphenylacetic acids.

Antibiotic susceptibility has not been determined. Other characteristics of the species are given in Table 143.

Source: black mud in San Francisco Bay, California, USA.

DNA G+C content (mol%): not reported.

Type strain: ATCC 25522, CCUG 9280, DSM 1682, JCM 1430, NCIB 10656, VPI 5303.

GenBank accession number (16S rRNA gene): X77841.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium propionicum* to fall within the radiation of the cluster XIV of the clostridia as defined by Collins et al. (1994). The closest relatives are *Clostridium neopropionicum* (98.1%) and *Clostridium lactatifermentans* (94.7%).

Clostridium propionicum differs from *Clostridium neopropionicum* in not utilizing glucose, staining Gram-stain-positive, and its temperature range for growth. Tholozan et al. (1992) demonstrated that *Clostridium propionicum* and *Clostridium neopropionicum* are distinct species based on a DNA–DNA reassociation value of 18%.

120. ***Clostridium proteoclasticum*** Attwood, Reilly and Patel 1996, 755^{VP}

pro.te.o.clas'ti.cum. N.L. neut. n. *proteinum* protein; Gr. v. *proteuein* to be first; N.L. adj. *clasticus* breaking; Gr. part. perf. *klastos* broken; N.L. adj. *proteoclasticum* protein-breaking.

Straight to slightly curved rods with tapered ends, 0.4–0.6 × 1.3–3.0 μm; found in short chains. Gram-stain-positive. Nonsporeforming. Cells have a single subterminal flagella, but are not motile in liquid media. Cells aggregate and sediment after overnight incubation, but disperse when shaken. Colonies grown on CC-glucose medium are 0.5 mm in diameter, tan, irregular, convex, viscous, smooth, and transparent. Colonies grown 2–3 d are 1 mm in diameter and granular. Colonies on blood agar are nonhemolytic.

Strictly anaerobic. Optimum temperature for growth is 39 °C with no growth at 25 or 39 °C. The pH range for growth is 5.8–7.0. Grows on amygdalin, arabinose, cellobiose, fructose, galactose, glucose, inulin, lactose, maltose, melibiose, rhamnose, salicin, starch, sucrose, xylan, and xylose. Weak growth on glycogen and mannose. No growth on adonitol, cellulose, dextrin, dulcitol, erythritol, galacturonic acid, glycerol, inositol, lactate, mannitol, melizitose, sorbitol, sorbose, and trehalose. Fermentation products are formate, butyrate, acetate, propionate, and traces of succinate. Hydrogen produced from growth on CC-glucose medium. Does not reduce nitrate. Does not produce indole. No catalase, lipase, or lecithinase activity. Hydrolyzes casein, gelatin, and esculin. Curd produced from milk.

Growth is inhibited by bile, stimulated by 20% rumen fluid, and unaffected by Tween 80 or hemin. Growth is inhibited on CC-glucose agar plates containing ampicillin, tetracycline, chloramphenicol, gentamicin, and monensin. Strain B316^T is not inhibited by streptomycin at concentrations up to 100 μg/ml

Source: rumen contents of grazing cattle in New Zealand.

DNA G+C content (mol%): 28 (T_m).

Type strain: B316, ATCC 51982, DSM 14932.

GenBank accession number (16S rRNA gene): U37378.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium proteoclasticum* to fall within the radiation of the cluster XIVa of the clostridia as defined by Collins et al. (1994). The closest relatives are *Butyrivibrio hungatei* (95.9%) and *Butyrivibrio fibrisolvans* (93.1%). The study of Kopečný et al. (2003) demonstrated that *Clostridium proteoclasticum* falls within the radiation of the genus *Butyrivibrio* based on 16S rRNA gene sequence analyses and shares many similarities in fatty acid composition patterns. Interestingly, the DNA G+C content of 28 mol% given by Attwood et al. (1996) for the type strain is well out of the range of the species of the genus *Butyrivibrio* (40–41 mol%). DNA G+C content values of ~40 mol% were found for other strains of *Clostridium proteoclasticum* (Kopečný et al., 2003). *Clostridium proteoclasticum* differs from *Butyrivibrio* species in showing proteolytic activities.

121. ***Clostridium proteolyticum*** Jain and Zeikus 1988, 328^{VP} (Effective publication: Jain and Zeikus 1988, 140.)

pro.teo.ly'ti.cum Gr. n. *proteo* protein; Gr. adj. *lyticus* dissolving; N.L. neut. adj. *proteolyticum* protein dissolving, proteolytic.

Rod-shaped cells, 0.5 × 2.2 μm. Nonmotile. Obligate anaerobe. Gram-stain-positive. Bilayered cell wall. Spore-forming. Colonies are small, flat, off-white in color, 1–1.5 mm in diameter. Cell walls are difficult to lyse with lysozyme and Pronase. Obligate anaerobe. Optimum growth occurs in the temperature range 30–37 °C and at pH 6.0–8.0.

Proteolytic. Utilizes gelatin, collagen, azocoll, peptone, meat, and poly pep. Grows slowly on casein and serum albumin. Does not grow on carbohydrates, single or mixtures of amino acids. No vitamins or growth factors are required for growth. Acetate is the major end product of fermentation. Ethanol, isobutyrate, isovalerate, and hydrogen are also produced. Significant amounts of butyrate produced from cooked meat medium. Cells are nonhemolytic. Sensitive to streptomycin and penicillin (100 μg/ml). Negative for catalase and oxidase activity.

Source: chicken manure.

DNA G+C content (mol%): 29.54 (T_m).

Type strain: CG, ATCC 49002, DSM 3090.

GenBank accession number (16S rRNA gene): X73448.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium proteolyticum* to fall within the radiation of the cluster II of the clostridia as defined by Collins et al. (1994). The closest relatives are *Clostridium limosum* (97.0%) and *Clostridium histolyticum* (96.1%).

122. ***Clostridium psychrophilum*** Spring, Merkhoffer, Weiss, Kroppenstedt, Hippe and Stackebrandt 2003, 1027^{VP}

psy.chro'phi.lum. Gr. adj. *psychros* cold; Gr. adj. *philos* loving; N.L. neut. adj. *psychrophilum* cold-loving.

Rod-shaped cells, 1.0–1.4 × 2.5–8.0 μm, occur singly, in pairs or short chains. Gram-stain-positive. Motile by peritrichous flagella. Filamentous cells are frequently present in agar grown cultures. Endospores are ellipsoidal, subterminal to terminal position; sporangium is not swollen. Colonies are 1–2 mm in diameter, round with often coarsely granulated margins, smooth, slightly raised, cream-white to grayish, semi-transparent to opaque, and nonhemolytic

on sheep-blood agar. The cell-wall peptidoglycan contains *meso*-DAP. The major cellular fatty acids are C_{16:1 ω9c}, C_{14:0}, C_{16:1 DMA ω9c}, C_{16:1 ω11c}, and C_{16:0}.

Optimum temperature for growth is 4 °C; no growth above 10 °C. Growth occurs in the pH range 5.5–7.5 with optimal growth at 6.5–7.0. Under optimal conditions, the doubling time is 33.9 h.

Carbohydrates utilized include: arabinose, cellobiose, fructose, glucose, inulin, maltose, mannose, sucrose, trehalose, and xylose. The following carbohydrates are not utilized: amygdalin, galactose, glycogen, inositol, lactose, mannitol, melezitose, melibiose, raffinose, rhamnose, ribose, salicin, sorbitol, and starch. Gelatin and starch are not hydrolyzed. The end products of fermentation are lactate, ethanol, 1-butanol, butyrate, hydrogen, and carbon dioxide.

Source: a microbial mat sample taken from a moated area around Lake Fryxell, Antarctica.

DNA G+C content (mol%): 31.8 (HPLC).

Type strain: A-1/C-an/I, ATCC BAA-582, DSM 14207.

GenBank accession number (16S rRNA gene): AJ297443.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium psychrophilum* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives of *Clostridium psychrophilum* are the two subspecies of *Clostridium estertheticum* (97.8%), *Clostridium frigoris* (97.7%), *Clostridium lacusfryxellense* (97.6%), and *Clostridium bowmanii* (97.0%). DNA–DNA reassociation studies show *Clostridium psychrophilum* to represent a distinct species even though the 16S rRNA gene sequence similarity values are 97.8% with the subspecies of *Clostridium estertheticum*. In addition, *Clostridium psychrophilum* can be differentiated from closely related species on the basis of optimum temperatures for growth, substrate utilization patterns, starch hydrolysis, and end products of fermentation.

123. ***Clostridium puniceum**** Lund, Brocklehurst and Wyatt 1981b, 216^{VP} (Effective publication: Lund, Brocklehurst and Wyatt 1981a, 17.)

pu.ni ce.um. L. neut. adj. *puniceum* purplish, referring to pink color of colonies on potato infusion agar.

This description is based on that of Lund et al. (1981a) and on study of the type and four other strains.

Cells in PYG broth culture are straight or curved rods, motile and peritrichous, 0.6 × 1.8–4.2 μm, granulose positive, and occur singly, in pairs, or in short chains. They are usually Gram-stain-negative, but Gram-stain-positive cells are sometimes present. Spores are oval, subterminal, and do not swell the cell. Free spores are common and have an extensive exosporium. Cell-wall content has not been reported. Surface colonies on blood agar plates are nonhemolytic, pinpoint–2 mm, circular, raised to convex, opaque, white, slightly shiny, and smooth, with an entire margin, and have a granular or mottled internal structure. On potato infusion agar, colonies are similar except that they are pale pink or deep pink and may have undulate or lobate margins.

Cultures in PYG broth are turbid with a viscous or flocculent sediment and have a pH of 5.2–5.5 after incubation

for 6 d. The optimum temperature for growth is 23–33 °C. Growth range is 7–39 °C. Strains grow moderately well in PY broth without fermentable carbohydrate; they do not grow in the defined medium of Lund et al. (1981a) unless fermentable carbohydrate is present. Abundant gas is detected in PYG deep agar cultures.

Slices of potato, carrot, radish, and turnip are digested. Pectin is fermented. Pectate is hydrolyzed; tributyrin is not attacked. Cultures grown in potato tissue form pectate lyase and pectinesterase but no pectic hydrolase. Products in PYG broth include acetic, butyric, and formic acids, and butanol. Abundant H₂ is produced.

All strains tested are susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Culture supernatants are not toxic for mice. Other characteristics of the species are given in Table 142.

Source: rotting potatoes, a cavity spot lesion in a carrot.

DNA G+C content (mol%): 28–29 (T_m).

Type strain: BL 70/20, ATCC 43978, DSM 2619, ICMP 12529, NCIMB 11596.

GenBank accession number (16S rRNA gene): X71857, X73444.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium puniceum* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives of *Clostridium puniceum* are the two subspecies of *Clostridium saccharoperbutylacetonicum* (99.1%), *Clostridium diolis* (98.8%), *Clostridium beijerinckii* (98.6%), *Clostridium saccharobutylicum* (98.5%), and *Clostridium butyricum* (97.5%).

124. ***Clostridium purinilyticum**** corrig. Dürre, Andersch and Andreesen 1981, 192^{VP}

pu.ri.ni.ly.ti.cum. N.L. n. *purum uricum* condensed as “purin”, a term proposed by E. Fisher for the basic ring system of uric acid; Gr. adj. *lutikos* dissolving; N.L. neut. adj. *purinilyticum* decomposing the purine ring.

This description is based on that of Dürre et al. (1981) and on study of the type strain.

Cells in PYG broth culture are Gram-stain-positive straight rods, 1.1–1.6 × 2.7–9.6 μm, motile with lateral and subterminal flagella, and occur singly or in pairs. Spores are round, terminal, and swell the cell. Sporulation occurs most readily on blood agar plates incubated anaerobically for 48 h or in chopped-meat broth incubated in an atmosphere of 90% N₂/10% CO₂. Higher spore yields may be obtained in a medium with added hypoxanthine or guanine. Cell walls contain *meso*-DAP.

Surface colonies on blood-agar plates prepared with rabbit blood are β-hemolytic, 2–3 mm in diameter, irregular, flat, transparent, slightly buff-colored, dull, and slightly pitted with an irregular or occasionally fringed margin, and have no visible internal structure.

Cultures in PYG broth incubated in an atmosphere of 90% N₂/10% CO₂ are turbid with a smooth sediment and have a pH of 7 after incubation for 4 d. Final pH of cultures after growth on purines or glycine is approximately 8.8.

The optimum temperature for growth is 36 °C; growth occurs at 42 °C. Selenite (0.1 μm) bicarbonate (0.2%),

and thiamin are required for growth; molybdate, tungsten, and yeast extract are stimulatory. Optimum pH for growth is 7.3–7.8; growth occurs at pH 6.5–9.0. No gas is detected in PYG deep agar cultures.

Utilizes only purines (including adenine, guanine, xanthine, hypoxanthine, uric acid, and others), glycine, and some glycine derivatives for growth. Hippurate (benzoylglycine) is hydrolyzed.

Products from the fermentation of purines are acetate, formate, CO₂, and ammonia. The major product of PYG cultures is acetate; no H₂ is formed. Pyruvate and threonine are converted to acetate; lactate is not utilized.

The type strain is susceptible to chloramphenicol, clindamycin, penicillin G, and tetracycline, but resistant to erythromycin. Other characteristics of the species are given in Table 143.

Source: soils exposed to chicken manure, sewage sludge enriched with adenine.

DNA G+C content (mol%): 29 (*T_m*).

Type strain: WA-1, ATCC 33906, DSM 1384.

GenBank accession number (16S rRNA gene): M60491.

Further comments: This species is very similar phenotypically to *Clostridium acidurici* and *Clostridium cylindrosporum*. However, Dürre et al. (1981) report that there is very low DNA–DNA homology between the type strain of *Clostridium purinilyticum* (DSM 1384), the type strain of *Clostridium acidurici* (ATCC 7906; DSM 604), and the type strain of *Clostridium cylindrosporum* (ATCC 7905; DSM 605). They may be differentiated by the ability of *Clostridium purinilyticum* to grow readily on adenine and hypoxanthine and to utilize glycine.

16S rRNA gene sequence comparisons show *Clostridium purinilyticum* to fall within the radiation of cluster XII of the clostridia as defined by Collins et al. (1994). The closest relative of *Clostridium puniceum* is *Clostridium acidurici* (93.8%). *Clostridium purinilyticum* is in fact unrelated to *Clostridium cylindrosporum* which is a member of cluster I as defined by Collins et al. (1994).

125. ***Clostridium putrefaciens**** (McBryde 1911) Sturges and Drake 1927, 125^{AL}. (*Bacillus putrefaciens* McBryde 1911, 50.) pu.tre.fa'ci.ens. L. adj. *putrefaciens* putrefying.

Cells in PYG broth cultures are Gram-stain-positive rods, nonmotile, 1.5–1.8 × 7.5–>15 μm. They often occur as long curving filaments. Cells occur singly, in pairs, in long chains or in tangled masses. Spores are round or oval, subterminal or terminal, and swell the cell. Sporulation occurs most readily in chopped-meat cultures held at room temperature. Cell walls contain LL-DAP and glycine.

Surface colonies on blood agar plates are β-hemolytic, pinpoint–0.5 mm, circular to irregular, flat to low convex, transparent to translucent, colorless, shiny, and smooth, with a slightly scalloped or rhizoid margin, and a crystal-line or mosaic internal structure.

Cultures in PYG broth are only slightly turbid with a smooth sediment and have a pH of 7.0 after incubation under 90% N₂/10% CO₂ gas for 1 week. The optimum temperature for growth is 15–22 °C; growth is good at 25 °C and 30 °C, slow at 5 °C; no growth at 37 °C. There is good growth between pH 6.2 and 7.4, moderate and slow

growth at a pH of 5.8 or 8.5. Growth is inhibited by 6.5% NaCl or 20% bile. No gas is detected in PYG deep agar cultures. Ammonia is formed slowly in chopped meat and gelatin cultures. Traces of H₂S are produced. Neutral red is reduced.

Cells contain both straight and branched chain fatty acids with saturated C₁₆, C₁₂, and unsaturated C₁₈ acids predominating.

Products in PYG broth are moderate amounts of acetate, formate, lactate, and succinate; no H₂ is produced. Pyruvate is not utilized; propionate is not formed from lactate or threonine. The amino acids serine, threonine, glycine, and arginine are utilized for growth, and alanine and valine are produced in 3% casein hydrolysate medium. There is no increase in products in threonine medium. Isobutyric acid is produced from valine; isovaleric acid is produced from leucine and isoleucine. Phenylacetic, hydroxyphenylacetic, and indoleacetic acids are produced from phenylalanine, tyrosine, and tryptophan, respectively.

Other characteristics of the species are given in Table 142. The type strain is nontoxic for mice.

Source: spoiled hams, hog muscle, chicken carcasses, human feces, urine specimens from pregnant women with bacteriuria.

DNA G+C content (mol%): 22–25 (*T_m*).

Type strain: ATCC 25786, BCRC (formerly CCRC) 14480, CCUG 30534, DSM 1291, JCM 1431, NCIMB 11406, NCTC 9836.

GenBank accession number (16S rRNA gene): AF127024, Y18177.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium putrefaciens* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relative of *Clostridium putrefaciens* is *Clostridium algidicarnis* (~99.0%); all other species are related at less than 95% 16S rRNA gene sequence similarity. In the paper describing *Clostridium algidicarnis* (Lawson et al., 1994), *Clostridium putrefaciens* was not included in the phylogenetic analysis or any other comparisons. Further phenotypic and genetic comparisons including DNA–DNA reassociation studies should be made between the type strains of the species *Clostridium algidicarnis* and *Clostridium putrefaciens*.

126. ***Clostridium quinii*** Svensson, Dubourguier, Prensier and Zehnder 1995, 879^{VP} (Effective publication: Svensson, Dubourguier, Prensier and Zehnder 1992, 102.)

quí'ni.i. N.L. gen. n. *quinii* of Quin; named after J.I. Quin, a South African microbiologist who first described a large ovoid bacterium.

Straight rods with pointed ends, 1.0 × 2.5–5 μm. Forms large ovoid cells. Strict anaerobe. Gram-stain-positive. Motile with peritrichous flagella but then become immotile. Chemoorganotroph. Form straight to slightly curved spores. Glycogen inclusions 5–10 × 3–6 μm occur in cells. Colonies are translucent and unpigmented.

Growth occurs in the temperature range 15–50 °C with optimal growth at 40–45 °C. The pH range for growth is 6.2–10.5 with optimal growth at 7.4.

Requires carbohydrates for growth. Utilizes glucose, fructose, xylose, galactose, mannose, sucrose, cellobiose,

maltose, raffinose, gentiobiose, turanose, mannitol, arbutin, and salicin as carbon and energy sources. Cellulose, starch, ribose, rhamnose, lactose, inositol, xylitol, sorbitol, dulcitol, glycerol, lactate, citrate, tartrate, fumarate, benzoate, pyruvate, hexanol, and acetone are not utilized for growth. Vitamins not required for growth. Biotin stimulates growth. Esculin is hydrolyzed, but gelatin is not. Nitrate and sulfate are not reduced. Indole, lecithinase, and urease are not present. Main fermentation products are formate, acetate, lactate, ethanol, and hydrogen with minor amounts of butyrate.

Source: anaerobic sludge.

DNA G+C content (mol %): 28 (T_m).

Type strain: BS1, DSM 6736.

GenBank accession number (16S rRNA gene): X76745.

Further comments: 16S rRNA gene sequence comparisons shows *Clostridium quinii* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives of *Clostridium quinii* are *Clostridium celatum* (98.4%) and *Clostridium disporicum* (97.6%). *Clostridium quinii* is differentiated from *Clostridium celatum* on the basis of morphology, endospore position, motility, and urease activity.

127. ***Clostridium ramosum**** (Veillon and Zuber 1898) Holdeman, Cato and Moore 1971, 39^{AL} ("*Bacillus ramosus*" Veillon and Zuber 1898; *Nocardia ramosa* Vuillemin 1931, 32) ra.mo'sum. L. neut. adj. *ramosum* much-branched.

Cells in PYG broth cultures stain Gram-positive or Gram-stain-negative and are nonmotile, straight rods, 0.5–0.9 × 2–12.8 μm, and occur singly, in pairs or in short chains often in "V" arrangements, with a "rail fence" appearance, or in irregular masses. Cells may have central or terminal swellings up to 1.6 μm in width. Spores are round, thin-walled, usually terminal, and swell the cell, but are very rarely seen and often are difficult to detect by heat tests. They can be demonstrated most readily from 3-week-old chopped-meat agar slants incubated at 30 °C, or in old chopped meat or PYG broth cultures. Cell walls contain *meso*-DAP; glutamic acid and alanine are present as well. Surface colonies on blood agar plates are nonhemolytic, 0.5–2 mm in diameter, circular to slightly irregular, convex or raised, colorless to gray-white, translucent or semiopaque, and smooth, with an entire, scalloped, or erose margin, and a mottled, mosaic, or granular internal structure.

Cultures in PYG broth are turbid with a smooth or ropy sediment and have a pH of 4.4–4.8 after incubation for 5 d. The optimum temperature for growth is 37 °C; most strains grow equally well at 30 °C and 45 °C and grow well at 25 °C. Growth is stimulated by fermentable carbohydrate, inhibited by 6.5% NaCl and reduced in 20% bile. Moderate gas is detected in glucose deep agar cultures. Production of ammonia and acetyl methyl carbinol is variable among strains. Some strains produce an extracellular β-glucuronidase.

Major products in PYG broth are acetic, formic, and lactic acids; small amounts of pyruvic and succinic acids may be detected, and ethanol often is present. Pyruvate is converted to acetate and formate; neither threonine nor lactate is utilized. H₂ production is variable.

All strains tested are susceptible to chloramphenicol; of 61 strains tested, 4 are resistant to penicillin G, 7 to clindamycin, 13 to erythromycin, and 31 to tetracycline. Strains are susceptible to achievable blood levels of carbenicillin and vancomycin but resistant to lincomycin, rifampin, and gentamicin; 37 of 48 strains tested are susceptible to metronidazole; the remaining strains are susceptible to high but achievable levels (25 μg/ml) of metronidazole. Niridazole, chemically similar to metronidazole, is approximately 15 times as effective as metronidazole.

Culture supernatants are not toxic to mice, but strains are pathogenic for guinea pigs; pathogenicity may be lost in laboratory cultures. Other characteristics of the species are given in Table 144.

Source: infant and adult feces; normal human cervix; human infections of the abdominal cavity, genital tract, lung, biliary tract; blood cultures.

DNA G+C content (mol %): 26 (T_m).

Type strain: ATCC 25582, BCRC (formerly CCRC) 14518, CCUG 24038, DSM 1402, JCM 1298, NCIMB 10673, NCTC 11812, VPI 0427.

GenBank accession number (16S rRNA gene): M23731, X73440.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium ramosum* to fall within the radiation of cluster XVIII of the clostridia as defined by Collins et al. (1994). The closest relative of *Clostridium ramosum* is *Clostridium spiroforme* (96.2%); these two species cluster together in a distinct lineage close to the mycoplasmas.

128. ***Clostridium rectum**** (Heller 1922) Holdeman and Moore 1972, 69^{AL} (*Hiblerillus rectus* Heller 1922, 17.) rec'tum. L. neut. adj. *rectum* straight.

Cells in PYG broth cultures are nonmotile, Gram-stain-positive straight rods, 0.5–1.1 × 1.6–3.1 μm, and occur singly or in pairs. Spores are oval, subterminal, and swell the cell. Sporulation occurs most readily in chopped-meat broth cultures. Cell walls contain *meso*-DAP. Surface colonies on blood agar plates are pinpoint–1 mm in diameter, translucent to semiopaque, convex, grayish white, shiny, and smooth, with entire margins and no visible internal structure. They may be slightly β-hemolytic.

Cultures in PYG broth are turbid with a smooth sediment and have a pH of 5.2–5.7 after incubation for 1 week. The optimum temperature for growth is 37–45 °C; moderate growth occurs at 25 °C and 30 °C. There is good growth at a pH of 8.5 or in 20% bile, no growth in 6.5% NaCl. Abundant gas is detected in PYG deep agar cultures. Ammonia and H₂S are produced. Neutral red and resazurin are reduced. The insecticide lindane can be degraded provided dithiothreitol or a leucine-proline mixture is present; isovaleric acid is formed.

The major product in PYG broth culture is butyric acid with moderate amounts of acetic and propionic, and a trace of valeric acid. Pyruvate is converted to acetate and butyrate; threonine is converted to propionate. Abundant H₂ is produced.

The type strain is susceptible to chloramphenicol, clindamycin, penicillin G, and tetracycline, but resistant to erythromycin. Culture supernatants are nontoxic to mice. Other characteristics of the species are given in Table 144.

Source: horse manure, beet rhizosphere, rice paddy soil.

DNA G+C content (mol%): 26 (T_m).

Type strain: ATCC 25751, DSM 1295, JCM 1412, NCIB 10651.

GenBank accession number (16S rRNA gene): X77850.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium rectum* to fall within the radiation of cluster XIX of the clostridia as defined by Collins et al. (1994). This species is clearly unrelated to the genus *Clostridium* as it shows highest 16S rRNA gene sequence similarity with species of the genus *Fusobacterium*. The closest relative based on 16S rRNA gene sequence similarity is *Fusobacterium necrogenes* (99.8%). This species should be reclassified to the genus *Fusobacterium*.

129. ***Clostridium roseum**** (ex McCoy and McClung (1935) nom. rev. Cato, George and Finegold 1988, 220^{VP} (Effective publication: Cato, George and Finegold 1986, 1186.) (*Clostridium roseum* McCoy and McClung 1935, 237) ro'se.um. L. neut. adj. *roseum* rosy.

Cells in corn mash cultures are 0.7–0.9 × 3.2–4.3 μm, granulose positive in corn mash or glucose-tryptone broth, and occur singly, in pairs, or in short chains. They are Gram-stain-positive, but rapidly become Gram-stain-negative. Vegetative cells are motile and peritrichous; sporulating cells are sluggish or nonmotile. Spores are oval, subterminal, and swell the cell. Sporulation occurs most rapidly in 5% corn meal mash medium. Cell-wall content has not been reported. Surface colonies on blood agar plates are 4 mm in diameter, irregular, flat, grayish-white with raised white centers, a dull rough surface, a rhizoid margin, and are nonhemolytic. On beef PYG agar, surface colonies are raised and smooth, with irregular margins and a pink to orange pigmentation. Colonies become purplish-black after exposure to air. Pigmentation is most pronounced in 5% corn meal mash semisolid medium. Cultures in PYG broth are only slightly turbid with a peach to orange rosy sediment and have a pH of 4.1 after incubation for 6 d.

The optimum temperature for growth is 37 °C; growth occurs between 20 °C and 47 °C. Growth is greatly stimulated by fermentable carbohydrate and an atmosphere of 90% N₂/10% CO₂. Abundant gas is formed in PYG deep agar cultures.

Gelatin is completely digested; there is a stormy fermentation in milk with an acid curd formed that is 50% digested in 3 weeks. H₂S is produced in 0.25% glucose-tryptone-sulfite or 0.25% glucose-tryptone-thiosulfate broth, but not in SIM which contains 0.02% thiosulfate and 0.02% sulfate. Pectin is strongly fermented (final pH 4.8). Gluconate is fermented to pyruvate and glyceraldehyde-3-phosphate by a modified Entner–Doudoroff pathway.

Products in PYG broth are butyric and acetic acids and butanol; a small amount of succinic acid also is detected. Neither pyruvate, lactate, nor threonine is utilized. In 5% corn mash medium, acetone and ethyl alcohol also are detected. Antibiotic susceptibility has not been determined. Strains are not pathogenic for guinea pigs or rabbits. Other characteristics of the species are given in Table 142.

Source: German maize (probable habitat is the soil).

DNA G+C content (mol%): not reported.

Type strain: ATCC 17797, DSM 7320.

GenBank accession number (16S rRNA gene): Y18170.

Further comments: For differentiation of this species from *Clostridium felsineum*, which it most closely resembles, see Further comments following the description of that species. In addition, strains of *Clostridium roseum* have been shown to be serologically distinct from strains of *Clostridium felsineum*. 16S rRNA gene sequence comparisons show *Clostridium roseum* to fall within the radiation of the species of cluster I of the clostridia as defined by Collins et al. (1994) and to be unrelated to *Clostridium felsineum* which is a member of cluster XI. The closest relative of *Clostridium roseum* based on 16S rRNA gene sequence comparisons is *Clostridium acetobutylicum* (98.9%); all other species are related at less than 95% sequence similarity.

130. ***Clostridium saccharobutylicum*** Keis, Shaheen and Jones 2001, 2101^{VP}

sac.cha.ro.bu.ty'li.cum. Gr. n. *saccharon* sugar juice; N.L. n. *butylum* butanol; N.L. neut. adj. *saccharon* sugar juice; N.L. n. *butylum* butanol; N.L. neut. adj. *saccharobutylicum* denoting the production of butanol from sugar.

Rods with rounded ends, 1.4 μm × 6.3 μm; can be 3.8–10 μm in length; occur singly, in pairs, or short chains. Motile with peritrichous flagella. Gram-positive cell-wall structure, but stain Gram-negative in older cultures. Older cells accumulate granulose and produce an extracellular slime or capsule. Form oval, terminal, to subterminal spores 1.8 × 1.7–3.9 μm. Colonies are smooth, yellow, have irregular margins, and 2–3 mm in diameter. Mesophilic. Optimum growth and solvent production in the temperature range 30–34 °C and pH 6.2–7.0.

Arabinose, xylose, glucose, mannose, cellobiose, lactose, maltose, sucrose, inositol, melibiose, methylglucopyranoside, raffinose, salicin, trehalose, turanose, amygdalin, starch, glycogen, and dextrin are fermented by all strains. Ribose is weakly fermented. Glycerol, dulcitol, sorbitol, melezitose, rhamnose, and pectin are not fermented. Mannitol, inulin, and D- and L-arabitol are fermented by some strains. Acetone, butanol, ethanol, CO₂, H₂, and acetic and butyric acids are fermentation products. Hydrolyzes esculin and gelatin. Tests negative for catalase, urease, and indole production. Curds milk.

DNA G+C content (mol%): 28–32 (genome sequencing).

Type strain: NCP 262, ATCC BAA-117, DSM 13864.

GenBank accession number (16S rRNA gene): U16147.

Further comments: Strains of this species used in industrial fermentations were isolated and patented by Commercial Solvents Corporation under the name “*Clostridium saccharo-butyl-acetonium-liquefaciens*” (Jones and Keis, 1995). These strains were later designated strains of the species *Clostridium acetobutylicum* (Keis et al., 2001), but 16S rRNA gene sequence analysis showed them to be unrelated to that species.

16S rRNA gene sequence comparisons show *Clostridium saccharobutylicum* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives of *Clostridium saccharobutylicum* are

Clostridium saccharoperbutylacetonicum (98.8%), *Clostridium diolis* (98.6%), *Clostridium beijerinckii* (98.6%), *Clostridium puniceum* (98.5%), and *Clostridium butylicum* (97.5%). *Clostridium saccharobutylicum* can be differentiated from *Clostridium saccharoperbutylacetonicum* on the basis of it being susceptible to rifampin and not utilizing melezitose and pectin.

131. ***Clostridium saccharogumia*** Clavel, Lippman, Gavini, Doré and Blunt 2007b, 893^{VP} (Effective publication: Clavel, Lippman, Gavini, Doré and Blunt 2007a, 23.)

sac.cha.ro.gu'mi.a. Gr. neut. n. *saccharon* sugar, L. fem. n. *gumia* eater, N.L. fem. n. *saccharogumia* sugar eater.

Helically coiled rods, 0.9×2.0 – $3.0 \mu\text{m}$, occurring as single cells. Gram-stain-positive in early exponential phase and Gram-stain-variable or Gram-stain-negative in other phases of growth. Strictly anaerobic. Spores not observed. Cells do not survive ethanol or heat treatments. Nonmotile. Colonies on Columbia-agar are circular, entire, up to 3 mm in diameter, convex to umbonate, opaque, grayish-white and nonhemolytic.

The temperature range for growth is 25–45 °C. pH Range for growth is 6–9. Utilizes cellobiose, fructose, galactose, glucose, lactose, mannose, sucrose, and salicin as the sole carbon and energy source. Maltose, melibiose, raffinose, rhamnose, and trehalose are not utilized. Catalase- and indole-negative. The major cellular fatty acids are C_{16:0} (20.2%) and C_{17:1iso 05c} (18.2%). Tolerant to penicillin and vancomycin at 0.5 µg/ml and to rifampin and metronidazole at concentrations of up to 15 µg/ml.

Source: feces of a healthy human male adult.

DNA G+C content (mol %): 29.4–31.7 (T_m , HPLC).

Type strain: SDG-Mt85-3Db, CCUG 51486, DSM 17460.

GenBank accession number (16S rRNA gene): DQ100445.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium saccharogumia* to fall within the radiation of cluster XVIII of the clostridia as defined by Collins et al. (1994). The closest relatives of *Clostridium saccharogumia* are *Clostridium cocleatum* (96.7%), *Clostridium ramosum* (96.6%), and *Clostridium spiroforme* (95.9%). Clavel et al. (2007a) differentiated *Clostridium saccharogumia* from these related species on the basis of fatty acid profiles and substrate utilization patterns. It is interesting to note that these are recorded as ND (not determined) for the type strains of the related species in Clavel et al. (2007a).

132. ***Clostridium saccharolyticum**** Murray, Khan and van den Berg 1982, 135^{VP}

sac'cha.ro.ly'ti.cum. Gr. n. *sacchar* sugar; Gr. adj. *lutikos* dissolving; N.L. neut. adj. *saccharolyticum* sugar-dissolving.

This description is based on that by Murray et al. (1982) and on study of the type strain.

Cells are Gram-stain-negative, atrichous, nonmotile, spindle-shaped straight rods, 0.5 – $0.7 \times 3.0 \mu\text{m}$. Spores are round, terminal, or subterminal and distend the cell. Sporulation occurs readily in chopped-meat carbohydrate broth. Cell-wall composition has not been reported.

Surface colonies on cellobiose-yeast extract agar after 48 h incubation are 0.5–1.5 mm in diameter, circular with smooth margins, convex and white. On blood agar

plates, colonies are pinpoint–1 mm in diameter, circular or slightly irregular, low convex, with entire or slightly scalloped margins and a mottled or crystalline internal structure.

Cultures in PYG broth are turbid with a smooth sediment and have a pH of 5.1 after incubation for 4 d.

The temperature for optimum growth is 37 °C; growth also occurs at 17 °C and 43 °C but not at 14 °C or 45 °C. Optimum pH for growth is 7.4; growth occurs between pH 6.0–8.8. Abundant growth occurs in PY media supplemented with vitamin K and heme, with or without carbohydrate. There is no growth in a defined carbohydrate-mineral salt-vitamin medium even when supplemented with synthetic mixtures of amino acids, purines, and pyrimidines; good growth is obtained in this medium upon addition of yeast extract or in co-culture with *Acetivibrio cellulolyticus*. In minimal medium, 0.1% yeast extract, fermentable carbohydrate, iron, and a reduced form of sulfur are required for growth; growth in this medium is enhanced by addition of B vitamins and phosphate.

Milk is curdled; acetyl methyl carbinol, ammonia, and H₂S are produced; and resazurin is reduced. Starch is hydrolyzed and nitrate reduced.

Products of fermentation in cellobiose-yeast extract broth after 7 d incubation detected by a flame-ionization detector are acetic acid, ethanol, and traces of pyruvic and lactic acids. Products in PYG broth are acetic, formic, and lactic acids. H₂ and CO₂ are produced. In naturally occurring habitats, the acetic acid and H₂ are utilized by methanogens and the ethanol and lactic acid are utilized by sulfate reducers to provide a favorable environment for cellulolytic anaerobes. The presence of calcium carbonate and of higher concentrations of yeast extract, or the presence of added H₂ in the headspace gas, produce a metabolic shift to less acetic acid production and greater ethanol production. Pyruvate is utilized; neither lactate nor threonine is utilized.

The type strain is susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Other characteristics of the species are shown in Table 144.

Source: a methanogenic cellulose-enrichment culture from sewage sludge.

DNA G+C content (mol %): 28 (T_m).

Type strain: WMI, ATCC 35040, DSM 2544, NRC 2533.

GenBank accession number (16S rRNA gene): Y18185.

Further comments: *Clostridium saccharolyticum* falls within the radiation of cluster XIVa (Collins et al., 1994) and shows highest 16S rRNA gene sequence similarity to the *Clostridium* species *Clostridium amygdalinum* (98.9%), *Clostridium celerecrescens* (98.5%), *Clostridium indolis* (98.5%), and *Clostridium aerotolerans* (98.4%). Strain WMI^T differs from *Clostridium amygdalinum* in its ability to utilize galactose, rhamnose, lactose, and mannose. *Clostridium saccharolyticum* does not degrade starch while *Clostridium amygdalinum* does. *Clostridium amygdalinum* is a moderate thermophile while *Clostridium saccharolyticum* is a mesophile.

133. ***Clostridium saccharoperbutylacetonicum*** Keis, Shaheen and Jones 2001, 2101^{VP}

sa.cha.ro.per.bu.tyl.a.ce.to'ni.cum. Gr. n. *saccharon* sugar juice; Gr. pron. *per* throughout; N.L. n. *butylum* butanol; N.L. adj. *aceticus* acetic; N.L. adj. *saccharoperbutylaceticum* denoting the production of a large amount of butanol and acetone from sugar.

Straight rods, $0.4\text{--}0.8 \times 3.1\text{--}6.2\ \mu\text{m}$; occurring singly or in pairs. Motile with peritrichous flagella. Gram-stain-positive in young cultures, and Gram-stain-negative in older cultures. Cells accumulate granules during late exponential growth. Form oval spores, $0.8\text{--}1.5 \times 1.6\text{--}2.2\ \mu\text{m}$. Colonies on CBM agar are white, smooth, domed, and 2–3 mm in diameter with entire/undulated margins.

Mesophilic. Optimum temperature for growth and solvent production is 25–35 °C; the optimum pH range for growth is 5.6–6.7.

Ferments arabinose, xylose, glucose, mannose, cellobiose, lactose, maltose, sucrose, mannitol, melibiose, raffinose, trehalose, salicin, turanose, amygdalin, starch, glycogen, dextrin, pectin, melezitose, D-arabitol, L-arabitol, and inulin. Ribose and glycerol are not fermented. Sorbitol, dulcitol, and inositol are fermented by the type strain. Rhamnose is fermented weakly. Acetone, butanol, ethanol, CO₂, H₂, and acetic and butyric acid are end products of fermentation.

Does not reduce nitrate. Ammonia produced from nitrite. Hydrogen sulfide is not produced from peptone-containing medium, is not produced or is weakly produced from the reduction of sulfites, but is produced from the reduction of thiosulfates. Does not produce catalase, oxidase, and indole. Hydrolyzes esculin and gelatin. Digestion of coagulated albumin is very weak or negative. Milk is not digested. Resistant to rifampin (100 ng). Used in the industrial setting for the production of the solvents acetone, butanol, and ethanol from sugar- and starch-based substrates.

DNA G+C content (mol%): 31 (T_m).

Type strain: N1-4 (HMT) (derived from strain N1-4), ATCC 27021 (derived from ATCC 13564), DSM 14923, NCIMB 12606.

GenBank accession number (16S rRNA gene): U16122.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium saccharoperbutylaceticum* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives based on 16S rRNA gene sequence similarity values are *Clostridium diolis* (99.1%), *Clostridium puniceum* (99.1%), *Clostridium beijerinckii* (99.1%), and *Clostridium saccharobutylicum* (98.8%).

134. *Clostridium sardiniense** corrig. Prévot 1938, 81^{AL} emend. Wang, Maegawa, Karasawa, Ozaki and Nakamura 2005, 1196.

sar.din.i.en'se. N.L. neut. adj. *sardiniense* from Sardinia.

Cells in PYG broth are Gram-stain-positive, straight or slightly curved rods, motile, and peritrichous. Motility may be lost on subculture. Cells occur singly, in pairs, or in short chains, and are $0.5\text{--}1.7 \times 1\text{--}10.0\ \mu\text{m}$. Spores are oval and subterminal, or occasionally terminal; very few spores are produced in usual media. Sporulation occurs most readily in 3-week-old chopped-meat broth cultures. Cell walls contain meso-DAP.

Surface colonies on blood agar plates are β-hemolytic, 1–3 mm in diameter, circular to irregular, raised or low convex, translucent or semiopaque, gray-white, shiny, and smooth, with a lobate or erose margin and usually with a granular or mottled internal structure. Cultures in PYG broth are turbid with a smooth or stringy sediment, and have a pH of 4.5–5.0 after incubation for 5 d.

The temperature for optimum growth is 25–37 °C; growth is poor at 45 °C. Growth is stimulated by fermentable carbohydrate but inhibited by 6.5% NaCl. Abundant gas is produced in PYG deep agar cultures. Ammonia is produced, neutral red and resazurin are reduced.

Products in PYG broth include large amounts of acetic, butyric, and lactic acids, sometimes with small amounts of formic and propionic acids. Abundant H₂ is produced. Pyruvate is converted to acetate and butyrate. Neither lactate nor threonine is converted to propionate.

All strains tested are susceptible to chloramphenicol, penicillin G, and tetracycline; 4 of 8 strains are resistant to clindamycin; 2 of 8 strains are resistant to erythromycin.

Culture supernatants are nontoxic to mice. Cultures injected subcutaneously or intramuscularly are pathogenic for sheep, guinea pigs, goats, dogs, rabbits, mice, rats, and chickens. Other characteristics of the species are given in Table 142.

Source: lesions of symptomatic anthrax in sheep, soil, water, feces of infants.

DNA G+C content (mol%): not determined.

Type strain: ATCC 33455, DSM 2632, VPI 2971.

GenBank accession number (16S rRNA gene): AB161367, AB161368.

Further comments: Cato et al. (1986) indicated the species is differentiated from *Clostridium absonum* by motility but that some strains designated to the species *Clostridium absonum* have been found to be motile. Subsequent phylogenetic analyzes using the 16S rRNA gene and PLC amino acid sequences show the type strains of *Clostridium sardiniense* and *Clostridium absonum* to be highly similar (Wang et al., 2005). DNA–DNA reassociation values of > 83% between strains of *Clostridium sardiniense* and *Clostridium absonum* indicated that the two species were heterotypic synonyms (Wang et al., 2005). This species is most easily differentiated from *Clostridium perfringens*, which it closely resembles phenotypically, by its motility and its lack of toxicity for mice. However, *Clostridium sardinense* is not closely related to *Clostridium perfringens* (94.8%) based on 16S rRNA gene sequence similarities. The closest relatives of *Clostridium sardinense* are *Clostridium baratii* (98.9%) and the *Eubacterium* species *Eubacterium budayi* (98.6%), *Eubacterium moniliforme* (98.2%), *Eubacterium nitritogenes* (98.2%), and *Eubacterium multiforme* (98.0%).

135. *Clostridium sartagoforme* corrig.* Partansky and Henry 1935, 564^{AL}

sar.ta.go.for'me. L. n. *sartago* frying pan; L. adj. suffix *-forme* shaped like; N.L. neut. adj. *sartagoforme* intended to mean shaped like a frying pan (in reference to a sporulating cell).

Cells in PYG broth culture are Gram-stain-positive, straight to slightly curved rods that occur singly or in pairs, and are $0.3\text{--}0.9 \times 2.2\text{--}8.0\ \mu\text{m}$. Motility is variable; cells of

motile strains are peritrichous. Spores are oval (occasionally round), terminal, and swell the cell. Sporulation occurs most readily in chopped-meat broth cultures. Cell wall does not contain DAP. The cell wall is susceptible to dissolution by lysozyme.

Surface colonies on blood agar plates are 1–3 mm in diameter, circular, with entire or erose margins, flat or convex, gray, translucent, with a matt surface, and are usually nonhemolytic. Colonies in agar are 1–1.5 mm in diameter and lenticular.

Cultures in PYG broth are turbid with a smooth, or occasionally, flocculent to ropy, sediment and have a pH of 4.8–5.1 after incubation for 5 d. Temperature range for optimum growth is 30–37 °C; growth also occurs at 25 °C and 45 °C. Growth is stimulated by a fermentable carbohydrate and is inhibited by 6.5% NaCl or 20% bile. Abundant gas is produced in PYG deep agar cultures.

Adonitol, dulcitol, erythritol, glycerol, inositol, and sorbose are not fermented. Ammonia is sometimes produced, hippurate is hydrolyzed by 1 of 3 strains tested, neutral red is reduced, and resazurin usually is reduced. Deoxyribonuclease activity is not present.

Products of fermentation in PYG broth are large amounts of acetic, butyric, and formic acids and sometimes large amounts of lactic acid. Abundant H₂ is produced. Neither lactate nor threonine is converted to propionate; pyruvate is converted to acetate and butyrate.

All strains tested are susceptible to chloramphenicol, erythromycin, and tetracycline. Of four strains tested, one is resistant to clindamycin, and a different one is resistant to penicillin G. Some strains are inhibited by 0.1–0.5 µg of cefoxitin/ml. Culture supernatants are nontoxic to mice.

Other characteristics of the species are given in Table 142.

Source: soil, mud, rumen fluid of healthy and bloating calves; the human gingival crevice; feces of neonates and infants; the feces of approximately 5% of adult subjects tested.

DNA G+C content (mol%): 28 (*T_m*).

Type strain: ATCC 25778, DSM 1292, JCM 1413.

GenBank accession number (16S rRNA gene): Y18175.

Further comments: 16S rRNA gene sequence analysis shows *Clostridium sartagoforme* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives of *Clostridium sartagoforme* based on 16S rRNA gene sequence similarities are *Clostridium tertium* (98.4%), *Clostridium carnis* (97.5%), *Clostridium isatidis* (97.2%), *Clostridium quinii* (97.0%), and *Clostridium chauvoei* (97.0%).

136. ***Clostridium scatologenes***^{*} (Weinberg and Ginsbourg 1927) Prévot 1948b, 191^{AL} (*Clostridium scatol* Fellers and Clough 1925, 128; *Bacillus scatologenes* Weinberg and Ginsbourg 1927, 54)

sca.to.lo'gen.es. Gr. n. *skatos* dung; Gr. v. *gennaio* to produce; N.L. part. adj. *scatologenes* meaning either an organism that produces a dung-like odor or an organism that produces skatol.

Cells in PYG broth are Gram-stain-positive straight rods that are motile and peritrichous, and are 0.5–1.6 ×

3.1–21.2 µm. Spores are oval, terminal, or occasionally subterminal, and distend the cell slightly. Cell walls contain *meso*-DAP. The cell wall is susceptible to dissolution by lysozyme. Surface colonies on blood agar are α-hemolytic, 0.5–2.0 mm in diameter, circular, convex, translucent, gray, with an entire or scalloped margin, a matt surface, and a granular or mottled internal structure. Cultures in PYG broth are turbid with a smooth sediment and a pH of 5.2–5.4 after incubation for 5 d.

The temperature for optimum growth is 30–37 °C; also grows at 25 °C but not at 45 °C. Grows well in absence of a fermentable carbohydrate. Growth inhibited by 20% bile, 6.5% NaCl, or a pH of 8.5. Abundant gas is produced in PYG deep agar cultures.

Produces ammonia and H₂S; two of three strains hydrolyze hippurate; reduces neutral red and usually reduces resazurin. Uracil is not utilized.

Products of fermentation in PYG broth are large amounts of acetic and butyric acids, and sometimes small amounts of formic, propionic, isobutyric, isovaleric, valeric, caproic, lactic, and succinic acids. Abundant H₂ is produced. Addition of valine to the medium results in increased production of isobutyric acid, whereas addition of either leucine or isoleucine results in production of increased amounts of isovaleric acid. Lactate is converted to acetate, butyrate, and caproate and occasionally to valerate; pyruvate is converted to acetate and butyrate and occasionally caproate; and threonine is converted to propionate. Serine and arginine are utilized and 2-aminobutyric acid and ornithine are produced in an amino acid-trypticase-yeast extract broth culture. Produces skatol.

The major fatty acid is normal, saturated C₁₆; in addition, normal saturated C₁₂, C₁₄, C₁₅, C₁₈, and normal unsaturated C₁₆ acids represent appreciable proportions of the total fatty acids detected. Small amounts of branched chain fatty acids are also present.

Two strains tested are susceptible to chloramphenicol, erythromycin, clindamycin; 2 of 3 strains are susceptible to penicillin G. One strain tested is susceptible to the following antimicrobials in the concentrations indicated: penicillin V, 2 U/ml; cephalothin, 64 µg/ml; cephalixin, 32 µg/ml; cephradine, 16 µg/ml; cefoxitin, 128 µg/ml; tetracycline, 64 µg/ml; and doxycycline, 16 µg/ml. Culture supernatants are nontoxic to mice. Reported to be nonpathogenic. Other characteristics of the species are given in Table 142.

Source: soil, contaminated food, feces of infants undersized at birth.

DNA G+C content (mol%): 27 (*T_m*).

Type strain: ATCC 25775, CCUG 9283, DSM 757, JCM 1414, NCIB 8855 NCTC 12292.

GenBank accession number (16S rRNA gene): M59104.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium scatologenes* to be a member of cluster I of the clostridia as defined by Collins et al. (1994). *Clostridium scatologenes* groups closely with the species *Clostridium carboxidivorans* and *Clostridium drakei* sharing 99.7% 16S rRNA gene sequence similarity with each of these species. The species status of each of three species is supported by DNA–DNA reassociation data, and the species can be

differentiated the basis of substrate utilization patterns and the fact that *Clostridium scatologenes* grows slowly on H₂/CO₂ (Liou et al., 2005).

137. ***Clostridium schirmacherense*** Alam, Dixit, Reddy, Dube, Palit, Shivaji and Singh 2006, 719^{VP}

schir.ma.cher.en'se. N.L. neut. adj. *schirmacherense* pertaining to Schirmacher Oasis in Antarctica.

Rods-shaped cells, 0.5–0.7 × 2–4 μm. Motile. Gram-stain-positive. Spores are subterminal and distend the cell. Contains diphosphatidylglycerol as the major phospholipids, and *meso*-diaminopimelic acid is present in the cell wall. The major cellular fatty acids are C_{15:0}, C_{16:0}, and C_{17:0}. Strictly anaerobic and chemoorganotrophic. Temperature range for growth is 5–35 °C; produces maximum cell mass at 5–10 °C. The pH range for growth is 6–9 with an optimum of pH 8.0. NaCl is not required for growth but is tolerated up to a concentration of 7.5%.

Esculin, gelatin, and casein are hydrolyzed. Does not reduce nitrate to nitrite. Negative for catalase, oxidase, lipase, indole production, and β-hemolysis. Raffinose, glucose, adonitol, rhamnose, and ribose are utilized but not sucrose, arabinose, mannose, mannitol, lactose, inositol, trehalose, maltose, dulcitol, xylan, arabitol, xylose, inulin, amygdalin, glycogen, galactose, or sorbitol. Complex substrates including yeast extract, Casamino acids, peptone, and gelatin are fermented. Arginine, serine, leucine, isoleucine, cysteine, and glutamate, are utilized while asparagine, proline, glutamine, aspartate, glycine, lysine, methionine, threonine, tryptophan, tyrosine, valine, 2-aminobutyric acid, ornithine, and phenylalanine are not utilized. H₂S produced. Sulfite and thiosulfate are reduced but sulfate, elemental sulfur and fumarate are not reduced.

The major fermentation end products are acetate, propionate, H₂, and CO₂ from glutamate; acetate and butyrate from isoleucine; acetate, propionate, H₂, and CO₂ from cysteine; formate, acetate, and propionate from arginine; acetate, propionate, H₂, and CO₂ from leucine; and acetate, isobutyrate, and butyrate from serine. Glucose is fermented to formate, acetate, propionate, butyrate, isovalerate, H₂, and CO₂.

Source: lake sediments of Schirmacher Oasis, Antarctica.

DNA G+C content (mol %): 24 (HPLC).

Type strain: AP15, DSM 17394, JCM 13289.

GenBank accession number (16S rRNA gene): AM114453.

Further comments: 16S rRNA gene sequence analysis shows *Clostridium schirmacherense* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives based on 16S rRNA gene sequence similarity values are *Clostridium subterminale* (99.6%) and *Clostridium argentinense* (99.4%). *Clostridium schirmacherense* can be differentiated from these close relatives based on its much lower temperature range for growth, esculin hydrolysis, production of formate and propionate, lower G+C content, and lack of β-hemolysis.

138. ***Clostridium scindens*** Morris, Winter, Cato, Ritchie and Bokkenheuser 1985, 478^{VP}

scin'dens L. part. adj. *scindens* splitting, because it produces a desmolase.

Pleomorphic, straight to slightly curved rods, 0.5–0.7 × 1.0–2.5 μm; occur singly or in chains. Nonmotile. Some coccus-shaped cells 0.4–0.6 μm are found. Grows anaerobically. Aerotolerant. Chemorganotrophic. Gram-stain-positive. Forms spores which are terminal and wider than the cells. Cultures survive heat treatment at 80 °C for 10 mins and absolute ethanol exposure for 30 mins. Many cells have fimbriae 3.0–3.5 nm in diameter, in clusters of 2–10. Colonies are circular to slightly irregular, smooth, grayish-white, convex, and 0.3–1 mm diameter. Nonhemolytic to sheep and rabbit erythrocytes.

Temperature optimum for growth is 42 °C with growth at 37 and 45 °C but not at 50 °C. Slow growth occurs at 25 °C. Ferments D-fructose, D-glucose, lactose, D-mannose, D-ribose, and D-xylose. Does not ferment amygdalin, L-arabinose, D-cellobiose, *meso*-erythritol, esculin, glycogen, *myo*-inositol, maltose, D-mannitol, D-melezitose, D-melibiose, D-raffinose, L-rhamnose, salicin, D-sorbitol, starch, sucrose, and D-trehalose. Ferments PYEG broth to acetic acid and ethanol. Converts pyruvate to acetate, and lactate is not used. Has desmolase enzymic activity. Reduces sulfate, but not nitrate. H₂S detected in sulfide-indole-motility medium. Does not digest gelatin, milk, or meat. Tests negative for catalase, indole, lecithinase, or lipase activity. Starch and esculin are not hydrolyzed. Produces at least four enzymes that cleave steroidal substrates. Produces desmolase. Sensitive to penicillin G (2U/ml). Resistant to chloramphenicol (12 μg/ml), clindamycin (1.6 μg/ml), erythromycin (3 μg/ml), and tetracycline (6 μg/ml).

Source: human feces.

DNA G+C content (mol %): 45 (*T_m*).

Type strain: Bokkenheuser strain 19, ATCC 35704, CIP 106687, DSM 5676, JCM 6567.

GenBank accession number (16S rRNA gene): AB020883, AF262238, Y18186.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium scindens* to fall within the radiation of cluster XIVa as defined by Collins et al. (1994). Previous studies have concentrated on the comparison of *Clostridium scindens* and *Clostridium hylemonae* (Kitahara et al., 2000). However, the 16S rRNA gene sequence similarity between these two species is only 93.0%. The closest relatives of *Clostridium scindens* based on 16S rRNA gene sequences are species of the genus *Dorea* including *Dorea longicatena* and *Dorea formicigenerans* (94.4 and 92.9%), and *Ruminococcus gnnavus* (93.6%).

139. ***Clostridium septicum**** (Macé 1889) Ford 1927, 726^{AL} (*Bacillus septicus* Macé 1889, 445)

sep'ti.cum. L. neut. adj. *septicum* putrefactive.

Cells in PYG broth culture are Gram-stain-positive in young cultures but may be Gram-stain-negative in older cultures; staining is often uneven, resulting in intensely Gram-stain-positive bars or spots interspersed with decolorized areas. Cells in broth are straight or curved rods that occur singly or in pairs, are usually motile and peritrichous, and are 0.6–1.9 × 1.9–35.0 μm. Forms long filaments on the peritoneal surface of the liver of infected animals in contrast to other pathogenic species of *Clostridium*. Cells may be extremely pleomorphic under certain conditions.

Spores are oval, subterminal, and distend the cell. There is no exosporium and the spore lacks appendages.

Cell wall contains L-lysine in place of DAP. Glutamic acid and alanine are present; cell-wall sugars are glucose, galactose, rhamnose, and mannose. The cell wall is susceptible to dissolution by lysozyme.

Colonies on the surface of blood agar are 1–5 mm in diameter, circular, with markedly irregular to rhizoid margins, slightly raised, translucent, gray, glossy, and β -hemolytic. Surface growth of most strains on 1.5% agar is an invisible film over the entire agar surface; this swarming often may be prevented by shortening the incubation period or using 4–6% agar in the medium. Subsurface colonies in 1% agar are spherical or lenticular and transparent; in 2% agar, colonies are brownish-yellow and heart shaped.

Cultures in PYG broth are turbid with a smooth sediment and have a pH of 4.7–5.3 after incubation for 5 d.

The temperature range for optimum growth is 37–40°C; most strains grow well at 44°C but not at all at 46°C. CO₂ is not required for growth, but good growth occurs in atmospheres containing up to 100% CO₂. Growth is stimulated by the presence of a fermentable carbohydrate, serum, or peptic digest of blood. In chopped-meat medium, the meat particles commonly turn pink after 48 h incubation. Factors essential for growth include biotin, nicotinic acid, pyridoxine, thiamin, cysteine, tryptophan, iron and, for some strains, pantothenate. Adenine, arginine, aspartic acid, histidine, isoleucine, phenylalanine, serine, threonine, tyrosine, and valine are also required. Exposure of exponential-phase cultures of this species to hyperbaric oxygen (100% O₂ at 3 atm) is relatively nonlethal compared with other species; approximately 50% of cells of *Clostridium septicum* survive this treatment. Abundant gas is produced in PYG deep agar cultures.

Adonitol, dulcitol, erythritol, and glycerol are not fermented; sorbose occasionally is fermented weakly. Neutral red and resazurin are reduced and ammonia is produced by some strains; hippurate is hydrolyzed by 3 of 17 strains tested.

Phage-like particles produced by a strain of *Clostridium septicum* inhibit the growth of a strain of *Clostridium sporogenes*. This strain of *Clostridium septicum* is in turn inhibited by strains of *Clostridium bif fermentans*, *Clostridium butyricum*, *Clostridium cadaveris*, *Clostridium perfringens*, *Clostridium tertium*, and *Clostridium tetani*. All of 16 strains of *Clostridium septicum* tested were susceptible to bacteriocins produced by 9 of 21 strains of *Streptococcus faecium* or *Streptococcus faecalis* studied. Bacteriocin produced by *Clostridium septicum* inhibited RNA and protein synthesis, and rapidly kills all 16 strains of *Clostridium septicum* and all 10 strains of *Clostridium chauvoei* tested, but none of a variety of other species of bacteria.

One strain of *Clostridium septicum* has been shown to hydrolyze the conjugated bile acids taurocholate and glycocholate. All of 26 strains tested produce deoxyribonuclease (beta toxin) and hyaluronidase (gamma toxin) in both acidic and alkaline conditions. An oxygen-stable hemolysin with necrotizing properties (alpha toxin), and an oxygen-labile hemolysin (delta toxin) are also

produced. A neuraminidase and a hemagglutinin are produced. Chitinase is produced. Uracil is not utilized. Although lipase is not detected on egg-yolk agar plates, traces of lipidolytic activity, detected by a gas-liquid chromatographic method, have been reported in a strain of this species.

Products in PYG broth include large amounts of acetic and butyric acids, and usually large amounts of formic acid. Abundant H₂ is produced. Electron capture gas-liquid chromatography has detected butanol, isoamyl alcohol, and propionic, isobutyric, isovaleric, and isocaproic as well as acetic and butyric acids in chopped-meat glucose cultures of *Clostridium septicum*. Lactate usually is not utilized, but increased butyrate may be formed in PY-lactate broth. Pyruvate is converted to acetate and butyrate and, occasionally, to formate. Threonine is not converted to propionate. Oleic acid is converted to hydroxystearic acid.

Ethylamine was detected in the head-space gas above a chopped-meat glucose culture of one isolate. All strains tested are susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline.

This species is capable of causing rapidly fatal infections in humans and other animals by production of its lethal hemolytic and necrotizing alpha toxin. A lethal disseminated infection can be produced in mice and guinea pigs by intramuscular injection of fewer than 10 spores plus CaCl₂; postmortem examination reveals bloodstained edema fluid, a deep red color of the muscle and soft tissue, gas formation in the inoculated limb, and dissemination of the organism to all parts of the body. In cattle, wound infection produces “malignant edema”, a disease similar to the experimental disease in laboratory animals, as described above; and in sheep, braxy, a fatal bacteremic infection following penetration of the abomasal wall. Similar diseases have been noted in other species of domestic and wild animals. *Clostridium septicum*, *Clostridium perfringens*, and *Clostridium novyi* are the three most common causes of clostridial myonecrosis (gas gangrene). Such infection may occur either by direct contamination of an infected traumatic wound or by metastatic infection following bacteremia from the gastrointestinal tract; in the latter case, a breach in the bowel mucosa (such as due to a malignancy) serves as the portal of entry. The mechanism of disease production apparently is similar to that of the animal model described above. Other characteristics of the species are given in Table 142.

Source: soil; probably the gastrointestinal tract contents of many domesticated animals; rattlesnake venom; feces of human infants and adults; animal infections including wound infections; myositis and enterotoxemia in ruminants and bacteremia; human infections including bacteremia, suppurative infections, necrotizing enterocolitis, and myonecrosis or gas gangrene.

DNA G+C content (mol %): 24 (*T_m*).

Type strain: ATCC 12464, CCM 5743, BCRC 14552, CCUG 4855, CIP 61.10, CN 3790, DSM 7534, JCM 8144, NCCB 47070, NCIB 547, NCTC 547, NRRL B-3197.

GenBank accession number (16S rRNA gene): U59278.

Further comments: 16S rRNA gene sequence analysis shows *Clostridium septicum* to fall within the radiation of

cluster I of the clostridia as defined by Collins et al. (1994). The type strain of *Clostridium septicum* shares 99.2% 16S rRNA gene sequence similarity with *Clostridium chauvoei*. Other related species include *Clostridium carnis* (98.2%) and *Clostridium tertium* (97.8%). *Clostridium chauvoei* and *Clostridium septicum* can be differentiated on the basis of substrate utilization patterns.

140. ***Clostridium sordellii**** (Hall and Scott 1927) Prévot 1938, 83^{AL} (*Bacillus sordellii* Hall and Scott 1927, 330)

syn. del. i. n. L. gen. n. *sordellii* pertaining to Professor A. Sordelli, an Argentinian bacteriologist.

Cells in PYG broth cultures are Gram-stain-positive straight rods, usually motile and peritrichous, 0.5–1.7 × 1.6–20.6 μm, and occur singly or in pairs. Spores are oval and central or subterminal, and often occur as free spores. They swell the cell slightly. Spores have a thick exosporium; most have tubular appendages. Sporulation occurs readily in chopped-meat broth cultures incubated for 24 h or on blood agar plates incubated 48 h.

Cell walls contain meso-DAP, glucose, and a trace of galactose. Glutamic acid and alanine also are present. Urease-negative strains that are homologous by DNA–DNA homology determinations with authentic urease-positive strains of *Clostridium sordellii* do not have glucose in their cell walls. Surface colonies on blood agar plates are 1–4 mm in diameter, circular to irregular, flat or raised, translucent or opaque, gray or chalk-white, with a dull or shiny surface, a granular or mottled internal structure, and a scalloped, lobate, or entire margin. Hemolysis is variable, with most strains being slightly β-hemolytic on rabbit blood agar.

The optimum temperature for growth is 30–37 °C. Strains grow moderately well at 25 °C and 45 °C. Growth is inhibited by 6.5% NaCl, by 20% bile, or by a pH of 8.5. Strains of *Clostridium sordellii* are inhibited by phage-like particles found in strains of *Clostridium bifermentans*; although similar particles have been found in these strains of *Clostridium sordellii*, the inhibition is not reciprocal. Strains of *Clostridium sordellii* share a cross-reactive carbohydrate cell surface antigen with both *Clostridium bifermentans* and *Clostridium difficile*. Abundant gas is detected in PYG deep agar cultures. Ammonia is produced; H₂S is produced in SIM by most strains; hippurate is hydrolyzed by most strains. Benzoic acid released from hydrolysis of hippurate can be detected by gas chromatography within 2–4 d.

Gelatin is digested by all strains; milk, casein, and meat are digested by nearly all strains but more slowly. Some strains produce DNase; some strains produce hyaluronatase. Supernatant culture fluids hydrolyze bile acid conjugates. Cholic acid is dehydroxylated at the 7α position to deoxycholic acid by the type strain. Oleic acid is converted to hydroxystearic acid *in vitro*, a reaction that may be important in the pathogenesis of diarrhea in humans. Supernatant culture fluids in protease peptone water broth contain substantial amounts of neuraminidase. A wide variety of straight-chain, iso-branched chain, and anteiso-branched chain fatty acids, both saturated and unsaturated, is present in the lipids of this species.

Acetic acid is the major product in PYG broth cultures. Large amounts of formic and moderate amounts of isocaproic acid usually are detected, and trace amounts of propionic, isobutyric, butyric, and isovaleric acids may be present. Ethanol and propanol also are detected. In the absence of glucose, the proportion of acids other than acetic is increased substantially. Abundant H₂ is produced. Pyruvate is converted to acetate and formate. Threonine is converted to propionate. Lactate is not utilized. Phenylalanine and tryptophan are converted to phenylacetic, phenylpropionic, phenyllactic acids, and indole. Leucine is converted to isovalerate, isocaproate, and CO₂. Isoleucine is converted to isovalerate and valine to isobutyrate. Phenylacetic acid is produced in trypticase-yeast extract medium. Proline, serine, threonine, alanine, aspartic acid, glycine, glutamic acid, and methionine are amino acids utilized for growth in 3% casein hydrolysate medium; γ-aminovalerate, γ-aminobutyrate, and valine are produced.

Of 37 strains tested, all are susceptible to chloramphenicol, erythromycin, and penicillin G; 3, are resistant to tetracycline, 1 is resistant to clindamycin. Culture supernatants of only 9 of 71 strains tested were toxic to mice and this toxicity may be lost on subculture. *Clostridium sordellii* is pathogenic for man, cattle, sheep, guinea pigs, and mice. Pathogenicity also may be ephemeral, and non-pathogenic, urease-positive strains are isolated frequently. Although antitoxin to *Clostridium sordellii* will neutralize the toxins of *Clostridium difficile*, the toxins of the two species have been shown to have different properties. Other characteristics of the species are given in Table 144.

Source: soil; normal human feces; human clinical specimens including wounds, penile lesions, blood cultures, abscesses, and abdominal and vaginal drainage; intestinal tracts of both normal and diseased pheasants; bony tissue from dogs with osteomyelitis; bovine intestinal inflammatory lesions; bovine uterus and muscle; alpaca and sheep infections; chicken skin.

DNA G+C content (mol%): 26 (T_m).

Type strain: ATCC 9714, BCRC 10649, CCUG 9284, CIP 103658, DSM 2141, JCM 3814, LMG 15708, NCIMB 10717.

GenBank accession number (16S rRNA gene): AB075771, M59105.

Further comments: 16S rRNA gene sequence shows *Clostridium sordellii* to fall within the radiation of the cluster XI as defined by Collins et al. (1994). The closest relatives based on 16S rRNA gene sequence similarity values are *Eubacterium tenue* (99.0%), *Clostridium ghonii* (98.6%), and *Clostridium bifermentans* (97.8%).

141. ***Clostridium sphenoides**** (Douglas, Fleming and Colebrook 1919) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 33^{AL} (*Bacillus sphenoides* Douglas, Fleming and Colebrook *in* Bulloch, Bullock, Douglas, Henry, McIntoch, O'Brien, Robertson and Wolf 1919, 43)

spheno'i'des. Gr. adj. *sphenoides* wedge-shaped.

Cells usually stain Gram-negative, are straight rods with tapered or rounded ends, motile and peritrichous, occur singly, in pairs, or in short chains and are 0.3–1.1 × 1.3–8.6 μm.

Spores are oval and subterminal or occasionally terminal, and swell the cell. Sporulation occurs most readily on blood agar plates incubated 48 h or on chopped-meat slants incubated at 30 °C. Cell wall contains *meso*-DAP. The cell wall is susceptible to dissolution by lysozyme. Colonies on the surface of blood agar are 1–2 mm in diameter, nonhemolytic, circular with an entire or erose margin, low convex, translucent, gray, with a glossy surface, often with a mottled internal structure.

Cultures in PYG broth are turbid with a smooth, or occasionally ropy sediment and a pH of 4.9–5.4 after incubation for 5 d. Optimum temperature for growth is 30–37 °C. There is good growth at 25 °C, little or none at 45 °C. Growth is slightly stimulated by the presence of a fermentable carbohydrate and inhibited by 20% bile. Abundant gas is produced in PYG deep agar cultures.

Adonitol, dulcitol, erythritol, glycerol, and inositol are not fermented; sorbose is weakly fermented. Ammonia and H₂S are produced, acetyl methyl carbinol is produced occasionally, neutral red is reduced, and resazurin is reduced by most strains. Citrate is used as both a carbon and an energy source with production of acetic acid, ethanol, CO₂, and H₂. Citrate utilization by this species may be unique among clostridia. Taurocholic and glycocholic acids are hydrolyzed, deoxyribonuclease is produced. The insecticide hexachlorocyclohexane is converted to tetrachlorocyclohexene. Phage-like particles are produced by one strain tested. Products of metabolism in PYG broth are large amounts of acetic and formic acids, and occasionally, small amounts of lactic acid, succinic acid, and ethanol. Lactate is not utilized, and threonine usually is not converted to propionate. Pyruvate is converted to acetate, occasionally with formate.

Of 20 strains tested, all are susceptible to erythromycin and tetracycline, 15 are susceptible to chloramphenicol, 12 to clindamycin, and 10 to penicillin G. Culture supernatants are nontoxic to mice.

Although *Clostridium sphenoides* occasionally is recovered from polymicrobial infections in humans, pathogenicity has not been reported. Other characteristics of the species are given in Table 144.

Source: soil; marine sediment; dog feces; normal human appendices; feces of from 4–6.4% of adult humans; infections in range animals; blood, bone, and soft tissue infections; intraperitoneal infections; war wounds; visceral gas gangrene; and renal abscess.

DNA G+C content (mol%): 41–42 (*T_m*).

Type strain: ATCC 19403, CIP 104283, DSM 632, JCM 1415, LMG 10390, NCCB 77027, NCTC 507.

GenBank accession number (16S rRNA gene): AB075772, X73449.

Further comments: *Clostridium sphenoides* falls within the radiation of cluster XIVa of the clostridia as defined by Collins et al. (1994). The closest relative based on sequence similarity values is the misclassified *Desulfotomaculum guttoideum* (99.5%). Other species showing similarity values in the range 97.5–99.0% include *Clostridium celerecrescens*, *Clostridium indolis*, *Clostridium saccharolyticum*, *Clostridium methoxybenzovorans*, *Clostridium aerotolerans*, and *Clostridium amygdalium*.

142. *Clostridium spiroforme** Kaneuchi, Miyazato, Shinjo and Mitsuoka 1979, 10^{Al}.

spi.ro.for'me. Gr. n. *spira* a coil; L. n. *forma* shape; N.L. neut. adj. *spiroforme* in the shape of a coil.

Cells on Eggerth–Gagnon agar after 2 d of incubation are Gram-stain-positive, nonmotile, 0.3–0.5 × 2.0–10.0 μm, and exhibit various degrees of coiling; long chains of organisms forming tight coils often are seen. After heating at 80 °C for 10 min, cells may be nearly straight and subsequent subcultures do not have coiled cells. Most strains produce round, terminal, or occasionally subterminal spores approximately 0.7 μm in diameter when incubated for 2 weeks at 30 °C on medium 10 (Kaneuchi et al., 1979) or on chopped-meat agar slants. Most strains survive heating to 70 °C for 10 min; survival after heating to 80 °C for 10 min is variable. Spore demonstration is sometimes difficult; fresh isolates from humans may not form spores or survive heating to 70 °C for 10 min.

Colonies on the surface of Eggerth–Gagnon agar after 2 d incubation and on medium 10 agar after 3 d incubation are 0.7–1.5 mm in diameter, have an entire or slightly erose margin, are circular, convex to slightly pulvinate, smooth, shiny, semiopaque to opaque, and are whitish to brownish-gray. Colonies on blood agar plates are non-hemolytic.

PYG broth cultures are slightly turbid with a smooth to flocculent sediment and have a pH of 4.9–5.2 after incubation for 7 d. The temperature for optimum growth is 30–37 °C; most strains grow poorly, if at all, at 25 °C or 45 °C. There is no growth at 15 °C. Growth is enhanced by the presence of a fermentable carbohydrate or of 10% rumen fluid. Growth of most strains is inhibited by 20% bile or 6.5% NaCl. Small to moderate amounts of gas are produced in PYG deep agar cultures. Acetyl methyl carbinol is produced; neutral red and resazurin are reduced. Esculin is fermented occasionally; dextrin, dulcitol, α-methylglucoside, and α-methylmannoside are not fermented. Urease is not produced. Large amounts of acetic and formic acids, and small amounts of lactic acid are produced in PYG broth. Abundant H₂ is produced. Lactate and threonine are not converted to propionate.

The type strain is susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. An organism that is identical to, or closely resembles, *Clostridium spiroforme* has been implicated as the cause in rabbits of an apparently toxin-induced diarrhea that occurs spontaneously and in association with antimicrobial therapy. The toxic effect can be neutralized by antitoxin to *Clostridium perfringens* type E iota toxin; this toxic effect is not produced by the type strain of the species. A toxin produced *in vitro* is lethal to mice and causes dermonecrosis in guinea pigs, but toxin is not produced by all strains. Other characteristics of the species are given in Table 144.

Source: the feces of healthy humans; the ceca of healthy chickens and rabbits; the ceca of rabbits with diarrhea.

DNA G+C content (mol%): 27 (*T_m*).

Type strain: ATCC 29900, CCUG 46510, CIP 106966, DSM 1552, JCM 1432, NCTC 11211, VPI C28-23-1A.

GenBank accession number (16S rRNA gene): X73441, X75908.

Further comments: *Clostridium spiroforme* can be distinguished from most other species of *Clostridium* by its coiled morphology and its failure to produce butyric acid. It is most readily distinguished from *Clostridium cocleatum*, which it most closely resembles, by its inability to ferment galactose. 16S rRNA gene sequence comparisons show *Clostridium spiroforme* to fall within the radiation of cluster XVIII of the clostridia (Collins et al., 1994). Sequence similarities in the range 95.6–96.4% are found to the species *Clostridium cocleatum*, *Clostridium ramosum*, and *Clostridium saccharogumia*. *Clostridium spiroforme* is most closely related to *Clostridium cocleatum*, but is a distinct species having 46–60% homology with strains of *Clostridium cocleatum* (Kaneuchi et al., 1979).

143. ***Clostridium sporogenes**** (Heller 1922) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 329^{AL}. (*Metchnikovillus sporogenes* Heller 1922, 29)

spo.ro'ge.nes. Gr. n. *sporos* seed; Gr. suff. *-genes* born of; N.L. neut. adj. *sporogenes* spore-producing.

Cells in PYG broth cultures are Gram-stain-positive straight rods, motile and peritrichous, that occur singly and are 0.3–1.4 × 1.3–16.0 μm. Spores are oval, subterminal, and distend the cell; sporulation occurs readily on most media. Following sporulation, the vegetative material may disintegrate rapidly to leave only free spores. Outgrowth of spores in meat slurries is inhibited by nitrites and nisin. Cell wall contains *meso*-DAP; galactose is the only cell-wall sugar. Glutamic acid and alanine are present. The cell wall is susceptible to dissolution by lysozyme. Surface colonies on blood agar plates are 2–6 mm in diameter, irregularly circular, possess a coarse rhizoid edge, have a raised yellowish-gray center and a flattened periphery composed of entangled filaments ("Medusa head" colony), are opaque, possess a matt surface, are usually β-hemolytic and are firmly adherent to the agar. Colonies on more moist agar are larger, flatter, gray, and less adherent. Colonies in agar are spherical, with an opaque center, and a woolly semi-translucent periphery; lenticular colonies with fine marginal outgrowths may be produced.

Cultures in PYG broth are turbid, with a smooth or occasionally ropy to flocculent sediment, and have a pH of 5.7–6.4 after incubation for 1 week. In chopped-meat medium with iron filings, there is often marked blackening of the meat particles. The temperature range for optimum growth is 30–40 °C; will grow at 25 °C and 45 °C. Good growth occurs in an atmosphere containing up to 100% CO₂. Growth in 6.5% NaCl, 20% bile, or at a pH of 8.5 is variable; there is no inhibition of some strains, others are completely inhibited. Abundant gas is produced in PYG deep agar cultures.

Adonitol, dulcitol, erythritol, glycerol, and sorbose are not fermented. Ammonia and H₂S are produced, neutral red is reduced and resazurin is reduced by some strains; a few strains produce urease and hydrolyze hippurate. Produces deoxyribonuclease, thiaminase, chitinase, kininase, L-methioninase, hyaluronatylase, and superoxide dismutase. Uracil is reduced to dihydrouracil. Cells contain

ferredoxin. Three flagellar antigens, four somatic antigens, and four spore antigens detected. Some strains of *Clostridium sporogenes* are capable of inhibiting growth and toxin production by *Clostridium botulinum* type A. Only a few strains were lysed by mitomycin C, whereas all strains of *Clostridium botulinum* tested were lysed. Nonlysogenic bacteriophages active against *Clostridium sporogenes* have been isolated from soil, sewage, and chicken feces. Bacteriocin-like substances that are active against other strains of *Clostridium sporogenes* are produced by *Clostridium sporogenes*. The mutagen, 1-nitropyrene, is reduced to 1-aminopyrene with concomitant decrease in mutagenicity by a strain of this species.

Products of metabolism in PYG broth include large amounts of acetic and butyric acids, and small amounts of isobutyric and isovaleric acids; propionic, valeric, isocaproic, lactic, and succinic acids also may be produced. Ethanol and abundant H₂ are produced. Lactate is converted to butyrate; pyruvate is converted to acetate and butyrate; threonine usually is converted to propionate. *Clostridium sporogenes* is capable of carrying out the "Stickland reaction" in which energy is obtained by the coupled oxidation and reduction of various amino acid pairs. Betaine may also serve as an oxidant in this type of reaction. When glycine is used as the oxidant, *Clostridium sporogenes* has an absolute requirement for selenium. Leucine and valine can be interconverted. In a thioglycollate-trypticase-yeast extract medium supplemented with casein hydrolysate, proline is converted to 5-aminovaleric acid, 2-aminobutyric acid is produced, phenylalanine is converted to phenylpropionic acid, tyrosine is converted to *p*-hydroxyphenylpropionic acid, and tryptophan is converted to indole propionic acid. Arginine and serine also can be utilized. Addition of valine to a basal medium results in increased isobutyric acid production; addition of leucine results in increased isovaleric and isocaproic acid production and addition of isoleucine results in increased isovaleric acid production. *Clostridium sporogenes* can metabolize monoacetone glucose.

The major cellular fatty acids produced by this species are normal saturated C₁₄, C₁₅, C₁₆, C₁₇, and C₁₈ acids, and normal unsaturated C₁₆ acid with a double bond at the 7 or 9 position. Small amounts of other normal and branched chain fatty acids also are present.

Of 105 strains tested by the broth disk method, 1 is resistant to penicillin G, 1 to tetracycline, 4 to chloramphenicol, 5 to erythromycin, and 57 to clindamycin; all others are susceptible. Determinations of MICs of various antibiotics against 18 strains of *Clostridium sporogenes* indicate that all are susceptible to penicillin G (2 U/ml), metronidazole (0.25 μg/ml), tinidazole (1 μg/ml), chloramphenicol (4 μg/ml), tetracycline (0.5 μg/ml), doxycycline (0.25 μg/ml), but resistant to streptomycin, neomycin, kanamycin, tobramycin, and amikacin; susceptibility to cephalothin, erythromycin, clindamycin, lincomycin, and gentamicin is variable between strains. Culture supernatants are not toxic to mice. Although *Clostridium sporogenes* is isolated from infections, these infections are usually polymicrobial and the role, if any, of this species as a pathogen in such infections has not been established.

Untoward effects are not seen when germ-free animals undergo gastrointestinal monoassociation. Self-limited, spontaneously healing abscesses are produced following intramuscular injection of a relatively large inoculum into guinea pigs. A generalized lethal disease, possibly egg-borne, in newly hatched chicks has been attributed to *Clostridium sporogenes*. Cerebrocortical necrosis in ruminant animals is thought to be due to thiamine deficiency; an association between this disease and colonization by thiaminase-producing strains of *Clostridium sporogenes* has been postulated, but not proven. The highly proteolytic nature of *Clostridium sporogenes* is thought possibly to act as an adjuvant and promote invasiveness of other bacteria in various mixed infections of animals and humans. Other characteristics of the species are given in Table 142.

Source: soil throughout the world; marine and fresh water lake sediment; preserved meat and dairy products; snake venom; feces of sheep and dogs; human infant and adult feces; infections in domestic animals; infections in humans including bacteremia, infective endocarditis, central nervous system, and pleuropulmonary infections; penile lesions; abscesses; war wounds; other pyogenic infections.

DNA G+C content (mol %): 26 (T_m).

Type strain: ATCC 3584, BCRC 11259, CCUG 15941, CIP 106155, DSM 795, NBRC 13950, JCM 1416, LMG 8421, NCIMB 10696, NCTC 13020.

GenBank accession number (16S rRNA gene): M59115, X68189.

Further comments: *Clostridium sporogenes* can be differentiated from proteolytic strains of *Clostridium botulinum* types A, B, and F, which it closely resembles phenotypically, by toxin neutralization in mice, by polyacrylamide gel electrophoretic examination of soluble cellular proteins, or by gas chromatography of trimethylsilyl derivatives of whole-cell hydrolysates (see *Clostridium botulinum*). *Clostridium sporogenes* and *Clostridium difficile* also are morphologically similar and have similar fermentation products; they differ, however, in mannitol fermentation, proteolytic activity in milk and meat, and in lipase production.

16S rRNA gene sequence comparisons show *Clostridium sporogenes* to fall within the radiation of cluster I of the clostridia (Collins et al., 1994). The highest 16S rRNA gene sequence similarities are to the species *Clostridium novyi* (99.8%; accession no. M59100) and *Clostridium botulinum* (99.6%; accession no. L37585). Olsen et al. (1995) proposed that the name *Clostridium sporogenes* be conserved for the nontoxic strains of this species cluster.

144. ***Clostridium sporosphaeroides**** Soriano and Soriano 1948, 39^{AL}

spo.ro.sphae.roi'des. Gr. n. *spora* seed; Gr. adj. *sphaeroides* globular; N.L. neut. adj. *sporosphaeroides* having spherical spores.

Cells in PYG broth are Gram-stain-positive but easily decolorized, nonmotile, straight rods, 0.5–0.6 × 1.8–5.5 μm. Spores are oval or round, and terminal. Sporulation occurs most readily on chopped-meat slants incubated at 30 °C. Cell wall contains *meso*-DAP. The cell wall is susceptible to dissolution by lysozyme.

Colonies on the surface of blood agar are 1–2 mm in diameter, circular, with a slightly lobate or scalloped margin, slightly raised, with a fried-egg appearance, gray-white, have a glossy surface, a mosaic internal structure, and are nonhemolytic.

Cultures in PYG broth are turbid with a smooth to ropy sediment and have a pH of 6.1 after incubation for 5 d. The temperature range for optimum growth is 37–45 °C. There is slight growth at 30 °C, no growth at 25 °C. Growth is inhibited by 20% bile and by 6.5% NaCl. A moderate amount of gas is produced in PYG deep agar cultures.

Adonitol, dulcitol, erythritol, glycerol, and sorbose are not fermented. Ammonia and H₂S are produced; hippurate is hydrolyzed; neutral red and resazurin are reduced.

An NADP-dependent 7 α-hydroxysteroid dehydrogenase capable of dehydrogenation of bile salts is produced. Deoxyribonuclease activity is not present.

Products of metabolism in PYG broth include large amounts of acetate and butyrate, and small amounts of propionate. Abundant H₂ is produced. Lactate is converted to propionate; pyruvate is converted to acetate; threonine is not utilized. *Clostridium sporosphaeroides* does not metabolize phenylalanine, tyrosine, or tryptophan. Glutamate is metabolized to ammonia, CO₂, acetate, and butyrate via a hydroxyglutarate pathway.

The type strain is susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Culture supernatants of the type strain are nontoxic to mice.

Other characteristics of the species are given in Table 143.

Source: canned food, human feces.

DNA G+C content (mol %): 27 (T_m).

Type strain: ATCC 25781, DSM 1294.

GenBank accession number (16S rRNA gene): M59116, X66002.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium sporosphaeroides* to fall within the radiation of cluster IV of the clostridia as defined by Collins et al. (1994). The closest relative of *Clostridium sporosphaeroides* is *Clostridium leptum* with which it shares 93.9% 16S rRNA gene sequence similarity.

145. ***Clostridium stercorarium*** Madden 1983, 839^{VP} emend. Fardeau, Ollivier, Garcia and Patel 2001, 1130

ster.cor.ar.i'um. N.L. adj. *stercorarium* pertaining to dung, referring to the source of the isolate, a compost heap.

Rod-shaped cells, 0.3–0.4 × 2–4 μm. Gram-stain-negative. Chemoorganotrophic. Motile with peritrichous flagella. Forms oval, terminal spores. Colonies are unpigmented, glossy, flat, and 3–5 mm in diameter.

Obligate anaerobe. Optimum temperature for growth is 65 °C. Optimum pH for growth is 7.3. Ferments cellulose, cellobiose, mellibiose, raffinose, fructose, and sucrose. Does not ferment arabinose, mannitol, sorbitol, gelatin, or casein. The end products of glucose fermentation produces are acetate, lactate, ethanol, H₂, CO₂, and small amounts of L-alanine. No sulfate reduction.

Source: compost.

DNA G+C content (mol %): 39 (T_m).

Type strain: ATCC 35414, DSM 8532, NCIMB 11754.

GenBank accession number (16S rRNA gene): AJ310082, L09174.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium stercorarium* subsp. *stercorarium* to fall within the radiation of group III of the clostridia as defined by Collins et al. (1994). *Clostridium stercorarium* subsp. *stercorarium*, *Clostridium stercorarium* subsp. *leptospartum*, and *Clostridium stercorarium* subsp. *thermolacticum* share 98.7–99.1% 16S rRNA gene sequence similarity. This subspecies cluster forms a distinct lineage within cluster III sharing less than 92% 16S rRNA gene sequence similarity to other *Clostridium* species of cluster III.

- 145a. ***Clostridium stercorarium* subsp. *stercorarium*** Madden 1983, 840^{VP} emend. Fardeau, Ollivier, Garcia and Patel 2001, 1130.)

See description above for *Clostridium stercorarium*.

- 145b. ***Clostridium stercorarium* subsp. *leptospartum*** (Toda, Saiki, Uozumi and Beppu 1988) Fardeau, Ollivier, Garcia, and Patel 2001, 1130^{VP} (*Thermobacteroides leptospartum* Toda, Saiki, Uozumi and Beppu 1988, 1343)

lep.to.spar'tum. Gr. adj. *leptos* thin, delicate, small; Gr. n. *sparton* rope; L. n. *spartum* rope; N.L. neut. n. *leptospartum* a thin rope.

Rod-shaped cells, 0.25–0.45 × 4.5–15 μm; found singly or paired. Obligate anaerobe. Gram-stain-negative. Non-motile. Spores not detected. Colonies are round, flat, colorless, and 2–3 mm in diameter. Temperature range for growth is 45–71 °C with an optimum temperature for growth of 60 °C. pH Range for growth is 6.7–8.9 with optimum growth at pH 7.5.

Utilizes lactose, galactose, cellobiose, xylose, and mannose. Arabinose, ribose, fructose, sucrose, gelatin, and casein are not utilized. Ferments glucose to produce acetate, lactate, and ethanol. Sulfate is not reduced. Cells are cellulolytic. Hydrolyzes esculin. Cells do not utilize fructose or sucrose. Gelatin and casein are not hydrolyzed.

- 145c. ***Clostridium stercorarium* subsp. *thermolacticum*** (Le Ruyet, Dubourguier, Albagnac and Prensier 1985) Fardeau, Ollivier, Garcia and Patel 2001, 1130^{VP} (*Clostridium thermolacticum* Le Ruyet, Dubourguier, Albagnac and Prensier 1985, 201)

ther.mo.lac.ti cum. Gr. adj. *thermos* hot; L. n. *lac*, *lactis* milk; N.L. neut. adj. *thermolacticum* pertaining to the high growth temperature and a growth substrate.

Rod-shaped cells, 0.7–0.8 × 2.7–7.7 μm. Nonmotile or motile by single lateral flagellum. Gram-stain-negative. Forms round, terminal spores. Colonies are translucent, flat, glossy, and 1–1.5 mm in diameter.

Strict anaerobe. Temperature range for growth is 50–70 °C with an optimum of 60–65 °C. pH Range for growth is 6.8–7.4 with an optimum of 7.0. Carbohydrates required for growth. Ferments glucose, starch, cellobiose, fructose, raffinose, ribose, sucrose, mannose,

lactose, xylan, salicin, melibiose, and rhamnose. End products of glucose fermentation are acetate, ethanol, CO₂, H₂, and L(+) lactate. Arabinose, gelatin, and casein are not utilized. Hydrolyzes esculin, but not gelatin. Catalase and urease-negative. Does not reduce nitrate or sulfate.

Source: compost.

DNA G+C content (mol%): 41 (T_m).

Type strain: TX 41, ATCC 43739, DSM 2910.

GenBank accession number (16S rRNA gene): X72870.

146. ***Clostridium sticklandii**** Stadtman and McClung 1957, 218^{AL}

stick.lan'di.i. N.L. gen. n. *sticklandii* pertaining to L.H. Stickland, British biochemist.

This description, unless stated otherwise, is based on that of Stadtman and McClung (1957) and on study of the type strain.

Cells in PYG broth are straight, slender Gram-stain-positive rods that are motile and peritrichous, 0.3–0.5 × 1.3–3.8 μm, and occur singly, in pairs, and sometimes in short chains. Spores are oval, subterminal, distend the cell slightly, but are rarely seen, and then only in old cultures. Cell-wall composition has not been reported.

Surface colonies on blood agar are 1–2 mm in diameter, circular with an entire or slightly undulated margin, convex, grayish-white, translucent or opaque, possess a glossy surface and a mottled internal structure, and are nonhemolytic. Colonies in agar are 1–2 mm in size and lenticular, becoming lobate.

Cultures in PYG broth are turbid with a smooth sediment and have a pH of 6.0 after incubation for 6 d. The temperature range for optimum growth is 30–37 °C; moderate growth occurs at 25 °C and 45 °C. Moderate gas is produced in PYG deep agar cultures.

Carbohydrates are not appreciably fermented. Ammonia is produced. Energy for growth is obtained by coupled oxidation-reduction reactions between certain amino acid pairs ("Stickland reaction"). Uracil is not utilized. Products in PY broth are large amounts of acetate, butyrate, and isovalerate, small amounts of propionate and isobutyrate, and a small amount of H₂. Lesser amounts of these products are detected when glucose is added to the basal medium. Pyruvate is converted to acetate; lactate is not utilized; threonine is converted to acetate and to propionate. Threonine is reduced to α-aminobutyrate by dried cells and cell-free extracts of *Clostridium sticklandii*. Ornithine is converted to δ-aminovalerate. In amino-acid-supplemented broth cultures, 2-aminobutyric acid is produced; arginine, glycine, lysine, methionine, and serine are utilized; proline is converted to 5-aminovaleric acid, phenylalanine to phenylacetic acid, tyrosine to *p*-hydroxyphenylacetic acid, valine to isobutyric acid, leucine and isoleucine to isovaleric acid, and tryptophan to indole acetic acid. The purines adenine, hypoxanthine, xanthine, and uric acid can serve as hydrogen acceptors. Lysine is converted to acetic and butyric acids and ammonia. Glutamate is fermented slowly by way of the methylaspartate pathway.

The major fatty acids of *Clostridium sticklandii* are normal, saturated C₁₄ and C₁₆ acids; small amounts of other

normal and branched chain fatty acids, both saturated and unsaturated, also are present.

The type strain is susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Culture supernatants of the type strain are not toxic to mice; strains are not pathogenic for guinea pigs. Other characteristics of the species are given in Table 143.

Source: soil, San Francisco Bay black mud, feces of one subject in Uganda.

DNA G+C content (mol %): 31 (T_m).

Type strain: ATCC 12662, BCRC (formerly CCRC) 14485, CCUG 9281, DSM 519, JCM 1433, NCIMB 10654.

GenBank accession number (16S rRNA gene): not reported.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium sticklandii* to fall within the radiation of cluster XI of the clostridia as defined by Collins et al. (1994). *Clostridium sticklandii* forms a distinct lineage and is related at ~90% 16S rRNA gene sequence similarity to the species *Clostridium litorale*, *Clostridium sordellii*, *Eubacterium tenue*, and *Clostridium ghonii*.

147. ***Clostridium straminisolvens*** Kato, Haruta, Cui, Ishii, Yokota and Igarashi 2004, 2046^{VP}

stra.mi.ni.sol'vens. L. neut. n. *stramen* straw; L. v. *solvere* to dissolve; N.L. part. adj. *straminisolvens* straw-dissolving.

Straight or slightly curved rods, 0.5–1.0 × 3.0–8.0 μm, occurring singly or in pairs. Anaerobic growth. Aerotolerant. Nonmotile. Forms subterminal, oval spores 0.5–1.0 × 1.0–1.5 μm. On cellobiose agar colonies are 1–2 μm in diameter, tan-yellow, round, with entire margins. Growth occurs under a gas phase containing up to 4% O₂. Temperature range for growth is 50–55 °C; no growth occurs at or below 45 °C or at 65 °C and above. The pH range for growth is 6.0–8.5 with an optimum of pH 7.5.

Cellulose and cellobiose are utilized as sole carbon and energy sources. Glucose, fructose, ribose, mannose, manitol, melibiose, sucrose, xylose, sucrose, lactose, xylan, and starch are not utilized as sole carbon and energy sources. The end products of fermentation are acetate, lactate, ethanol, hydrogen, and carbon dioxide. Esculin is hydrolyzed. Nitrate is not reduced. Casein is not digested. Lipase, lectinase, and indole are not produced.

Source: a cellulose-degrading bacterial community.

DNA G+C content (mol %): 41.3 (HPLC).

Type strain: CSK1, DSM 16021, IAM 15070, JCM 21531, NBRC 103399.

GenBank accession number (16S rRNA gene): AB125279.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium straminisolvens* to fall within the radiation of cluster III of the clostridia as defined by Collins et al. (1994). The closest relatives of *Clostridium straminisolvens* based on 16S rRNA gene sequence similarity values are *Clostridium thermocellum* (97.1%), *Acetivibrio cellulolyticus* (96.3%), *Clostridium alkalicellulosi* (96.2%), and *Clostridium aldrichii* (95.9%). *Clostridium straminisolvens* differs from its closest relatives in its temperature range for growth and its aerotolerance (Kato et al., 2004). A DNA–DNA reassociation value of 23% indicated that *Clostridium thermocellum* and strain CSK1^T are distinct species.

148. ***Clostridium subterminale***^s (Hall and Whitehead 1927) Spray 1948, 786^{AL} (*Bacillus subterminalis* Hall and Whitehead 1927, 67)

sub.ter.mi.na'le. L. pref. *sub* under; L. adj. *terminalis* terminal; N.L. neut. adj. *subterminale* near the end, subterminal.

Cells in PYG broth are Gram-stain-positive, straight rods, usually motile and peritrichous, and are 0.5–1.9 × 1.6–11.0 μm. Spores are without appendages and are oval and usually subterminal (occasionally central), and dis-tend the cell. Sporulation occurs readily on blood agar, egg-yolk agar, and chopped-meat agar. Cell walls contain meso-DAP. The cell wall is digested by lysozyme.

Surface colonies on blood agar are 1–4 mm in diameter, raised or low convex, translucent, gray, irregularly circular with a lobate or scalloped margin and a matt surface, and usually are β-hemolytic. They often have a crystalline, mottled, or mosaic internal structure.

Cultures in PYG broth are turbid with a smooth or ropy sediment and have a pH of 6.0–6.4 after incubation for 5 d. The temperature for optimum growth is 37 °C; most strains also grow at 25 °C and 45 °C. Growth is inhibited by 20% bile or 6.5% NaCl. Moderate amounts of gas are produced in PYG deep agar cultures. Ammonia is produced, H₂S is produced by most strains, neutral red is reduced, and resazurin occasionally is reduced. An occasional strain may produce a slight amount of lecithinase. Cells possess deoxyribonuclease. Neuraminidase is not produced.

Metabolic products in PYG broth include large amounts of acetate, butyrate, and isovalerate and small amounts of isobutyrate; small amounts of formate, propionate, isocaproate, lactate, and succinate may be produced. Ethanol and traces of other alcohols are usually detected. Phenylacetate is produced by the type strain. Abundant H₂ is produced. Threonine is converted to propionate by 6 of 22 strains tested; pyruvate is converted to acetate and usually to butyrate; lactate is not utilized. Valine is converted to isobutyrate; leucine and isoleucine are converted to isovalerate. In amino acid-containing broth cultures, arginine, glycine, lysine, and serine are utilized, and phenylalanine is converted to phenylacetic acid, tyrosine to *p*-hydroxyphenylacetic acid, and tryptophan to indole acetic acid.

The major fatty acids of *Clostridium subterminale* are normal, saturated C₁₂, C₁₄, and C₁₆ acids; lesser amounts of saturated iso-branched C₁₅ and normal unsaturated C₁₆ acids with a double bond at the 7 or 9 position; small amounts of other normal and branched chain fatty acids also are present.

Of 31 strains tested, all are susceptible to erythromycin, penicillin G, and tetracycline; 25 are susceptible to chloramphenicol, and 22 are susceptible to clindamycin. One strain was inhibited by 0.19 μg of erythromycin/ml. Culture supernatants are nontoxic when injected into mice. Other characteristics of the species are given in Table 142.

Source: marine sediment; soil; bovine feces; the small bowel contents of adult humans; feces of healthy humans, of humans with antimicrobial-associated diarrhea; infection in animals; rarely (and usually as part of

a polymicrobial flora) from blood, biliary tract infections, empyema fluid, and soft tissue or bone infections of humans.

DNA G+C content (mol %): 28 (T_m).

Type strain: ATCC 25774, BCRC (formerly CCRC) 14486, CCUG 21841, CDC KAI52, DSM 6970, JCM 1417, NCIMB 10746, VPI 20231.

GenBank accession number (16S rRNA gene): AF241844, L37595, M59106, X68451.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium subterminale* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relative of *Clostridium subterminale* based on 16S rRNA gene sequence similarity values is *Clostridium thiosulfatireducens* (99.9%). DNA–DNA reassociation data and phenotypic differences including the fact that *Clostridium subterminale* does not use sulfate as an electron acceptor differentiate *Clostridium subterminale* from *Clostridium thiosulfatireducens*.

149. ***Clostridium symbiosum**** (Stevens 1956) Kaneuchi, Watanabe, Terada, Benno and Mitsuoka 1976b, 202^{AL} (*Bacteroides symbiosus* Stevens 1956, 100)

sym.bi.o'sum. Gr. n. *symbios* a companion; N.L. neut. adj. *symbiosum* living together with, symbiotic (refers to its use as a symbiote for cultivation of *Entamoeba histolytica*).

Cells on Eggerth–Gagnon agar are Gram-stain-negative, are usually motile and peritrichous, straight rods, often with pointed ends, 0.5–0.6 × 1.5–2.0 μm, and occur singly, in pairs, or in chains. Spores are round or oval, and subterminal; spores survive heating to 70 °C for 10 min but may not survive 80 °C for 10 min. Cell walls contain meso-DAP. Surface colonies on Eggerth–Gagnon agar after 3 d of incubation are minute–1.0 mm in diameter, circular, entire, low convex, smooth (sometimes with a slightly irregular surface and margin), translucent, grayish to whitish, and have a whitish-gray or reddish mottled center when viewed through a dissecting microscope. On blood agar, strains may be slightly β-hemolytic.

Cultures in PY-Fildes solution-glucose broth are turbid with a smooth sediment, abundant gas, and have a pH of 5.3–6.0 after 10 d incubation. This species grows well at 37 °C. Growth is nearly as good as at 30 °C, but poor at 25 °C or 45 °C. Growth is stimulated by a fermentable carbohydrate and inhibited by 20% bile or 6.5% NaCl.

Dextrin, glycerol, inositol, and sorbose are not fermented. Ammonia and H₂S are produced, acetyl methyl carbinol usually is produced, neutral red is reduced, and resazurin usually is reduced. Phage-like particles have been demonstrated from a strain of *Clostridium symbiosum*.

Large amounts of acetic acid, butyric acid, and lactic acid are produced in PYG broth; ethanol and formic acid may be detected as well. Abundant H₂ is produced. Pyruvate is converted to acetate and butyrate; neither lactate nor threonine is utilized. Glutamate is fermented to ammonia, CO₂, and acetic and butyric acids via a hydroxyglutarate pathway. Other characteristics of the species are given in Table 144.

Source: feces of healthy humans, liver abscesses and blood infections in humans, occasionally from human infections derived from the bowel flora.

DNA G+C content (mol %): 46 (T_m).

Type strain: ATCC 14940, DSM 934, JCM 1297.

GenBank accession number (16S rRNA gene): M59112.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium symbiosum* to fall within the radiation of cluster XIVa of the clostridia as defined by Collins et al. (1994). The closest relative based on 16S rRNA gene sequence similarity values is *Clostridium bolteae* (94.5%).

150. ***Clostridium tepidiprofundum*** Slobodkina, Kolganova, Tourova, Kostrikina, Jeanthon, Bonch-Osmolovskaya and Slobodkin 2008, 854^{VP}

te.pi.di.pro.fun'di. L. adj. *tepidus* moderately warm; L. n. *profundum* the depths of the ocean, N.L. gen. n. *tepidiprofundum* of the warm bottom of the ocean.

Cells are straight to slightly curved rods, 0.4–0.6 × 2.0–3.0 μm. Spore formation is observed only below pH 5.5. Colonies are white, lens shaped, 0.1–0.2 mm in diameter in agar-shake cultures. Anaerobic. The temperature range for growth is 22–60 °C, with optimum growth at 50 °C. The pH range for growth is 4.0–8.5, with optimum growth at pH 6.0–6.8. Growth occurs at NaCl concentrations of 1.0–6.0% (w/v), with optimum growth at 2.5% (w/v). Substrates utilized include casein, peptone, tryptone, yeast extract, beef extract, starch, maltose, and glucose. Pyruvate, L-valine, L-arginine, DL-alanine, L-proline, DL-alanine plus L-proline, glycine, DL-alanine plus glycine, fructose, xylose, cellobiose, sucrose, L-arabinose, glycerol, acetate, butyrate, lactate, formate, methanol, fumarate, betaine, olive oil, xylan, CM-cellulose, filter paper, chitin, and H₂/CO₂ are not utilized. The end products of glucose fermentation are ethanol, acetate, H₂, formate, and CO₂. Reduces elemental sulfur to hydrogen sulfide. Is not able to utilize nitrate, fumarate, sulfate, sulfite, thiosulfate, amorphous iron (III) oxide, iron(III) citrate, or oxygen (20%, v/v, in the gas phase) as electron acceptors.

Source: a deep-sea hydrothermal vent chimney located at 13° N on the East Pacific Rise.

DNA G+C content (mol %): 30.9 (T_m).

Type strain: SG 508, DSM 19306, VKM B-2459.

GenBank accession number (16S rRNA gene): EF197795.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium tepidiprofundum* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The highest sequence similarities were to the species *Clostridium pascei* (93.0%), *Clostridium cochlearium* (92.6%), and *Clostridium peptidivorans* (92.5%). *Clostridium tepidiprofundum* can be differentiated from its closest relatives on the basis of its thermophilic nature, marine origin and subsequent NaCl requirements for optimal growth.

151. ***Clostridium termitidis*** Hethener, Brauman and Garcia 1992a, 327^{VP} (Effective publication: Hethener, Brauman and Garcia 1992b, 57.)

ter.mi'ti.dis. L. n. *tarmes*, *tarmit-* (L.L. var. *termes*, *termit-*) worm that eats wood; N.L. adj. *termitidis* pertaining to the termite.

Straight to slightly curved rods, 0.5 × 4–6 μm. Gram-stain-positive. Motile by peritrichous flagella. Oval terminal spores that cause cell swelling. Deep colonies in

roll tubes are small, circular, and slightly yellow. On agar surface colonies are widespread. Obligate anaerobe. Temperature range for growth is 20–48 °C with an optimum of 37 °C. The pH range for growth is 5.0–8.2 with an optimum pH of 7.5.

Ferments cellulose, cellobiose, glucose, fructose, galactose, lactose, mannose, ribose, sorbose, xylose, maltose, melibiose, mannitol, sorbitol, and glycerol. Adonitol, arabinose, dulcitol, melezitose, pectin, raffinose, rhamnose, ribose, salicin, sucrose, and trehalose are not utilized. End products of fermentation are acetate, ethanol, H₂, and CO₂. No growth factors required. Enhanced growth observed with the addition of yeast extract, Biotrypcase, or vitamins.

Source: gut of wood-feeding termite (*Nasutitermes lujae*) from Mayombe tropical rainforest, Congo, Central Africa.

DNA G+C content (mol%): 39.2 (*T_m*).

Type strain: CT1112, ATCC 51846, DSM 5398.

GenBank accession number (16S rRNA gene): X71854.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium termitidis* to fall within the radiation of cluster III of the clostridia as defined by Collins et al. (1994). The closest relatives based on 16S rRNA gene sequence similarity values are *Clostridium cellobioparum* (99.1%), *Clostridium josui* (97.7%), *Clostridium cellulolyticum* (97.3%), *Clostridium papyrosolvens* (97.1%), and *Clostridium hungatei* (97.1%). *Clostridium termitidis* can be differentiated from *Clostridium cellobioparum* on the basis of Gram-staining reaction, substrate utilization tests, and G+C content of the DNA.

152. ***Clostridium tertium**** (Henry 1917) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 332^{AL} (*Bacillus tertius* Henry 1917, 347)

ter'ti.um. L. neut. adj. *tertium* third, referring to it being the anaerobe third most frequently isolated by Henry (1917) from open war wounds.

Cells in broth cultures are Gram-stain-positive, motile and peritrichous, and are 0.5–1.4 × 1.5–10.2 μm. They occur singly or in pairs. Spores are large, oval, terminal, or occasionally subterminal, and markedly distend the cell. Although optimal growth is achieved by incubation under anaerobic conditions, the species is aerotolerant and will grow on the surface of freshly prepared blood agar incubated in air. Spores are formed readily in most media incubated anaerobically, but not under aerobic conditions. The cell wall contains lysine rather than DAP; glucose alone or glucose and mannose are the cell-wall sugars. Colonies on the surface of blood agar incubated anaerobically are 2–4 mm in diameter, circular, low convex, have slightly irregular margins, are white to gray, and have a matt surface and usually a mottled or granular internal structure. Hemolysis is variable and, when present, colonies may be α- or β-hemolytic. Surface colonies after aerobic incubation are 1 mm, circular with entire edges, are dome shaped, and have an opalescent appearance. Colonies in agar are small and lenticular.

Cultures in PYG broth grow well and are turbid with a smooth, ropy, or flocculent sediment. The optimum

temperature for growth is 37 °C; growth also occurs readily at 50 °C. Growth is stimulated by the presence of a fermentable carbohydrate and inhibited by 20% bile or by 6.5% NaCl. Abundant gas is produced in PYG deep agar cultures. Adonitol, dulcitol, erythritol, glycerol, inositol, and sorbose are not fermented. Ammonia is produced by some strains, and neutral red and resazurin are reduced. Nitrate reduction is dissimilatory rather than assimilatory. Enzymes produced include deoxyribonuclease, neuraminidase, and an inducible chitinase. Bile acid deconjugation and Δ⁴-steroid dehydrogenase activity that may be related to the etiology of colon cancer have been reported.

Products of fermentation of PYG broth include large amounts of acetic, butyric, and lactic acids, and occasionally small amounts of formic and succinic acids and ethanol. Abundant H₂ is produced. Neither lactate nor threonine is utilized; pyruvate is converted to acetate and occasionally also to butyrate and formate.

Of 20 strains tested, all are susceptible to chloramphenicol and tetracycline, 19 to erythromycin, 10 to penicillin G, and 7 to clindamycin. *Clostridium tertium* is relatively non-pathogenic. Culture supernatants are not toxic to mice. *Clostridium tertium* increases the severity of a lethal enteritis induced by *Clostridium difficile* in gnotobiotic newborn hares. *Clostridium tertium* was found to be only weakly pathogenic when compared with several other species of *Clostridium* in a study of experimental intestinal strangulation in mono-associated gnotobiotic rats. Pneumatosis cystoides intestinalis can occur in these mono-associated animals. Other characteristics of the species are shown in Table 142.

Source: soil; guano in Antarctica; the nares of a beagle dog; feces of healthy neonates and infants; appendices of healthy adults; the feces or colonic mucosa of healthy adults; osteomyelitis in a dog; infection in a calf; a variety of conditions in humans including brain abscess, the gingival sulcus of two patients with periodontitis, infections related to the intestinal tract, soft tissue infections, war wounds, and blood.

DNA G+C content (mol%): 24–26 (*T_m*).

Type strain: ATCC 14573, CCUG 4219, DSM 2485, IAM 14196, JCM 6289, NCIMB 10697, NCIMB 541, NCTC 541.

GenBank accession number (16S rRNA gene): AJ245413, Y18174.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium tertium* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives of *Clostridium tertium* based on 16S rRNA gene sequence similarity values are *Clostridium carnis* (99.8%), *Clostridium sartagoforme* (98.2%), *Clostridium chauvoei* (97.6%), *Clostridium isatidis* (97.4%), and *Clostridium septicum* (97.3%). This species can be differentiated from *Clostridium carnis* on the basis of mannitol and melibiose fermentation.

153. ***Clostridium tetani**** (Flügge 1886) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 330^{AL} (*Bacillus tetani* Flügge 1886, 274)

te'ta.ni. L. n. *tetanus* (from Gr. n. *tetanos*) tension, tetanus; L. gen. n. *tetani* of a tension, of tetanus.

Cells in young cultures are Gram-stain-positive, but become Gram-stain-negative after approximately 24h incubation. Most strains are motile and peritrichous. Cells are $0.5\text{--}1.7 \times 2.1\text{--}18.1\mu\text{m}$ and occur singly or in pairs. Spores are usually round and terminal; occasionally they may be oval or subterminal, or both. Spores will germinate in liver broth at a starting O/R potential of up to +580 mV, but vegetative growth does not occur unless the culture is covered with liquid paraffin. When spores of *Clostridium tetani* were introduced orally or intrarectally into germ-free rats, the spores remained viable in the intestinal tract but were unable to germinate. Vegetative cells given by oral swabs did colonize the intestinal tract and stimulated the production of antitoxin, but no toxin was detected. Cell wall contains *meso*-DAP; cell-wall sugars are primarily glucose and rhamnose with traces of galactose and mannose. Cell wall is susceptible to dissolution by lysozyme.

Colonies on the surface of blood agar are 4–6mm in diameter, flat, translucent, gray, with a matt surface, irregular and rhizoid margins, and usually cause a narrow zone of β -hemolysis. There is a tendency to swarm that is more marked on moist plates. Colonies in agar are transparent and very woolly.

Cultures in PYG broth are turbid with a smooth or ropy sediment and have a pH of 6.1–6.5 after incubation for 5 d. The optimum temperature for growth is 37 °C; there is moderate growth at 30 °C, little or none at 25 °C or 45 °C. Growth is inhibited by 20% bile or 6.5% NaCl. Exposure of exponential phase cultures to hyperbaric oxygen (100% O₂ at 3 atm) resulted in death of more than 99.9% of cells. Moderate to abundant gas is produced by most strains in PYG deep agar cultures. Ammonia and H₂S are produced, neutral red is reduced, and resazurin is usually reduced. Deoxyribonuclease is produced; neuraminidase is not produced.

Products of metabolism in PYG broth are butanol, large amounts of acetate and butyrate, and small amounts of propionate; lactate and succinate may also be produced. Abundant H₂ is produced. Lactate and threonine are converted to propionate, pyruvate is converted to butyrate and acetate. Phenol is produced by all strains and indole by some strains in broth supplemented with L-phenylalanine, L-tryptophan, and L-tyrosine. All strains utilize aspartate, glutamate, histidine, and serine for growth; some strains utilize methionine, threonine, and tyrosine. Glutamate is converted to ammonia, CO₂, acetate and butyrate via a methylaspartate pathway.

All of seven strains tested are susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline.

Major lipid fatty acids formed in a trypticase-yeast extract-thioglycollate medium without glucose are normal saturated C₁₂, C₁₄, C₁₆, and C₁₈ acids and smaller amounts of unsaturated C₁₈ and C₁₆ acid with a double bond at the 7 or 9 position. Branched chain fatty acids are not present.

Two pathogenic soluble antigens, tetanolysin and tetanospasmin, are produced. Injection of partially purified tetanolysin produces electrocardiographic changes in monkeys and mice and intravascular hemolysis in rab-

bits and monkeys; there is little evidence, however, that tetanolysin is normally involved in disease production. Tetanospasmin, the cause of clinical tetanus in humans and other animals, is an extremely potent neurotoxin that probably spreads to the central nervous system both by passage up perineural tissue, and by lymphatic and hematogenous routes from a localized site of production; the toxin suppresses central inhibitory influences on motor neurons thereby leading to excessive muscle activity that is manifest by spasticity and tetanic contractions. Localized forms of tetanus may also occur. A “nonspasmodogenic toxin” has been detected (in partially purified form) and may interfere with function of motor nerve. A high molecular mass hemolysin that is distinct from tetanolysin has been detected. Although bacteriophages have been recovered from some strains, they do not appear to be involved in toxigenicity. Toxigenicity is probably plasmid-related. Other characteristics of the species are given in Table 142.

This is a ubiquitous organism.

Source: soil throughout the world; human and other animal feces particularly horse feces; the atmosphere in a hospital; occasionally from wounds in animals and wounds in humans including infected gums and teeth, corneal ulcerations, mastoid and middle ear infections, intraperitoneal infection, omphalitis (tetanus neonatorum), postpartum uterine infections, various soft tissue infections related to trauma (including abrasions and lacerations), use of contaminated needles and catgut.

DNA G+C content (mol %): 25–26 (*T_m*).

Type strain: ATCC 19406, CCUG 4220, NCTC 279.

GenBank accession number (16S rRNA gene): X74770.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium tetani* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relative based on 16S rRNA gene sequence similarity values is *Clostridium cochlearium* (98.1%). Similarity values to other species are below 95%.

154. ***Clostridium tetanomorphum*** (*ex* Bulloch, Bulloch, Douglas, Henry, McIntosh, O'Brien, Robertson and Wolf 1919) Wilde, Hippe, Tosunoglu, Schallehn, Herwig and Gottschalk 1989, 133^{VP} (“*Clostridium tetanomorphum*” Bulloch, Bulloch, Douglas, Henry, McIntosh, O'Brien, Robertson and Wolf 1919)

te.ta.no.mor'phum. L. gen. n. *tetani* a bacterial specific epithet; Gr. n. *morphe* shape; N.L. adj. *tetanomorphum*, [*Clostridium*] *tetani*-shaped.

Slender rods, 0.7–1.0 × 3.0–10.0 μm; found singly or in pairs and sometimes curved. Anaerobic. Motile with peritrichous flagella. Gram-stain-positive. Form terminal to subterminal spherical or elliptical spores, which cause cell swelling. Surface colonies on PY agar are 2–5 mm in diameter, flat, gray, semitranslucent with glossy surfaces, and irregular margins. Colonies on PYG agar are white, opaque, and convex, with a mottled internal structure. Swarm on moist agar surfaces. Cell wall contains *meso*-diaminopimelic acid.

Anaerobic. Growth on media after 5 d reduces pH from 6.9 to 5.0. Optimal temperature for growth is 37 °C. Ferments glucose and maltose to acid and gas. Most strains

ferment inositol, ribose, and xylose. Some strains ferment cellobiose, fructose, salicin, and sorbitol. Growth aided with a fermentable carbohydrate. Cannot ferment arabinose, adonitol, galactose, lactose, mannose, rhamnose, sucrose, and sorbose. Fermentable carbohydrates stimulate growth. Fermentation products from glucose are *n*-butanol, ethanol, acetate, and butyrate. Glutamate is fermented via the methylaspartate pathway to acetate, butyrate, CO₂, and NH₃. Histidine is fermented. Threonine is degraded to propionate; tyrosine is degraded to phenol. Ethanolamine is fermented to acetate, ethanol, and NH₃. Betaine, choline, and creatine are not fermented.

Catalase-negative. Gelatin is not hydrolyzed. Indole production and nitrate reduction vary with strains. Lecithinase-negative. Meat, casein, and milk are not digested. Nontoxicogenic.

Source: septic wounds in London, UK (in 1920).

DNA G+C content (mol %): 25.4–28.5 (T_m).

Type strain: Robertson 259E, ATCC 49273, DSM 4474, NCTC 543.

GenBank accession number (16S rRNA gene): DQ241819.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium tetanomorphum* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relative of *Clostridium tetanomorphum* based on 16S rRNA gene sequence similarities is *Clostridium lundense* (97.9%). *Clostridium tetanomorphum* differs from *Clostridium lundense* in colony morphology and substrate utilization patterns. DNA–DNA reassociation studies have shown the distinct species status of these two species.

155. ***Clostridium thermoalcaliphilum*** Li, Engle, Weiss, Mandelco and Wiegel 1994, 113^{VP}

ther.mo.al.cal.i.phil'um. Gr. adj. *thermos* hot; N.L. n. *alcali* from the arabic *al-qili* the ashes of the saltwort plant; N.L. adj. *philus* from Gr. adj. *philos* dear, loving; N.L. adj. *thermoalcaliphilum* referring to the organism's optimal growth under alkaline growth conditions at elevated temperatures.

Rod-shaped cells, 0.8–1.2 × 3–20 μm in length. Gram-stain-positive cell-wall structure; Gram-stain-negative staining reaction. Nonsporeforming. Motile with 2–12 peritrichous flagella. Motile at pH 7.0–10.6, optimal motility at pH 9.8. Glucose required for motility of almost all cells. Pseudofilaments formed when grown at pH values of 10.9–11.0. At pH values of 10.1–11.0 swollen sporangium-like structures form. Temperature and pH affect motility. Surface colonies are circular and white with a yellow tint. Colonies are lens shaped in agar. The cell-wall type is A4β (L-Orn–D-Asp). The main fatty acids are C_{15:0 iso}, C_{15:0 ante}, C_{13:0 iso}, C_{16:0}, C_{17:0 iso}, C_{14:0} and C_{18:0}.

Obligate anaerobe. The temperature range for growth at pH 10.1 is 27–57.5 °C with optimal growth at 48–51 °C. The pH range for growth is 7.0–11.0 at 50 °C with optimal growth at 9.5–10.0. Shortest doubling time of 19 min observed at pH 10.1, 50 °C in YTG medium. Yeast extract required for growth. Tryptone but not peptone can be used to substitute for yeast extract. The Na⁺ concentration range for growth is 5–1.25 mM. Utilizes glucose, fructose, sucrose, maltose, cellobiose, and Casamino acids.

Galactose, lactose, xylose, ribose, mannose, rhamnose, raffinose, salicin, sorbitol, mannitol, glycerol, lactate, formate, methanol, xylan, cellulose, starch, pectin, and H₂-CO₂ are not utilized. The end products of fermentation from yeast extract and glucose at pH 10.5 and 50 °C are acetate, H₂, isovalerate, lactate, and traces of succinate and malate. No sulfate reduction in presence of glucose, acetate, and lactate.

API AN-IDENT strips gave positive results for indole acetate, α-glucosidase, arginine aminopeptidase, and arginine utilization. Negative results for *N*-acetyl-glucosaminidase, β-glucosidase, α-fucosidase, phosphatase, α-galactosidase, β-galactosidase, leucine aminopeptidase, proline aminopeptidase, pyroglutamic acid arylamidase, tyrosine aminopeptidase, alanine aminopeptidase, glycine aminopeptidase, arabinosidase, indole production, and catalase. Cells are susceptible to 50 μg penicillin G/ml, 50 μg ampicillin/ml, 50 μg metroimidazole/ml, 50 μg gentamicin/ml, and 50 μg rifampin/ml.

Source: sewage plant in Atlanta, Georgia, USA.

DNA G+C content (mol %): 32 (HPLC).

Type strain: JW/YL23-2, ATCC 51508, CIP 105528, DSM 7309.

GenBank accession number (16S rRNA gene): L11304.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium thermoalcaliphilum* to fall within the radiation of cluster XI of the clostridia as defined by Collins et al. (1994). The closest relative based on sequence similarities is *Clostridium paradoxum* at 98.1% 16S rRNA gene sequence similarity. *Clostridium thermoalcaliphilum* can be differentiated from *Clostridium paradoxum* on the basis of differences in cell-wall type, the lack of viable heat-resistant spores in *Clostridium thermoalcaliphilum* and the fact that *Clostridium thermoalcaliphilum* is considered a thermolerant organism while *Clostridium paradoxum* is a thermophile.

156. ***Clostridium thermobutyricum*** Wiegel, Kuk and Kohring 1989a, 200^{VP}

ther.mo.bu.ty'ri.cum. Gr. adj. *thermos* hot; Gr. n. *boutyron* butter; N. L. neut. adj. *thermobutyricum* referring to the production of butyrate under thermophilic conditions.

Straight to slightly curved rods, 0.9–1.1 × 2.0–4.5 μm, occur singly, in pairs, or chains (up to 15 cells). Gram-stain-positive cell-wall structure; Gram-negative staining reaction. Some very early exponential-phase cells may stain Gram-positive. Central to subterminal spores form at pH values below 6.2. Cells have 5–12 peritrichous flagella, but pronounced motility is not observed. The organism has an *m*-DPM-direct cell-wall type. Colonies in agar roll tubes are irregular, circular with lobate margins, and white to cream color. Colonies 3 weeks old turn brown, but do not contain a water-soluble pigment.

Anaerobic, showing no growth in medium in which the resazurin is slightly pink. Yeast extract required for growth. Yeast extract cannot be replaced by tryptone, casein, or vitamin mixture. Moderate thermophile. Temperature range for growth is 26–61.5 °C with optimal growth at 55 °C. pH Range for growth is 5.8–9.0, with optimal growth at 6.8–7.1.

Grows with yeast extract (0.3%) alone. The following substrates stimulate growth and result in a pH drop in the culture medium: D-glucose, D-fructose, maltose, D-xylose, D-ribose, cellobiose D-glucuronic acid, D-galacturonic acid, and pyruvate. Growth is not stimulated by D-arabinose, D-galactose, D-mannose, sucrose, xylitol, pectin, polygalacturonic acid, D-raffinose, starch, beech or birch hemicellulose, succinate, and fumarate (with or without formate, and malate). Growth is not stimulated by H₂ plus CO₂, H₂ plus S⁰ with or without CO₂, 0.3% (w/v) methanol, gelatin, or ethanol. The addition of 25 mM threonine, 25 mM valine, 25 mM phenylalanine, 25 mM leucine, or 25 mM isoleucine does not support, stimulate, or inhibit growth on medium containing 0.3% yeast extract and 0.25% (w/v) glucose. Fermentation of glucose produces butyrate, H₂, CO₂, and small amounts of acetate and lactate.

API AN-IDENT strips give positive results for L-glucosidase and arginine aminopeptidase. Phosphatase reaction and gelatin hydrolysis give weak positive reactions. The following reactions are negative: ammonia production from arginine; casein hydrolysis; nitrate reduction; denitrification; indole production; N-acetylglucosaminidase; L-arabinosidase; β-glucosidase; L-fucosidase; L-galactosidase; β-galactosidase; pyroglutamic acid arylamidase; indoxyl acetate reaction; leucine, proline, tyrosine, alanine, histidine, phenylalanine, glycine aminopeptidases, and formate-plus fumarate utilization.

Negative reactions for nitrate reduction, indole production, catalase, meat digestion, and denitrification. *Clostridium thermobutyricum* is not susceptible to cycloheximide, amphotericin B, actinomycin D, and novobiocin at concentrations of 100 µg/ml. Susceptible to erythromycin, tetracycline, neomycin sulfate (B + C mixture), polymyxin B sulfate, and metroimidazole at 5 µg/ml.

Source: horse manure compost containing straw and wood shavings.

DNA G+C content (mol %): 37 (T_m).

Type strain: JW171K, ATCC 49875, DSM 4928.

GenBank accession number (16S rRNA gene): X72868.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium thermobutyricum* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relative based on 16S rRNA gene sequence similarities is *Clostridium thermopalmarium* (98.5%). These two species differ in that *Clostridium thermopalmarium* produces ethanol from glucose fermentation and ferments sucrose; *Clostridium thermobutyricum* does not produce ethanol or ferment sucrose.

157. ***Clostridium thermocellum**** Viljoen, Fred and Peterson 1926, 7^{AL}

ther.mo.cel'lum. Gr. adj. *thermos* hot; N.L. n. *cellulosum* cellulose; N.L. neut. adj. *thermocellum* a thermophile that digests cellulose.

This description is based on that by Ng et al. (1977) and on study of the type strain.

Cells in PY-cellobiose broth cultures are nonmotile, 0.5–0.7 × 2.5–5.0 µm and are Gram-stain-negative. They are straight or slightly curved rods, often with tapered

ends, and occur singly or in pairs. Spores are oval, terminal, and swell the cell.

Surface colonies are watery, slightly convex, and frequently produce an insoluble yellow pigment. Deep colonies in cellulose-agar roll tubes are tannish yellow, round, and filamentous. Cultures in PY-cellobiose broth are slightly turbid with a smooth sediment and have a pH of 5.6–5.8 after incubation for 4 d. Gelatin is hydrolyzed when cellobiose is included in the medium. Growth on most media requires the presence of cellulose, cellobiose, or one of the hemicelluloses. Medium 122, described in the 1983 DSM catalogue of strains, has been recommended. In a chemically defined medium, growth factors required are biotin, pyridoxamine, vitamin B12, and *p*-aminobenzoic acid.

The optimum temperature for growth is 60–64 °C; there is no growth at 37 °C. Acetyl methyl carbinol is produced and resazurin is reduced. Although xylan does not serve as a carbon source, xylanase is produced when *Clostridium thermocellum* is grown in cellobiose medium.

An extracellular, inducible cellulase that exists as a complex and is stable at 70 °C is produced. One component of this complex, an endo-β-1,4-glucanase, has been isolated. Approximately 5% of the total cellulase is an intracellular β-glucanase. A cell-bound β-glucosidase is present which increases the amount of glucose liberated during cellulose fermentation.

Products of metabolism in PY-cellobiose broth are acetic and lactic acids, ethanol, CO₂, and abundant H₂. *Clostridium thermocellum* is an important organism for its ability to convert cellulosic waste products to ethanol and H₂. Other characteristics are given in Table 145.

Source: sewage digester sludge, said to be present in "nearly all decaying organic material" (Wiegel, 1980).

DNA G+C content (mol %): 38–39 (T_m).

Type strain: ATCC 27405, DSM 1237, JCM9322, LMG 10435, NCIMB 10682, NBRC 103400, NRRL B-4536.

GenBank accession number (16S rRNA gene): L09173.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium thermocellum* to fall within the radiation of cluster III of the clostridia as defined by Collins et al. (1994). The closest relatives of *Clostridium thermocellum* based on 16S rRNA gene sequence similarity values are *Clostridium straminisolvens* (97.1%), *Clostridium alkalocellulosi* (95.4%), *Acetivibrio cellulolyticus* (94.9%), and *Clostridium aldrichii* (94.4%). A DNA–DNA reassociation value of 23% indicated that *Clostridium thermocellum* and *Clostridium straminisolvens* are distinct species.

158. ***Clostridium thermopalmarium*** Soh, Ralambotiana, Ollivier, Prensier, Tine and Garcia 1991a, 331^{VP} (Effective publication: Soh, Ralambotiana, Ollivier, Prensier, Tine and Garcia 1991b, 138.)

ther.mo.pal.mar'ri.um. Gr. adj. *thermos* hot; L. adj. *palmaris* of palm tree; L. neut. adj. *thermoplamarium* referring to its thermophily and isolation from palm wine.

Straight rods, 0.7–1.0 × 2.0–8.0 µm. Gram-stain-positive cell-wall structure; Gram-stain-negative staining reaction. Motile with peritrichous flagella. Produce subterminal to terminal spores with slightly swollen sporangia.

Strictly anaerobic. Optimum temperature for growth is 50–55 °C, with no growth above 60 °C. The pH range for growth is 6.0–8.2 with optimum growth at 6.6. Ferments glucose, fructose, maltose, pyruvate, xylose, ribose, rhamnose, mannitol, sucrose, and cellobiose. Yeast extract was necessary for growth and could not be replaced by a vitamin solution. Does not utilize H₂-CO₂, acetate, propionate, butyrate, lactate, lactose, sorbose, melibiose, galactose, arabinose, amylose, glycerol, adonitol, dulcitol, methanol, starch, cellulose, and Biotrypcase. The end products of fermentation of carbohydrates are butyrate, H₂, CO₂, and small amounts of acetate, lactate, and ethanol. Yeast extract is required for growth. Sulfate, thiosulfate, and sulfite were not reduced to H₂S.

Source: palm wine in Senegal.

DNA G+C content (mol%): 35.7 (*T_m*).

Type strain: BVP, ATCC 51427, DSM 5974.

GenBank accession number (16S rRNA gene): X72869.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium thermopalmarium* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relative based on 16S rRNA gene sequence similarities is *Clostridium thermobutyricum* (98.5%).

159. ***Clostridium thermopapyrolyticum*** Méndez, Pettinari, Ivanier, Ramos and Siñeriz 1991, 282^{VP}

ther.mo.pa.py.ro.ly'ti.cum. Gr. adj. *thermos* hot; Gr. n. *papyros* paper; Gr. adj. *lutikos* dissolving; N.L. neut. adj. *thermopapyrolyticum* a paper-degrading thermophile.

Straight to slightly curved rods, 0.5–0.6 × 4–7 μm. Gram-stain-positive in early growth stages, and some cells Gram-stain-negative in the late growth stages. Motile. Form subterminal spores on glucose media after 8 d.

Colonies on cellobiose or glucose agar are cream in color and measure 1.5–2.0 mm in diameter. On cellulose agar colonies are 0.5–0.8 mm after 7 d incubation and do not show zones of clearing.

Strictly anaerobic. Temperature range for growth is 45–66 °C with optimal growth at 59 °C. Utilizes filter paper as sole carbohydrate source. Grows on cellobiose, cellulose, arabinose, mannitol, xylose, lactose, maltose, fructose, starch, glucose, and galactose. Acid is produced from all substrates supporting growth. Does not utilize sucrose, melibiose, glycerol, sorbitol, raffinose, or inulin. Hydrolyzes gelatin. Negative for nitrate reduction and indole production. End products of glucose fermentation are ethanol, acetate, butyrate, lactate, butanol, H₂, CO₂, and H₂S.

Source: sediment from a river bank in Buenos Aires, Argentina.

DNA G+C content (mol%): 34 (*T_m*).

Type strain: SABAMMRCCC UBA 305 (deposited in the South American Biotechnology and Applied Microbiology Microbiological Resource Center Culture Collection in Tucuman, Argentina).

GenBank accession number (16S rRNA gene): not reported.

160. ***Clostridium thermosuccinogenes*** Drent, Laphor, Wiegant and Gottschal 1995, 879^{VP} (Effective publication: Drent,

Laphor, Wiegant and Gottschal 1991, 460.)

ther.mo'suc.ci.no'ge.nes. Gr. adj. *thermos* hot; N.L. n. *acidum succinicum* succinic acid; Gr. v. *gennaio* produce; N.L. adj. *thermosuccinogenes* succinic acid producing in heat.

Straight rods, 0.3–0.4 × 2–4 μm. Motile with peritrichous flagella. Gram type positive cell-wall structure; Gram-stain-negative staining reaction. Forms round, terminal spores. Cells contain hexagonally arranged particles. Colonies are 1–2 mm in diameter, white, and round.

Anaerobic. Temperature range for growth is 40–65 °C with an optimum of 58 °C. Optimal pH for growth is 7.0. Utilizes fructose, glucose, galactose, inulin, xylose, ribose, sucrose, lactose, maltose, cellobiose, raffinose, and starch. No growth was observed with methanol (both 10 mM and 30 mM tested), glutamate, glycerol, pyruvate, citrate (30 mM each), arabinose (10 mM), Casamino acids (5 g/l), xylan, pectin, cellulose (1.5 g/l), or H₂-CO₂. Formate, acetate, lactate, succinate, and H₂ are the end products of fermentation of inulin. Nitrate or sulfur are not reduced. Milk is curdled, and esculin is hydrolyzed.

Source: beet pulp at a sugar refinery, soil around a Jerusalem artichoke, fresh cow manure, mud from a tropical pond in a botanical garden.

DNA G+C content (mol%): 35.9 (*T_m*).

Type strain: IC, DSM 5807.

GenBank accession number (16S rRNA gene): Y18180.

Further comments: 16S rRNA gene sequence comparisons shows *Clostridium thermosuccinogenes* to fall within the radiation of cluster III of the clostridia as defined by Collins et al. (1994). Stackebrandt et al. (1999) indicated that the primary structure of the 16S rRNA was different from other species of this cluster and contained a large insertion of about 200 nucleotides between positions 70 and 100 of the gene.

161. ***Clostridium thiosulfatireducens*** Hernández-Eugenio, Fardeau, Cayol, Patel, Thomas, Macarie, Garcia and Olivier 2002, 1466^{VP}

thi.o.sul.fa.ti.re.du'cens. N.L. n. *thiosulfas* (-atis) thiosulfate; L. v. *reduco* to draw backwards, bring back to a state or condition; N.L. part. adj. *thiosulfatireducens* thiosulfate-reducing.

Rod-shaped cells, 0.5–0.6 × 2–4 μm, occurring singly or in pairs. Gram-stain-positive; Gram-stain-positive cell-wall ultrastructure. Terminal spores with swollen sporangia. Motile with peritrichous flagella. Colonies appearing after 1 d of incubation in peptone-rich medium at 37 °C, are 1 mm in diameter, arborescent, and translucent.

Anaerobic. Temperature range for growth is 18–45 °C with optimal growth at 37 °C. The pH range for growth is 6.0–9.8 with an optimum of 7.4. Tolerates NaCl concentrations up to 60 g/l. Yeast extract is required for growth on amino acids but not for growth on peptides. Gelatin, peptone, bio-Trypcase, and Trypticase soy are used as carbon and energy sources in the absence of thiosulfate. Alanine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, serine, threonine, and valine are used as carbon and energy sources in the presence of thiosulfate. Pyruvate is converted to acetate. Arginine, asparagine, aspartate, cysteine, glutamine, glycine, tryptophan, tyrosine, L-arabi-

nose, D-fructose, D-galactose, D-glucose, maltose, mannitol, D-ribose, L-xylose, D-xylose, formate, acetate, butyrate, propionate, valerate, ethanol, *n*-butanol, *n*-propanol, fumarate, lactate, malate, and succinate are not utilized., Casamino acids, gelatin, peptone, and Trypticase soy are fermented to acetate, butyrate, isobutyrate, isovalerate or 2-methylbutyrate, CO₂, and sulfide in the presence of thiosulfate. In the absence of thiosulfate, acetate is the major end product of the metabolism of proteinaceous compounds. Acetate is the only fatty acid detected from alanine and threonine oxidation, whereas isoleucine is oxidized to 2-methylbutyrate, leucine to isovalerate, valine to isobutyrate, and phenylalanine to phenylacetate. The isolate ferments serine to acetate, lysine to acetate and butyrate, methionine to propionate, and histidine to an unidentified product. Stickland reaction is carried out using alanine as an electron donor and methionine and serine as electron acceptors. Thiosulfate and sulfur, but not sulfate, sulfite, nitrate, or nitrite, are used as electron acceptors. Adverse effects on animals and humans are not known.

Source: upflow anaerobic sludge blanket digestors in Mexico treating industrial wastewaters.

DNA G+C content (mol %): 31.4 (HPLC).

Type strain: Lup 21, CIP 106908, DSM 13105.

GenBank accession number (16S rRNA gene): AB317650, AF317650, AY024332.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium thiosulfatireducens* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relative of *Clostridium thiosulfatireducens* is *Clostridium subterminale* (99.6%). *Clostridium subterminale* (DSM 6970^T) does not reduce thiosulfate, differentiating it from *Clostridium thiosulfatireducens*. DNA–DNA reassociation studies showed *Clostridium thiosulfatireducens* and *Clostridium subterminale* to represent distinct species (Hernandez-Eugenio et al., 2002).

162. ***Clostridium tyrobutyricum**** van Beynum and Pette 1935, 205^{AL}

ty.ro.bu.ty'ri.cum. Gr. n. *tyros* cheese; N.L. n. *acidum butyricum* butyric acid; N.L. neut. adj. *tyrobutyricum* the butyric acid-producing organism from cheese.

Cells are Gram-stain-positive, usually motile and peritrichous, 1.1–1.6 × 1.9–13.3 μm, and occur singly or in pairs. Spores are oval, subterminal, and swell the cell. Acetate kinase and phosphotransacetylase are involved in spore germination. Sporulation occurs most readily on chopped-meat agar slants or in old PYG cultures. Cell walls contain *meso*-DAP; glucose is the only cell-wall sugar. Glutamic acid and alanine are present. The cell wall is susceptible to dissolution by lysozyme. Colonies on the surface of blood agar are circular, 0.5 mm in diameter, convex with an entire margin, gray, translucent, have a glossy surface, and are often β-hemolytic.

Cultures in PYG broth are turbid with a smooth sediment and have a pH of 5.0–5.4 after incubation for 1 week. Optimum temperature for growth is 30–37 °C; growth is moderate at 25 °C; poor or no growth at 45 °C. Growth in broth is stimulated by a fermentable carbohydrate but inhibited by 6.5% NaCl or 20% bile. Abundant gas is pro-

duced in PYG deep agar cultures. Ammonia occasionally is produced; neutral red is reduced.

Roux and Bergere (1997) noted that of 77 strains studied, 82% fermented mannitol, 56% fermented mannose, and 27% fermented xylose. Kininase-like activity has been detected in one strain. Cells contain rubredoxin which is involved in NAD oxidation-reduction reactions. Immunologically similar enoate reductases have been isolated from the type and three other strains that are 81–89% homologous with the type strain. Deoxyribonuclease is not produced. Products of fermentation in PYG broth are large amounts of butyric and acetic acids, and small amounts of succinic acid; traces of formic acid may be detected. Abundant H₂ is produced. Pyruvate is converted to butyrate and acetate; threonine is not converted to propionate; in the presence of acetate, *Clostridium tyrobutyricum* converts lactate to butyrate, CO₂, and H₂.

One strain tested is susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline. Culture supernatants are not toxic to mice. Nonpathogenic for humans and other animals. Other characteristics of the species are given in Table 142.

Source: gley soil, dairy products, silage, feces of beagle dogs, bovine feces, human adult and infant feces.

DNA G+C content (mol %): 28 (T_m).

Type strain: ATCC 25755, CCUG 48315, CIP 105092, DSM 2637, JCM 11008, LMG 1285, NCIB 10635).

GenBank accession number (16S rRNA gene): M59113.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium tyrobutyricum* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives of *Clostridium tyrobutyricum* based on 16S rRNA gene sequence similarity values are *Clostridium carboxidivorans* (94.2%) and *Clostridium aciditolerans* (94.1%).

163. ***Clostridium uliginosum*** Matthies, Kuhner, Acker and Drake 2001, 1124^{VP}

u.li.gi.no'sum. L. n. *uligo -inis* moisture of the soil, swamp; L. neut. adj. *uliginosum* swampy.

Rod-shaped cells, 1.0 × 8.0 μm, singly or in chains. Cells in chains are linked by a connecting filament with a core and outer sheath. Terminal spores are formed. Motile with 2–4 peritrichous flagella. Gram-stain-negative. Cells do not contain cytochromes.

Anaerobic. Chemoorganotrophic with fermentative metabolism. Utilizes glucose, cellobiose, sucrose, xylose, mannose, mannitol, and peptone. No growth occurs with lactose, maltose, glycerol, arabinose, raffinose, Casamino acids, H₂/CO₂, CO/CO₂, canillate, or various purines or pyrimidines. Ferments glucose to acetate, butyrate, lactate, H₂, and CO₂. Cannot reduce nitrate or sulfate. Temperature range for growth is 10–30 °C with an optimum of 20–25 °C. Acid tolerant with a pH range for growth of 4.0–9.0 and optimal growth occurring at pH 6.5.

Source: acidic forest bog.

DNA G+C content (mol %): 28.0 (T_m).

Type strain: CK55, ATCC BAA-53, DSM 12992.

GenBank accession number (16S rRNA gene): AJ276992.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium uliginosum* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives of *Clostridium uliginosum* based on 16S rRNA gene sequence similarity values are *Clostridium saccharobutylicum* (97.3%), *Clostridium puniceum* (96.9%), *Clostridium saccharoperbutylacetonicum* (96.8%), *Clostridium beijerinckii* (96.8%), and *Clostridium diolis* (96.7%). In addition, *Clostridium uliginosum* shares 97% 16S rRNA gene sequence similarity with strains of *Clostridium botulinum* types B, E, and F (a *Clostridium botulinum* strain cluster unrelated to the type strain of *Clostridium botulinum*) (see Figure 128).

164. ***Clostridium ultunense*** Schnürer, Schink and Svensson 1996, 1151^{VP}

ul.tu.nen'se. Ull ancient Nordic god associated with winter sports and duels; tuna place of worship; L. ending *ense*; N.L. adj. *ultunense* referring to Ultuna, the area where the Swedish University of Agricultural Sciences is located.

Straight to slightly curved rods, 0.5–7.0 × 0.5–7.0 μm; occur singly, in pairs or in chains. Gram-stain-negative. Motile with a polar flagellum in early growth stages; becomes nonmotile. Forms terminal, round spores. Colonies are white, disc shaped, and 0.5–1 mm in diameter.

Strict anaerobe. Temperature range for growth is 15–50 °C with optimal growth at 37 °C. pH Range for growth is 5–10 with optimal growth at 7.0. Utilizes formate, glucose, cysteine, pyruvate, betaine, and ethylene glycol. Does not utilize other sugars, H₂-CO₂, CO, methoxylated aromatic compounds, alcohols, and all amino acids except cysteine. Yeast extract required for growth in mineral medium. Main fermentation product is acetate, but formate can also be formed. Small amounts of alanine are formed from cysteine and betaine. Sulfate, sulfite, thiosulfate, sulfur, nitrate, fumarate, malate, glycine, and ferric ion are not used as electron acceptors. Negative for gelatin hydrolysis, catalase, and oxidase activity. Produces indole from tryptophan.

Source: anerobic digester sludge.

DNA G+C content (mol%): 32 (*T_m*).

Type strain: BS, ATCC 700254, DSM 10521.

GenBank accession number (16SrRNA gene): Z69293.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium ultunense* to fall within the radiation of cluster XII of the clostridia as defined by Collins et al. (1994).

165. ***Clostridium vincentii*** Mountfort, Rainey, Burghardt, Kaspar and Stackebrandt 1997a, 915^{VP} (Effective publication: Mountfort, Rainey, Burghardt, Kaspar and Stackebrandt 1997b, 59.)

vin.cen'ti.i. N.L. masc. gen. n. *vincenti* of Vincent, in honor of Warwick Vincent for his contribution to our understanding of microbial ecosystems in Antarctica.

Slightly curved rods, 0.6 × 5.0 μm. Gram-stain-positive. Motile with peritrichous flagella. Temperature range for growth 2–20 °C with optimum growth at 12 °C. pH range for growth 5.5–8.0 with optimum growth at 6.5. Growth occurs at 0–3% NaCl (w/v) with optimum growth at <0.5%. Obligate anaerobe. Utilizes xylan, fructose, galac-

tose, glucose, *N*-acetylglucosamine, xylose, cellobiose, lactose, maltose, mannose, and sucrose. Esculin supports growth. Starch, cellulose, glycogen, rhamnose, sorbitol, valine, isoleucine, fumarate, lactate, formate, glycerol, malate, yeast extract, and Casamino acids are not utilized as growth substrates. Glucose and lactose are fermented to acetate, butyrate, formate, H₂, and CO₂. Nitrate and sulfate are not reduced.

Source: sediment below the cyanobacterial mat of a low-salinity pond on the McMurdo Ice Shelf in Antarctica.

DNA G+C content (mol%): 33 (*T_m*).

Type strain: lac-1, DSM 10228.

GenBank accession number (16S rRNA gene): X97432.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium vincentii* to fall within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The closest relatives based on 16S rRNA gene sequence similarity values are *Clostridium paraputrificum* (97.1%), *Clostridium aurantibutyricum* (96.7%), and *Clostridium chartatabidum* (96.3%). *Clostridium vincentii* is a psychrophilic species growing optimally at 12 °C while *Clostridium paraputrificum* is a mesophile which grows optimally between 30 and 37 °C.

166. ***Clostridium viride*** Buckel, Janssen, Schuhmann, Eikmanns, Messner, Sleytr and Liesack 1995, 619^{VP} (Effective publication: Buckel, Janssen, Schuhmann, Eikmanns, Messner, Sleytr and Liesack 1994, 393.)

vi'ri.de. L. adj. *viridis*, *e* green, greenish; in reference to the green-colored cells and green FAD-containing enzymes of this organism.

Cells are pointed-ended to oval rods, 0.8 × 1.2–1.5 μm. Motile by two subpolar flagella. Gram-stain-positive. Cells are yellowish to green in color.

Strict anaerobe. Temperature range for growth is 19–40 °C. No growth was observed at 44 °C. Sample was isolated from anaerobic sewage sludge. Ferments 5-aminovalerate (to acetate, propionate, valerate, and ammonia), 5-hydroxyvalerate (to acetate, propionate, and valerate), crotonate, vinylacetate, and 4-hydroxybutyrate (to acetate and butyrate). No significant H₂ produced from 5-aminovalerate.

Growth is not supported by glucose, fructose, galactose, ribose, xylose, arabinose, melibiose, mannose, cellobiose, maltose, sucrose, lactose, cellulose, starch, pectin, formate, pyruvate, lactate, succinate, malate, fumarate, glycerol, mannitol, DL-3-hydroxybutyrate, tartrate, 1,2-propanediol, acrylate, citrate, betaine, alanine, β-alanine, aspartate, norvaline, 2-aminobutyrate, 4-aminobutyrate, 6-aminocaproate, glutamate, isoleucine, arginine, proline, urea, valine, leucine, tryptophan, trypticase yeast extract, and Casamino acids. 5-Aminovalerate is metabolized via the 2,4-pentadienoyl-CoA and 2-pentenoyl-CoA that utilizes two FAD-containing enzymes that form green crystals. Yeast extract and L-cysteine are required for growth on 5-aminovalerate. Sulfur is reduced. Nitrate, sulfate, amorphous ferric hydroxide, and fumarate are not used as electron acceptors. Does not produce indole. Catalase is not produced. Gelatin, esculin, and urea are not hydrolyzed.

DNA G+C content (mol%): 41.5 (HPLC).

Type strain: T2-7, ATCC 43977, DSM 6836.

GenBank accession number (16S rRNA gene): X81125.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium viride* to fall within the radiation of cluster IV of the clostridia as defined by Collins et al. (1994).

167. ***Clostridium xylanolyticum*** Rogers and Baecker 1991, 142^{VP} (emend. Chamkha, Garcia and Labat 2001a, 2109^{VP})

xyl.an.o.ly'ti.cum. Gr. n. *xylanosum* xylan; Gr. adj. *lutikos* dissolving, loosening; N.L. part. adj. *xylanolyticum* xylan-dissolving.

Rod-shaped cells, 1.8–3.0 × 0.5–0.8 μm. Gram-stain-negative. Each cell forms single, terminal, round spores, which distend the cell wall. Motile with peritrichous flagella. Cells have a five layer cell wall.

Obligate anaerobe. Temperature range for growth is 25–55 °C with optimum growth at 35 °C. The pH range for growth is 5.0–8.0 with optimum growth at 7.2. Good growth observed with xylan. Does not ferment amygdalin, arabinose, glycogen, inositol, lactose, mannitol, ribose, sorbitol, and trehalose. Ferments PYG to formic, lactic, and acetic acid. β-hemolytic. Resistant to clindamycin. Reduces the double bond of side chain cinnamic acids: cinnamic, *o*-, *m*-, *p*-coumaric, *o*-, *m*-, *p*-methoxycinnamic, *p*-methylcinnamic, caffeic, ferulic, isoferulic, and 3,4,5-trimethoxycinnamic acids. End products from cinnamic acid metabolism are the corresponding phenylpropionic acids: 3-phenyl, 3-(2-hydroxyphenyl), 3-(3-hydroxyphenyl), 3-(4-hydroxyphenyl), 3-(2-methoxyphenyl), 3-(3-methoxyphenyl), 3-(4-methoxyphenyl), 3-(4-methylphenyl), 3-(3,4-dihydroxyphenyl), 3-(4-hydroxy-3-methoxyphenyl), 3-(3-hydroxy-4-methoxyphenyl), and 3-(3,4,5-trimethoxyphenyl) propionic acids. Addition of glucose markedly increases the rate of conversions. Cinnamyl alcohol and phenylpropionic acids, including 3-phenylpropionic acid and 3,4-dihydroxyphenylpropionic acid, are not transformed. Does not produce lecithinase, urease, indole, catalase, or lipase. Does not hydrolyze gelatin. Nitrate is not reduced.

Source: wood chips from *Pinus patula* that was exposed to the environment for 10 weeks.

DNA G+C content (mol%): 40 (T_m).

Type strain: ATCC 49623, DSM 6555.

GenBank accession number (16S rRNA gene): X71855, X76739.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium xylanolyticum* to fall within the radiation of cluster XIVa of the clostridia as defined by Collins et al. (1994). The closest relative based on 16S rRNA gene sequence similarity values is *Clostridium aerotolerans* (99.4%).

168. ***Clostridium xylanovorans*** Mechichi, Labat, Garcia, Thomas and Patel 2000b, 3^{VP} (Effective publication: Mechichi, Labat, Garcia, Thomas and Patel 1999a, 370.)

xyl.a.no.vo'rans. Gr. n. *xylanosum* xylan; L. v. *vorare* devour, to eat; N.L. neut. adj. *xylanovorans* xylan-eating bacterium.

Rod-shaped cells, 0.8–1.0 × 4–10 μm. Gram-stain-positive. Motile with subpolar to laterally inserted flagella. Forms terminal spherical spores.

Strict anaerobe. Chemoorganotrophic. Temperature range for growth is 25–42 °C with an optimum for growth of 37 °C. pH Range for growth is 6–8 with an optimum of 7.0. Grows on NaCl concentrations of 0–1%. Grows on fructose, glucose, lactose, trehalose, maltose, raffinose, sucrose, xylan, mannitol, cellobiose, galactose, mannose, melibiose, and ribose. Does not grow on xylose, sorbose, sorbitol, *myo*-inositol, arabinose, arabitol, cellulose, formate, acetate, propionate, butyrate, valerate, crotonate, malonate, malate, lactate, citrate, succinate, ethanol, propanol, 2-propanol, butanol, isobutanol, biotrypcase, yeast extract, casamino acids, gelatin, and peptone. The major end products from the fermentation of fructose, glucose, lactose, trehalose, maltose, raffinose, sucrose, xylan, mannitol, cellobiose, galactose, mannose, melibiose and ribose are acetate, butyrate, formate, ethanol, H₂, and CO₂. Reduces fumarate to acetate. Does not reduce nitrate, sulfate, thiosulfate, and sulfur.

Source: olive mill wastewater treatment digester.

DNA G+C content (mol%): 40 (T_m).

Type strain: HESPI, DSM 12503.

GenBank accession number (16S rRNA gene): AF116920.

Further comments: 16S rRNA gene sequence comparisons show *Clostridium xylanovorans* to fall within the radiation of cluster XIVa of the clostridia as defined by Collins et al. (1994). The closest relative based on 16S rRNA gene sequence similarity values are *Clostridium jejuense* (96.6%) and *Clostridium aminovalericum* (93.6%). These two species can be differentiated on the basis of substrate utilization patterns.

Genus II. ***Alkaliphilus*** Takai, Moser, Onstott, Spoelstra, Pfflner, Dohnalkova and Fredrickson 2001, 1245^{VP} emend. Cao, Liu and Dong 2003, 974

KEN TAKAI

Al.ka.li'phil.us. N.L. n. *alkali* alkali; Gr. adj. *philos* loving; N.L. masc. n. *alkaliphilus* bacterium liking alkaline environments.

Straight to slightly curved rods, 0.4–0.7 × 2.0–6.0 μm. Gram-stain-positive and endosporeforming. The cells exhibit motility with flagella. Slightly halophilic and mesophilic with optimum growth at 35–40 °C. **Strictly anaerobic, and neutrophilic to alkaliphilic heterotrophs**. Proteinaceous substrates such as yeast extract, peptone, and tryptone are utilized as energy and carbon sources. **Fermentation and/or respiration of organic substrates in the presence and/or**

or absence of the electron acceptors such as S⁰, thiosulfate, fumarate, crotonate, Fe(III), Co(III), or Cr(VI) supports growth. Predominant cellular fatty acids are variable among the species but C_{14:0}, C_{14:1}, C_{15:0 iso}, C_{16:0}, C_{16:1 ω7c} are major components. Cell walls contain *m*-diaminopimelic acid, glycine, aspartate, glutamate, and ribose. Isolated from a deep-subsurface alkaline environment, an aerobic digester of wastewater, and a boron-rich leachate pond.

DNA G+C content (mol%): 30.6–36.4.

Type species: *Alkaliphilus transvaalensis* Takai, Moser, Onstott, Spoelstra, Pfiffner, Dohnalkova and Fredrickson 2001, 1245^{VP}.

Enrichment and isolation procedures

The type strain was isolated from alkaline water and sedimentary materials (pH 11.6) in a containment dam located at a depth of 3.2 km below surface (kmbls) in a South African gold mine (Takai et al., 2001). The slurried sample was directly inoculated into the standard medium (SM) for anaerobic, alkaliphilic heterotrophs at pH 10.5 (Takai et al., 2001), and the enrichment was performed at 37 °C for 2 d. After 2 d of incubation, growth of motile, straight to slightly curved rods was observed. The isolation of the type strain was performed on SM plates solidified with 1.2% (w/v) gelrite gellan gum. The strains of a second species of this genus (*Alkaliphilus crotonatoxidans*) were isolated from a methanogenic butyrate-degrading consortium (triculture) originally enriched from an aerobic digester for the wastewater treatment of a bean curd farm in Beijing, China (Cao et al., 2003). The strain was isolated with a crotonate-containing, anaerobic heterotrophic medium at 37 °C by the Hungate roll-tube technique (Hungate, 1969). Strains of the third species of this genus ("*Alkaliphilus metalliredigens*") which is not yet validly described were isolated from the partially dried soft sediments around alkaline leachate ponds hosting algal and cyanobacterial blooms. The strains were enriched with an anaerobic heterotrophic medium for soluble iron-reduction using lactate as the energy and carbon source and Fe(III)-citrate as the electron acceptor (Ye et al., 2004). The enrichment was performed at 20 °C, and the growth was observed after 5 d incubation. The isolates were obtained from the same medium for enrichment solidified by 2% (w/v) agar.

Maintenance procedures

All the species produce endospores at the late exponential and stationary growth phases. After growth, the strains are preserved

in culture tubes at 4 °C. Lyophilized cultures are also used for a longer maintenance.

Taxonomic comments

16S rRNA gene sequence analysis (Takai et al., 2001) placed this genus within cluster XI of the low G+C Gram-positive group of Collins et al. (1994). According to the revised roadmap for Volume 3 (Figure 5, Ludwig et al., this volume), *Alkaliphilus* is placed in family *Clostridiaceae*, order *Clostridiales*, class *Clostridia*, phylum *Firmicutes*.

Differentiation of the genus *Alkaliphilus* from other genera

Table 146 lists characteristics differentiating *Alkaliphilus* from other genera of the family *Clostridiaceae* that are phylogenetically related to *Alkaliphilus*. The most outstanding physiological property of *Alkaliphilus* distinguishing it from other genera is its versatile utilization of electron acceptors. The potential electron acceptors for *Alkaliphilus* are elemental sulfur, thiosulfate, fumarate, crotonate, Fe(III), Co(III), and Cr(VI). In contrast, none of the *Alkaliphilus* species is able to grow on amino acids by the Stickland reaction. 16S rRNA gene sequences of *Alkaliphilus* species also possess a low level of similarity with members of other *Clostridiaceae* genera (<92%).

Differentiation of the species of the genus *Alkaliphilus*

Table 146 also lists characteristics distinguishing species of the genus *Alkaliphilus*. The pH and NaCl ranges for growth are key to distinguishing the species of the genus *Alkaliphilus*. Within this genus, *Alkaliphilus transvaalensis* is the most alkaliphilic (capable of growth at up to pH 12.4), and it is moderately halophilic. "*Alkaliphilus metalliredigens*" is moderately alkaliphilic and the most halophilic. Lastly, *Alkaliphilus crotonatoxidans* is neutrophilic and the least halophilic. In addition, the *Alkaliphilus* species utilize different electron acceptors. Different cellular fatty acid compositions are also described (Cao et al., 2003; Ye et al., 2004).

List of species of the genus *Alkaliphilus*

- 1. *Alkaliphilus transvaalensis*** Takai, Moser, Onstott, Spoelstra, Pfiffner, Dohnalkova and Fredrickson 2001, 1254^{VP}
trans.vaa.len'sis. N.L. adj. transvaalensis of Transvaal, a region of South Africa.
Gram-stain-positive, straight to slightly curved rods that are 0.4–0.7 × 3–6 μm. Cells occur singly or in pairs. Exhibits motility with flagella. Vegetative cells swell to form terminal spherical spores. Strictly anaerobic. The temperature range for growth is 20–50 °C, with the optimum being 40 °C. The pH range for growth is 8.5–12.5, with the optimum growth occurring at pH 10.0. NaCl is not absolutely required for growth but enhances the growth. Heterotrophic growth with yeast extract, peptone, tryptone, or casein. Elemental sulfur, thiosulfate, fumarate, and crotonate stimulate growth as electron acceptors. The major phospholipid fatty acids are C_{14:0}^o, C_{15:1 iso ω7c}^o, C_{15:0 iso}^o, C_{16:0}^o, C_{17:1 iso ω7c}^o and C_{17:0 iso}^o.
DNA G+C content (mol%): 36.4 (HPLC).
Type strain: SAGM1, ATCC 700919, CIP 107133, JCM 10712.
GenBank accession number (16S rRNA gene): AB037677.
- 2. *Alkaliphilus crotonatoxidans*** Cao, Liu and Dong 2003, 973^{VP}
cro.to.nat.ox'i.dans. N.L. part. adj. *crotonatooxidans* of the one that oxidizes crotonate.
Gram positive, straight to slightly curved rods (0.4–0.6 × 2–3 μm). Cells occur singly or in pairs. Exhibits motility with multiple flagella. Vegetative cells swell to form terminal spherical spores. Strictly anaerobic. The temperature range for growth is 15–45 °C, with the optimum being 37 °C. The pH range for growth is 5.5–9.0, with the optimum growth occurring at pH 7.5. Heterotrophic growth with yeast extract, peptone, fructose, cellobiose, maltose, trehalose, xylose, ribose, citrate, malate, and crotonate, but not with glucose, lactose, sucrose, galactose, lactate, succinate, or butyrate. Crotonate is dismutated to acetate and butyrate. Growth is not stimulated by other electron acceptors. Cell wall contains *m*-diaminopimelic acid, glycine, aspartate, glutamate, and ribose. The major cellular fatty acids are C_{13:0 iso}^o, C_{13:1 iso ω2c}^o, C_{14:0}^o, C_{15:1 iso ω7c}^o, C_{15:0 iso}^o, C_{15:0 ante}^o, C_{16:0}^o, C_{16:1ω7c}^o and C_{17:0 ante}^o.

DNA G+C content (mol%): 30.6 (T_m).

Type strain: B11-2, AS 1.2897, JCM 11672.

GenBank accession number (16S rRNA gene): AF467248.

Other organisms

1. "*Alkaliphilus metalliredigens*"

Described by Ye et al. (2004), this interesting organism has not yet been deposited in culture collections and is not validly published. Nevertheless, it provides insight into the phenotypic diversity of this genus. Cells are Gram positive, straight to slightly curved rods (0.5 × 3-6 μm) and exhibit motility. Vegetative cells swell to form terminal spheri-

cal spores. Strictly anaerobic. The temperature range for growth is 4-45 °C, with the optimum being 35 °C. The pH range for growth is 8.0-10.0, with optimum growth occurring at pH 9.5. NaCl is not absolutely required for growth but enhances the growth optimally at 2% (w/v). Heterotrophic growth with yeast extract, lactate, and acetate. Soluble forms of Fe(III), Co(III), and Cr(VI) serve as electron acceptors. The organism is able to grow in the presence of 10 mM sodium borate.

DNA G+C content (mol%): not determined.

Type strain: QYMF.

GenBank accession number (16S rRNA gene): AY137848.

Genus III. **Anaerobacter** Duda, Lebedinsky, Mushegjan and Mitjushina 1996, 625^{VP} (Effective publication: Duda, Lebedinsky, Mushegjan and Mitjushina 1987, 126.)

THE EDITORIAL BOARD

An.ae.ro.bac'ter. Gr. pref. *an-* not; Gr. masc. n. *aer* air; N.L. masc. n. *bacter* the equiv. of Gr. neut. dim. n. *bakterion* small rod, staff; N.L. masc. n. *Anaerobacter* rod not [living] in air.

Cells are **thick rods, ovals or spheres**, depending upon the growth conditions. Oval and spherical cells **form three or more endospores per cell**. **Gram-stain-positive** cell-wall structure. **Obligate anaerobe that ferments carbohydrates and fixes N₂**. Nonmotile. Sulfate and nitrate are not reduced. Nitrite is reduced to ammonia in a dissimilatory process.

DNA G+C content (mol%): 29.

Type species: **Anaerobacter polyendosporus** Duda, Lebedinsky, Mushegjan and Mitjushina 1996, 625^{VP} (Effective publication: Duda, Lebedinsky, Mushegjan and Mitjushina 1987, 127.).

Further descriptive information

This description is as given previously by Duda et al. (1987) and Siunov et al. (1999). Cells are oval (4-8 μm in length and

3–4 µm in diameter) or spherical (4–6 µm in diameter) on solid media. In liquid media, the cells are thick rods with rounded ends (1.5–3 µm in diameter and 4–8 µm in length). Nonmotile. Surrounded by a polysaccharide capsule. The rod-shaped cells form one or two subterminal endospores at opposite poles. The oval and spherical cells form from one up to five round or oval endospores. The endospores possess spore coats, exosporium, inner and outer membranes, cortex and core. The cell wall consists of one layer and is sensitive to penicillin and lysozyme. Prosthecae-like appendages surrounded by cytoplasmic membrane and cell wall and containing cytoplasm are sometimes formed. Extensive lipid leaves form in the cytoplasmic membrane, located between the outer and internal lipid layers.

Colonies on the surface of solid media are large (up to 5 mm in diameter), round, smooth, opaque, brownish-white, viscous, navel-shaped, with entire margins.

Moderately aerotolerant anaerobe. Growth on solid media containing no reductants is possible at $pO_2 \leq 500$ Pa. A weak catalase activity can sometimes be detected after growth at pO_2 of 500 Pa. Cytochromes are not present. Neutrophilic and mesophilic. Growth occurs in the pH range of 5.5–8.5, with an optimum at 6.5–7.5. The temperature range for growth is 15–45 °C, with an optimum at 25–35 °C. Substrates supporting growth include cellobiose, fructose, galactose, glucose, inulin, maltose, mannitol, mannose, raffinose, salicin, sorbitol, sucrose, trehalose, xylose and lactate. Starch is hydrolysed but cannot support growth as the sole source of carbon and energy. Amino acids, alcohols and organic acids other than lactate do not support growth. Gelatin is not liquefied. Lipase, lecithinase and urease are not produced. Indol and sulfide are not formed. The end products of glucose fermentation include acetate, lactate,

butyrate, ethanol, butanol, H_2 and CO_2 . Sulfate and nitrate are not used as electron acceptors, but nitrite is reduced to ammonia in a dissimilatory process.

Isolated from meadow-gley soil under rice under anaerobic conditions on potato agar containing 0.5% glucose, 0.1% yeast extract, and 0.04% sodium thioglycollate.

Taxonomic comments

Based upon 16S rRNA gene sequence comparisons, *Anaerobacter polyendosporus* falls within the radiation of cluster I of the clostridia as defined by Collins et al. (1994). The original description of *Anaerobacter polyendosporus* did not include phylogenetic analyses, and the justification for the creation of a novel genus was based upon the morphological characteristics as well as the ability to form numerous spores within a single cell (Duda et al., 1987). Subsequent sequencing of its 16S rRNA gene identified a close relationship with cluster I of the clostridia as defined by (Collins et al., 1994; Siunov et al., 1999; Stackebrandt et al., 1999b). Siunov et al. (1999) suggested that the unusual morphological characteristics justified the existence of a novel genus even though the rRNA sequence fell within the species of the genus *Clostridium sensu stricto*. Stackebrandt et al. (1999b) suggested that *Anaerobacter polyendosporus* should be reclassified as a species of the genus *Clostridium*. *Anaerobacter polyendosporus* shows highest 16S rRNA gene sequence similarity to the species *Clostridium fallax* (95.6%), *Eubacterium tarantellae* (95.1%), *Clostridium putrefaciens* (94.9%), *Clostridium intestinale* (94.8%) and *Clostridium chauvoei* (94.7%). In an attempt to further the reorganization of the genus *Clostridium*, the species *Anaerobacter polyendosporus* is transferred to the genus *Clostridium* as *Clostridium polyendosporum* comb. nov. (Rainey et al., 2009).

List of species of the genus *Anaerobacter*

1. ***Anaerobacter polyendosporus*** Duda, Lebedinsky, Mushegjan and Mitjushina 1996, 625 (Effective publication: Duda, Lebedinsky, Mushegjan and Mitjushina 1987, 127.)
po.ly.en.do.spo'rum. Gr. pref. *poly* many; Gr. pref. *endo* within; Gr. n. *spora* spore; N.L. adj. *polyendosporus* (forming) several endospores.

The description is the same as for the genus.

DNA G+C content (mol%): 29 (T_m).

Type strain: PS-1, DSM 5272, VKM B-1724.

GenBank accession number (16S rRNA gene): Y18189.

Genus IV. **Anoxynatronum** Garnova, Zhilina and Tourova 2003a, 1219^{VP} (Effective publication: Garnova, Zhilina and Tourova 2003b, 217.)

ELENA S. GARNOVA AND TATJANA N. ZHILINA

An.ox'y.na.tro'num. Gr. pref. *an*-without; Gr. adj. *oxys* acid or sour, and in combined words indicating oxygen; N. Gr. n. *natron* (arbitrarily derived from Ar. n. *natrun* or *natron*) soda; N.L. neut. n. *Anoxynatronum* organism which inhabits anaerobic and soda environment.

Slightly curved rods with pointed ends, 0.5–0.7 × 3.8–5 µm. Gram-stain-positive cell-wall structure. Motile. Nonsporeforming. **Moderately alkaliphilic** with good growth at pH 7.6–9.5. **Growth requires sodium and bicarbonate** but not chloride ions. **Catalase-positive anaerobe** which possesses fermentative metabolism. **Chemoorganoheterotroph:** able to utilize mono- and disaccharides, sugar alcohols, and proteinaceous substrates. The products of glucose fermentation are acetate and ethanol. Yeast extract is required for growth. Habitat is saline-carbonate lakes. The genus is monotypic.

DNA G+C content (mol%): 48.1–48.4.

Type species: ***Anoxynatronum sibiricum*** Garnova, Zhilina and Tourova 2003a, 1219^{VP} (Effective publication: Garnova, Zhilina and Tourova 2003b, 219.).

Further descriptive information

Cells occur singly or in pairs and multiply by binary division (Figure 129). In the stationary phase, very long chains are rarely formed. Actively motile; the flagellation is peritrichous. Sporulation was not observed. Viability is retained upon heating to 70 °C

FIGURE 129. Morphology of *Anoxynatronum sibiricum* cells as viewed under phase contrast microscope. Bar = 10 μm .

for 10 or 20 min but not for 50 min. Catalase-positive anaerobe. Tolerates up to 4.5% O_2 in nitrogen gas phase; growth is possible without any reducing agents in the medium.

A typical athalassophile (i.e., adapted to continental waters), it obligately requires sodium carbonate but not chloride ions. The optimum pH for growth is 9.1, with a range of pH 7.1–10.1. Requires Na^+ , and no growth is observed after replacing sodium with potassium ions. Grows when the total concentration of Na^+ is in the range of 0.08–1.3M, with a relatively broad optimum between 0.25–0.86M Na^+ . The broad optimum allows adaption to seasonal changes in salt content. The type species has an optimal growth temperature of 35 °C. Due to the cryoarid climate of the region, the temperature of sediments rarely exceeds 40 °C, which might explain the rapid decline of the growth rate above 41 °C and its upper limit at 46 °C.

Metabolism is fermentative. *Anoxynatronum* is incapable of dissimilatory reduction of nitrite, nitrate, or sulfur compounds (S , SO_4^{2-} , SO_3^{2-} , $\text{S}_2\text{O}_3^{2-}$, $\text{S}_2\text{O}_4^{2-}$), but it reduces Fe^{3+} to Fe^{2+} without energy generation. Vitamins are not required, but they improve the growth rate. Does not assimilate N_2 . Possible sources of nitrogen are NH_4Cl , NaNO_3 , and organic nitrogen from yeast extract.

Physiologically, *Anoxynatronum* is a primary anaerobe; in a trophic chain of bacterial community it consumes low-molecular-mass organic compounds produced by hydrolytic microorganisms. Some of *Anoxynatronum* fermentation products are metabolized by second anaerobes, e.g., sulfate-reducing bacteria. *Anoxynatronum* utilizes a wide variety of catabolic substrates including monosaccharides (ribose, glucose, mannose, and fructose), disaccharide (sucrose), sugar alcohols (glycerol and L-inositol), a few amino acids (Table 147), and proteinaceous compounds (peptone, tryptone, meat extract, and yeast extract). It also grows slowly on dried *Spirulina* biomass, which could be a nutritional source in its natural habitat in addition to the microbial products of plant cellulose decomposition. During the fermentation of glucose, it forms 2.5 mol of acetate and 0.48 mol of ethanol per mol of glucose. Because acetate is the major product, *Anoxynatronum* should be considered an acetogen. In the trophic food chain of the anaerobic community in soda lakes, it could be regarded as a copiotrophic component of the saccharolytic pathway of biomass degradation.

Methods of isolation and cultivation of pure cultures

The type strain was isolated from an anaerobic enrichment on glucose originally inoculated with a mixture of mud and surface cyanobacterial mat from a lagoon of Lake Nizhnee Beloe (south-eastern Transbaikal region, Russia). Pure cultures were obtained by serial dilutions in liquid medium under strictly anaerobic conditions. The mineral medium which was used for the enrichment culture mimicked the mineral composition of Lake Nizhnee Beloe water and contained (per liter): NaCl , 3.4 g; Na_2CO_3 , 4.45 g; NaHCO_3 , 5.5 g; and glucose, 5 g. Incubations were performed anaerobically under N_2 gas at pH 9.5 and 36 °C. To obtain a pure culture, colonies were isolated from Hungate roll tubes (Hungate, 1969) containing the same medium plus 3% agar (w/v). The uniform colonial and cellular morphologies confirmed culture purity. After optimization of the growth conditions, the *Anoxynatronum* medium contained (per liter): KH_2PO_4 , 0.2 g; MgCl_2 , 0.1 g; NH_4Cl , 0.5 g; KCl , 0.2 g; Na_2CO_3 , 9.3 g; NaHCO_3 , 44.1 g; $\text{Na}_2\text{S}\cdot 9\text{H}_2\text{O}$, 0.7 g; yeast extract, 0.2 g; glucose, 5.0 g; trace element solution, 1 ml (Kevbrin and Zavarzin, 1992); vitamin solution, 10 ml (Wolin et al., 1963); and resazurin, 0.001 g. The pH was 9.05, and the gas phase was 100% N_2 .

Maintenance procedures

The type strain remains viable when stored in *Anoxynatronum* medium at 4 °C and transferred every six months. Glycerol (15%) stocks are stored in liquid nitrogen.

Differentiation of the genus *Anoxynatronum* from other genera

Based on 16S rRNA analyses, *Anoxynatronum sibiricum* belongs to the *Clostridium felsineum* subgroup of cluster XI of Collins et al. (Collins et al., 1994). In the phylogenetic analysis by Ludwig et al. presented in the roadmap to the current volume, *Anoxynatronum* is placed in the family *Clostridiaceae*, order *Clostridiales*, class *Clostridia*, phylum *Firmicutes* (Figure 5). The closest relative among the validly published alkaliphilic representatives of this subgroup is the anaerobic ammonifier *Tindallia* (Kevbrin et al., 1998), with a 16S rRNA sequence similarity of 94.2%. For the other alkaliphiles, *Alkaliphilus* (Takai et al., 2001) and *Natron-*

incola (Zhilina et al., 1998), the sequence similarity is 91.7% and 89.5%, respectively (Figure 130). However, the DNA G+C content of *Anoxynatronum sibiricum* differs from that of *Tindallia* by 10 mol%, and they have a very low DNA–DNA similarity value of 11%. Other physiological characteristics which distinguish *Anoxynatronum* from *Tindallia* and related alkaliphiles are its ability to ferment sugars, the spectrum of substrates utilized, and the fermentation products (Table 147).

Taxonomic comments

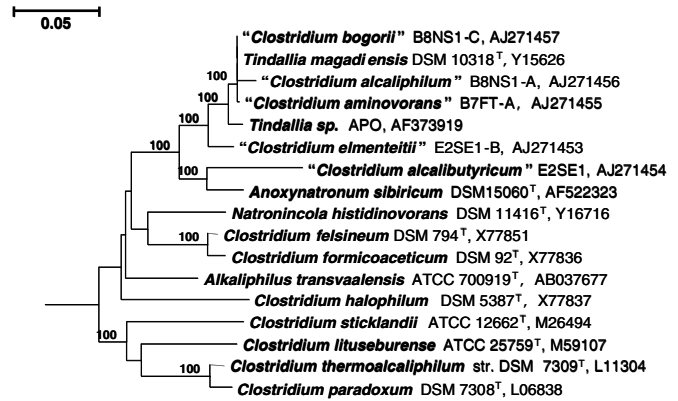

Phylogenetic analyses of the 16S rRNA gene suggests that *Anoxynatronum sibiricum* forms a separate clade with the alkaliphile “*Clostridium alcalibutyricum*” E2SE1 from Lake Elmenteita, Kenya (Jones et al., 1998; Figure 130). In addition to acetate, “*Clostridium alcalibutyricum*” produces butyrate which was not detected among the fermentation products of *Anoxynatronum sibiricum*. Because very limited information about the taxonomy and physiology of “*Clostridium alcalibutyricum*” is available, it is not possible to make a complete comparison between these two species.

List of species of the genus *Anoxynatronum*

- Anoxynatronum sibiricum*** Garnova, Zhilina and Tourova 2003a, 1219^{VP} (Effective publication: Garnova, Zhilina and Tourova 2003b, 219.)
si.bi'ri.cum. N.L. neut. adj. *sibiricum* pertaining to Siberia, a Russian region.

The description for the type species is as given for the genus and as listed in Table 147. Another strain of *Anoxynatronum sibiricum*, Z-7981, was isolated from Lake Nizhnee Beloe. Aside from small differences in cell diameter, it is similar to the type strain (Tourova et al., 1999). These two strains have 98% DNA–DNA

FIGURE 130. Phylogeny of *Anoxyratronum* and other representatives of the *Clostridium felsineum* subgroup of *Clostridium* cluster XI of Collins et al. (1994). *Clostridium butyricum* was taken as an outgroup. Based on the nucleotide sequence of the 16S rRNA gene, where the bar corresponds to 5 substitutions per 100 positions. Bootstrap values >95 (expressed as percentage of 100 replications) are shown at branch points.

similarity and DNA G+C contents of 48.4 mol% for Z-7981 and 48.1 mol% for Z-7981.

Habitat: saline-carbonate lake.

DNA G+C content (mol%): 48.4 (T_m).

Type strain: Z-7981, DSM 15060, Uniqem U-262.

GenBank accession number (16S rRNA gene): AF522323.

Genus V. **Caloramator** Collins, Lawson, Willems, Cordoba, Fernández-Garayzábal, Garcia, Cai, Hippe and Farrow 1994, 812^{VP} emend. Chrisostomos, Patel, Dwivedi and Denman 1996, 497

SANDRA BAENA AND BHARAT K. C. PATEL

Ca.lora.ma'tor. L. n. *calor* heat; L. masc. n. *amator* lover; N. L. masc. n. *Caloramator* heat lover.

Straight to slightly curved rods or filaments (2–100 × 0.4–0.8 μm), which occur singly or pairs. Cells stain Gram-negative or Gram-positive but possess a Gram-positive cell-wall ultra-structure. May be **motile or nonmotile**. Endospores may or may not be produced and if present, are spherical and located terminally or subterminally and do not distend the sporangia. All species grow at **thermophilic** temperatures (growth temperature optimum between 50 and 68 °C). The metabolism is heterotrophic and **saccharolytic** and the end products from glucose fermentation are acetate, isobutyrate, isovalerate, valerate, lactate and ethanol. Unable to grow autotrophically or produce sulfur from thiosulfate.

DNA G+C content (mol%): 25–39.

Type species: **Caloramator fervidus** (Patel, Monk, Littleworth, Morgan and Daniel 1987) Collins, Lawson, Willems, Cordoba, Fernández-Garayzábal, Garcia, Cai, Hippe and Farrow 1994, 812^{VP} (*Clostridium fervidus* Patel, Monk, Littleworth, Morgan and Daniel 1987, 125).

Further descriptive information

To date, six species of the genus *Caloramator* have been described. The first member of the genus *Caloramator*, *Caloramator fervidus* (formerly *Clostridium fervidus*) was isolated from a hot spring in New Zealand and subsequently other members were isolated from volcanic as well as non-volcanically heated environments: *Caloramator indicus* was isolated from an Indian thermal artesian basin (Chrisostomos et al., 1996), "*Caloramator celer*" (formerly *Thermobrachium celere*) from a New Zealand hot spring (Engle et al., 1996), *Caloramator proteoclasticus* from sludge of a mesophilic granular methanogenic digester (Tarlera et al., 1997), *Caloramator coolhaasii* from sludge of a thermophilic granular digester (Plugge et al., 2000) and *Caloramator viterbiensis* from an Italian hot spring (Seyfried et al., 2002).

Cells of the genus *Caloramator* are straight to slightly curved rods or filaments measuring 2–100 μm × 0.4–0.8 μm, and occur singly, or pairs. Spores have so far only been observed in *Caloramator fervidus* and *Caloramator proteoclasticus*. With the exception of *Caloramator viterbiensis*, all other species stain Gram-negative but ultrathin sections of cells reveal a multilayered, complex, thick cell wall with an external S-layer similar to that of Gram-stain-positive cell-walls. All species are strictly anaerobic chemo-organotrophs, which grow at temperatures ranging from 37 to 80 °C, with an optimum between 50 and 68 °C. No growth is observed below 37 and above 80 °C. The pH range for growth is between pH 5.0 and 9.5 and the optimum pH for growth is between 6.0 and 8.1.

The presence of thermoresistant endospores has been demonstrated in *Caloramator fervidus* and *Caloramator proteoclasticus*, but not in *Caloramator indicus*, *Caloramator coolhaasii*, *Caloramator viterbiensis* and "*Caloramator celer*". The value of spore formation as an important criterion in classification has been questioned (Chrisostomos et al., 1996) as sporulation genes can be identified in non-sporulating bacteria.

Members of the genus *Caloramator* ferment glucose, starch, amylose, maltose, xylan, mannose, galactose, fructose, ribose, xylose, mannose, sucrose, cellobiose, lactose, galactose, and dextrin (Table 148) but only in the presence of yeast extract and/or peptone suggesting that trace components present in yeast extract and/or peptone are required for growth. Limited growth occurs in yeast extract and/or peptone in the absence of fermentable substrates. *Caloramator* species also utilize a range of amino acids (Table 148). The end products of glucose fermentation are acetate, *i*-butyrate, *i*-valerate, *n*-valerate, ethanol, lactate, formate, H₂ and CO₂ but the pattern produced depends on the species (Table 148).

^aSymbols: +, positive; –, negative; w, weak reaction; ND, not determined.

^bGrows well on glucose, maltose, xylose, starch, xylan, mannose and pyruvate but not sucrose, galactose, rhamnose, arabinose and cellulose.

^cGrows well on glucose, fructose, galactose, maltose and sucrose but not cellobiose, ribose, mannose, arabinose, xylose, glucuronic acid and xylan.

^dGrows well on glucose, fructose, galactose, sucrose, maltose, ribose, xylose, starch, cellobiose and mannose but not arabinose, rhamnose, lactose and cellulose.

^eGrows well on glucose, fructose, starch, amylose, dextrin, amylopectin, cellobiose, lactose, mannose and sucrose but not cellulose, dextran and chitin.

^fGrows well on glucose, fructose, starch, cellobiose and mannose but not lactose, xylose, malate, xylan, and cellulose.

^gGrows well on glucose, fructose, sucrose, cellobiose, lactose, galactose, starch and mannose but not xylose and arabinose.

Sulfate, thiosulfate, elemental sulfur, sulfite, nitrate and fumarate are not utilized as electron acceptors.

Enrichment and isolation procedures

Various media have been used to enrich, isolate and characterize the members of genus *Caloramator*. All media are prepared anaerobically. *Caloramator fervidus* was enriched at 70 °C on

Trypticase peptone-Yeast extract-Xylan (TYEX) medium and isolated by serial dilution in agar shakes (Patel et al., 1987). *Caloramator indicus* was enriched at 70 °C without agitation in a pre-reduced anaerobic Trypticase peptone-Yeast extract-Glucose (TYEG) medium and isolated by end point dilution in TYEG agar (2.5%) shake tubes. A peptone yeast extract medium supplemented with 0.4 g/l glucose and an incubation temperature

of 55 °C, was used to enrich *Caloramator proteoclasticus* and isolation of the pure culture was achieved in 1.5% agar roll tubes (Holdeman et al., 1977b; Hungate, 1969). A bicarbonate-buffered anaerobic medium supplemented with 0.02% yeast extract was used to enrich *Caloramator coolhaasii* (Stams et al., 1993) and isolation of a pure culture was achieved on Wilkens-Chalgren broth medium (16 g/l) fortified with agar (WC broth, Oxoid). *Caloramator viterbiensis* was enriched at 60 °C in a basal medium containing yeast extract and a dilution series of the enrichment plated on the same medium fortified with 1.5% agar for isolation of a pure culture (Seyfried et al., 2002). “*Caloramator celer*” (formerly *Thermobrachium celere*) was enriched and isolated in a complex medium (Engle et al., 1996). We routinely use pre-reduced anaerobic TYEG medium and an incubation temperature of between 55–65 °C in our laboratory to culture all the six *Caloramator* species and other as yet uncharacterized species (Patel et al., 1985b, 1985a).

Maintenance procedures

In our laboratory, mid-exponential phase grown cultures of *Caloramator* species are resuspended in 10 ml TYEG medium containing 20% glycerol (v/v) and 0.1 mol of amorphous ferrous sulfide and stored at –20 and/or –80 °C. Amorphous ferrous sulfide is prepared according to the method of Brock and Od’ea (1997). Seyfried et al. (2002) have reported that *Caloramator viterbiensis* can be kept at room temperature or preferably at 4 °C for several days in a medium of Kell et al. (1981). For long-term storage, *Caloramator viterbiensis* is grown to mid- to late-exponential growth phase in a modified medium of Kell et al. (1981) containing 2% yeast extract and 3 g/l glycerol; 10% glycerol (v/v, final concentration) and 10% DMSO (v/v, final concentration) added, the culture kept for 15 min at room temperature before being frozen and stored at –75 °C. Cultures were viable under these conditions for more than 28 months.

Differentiation of the genus *Caloramator* from other genera

All six species of the genus *Caloramator* are thermophilic, carbohydrate fermenting, strict anaerobes, and form a cohesive and independent cluster within the radiation of members of the family *Clostridiaceae*, in the order *Clostridiales*, class *Clostridia*, phylum *Firmicutes* (Figure 5). This unique phylogenetic placement differentiates them from the other phenotypically similar members of the genus *Clostridium* which include, for example, *Clostridium thermocellum*, *Clostridium cellulosi*, *Clostridium thermobutyricum*, *Clostridium thermopalmarium*, *Clostridium thermolacticum* and *Clostridium stercorarium*, and also from members of the genera *Thermoanaerobacter*, *Thermoanaerobium*, and *Thermoanaerobacterium*.

Caloramator fervidus, *Caloramator proteoclasticus*, *Caloramator coolhaasi*, and *Caloramator viterbiensis* use a number of amino acids, such as serine, glutamate, threonine, methionine, asparagine, arginine, histidine, leucine, and valine, as a carbon source. In addition, *Caloramator proteoclasticus* and *Caloramator coolhaasii* use glutamate in co-culture with hydrogen-scavenging methanogens. These traits in common with a number of other phylogenetically distant fermentative mesophilic anaerobes which include *Thermanaerovibrio acidaminovorans* (Baena et al., 1999; Cheng et al., 1992) and *Aminobacterium* species (Baena et al., 2000, 1998). Amino acid utilization in *Caloramator indicus* and “*Caloramator celer*” is yet to be investigated and once determined will provide a clearer picture into whether this is a common trait in the genus.

Differentiation of the species of the genus *Caloramator*

Table 148 lists the features that differentiate the six species of the genus. A number of characteristics are useful in distinguishing the species from each other (Table 148). All members of the genus use carbohydrates, but not all use the same carbohydrates and this carbohydrate utilization pattern could be used to differentiate the six species. The use of amino acids by four of six *Caloramator* species could also be considered as characteristic of the species and the range used as a criterion for further differentiation. The data from the remaining two species, namely *Caloramator indicus* and “*Caloramator celer*” should be included once this is available. *Caloramator viterbiensis* but not “*Caloramator celer*” ferments glycerol to 1,3 propanediol, a property and could be used as a distinguishing and differentiating trait provided it has been tested for the remaining four members of the genus. The growth temperature optimum is also a useful criterion for species differentiation: *Caloramator proteoclasticus*, *Caloramator coolhaasii* and *Caloramator viterbiensis*, which grow optimally between 50 and 58 °C, can be considered as moderate thermophiles whereas *Caloramator fervidus*, *Caloramator indicus* and “*Caloramator celer*,” which grow optimally at or above 60 °C, can be considered as thermophiles.

Taxonomic comments

The 16S rRNA analysis presented in the roadmap to Volume 3 (Figure 5) places the six members of the genus *Caloramator* as a cohesive cluster in the family *Clostridiaceae*, order *Clostridiales*, class *Clostridia*, phylum *Firmicutes*. The closest relative is *Clostridium cylindrosporium* (DSM 605^T, Y18179) with a mean similarity value of 92% (Figure 131).

List of species of the genus *Caloramator*

1. ***Caloramator fervidus*** (Patel, Monk, Littleworth, Morgan and Daniel 1987) Collins, Lawson, Willems, Cordoba, Fernández-Garayzabal, García, Cai, Hippe and Farrow 1994, 812^{VP} (*Clostridium fervidus* Patel, Monk, Littleworth, Morgan and Daniel 1987, 125)
fervidus. L. adj. *fervidus* hot.

Sluggishly motile rod-shaped cells (2–2.5 µm by 0.65–0.75 µm) with rounded to slightly tapered ends. Cells occur singly and rarely in pairs on in chains and stain Gram-

negative but thin sections reveal a single-layered Gram-positive cell-wall structure. Many cells contain Gram-stain-positive granules which appear as small spherical refractive bodies under a phase-contrast microscope. Spherical subterminal to terminal spores, which do not swell the sporangium are present. Obligate anaerobe. Yeast extract and/or Trypticase peptone can be used as a carbon and energy source and is required for the fermentation of glucose, maltose, mannose, xylose, xylan, starch and pyruvate. Vitamins or Casamino

FIGURE 131. Phylogenetic position of *Caloramator* species amongst members of the family *Clostridiaceae*, order *Clostridiales*, class *Clostridia*, phylum *Firmicutes*. Sequences were aligned and manually adjusted according to the 16S rRNA secondary structure using BioEdit (Hall, 1999). Sequence uncertainties were omitted and phylogenetic reconstruction was achieved with 1233 unambiguous nucleotides using TreeCon (Van de Peer and De Wachter, 1994) in which pairwise evolutionary distances were computed from percentage similarities (Jukes and Cantor, 1969) and phylogenetic trees constructed from the evolutionary distances using the neighbor-joining method (Saitou and Nei, 1987). Tree topology was re-examined by the bootstrap method of resampling using 1000 bootstraps (Felsenstein, 1985). The strains used in the analysis, their culture collection numbers and corresponding 16S rRNA gene sequences extracted from GenBank are shown in parentheses. The clusters represented as triangles are for the following species: *Sarcina maxima* (DSM 316^T, X76650), *Sarcina ventriculi* (DSM 286^T, X76649), *Alkaliphilus transvaalensis* (ATCC 700919^T, AB037677), *Alkaliphilus crotonatoxidans* (JCM 11672^T, AF467248), *Dorea longicatena* (JCM 11232^T, AJ132842), *Dorea formicigenans* (ATCC 27755^T, L34619), *Hespellia porcina* (ATCC BAA-674^T, AF445239), *Hespellia stercorisuis* (ATCC BAA-677^T, AF445264), *Tepidibacter thalassicus* (DSM 15285^T, AY158079), *Tepidibacter formicigenes* (DSM 15518^T, AY245527), *Tindallia magadiensis* (DSM 10318^T, AY15626) and *Tindallia californiensis* (ATCC BAA-393^T, AF373919). Bootstrap values (≥ 95) from 100 resampling are shown. Bar indicates 10 nucleotide changes per 100 nucleotides. The following abbreviations have been used: T, Type culture; ATCC, American Type Culture Collection; DSM, Deutsche Sammlung von Mikroorganismen und Zellkulturen; JCM, Japan Collection of Microorganisms, CNCM, Collection Nationale de Cultures Microbiennes; NCCB, Netherlands Culture Collection of Bacteria; ACM, Australian Collection of Microorganisms; NCIMB, National Collections of Industrial Food and Marine Bacteria; and CCUG, Culture Collection of the University of Göteborg, Sweden.

acids cannot replace yeast extract or Trypticase peptone. Serine, but not carbohydrates and other amino acids, can be used as a sole carbon and energy source. The optimum growth temperature and pH are 68 °C and pH 7–7.5, respectively. Glucose fermentation end products in the presence of Trypticase peptone are acetate, ethanol, lactate, *i*-butyrate, *i*-valerate, *n*-valerate, H₂ and CO₂. Growth is inhibited by tetracycline, penicillium, chloramphenicol, and streptomycin. Isolated from a New Zealand geothermal spring (70 °C, pH 7.2).

DNA G+C content (mol%): 39 (T_m).

Type strain: Rt4-B1, ATCC 43204, DSM 5463.

GenBank accession number (16S rRNA gene): L09187.

- 2. *Caloramator celer* comb. nov.** (basonym *Thermobrachium celer* Engle, Li, Rainey, DeBlois, Mai, Reichert, Mayer, Messner and Wiegel 1996).

ce'ler. L. masc. adj. *celer* fast, referring to the unusual fast growth of the bacterium.

The following description is from Engle et al. (1996) and unpublished results from the laboratory of Juergen Wiegel. Obligate anaerobe which can survive exposure to oxygen for more than 24h but does not grow under microaerophilic or aerobic conditions. Colonies are white and circular. Rod-shaped cells, which measure 1.5–14 μm by 0.5–1.2 μm. Between 1 to 10% of the cells show true branching but this diminishes to 0.2% with extended periods of subculturing. Cells in the late exponential growth phase are in chains, cells tend to form filaments and L-forms are commonly observed. Cells are peritrichously flagellated and are sluggishly motile. The cells stain Gram-positive and possess a typical Gram-positive cell-wall ultrastructure consisting of an S-layer. Spores have not been observed but sporulation specific genes have been demonstrated. Chemo-organotrophic and proteolytic but not cellulolytic. 0.05% yeast extract is required for visible growth and yeast extract between 0.1–2% can serve as a sole carbon and energy source. Glucose, sucrose, fructose, galactose, and maltose, but not cellobiose, ribose, mannose, arabinose, xylose, glucuronic acid, xylan, Casamino acids, and pyruvate, are utilized. The fermentation products from glucose in the presence of yeast extract are acetate, formate, ethanol, CO₂, and H₂. The optimum growth temperature is 66 °C (temperature growth range is 43–75 °C) and the optimum pH is 8.2 (pH range growth range is pH 5.4–9.5). A doubling time of 10min is obtained in a medium (250 ml) containing 0.5% glucose ad 2% yeast extract under pH controlled batch fermentation.

DNA G+C content (mol%): 30–31 (HPLC).

Type strain: JW/YL-NZ35^T, DSM 8683^T, ATCC 700318^T.

GenBank accession number (16S rRNA gene): X99238.

- 3. *Caloramator coolhaasii* Plugge, Zoetendal and Stams 2000, 1161^{VP}**

cool.haas'i. N.L. gen. *coolhaasii* named after Caspar Coolhaas, a Dutch microbiologist, who was the first to describe thermophilic protein degradation under methanogenic conditions.

Rods to filamentous cells (2–40 μm × 0.5–0.7 μm) are nonmotile, do not form spores and stain Gram-negative but have a Gram-positive cell-wall ultrastructure. Moderately thermophilic. Temperature range for growth is 37–65 °C (optimum 50–55 °C). and pH growth range is pH 6.0–8.5

(optimum pH 7.0–7.5). Strictly anaerobic chemoorganoheterotroph. Utilizes glutamate, aspartate, alanine, arginine, methionine, glucose, fructose, galactose, sucrose, maltose, ribose, xylose, starch, cellobiose and mannose, Casamino acids, yeast extract, gelatin, casein, peptone, pyruvate, and WC broth for growth. Growth on glutamate, aspartate, alanine, arginine, methionine, mannose, ribose and pyruvate is enhanced in the presence of the methanogen *Methanobacterium thermoautotrophicum* Z-245^T. Acetate, lactate, CO₂ and H₂ are produced from glucose fermentation. Yeast extract stimulates growth on glutamate, but is not required. No Strickland reaction could be observed. Sulfide-reduced media was required for growth. No reduction of oxygen, nitrate, sulfate, thiosulfate or fumarate.

Habitat: anaerobic thermophilic methanogenic sludge.

DNA G+C content (mol%): 31.7 ± 0.4 (HPLC).

Type strain: Z^T = DSM 12679^T.

GenBank accession number (16S rRNA gene): AF104215.

4. **Caloramator indicus** Chrisostomos, Patel, Dwivedi and Denman 1996, 500^{VP}

in'di.cus. N.L. adj. *indicus* of India, the country from which the organism was isolated.

Nonmotile rod to filamentous cells (10–100 × 0.6–0.8 μm) which stain Gram-negative but possess a Gram-positive cell-wall ultrastructure. Spores have not been found. Chemoorganotrophic and obligately anaerobic. The optimum temperature for growth is between 60–65 °C and no growth occurs at temperatures below 37 °C or above 75 °C. The optimum pH for growth is between 7.5 and 8.1, and no growth occurs at pH values below 6.2 or above 9.2. Utilizes glucose, amylopectin, starch, amylose, dextrin, cellobiose, fructose, lactose, mannose and sucrose but not cellulose, dextran and chitin. Trypticase peptone and/or yeast extract is required for growth on carbohydrates though either of these can be used as a sole carbon and energy source in the absence of carbohydrates. Produces ethanol, acetate, lactate, CO₂ and H₂ from glucose fermentation. Growth is inhibited by tetracycline, penicillium G, chloramphenicol, novobiocin, polymyxin B and rifampin.

DNA G+C content (mol%): 25.6 ± 0.3 (*T_m*).

Type strain: IndiB4, ACM 3982.

GenBank accession number (16S rRNA gene): X75788.

5. **Caloramator proteoclasticus** Tarlera, Muxí, Soubes and Stams 1997, 655^{VP}

pro.te.o.clas'ti.cus. Gr. adj. *protos* first; Gr. adj. *clasticus* breaking, from Gr. part. perf. *klastos* broken; N.L. masc. adj. *proteoclasticus* protein-breaking.

Strictly anaerobic straight or slightly curved rods (2.4–4.0 μm × 0.4 μm) with pointed ends which occur singly or in pairs. Surface colonies (4 mm) are golden, circular, smooth, opaque and bluish around the edges. Cells stain Gram-negative and possess an atypical two-layered Gram-positive cell-wall ultrastructure. Tumbling motility by means of peritrichous flagella. Spores are produced in a yeast extract and gelatin medium in the late exponential growth phase.

Cell lysis occurs in carbohydrate grown stationary phase cultures. Moderately thermophilic, with an optimum growth temperature of 55 °C (temperature growth range is between 30 and 68 °C). The pH growth optimum is pH 7.0–7.5 (pH range for growth is 6.0–9.5). Chemo-organotrophic, requiring yeast extract for fermentation of complex proteins (casein, gelatin, peptone, Casamino acids), amino acids (glutamate, arginine, histidine, threonine, methionine, glycine, leucine, valine, aspartate), carbohydrates (glucose, mannose, fructose, cellobiose, starch) and pyruvate. Casein, gelatin, peptone, Casmino Acids are fermented to acetate, propionate, butyrate, branch-chain fatty acids, formate and H₂; glutamate, arginine and histidine to acetate, formate and H₂; threonine and methionine to propionate; glutamate to alanine, formate and branched-chain amino acids; alanine and glycine to branch-chain fatty acids and acetate respectively. A complete Strickland reaction is observed with leucine and glycine. The end products from carbohydrate and pyruvate fermentation include acetate, lactate, ethanol, formate and H₂. Substrates such as ornithine, proline, acetate, H₂-CO₂ (80:20), formate, 2-oxoglutarate, lactose, xylose, malate, xylan, and cellulose are not utilized. Sulfate, thiosulfate, nitrate, and fumarate are not reduced. Isolated from a mesophilic whey-fermenting upflow anaerobic sludge blanket reactor.

DNA G+C content (mol%): 31 (HPLC).

Type strain: U^T, DSM 10124^T.

GenBank accession number (16S rRNA gene): X90488.

6. **Caloramator viterbiensis** Seyfried, Lyon, Rainey and Wiegel 2002, 1183^{VP}

vi.ter.ben'sis. L. masc. adj. *viterbiensis* pertaining to Viterbo in Italy (ancient name Viterbium), the region from which the strain was isolated.

Non-sporulating and nonmotile rods occur singly, are straight to slightly curved (0.4–0.6 × 2.0–3.0 μm) and stain Gram-positive. Ultrathin sections also reveal a Gram-positive cell wall structure. The temperature range for growth is 33–64 °C with an optimum of 58 °C. The pH range for growth is pH 5.0–7.8, with an optimum pH at 6.0–6.5. Growth is observed with glycerol, glucose, fructose, mannose, galactose, sucrose, cellobiose, lactose, starch and yeast extract. Xylose, arabinose, acetate, lactate, formate, methanol, ethanol, n-propanol, iso-propanol, n-butanol, propionate, acetone, succinate, ethylene glycol, 1,2-propanediol, phenol and benzoate are not fermented. Various single amino acids (0.5%, w/v) which include serine, glutamine, threonine, leucine, methionine, aspartate, valine and histidine but not arginine, are utilized. No growth occurs under autotrophic conditions in the presence of H₂/CO₂. Fermentation of glycerol yields acetate, 1,3-propanediol and H₂ whereas glucose fermentation yields ethanol, acetate, CO₂ and H₂. Ampicillin, chloramphenicol, rifampin, kanamycin and erythromycin inhibits growth.

DNA G+C content (mol%): 32 (HPLC).

Type strain: JW/MS-VS5^T = DSM 13723^T, ATCC PTA 584^T.

GenBank accession number (16S rRNA gene): AF181848.

Genus VI. **Caloranaerobacter** Wery, Moricet, Cueff, Jean, Pignet, Lesongeur, Cambon-Bonavita and Barbier 2001, 1795^{VP}

GEORGES BARBIER AND NATHALIE WERY

Ca.lor.an.ae.ro.bac'ter. L. n. *calor* heat; Gr. pref. *an* not; Gr. n. *aer* air; N.L. *bacter* masc. equiv. of Gr. neut. dim. n. *bakterion* small rod or staff; N.L. masc. n. *Caloranaerobacter* a thermophilic, anaerobic rod

Motile rod-shaped cells. Under optimal conditions are short rods, about $0.3\text{--}0.5 \times 0.5\text{--}2\ \mu\text{m}$, found singly, in pairs, or in short chains (less than 5 cells). **Gram-stain-negative**. **Thermophilic**; temperature range for growth $45\text{--}65\ ^\circ\text{C}$, optimum growth at $65\ ^\circ\text{C}$. **Adapted to the pH and salinity of ocean waters**. pH range $5.5\text{--}9.0$, optimum pH 7.0 . Salinity range $10\text{--}100\ \text{g}$ sea salts per liter, optimum $30\ \text{g}$ sea salts per liter. **Anaerobic, chemo-organotrophic**, able to ferment carbohydrates and proteinaceous substrates. Sulfur not required for growth. On the basis of 16S rRNA gene sequence analysis presented in the roadmap to Volume 3 (Figure 5), *Caloranaerobacter* is located in the family *Clostridiaceae*, order *Clostridiales*, class *Clostridia*, in the phylum *Firmicutes*; formerly, it was classified in cluster XII of the *Clostridium* subphylum (Collins et al., 1994).

Habitat: minerals from a deep-sea hydrothermal diffuser supporting mussels, mid-Atlantic Ridge, site Lucky Strike ($32^\circ 16' \text{W}$, $37^\circ 17' \text{N}$, 1650 m depth).

DNA G+C content (mol%): 27 (T_m).

Type species: *Caloranaerobacter azorensis* Wery, Moricet, Cueff, Jean, Pignet, Lesongeur, Cambon-Bonavita and Barbier 2001, 1795^{VP}.

Further descriptive information

Cells are motile round-ended rods, and flagella were observed by negative staining (Figure 132). *Caloranaerobacter* cells stain Gram-negative and ultrathin sections indicate a typical cell envelope with cytoplasmic and outer membranes. Cells more than $20\ \mu\text{m}$ long can sometimes be observed. No spores, but cells able to survive after 20 min at $100\ ^\circ\text{C}$. When stored for a few days at $4\ ^\circ\text{C}$, inoculated in poor media, or grown at high pH or at high hydrostatic pressure (65 MPa) some terminal, round, external bodies are produced. Under optimal conditions, growth is very fast, generation time is about 15 min and such a culture produces a maximum cell yield of 2×10^9 cells per ml.

FIGURE 132. Scanning electron micrograph showing a typical cell of *Caloranaerobacter azorensis* with flagella.

Caloranaerobacter is barotolerant; hydrostatic pressure has no significant effect on growth until 40 MPa. At higher pressures growth efficiency decreases; growth stops at 65 MPa.

Anaerobic heterotrophic growth is possible with proteinaceous substrates (gluten, brain heart infusion) and with pyruvate or carbohydrates (starch, glucose, xylan, xylose, arabinose, ribose, galactose, fructose, or sorbose) in the presence of yeast extract and tryptone. Growth was not observed with sucrose, lactose, maltose, cellobiose, cellulose, and other organic acids or alcohols. Sulfur, thiosulfate, nitrate and ferric iron do not enhance growth. No growth in presence of nitrite or sulfite. Significant production of H_2S in presence of sulfur.

Caloranaerobacter was isolated from a deep-sea hydrothermal diffuser supporting mussels that was sampled at mid-Atlantic Ridge, site Lucky Strike. 16S rRNA gene sequences available in databases indicate that the closest studied micro-organism (GenBank accession no. L10086, 98.5% similarity) is an unpublished isolate obtained from the gut content of a polychaete worm sampled at Juan de Fuca Ridge, North East Pacific (J. A. Baross, personal communication). This isolate most likely belongs to the same genus suggesting a wide oceanic distribution.

Enrichment and isolation procedures

Caloranaerobacter was enriched at $65\ ^\circ\text{C}$, pH 7.5, at atmospheric pressure, under an anoxic gas phase $\text{N}_2/\text{H}_2/\text{CO}_2$ (90:5:5). YPXS medium (yeast extract, 0.5 g/l; peptone, 1 g/l; oat spelt xylan, 5 g/l; sulfur, 10 g/l; sea salts, 30 g/l; PIPES buffer, 6.05 g/l; resazurin, 1 mg/l) was used for enrichment and isolation and then efficiently replaced by YTG medium (yeast extract, 1 g/l; tryptone, 1 g/l; glucose, 2.5 g/l; sea salts, 30 g/l; PIPES buffer, 6.05 g/l; resazurin, 1 mg/l). Vent minerals were crushed in sterile sea water in anaerobic conditions; this mixture was inoculated. Motile rods were observed after several days of incubation.

Maintenance procedures

Cultures of *Caloranaerobacter* can be maintained for short periods (several months) at $4\ ^\circ\text{C}$. Long-term storage of *Caloranaerobacter* is possible in a freezer ($-70\ ^\circ\text{C}$) and liquid nitrogen after addition of DMSO 5% (v/v) to exponentially growing cultures in anaerobic conditions.

Differentiation of the genus *Caloranaerobacter* from other genera

Comparisons of 16S rRNA gene sequences place *Caloranaerobacter* close to *Thermohalobacter berrensis* (Cayol et al., 2000b), a moderate halophile isolated from a solar saltern, and *Clostridium acidurici* (Barker, 1938; Liebert, 1909), *Clostridium purinilyticum* (Dürre et al., 1981), and *Eubacterium angustum* (Beuscher and Andreesen, 1984), three terrestrial species. 16S rDNA similarity values with these four species are less than 93%. Phenotypic characteristics also differentiate those genera. *Caloranaerobacter* differs from the three terrestrial species because it stains Gram-negative, because of its thermophily and adaption to marine

salinity, and because it is metabolically more diverse. *Caloranaerobacter*, which has a DNA G+C content 6 mol% lower, differs from *Thermohalobacter berrensensis* because it is less halophilic and it does not use the same carbohydrates.

Acknowledgements

We would like to thank JAMSTEC (Japanese Marine Science and Technology Center), specially Dr C. Kato and Professor K. Horikoshi, for cultures in the Deep Bath System (effect of hydrostatic pressure on growth).

List of species of the genus *Caloranaerobacter*

1. ***Caloranaerobacter azorensis*** Wery, Moricet, Cueff, Jean, Pignet, Lesongeur, Cambon-Bonavita and Barbier 2001, 1795^{VP} a.zo.ren'sis. N.L. masc. adj. *azorensis* of the Azores.

Only one species has been described for this genus; the species description is the same as that of the genus.

DNA G+C content (mol%): 27 (T_m).

Type strain: MV1087, CNCM I-2543, DSM 13643.

Gram-stain-negative. Motile, sporeforming, rod-shaped cells. Thermophilic. Adapted to the pH and salinity of the ocean. Anaerobic and heterotrophic. Ferments proteinaceous substrates and carbohydrates. Member of the family *Clostridiaceae* based on 16S rRNA gene sequence comparisons (Figure 5).

DNA G+C content (mol%): 24.2.

Type species: ***Caminiella sporogenes*** Alain, Pignet, Zbinden, Quillevère, Duchiron, Donval, Lesongeur, Raguènes, Crassous, Querellou and Cambon-Bonavita 2002, 1627^{VP}.

Taxonomic comment

The genus *Caminiella* was described on the basis of a single strain that was phenotypically and phylogenetically distinct from related taxa. The 16S rRNA gene sequence of *Caminiella sporogenes* shows highest similarity to the species *Clostridium caminithermale* (93.0%), and *Clostridium halophilum* (92.7%). The phylogenetic relationships are shown in Figure 133. *Caminiella sporogenes* represents a distinct lineage that clusters with *Clostridium caminithermale* and *Clostridium halophilum*.

List of species of the genus *Caminiella*

1. ***Caminiella sporogenes*** Alain, Pignet, Zbinden, Quillevère, Duchiron, Donval, Lesongeur, Raguènes, Crassous, Querellou and Cambon-Bonavita 2002, 1627^{VP} spo.rog.en'és. Gr. n. *spora* a spore; Gr. v. *gemmaio* produce; N.L. part. adj. *sporogenes* spore-producing.

Cells are rod-shaped and motile by means of peritrichous flagella. Exhibit a Gram-stain-negative cell-wall ultrastructure. Cells are up to 3.0–10 µm in length and 0.5–0.7 µm in width. Sporulation is observed in the late stationary phase of growth. The temperature range for growth is 45–65 °C; optimum at 55–60 °C. Growth occurs in the pH range 4.5–8.0; optimum at pH 7.5–8.0. Growth occurs at sea salt concentrations in the range 20–60 g/l; optimum at 25–30 g/l. The maximum doubling time is approximately 45 min; the maximum cell yield is

8×10^8 cells/ml. Anaerobic. Ferments yeast extract, brain heart infusion, D(+)-glucose, maltose. Weak growth on peptone, galactose, and a mixture of 20 amino acids. The fermentation products on GYPS medium (Alain et al., 2002) are H₂, CO₂, butyrate, ethanol, acetate, formate, and L-alanine. The 16S rRNA gene sequence similarities to *Clostridium halophilum* and *Clostridium caminithermale* are 92.7% and 93.1%, respectively.

The type strain was from young entire *Alvinella pompejana* tubes attached to small fragments of chimney rocks that were collected from the hydrothermal site Elsa (HOT3) in the East-Pacific Rise (103°56'326 W, 12°48'200 N).

DNA G+C content (mol%) of the type strain: 24.2 (T_m).

Type strain: AM1114, CIP 107141, DSM 14501.

GenBank accession number (16S rRNA gene): AJ320233.

Nat.ron'in.co.la. N.Gr. n. *natron* (arbitrarily derived from Ar. n. *natrun* or *natron*) soda; L. masc. or fem. n. *incola* inhabitant, dweller; N.L. masc. n. *Natronincola* an organism indigenous to soda deposits.

Cells are rod-shaped, flexible, and motile by peritrichous flagella. The cell wall has a Gram-stain-positive structure. Obligately anaerobic. Chemo-organotrophic with fermentative metabolism. **Certain amino acids** (and pyruvate by some strains) are **utilized** as a sole source of energy, **using CO-dehydrogenase pathway, with acetate as a main product.** Ammonium is formed in large quantities as the product. **Moderately halophilic and extremely alkaliphilic. Obligately dependent on Na⁺ and CO₃²⁻ ions. Endospores may be produced by some strains.**

DNA G+C content (mol%): 31.9–32.3 (*T_m*).

Type species: Natronincola histidinovorans corrig. Zhilina, Detkova, Rainey, Osipov, Lysenko, Kostrikina and Zavarzin 1999, 1^{VP} (Effective publication: Zhilina, Detkova, Rainey, Osipov, Lysenko, Kostrikina and Zavarzin 1998, 183.).

Further descriptive information

Phylogenetic position. Currently, a single species is classified within the genus, namely *Natronincola histidinovorans*. Analysis of the 16S rRNA gene sequence of the type species demonstrated that genus *Natronincola* (Zhilina et al., 1998) falls within the radiation of the clostridia *Clostridium felsineum* (Hippe et al., 1992), *Clostridium formicoaceticum* (Andreesen et al., 1970), and *Tindallia magadiensis* (Kevbrin et al., 1998) and belonging to “clostridial group” cluster XI of the low G+C Gram-positive bacteria as defined by Collins et al. (1994). In the phylogenetic analysis presented in the roadmap to this volume (Figure 5), *Natronincola* is placed in family *Clostridiaceae*, order *Clostridiales*, class *Clostridia*, phylum *Firmicutes*.

Cell morphology and fine structure. Cells are flexible motile rods 0.7–1 × 2–6 μm, differing in length, and sometimes forming long filaments. Motile by peritrichous flagella. Multiplication is by fission, often unequal (Figure 134). Formation of terminal round minicells is characteristic; sometimes these minicells retain motility. Side blebs of minicell dimensions are observed (Figure 134). Asporogenous or oligosporic; spores, if present, are round and terminal. Not thermoresistant, but

resistant to desiccation. The cell wall is of Gram-stain-positive structure and has no outer membrane.

Growth conditions and nutrition. Truly alkaliphilic and moderately halophilic. Obligately dependent on sodium and carbonate ions. In the high-alkalinity medium 1 (Zhilina and Zavarzin, 1994) with the composition (g/l) NaHCO₃:Na₂CO₃:NaCl = 38.3:68.3:15.7, the pH optimum for growth is pH 9.4 within the range pH 8.0–10.5. Growth occurs at salinities not less than 4% NaCl but not at salinities greater than 16% with a growth optimum around 8–10%. Mesophilic: optimal growth at 37–40 °C, no growth above 45 °C.

Strictly anaerobic. The type strain Z-7940 ferments only histidine or glutamate with acetate as a main end product of fermentation. Ammonium is formed in large quantities. With histidine as the substrate, a minor production of formate was recorded. H₂ production was not found. Per 1 mmol of metabolized histidine, 2.34 mmol acetate, 0.27 mmol formate, and 3.15 mmol ammonium are produced. The *K_m* was 2.13 mM. The optimal concentration of histidine for growth ranges from 4.77–11.93 mM; at higher concentrations growth is inhibited. Moderate growth is observed with media containing peptone, yeast extract, and Casamino acids. In addition, strain Z-7939 is able to utilize pyruvate. Both strains require yeast extract for anabolism. Carbohydrates, other amino acids, alcohols, and organic acids are not utilized.

Metabolic properties. *Natronincola histidinovorans* uses the noncyclic acetyl-CoA pathway for CO₂ fixation with acetate as the main product. The key enzyme is CO-dehydrogenase with optimal pH 9.5. Growth and metabolism are completely inhibited by N,N'-dicyclohexylcarbodiimide (DCCD) indicating a chemiosmotic type of ATP formation by insensitive-to-vanadate F₁F₀-type ATPase. Monensin (14 μM) completely stops acetate formation but, in contrast to other haloalkaliphiles, *Natronincola* cell suspensions do not undergo lysis at the action of energy uncouplers as 3,5-di-tert-butyl-4-hydroxybenzylidene malonitrile (FCCP) or carbonyl cyanide m-chlorophenylhydrazone, 100 μM (CCCP) indicating energy-independent osmotic stability (Pushova et al., 1999).

FIGURE 134. Morphology of *Natronincola histidinovorans*. (A) anoptical microscopy (bar = 10 μm); (B) negatively stained 2% phosphotungstic acid cell with flagella (bar 1 μm). Blebs on the left side of the cell.

Ecology

Two strains of *Natronincola histidinovorans*, asporogenous Z-7940^T and sporogenous Z-7939, were isolated from flowing masses of cyanobacterial bloom in soda-depositing Lake Magadi, Kenya after the rainy season. These bacteria grew rather poorly on peptone but proliferated in media containing certain amino acids and a low concentration of yeast extract for anabolic needs. They are the representatives of the alkaliphilic, acetogenic, ammonifiers of the proteolytic pathway in the anaerobic community in the soda lakes (Zavarzin and Zhilina, 2000; Zavarzin et al., 1999). They might be involved in decomposition of osmoprotective compounds such as glutamate.

Enrichment and isolation procedures

The type strain Z-7940 was a component of an anaerobic enrichment with H₂ as the substrate in selective carbonate medium 1 with 0.2 g/l yeast extract (Zhilina and Zavarzin, 1994) where acetate was formed as the main end product. However, after isolation of the type strain Z-7940 in pure culture, it was found to be incapable of chemolithotrophic growth with H₂ or CO and was quite restricted in its metabolic capacities to histidine and glutamate and to slow growth with peptone. In addition, strain Z-7939 was isolated by a selective procedure on histidine-containing medium from a desiccated sample that had been stored for 3 years in a refrigerator. This strain showed 94% DNA–DNA homology with the type strain. However, the two strains differed in that strain Z-7939 had round terminal spores in some cells (representing an oligosporous type), utilized pyruvate as an additional substrate, and differed in the fatty acid profile. This demonstrated the use of a selective procedure with histidine as the substrate in alkaline, strictly anaerobic sodium carbonate medium at pH 9–9.5 and using N₂ as gas phase.

Maintenance procedure

A pure culture may be stored in the laboratory with regular transfers at weekly intervals and/or in early exponential phase in a refrigerator for 1–2 months. Old cultures are nonviable,

making maintenance a problem. For long-term preservation, storage in liquid nitrogen is recommended.

Differentiation of the genus *Natronincola* from other genera

Natronincola histidinovorans can be phylogenetically differentiated from other closely related genera and species of Collins et al. (1994) cluster XI of the low G+C Gram-positive bacteria by 16S rRNA gene sequence comparisons. The closest relatives were found to be *Clostridium felsineum* (92.1% similarity), *Clostridium formicoaceticum* (91.5% similarity), and *Tindallia magadiensis* (90% similarity), but it is phylogenetically unrelated to the type species of the genera *Clostridium* and *Tindallia*. *Natronincola histidinovorans* obligately depends on sodium and carbonate ions. This differentiates it from *Clostridium felsineum* and *Clostridium formicoaceticum*. In contrast to these organisms, *Natronincola histidinovorans* cannot utilize carbohydrates. It can be differentiated from the alkaliphilic *Tindallia magadiensis* on the basis of morphology, lipid profile, and inability to utilize amino acids of the ornithine cycle.

Chemotaxonomically, *Natronincola* Z-7940^T is differentiated from *Tindallia* based on its fatty acid profile with major membrane fatty acids C_{16:1 ω7}, C_{16:0}, C_{14:0} and C_{18:0} which contribute about 65% of total acids. The major (about 25%) palmitoleic aldehyde was C₁₆ with C_{16:1 ω7}, C_{18:1 ω9} and C₁₈ as a minor component. Strain Z-7939 contains plasmalogen in the membrane together with palmitine (20%) and palmitoleic aldehyde (3%) and an unusual combination of aldehydes with branched acids (C_{15 iso}, 11.4%). This combination is not found among previously described bacteria. The lipid profiles alone indicate that strains of *Natronincola* represented a new taxon.

Taxonomic comments

Taxonomically, *Natronincola* (the original spelling, *Natronoincola* (sic), was corrected on validation according to Rule 61, see footnote to Validation List no. 68. Int. J. Syst. Bacteriol. 1999, 49:1–3) groups within the *Bacteria* as a Gram-positive organism with a low G+C value belonging to the *Firmicutes* and the order *Clostridiales*. It represents a distinct lineage of generic status in the family *Clostridiaceae*.

List of species of the genus *Natronincola*

1. ***Natronincola histidinovorans*** corrig. Zhilina, Detkova, Rainey, Osipov, Lysenko, Kostrikina and Zavarzin 1999, 1^{VP} (Effective publication: Zhilina, Detkova, Rainey, Osipov, Lysenko, Kostrikina and Zavarzin 1998, 183.)

tate and butyrate; from catabolism of methoxybenzenoids are butyrate and hydroxybenzenoids. Sugars, amino acids, organic acids and alcohol are not utilized as energy sources.

DNA G+C content (mol%): 38.0 (T_m).

Type species: Oxobacter pfennigii (Krumholz and Bryant 1985) Collins, Lawson, Willems, Cordoba, Fernandez-Garayzabal, Garcia, Cai, Hippe and Farrow 1994, 822^{VP} (*Clostridium pfennigii* Krumholz and Bryant 1985, 455).

Taxonomic comments

Oxobacter pfennigii was originally described as *Clostridium pfennigii* on the basis of its ability to produce heat-resistant spores (Krumholz and Bryant, 1985). The determination of the 16S rRNA gene sequence of the type strain of *Clostridium pfennigii* and comparison to a large number of taxa in the low G+C Gram-positive phylum (*Firmicutes*) indicated a novel phylogenetic position of this organism (Collins et al., 1994). *Clostridium pfennigii* fell at the base of, but distinct from, cluster I defined as the group of *Clostridium* species related to the

type species of the genus *Clostridium*, *Clostridium butyricum*, and representing the genus *Clostridium sensu stricto* (Collins et al., 1994). The 16S rRNA gene sequence of *Clostridium pfennigii* shows less than 89% sequence similarity to its nearest neighbors, the *Clostridium* species of cluster I and species of the genus *Caloramator*. This distinct phylogenetic position, unique metabolic characteristics, and lack of relationship to species of the genus *Clostridium sensu stricto* justified the description of *Clostridium pfennigii* as *Oxobacter pfennigii* comb. nov. (Collins et al., 1994). No additional species have been added to this genus and a search of the current GenBank database of 16S rRNA gene sequences shows no cultured strains closely related to this taxon. In the 16S rRNA phylogenetic analysis presented in the roadmap to the current volume, *Oxobacter* is in the family *Clostridiaceae*, order *Clostridiales*, and class *Clostridia* in the phylum *Firmicutes* (Figure 5).

List of species of the genus *Oxobacter*

1. ***Oxobacter pfennigii*** (Krumholz and Bryant 1985) Collins, Lawson, Willems, Cordoba, Fernandez-Garayzabal, Garcia, Cai, Hippe and Farrow 1994, 822^{VP} (*Clostridium pfennigii* Krumholz and Bryant 1985, 455)

pfennigii i.i. N.L. gen. n. *pfennigii* of Pfennig, named after Norbert Pfennig, who first documented the catabolism of methyl groups of benzenoid compounds by an anaerobic bacterium.

Gram-stain-positive, motile, slightly curved rods, with slightly tapered ends, 0.4 µm in diameter and 1.6–3.5 µm in length. Oval, subterminal to terminal endospores formed. Spores are resistant to boiling for 3 mins, slightly swell the sporangium, and are 0.4 µm in diameter and 0.4–0.8 µm in length. Colonies in roll tubes are smooth, convex, entire, opaque and 2–3 mm in diameter after 1 week of incubation in media containing 5 mM vanillate. The optimum temperature for growth is between 36 and 38 °C in the range 29–39 °C. The pH range is 6.3–8.0, with an optimum at pH 7.3. Only methoxybenzenoids

(vanillate, vanillin, ferulate, and syringate), pyruvate, or CO supports growth. Butyrate and hydroxybenzenoids are produced from methoxybenzenoids. CO is catabolized to acetate, butyrate, and CO₂. Pyruvate is fermented to acetate and CO₂. Hydrogen, other organic acids, ethanol, or methanol is not produced. Cell yields from growth are increased when grown on ferulate. Rumen fluid and yeast extract enhance growth. Little growth without rumen fluid. Growth on syringate is not stimulated by the addition of Casitone, Casamino acids, 1,4-naphthoquinone, hemin, or a mixture of volatile fatty acids to media with or without rumen fluid. Growth is not stimulated by sulfate, thiosulfate, nitrate, or fumarate. Nitrate is not reduced. Sulfate does not allow growth on lactate or ethanol. Gelatin is not liquefied. Isolated from rumina of cattle.

DNA G+C content (mol%): 38.0 (T_m).

Type strain: strain V5-2, ATCC 43583, DSM 3222.

GenBank accession number (16S rRNA gene): X77838.

Genus X. **Sarcina** Goodsir 1842, 434^{AL*}

ERCOLE CANALE-PAROLA

Sar.cí'na. L. fem.n. *Sarcina* a package, bundle.

Nearly spherical cells, 1.8–3.0 µm in diameter; **occurring in packets** of eight or more. Some of the cells in cultures may be present singly, or as groups of fewer than eight cells. Generally the cells are flattened in the areas of contact with adjacent cells. **Division occurs in three perpendicular planes.** Spore formation by these organisms has been reported (Knöll, 1965; Knöll and R. Horschak, 1971). **Gram-stain-positive. Nonmotile. Chemo-organotrophic anaerobes, having an exclusively fermentative metabolism.** Relatively aerotolerant. **Carbohydrates are the fermentable substrates.** The main products of glucose fermentation are CO₂, H₂, acetic acid as well as ethanol for *Sarcina ventriculi* and butyric acid for *Sarcina maxima*. Not pigmented. Catalase-negative. The minimal growth requirements include numerous amino acids and few vitamins, in addition to a fermentable substrate and inorganic salts. Grow at pH values near 1 and up to pH 9.8.

DNA G+C content (mol%): 28–31.

Type species: Sarcina ventriculi Goodsir 1842, 437^{AL}.

Further descriptive information

Usually, packets of *Sarcina ventriculi* consist of a greater number of cells than those of *Sarcina maxima*. Many of the cells in large packets of *Sarcina ventriculi* (e.g., packets comprising approximately 64 or more cells) have flattened shapes and are irregularly arranged (Canale-Parola et al., 1961; Holt and Canale-Parola, 1967; Smit, 1930). Thus, large packets tend to have a distorted appearance. Holt and Canale-Parola (1967) isolated strains of *Sarcina ventriculi* that consistently form small packets. These strains are especially difficult to distinguish from *Sarcina maxima* by means of light microscopy.

Cells of *Sarcina ventriculi* are surrounded by a thick, fibrous layer of cellulose usually 150–200 nm in thickness (Canale-Parola et al., 1961; Canale-Parola and Wolfe, 1964). The cellulose layer

*This chapter was largely reprinted from the First Edition.

around each cell is either continuous with, or attached to, the cellulose layer surrounding adjacent cells in the same packet (Canale-Parola et al., 1961; Holt and Canale-Parola, 1967). Apparently the cellulose layer functions as a matrix or cementing material that holds together cells of *Sarcina ventriculi* into the large packets typical of this bacterium (Canale-Parola et al., 1961). In fact, strains of *Sarcina ventriculi* that produce little or no cellulose form packets consisting of relatively few cells, loosely bound to one another (Canale-Parola et al., 1961; Holt and Canale-Parola, 1967). In contrast, cells of strains that form large packets are surrounded by a thick, fibrous layer of cellulose, with the result that the packets are crisscrossed by an intercellular network of this polymer. It has been suggested that nutrients diffuse from the external environment into the interior regions of the packets via this network of cellulose fibers (Canale-Parola, 1970). In this manner nutrients may reach cells that have no direct contact with the growth medium because they are located in the interior regions of the packets (Canale-Parola, 1970).

The cellulose layer is absent from cells of *Sarcina maxima* (Canale-Parola, 1970).

The peptidoglycans of *Sarcina ventriculi* and *Sarcina maxima* contain LL-diaminopimelic acid. The interpeptide bridge consists of one glycine residue (Kandler et al., 1972). This type of peptidoglycan is not found in aerobic packet-forming cocci (Kandler et al., 1972).

Subsurface colonies of *Sarcina ventriculi* in agar media grow to several millimeters in diameter and are irregularly cubical or star-shaped. *Sarcina maxima* forms smaller subsurface colonies, which may be cuboid with protuberances or shaped as uneven spheres. On the surface of agar media, in an anaerobic atmosphere, both organisms form roundish colonies which frequently have jagged edges.

Knöll (1965) and Knöll and Horschak (1971) reported that both *Sarcina ventriculi* and *Sarcina maxima* form endospores. The procedure they used to induce sporulation involved incubation of growing cells in CO₂ atmosphere, followed by addition of phosphate buffer and alkali to raise the pH of the cultures rapidly to 7.5 for *Sarcina ventriculi* and to 9-10 for *Sarcina maxima*. Spore formation occurred during further incubation of the cultures in N₂. Spherical spores were formed by *Sarcina ventriculi*, oval spores by *Sarcina maxima*. The spores were heat-resistant and stained green with Wirtz's (1908) spore stain (Knöll and Horschak (1971) Knöll, personal communication).

The optimum temperature range for growth is 30-37°C for *Sarcina ventriculi* and 30-35°C for *Sarcina maxima*. Growth of both species occurs between pH 1 and 9.8 (Smit, 1930, 1933), an extraordinarily wide pH range. *Sarcina ventriculi* strains freshly isolated from natural environments can be subcultured indefinitely in media of very low pH, but when the strains are subcultured repeatedly at near neutral pH they tend to lose their ability to grow in media of pH 4.5 or lower (Canale-Parola, 1970).

^bThe following substrates are not fermented by either species: trehalose, raffinose, dextrin, starch, glycogen, glycerol, dulcitol, mannitol and amino acids. Citrate, gluconate and succinate are not fermented by *Sarcina ventriculi* (fermentation of these compounds by *Sarcina maxima* was not tested).

^cData from Smit, 1933; Canale-Parola and Wolfe (1960b); Claus and Wilmanns (1974).

^dSmit (1933) reported that *Sarcina maxima* ferments lactose.

Sarcina ventriculi and *Sarcina maxima* require for growth a fermentable carbohydrate (Table 150), vitamins, amino acids, as well as inorganic salts. For example, *Sarcina ventriculi* strain EC-1 requires biotin, nicotinic acid and 11 amino acids (serine, histidine, isoleucine, leucine, tyrosine, methionine, tryptophan, phenylalanine, arginine, valine and glutamic acids) (Canale-Parola and Wolfe, 1960b). A chemically defined medium containing glucose, inorganic salts and the above-mentioned vitamins and amino acids supports abundant growth of the organism (Canale-Parola and Wolfe, 1960b). A strain of *Sarcina maxima* studied required thiamine, threonine, alanine and aspartic acid, in addition to the vitamins and amino acids required by *Sarcina ventriculi* EC-1 (Knöll and R. Horschak, 1964).

In complex media (e.g., 2g each of glucose and yeast extract/100 ml distilled water (DW) *Sarcina ventriculi* EC-1 grew to cell yields of 8-12g (wet wt)/liter (Canale-Parola et al., 1961). A complex medium for *Sarcina maxima* consists of (g/100 ml DW): glucose and peptone, 1.0 each; yeast extract, 0.5; L-cysteine, 0.05; and FeSO₄·7H₂O, 0.005 (Kupfer and Canale-Parola, 1967). One liter of this medium yielded approximately 2.4g (wet wt) of *Sarcina maxima* strain 11 cells. Cultivation procedures for both species of *Sarcina* have been described (Canale-Parola, 1970; Canale-Parola et al., 1961; Kupfer and Canale-Parola, 1967).

^cFermentation products of growing cells, except for the data in column 2 which were obtained with cell suspensions. Data in column 1 are from Kluyver (1931), in column 2 from Milhaud et al. (1956), in column 3 from Canale-Parola and Wolfe (1960a), in column 4 from Smit (1930) and in column 5 from Kupfer and Canale-Parola (1967). Data in columns 1 and 4 were originally reported as percentages of glucose fermented.

^dExpressed as micromoles of product/100 μ M of glucose fermented.

^eDetected when cells were grown in media containing CaCO_3 .

Carbohydrate fermentation by *Sarcina ventriculi* yields mainly ethanol, acetate, CO_2 and H_2 , whereas *Sarcina maxima* ferments sugars primarily to butyrate, acetate, CO_2 , and H_2 (see Table 151). Both species utilize the Embden–Meyerhof pathway for the fermentation of carbohydrates (Canale-Parola, 1970). Two enzymic systems for pyruvate metabolism are present in *Sarcina ventriculi*: a yeast-type decarboxylase that produces acetaldehyde and CO_2 from pyruvate, and a clostridial-type ferredoxin-dependent pyruvate clastic system that yields acetyl phosphate, CO_2 and H_2 . Furthermore, CO_2 and H_2 are produced from formate by *Sarcina ventriculi* via a reaction catalyzed by formate hydrogen-lyase (Stephenson and Dawes, 1971). Like *Sarcina ventriculi*, *Sarcina maxima* possesses a clostridial-type pathway for pyruvate cleavage and metabolism. Cleavage of pyruvate by *Sarcina maxima* result in the production of acetyl-CoA, CO_2 and electrons which are transferred to ferredoxin (Kupfer and Canale-Parola, 1967). Phosphotransacetylase (EC 2.3.1.8) catalyzes the conversion of acetyl-CoA to acetyl phosphate, which is metabolized to acetate in a reaction catalyzed by acetate kinase (EC 2.7.2.1). Furthermore, acetyl-CoA is metabolized to butyrate via a pathway similar to that present in saccharolytic clostridia and involving butyryl-CoA dehydrogenase (EC 1.3.99.2), phosphate butyryltransferase (EC 2.3.1.19), and butyrate kinase (EC 2.7.2.7) (Kupfer and Canale-Parola, 1968). *Sarcina maxima* utilizes a hydrogenlyase system to convert formate to CO_2 and H_2 (Kupfer and Canale-Parola, 1967). The occurrence of the latter enzymic activity and the accumulation of small amounts of formate in cultures fermenting glucose suggest that, in addition to the clostridial-type system, *Sarcina maxima* possesses a coliform-type pyruvate clastic system (Kupfer and Canale-Parola, 1967). The latter enzymic system catabolizes pyruvate to acetyl phosphate and formate in coliform bacteria.

Growth of *Sarcina ventriculi* takes place in the human stomach as a result of the development of certain pathological conditions (e.g., pyloric ulceration, stenosis) that retard the flow of food to the intestine. Under these abnormal circumstances,

at the acid pH of the stomach and in the presence of carbohydrates and other growth nutrients contained in food, *Sarcina ventriculi* thrives and multiplies rapidly (Smit, 1933). The sarcinae, which occur commonly in soil, are ingested with soil particles present in food.

Sarcina ventriculi has been isolated from soil, mud, contents of diseased human stomach, rabbit and guinea pig stomach contents, elephant dung, human feces and the surface of cereal seeds. *Sarcina maxima* has been isolated from the hull or outer coat of cereal grains, such as wheat, oat, rice and rye. It was also isolated from fresh wheat bran, horse manure and soil.

Enrichment and isolation procedures

Selective isolation procedures for *Sarcina ventriculi* and *Sarcina maxima* are based on the ability of these bacteria to grow anaerobically at very low pH (e.g., 2.0–2.5) in the presence of a fermentable carbohydrates.

The following is a procedure for the isolation of *Sarcina ventriculi* (Canale-Parola, 1970). “The enrichment medium contains (g/100 ml of distilled or tap water): maltose, technical (Pfanstiehl Lab, Inc., Waukegan, IL), 2.0; malt extract broth (powder, BBL or Difco), 5.0; peptone (Difco), 0.5. The pH of the medium is adjusted to 2.2 ± 0.1 with diluted acid (e.g., 1 vol. of H_2SO_4 (specific gravity 1.84) to 9 vols of H_2O). The medium is boiled for 2 or 3 min and, while still hot, it is poured into 60-ml glass-stopper bottles. The bottles, completely filled with medium, are cooled to 40 °C in a cold-water bath. Garden soil (preferably saturated with water or growth medium to decrease the amount of air introduced in the bottles) is added to form a layer (2–4 mm) on the bottom of each bottle. The bottles are stoppered without trapping air bubbles and are incubated at 37 °C.

After 16–48 h, successful enrichments exhibit vigorous gas production. Fine gas bubbles originating from the sarcinae in the sediment rise through the medium and form a layer of foam in the upper part of the bottles. Unless gas production is

so active that it resuspends part of the sediment, the supernatant liquid is clear and essentially free of microbial growth since the large sarcina packets remain settled on the bottom. The supernatant liquid of enrichments containing a large number of contaminating organisms (frequently rod-shaped bacteria or yeasts) is turbid; the contamination develops as a result of a rise in pH, generally due to reactions between the acid in the culture and material present in the soil. When very alkaline soil is used, the initial pH of the medium should be lower than 2.2.

Second enrichment cultures, also in bottles, are prepared without delay by using the same procedure, except that 1–2 ml of sediment from the first enrichments is used as the inoculum. After 16–48 h of incubation, cells from the second enrichments may be used to inoculate identical third enrichments for the purpose of accomplishing further dilution of contaminating organisms. Serial dilutions of the growth in these cultures are plated to obtain isolated colonies.

Preparation of third enrichments may not be necessary since the sarcinae in the second enrichments are often so numerically predominant over other organisms that it is advantageous to plate serial dilutions directly from the second enrichments. The following medium (MYA) is used for plating (g/100 ml of distilled water): malt extract broth (powder, BBL or Difco), 2; maltose, technical (Pfanstiehl), 2; yeast extract (Difco), 0.1; agar, 2. The pH of the medium is adjusted to 6.0 ± 0.2 with 5% (w/v) KOH and the medium is sterilized. Serial dilutions are prepared in tubes of melted medium MYA at 45 °C. These are poured in sterile Petri dishes and, after solidification, are incubated anaerobically, or 15 ml of medium MYA is poured on the surface of the medium in each plate (double-layer plates) and the cultures are incubated in air.

Colonies of *Sarcina ventriculi* appear after 10–32 h. Cells from the colonies are transferred to tubes containing medium MYA from which the agar has been omitted. The medium in the tubes is heated for 5–10 min in a boiling-water bath, then cooled to 40 °C before inoculation. Serial dilutions of the growth in these tubes are plated as described above to obtain pure cultures.

A selective method for the isolation of *Sarcina maxima* from soil has been described by Claus and Wilmanns (1974). In this method, D-xylose is used as the fermentable substrate in the enrichment medium to exclude growth of *Sarcina ventriculi*, which does not ferment this pentose. The enrichment medium contains (g/100 ml DW): peptone (Difco), 0.5; yeast extract (Difco), 0.5; D-xylose, 2.0. The medium is adjusted to pH 2 or 3 with HCl. The isolation procedure is similar to that describe above for *Sarcina ventriculi*.

Maintenance procedures

Cells of *Sarcina ventriculi* and *Sarcina maxima* are viable only for 2–4 d in broth cultures in which nutrients are present at concentrations that do not limit growth. Thus, it is prudent to transfer the organisms on alternate days so that viable cells may be maintained in such cultures. The physiological bases for the rapid loss of viability have not been elucidated. Viability of *Sarcina ventriculi* cells can be prolonged by using growth-limiting concentrations of fermentable carbohydrate or of other nutrients in the culture medium (Canale-Parola and Wolfe, 1960a). Furthermore, when K_2HPO_4 or $NaHCO_3$ is added to culture media containing a growth-limiting concentration of fermentable sub-

strate, most strains of *Sarcina ventriculi* survive for 30 d under anaerobic conditions (Claus et al., 1970).

A convenient method for maintenance of *Sarcina ventriculi* or *Sarcina maxima* involves heavy inoculation of the organism in a small well, melted through the surface of a relatively large volume of agar medium contained in an Erlenmeyer flask (Canale-Parola and Wolfe, 1960a). These flask stock cultures must be kept at a temperature (e.g., 30 or 37 °C) that allows continuous growth of the cells. Cells grow only within or near the well and remain viable for approximately 2 months.

Cells of *Sarcina ventriculi* and *Sarcina maxima* retain viability for at least several years in liquid N_2 storage (Canale-Parola, 1970).

Procedures for testing special characters

The fact that cells of *Sarcina ventriculi* are surrounded by a layer of cellulose (see *Further descriptive information*, above), whereas those of *Sarcina maxima* are not, is a useful characteristic for differentiation. The following staining procedure may be used to demonstrate the presence or absence of the cellulose layer in sarcina packets (E. Canale-Parola, unpublished data).

Approximately 5 g (wet wt) of *Sarcina ventriculi* or *Sarcina maxima* cells are refluxed in 100 ml boiling 2% (w/v) KOH for 1 h to remove most of the cytoplasmic material from the cells. Then the cells are harvested by centrifugation and washed four times (centrifugation) with DW. The white, washed pellet consists of almost “empty” cells still arranged in packets. Material from the pellet, from which as much water as possible has been drained, is smeared thickly on a glass microscope slide and the staining solution applied dropwise directly on the smear.

An Iodine-Zinc chloride (I-ZnCl₂) solution used for staining is prepared as follows. Twenty grams ZnCl₂ are dissolved in 8.5 ml water and the solution is allowed to cool to room temperature. Then, iodine solution (DW, 60 ml; KI, 3 g; I, 1.5 g) is added to the ZnCl₂ solution dropwise until iodine begins to precipitate. Only a few ml of iodine solution is required. When the I-ZnCl₂ solution is added to the treated *Sarcina ventriculi* cells smeared on a glass slide, the cellulose present in *Sarcina ventriculi* packets stains blue and, consequently, the smear on the glass slide appears blue. In contrast, smears of *Sarcina maxima* cells (refluxed with KOH solution and washed as described above) remain colorless when treated with I-ZnCl₂ solution. Cellulose powder (Nutritional Biochemicals), treated with the same procedure, and untreated filter paper stain blue with the I-ZnCl₂ solution.

Smit's cellulose-staining solution (Smit, 1930) may be used instead of the I-ZnCl₂ solution. Smit's solution consists of: DW, 100 ml; KI, 26 g; I, 0.4 g; and ZnCl₂, 85 g. Prior to staining, the cells are refluxed with KOH solution, washed and smeared on a glass slide as described above. Smears of *Sarcina ventriculi* cells stained with Smit's solution become dark brown with a reddish-purple tinge. The same color appears when treated cellulose powder or untreated filter paper is stained with Smit's solution. Smears of treated *Sarcina maxima* cells remain colorless.

Ethanol, which is a major fermentation end product of *Sarcina ventriculi* but is not formed by *Sarcina maxima*, may be determined enzymically or by gas-liquid chromatography techniques. Butyrate, produced by *Sarcina maxima* but not by *Sarcina ventriculi*, and acetate (produced by both species) are assayed by gas-liquid chromatography.

Taxonomic comments

John Goodsir discovered and named *Sarcina ventriculi* in 1842 (Goodsir, 1842). Subsequently, other investigators described and cultivated various packet-forming cocci, which were assigned to the genus *Sarcina*. Some of these packet formers were aerobes (e.g., *Sarcina lutea*), others anaerobes (e.g., *Sarcina methanica*). Some of the aerobic packet-forming cocci were flagellated and formed spores (e.g., *Sarcina ureae*). In time it became evident that *Sarcina ventriculi*, and the closely related *Sarcina maxima*, are phylogenetically distant from other packet-forming cocci (Canale-Parola, 1970; Canale-Parola et al., 1967). Aerobic, non-sporeforming, nonmotile, packet-forming cocci were assigned to the genus *Micrococcus*; anaerobic, methanogenic, packet-forming cocci to the genus *Methanosarcina*; and aerobic, spore-forming sarcinae to the genus *Sporosarcina*. Only the anaerobic,

sugar-fermenting species (*Sarcina ventriculi* and *Sarcina maxima*) were retained in the genus *Sarcina* (Canale-Parola, 1970).

According to 16S rRNA sequence characterization, *Sarcina ventriculi* and *Sarcina maxima* are closely related phylogenetically to *Clostridium butyricum* and other clostridia, but it is distant from packet-forming cocci in the genera *Micrococcus*, *Methanosarcina*, and *Sporosarcina* (Fox et al., 1980). In the 16S rRNA phylogeny presented in the roadmap to this volume, *Sarcina* clusters with *Clostridium* and *Anaerobacter* in the family *Clostridiaceae*, order *Clostridiales*, and class *Clostridia* (Figure 5).

Differentiation and characteristics of the species of the genus *Sarcina*

The differential characteristics of the species of *Sarcina* are listed in Table 149. Other characteristics of the species are indicated in Table 150 and Table 151.

List of species of the genus *Sarcina*

1. *Sarcina ventriculi* Goodsir 1842, 437^{AL}

ven.tri'cu.li. L. n. *ventriculus* the stomach; L. gen. n. *ventriculi* of the stomach.

Nearly spherical cells, 1.8–2.4 µm in diameter, occurring in packets of eight to several hundred or more. Large packets (e.g., consisting of approximately 60 or more cells) tend to have an irregular or distorted appearance. Frequently, cells in these packets exhibit flattened shapes and are irregularly arranged. A fibrous layer 150–200 nm thick, composed either totally or in great part of cellulose, is present on the outer surface of the cell wall. This layer is absent in some strains. Reported to form spherical spores (Knöll, 1965). Subsurface colonies in agar media are star-shaped or irregularly cubical, and measure up to several mm in diameter. Surface colonies (anaerobic) are roundish, often with rugged edges.

Carbohydrates are fermented. Amino acids are not fermented. Carbohydrate fermentation patterns and other physiological characteristics are summarized in Table 150. The main products of glucose fermentation are ethanol, acetate, CO₂, and H₂ (Table 151). Two strains studied required for growth two vitamins (biotin, nicotinic acid and 11 amino acids (see *Further descriptive information*, above), in addition to a fermentable carbohydrate and inorganic salt.

Temperature optimum for growth is 30–37 °C.

Isolated from soil, mud, contents of diseased human stomach, rabbit and guinea pig stomach contents, elephant dung, human feces and the surface of cereal seeds.

Phase-contrast photomicrographs and electron micrographs of this species have been published (Canale-Parola, 1970; Canale-Parola et al., 1961).

DNA G+C content (mol%): 30.6 ± 1 (Bd).

Type strain: DSM 286 (ATCC 19633).

GenBank accession number (16S rRNA gene): X77838, X76649.

2. *Sarcina maxima* Lindner 1888, 54^{AL}

max'i.ma. L. sup. adj. *maximus* greatest, largest.

Nearly spherical cells, 2–3 µm in diameter, occurring in packets of eight or more. The cells lack a cellulose outer layer. Reported to form oval spores (Knöll, 1965). Subsurface colonies in agar media are cuboid with protuberances or unevenly spherical. Surface colonies (anaerobic) are roundish, often with rugged edges.

Carbohydrates are fermented. Amino acids are not fermented. Carbohydrate fermentation patterns and other physiological characteristics are summarized in Table 150. The main products of glucose fermentation are butyrate, acetate, CO₂, and H₂ (Table 151). A strain studied required for growth three vitamins (thiamine, biotin, nicotinic acid) and 14 amino acids (see *Further descriptive information*, above), in addition to a fermentable carbohydrate and inorganic salts.

Temperature optimum for growth is 30–35 °C.

Isolated from the hull or outer coat of cereal grains, such as wheat, oat, rice and rye. Fresh wheat bran has been used as a source. Also isolated from horse manure, field soil, and garden soil.

Phase-contrast photomicrographs and electron micrographs of this species have been published (Canale-Parola, 1970; Smit, 1930).

DNA G+C content (mol%): 28.6 ± 1 (Bd).

Type strain: DSM 316.

GenBank accession number (16S rRNA gene): X76650.

Genus XI. **Thermobrachium** Engle, Li, Rainey, DeBlois, Mai, Reichert, Mayer, Messner and Wiegel 1996, 1032^{VP}

JUERGEN WIEGEL

Ther.mo.bra'chi.um. Gr. adj. *thermos* hot; L. n. *brachium* arm, branch; N.L. neut. n. *Thermobrachium* referring to the branched cells observed frequently with this thermophilic bacterium.

Cells are usually **rod-shaped** and frequently **exhibit true branching**. **Gram-stain-positive**, although cells of some strains are easily decolorized. An **S-layer with a hexagonal lattice** is present. Cells are flagellated and only sluggishly motile. **Chemoorganoheterotrophic**. Habitats include anthropogenically heated environments (composts) and geothermally heated environments (hot springs and sediments) as well as mesobiotic freshwater sediments.

DNA G+C content (mol%): 30–31.

Type species: **Thermobrachium celere** Engle, Li, Rainey, DeBlois, Mai, Reichert, Mayer, Messner and Wiegel 1996, 1032^{VP}.

Taxonomic comments

The genus *Thermobrachium* with its type and only species, *Thermobrachium celere* (Engle et al., 1996), was validly pub-

lished about the same time as the genus *Caloramator* with its type species *Caloramator fervidus*. At that time, the evolutionary distance of 93.3% justified placement of the two taxa in different genera. *Caloramator* was subsequently extended by the description of two other species. The 16S rDNA sequence analyses of all the species, especially the resulting evolutionary distance to *Caloramator indicus*, suggested that *Thermobrachium celere* was within the radiation of the genus *Caloramator*. Thus, it is now assigned to the genus *Caloramator* as *Caloramator celer* comb. nov. despite the relatively large distance of some *Caloramator* species to the type species *Caloramator fervidus*. The description of *Caloramator celer* is included in the genus *Caloramator* chapter, above (Baena and Patel, 2009).

Genus XII. **Thermohalobacter** Cayol, Ducerf, Patel, Garcia, Thomas and Ollivier 2000a, 562^{VP}

JEAN-LUC CAYOL, JEAN-LOUIS GARCIA AND BERNARD OLLIVIER

Ther.mo.ha.lo.bac'ter. Gr. adj. *thermos* hot; Gr. n. *hals* salt; N.L. n. *bacter* masc. equiv. of Gr. neut. dim. n. *bakterion* small rod; N.L. masc. n. *Thermohalobacter* a thermophilic fermentative halophile.

Rod-shaped cells, generally occurring singly or in pairs, about $0.5 \times 3\text{--}8\mu\text{m}$. Motile by laterally inserted flagella. Spores are not observed under different growth conditions and at different growth phases. **Gram-stain-negative**. Obligately anaerobic. Halophilic and thermophilic; optimum growth temperature is 65 °C, optimal pH is 7.0, optimum NaCl concentration is 5%. **Chemo-organotrophic growth. Ferments sugars**. Products from glucose fermentation are acetate, ethanol, H₂, and, presumably, CO₂. External electron acceptors are not used.

DNA G+C content (mol%): 33.

Type species: **Thermohalobacter berrensis** Cayol, Ducerf, Patel, Garcia, Thomas and Ollivier 2000a, 562^{VP}.

Further descriptive information

Thermohalobacter berrensis is the only species described within the genus *Thermohalobacter* so far. It is a rod-shaped bacterium measuring $0.5 \times 3.0\text{--}8.0\mu\text{m}$ which grows singly or in pairs (Figure 135). The cells are motile with laterally inserted flagella and stain Gram-negative. Electron microscopy of thin sections of *Thermohalobacter berrensis* reveals a cell-wall ultrastructure typical of Gram-stain-negative bacteria. Despite spores not being observed under different growth conditions and at different growth phases, cells survive pasteurization at 100 °C for 20 min, thus suggesting the presence of heat-resistant forms.

Thermohalobacter berrensis does not grow in anaerobic medium that contains traces of oxygen and is therefore ascribed as a strict anaerobe. It grows at temperatures ranging from 45–70 °C, with optimum at 65 °C at pH 7.0. The isolate grows in the presence of NaCl concentrations ranging from 2–15%, with an optimum of 5% NaCl at pH 7.0 and 65 °C. Growth occurs from pH 5.2–8.8 at 65 °C with an optimum pH of 7.0. The doubling time under optimal growth conditions is 0.46 h.

Yeast extract or bio-Trypticase are required for growth on carbohydrates. *Thermohalobacter berrensis* grows on sugars, glycerol, pyruvate, and bio-Trypticase. Acetate, ethanol, H₂, and, presumably, CO₂ are produced during glucose fermentation. *Thermohalobacter berrensis* does not reduce thiosulfate, sulfate, or sulfur into sulfide.

Enrichment and isolation procedures

Enrichment and isolation should be performed using a growth medium which contains (per liter of distilled water): NH₄Cl,

FIGURE 135. Photomicrograph of *Thermohalobacter berrensis*. Bar = 10 μm.

0.1 g; K₂HPO₄, 0.3 g; KH₂PO₄, 0.3 g; MgCl₂, 2 g; CaCl₂, 0.2 g; CH₃COONa, 0.5 g; NaCl, 100 g; KCl, 4 g; glucose, 10 g; cysteine-HCl, 0.5 g; yeast extract, 1 g; bio-Trypticase, 1 g; trace mineral element solution (Imhoff-Stuckle and Pfennig, 1983), 1 ml; resazurin, 1 mg. The pH is adjusted to 7.0 with 10 M KOH, after which the medium is boiled under a stream of O₂-free N₂ gas and cooled to room temperature. Five ml or 20 ml aliquots are dispensed into Hungate tubes or serum bottles, respectively, under a stream of N₂/CO₂ (80:20 v/v) gas, and the vessels are autoclaved for 45 min at 110 °C. Prior to inoculation, Na₂S·9H₂O and NaHCO₃ are injected from sterile stock solutions to obtain a final concentration of 0.04% (w/v) and 0.2% (w/v), respectively.

For initiating enrichment cultures, a small portion of the sediment sample is inoculated into growth medium followed by incubation at 62 °C without agitation. The culture is purified by repeated use of the Hungate roll tube method (Hungate, 1969; Macy et al., 1972; Miller and Wolin, 1974) in growth medium amended with 2% (w/v) agar. Enrichment cultures are positive after 3 d of incubation at 62 °C. Colonies 1 mm in diameter develop in roll tubes after 48 h incubation at 62 °C. Single colonies are picked and ten-fold serial dilutions in roll tubes are repeated at least twice before the culture is considered pure.

Maintenance procedures

Stock cultures can be maintained on medium described by Cayol et al. (2000a) by monthly transfers. Liquid cultures retain

viability after several weeks storage at 4 °C, at ambient temperature or when lyophilized or after storage at -80 °C in the basal medium containing 20% glycerol (v/v). Viability is best maintained from mid-exponential phase cultures.

Differentiation of the genus *Thermohalobacter* from other genera

The genus *Thermohalobacter*, represented only by one species, *Thermohalobacter berrensis*, is a heterotrophic, moderately halophilic member of domain *Bacteria*. Within this domain, the main characteristic of being moderately halophilic is shared by members of the family *Halanaerobiaceae* with the exception of *Halanaerobium lacusrosei*, an extreme halophilic bacterium isolated from Retba lake in Senegal (Africa) (Cayol et al., 1995). *Thermohalobacter berrensis* is not only halophilic, but is also a strict thermophile growing optimally at 65 °C. The family *Halanaerobiaceae* is comprised exclusively of mesophilic to thermotolerant micro-organisms (Ollivier et al., 1994). *Halothermothrix orenii* is the only true thermophile belonging to this family, growing at temperatures up to 68 °C (Cayol et al., 1994) (Table 152). Due to its typical salt requirement, *Thermohalobacter* is related neither to members of the genus *Thermoanaerobacter*, which are described as halotolerant micro-organisms (Lee et al., 1993), nor to the thermophilic and hyperthermophilic members of the genus *Thermotoga*, order *Thermotogales*, which do not grow at NaCl concentrations above 6–7% (Huber et al., 1986; Windberger et al.,

TABLE 152. Salient features of *Thermohalobacter berrensis* and *Halothermothrix orenii*^a

FIGURE 136. Phylogenetic tree based on 16S rRNA gene sequence comparison and obtained by a neighbor-joining algorithm (PHYLIP package), indicating the position of *Thermohalobacter berrensensis* among the members of the cluster XII of the *Firmicutes*. These clusters are defined based on the guidelines described by Collins et al. (1994). Bootstrap values are shown at branching points. Only values above 80% were considered significant and reported. Scale bar indicates 5 nucleotide substitution per 100 nucleotides.

1989). Additionally within this order, the thermophilic *Geotoga*, *Petrotoga*, and *Marinitoga* species do not grow in the presence of 12.5% NaCl (Davey et al., 1993; Postec et al., 2005). Interestingly, the growth temperature optimum for *Thermohalobacter berrensensis* (65 °C) is higher than that of any moderately to extremely halophilic microbe reported to date including the extremely halophilic thermophilic archaeon *Methanohalobium evestigatum* (Zhilina and Zavarzin, 1987) and the moderately halophilic thermophilic bacterium, *Halothiobacillus orenii* (Cayol et al., 1994). Taking into account all of these observations, the phenotypically closest relative of *Thermohalobacter berrensensis* is *Halother-*

mothrix orenii. However, the 16S rRNA gene sequence analysis indicates that it is not a member of the *Halanaerobiaceae* but a member of cluster XII of the *Clostridiales* (Collins et al., 1994) (Figure 136). *Thermohalobacter berrensensis* also differs phenotypically from *Halothermothrix orenii* (Table 152). Cluster XII of the order *Clostridiales* comprises *Clostridium* species (*Clostridium hastiforme*, *Clostridium acidurici*, *Clostridium purinilyticum*, and *Clostridium ultunense*), *Sedimentibacter* species (*Sedimentibacter saalensis* and *Sedimentibacter hydroxybenzoicus*), *Tissierella* species (*Tissierella creatinophila*, *Tissierella creatinini*, and *Tissierella praeacuta*), *Soehngenia saccharolytica*, *Eubacterium angustum*, and *Sporanaerobacter acetigenes*. None of these species is reported as thermophilic and/or halophilic. The only moderately halophilic micro-organism so far described within the genus *Clostridium* is *Clostridium halophilum*, but it does not grow at 50 °C (Fendrich et al., 1990) and is phylogenetically related to cluster XI of the *Clostridiales* (Collins et al., 1994). The only thermophilic micro-organisms belonging to the cluster XII of this latter order are *Garciella nitratreducens* isolated from an oilfield separator (Miranda-Tello et al., 2003), and *Caloranaerobacter azorensis* isolated from a deep-sea hydrothermal vent (Wery et al., 2001) which are thermotolerant and slightly halophilic, respectively. In contrast to *Garciella nitratreducens*, *Thermohalobacter berrensensis* does not reduce thiosulfate into sulfide. *Caloranaerobacter azorensis* markedly differs from *Thermohalobacter berrensensis* by (i) its optimum NaCl concentration for growth, (ii) the end products of glucose metabolism, and (iii) having a lower G+C content in its DNA (27 mol% for *Caloranaerobacter azorensis* and 33 mol% for *Thermohalobacter berrensensis*).

Taxonomic comments

Thermohalobacter is a newly defined genus consisting of one species (*Thermohalobacter berrensensis*). Phenotypic and genotypic characteristics clearly place it within the cluster XII of the order *Clostridiales*. Within this cluster, it is the only thermophilic, moderately halophilic microbe. The isolation and characterization of more species representative of this genus should be helpful to confirm the classification of this genus.

List of species of the genus *Thermohalobacter*

1. ***Thermohalobacter berrensensis*** Cayol, Ducerf, Patel, Garcia, Thomas and Ollivier 2000a, 562^{VP}

ber.ren'sis. N.L. adj. *berrensensis* from Berre, south of France.

Cells are rods (0.5 × 3–8 μm), occurring singly or in pairs, motile by laterally inserted flagella. Spores are not observed under different growth conditions and at different growth phases. The cells stain Gram-negative. Round colonies (diameter, 1 mm) are present after 2 d of incubation at 62 °C. Chemo-organotrophic and obligately anaerobic member of the domain *Bacteria*. The optimum temperature for growth is 65 °C at pH 7.0; temperature range for growth 45–70 °C. The optimum pH is 7.0 at 65 °C; growth occurs between pH 5.2 and pH 8.8. The optimum NaCl concentration for growth is 5% at 65 °C and pH 7.0; growth occurs at NaCl

concentration ranging from 2–15%. Ferments cellobiose, fructose, glucose, maltose, mannose, mannitol, sucrose, glycerol, *N*-acetylglucosamine, starch, pyruvate, and bio-Trypticase, but not arabinose, galactose, lactose, melibiose, raffinose, rhamnose, ribose, sorbose, trehalose, xylose, glycine betaine, fatty acids (formate, acetate, fumarate, and lactate), Casamino acids, cellulose, and yeast extract. Acetate, ethanol, H₂, and, presumably, CO₂ are produced during glucose fermentation. Elemental sulfur, sulfate, and thiosulfate cannot be used as electron acceptors. Isolated from sediment of a feeding canal of a solar saltern.

DNA G+C content (mol%): 33 (HPLC).

Type strain: CTT3, CNCM 105955.

GenBank accession number (16S rRNA gene): AF113543.

Genus XIII. *Tindallia* Kevbrin, Zhilina, Rainey and Zavarzin 1999, 2^{VP} (Effective publication: Kevbrin, Zhilina, Rainey and Zavarzin 1998, 100.)

ELENA V. PIKUTA

Tin.dal'li.a. N.L. fem. n. *Tindallia* derived from the name of Brian J. Tindall, who pioneered the study of alkaliphilic micro-organisms in Lake Magadi.

Cells are **slightly curved rods**, with **rounded and slightly pointed ends** (Figure 137, top). Cells occur **singly, in pairs, or in short chains**; size is **0.4–0.7 × 1.2–5.0 μm**. **Gram-stain-positive**. **Motile**. **Asporogenous or oligospore forming**. **Endospores are round or oval and located in cells subterminally, terminally, or centrally**. **Sporangium is not swollen**. The ultrastructure of cell surfaces has **S-layers**. **Obligate anaerobes and catalase-negative**. Dissimilatory and **chemoorganoheterotrophs** with **fermentative metabolism or respiration** by the **Stikland reaction**. **Halotolerant alkaliphiles, no growth below pH 7.0**. **Obligately dependent on Na⁺ ions**. **Mesophilic**. **Acetogenic ammonifiers**. The **homoacetic or acetyl-coenzyme A-CO-dehydrogenase pathway** participates in metabolism.

DNA G+C content (mol%): 37.6–44.4.

Type species: *Tindallia magadiensis* corrig. Kevbrin, Zhilina, Rainey and Zavarzin 1999, 2^{VP} (Effective publication: *Tindallia Magadii* Kevbrin, Zhilina, Rainey and Zavarzin 1998, 100.).

Further descriptive information of the genus *Tindallia*

The first work that mentioned strain Z-7934 was published in *Current Microbiology* (Zhilina and Zavarzin, 1994), where it was described as a member of an anaerobic haloalkaliphilic microbial community from sediments of soda Lake Magadi in Kenya (Equatorial Africa). This strain was described as a primary anaerobe and dissimilatory, participating in organic decomposition on a level with proteolysis products and amino acids. A complete taxonomic description of this isolate as a new species of a new genus was published in the same journal in 1998 with the name *Tindallia magadii* (Kevbrin et al., 1998); the species name was corrected and validated as *Tindallia magadiensis* (Kevbrin et al., 1999).

The phylogenetic position for strain Z-7934^T placed it within cluster XI of the low G+C Gram-positive bacteria, as defined on the basis of 16S rDNA analyses of *Clostridium* species and related taxa (Collins et al., 1994). The 16S rRNA phylogenetic analysis presented in the roadmap to this volume classifies *Tindallia* as in the family *Clostridiaceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*.

Cell morphology of all species is similar with slight variations in sizes. Species of the genus are asporogenous or oligospore forming and motile: the genus *Tindallia* was originally described as nonsporeforming and nonmotile, but later the motile cells and spores of the type species were detected. Flagella of *Tindallia californiensis* are attached laterally (Figure 137, middle). Cells of *Tindallia texcoconensis* have peritrichous flagella.

The ultrastructure of the cell surface demonstrates the presence of S-layers: *Tindallia californiensis* APO^T has the outer S-layer with tetragonal texture (Figure 137, bottom). Cells multiply by binary fusion with the formation of two daughter cells. Cells occur singly, in pairs, or in short irregularly curved chains.

Colonies in deep agar were described for *Tindallia californiensis*; they have a typical (for anaerobes) lens shape with smooth edges, 1.0–2.2 mm in diameter, and are matt yellowish. The colonies of *Tindallia texcoconensis* are round, white in color, and 2–4 mm in diameter.

Tindallia species have a truly alkaliphilic nature, not one could grow below pH 7.0, but they are not dependent on car-

bonate ions. Previous diagnosis of *Tindallia magadiensis* tested positive for the dependence on carbonate ions, and since the experiment was performed on tris-buffered medium with different concentrations of carbonates it was concluded that strain Z-7934^T was obligately dependent upon carbonates. Comparative study of *Tindallia magadiensis* with *Tindallia californiensis* has demonstrated that both species could grow on the L-serine-buffered medium without carbonates at pH 9.0 adjusted by 6N NaOH. All three species of the genus are obligately dependent

FIGURE 137. Transmission electron microscope image of *Tindallia californiensis* strain APO^T. (top) Rod-shaped cells. Bar = 1 μm. (middle) Laterally attached flagellum. Bar = 1 μm. (bottom) Cell surface with tetragonal structure of outer S-layer.

upon Na⁺ ions and they are halotolerant with optimum NaCl at about 3–7% (w/v). The halotolerance of *Tindallia californiensis* is twice as high of *Tindallia magadiensis*: it is capable of growing at 20% (w/v) NaCl, but the maximum concentration of NaCl for *Tindallia magadiensis* is only 10% (w/v). *Tindallia texcoconensis* has maximum of NaCl concentration for growth at 25% (w/v). Members of the genus are mesophiles with an optimum at around 35 °C and maximum temperature of 47–48 °C. The temperature characteristic is significantly different at the minimum values: *Tindallia californiensis* could grow at 10 °C, but *Tindallia magadiensis* has a minimum temperature growth at 19 °C and cells of *Tindallia texcoconensis* have minimum growth at 25 °C.

Concerning the oxygen requirement, *Tindallia* species are strictly anaerobic and catalase-negative. Species of the genus are acetogens and have a fermentative metabolism with the functioning of the homoacetic or acetyl-coenzyme A-CO-dehydrogenase pathway. The key enzymes of this pathway CO-dehydrogenase and hydrogenase with their high activity were detected in cells of *Tindallia magadiensis* and *Tindallia californiensis*. The species specialize in using proteolysis products as peptone, bacto-tryptone, Casamino acids, yeast extract, some amino acids, and pyruvate. It means that in bacterial communities they could play the role of primary anaerobes and dissipotrophs. Species of the genus cannot use sugars and alcohols. Species of the genus are capable of respiration by the Stickland reaction, but the lists of amino-acid pairs are different (Table 153 and Table 154)

Antibiotic susceptibility was checked for two species and it was shown that *Tindallia californiensis* was sensitive to ampicillin, tetracycline, gentamicin, and chloramphenicol. However, the strain was resistant to kanamycin (typically for anaerobes) and to rifampin. *Tindallia magadiensis* was sensitive to ampicillin, tetracycline, gentamicin, chloramphenicol, and rifampin, but resistant to kanamycin.

Ecology for the *Tindallia* species is similar: they all were isolated from soda lakes but geographically distant continents:

Africa and North America. They could be found in anaerobic layers of mud sediments in Lake Magadi (Kenya), soda Mono Lake (North California), and in underground water near athalassic saline alkaline Texcoco lake in Mexico.

The non-validly published species “*Clostridium aminovorans*”, “*Clostridium bogorii*”, and “*Clostridium alcaliphilum*” by 16S rRNA sequence analysis have about 99.1% similarity to *Tindallia californiensis* (Figure 138); in the future these species probably will be described as *Tindallia* species. From validly published taxa, the most closely related to *Tindallia californiensis* after *Tindallia magadiensis* (with a 98.49% similarity) are: *Natronincola histidinovorans* (90.35% similarity), *Clostridium felsineum* (90.26% similarity), and *Clostridium formicoaceticum* with *Clostridium halophilum* (less than 90% similarity). *Tindallia texcoconensis* has 97.5% similarity with *Tindallia californiensis* and 96.4% with *Tindallia californiensis* (Figure 139).

The DNA–DNA hybridization between *Tindallia magadiensis* and *Tindallia californiensis* showed 55% homology, and between *Tindallia texcoconensis* and *Tindallia californiensis* it was 42.2%. The G+C content of the DNA of *Tindallia magadiensis* is 37.6 mol% (by T_m), for *Tindallia californiensis* it is 44.4 ± 0.2 mol% (by HPLC), and for *Tindallia texcoconensis* it is 40.0 mol% (by HPLC).

Pathogenicity, antigenic structure, mutants, plasmids, phages, and phage typing for all species were not studied.

Enrichment and isolation procedures

Anaerobic techniques should be used for *Tindallia* cultures. Isolation of species was performed with a selective medium at pH 10.0–10.3, and pure cultures were received by the dilution method on peptone-containing media. The medium contains (per l): NaCl, 30.0 g; Na₂CO₃, 2.76 g; NaHCO₃, 24.0 g; KCl, 0.2 g; K₂HPO₄, 0.2 g; MgCl₂·6H₂O, 0.1 g; NH₄Cl, 1.0 g; Na₂S·9H₂O,

Source of isolation (habitat)	Anaerobic sediments of Lake Magadi (Kenya)	Anaerobic sediments of Mono Lake (California)	Underground water sample near Texcoco lake in Mexico
Type strain	Z-7934 ^T (DSM 10318)	APO ^T (ATCC BAA-393, DSM 14871, CIP 107910)	IMP-300 ^T (DSM 18041, JCM 13990)

^a+, Good growth; –, no growth; (+), weak growth; ND, not determined.

^bMotility was observed in the culture from DSM 10318^T, but in original article strain Z-7934^T was described as nonmotile.

^cGrowth required 0.5–1.0 g/l of yeast extract.

0.4 g; resazurin, 0.001 g; yeast extract, 0.5; peptone, 5.0 g; vitamin solution (Wolin et al., 1963), 2 ml; and trace mineral solution (Whitman et al., 1982), 1 ml. The final pH is adjusted to 9.0–9.5 by 6 M NaOH. High-purity nitrogen is used for the gas phase. Colonies could be obtained on 3% agar medium by the “roll tubes” method, but carbonate solutions are added separately after sterilization. As a negative control for detection of culture purity (test on contamination), the media (pH 7.0) with a mixture of glucose, peptone, and yeast extract could be applied.

Maintenance procedures

The cultures of both species can be maintained on a liquid or agar-containing anaerobic medium for 4–5 months. The best method for the long-term preservation of *Tindallia* cultures is lyophilization.

Procedures for testing special characters

The detection of a mesophilic nature, the haloalkaliphilic features, and a relationship to oxygen have been performed by traditional techniques. Since the spore formation for species *Tindallia* has

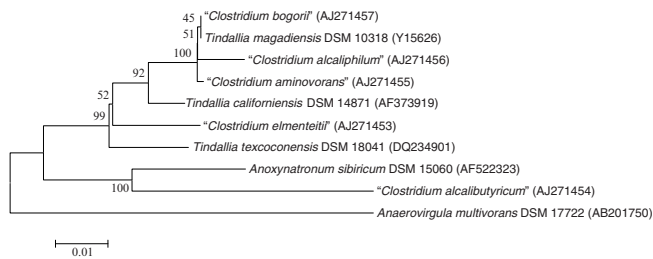

FIGURE 138. Evolutionary relationships in the genus *Tindallia* and closest relatives (including non-validated published names). The bootstrap consensus tree inferred from 2000 replicates is taken to represent the evolutionary history of the taxa analyzed. The percentages of replicate trees in which the associated taxa clustered together in the bootstrap test (2000 replicates) are shown next to the branches.

been detected in exclusively rare cases it requires specific procedures, as an action by acetate buffer (pH 4.0), or by antibiotics, or by transferring cultures from carbonate media to serine-buffered medium without peptone. Isolation of DNA and amplification were performed by the usual methods: phenol/chloroform extraction and PCR (by *Thermus aquaticus* DNA thermostable polymerase).

Differentiation from closely related taxa

Phenotypic and genotypic differences of the genus *Tindallia* and other related taxa shown in Table 155.

Taxonomic comments

The genus *Tindallia* includes three species, *Tindallia magadiensis*, *Tindallia californiensis*, and *Tindallia texcoconensis*. These species

FIGURE 139. Evolutionary relationships of the genus *Tindallia* and closely related species (validly published names only). The bootstrap consensus tree inferred from 2000 replicates is taken to represent the evolutionary history of the taxa. The percentages of replicate trees in which the associated taxa clustered together in the bootstrap test (2000 replicates) are shown next to the branches.

have a 98.2% 16S rDNA sequence similarity by analysis but have DNA–DNA hybridization homology of 55%; this and differences in physiological properties allowed them to be separated into different species.

Hoover (National Space Sciences and Technologies Center/NASA) and D. Marsic (University of Alabama in Huntsville) for assistance.

List of species of the genus *Tindallia*

- Tindallia magadiensis*** corrig. Kevbrin, Zhilina, Rainey and Zavarzin 1999, 2^{VP} (Effective publication: *Tindallia magadii* Kevbrin, Zhilina, Rainey and Zavarzin 1998, 100.) ma.ga.di.en'sis. N.L. fem. adj. *magadiensis* pertaining to Lake Magadi in Kenya, equatorial Africa.

Data are from Kevbrin et al. (1998), Pikuta et al. (2003b). Slightly curved rods, 0.5–0.6 (1.2–2.5 μm in size, occurred singly, in pairs, and in short chains. Cells are Gram-stain-positive and motile. Oligospore-forming; forms oval or round endospores. Strictly anaerobic; sulfide is needed only as a reductant.

Mesophilic. Grows at 19–47 °C, with an optimum at 37 °C. Obligate alkaliphile that cannot grow at pH 7.0; grows in a pH range of 7.5–10.5 with an optimum 8.5. CO₃²⁻ is obligately required. Halotolerant, has optimum growth at 3% NaCl, tolerant to no more than 10% NaCl. Requires Na⁺ ions, no growth at 0% NaCl. Chemoorganoheterotrophic. Fermentative, nonhydrolytic, growth on proteolysis products as peptone, bacto-tryptone, yeast extract, Casamino acids, gluconate, pyruvate, citrate, 2-oxoglutarate, 2,3-butanediol, uracil, and amino acids (arginine, ornithine, citrulline, histidine, aspartate, glutamate, glutamine, serine, threonine, glycine). Production of ammonium from arginine and compounds of the ornithine cycle, which are preferred substrates. Ammonium is stimulatory at low concentrations but is inhibitory at concentrations over 9 mM and at high pH. The

major fermentation product is acetate. Minor end products are formate, propionate, isovalerate, and hydrogen depending on the substrate. Stickland reaction performs on the following amino acids pairs: L-tryptophan + L-valine; glycine + L-alanine; glycine + L-valine; glycine + L-leucine; glycine + isoleucine; L-proline + L-valine; L-proline + L-leucine; L-proline + L-isoleucine. Reduces DMSO to DMS and Fe(III) to Fe(II). For anabolic needs they utilize amino acids, do not require vitamins. Resistant to kanamycin, but sensitive to ampicillin, rifampin, tetracycline, gentamicin, and chloramphenicol.

Habitat: anaerobic sediments of soda Lake Magadi, Kenya (equatorial Africa).

DNA G+C content (mol%): 37.6 (*T_m*).

Type strain: Z-7934, DSM 10318.

GenBank accession number (16S rRNA gene): Y15626.

- Tindallia californiensis*** Pikuta, Hoover, Bej, Marsic, Detkova, Whitman and Krader 2003b, 1701^{VP} (Effective publication: Pikuta, Hoover, Bej, Marsic, Detkova, Whitman and Krader 2003a, 333.) ca.li.for.nien'sis. N.L. fem. adj. *californiensis* pertaining to California, the region where Mono Lake is located, from which this organism was isolated.

Data are from Pikuta et al. (2003b). Slightly curved rods, motile with single laterally attached flagellum; cells sizes are between 0.55 and 0.7 μm wide and 1.7 and 3.0 μm long. Gram-

^fHomoacetogen.

stain-positive structure of cell wall. Oligospore forming (central or subterminal location) without swelling of sporangium.

Haloalkaliphilic: the pH range for growth is 8.0–10.5, with optimum growth at pH 9.5. Growth depends on Na⁺ but not CO₃²⁻ ions. Range of NaCl is >1–20% (w/v) with optimum growth at 3–5% (w/v). Mesophilic: the temperature range for growth is 10–48 °C, with the optimum being 37 °C.

Strictly anaerobic, catalase-negative, and does not reduce sulfate. Chemorganoheterotroph. Using peptone, bacto-tryptone, Casamino acids, yeast extract, L-serine, L-lysine, L-histidine, L-arginine, pyruvate, and citrate as substrates. Capable of growth by performing the Stickland reaction on the following amino acid pairs: L-proline + L-alanine; glycine + L-alanine; glycine + L-leucine; and L-tryptophan + L-valine. Main end product is acetate; minor end products are propionate, lactate, and ethanol. Requires yeast extract for growth (on citrate no less than 0.5–1.0 g/l). Resistant to kanamycin and rifampin, but sensitive to ampicillin, tetracycline, gentamicin, and chloramphenicol.

Habitat: isolated from the mud sediments of the hypersaline, meromictic, alkaline Mono Lake in California, USA.

DNA G+C content (mol%): 44.4 (HPLC).

Type strain: APO, DSM 14871, CIP 107910, ATCC BAA-393.

GenBank accession number (16S rRNA gene): AF 373919.

3. *Tindallia texcoconensis* Alazard, Badillo, Fardeau, Cayol, Thomas, Roldan, Tholozan and Ollivier 2009, 1555^{vp} (Effective publication: Alazard, Badillo, Fardeau, Cayol, Thomas, Roldan, Tholozan and Ollivier 2007, 38.)

tex.co.con.en'sis. N.L. adj. *texcoconensis* pertaining to Texcoco lake in Mexico, from which this micro-organism was isolated.

Data are from Alazard et al. (2007). Thin straight rods, motile by peritrichous flagella; with sizes 0.4–0.6×3.0–5.0 μm. Gram-stain-positive. Asporogenous. Strictly anaerobic.

Haloalkaliphilic: the pH range for growth is 7.5–10.5, with optimum growth at pH 9.5. Obligately depends on Na⁺ ions. Range of NaCl is 25–250 g/l with optimum growth at 50–100 g/l. Mesophilic: the temperature range for growth is 25–45 °C, with the optimum at 35 °C.

Under optimal growth conditions, the generation time is 28 h. Chemorganoheterotroph. Fermentative; uses only a few organic compounds as substrates: peptone, Casamino acids, arginine, ornithine, alanine, pyruvate, and citrate. Reduces Fe(III) to Fe(II) (with peptone as electron donor), but incapable of dissimilatory reduction of nitrite, nitrate, or thiosulfate and sulfate. Capable of respiration by performing the Stickland reaction on the following amino acid pairs: L-leucine + L-proline, L-leucine + L-tryptophan, L-isoleucine + glycine, L-isoleucine + L-proline, and L-isoleucine + L-tryptophan. Yeast extract stimulate the growth. The main products of amino acids fermentation were acetate, propionate and hydrogen. With peptone as substrate, isovalerate was detected, ethanol was as minor end product.

Source: underground water sample near the athalassic saline alkaline Texcoco lake in Mexico.

DNA G+C content (mol%): 40.0 (HPLC).

Type strain: IMP-300, DSM 18041, JCM 13990.

GenBank accession number (16S rRNA gene): DQ234901.

Other bacteria

Figure 138 shows a phylogenetic tree with three closely related, but not validly named, "*Clostridium*" species. These three species were mentioned in a paper in *Extremophiles* journal (Jones et al., 1998). In the future they could be described as a species of *Tindallia*.

Family II. **Eubacteriaceae** fam. nov.

WOLFGANG LUDWIG, KARL-HEINZ SCHLEIFER AND WILLIAM B. WHITMAN

Eu.bac.te.ri.a'ce.ae. N.L. neut. n. *Eubacterium* type genus of the family; suff. *-aceae* ending denoting family; N.L. fem. pl. n. *Eubacteriaceae* the *Eubacterium* family.

The family *Eubacteriaceae* is circumscribed for this volume on the basis of phylogenetic analyses of the 16S rRNA gene sequences and includes the genus *Eubacterium* and its close relatives. However, large numbers of validly published species have historically been misclassified within this genus. They continue to be described in the *Eubacterium* chapter although, based on their phylogenetic assignment, they belong to other families (Wade, this volume). More recent investigations suggest that the genus *Eubacterium* should be restricted to the type species *Eubacterium limosum* and its close relatives, such as *Eubacterium aggregans*, *Eubacterium barkeri*, and *Eubacterium callanderi*.

The family is then restricted to genera related to these species, such as *Acetobacterium*, *Alkalibacter*, *Anaerofustis*, *Pseudoramibacter*, and possibly *Garciella*. The family *Eubacteriaceae* is then composed of Gram-stain-positive rods, which are frequently thin (~0.5 µm). Formation of endospores is rare. May be motile by a single flagellum or nonmotile. Obligately anaerobic, catalase-negative. Chemo-organotrophs, many of which ferment sugars and utilize proteinaceous nitrogen sources. Mesophilic to moderately thermophilic. Neutrophilic to alkaliphilic. Some species are halotolerant.

Type genus: Eubacterium Prévot 1938, 294^{AL}.

Genus I. **Eubacterium** Prévot 1938, 294^{AL}

WILLIAM G. WADE

Eu.bac.te'ri.um. Gr. pref. *eu-* good-, well-, beneficial (not as opposed to pseudo-); Gr. neut. dim. n. *bakterion* a small rod; N.L. neut. n. *Eubacterium* beneficial bacterium.

Uniform or pleomorphic **nonspore-forming**, Gram-stain-positive **rods**. Nonmotile or motile. **Obligately anaerobic**. **Chemo-organotrophs**, saccharoclastic or nonsaccharoclastic. Usually **produce mixtures of organic acids from carbohydrates or peptone, often including** large amounts of **butyric, acetic, or formic acids**. Do not produce:

1. Propionic as a major acid product (see *Propionibacterium*).
2. Lactic as the sole major acid product (see *Lactobacillus*).
3. Succinic (in the presence of CO₂) and lactic acids with small amounts of acetic or formic acids (see *Actinomyces*).
4. Acetic and lactic (acetic > lactic) acids, with or without formic acid, as the sole major acid products (see *Bifidobacterium*).

DNA G+C content (mol%): 47 (T_m).

DNA G+C content (mol%) of the other species examined: 30–57 (determined by a variety of methods).

Type species: Eubacterium limosum (Eggerth 1935) Prévot 1938, 295^{AL} (*Bacteroides limosus* Eggerth 1935; *Butyribacterium rerrgeri* Barker and Haas 1944, 303).

Further descriptive information

The species and strains within species vary in sensitivity to oxygen; some can be cultured only in prereduced media. Catalase usually is not produced (trace amounts are detected in some strains). Hippurate usually is not hydrolyzed. Growth usually is most rapid at 37°C and pH near 7.

Found in cavities of man and other animals, animal and plant products, infections of soft tissue, and soil. Some species may be pathogenic.

Enrichment and isolation procedures

Strains of *Eubacterium* species found in clinical infections can be isolated on usual complex media appropriate for culture of anaerobes. Such media include blood agar plates or pre-re-

duced media in roll tubes made with a peptone base including or supplemented with 0.5% (w/v) yeast extract, 0.2% glucose, 0.001 µl/ml vitamin K₁, and 0.005 µg/ml (w/v) hemin. Species from the rumen or feces usually are isolated in rumen fluid-glucose-cellobiose agar (RGCA), RGCA supplemented with 1% peptone, or similar medium containing hemin and volatile fatty acids. The addition of 0.5% arginine to culture media stimulates the growth of a number of species. Some rumen bacteria grow better in media containing 1,4-naphthoquinone than in media with menadione, vitamin K₁, or vitamin K₅ (Gomez-Alarcon et al., 1982). Although this effect was observed with a Gram-stain-negative anaerobe (*Succinivibrio dextrinosolvens*), it also might apply to the Gram-stain-positive anaerobes.

Maintenance procedures

Lyophilization of cultures in the early stationary phase of growth in a medium containing no more than 0.1–0.2% fermentable carbohydrate is recommended for long-term storage of most strains. For short-term storage, cultures should be grown in a nutritionally adequate medium containing no, or minimal, fermentable carbohydrate and stored at room temperature (~22°C). Saccharoclastic strains should be transferred every 7–10 d, nonsaccharoclastic strains every 2–3 weeks.

Procedures and methods for characterization tests

The description given here is taken from the previous edition of the *Manual* (Moore and Holdeman Moore, 1986). These remain the most robust methods for use in the characterization of this group of organisms. Some *Eubacterium* species require specific nutrients and conditions for growth; these are given in the species descriptions, where appropriate.

Use of heavy inoculum (~5% v/v of broth culture) of a young culture (late log or early stationary phase of growth) gives the most reliable results for biochemical reactions based upon growth of the organism in the substrate. Results of tests for con-

stitutive enzymes with heavy inocula on dehydrated substrates may differ from results based upon growth of the organism in the substrate where adaptive enzymes are also detected. Unless otherwise cited, the characteristics listed here for the species were determined with prereduced anaerobically sterilized media by the methods described in Holdeman et al. (1977), and susceptibility to antimicrobial agents was tested by the broth-disk method of Wilkins and Thiel (1973). The basal prereduced peptone-yeast extract (PY) medium contained (per 100 ml): 0.5 g trypticase, 0.5 g peptone, 1 g yeast extract, 100 µg vitamin K₁, 500 µg hemin, 0.05 g cysteine hydrochloride, and 4 ml salts solution (0.02% anhydrous CaCl₂, 0.02% anhydrous MgSO₄, 0.1% K₂HPO₄, 0.1% KH₂PO₄, 1% NaHCO₃, and 0.2% NaCl).

Morphology and Gram reaction. For determination of Gram reaction, a buffered Gram's stain (such as Kopeloff's modification) of cells from young cultures (exponential phase of growth) is recommended. Cells of many Gram-stain-positive species stain Gram-negative in older cultures or where acid has been produced in the culture medium.

Hydrogen production. H₂ production was determined by gas chromatography of the headspace gas of cultures grown in tubes closed with rubber stoppers (Holdeman et al., 1977). Production of H₂ may not disrupt the agar in PY-glucose (PYG) agar deep cultures.

Gas production. Gas production was determined by disruption of agar in loosely covered PYG agar deep cultures. Accumulation of small (lenticular) bubbles near the colonies in the agar deep tube was recorded as "1" gas, a small split of the agar column across the tube as "2" gas, agar separated and displaced in one or more places as "3" gas, and agar forced to the top of the tube as "4" gas.

Esculin hydrolysis and esculin fermentation. These are independent reactions. Hydrolytic products are detected by the appearance of a black color upon addition of ferric ammonium citrate reagent to esculin-PY broth cultures. Acid production is determined by pH measurement.

Indole. Cultures in media containing sufficient tryptophan (chopped meat medium, tryptone-yeast extract medium, etc.) and no fermentable carbohydrate are required. The culture medium should be extracted with xylene and the reagent (either Ehrlich's or Kovac's) poured down the side of the tube to layer next to the xylene. Do not shake the tube after the reagent has been added. Alternatively, a loopful of growth from a pure culture can be smeared on filter paper saturated with 1% *p*-dimethylaminocinnamaldehyde in 10% (v/v) HCl (Sutter et al., 1980). Development of a blue color indicates indole. This method may not detect weak indole production.

Gelatin digestion. Incubated cultures of PY medium containing 10% gelatin and 1% glucose and uninoculated tubes of the same medium are chilled until the originally liquid controls are solid (about 15 min at 4°C). Failure of the gelatin culture to solidify at 4°C indicates complete digestion (+). Liquefaction of cultures at room temperature within 30 min, or in less than half the time of the control tube, indicates partial liquefaction (w).

Milk proteolysis. Acid production in milk often causes protein coagulation. The curd may or may not show evidence of streaks caused by evolution of gas. Shrinking of the curd may leave a clear whey. This liquid is sometimes mistaken

for digestion (proteolysis) of the milk. Digestion of curd is evidenced by dissolution of the curd (first) and increasing turbidity of the whey and often takes many days. Digestion may occur without previous curd formation and results (usually slowly) in clear liquid after extended incubation (up to 3 weeks). (*Clostridium sporogenes* is a good positive control culture for milk proteolysis.)

Acid production. Positive reactions listed for carbohydrate fermentation represent a pH below 5.5 and a decrease in pH of at least 0.5 pH units below the control PY basal medium culture. Weak (w) acid production represents a pH of 5.5–5.9 and at least 0.3 pH units below the PY culture control. A pH of 5.9 or above, or within 0.3 pH unit of the PY control culture pH, is considered negative. When in doubt, examination of the amount of growth in the sugar-containing medium vs that in medium without sugar can help in interpretation of weak reactions, i.e., with slight pH decrease, if growth is much better in the sugar-containing medium, the carbohydrate probably was fermented. For rapid-growing saccharoclastic species, the final pH is reached after incubation for 18–24 h in nutritionally adequate media. Uninoculated xylose and arabinose, under CO₂, are often pH 5.9. For cultures in these media, a final pH of 5.4 or below is considered strong acid production.

Differentiation of the genus *Eubacterium* from other genera

The genera of anaerobic, nonspore-forming, Gram-stain-positive, rod-shaped bacteria are differentiated according to the major metabolic pathways and products of these organisms as described above. The current classification, based on assignment of species to the genus *Eubacterium* by a process of elimination from other anaerobic genera, has led to a taxon that includes somewhat diverse but well-recognized species in three subgroups: those that produce butyric acid, usually in combination with other volatile fatty acids and sometimes with alcohols; those that produce various combinations of lactate, acetate, and formate together with H₂ gas; and those that produce little if any detectable fermentation acid. Hydrogen gas is not produced by anaerobic species or strains of *Lactobacillus*, *Bifidobacterium*, or *Actinomyces* that may also produce combinations of lactate, acetate, and formate. The genus *Eubacterium* includes a wide range of species, many of which are phylogenetically distant from each other. Although previously the genus has served a useful purpose for effective scientific communication, clarification of the taxonomy is now required, particularly the relationships between members of this and other genera. The establishment of a robust taxonomy will allow the determination of the relationship between phylogeny and function and further understanding of the role of these organisms in bacterial communities in the environment and associated with mammalian hosts.

All descriptions are based on strains in which no spores have been detected. Heat-resistant spores, often difficult to detect, have been found in organisms similar to some described species, especially motile or filamentous species; these strains are members of the genus *Clostridium*.

Taxonomic comments

The genus *Eubacterium* is highly heterogeneous, largely because, as mentioned above, it is defined by default. Phylogenetic studies have shown that species within the genus are widely distributed among the phylum *Firmicutes*. Indeed, some taxa have even been found within the *Actinobacteria*, such as the former

Eubacterium lentum, now renamed *Eggerthella lenta* (Wade et al., 1999a). Other novel genera within the *Actinobacteria*, formerly classified as “*Eubacterium*”, include *Slackia* (Wade et al., 1999a) and *Cryptobacterium* (Nakazawa et al., 1999, 2000). However, 16S rRNA gene sequence analysis indicates that 42 of the 44 current *Eubacterium* species fall within the phylum *Firmicutes*. The phylogenetic position of *Eubacterium coprostanoligenes* remains to be determined while that of *Eubacterium combesii* is uncertain. A 16S rRNA gene sequence for this species has been deposited in GenBank under the accession number L34614. Comparative analysis of this sequence indicates that *Eubacterium combesii* is closely related to members of the genus *Propionibacterium*. However, since *Eubacterium combesii* does not produce propionic acid as a major end product of metabolism, this identification should be regarded with caution.

It has been suggested that *Eubacterium sensu stricto* should be restricted to *Eubacterium limosum*, the type species, *Eubacterium callanderi*, and *Eubacterium barkeri* (Willems and Collins, 1996). Phylogenetic analysis suggests that these species should be joined by *Eubacterium aggregans* (Figure 140), although the G+C content of its DNA at 55 mol% is significantly different from those of *Eubacterium limosum*, *Eubacterium barkeri*, and *Eubacterium callanderi* at 47–48 mol% (Mechichi et al., 1998).

The remaining *Eubacterium* species should therefore be incorporated into either existing or novel genera. Many species have, as their closest phylogenetic relatives, members of the genus *Clostridium*, another highly heterogeneous genus. One of the principal definitions for *Clostridium* is the formation of spores. However, many lineages within the *Firmicutes* contain both spore-forming and nonspore-forming taxa which suggests that the formation of spores is not a reliable evolutionary marker. It could be that the ability to form spores has been acquired by horizontal gene transfer or that some nonspore-forming species have nonfunctioning sporulation genes. Whatever the reason, if phylogeny is used as a basis for taxonomy, the importance of spore formation as a taxonomic character should be downplayed.

Eubacterium angustum is most closely related to *Clostridium purinilyticum* and both species are obligate purine fermenters that produce acetate, formate, CO₂, and ammonia as metabolic end products. However, despite their phenotypic similarities, they share only 92% 16S rRNA gene sequence similarity, and the G+C content of their DNA differs by 11 mol%: 40 mol% for *Eubacterium angustum* and 29 mol% for *Clostridium purinilyticum*. Further work is required to determine if these two species should be combined in a single novel genus.

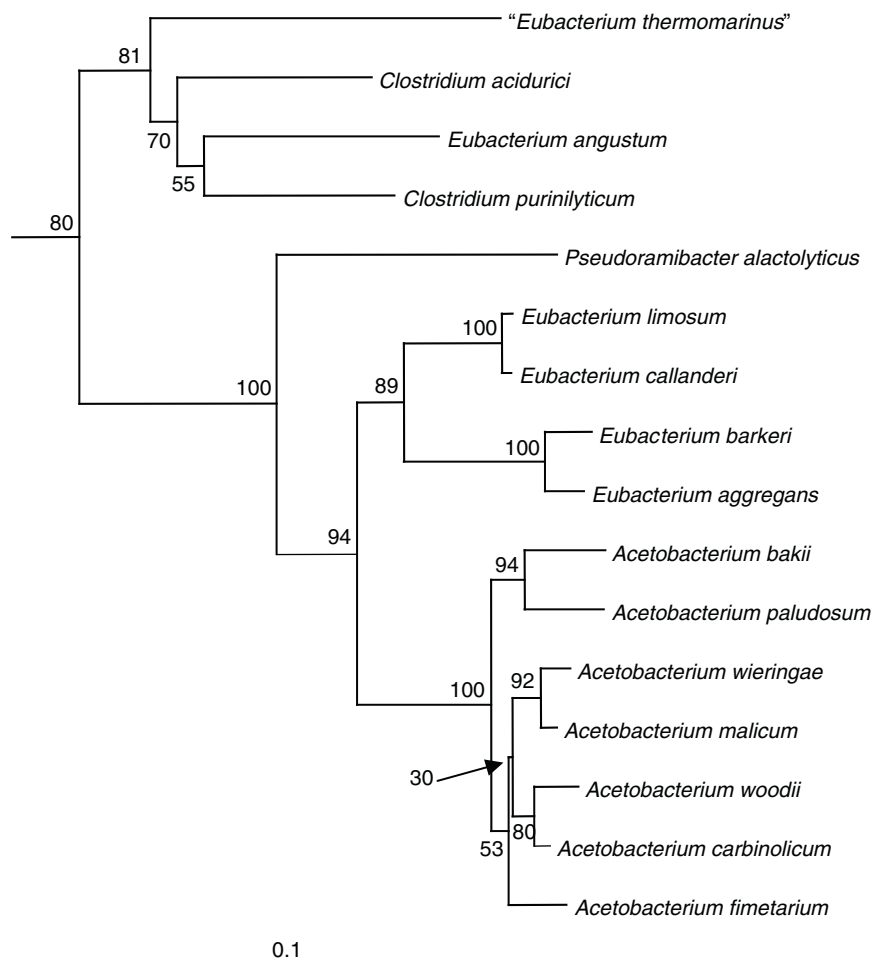

FIGURE 140. Phylogenetic tree based on 16S rRNA gene sequence comparisons over 1354 aligned bases showing relationship between *Eubacterium limosum* and related species. Tree was constructed using the neighbor-joining method following distance analysis of aligned sequences. Numbers represent bootstrap values for each branch based on data for 100 trees.

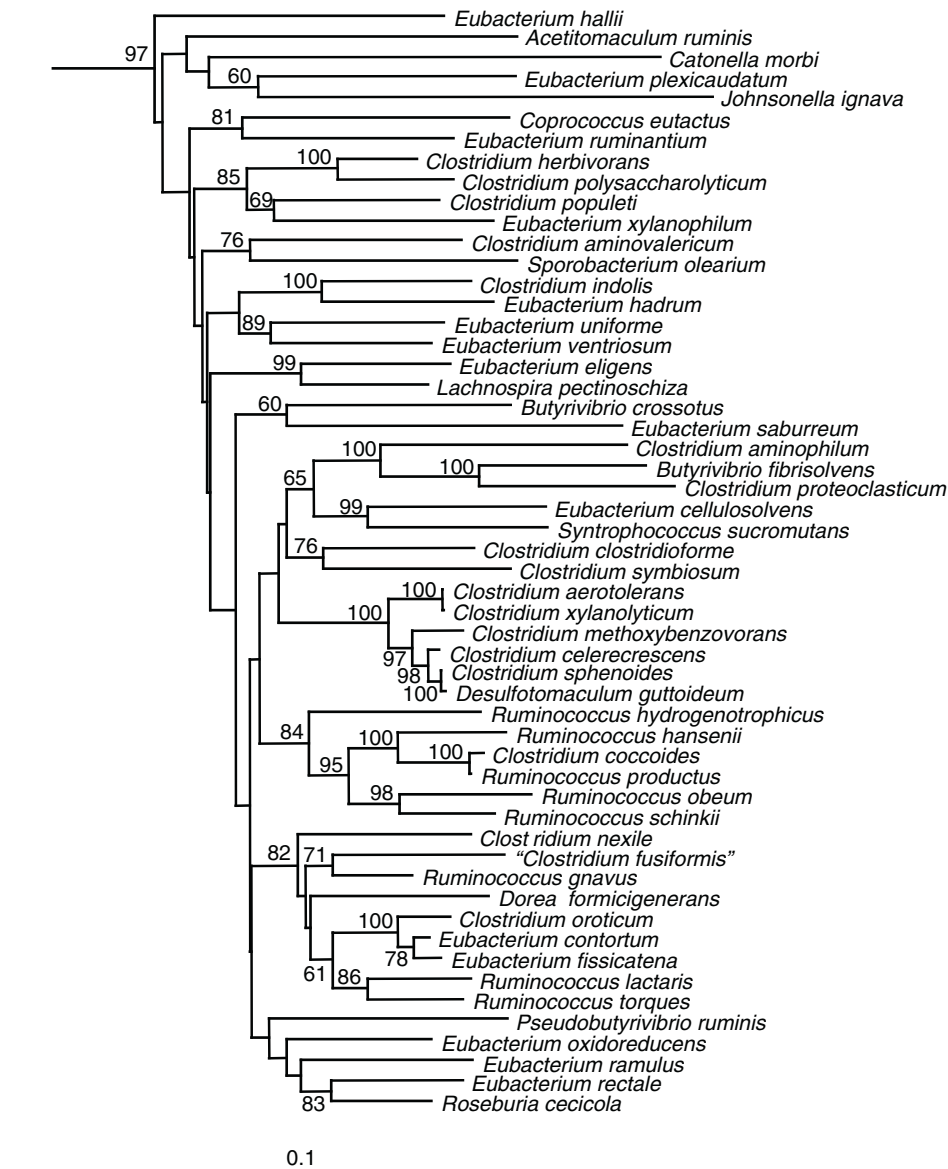

FIGURE 141. Phylogenetic tree based on 16S rRNA gene sequence comparisons over 1230 aligned bases showing relationship between *Eubacterium cellulosolvens* and related species. See legend to Figure 140 for methodology and bootstrap labels.

Figure 141 shows the phylogeny of 15 *Eubacterium* species, all of which can be provisionally assigned to the family *Lachnospiraceae*. *Eubacterium contortum* and *Eubacterium fissicatena* form a tight cluster with *Clostridium oroticum*. These three species are phenotypically similar, all producing acetate, formate, and ethanol as principal metabolic end products and the G+C content of their DNA is in the range of 44–45 mol%. A new genus should be created to include these species.

A looser phylogenetic group is formed by *Eubacterium oxidoreducens*, *Eubacterium ramulus*, *Eubacterium rectale*, *Roseburia cecicola*, and *Roseburia intestinalis* (not shown). All these species produce butyrate and with the exception of *Eubacterium oxidoreducens* are saccharolytic. The taxonomic relationships among members of this group are discussed by Duncan et al. (2002); it would appear that some, at least, should be brought together in a new genus.

Eubacterium eligens and *Lachnospira pectinoschiza* cluster together in the phylogenetic tree and are both motile rods with peritrichous flagella that require fermentable carbohydrate for good growth in broth cultures. It would appear then that *Eubacterium eligens* should be transferred to the genus *Lachnospira*.

The remaining species in this group, *Eubacterium cellulosolvens*, *Eubacterium hallii*, *Eubacterium indolis*, *Eubacterium plexicaudatum*, *Eubacterium ruminantium*, *Eubacterium saburreum*, *Eubacterium uniforme*, *Eubacterium ventriosum*, and *Eubacterium xylanophilum* appear to be sufficiently distinct (on the basis of phenotypic and phylogenetic evidence) from other named taxa to warrant the creation of a novel genus for each one. Polyphasic taxonomic studies are required to confirm this.

The phylogeny of the mainly oral human species related to *Eubacterium minutum*, within the family *Eubacteriaceae*, is shown in Figure 142. On the basis of their phylogeny and phenotypes,

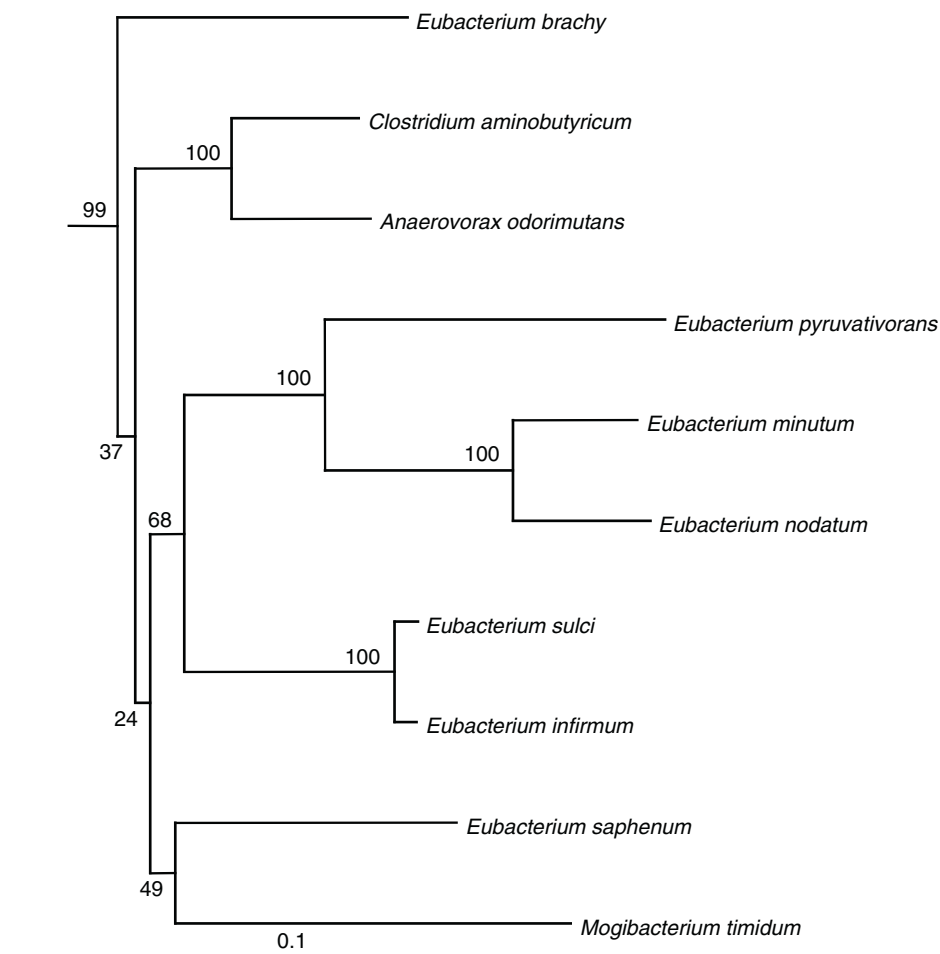

FIGURE 142. Phylogenetic tree based on 16S rRNA gene sequence comparisons over 1238 aligned bases showing relationship between *Eubacterium minutum* and related species. See legend to Figure 140 for methodology and bootstrap labels.

novel genera could be created for the majority of the *Eubacterium* species here with the exception of the pairs of species *Eubacterium minutum* and *Eubacterium nodatum*, and *Eubacterium sulci* and *Eubacterium infirmum*, which are closely related. The former *Eubacterium* species, *Mogibacterium timidum* (Nakazawa et al., 2000), belongs to this group.

Eubacterium acidaminophilum, *Eubacterium tenue*, and *Eubacterium yurii* fall into the clostridial cluster XI described by Collins et al. (1994) (Figure 143). *Eubacterium acidaminophilum* is most closely related to *Clostridium litorale* while *Eubacterium yurii* clusters with, but is distinct from, the genus *Filifactor*. *Eubacterium tenue* is closely related to *Clostridium ghonii* and *Clostridium sordellii*; they produce similar metabolic end products and the DNA of *Clostridium ghonii* and *Clostridium sordellii* have similar G+C contents (26–27 mol%). The G+C content of the DNA of *Eubacterium tenue* has not been determined. Comparative genetic and phenotypic studies are required to determine whether these species constitute a novel genus.

Four species including *Eubacterium bifforme*, *Eubacterium cylindroides*, *Eubacterium dolichum*, and *Eubacterium tortuosum* fall within the family *Erysipelotrichaceae* (Figure 144). *Eubacterium bifforme* and *Eubacterium cylindroides* form a cluster with *Streptococcus pleomorphus*, while *Eubacterium dolichum* and *Eubacterium*

tortuosum are grouped with *Clostridium innocuum*. As is the case with many *Eubacterium* species, additional phenotypic and genetic characterization is required to confirm the validity of the phylogenetic grouping.

Eubacterium budayi, *Eubacterium moniliforme*, *Eubacterium multiforme*, and *Eubacterium nitritogenes* are found in clostridial Cluster I (Collins et al., 1994) and are related to *Clostridium absonum* and *Clostridium barati* (Figure 145). The relationship between *Eubacterium budayi* and *Eubacterium nitritogenes* is not clear as, phenotypically, they are virtually indistinguishable. *Eubacterium tarantellae* is a member of the same cluster and most closely related phylogenetically to the genus *Sarcina* but is phenotypically quite distinct.

Eubacterium desmolans, *Eubacterium plautii*, and *Eubacterium siraeum* cluster in two branches of a group related to *Clostridium leptum* and which includes a number of *Ruminococcus* species (Figure 146). *Eubacterium plautii* and *Clostridium orbiscindens* share 99% 16S rRNA gene sequence identity; further studies are required to determine if they are the same species. *Eubacterium desmolans* and *Eubacterium siraeum* have no close relatives and each would appear to represent a novel genus.

It can be seen, therefore, that substantial attention to the taxonomy of the genus *Eubacterium* is required. The benefit of

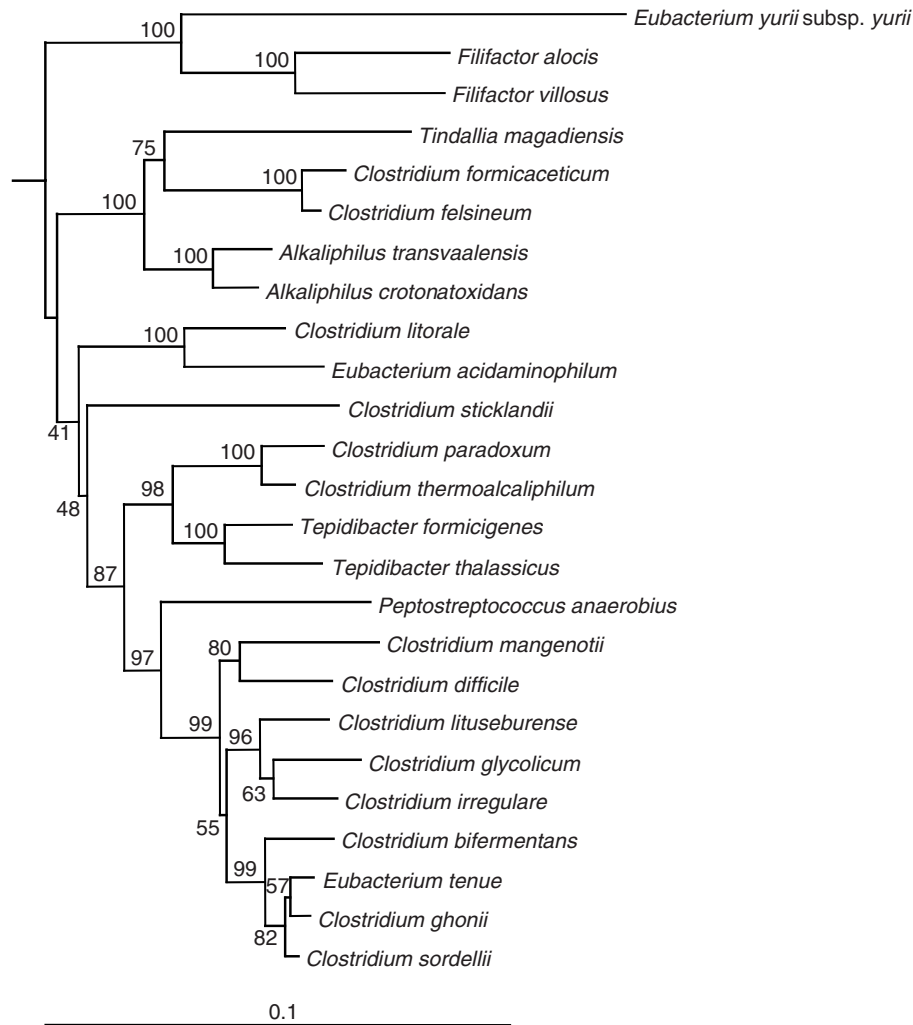

FIGURE 143. Phylogenetic tree based on 16S rRNA gene sequence comparisons over 1251 aligned bases showing relationship between *Eubacterium acidaminophilum* and related species. See legend to Figure 140 for methodology and bootstrap labels.

the phylogenetic approach has been to identify closely related species hitherto classified in disparate genera. The clarification of the taxonomy of this group will be extremely beneficial to the understanding of the physiology of its members and their role in the environment and in human and animal disease.

Acknowledgements

Much of the data given below in the species descriptions were generated by Drs W.E.C. Moore and L.V. Holdeman Moore for the last edition of the *Manual*. Their contribution to this chapter, and anaerobic microbiology in general, is gratefully acknowledged.

I thank my colleague Julia Downes for numerous helpful discussions and for her contribution to the recent work described in this chapter. I should also like to thank the following individuals who have contributed to work on “*Eubacterium*” species in my laboratory over many years: Sarah Cheeseman, Sarah Hiom, Susan Milsom, David Dymock, David Spratt, and Mark Munson. I should also like to thank the following individuals who have collaborated with me in this work: Andrew Weightman, Anne Tanner, Floyd Dewhirst, and Bruce Paster.

Differentiation of the species of the genus *Eubacterium*

Characteristics by which species in the genus can be differentiated are given in Table 156. Acid production in the key refers to both strong and weak fermentations, i.e., a species is positive if the terminal pH is below 5.9 and 0.3 pH units below the control basal medium culture. Additional characteristics concerning each species are given in the text. A number of recently proposed species have unusual and specific growth requirements. These often prevent the performance of “standard” biochemical and physiological tests; the results of such tests that have been reported are included for completeness, but, inevitably, the usefulness of the table for the identification of these species is limited. In my own laboratory, 16S rRNA gene sequence analysis (augmented by relevant phenotypic tests) is the primary method used for preliminary identification. This method is now becoming widely available and allows the easy recognition of currently un-named taxa, of which there are a large number within this genus.

FIGURE 144. Phylogenetic tree based on 16S rRNA gene sequence comparisons over 1355 aligned bases showing relationship between *Eubacterium dolichum* and related species. See legend to Figure 140 for methodology and bootstrap labels.

Colony descriptions are from blood agar plates or streak tube cultures incubated anaerobically for 2 d, unless otherwise indicated. Reported G+C contents of the DNAs are expressed as the

nearest whole number. Unless specified otherwise in the text, cells are nonmotile.

List of species of the genus *Eubacterium*

1. ***Eubacterium limosum*** (Eggerth 1935) Prévot 1938, 295^{AL} (*Bacteroides limosus* Eggerth 1935, 290; *Butyribacterium rettgeri* Barker and Haas 1944, 303)

li.mo'sum. L. neut. adj. *limosum* full of slime, slimy.

Type species of the genus *Eubacterium* (Cato et al., 1981; Wayne, 1982). This description is based on examination of the type and 50 similar strains (Moore and Holdeman Moore, 1986). Cells of the type strain grown in PYG broth are nonmotile, 0.6–0.9 × 1.6–4.8 μm, often with swollen ends and bifurcations, and occur singly, and in pairs and small clumps. Cell walls contain peptidoglycan of the group B type (Guinand et al., 1969; Schleifer and Kandler, 1972). Surface colonies on blood agar are punctiform to 2 mm in diameter, circular, entire, convex, translucent to slightly opaque, and sometimes with mottled appearance when viewed by obliquely transmitted light. Glucose broth cultures are turbid with viscous, stringy, or smooth sediment and a terminal pH of 4.5–5.2. Growth often is better with a fermentable carbohydrate. The optimum temperature for growth is 37°C. Most strains grow well at temperatures between 30 and 45°C, but growth often is inhibited at 25°C.

Abundant gas is produced in PYG agar deep cultures. Adonitol and pectin are fermented; some strains ferment galactose. Dextrin, dulcitol, glycerol, inulin, and sorbose are not fermented. Hippurate is not hydrolyzed. Some strains produce ammonia from arginine. Catalase and urease are not produced. H₂S may be produced. Synthesizes vitamin B₁₂. Products (milliequivalents per 100 ml of culture) in PYG cultures are acetic (1–3), butyric (0.5–2.5), and lactic (1–3) acids, occasionally with small amounts of succinic, iso-butyric and iso-valeric acids. Carbon dioxide and copious amounts of H₂ are produced in PYG broth cultures. Products in PY broth cultures are acetate, iso-butyrate, butyrate (small amounts), and iso-valerate, sometimes with traces of propionate. Glucose spares amino acid (peptone) metabolism, and the branched chain acids (iso-butyric and iso-valeric) usually are not detected in PYG cultures. Lactate and pyruvate are converted to acetate and butyrate.

Carbon monoxide can be used as the sole energy source; acetate and CO₂ are the major products (Genthner and Bryant, 1982). Other energy sources include methanol, H₂ (in the presence of CO₂), adonitol, arabitol, erythritol,

FIGURE 145. Phylogenetic tree based on 16S rRNA gene sequence comparisons over 1322 aligned bases showing relationship between *Eubacterium tarantellae* and related species. See legend to Figure 140 for methodology and bootstrap labels.

fructose, glucose, isoleucine, lactate, mannitol, ribose, and valine. Ammonia, or each of several amino acids, serves as the main nitrogen source. Acetate, cysteine, CO₂, calcium-D-pantothenate, and lipoic acid are required for growth on a chemically defined methanol medium. Acetate, butyrate, and caproate are produced from methanol. Ammonia and branched chain fatty acids are produced from amino acids. Arabinose, galactose, galacturonic acid, gluconate, mannose, rhamnose, cellobiose, lactose, maltose, melibiose, sucrose, trehalose, melezitose, raffinose, dextrin, pectin, starch, dulcitol, salicin, xylitol, ethanol, propanol, butanol, inositol, acetate, fumarate, malate, succinate, adenine, thymine, cytosine, uracil, allantoin, urea, methylamine, and esculin are not utilized as energy sources although esculin is hydrolyzed (Genthner et al., 1981). Although *Eubacterium limosum* may grow slightly when pectin is autoclaved in the medium, the organism probably is not using pectin but is growing on methanol that is hydrolyzed from the pectin during autoclaving (Rode et al., 1981).

Most strains are susceptible to chloramphenicol (12 µg/ml) and clindamycin (1.6 µg/ml). Some strains are resistant to erythromycin (3 µg/ml), penicillin G (2 units/ml), or tetracycline (6 µg/ml).

Isolated from feces of man; rumen; intestinal contents of man, rats, poultry, and fish; various human and animal infections (rectal and vaginal abscesses, blood, wounds); sewage sludge; and mud. Other characteristics of the species are given in Table 156.

DNA G+C content (mol%): 47 (*T_m*).

Type strain: ATCC 8486, CCUG 16793, CIP 104169, DSM 20543, JCM 6421, JCM 9978, NCIB 9763.

GenBank accession number (16S rRNA gene): M59120.

- Eubacterium acidaminophilum*** Zindel, Freudenberg, Rieth, Andreesen, Schnell and Widdel 1989, 93^{VP} (Effective publication: Zindel, Freudenberg, Rieth, Andreesen, Schnell and Widdel 1988, 264.)

a.cid.a.mi.no'phi.lum. N.L. n. *acidum* acid; N.L. pref. *amino* amino group containing; N.L. neut. adj. *philum* from Gr. adj. *philos* loving; N.L. neut. adj. *acidaminophilum* loving amino acids.

Rod-shaped cells, 0.7–1.0 × 1.3–6 µm, mostly with pointed ends, usually single, sometimes in chains; slow tumbling motility by means of a subpolar to polar flagellum. Gram-stain-positive.

Fast growth (doubling time about 1 h) occurs by fermentation of glycine to acetate, ammonia, and CO₂. Glycylglycine,

FIGURE 146. Phylogenetic tree based on 16S rRNA gene sequence comparisons over 1300 aligned bases showing relationship between *Eubacterium desmolans* and related species. See legend to Figure 140 for methodology and bootstrap labels.

glycylglycylglycine, *N*-carbamoylglycine, hydantoin, the glycine moiety of hippurate and glutathione, serine, and pyruvate are also fermented. Glycine derivatives such as betaine, sarcosine, and creatine serve as substrates only in the presence of an electron donor such as formate. Pure cultures grow very poorly by fermentation of alanine or aspartate to acetate, ammonia, CO₂, and H₂. Good growth on alanine or aspartate occurs in co-cultures with H₂-utilizing, sulfate-reducing, methanogenic or homoacetogenic bacteria. Valine, leucine, and malate are also oxidized by the co-cultures or in the presence of an electron-accepting substrate. Glutamate, glucose, and fructose are not fermented. Sulfate, thiosulfate, sulfur, and nitrate are not used as electron acceptors.

Grows in defined sulfide-reduced, bicarbonate-buffered media with biotin as a vitamin. NaCl concentrations higher than approximately 30g/l are inhibitory. Enrichment is possible with alanine at low H₂ partial pressure, e.g., in the presence of sulfate and *Desulfovibrio vulgaris*. Selenite (≥0.1 μM) is required for growth on glycine, betaine, sarcosine, or creatine, but not on other substrates. Temperature range 10–40°C, optimum at 32–36°C; pH range 6.5–8.5, optimum 7.1–7.4.

Isolated from black, anaerobic mud.

DNA G+C content (mol%): 44 (T_m).

Type strain: a1-2, ATCC 49065, DSM 3953.

GenBank accession number (16S rRNA gene): AF071416.

3. ***Eubacterium aggregans*** Mechichi, Labat, Woo, Thomas, Garcia and Patel 2000, 1699^{VP} (Effective publication: Mechichi, Labat, Woo, Thomas, Garcia and Patel 1998, 290.)

ag'gre.gans. L. v. *aggregare* to flock or band together; L. pres. part. *aggregans* assembling (aggregating).

Cells are nonspore-forming, 2–3 μm × 0.4–0.8 μm, non-motile and stain Gram-positive. The temperature range for growth is 20–42°C and the optimal temperature is 35°C. The pH range for growth is 6–9 and the optimum is 7.2. There is growth at NaCl concentrations from 0–3.5%. Utilizes glucose, fructose, sucrose, lactate, formate, methanol, H₂ + CO₂, betaine, crotonate, and methoxyl groups from the following compounds: 2-methoxyphenol, 3,4- and 3,5-dimethoxybenzoates, 3,4-dimethoxybenzaldehyde, 3,4,5-trimethoxycinnamate, 3,4,5-trimethoxybenzoate, 4-hydroxy-3,5-dimethoxybenzoate, 4-hydroxy-3,5-dimethoxycinnamate, 3-hydroxy-4-methoxybenzoate,

4-hydroxy-3-methoxybenzoate, 4-hydroxy-3-methoxycinnamate, 3-hydroxy-3-methoxycinnamate, 3-hydroxy-4-methoxybenzaldehyde, 4-hydroxy-3-methoxybenzaldehyde, and 4-hydroxy-3-methoxycinnamylalcohol. No growth occurs with xylose, sorbose, galactose, *myo*-inositol, lactose, cellobiose, xylan, and cellulose.

Isolated from a digester loaded with olive mill wastewater.

DNA G+C content (mol%): 55 (HPLC).

Type strain: SR12, DSM 12183.

GenBank accession number (16S rRNA gene): AF073898.

4. **Eubacterium angustum** Beuscher and Andreesen 1985, 535^{VP} (Effective publication: Beuscher and Andreesen 1984, 7.)

an.gus'tum. L. adj. *angustum* restricted, scanty, narrow (substrate spectrum).

Straight, angular rods, 1.1–1.5 µm wide and 3–6.5 µm long, older cultures form chains, often clumps. Nonmotile but has flagella, mostly laterally inserted. Colonies are non-pigmented, flat, circular, and 0.5–1.5 mm in diameter. Gram-stain-positive.

Strictly anaerobic; optimal temperature for growth is 37°C although growth occurs at 18 and 45°C; pH range for growth is 6.5–10; optimum range, pH 8.0–8.2. Chemo-organotrophic. For growth, utilizes only uric acid, xanthine, and guanine, hypoxanthine in connection with uric acid, requires thiamine. Acetate, formate, CO₂, and NH₃ are metabolic end products. Hydrogen, succinate, butyrate, acetoin, diacetyl, 2,3-butanediol, indole, and sulfide are not produced. Nitrate and sulfate are not reduced. Hydrolysis of gelatin, starch, and esculin does not occur. No hemolysis. Catalase, lipase, lecithinase, and urease are not produced. No cytochromes are detected. Growth not influenced by the presence of 2% bile extract. Peptidoglycan is directly cross-linked via *meso*-diaminopimelic acid.

Isolated from sludge from sewage plants.

DNA G+C content (mol%): 40 (T_m).

Type strain: MK-1, ATCC 43737, DSM 1989.

GenBank accession number (16S rRNA gene): L34612.

5. **Eubacterium barkeri** (Stadtman, Stadtman, Pastan and Smith 1972) Collins, Lawson, Willems, Cordoba, Fernandez-Garayzabal, Garcia, Cai, Hippe and Farrow 1994, 824^{VP} (*Clostridium barkeri* Stadtman, Stadtman, Pastan and Smith 1972, 760)

bar'ker.i. N.L. gen. n. *barkeri* of Barker named for H.A. Barker, American biochemist.

Based on the description by Stadtman et al. (1972), Holdeman et al. (1977), and study of the type strain (Moore and Holdeman Moore, 1986). Cells in PYG broth are Gram-stain-positive, nonmotile, and 0.3–0.5 by 1.6–9.7 µm, and occur singly or in pairs. Spores are oval, terminal, and swell the cell. Sporulation occurs most reliably on chopped meat slants incubated at 30°C. Cell walls do not contain diaminopimelic acid (DAP). They do contain the B type of peptidoglycan as described by Schleifer and Kandler (1972) and the cross-linking amino acids D-lysine and small amounts of D-ornithine. Surface colonies on blood agar are 0.5–1.0 mm, circular, entire, convex, translucent to slightly opaque, mosaic, white, shiny, smooth, and nonhemolytic. Broth cultures are turbid with smooth sediment. After 5 d incubation, the pH of PYG cultures is 4.5. Optimum temperature

for growth is 37°C. Growth is good at 30°C, fair at 25°C and poor at 45°C. Good growth at a pH of 8.5. No growth in 6.5% NaCl or 20% bile. Ammonia is not produced. Neutral red, but not resazurin, is reduced.

Fermentation products from glucose include butyric and lactic acids and large amounts of H₂; moderate amounts of acetic acid may be formed. Pyruvate is converted to acetate and butyrate. Neither threonine nor lactate is converted to propionate. Nicotinic acid is fermented to propionic and acetic acids, CO₂, and ammonia (Stadtman et al., 1972). Vitamin B₁₂ is formed by a pathway similar to that of *Eubacterium limosum*, with glycine and methionine as precursors (Hollriegel et al., 1982).

The type strain is sensitive to chloramphenicol, clindamycin, erythromycin, and tetracycline, but resistant to penicillin G. Culture supernatants are nontoxic to mice.

Isolated from Potomac River mud and human feces (Finegold et al., 1983).

DNA G+C content (mol%): 45 (T_m).

Type strain: ATCC 25849, CIP 104307, DSM 1223, JCM 1389, NCIB 10623, VKM B-1775.

GenBank accession number (16S rRNA gene): M23927.

6. **Eubacterium bifforme** (Eggerth 1935) Prévot 1938, 295^{AL} (*Bacteroides bifformis* Eggerth 1935, 283)

bi.for'me. L. adj. *bifformis* two-formed (pertaining to cellular morphology).

Cells from PYG broth cultures are nonmotile, 0.6–2.7 µm in diameter × 1.6–15 µm long in pairs and chains. Definite rods and coccoid forms often occur in the same chain. Central swellings ("pelton de jardinier") are present in some cultures, particularly among cells from growth on solid media. After incubation for 5 d in RGCA, subsurface colonies are 0.5–1.0 mm in diameter, white to tan, and usually lenticular and translucent, opaque or translucent with opaque centers, sometimes with diffuse edges. Occasional colonies look like "woolly balls". Surface colonies on blood agar plates incubated for 2 d are 0.5–2.0 mm in diameter, circular, entire to slightly erose, flat to low convex, white, shiny, smooth, translucent with dense centers, and nonhemolytic. The temperature for optimal growth is 37°C; some strains grow at 45°C. Most strains do not grow at 30°C.

PYG-0.2% Tween 80 broth cultures have abundant growth with smooth sediment, little or no turbidity, and a pH of 4.5–5.0 in 1–2 d. Growth of most strains is stimulated by 0.02% Tween 80 but not by rumen fluid and may be inhibited by 20% bile. Growth is markedly stimulated by fermentable carbohydrate. Variable amounts of gas are detected in glucose agar deep cultures. Most strains produce acid from galactose. Neutral red is reduced. A small amount of ammonia may be produced in chopped meat cultures.

Products (milliequivalents per 100 ml of culture) in PYG-0.02% Tween 80 cultures are butyric (0.4–1.2), caproic (0.01–0.07), and lactic (2.0–5.0) acids. Moderate to abundant H₂ is produced from PYG-Tween 80 cultures. Caproic acid is produced irregularly and probably is dependent upon the amount of growth and the age of the culture analyzed. Pyruvate is converted to butyrate, often with lactate and acetate, sometimes with formate, and a small amount of caproate. Lactate and gluconate are not utilized.

The type strain is susceptible to 12 µg/ml of chloramphenicol, 1.6 µg/ml of clindamycin, 3 µg/ml of erythromycin, 2 units/ml of penicillin G, and 6 µg/ml of tetracycline. Other characteristics of the species are given in Table 156.

Isolated from human feces at 1–3% of the flora (Holdeman et al., 1976; Moore and Holdeman, 1974).

DNA G+C content (mol%): 32 (T_m).

Type strain: ATCC 27806, CCUG 28091, DSM 3989.

GenBank accession number (16S rRNA gene): M59230.

Further comments: Moore and Holdeman Moore (1986) reported that definite rod-shaped cells did not appear in all cultures of each strain. The production of caproic acid in small amounts was a distinguishing characteristic, but was sometimes detected only on repeated culture. The morphology of the cells and the production of H₂ and of small amounts of caproic acid by *Eubacterium bifforme* were useful characters in distinguishing this species from *Eubacterium cylindroides*.

7. ***Eubacterium brachy*** Holdeman, Cato, Burmeister and Moore 1980, 167^{VP}

bra'chy. N.L. neut. adj. *brachy* (from Gr. neut. adj. *brachu*) short; referring to the length of the cells.

Cells from PY broth cultures are 0.4–0.8 × 1.0–3.0 µm and occur predominantly in long chains. Although some cells in a chain might be coccoid, definite rods can be seen upon close examination of the smears. After 5 d of incubation, sub-surface colonies in supplemented brain heart infusion agar (BHIA-S, Holdeman et al., 1977) enriched with 5% v/v rabbit serum and 0.02 g each of sodium formate and ammonium fumarate and 400 µg thiamine pyrophosphate/100 ml are 0.5–2.0 mm in diameter, lenticular to trifoliate, and transparent to opaque. After incubation for 2 d, surface colonies on BHIA-S streak tubes are less than 0.5 mm in diameter, circular, entire, low convex, white, shiny, and smooth. Surface colonies on chopped meat broth agar are similar to those on BHIA-S but are larger (1.0 mm in diameter). Surface growth is obtained more reliably on chopped meat broth agar than on BHIA-S tubes or anaerobic blood agar plates.

Broth cultures have a small amount of fine, granular to smooth sediment, often without turbidity. Broth cultures often require incubation for 2–3 d to attain maximum growth, which at best is 2+, as graded on a scale of negative to 4+. Carbohydrates are not fermented.

The temperature for optimal growth is 37°C; most strains do not grow at 30 or 45°C. Growth is inhibited by 6.5% NaCl and slightly inhibited by 2% oxgall (20% bile). Growth is neither inhibited nor stimulated by the addition of 0.02% Tween 80, 5% (v/v) rumen fluid, or 10% (v/v) serum with thiamine pyrophosphate.

A small amount of gas is produced in glucose agar deep cultures. Ammonia is produced in PY broth cultures.

Products (milliequivalents per 100 ml of culture) in PYG broth are acetate (0.1–0.4), iso-butyrate (0.1–0.4), iso-valerate (0.2–0.4), and iso-caproate (0.2–0.5), often with trace amounts of formate, propionate, butyrate, or valerate. Headspace gas of 5-d-old PY broth cultures contains 2–3% H₂.

Strains tested are susceptible to chloramphenicol (12 µg/ml), clindamycin (1.6 µg/ml), erythromycin (3 µg/ml), penicillin G (2 units/ml), and tetracycline (6 µg/ml). Other characteristics of the species are given in Table 156.

Isolated from a variety of oral infections including periodontitis, endodontic infections, and dental caries. One isolate from a human lung abscess has been reported (Rochford, 1980).

DNA G+C content (mol%): not determined because of the sparse amount of growth.

Type strain: ATCC 33089, CIP 104210, DSM 3990, VPI D6B-23.

GenBank accession number (16S rRNA gene): U13038.

Further comments: Because of the fermentation products and the occurrence of short cells in chains, *Eubacterium brachy* resembles *Peptostreptococcus anaerobius*. It does not grow as well in standard media as *Peptostreptococcus anaerobius*, and definite rod-shaped cells can be seen in Gram stains. Additionally, growth of *Eubacterium brachy* is not inhibited by sodium polyanetholsulfonate.

8. ***Eubacterium budayi*** (Le Blaye and Guggenheim 1914) Holdeman and Moore 1970, 23^{AL} (*Bacterium budayi* Le Blaye and Guggenheim 1914, 402)

bu.day'i. N.L. gen. n. *budayi* of Buday; named for K. Buday, the bacteriologist who first isolated the organism.

The description is from Prévot et al. (1967) and study of the type strain (Moore and Holdeman Moore, 1986). Cells in PYG broth cultures are 0.8–1.7 µm in diameter × 3.0 to more than 78 µm in length and are straight or slightly curved. Cells occur singly and in pairs with angular and parallel arrangements. Short forms may occur in media without a fermentable carbohydrate. Surface colonies on McClung-Toabe egg yolk agar (EYA) are 4–5 mm, irregular, low convex, scalloped, yellowish, and are surrounded by a small opaque zone in the agar. Colonies in deep agar look like snowflakes, often with rhizoids. Glucose broth cultures are turbid with smooth sediment and pH of 5.0.

The optimal temperature for growth is 37°C. Moderately good growth occurs at 25–30°C but not at 45°C. Growth is stimulated by 0.02% Tween 80. Moderate growth occurs in peptone-yeast extract broth; growth usually is stimulated by a fermentable carbohydrate. Growth is inhibited by 6.5% NaCl. Growth occurs in PYG with 20% bile, but fermentation may be suppressed.

Abundant gas is produced in PYG agar deep cultures. Galactose is fermented. Adonitol, dulcitol, inulin, pectin, and sorbose are not fermented; little or no ammonia is produced from peptone, arginine, threonine, or chopped meat medium; H₂S is not produced in SIM medium. Slight lecithinase activity may be observed on EYA.

Products (milliequivalents per 100 ml of culture) in PYG cultures are acetic (0.4), butyric (0.8), L-(+)-lactic (1.4), and pyruvic (0.1) acids. Copious H₂ is produced. Other characteristics of the species are given in Table 156.

Isolated from a cadaver by Buday and from poorly sterilized catgut, mud, and soil by Prévot et al.

DNA G+C content (mol%): not determined.

Type strain: ATCC 25541, CIPP ECI, DSM 3981, JCM 9989.

GenBank accession number (16S rRNA gene): AB018183.

9. ***Eubacterium callanderi*** Mountfort, Grant, Clarke and Asher 1988, 257^{VP}

call.and'er.i. N.L. gen. n. *callanderi* of Callander, named in honor of John Callander for his pioneering work on anaerobic digestion of wood-based materials.

Cells are obligately anaerobic, nonmotile, nonspore-forming, Gram-stain-positive rods, $0.9 \times 1.5\text{--}3.0\ \mu\text{m}$. Cell walls contain the peptidoglycan components muramic acid, glucosamine, lysine, ornithine, serine, glutamic acid, and alanine, but diaminopimelic acid is not present.

Cleaves the phenylether bonds of the methoxylated aromatic substrates ferulate, sinapate, syringate, vanillate, 3,4,5-trimethoxycinnamate, and vanillin to give the corresponding hydroxyaromatic derivatives and acetate, butyrate, and formate. In addition, lactate and H_2 are produced from the fermentation of glucose. No reduction of SO_4^{2-} or NO_3^- occurs during fermentation of glucose or methoxylated aromatic compounds. Methanol, $\text{H}_2\text{-CO}_2$, formate, carbon monoxide, and isoleucine are not utilized for growth.

The best conditions for growth are in basal medium supplemented with 5% rumen fluid. No growth occurs on glucose in defined medium (rumen fluid absent) unless acetate is present. The pH range for growth is 6.0 to at least 8.5, and the pH optimum is 7.0. The temperature range for growth is $25\text{--}43^\circ\text{C}$ and the optimum temperature is 37°C .

Isolated from an anaerobic digester fed with the contents of a wood to fiber to alcohol fermentation plant.

DNA G+C content (mol%): 47 (T_m).

Type strain: FD, ATCC 49165, DSM 3662, JCM 10284.

GenBank accession number (16S rRNA gene): X96961.

10. **Eubacterium cellulosolvans** (Bryant, Small, Bouma and Robinson 1958) Holdeman and Moore 1972, 39^{AL} (*Cillobacterium cellulosolvans* Bryant, Small, Bouma and Robinson 1958, 529)

cel.lu.lo.sol'vens. N.L. n. *cellulosum* cellulose; L. part. adj. *solvans* dissolving; N.L. part. adj. *cellulosolvans* cellulose-dissolving.

The description is from Bryant et al. (1958), van Gylswyk and Hoffman (1970), and from study of one strain from van Gylswyk and Hoffman (1970) and one isolate from the intestinal tract of a hog (Moore and Holdeman Moore, 1986). Cells in PYG broth usually are motile with peritrichous flagella and are $0.3\text{--}0.8 \times 0.8\text{--}3.1\ \mu\text{m}$. They occur singly, in pairs, and in clumps.

Surface colonies on anaerobic streak tubes of BHIA-S are 3–5 mm, circular, entire, flat to slightly convex, translucent, and light tan to colorless. Subsurface colonies are lenticular. No growth is produced on the surface of blood agar plates incubated in anaerobic jars. PYG-Tween 80 broth cultures are turbid with smooth sediment and have a terminal pH of 4.9–5.4.

The temperature for optimal growth is 37°C . Growth is slightly inhibited at 45°C and markedly inhibited at 30°C . Growth is stimulated by 0.02% Tween 80. Growth is inhibited by 20% bile or 6.5% NaCl and at pH 9.6. Poor to moderate growth occurs without fermentable carbohydrate.

Variable amounts of gas are detected in glucose agar deep cultures of the strains available for study. Cellulose is digested. Pectin is fermented by some strains; xylan usually is not fermented or only weakly fermented; dextrin and gum arabic are not fermented. Adonitol, dextrin, dulcitol, galactose, glycerol, inulin, and sorbose are not fermented. Resazurin is not reduced. Hippurate is not hydrolyzed and acetylmeth-

ylcarbinol is not produced. Ammonia is not produced from arginine or threonine and only small amounts are produced from peptone. H_2S is not detected in SIM medium.

Products (milliequivalents per 100 ml of culture) in PYG broth are acetic (0.1–0.3), butyric (0.1–0.3), and lactic (3.0–5.0) acids; trace amounts of formic or succinic acids also may be detected. Little or no H_2 is detected in head-space gas of cultures of strains available for study. Pyruvate and lactate are not utilized; threonine is not converted to propionate. Other characteristics of the species are given in Table 156.

Isolated from rumen contents of sheep and cows.

DNA G+C content (mol%): not determined.

Type strain: van Gylswyk and Hoffman strain 6, ATCC 43171, JCM 9499.

GenBank accession number (16S rRNA gene): L34613, X71860.

Further comments: The type strain Bryant B348 has been lost; the type strains listed above are neotype strains. The strains studied by Bryant et al. (1958) produce primarily lactic acid with small amounts of acetic and formic but no butyric, propionic, and succinic acids or H_2 . Strains isolated by van Gylswyk and Hoffman (1970) also produce small amounts of butyric and valeric acids. Moore and Holdeman Moore (1986) detected butyric acid (0.25–0.40 meq/100 ml) in one strain from van Gylswyk and Hoffman. Van Gylswyk and Hoffman suggested that the species description of Bryant et al. (1958) be emended to include organisms that produce a small amount of butyrate and valerate.

11. **Eubacterium combesii** (Prévot and Laplanche 1947) Holdeman and Moore 1970, 23^{AL} (*Cillobacterium combesii* Prévot and Laplanche 1947, 688)

com.be'si.i. N.L. gen. n. *combesii* of Combes; named for Combes.

This description is mainly from Prévot et al. (1967) and the study of the type strain and 12 other strains. Cells are motile with peritrichous flagella. Cells in PYG broth cultures are $0.6\text{--}0.8 \times 3.0\text{--}10.0\ \mu\text{m}$ and occur as single cells and in pairs, short chains, and palisade arrangements. Surface colonies of the type strain on horse blood agar are 0.5–2.0 mm, circular, entire to irregular, convex, semi-opaque, whitish yellow, shiny, and smooth with fine granular or mosaic appearance when viewed by obliquely transmitted light. The type and most other strains are β -hemolytic.

Glucose broth cultures are turbid with flocculent sediment and pH of 6.4. The optimum temperature for growth is $35\text{--}37^\circ\text{C}$. The range of temperatures at which growth occurs is variable. Moderate to abundant gas is produced in glucose agar deep cultures. Ammonia is produced from peptone; neutral red and resazurin are reduced. H_2S usually is produced in SIM medium.

Products (milliequivalents per 100 ml of culture) in PYG broth cultures are acetate (1.5–3.8), iso-butyrate (0.05–0.37), butyrate (trace to 1.8), iso-valerate (0.1–1.3), and lactate (0.1–0.7), usually with ethanol, propanol, iso-butanol, butanol, and iso-amyl alcohols. Variable amounts of formate and small amounts of propionate may be detected. Abundant H_2 is produced. Pyruvate is converted to acetate.

Lactate is not utilized and threonine is not converted to propionate.

Four clinical isolates tested are susceptible to chloramphenicol (12 µg/ml), clindamycin (1.6 µg/ml), penicillin G (2 units/ml), and tetracycline (6 µg/ml). One of these strains was resistant to erythromycin (3 µg/ml). Culture supernatants of 1-d-old chopped meat broth cultures of two strains tested are not toxic for mice (0.5 ml intraperitoneally). Other characteristics of the species are given in Table 156.

Isolated from human infections and African soil.

DNA G+C content (mol%): not reported.

Type strain: ATCC 25545, CIPP A13D, DSM 20696, JCM 9988.

GenBank accession number (16S rRNA gene): AY533380.

Further comments: Although no spores have been detected in the strains on which this description is based, some strains that are otherwise like *Eubacterium combesii* produce spores and were identified by Moore and Holdeman Moore (1986) as *Clostridium subterminale*. Analysis of the original 16S rRNA gene sequence (L34614) indicated that *Eubacterium combesii* belonged to the genus *Propionibacterium*. However, *Eubacterium combesii* does not resemble *Propionibacterium* phenotypically. The strain was re-sequenced for this study and found to be a close relative of *Clostridium botulinum*.

12. ***Eubacterium contortum*** (Prévot 1947) Holdeman, Cato and Moore 1971, 306^{AL} (*Catenabacterium contortum* Prévot 1947, 414)

con.tor'tum. L. neut. adj. *contortum* twisted.

This description is from study of the type and ten other strains (Moore and Holdeman Moore, 1986). Cells in PYG broth cultures are ovoid, 0.4–0.9 × 1.4–2.3 µm and occur in pairs and short or long twisted chains. Surface colonies on horse blood agar are 0.5 mm, circular, entire to erose, low convex, and translucent. There may be slight clearing of the blood under the area of heavy growth. Glucose broth cultures usually are turbid with heavy sediment (gelatinous or granular) and a terminal pH of 4.8–5.0.

The optimum temperature for growth is 35–37°C. Strains grow well at 30 and 45°C but poorly at 25°C. Growth is not affected by 0.02% Tween 80; growth of some strains is inhibited by 20% bile.

Abundant gas is detected in PYG agar deep cultures. Acid is produced from galactose. No acid is produced from adonitol, dextrin, dulcitol, glycerol, inulin, or sorbose. Little or no ammonia is produced from peptone and no ammonia is produced from arginine or threonine. Urease and acetylmethylcarbinol are not produced. H₂S is not produced in SIM medium. Hippurate is not hydrolyzed.

Products (milliequivalents per 100 ml of culture) in PYG broth are acetic (0.5–4.6) and formic (0.1–5.3) acids, with large amounts of ethanol. Trace amounts of lactic and succinic acids may be detected.

The type and seven other strains tested are susceptible to chloramphenicol (12 µg/ml). Two of these strains are resistant to clindamycin (1.6 µg/ml), four are resistant to erythromycin (3 µg/ml), one is resistant to penicillin G (2 units/ml), and three are resistant to tetracycline (6 µg/ml). Other characteristics of the species are given in Table 156.

Isolated from human feces, vaginal swab, and human clinical specimens, including blood (post-kidney transplant), abdominal aortic aneurism, and wounds. Sera from 36–50% of patients with Crohn's disease are reported to contain agglutinating antibodies to strains of *Eubacterium contortum* (van de Merwe, 1981).

DNA G+C content (mol%): 45 (method unknown).

Type strain: ATCC 25540, DSM 3982.

GenBank accession number (16S rRNA gene): L34615.

13. ***Eubacterium coprostanoligenes*** Freier, Beitz, Li and Hartman 1994, 141^{VP}

co.pro.stan.ol.i'gen.es. N.L. n. *coprostanol* coprostanol; Gr. v. *gennaô* produce; N.L. part. adj. *coprostanoligenes* producing coprostanol.

Cells are Gram-stain-positive, nonmotile, nonspore-forming coccobacilli, 0.5–0.7 µm × 0.7–1.0 µm, occurring singly and in pairs. Surface colonies on anaerobically incubated MLA plates are small, white, and circular, with a powdery texture. Growth and coprostanol production are optimal at pH 7.0–7.5 and at 35°C. Growth and coprostanol production do not occur at pH 5.5 or 8.0 or at incubation temperatures of 25 or 45°C.

Aerotolerant, anaerobic, and chemo-organotroph. Phosphatidyl choline is metabolized and is required for growth. Cholesterol is reduced to coprostanol, but is not required for growth. Nitrate is not reduced and indole is not produced. Starch and gelatin are not hydrolyzed and cells produce β-glucosidase. Acid is produced from amygdalin, lactose, and salicin. L-arabinose, cellobiose, fructose, glucose, mannose, and melibiose are weakly fermented. Moderate amounts of H₂ and small amounts of CO₂ are produced. Acetic, formic, and succinic acids are produced. No alcohols are produced.

DNA G+C content (mol%): 41 (*T_m*).

Type strain: HL, ATCC 51222.

GenBank accession number (16S rRNA gene): not determined.

14. ***Eubacterium cylindroides*** (Rocchi 1908) Holdeman and Moore 1970, 23^{AL} (*Bacterium cylindroides* Rocchi 1908, 479)

cy.lin.dro.i'des. L. n. *cylindrus* a cylinder; L. suff. *-oides* resembling, similar; N.L. neut. adj. *cylindroides* cylinder-shaped.

The description is from Cato et al. (1974) and study of the type and 20 other strains (Moore and Holdeman Moore, 1986). Cells in PYG broth cultures are 0.7–1.0 µm in diameter by 1.5–18.0 µm long and occur singly, in pairs, and in long chains. Gram-stain-positive cells usually are seen only in young cultures (exponential phase or early stationary phase of growth); cells of older cultures destain very easily. Surface colonies on horse blood agar incubated for 2 d are punctate to 2 mm, circular to slightly irregular, entire to diffuse, flat to low convex, and translucent. They sometimes have a mottled appearance when viewed by obliquely transmitted light. Glucose broth cultures are turbid with smooth or ropy sediment and terminal pH of 4.8–5.5.

Growth is most rapid at 37–45°C; most strains grow at 25°C. Glucose or fructose enhances growth. Cell density is not markedly enhanced by 0.02% Tween 80. Rumen fluid

(5% final concentration) often increases the amount of acid produced. Comparatively less growth or acid production occurs in glucose media containing 20% bile.

Little or no gas is detected in glucose agar deep cultures. The type strain ferments inulin and pectin (weakly) and produces ammonia from peptone. Neutral red is reduced. The type strain does not ferment adonitol, dextrin, dulcitol, galactose, glycerol, or sorbose and does not hydrolyze hippurate or produce acetylmethylcarbinol. Acetylmethylcarbinol is produced by 8 of 21 strains tested (Cato et al., 1974).

Products (milliequivalents per 100 ml of culture) in PYG broth cultures are butyric (0.3–1.4) and DL-lactic (1.0–3.0) acids, often with smaller amounts of acetic, formic, and succinic acids. Little or no H₂ is detected in headspace gas. Pyruvate is converted to acetate, formate, and butyrate. Lactate is not utilized; threonine is not converted to propionate.

The type strain is susceptible to chloramphenicol (12 mg/ml), clindamycin (1.6 µg/ml), erythromycin (3 µg/ml), and penicillin G (2 units/ml). Susceptibility to tetracycline (6 µg/ml) is variable. Other characteristics of the species are given in Table 156.

Isolated from human feces.

DNA G+C content (mol%): 31 (*T_m*).

Type strain: ATCC 27803, DSM 3983, JCM 10261.

GenBank accession number (16S rRNA gene): L34617.

15. **Eubacterium desmolans** Morris, Winter, Cato, Ritchie and Bokkenheuser 1986, 184^{VP}

des'mo.lans. Gr. n. *desmos* a bond, mod. chem. term desmolase, an enzyme that splits a carbon-carbon bond; N.L. part. adj. *desmolans* making desmolase.

Cells are Gram-stain-positive plump rods that are 0.8–1.1 µm × 1.7–2.3 µm and occur singly or in short chains. Some cells are capsulated. Tumbling motility, due to four to six long peritrichous flagellae. Internal mesosomes are present, especially in dividing cells. Spores are not formed, and the organism does not survive exposure to 80°C for 10 min or treatment with absolute alcohol for 30 min. Primary colonies on Columbia agar plates supplemented with 5% sheep blood (BAP) incubated at 37°C are invisible to the naked eye. Subcultures on the same medium yield circular to slightly irregular, convex, shiny, entire, semi-opaque, white to colorless colonies with a diameter of 0.6–0.8 mm. Neither sheep nor rabbit erythrocytes are hemolyzed. Growth in supplemented peptone broth (SPB) is light and slightly turbid, with a fine precipitate after 3–4 d. Addition of 1% inositol enhances growth; 20% bile (2% oxgall) is tolerated but has no effect on multiplication.

Acid is formed from inositol. Indole is produced. H₂S is not produced on sulfide indole motility medium. Gelatin, milk, and meat are not digested. Acetate and butyrate and trace amounts of succinate and lactate are formed as end products of the fermentation of inositol. Hydrogen is not produced. Acid is not formed from amygdalin, arabinose, cellobiose, erythritol, esculin, glycogen, fructose, glucose, lactose, altose, mannitol, mannose, melezitose, melibiose, pectin, raffinose, rhamnose, ribose, salicin, sorbitol, sucrose, trehalose, and xylose. Starch is not hydrolyzed.

Lipase, lecithinase, oxidase, and catalase are not produced. Nitrate and resazurin are not reduced. At least two enzymes with activity on corticoids are produced: a desmolase which cleaves the side chain of 17α-hydroxysteroids between C₁₇ and C₂₀ and a 20-β-hydroxysteroid dehydrogenase which reduces the 20-keto group of both 17α-hydroxy- and 17-deoxysteroids. Many C₂₀ steroids are also reduced.

Eubacterium desmolans is susceptible to chloramphenicol (12 µg/ml), erythromycin (3 µg/ml) and clindamycin (1.6 µg/ml) but resistant to penicillin G (2 U/ml) and tetracycline (6 µg/ml).

Isolated from cat feces.

DNA G+C content (mol%): 35 (*T_m*).

Type strain: ATCC 43058, CCUG 27818, JCM 6566.

GenBank accession number (16S rRNA gene): L34618.

16. **Eubacterium dolichum** Moore, Johnson and Holdeman 1976, 246^{AL}

do'li.chum. N.L. neut. adj. *dolichum* (Gr. neut. adj. *dolichon*) long, referring to the long chains formed in broth cultures.

Cells from PYG broth cultures are nonmotile, thin rods in long chains. The ends of the cells usually are slightly tapered. Cells are 0.4–0.6 × 1.6–6.0 µm. Subsurface colonies in RGCA incubated for 5 d are 0.2–0.5 mm in diameter, lenticular, and transparent to translucent. Surface colonies on BHIA-S streak tubes are 0.5–1.5 mm in diameter, circular, entire, convex, opaque to translucent, granular, dull, and smooth. None of the four strains tested grew on anaerobically incubated blood agar plates. Three of four strains tested grew on EYA plates incubated anaerobically. PY broth cultures have a stringy to ropy sediment without marked turbidity. In general, growth is poor in most broth media. Growth often is enhanced in a broth medium containing fructose, glucose, maltose, starch, or sucrose, although the pH is not necessarily lowered.

Best growth is obtained at 37°C, although most strains grow at 45°C and, to a limited extent, at 30°C. Growth usually is stimulated by 0.02% Tween 80 and sometimes is inhibited by 20% bile.

No gas is produced in glucose agar deep cultures. The type strain does not ferment adonitol, dextrin, dulcitol, galactose, glycerol, inulin, or sorbose. Ammonia is not produced from peptone, arginine, or chopped meat. Hippurate is not hydrolyzed. The type strain reduces neutral red and resazurin.

The product (milliequivalents per 100 ml of culture) in PYG broth is butyrate (0.2–1.7), often with small amounts of acetate and lactate. Little or no H₂ is detected in the headspace gas. Lactate and pyruvate are not utilized. Threonine is not converted to propionate. Other characteristics of the species are given in Table 156.

Isolated from human feces.

DNA G+C content (mol%): not determined because of the sparse growth (Moore et al., 1976).

Type strain: ATCC 29143, DSM 3991.

GenBank accession number (16S rRNA gene): L34682.

17. **Eubacterium eligens** Holdeman and Moore 1974, 273^{AL}
e'l'i.gens. L. adj. *eligens* choosy, referring to its generally poor growth without fermentable carbohydrate.

Cells from PYG broth cultures are straight to slightly curved rods, occurring singly or in pairs, occasionally in short chains of three to six cells, and are $0.3\text{--}0.8 \times 1.9\text{--}4.9\ \mu\text{m}$. Central or eccentric swellings predominate in some strains. Twenty-four of 33 strains tested were motile and flagella were peritrichous. Cells decolorize easily in older cultures, but some Gram-stain-positive cells usually are seen. After incubation for 5 d in RGCA, subsurface colonies are $0.5\text{--}1.0\ \text{mm}$ in diameter, white to tan, and lenticular. Surface colonies on BHIA-S are punctiform, circular, entire, transparent to translucent, white to tan, and smooth. Surface colonies on 2-d-old anaerobic BHIA-S blood agar plates are $0.5\text{--}1.0\ \text{mm}$ in diameter, circular, entire, convex, smooth, translucent to semi-opaque, shiny, white, and not hemolytic (sheep blood). PY-fructose broth cultures are turbid with a smooth sediment and pH of $4.6\text{--}5.8$ in 5 d.

The temperature for optimal growth is 37°C . Most strains grow well at 45°C ; little or no growth occurs at 30°C . Tween 80 (0.02%) sometimes enhances growth. Growth usually is not effected by addition of 10–30% (v/v) rumen fluid. Bile (20%) inhibits acid production and may inhibit growth. There is limited, if any, growth in PY broth without a fermentable carbohydrate. Little or no gas is produced in PYG agar deep cultures.

Neutral red is reduced. Adonitol, dextrin, dulcitol, galactose, glycerol, inulin, and sorbose are not fermented. Ammonia is not produced from PY broth or arginine. Acetyl methyl carbinol is not produced. H_2S is not produced in SIM medium.

Products (milliequivalents per 100 ml of culture) in PYG broth cultures are acetic (0.7–2.3), formic (0.8–3.7), and lactic (0.1–0.9) acids and ethanol, occasionally with a trace of succinic acid. No H_2 is detected in headspace gas. Pyruvate and gluconate are converted to acetate, formate, lactate, and ethanol. Lactate is not utilized. Other characteristics of the species are given in Table 156.

Isolated from human feces.

DNA G+C content (mol%): 36 (T_m).

Type strain: ATCC 27750, DSM 3376, VPI C15-48.

GenBank accession number (16S rRNA gene): L34420.

18. **Eubacterium fissicatena** Taylor 1972, 462^{AL}

fiss.i.ca.te'na. L. n. *fissum* a cleft; L. n. *catena* a chain; N.L. n. *fissicatena* a broken chain.

The description is from Taylor (1972) and study of the type and seven other strains (Moore and Holdeman Moore, 1986). Cells in glucose broth cultures are motile, $0.3\text{--}0.8 \times 1.4\text{--}8.0\ \mu\text{m}$, and occur singly and in pairs, often with parallel arrangement. Surface colonies on blood agar are $0.5\ \text{mm}$, circular, entire to slightly scalloped, low convex, opaque, grayish white, shiny, and smooth. Glucose broth cultures are turbid with smooth sediment and terminal pH of $5.0\text{--}5.5$.

The optimum temperature for growth is 37°C . All strains grow at 25°C but rarely grow at 13°C . There usually is no growth at 45°C . Growth occurs at pH 9.6 and is unaffected by Tween 80. Although growth is not inhibited in PY broth containing 20% bile, acid production is decreased. Growth is inhibited by 6.5% NaCl.

Abundant gas is detected in PYG agar deep cultures. Galactose is fermented. Neutral red is reduced. Small amounts of

ammonia are produced from peptone. All strains produce H_2S from yeast extract broth (Taylor, 1972). Some strains produce H_2S in SIM medium. Adonitol, dextrin, dulcitol, glycerol, inulin, and sorbose are not fermented. Hippurate is not hydrolyzed. Acetylmethylcarbinol is not produced. Hydroxyethylflavine is produced from riboflavin.

Products (milliequivalents per 100 ml of culture) in PYG broth are acetic (0.7–2.5) and formic (0.4–2.1) acids and large amounts of ethanol. Trace amounts of lactic and succinic acids may be detected. Carbon dioxide and abundant H_2 are produced. Pyruvate is converted to acetate, formate, and ethanol. Some cultures produce methane in media without glucose. Lactate is not utilized. Threonine is not converted to propionate. Other characteristics of the species are given in Table 156.

Isolated from the alimentary tract of goats.

DNA G+C content (mol%): 46 (reported by Taylor, 1972, but method not given).

Type strain: ATCC 33661, DSM 3598, JCM 9983, NCIMB 10446.

The 16S rRNA gene sequence of the type strain is available from the Ribosomal Database Project.

19. **Eubacterium hadrum** Moore, Johnson and Holdeman 1976, 247^{AL}

had'rum. N.L. neut. adj. *hadrum* (from Gr. n. adj. *hadron*) thick, bulky (referring to the relatively large size of the cell).

The description is from Moore et al. (1976), who studied the type and 17 other similar strains (Moore and Holdeman Moore, 1986). Cells from PYG broth cultures are nonmotile rods of uniform width with rounded ends, occurring in pairs and short chains, and are $0.7\text{--}1.0\ \mu\text{m}$ in diameter and $3.0\text{--}10.0\ \mu\text{m}$ long. Subsurface colonies in RGCA incubated for 5 d are woolly balls $1\text{--}2\ \text{mm}$ in diameter. Surface colonies on BHIA-S streak tubes or BHIA-S blood agar plates incubated anaerobically are $2\text{--}3\ \text{mm}$ in diameter, circular, entire to erose, convex, opaque to translucent, and smooth. Some strains produce slight greening hemolysis on rabbit blood. The type and one other strain tested did not grow on EYA. Glucose broth cultures have abundant growth and are turbid with smooth, sometimes ropy, sediment. After incubation for 1 d, the pH in glucose broth cultures is $4.9\text{--}5.4$.

The optimum temperature for growth is 37°C ; good growth also occurs at 45°C but lesser growth is obtained at 30°C . Growth is stimulated by 0.02% Tween 80. No growth occurs in medium containing 6.5% NaCl. Growth occurs in PYG with 20% bile, but no acid is produced. Abundant gas is observed in glucose agar deep cultures.

Products (milliequivalents per 100 ml of culture) from PYG broth cultures are butyric (1–6) and lactic (0.1–2) acids with little or no acetic acid; trace amounts of pyruvic and succinic acids sometimes may be detected. Abundant H_2 is produced from fermentation of carbohydrates. Pyruvate is converted to butyrate and acetate; little or no lactate is utilized.

The type strain ferments galactose and sorbose but does not ferment adonitol or glycerol. Neutral red and resazurin are reduced. Hippurate is not hydrolyzed. Ammonia is not produced from peptone or arginine. Other characteristics of the species are given in Table 156.

Isolated from human feces.

DNA G+C content (mol%): 32–33 (T_m).

Type strain: ATCC 29173, DSM 3319, JCM 9980, VPI B2-52.

The 16S rRNA gene sequence of the type strain is available from the Ribosomal Database Project.

Further comments: Moore and Holdeman Moore (1986) noted that although *Eubacterium hadrum* has large cells typical of those found in many species of *Clostridium*, and even though slight swellings in the cells are very occasionally observed, no typical spores are seen, and cultures with swellings do not survive heating at 80°C for 10 min.

20. **Eubacterium hallii** Holdeman and Moore 1974, 275^{Al}.

hall'i.i. N.L. gen. n. *hallii* of Hall, named for Ivan C. Hall, an American bacteriologist.

Cells from PYG broth cultures are nonmotile rods occurring singly and in pairs, occasionally in short chains. Cells are 0.8–2.4 µm in diameter × 4.7 µm to more than 25.0 µm in length. Although subterminal and terminal swellings sometimes are observed, cultures do not survive heating at 80°C for 10 min. Subsurface colonies in RGCA incubated for 5 d are 0.5–1.0 mm in diameter and lenticular or woolly balls. Surface colonies in BHIA-S streak tubes or BHIA-S blood agar plates are 1–2 mm in diameter, circular to slightly irregular, entire to slightly erose, low convex, semi-opaque, white to yellowish, smooth, shiny, and not hemolytic (rabbit blood). Glucose broth cultures have abundant growth and smooth or ropy sediment with little or no turbidity. The pH of 5 d-old cultures in PYG is 4.7–5.5. Moderate growth occurs in PY broth without a fermentable carbohydrate.

The temperature for optimum growth is 37°C. Most strains grow at 30°C, but less well than at 37°C. Strains usually do not grow at 25 and 45°C. Growth is inhibited by 6.5% NaCl, may be inhibited by 20% bile, but is unaffected by 0.02% Tween 80. Growth is poor in the absence of fermentable carbohydrate.

Abundant gas is produced in glucose agar deep cultures. The type strain and five other strains produce acid from galactose and reduce neutral red. Strains do not produce acetylmethylcarbinol, ammonia, urease, or H₂S in SIM medium and do not hydrolyze hippurate.

Products (milliequivalents per 100 ml of culture) from PYG broth are acetic (0.1–0.8), formic (0.1–0.8), and butyric (2.0–4.0) acids and large amounts of butanol. Trace amounts of lactic and succinic acids sometimes are detected. Abundant H₂ is produced from fermentation of carbohydrates. The type strain converts pyruvate to butyrate and acetate. Lactate and gluconate are not utilized; threonine is not converted to propionate.

The type and one other strain tested are susceptible to chloramphenicol (12 µg/ml), clindamycin (1.6 µg/ml), erythromycin (3 µg/ml), penicillin G (2 units/ml), and tetracycline (6 µg/ml). Other characteristics of the species are given in Table 156.

Isolated from human feces.

DNA G+C content (mol%): 38 (T_m).

Type strain: ATCC 27751, DSM 3353, VPI B4-27.

GenBank accession number (16S rRNA gene): L34621.

21. **Eubacterium infirmum** Cheeseman, Hiom, Weightman and Wade 1996, 958^{VP}

in.fir'mum. L. neut. adj. *infirmum* delicate, referring to the delicate growth of the organism.

Cells are obligately anaerobic, nonspore-forming, nonmotile, Gram-stain-positive, short rods (0.5 µm by 1–2 µm). Cells occur singly. After incubation for 7 d on fastidious anaerobe agar plates, colonies are approximately 1 mm in diameter, circular, convex, and translucent. No hemolysis occurs on blood-containing media.

No acid is produced from arabinose, cellobiose, galactose, glucose, lactose, mannitol, raffinose, ribose, salicin, sucrose, or xylose. Moderate amounts of acetic and butyric acids are produced in PYG. Catalase, urease, and indole are not produced, and ammonia is not produced from arginine.

Isolated from human periodontal pockets.

DNA G+C content (mol%): 38 (T_m).

Type strain: W 1471, NCTC 12940.

GenBank accession number (16S rRNA gene): U13039 (from strain W 1471).

Further comments: *Eubacterium sulci* is a closely related species. There are no phenotypic characters that distinguish *Eubacterium sulci* from *Eubacterium infirmum*. The two species may represent subspecies of the same taxon.

22. **Eubacterium minutum** Poco, Nakazawa, Sato and Hoshino 1996, 33^{VP}

mi.nu'tum. L. neut. adj. *minutum* minute, small, referring to the minute colonies formed by the organism.

Cells are obligately anaerobic, nonspore-forming, nonmotile, Gram-stain-positive, short rods. Cells are 0.5 µm by 1.0–1.5 µm and occur singly, in pairs, and in clumps. Cells in actively growing cultures are Gram-stain-positive, but often cells in older cultures are Gram-stain-negative. Growth in broth media is poor, and growth is moderately enhanced by the addition of 5% bovine serum and 0.3% MgSO₄. After 1 week of anaerobic incubation, colonies on BHI-blood agar plates are 0.3–0.5 mm in diameter, circular, convex, entire, and translucent. No hemolysis occurs on blood-containing agar plates.

Starch and esculin are not hydrolyzed, nitrate is not reduced, no liquefaction of gelatin occurs, ammonia is not produced from peptone or arginine and indole, urease and catalase are not produced. No acid is produced from adonitol, amygdalin, arabinose, cellobiose, erythritol, esculin, fructose, galactose, glucose, glycogen, inositol, lactose, maltose, mannitol, mannose, melezitose, melibiose, rhamnose, ribose, salicin, sorbitol, starch, sucrose, trehalose, or xylose. Moderate amounts of butyrate are produced in peptone-yeast extract medium supplemented with glucose or peptone-yeast extract-glucose broth.

Isolated from human periodontal pockets.

DNA G+C content (mol%): 38–40 (HPLC).

Type strain: M-6, ATCC 700079, CIP 104795.

GenBank accession number (16S rRNA gene): AJ005636.

Further comments: *Eubacterium minutum* is a senior heterotypic synonym of "*Eubacterium tardum*" (Wade et al., 1999b).

23. **Eubacterium moniliforme** (Repaci 1910) Holdeman and Moore 1970, 23^{AL} (*Bacillus moniliformis* Repaci 1910, 412) mo.ni.li.for'me. L. n. *monile* a necklace; L. n. *forma* shape; N.L. neut. adj. *moniliforme* necklace-shaped.

The description is from study of the type and 20 other strains (Moore and Holdeman Moore, 1986). Cells of young cultures are motile with peritrichous flagella. Cells of the type strain are 0.6–0.9 µm in diameter × 1.7–9.4 µm long and occur singly and in short chains, often in palisade arrangement. Surface colonies on horse blood agar (2 d) are 2–8 mm, circular with irregular edges, pulvinate or umbonate, and opaque. Glucose broth cultures are turbid with a smooth sediment and a terminal pH of 5.0–5.6.

All strains grow at 45°C, most grow at 30°C, and some grow at 25°C. Moderate to good growth occurs in PY broth cultures. Growth is slightly greater in media with a fermentable carbohydrate. Growth is not affected by 0.02% Tween 80 or 20% bile.

Abundant gas is produced in glucose agar deep cultures. The type strain does not produce lecithinase, but lecithinase activity is detected in some other strains. Ammonia is produced from peptone and arginine. The type strain ferments galactose, produces H₂S in SIM medium, and reduces neutral red and resazurin. The type strain does not produce acetylmethylcarbinol, does not hydrolyze hippurate, and does not produce acid from adonitol, dextrin, dulcitol, glycerol, inulin, and sorbose.

Products (milliequivalents per 100 ml of culture) in PYG are acetic (0.5–2.5), butyric (1.3–2.3), and L-(+) (or DL-) lactic (1.0–4.9) acids and butanol, sometimes with trace amounts of formic, propionic, and succinic acids. Abundant H₂ is produced. The type strain converts pyruvate principally to acetate. Lactate is not utilized, and threonine is not converted to propionate.

Of nine strains tested, four were resistant to erythromycin (3 µg/ml) and one was resistant to tetracycline (6 µg/ml). All were susceptible to chloramphenicol (12 µg/ml), clindamycin (1.6 µg/ml), and penicillin G (2 units/ml). Other characteristics of the species are given in Table 156.

Isolated from blood, various kinds of human clinical infections, intestinal tract, and soil.

The mol% G+C of the DNA: has not been determined.

Type strain: ATCC 25546, CCUG 28088, CIPP 2055, DSM 3984, JCM 9990.

GenBank accession number (16S rRNA gene): L34622.

24. **Eubacterium multiforme** (Distaso 1911) Holdeman and Moore 1970, 23^{AL} (*Bacillus multiformis* Distaso 1911, 101) mul.ti.for'me. L. adj. *multus* much, many; L. n. *forma* shape; N.L. neut. adj. *multiforme* many-shaped.

The description is based on Distaso (1911), Prévot et al. (1967), and study of the type and four other strains (Moore and Holdeman Moore, 1986). Cells are 0.6–0.8 × 0.8–8.0 µm and are motile with single or multiple subpolar flagella. One strain is not motile. Cells occur singly and in pairs, often in a palisade arrangement. *meso*-DAP is present in the cell walls of the type and one other strain. Surface colonies on blood agar incubated for 2 d are 1–2 mm, circular, erose, convex, translucent, gray-white, smooth, and slightly shiny

with mosaic appearance when viewed by obliquely transmitted light. Glucose broth cultures are turbid with a smooth, granular, or flocculent sediment and pH of 5.3–5.6.

The optimal temperature for growth is 37°C. Strains grow well at temperatures between 25 and 45°C. Growth may be slightly stimulated by Tween 80 and is inhibited by 6.5% NaCl. Growth and acid production may be inhibited by 20% bile.

Abundant gas is produced in PYG agar deep cultures. Galactose may be fermented. Adonitol, dextrin, dulcitol, inulin, pectin, and sorbose are not fermented. Ammonia is produced from peptone. Hippurate may be hydrolyzed. Acetylmethylcarbinol generally is not produced. Neutral red and resazurin are reduced.

Products (milliequivalents per 100 ml of culture) in PYG cultures are acetic (1.0–3.0), butyric (1.5–4.3) and lactic (0.6–3.6) acids, sometimes with trace amounts of formic, propionic, or succinic acids. Copious H₂ is produced. Pyruvate is converted to acetate, formate, and butyrate. Little or no lactate is used.

Two of three strains tested were resistant to erythromycin (3 µg/ml). All three strains were susceptible to chloramphenicol (12 µg/ml), clindamycin (1.6 µg/ml), penicillin G (2 units/ml), and tetracycline (6 µg/ml). Other characteristics of the species are given in Table 156.

Isolated from soil of the Ivory Coast (Africa) and a gunshot wound.

DNA G+C content (mol%): not determined.

Type strain: ATCC 25552, CCUG 27817, DSM 20694, JCM 6484, Prévot collection 06A.

GenBank accession number (16S rRNA gene): AB018184.

25. **Eubacterium nitritogenes** Prévot 1940, 355^{AL}

ni.tri.to'ge.nes. N.L. n. *nitritum* nitrite; N.L. verbal suff. *-genes* from Gr. v. *gennaio* beget, produce; N.L. adj. *nitritogenes* nitrite-producing.

The description is from Prévot et al. (1967) and study of the type strain and three similar strains (Moore and Holdeman Moore, 1986). Cells of the type strain are straight rods with blunt ends and are 0.8–1.6 × 1.6–16.0 µm. Cells occur singly and in short chains and may occur in palisade arrangement. Occasionally have central swellings. In many cultures, approximately one-half of the cells stain uniformly Gram-positive, a few stain Gram-positive only at one end, and the remainder stain Gram-negative. Surface colonies on horse blood agar (2 d) are 0.5–2.0 mm, circular to slightly irregular with scalloped edge, low convex, translucent to opaque, sometimes with mottled appearance when viewed by obliquely transmitted light. Glucose broth cultures are turbid with sediment and terminal pH of 5.1–5.3.

Growth is most rapid at a pH of 6.5–7.8. Optimum temperature is 37°C but good growth generally occurs at temperatures between 30 and 45°C; three of four strains tested grew at 25°C. Growth is not affected by 0.02% Tween 80.

Abundant gas is produced in PYG agar deep cultures. Galactose is fermented by the type and one other strain. Adonitol, dulcitol, dextrin, inulin, and sorbose are not fermented. Growth is inhibited in media containing 6.5% NaCl or 20% bile. Small amounts of ammonia are produced from PY broth. Hippurate hydrolysis is variable for the spe-

cies. Lecithinase is not produced by the type and one other strain but is produced by two of the strains. Neutral red and resazurin are reduced.

Products (milliequivalents per 100 ml of culture) in PYG broth cultures are acetic (0.7–2.4), butyric (1.0–3.0), and DL-lactic (1.0–3.0) acids; small amounts of formic or succinic acids may be detected. Abundant H₂ is produced. Other characteristics of the species are given in Table 156.

Isolated from soil and human infections.

DNA G+C content (mol%): not determined.

Type strain: ATCC 25547, DSM 3985, JCM 6485.

GenBank accession number (16S rRNA gene): AB018185.

Further comments: The relationship between *Eubacterium nitritogenes* and *Eubacterium budayi* is not clear. They are exceedingly difficult, if not impossible, to differentiate by the usual phenotypic tests.

26. **Eubacterium nodatum** Holdeman, Cato, Burmeister and Moore 1980, 167^{VP}

no.da'tum. L. neut. adj. *nodatum* entangled, referring to the tangled arrangement of the cells.

The phenotypic description is from Holdeman et al. (1980), who studied the type and 49 other isolates. Cells from PY broth are nonmotile and occur in clumps. Individual cells are 0.5–0.9 × 2.0–12.0 μm and appear branched, somewhat filamentous, or club shaped. Subsurface colonies on BHIA-S enriched with 5% (v/v) rabbit serum, 0.02 g each of formate and fumarate, and 400 μg thiamine pyrophosphate/100 ml, are 0.5–2.0 mm in diameter, translucent to opaque, and raspberry shaped. After incubation for 2–4 d, surface colonies on BHIA-S streak tubes or anaerobically incubated blood agar plates are less than 0.5–1.0 mm in diameter, generally circular, entire to lobate, and heaped or berry-like in appearance. There is no hemolytic action on rabbit blood cells. No growth occurs on EYA plates incubated anaerobically. PY broth cultures are not turbid and have a small to moderate amount of flocculent, granular or bread crumb-like sediment.

The temperature for optimum growth is 37°C. Most strains grow at 30 and 45°C, but only an occasional strain grows at 25°C. Growth is inhibited by 20% bile and 6.5% NaCl, may be stimulated by 0.02% Tween 80, and is neither inhibited nor enhanced by the addition of 5% rumen fluid, 10% serum with thiamine pyrophosphate, or 0.05% sodium polyanetholsulfonate.

Little or no gas is detected in agar deep cultures. Neutral red is reduced. The type strain does not produce H₂S in SIM medium. Ammonia is produced from peptone and may be produced from arginine. Carbohydrates are not fermented.

Products (milliequivalents per 100 ml of culture) in PYG broth are acetate (0.04–0.36) and butyrate (0.3–1.6), often with trace amounts of formate, lactate, and succinate. No H₂ is detected in headspace gas of broth cultures. Neither lactate nor pyruvate is utilized.

The 32 strains tested were susceptible to chloramphenicol (12 μg/ml), clindamycin (1.6 μg/ml), erythromycin (3 μg/ml), penicillin G (2 units/ml), and tetracycline (6 μg/ml). Other characteristics of the species are given in Table 156.

Isolated from subgingival samples and from supragingival tooth scrapings from persons with periodontal disease.

DNA G+C content (mol%): 36–38 (T_m).

Type strain: ATCC 33099, CCUG 15996, CIP 104213, DSM 3993, JCM 9977, VPI D6A-5.

GenBank accession number (16S rRNA gene): U13041.

27. **Eubacterium oxidoreducens** corrig. Krumholz and Bryant 1986a, 489^{VP} (Effective publication: Krumholz and Bryant 1986b, 13.)

ox.i.do.re.du'cens. *oxido* combining form of modern chemical term, oxide, L. part. adj. *reducens* reducing; N.L. part. adj. *oxidoreducens* reducing compounds (containing) oxygen.

Rod-shaped curved cells; 0.45 × 1.5–22 μm in size, with rounded ends; singles, or in pairs or in small clumps. Nonmotile. No spore formation (pasteurized cultures are not viable). Gram-stain-positive.

Strictly anaerobic chemo-organotroph. Requires formate or hydrogen as electron donor to catabolize approximately equimolar gallate, pyrogallol, phloroglucinol, or quercetin to acetate, butyrate, and sometimes CO₂. No exogenous electron donor is required for catabolism (fermentation) of crotonate (growth rate much faster with 60 mM than with 30 mM or less) to acetate and butyrate. No other compounds are used as energy sources with or without formate present. These include rutin, hesperidin, monobenzenoids with or without methoxyl groups, fatty acids, citrate, acrylate, lactate, pyruvate, dicarboxylic acids, alcohols, sugars, amino acids, and peptides. It also does not grow in co-culture with *Desulfovibrio* species (with sulfate and with or without formate) with butyrate, protocatechuate, 3,5-dihydroxybenzoate, benzoate, phenol, 4-hydroxybenzoate, hydroquinone, or caffeate as substrate. Sulfate does not serve as a dissimilatory electron acceptor with formate in the medium. Nitrate is not reduced. It grows well in defined medium containing utilizable energy sources, minerals, including NH₄Cl, CO₂-bicarbonate (required), B-vitamins, sulfide, and cysteine. Gelatin is not hydrolyzed, ammonia is not produced from arginine or Casitone, but ammonia is essential as the main nitrogen source. The pH range for growth is 6.9–7.8 with the optimum at 7.4. Temperature range: 30–43°C, optimum 39–41°C.

Isolated from the bovine rumen

DNA G+C content (mol%): 36 (T_m).

Type strain: G41, ATCC 43585, DSM 3217.

GenBank accession number (16S rRNA gene): AF202258 (from strain DAS110, not the type strain).

28. **Eubacterium plautii** (Séguin 1928) Hofstad and Aasjord 1982, 347^{VP} (*Fusobacterium plautii* Séguin 1928, 439)

plau'ti.i. N.L. gen. n. *plautii* of Plaut; named for Hugo Carl Plaut, the bacteriologist who first described this organism.

This description is from study of the type strain (Moore and Holdeman Moore, 1986) and from Hofstad and Aasjord (1982). Cells of the type strain are straight rods with rounded ends and are 0.4–0.8 μm in diameter × 2.0–10.0 μm in length. Cells are motile with peritrichous flagella and occur singly, and in pairs, or short chains. Cells stain Gram-negative with very occasional weak Gram-stain-positive areas. Surface colonies on horse blood agar (2 d) are 0.5 mm, circular with diffuse edges, gray-white, dull, smooth, and translucent with mottled appearance when viewed by obliquely transmitted light. Glucose broth cultures are moderately turbid with a smooth (occasion-

ally flocculent) sediment and final pH of 5.2. Small amounts of gas may be present in PYG agar deep cultures.

Products (milliequivalents per 100 ml of culture) in PYG broth cultures are lactic (2), butyric (0.7), and acetic (0.2) acids, often with a trace amount of succinic acid. Pyruvate is converted to acetate, butyrate, and lactate. Lactate is not utilized; threonine is not converted to propionate. No H₂ is detected in headspace gas of PYG cultures. Other characteristics of the species are given in Table 156.

Isolated from cultures of *Entamoeba histolytica*.

DNA G+C content (mol%): not determined.

Type strain: Prévot S1, ATCC 29863, CCUG 28093, DSM 4000, VPI 0310.

GenBank accession number (16S rRNA gene): AY724678.

Further comments: Moore and Holdeman Moore (1986) reported that motility was difficult to demonstrate and found that best results were obtained from microscopic examination of cells in the water of syneresis of a PYG agar slant.

29. **Eubacterium plexicaudatum** Wilkins, Fulghum and Wilkins 1974, 408^{AL}

plex.i.cau.da'tum. Gr. adj. *plectos* twisted or braided; N.L. adj. *caudatus* with a tail; N.L. neut. adj. *plexicaudatum* with a braided tail, referring to the tuft of subpolar flagella that are twisted together to form the "large flagellum" often visible by darkfield or phase-contrast microscopy.

This description is from Wilkins et al. (1974) and the study of the type and 16 other strains (Moore and Holdeman Moore, 1986). Cells in PYG broth cultures are motile, have bipolar tufts of flagella, and are 0.8–1.6 × 4.0–10.0 μm; often have tapered ends. By phase-contrast or darkfield microscopy, the tufts of bipolar flagella may appear to be single polar flagella. Upon initial isolation, the cells are slightly curved and may have a double curvature. After several transfers in culture media, the cells often are thinner and usually straight. Cells may decolorize easily. They may have refractile areas or swellings but do not survive heating at 70°C for 10 min or treatment with ethanol. Surface colonies on RGCA or BHIA-S in anaerobic streak tubes incubated for 5 d are 0.5–1 mm, circular to slightly irregular, convex, translucent, dull, smooth, and white to light gray. In the lower portion of the streak tubes, the organisms often grow as a translucent film. No growth occurs on agar plates incubated in anaerobic jars. Cultures in PYG broth incubated in O₂-free N₂ are turbid, usually with no sediment, and have a terminal pH of 6.0–6.8. The pH of PY cultures is 7.0–7.6. Optimum growth occurs at a pH near neutrality. Growth often is stimulated by 20% bile or 15% rumen fluid.

Moderate to abundant gas is produced in glucose agar deep cultures. Growth in media containing galactose and various carbohydrates decreases the pH to between 6.0 and 7.0 (but not below 6.0) in any sugar medium tested. Neutral red is reduced; resazurin is not reduced. The type strain does not produce acid from adonitol, dextrin, glycerol, inulin, and sorbose. Ammonia is not produced from peptone or arginine. H₂S is not produced in SIM medium. Hippurate is not hydrolyzed.

Products (milliequivalents per 100 ml of culture) in PYG broth are butyrate (1.0–2.5), usually with acetate (0.02–0.12), and butanol. Trace amounts of pyruvate and

succinate may be detected. Hydrogen is produced. Pyruvate and lactate are not utilized. Threonine is not converted to propionate. Other characteristics of the species are given in Table 156.

Isolated from the ceca of mice or rats.

DNA G+C content (mol%): 44 (T_m).

Type strain: VPI 7582.

GenBank accession number (16S rRNA gene): AF157058.

Further comments: Moore and Holdeman Moore (1986) found that many strains of *Eubacterium plexicaudatum* were difficult to grow, which might explain the variation seen in carbohydrate fermentation reactions. They further found that the organisms were quite susceptible to oxidation and therefore difficult to preserve in a lyophilized or frozen state. Cultures streaked on BHIA-S streak tubes survived if stored at 37°C and transferred monthly.

30. **Eubacterium pyruvativorans** Wallace, McKain, McEwan, Miyagawa, Chaudhary, King, Walker, Apajalahti and Newbold 2003, 969^{VP}

pyr.uv.at'i.vor.ans. N.L. n. *pyruvatum* pyruvate; L. part. *vorans* devouring, eating greedily; N.L. part. adj. *pyruvativorans* pyruvate-devouring.

Cells are straight to slightly curved rods, 0.3–0.5 μm wide × 1.0–1.5 μm long, occurring in short chains. Colonies on M2 agar are light tan in color and 2 mm in diameter with slightly irregular edges after 72 h anaerobic incubation. Growth is supported by pyruvate and, to a lesser extent, lactate. Amino acids can be used as the sole source of carbon and energy, with yields much lower than those obtained with pyruvate. Sugars are not fermented. Caproate is the principal metabolic end product from a complex rumen fluid containing medium.

Isolated from the sheep rumen.

DNA G+C content (mol%): 57 (differential dye-binding).

Type strain: I-6, ATCC BAA-574, NCIMB 13911.

GenBank accession number (16S rRNA gene): AJ310135 (from isolate 6).

31. **Eubacterium ramulus** Moore, Johnson and Holdeman 1976, 249^{AL}

ra'mu.lus. L. n. *ramulus* twig, referring to the shape of the cell.

Cells are regular rods with rounded ends, 0.5–0.9 μm in diameter × 1.0–5.0 μm long with filaments exceeding 25.0 μm in length. Cells usually stain boldly in young cultures and are arranged in pairs or short chains. The filaments present in some cultures appear to be either undivided cells or long chains of distinct cells. Cells in the long chains often are of unequal length and occasionally have marked swellings. Cultures having cells with swellings do not survive heating at 80°C for 10 min.

Subsurface colonies in RGCA incubated for 5 d are 1–4 mm in diameter and have the appearance of woolly balls or balls of fuzz or are cauliflower-like, or sometimes are of such indefinite form that there is doubt that the area picked (under × 10 magnification) truly contained a colony. Surface colonies on BHIA-S roll streak tubes are 1–4 mm in diameter, circular to slightly irregular, entire or slightly lobate, raised to low convex or umbonate, translucent,

and white to beige. Three of eight strains tested did not grow on the surface of anaerobically incubated blood agar or EYA plates. When there is growth, there is no reaction on EYA and no hemolytic activity on rabbit blood. Glucose broth cultures have stringy or flocculent sediment, usually without turbidity. The pH of 1-d-old cultures in PYG is 4.8–5.3.

Best growth is obtained reliably at 37°C, although most strains grow equally well at 30 and 45°C. Strains grow not at all or poorly at 25°C. Growth is not stimulated by 0.02% Tween 90; 20% bile may inhibit growth or fermentation. Growth usually is best in media containing fermentable carbohydrate. Abundant gas is observed in glucose agar deep cultures.

Products (milliequivalents per 100 ml of culture) in PYG cultures are acetic (0.1–1.0), formic (0.5–2.3), butyric (1.6–3.0), and lactic (0.1–0.7) acids; trace amounts of succinic acid sometimes are detected. Abundant H₂ is produced from fermentation of carbohydrates.

The type strain is susceptible to chloramphenicol (12 µg/ml), clindamycin (1.6 µg/ml), penicillin G (2 units/ml), and tetracycline (6 µg/ml), and is resistant to erythromycin (3 µg/ml). Other characteristics of the species are given in Table 156.

Isolated from human feces.

DNA G+C content (mol%): 39 (T_m).

Type strain: ATCC 29099, DSM 3995.

GenBank accession number (16S rRNA gene): L34623.

32. **Eubacterium rectale** (Hauduroy, Ehringer, Urbain, Guillot and Magrou 1937) Prévot 1938, 294^{AL}. (*Bacteroides rectalis* Hauduroy, Ehringer, Urbain, Guillot and Magrou 1937, 72)

rec.ta'le. N.L. n. *rectum* the straight bowel; N.L. neut. adj. *rectale* rectal.

The phenotypic description is from Prévot et al. (1967), Holdeman and Moore (1974), and study of the type and 22 other strains (Moore and Holdeman Moore, 1986). Cells in PYG broth cultures are 0.5–0.6 × 1.7–4.7 µm and occur singly and in short chains and small clumps. Cells may be slightly curved and may have central or terminal swellings. Some strains are motile with peritrichous flagella. Surface colonies are 0.5–2.0 mm, circular to irregular, entire to scalloped, convex, translucent, smooth, and shiny. They may be mottled when viewed by obliquely transmitted light. The type strain is nonhemolytic on horse blood. Some strains will not grow on the surface of blood agar plates incubated in an anaerobe jar. Glucose broth cultures are turbid with a smooth or flocculent sediment and have a terminal pH of 4.7–5.5, usually around 5.0. Growth in prerduced PY broth is questionable or very sparse.

The optimal temperature for growth is 37°C. Most strains grow at 25–45°C. Growth is stimulated markedly by a fermentable carbohydrate. Growth usually is not stimulated by 0.02% Tween 80 and is inhibited by 20% bile.

Moderate to large amounts of gas are produced in PYG agar deep cultures. The type strain ferments dextrin, galactose, inulin, and pectin and reduces neutral red. The type strain does not ferment adonitol, dulcitol, glycerol, or sorbose; does not produce acetylmethylcarbinol or catalase;

does not produce ammonia from peptone, arginine, or threonine; does not produce H₂S in SIM medium, does not grow in medium containing 6.5% NaCl, and does not hydrolyze hippurate.

Products (milliequivalents per 100 ml of culture) in PYG cultures are butyric (0.5–1.5), lactic (1.5–5.5), and acetic (0–0.4) acids, occasionally with a trace of propionate or succinate. Copious H₂ is produced. Pyruvate is converted to acetate, butyrate, and lactate. Lactate is not utilized. Other characteristics of the species are given in Table 156.

Isolated from human colon and feces.

DNA G+C content (mol%): 30 (T_m).

Type strain: VPI 0989, ATCC 33656.

GenBank accession number (16S rRNA gene): L34627.

Further comments: VPI 0989, the type strain in the Approved Lists (Skerman et al., 1980) was deposited in ATCC (25578) but was lost in both collections. A different isolate, VPI 0990, from the same fecal sample was deposited to represent the type strain as ATCC 33656. Moore and Holdeman Moore (1986) believed that, because these isolates came from the same sample, they are the same strain.

Strains of fecal bacteria with the general characteristics of *Eubacterium rectale* comprise at least five distinct groups (Moore and Holdeman, 1974). All strains ferment cellobiose, fructose, glucose, maltose, and starch. They decolorize readily, and Gram-stain-positive cells cannot be demonstrated in some strains. The rods are usually curved and motile with flagella singly, in pairs, or in tufts at one or both ends of the cells.

Strains of *Eubacterium rectale*, referred to as “*Eubacterium rectale*-I” in Moore and Holdeman (1974), are slender curved rods, generally longer than the other phenotypes, frequently with large central or terminal swellings. They uniformly ferment arabinose, melezitose, melibiose, raffinose, sucrose, and xylose, and produce large quantities of H₂. Strains of *Fusobacterium mortiferum* may be similar to *Eubacterium rectale* except that they have no flagella and are thicker rods showing more pleomorphism, especially when stained from growth on blood agar. Strains designated “*Eubacterium rectale*-II” differ from “*Eubacterium rectale*-I” strains in that they fail to ferment melezitose and may or may not ferment melibiose and sucrose. Cells are generally shorter, more uniform, curved rods. Strains of “*Eubacterium rectale*-III-H” differ from “*Eubacterium rectale*-II” strains in that they fail to ferment raffinose. Strains designated “*Eubacterium rectale*-III-F” have the same reactions as do strains of “III-H” except that they produce major amounts of formic acid and no H₂. Strains designated “*Eubacterium rectale*-IV” are similar to strains of “III-HV” except that they fail to ferment xylose, may or may not ferment raffinose, and never reduce the pH in arabinose to below 5.5. Heat resistant spores have been detected in some strains otherwise similar to *Eubacterium rectale* subgroups I, II, and III-H. These strains were called unnamed “*Clostridium* species A” (Moore and Holdeman, 1974). However, not all strains with swellings resist heating at 80°C for 10 min or treatment with absolute ethanol for 30 min.

The relationship between *Eubacterium rectale* and *Butyrivibrio fibrisolvens* is in question and has been discussed by

Moore and Holdeman (1974). They report that strains of *Butyrivibrio fibrisolvens* stain only Gram-negative and are monotrichously flagellated and generally are more fastidious than strains of *Eubacterium rectale*.

33. **Eubacterium ruminantium** Bryant 1959, 140^{AL}

ru.mi.nan'ti.um. N.L. pl. n. *ruminantia* ruminants; N.L. gen. pl. n. *ruminantium* of ruminants.

The phenotypic description is from Bryant (1959) who studied 20 strains and from study of the type and one other strain (Moore and Holdeman Moore, 1986). Cells in PYG broth cultures are 0.2–0.3 × 0.8–2.5 μm and occur singly and in pairs. Cells decolorize readily. Surface colonies on RGCA are entire, low convex, smooth, translucent to opaque, and light buff-colored. Subsurface colonies are lenticular and do not produce gas. No growth occurs on the surface of BHIA-S with 5% blood, even when rumen fluid is added to the medium. EYA does not support growth of the type strain. PYG broth cultures are turbid in 18 h with smooth or rosy sediment; the terminal pH (5 d) is 5.0–5.5.

The optimal temperature for growth is 37°C, little or no growth occurs at 30 or 45°C, no growth occurs at 22 or 50°C. Less growth is produced when rumen fluid in the medium is replaced by 0.5% yeast extract and 1.5% trypticase. Growth is unaffected by heme (0.5 mg/100 ml), 20% bile, or 0.02% Tween 80. Growth of a test strain was inhibited by 20 μg/ml of either HgCl₂ or CuCl₂ but not by 100 μg/ml of CdCl₂ (Forsberg, 1978). No growth occurs at Na⁺ concentrations of 3.1 mM or less; best growth occurs with at least 91 mm Na⁺ (Caldwell and Hudson, 1974).

No gas is detected in glucose agar deep cultures. The type and one other strain tested do not ferment adonitol, dextrin, dulcitol, galactose, glycerol, inulin, or sorbose. Pectin is weakly fermented. Hydrogen sulfide is not produced in SIM medium. Ammonia is not produced from arginine or threonine, but small quantities may be detected in peptone cultures. The type strain does not produce acetylmethylcarbinol or hydrolyze hippurate. Neutral red and resazurin are not reduced. Nine of 20 strains tested ferment xylan; none ferment gum arabic.

Products (milliequivalents per 100 ml of culture) in PYG-10% rumen fluid broth cultures are formic (0.5–2.0), acetic (0.01–2.5), butyric (0.3–0.6), DL-lactic (0.4–1.5), and succinic (0.05–0.15) acids. Small amounts of CO₂ are produced. Little or no H₂ is detected in headspace gas. Galacturonic acid is utilized (Tomerska and Wojciechowicz, 1973). Pyruvate and lactate are not utilized and threonine is not converted to propionate.

Exogenous ammonia is required for growth and is the preferred nitrogen source, even in very complex media (Bryant and Robinson, 1962) and amino acids (mainly alanine, valine, and isoleucine) are excreted into the medium during the exponential phase of growth (Stevenson, 1978). One or more of *n*-valerate, iso-valerate, 2-methyl-*n*-butyrate, or iso-butyrate, but not amino acids, are required as carbon sources for growth (Bryant and Robinson, 1962, 1963). Other characteristics of the species are given in Table 156.

Isolated from bovine rumen contents where it represents up to 7.3% of the total isolates.

DNA G+C content (mol%): not determined.

Type strain: ATCC 17233, Bryant GA 195, DSM 20704.

GenBank accession number (16S rRNA gene): AB008552.

Further comments: Bryant described two biotypes, with eight strains in biotype 1 and five in biotype 2. The other seven strains seemed to be intermediates between the two biotypes.

In differentiating human fecal isolates of *Eubacterium ruminantium* from *Eubacterium ventriosum*, Moore and Holdeman (1974) designated *Eubacterium ruminantium* those strains that ferment cellobiose and produce no H₂; these strains did not produce acid from mannose but usually produced acid from salicin. Strains designated *Eubacterium ventriosum* either did not ferment cellobiose or they produced H₂; they often fermented mannose and did not ferment salicin.

Moore and Holdeman Moore (1986) noted that although the reactions of *Eubacterium ruminantium* are similar to those of *Gemmiger formicilis* (Gossling and Moore, 1975), the cells and attached "buds" of *Gemmiger formicilis* are more nearly spherical than are the cells of *Eubacterium ruminantium* (Moore and Holdeman, 1974).

34. **Eubacterium saburreum** (Prévot 1966) Holdeman and Moore 1970, 23^{AL} (*Catenabacterium saburreum* Prévot 1966, 171)

sa.bur're.um. L. n. *saburra* sand; N.L. neut. adj. *saburreum* sandy.

Nineteen strains were isolated and described but not named by Theilade and Gilmour. This description is from Theilade and Gilmour (1961), Hofstad (1967), and study of the type and 37 other strains (Moore and Holdeman Moore, 1986).

Cells of the type strain in PYG broth cultures are 0.7–1.1 × 6–18 μm and occur in pairs and short chains of cells, often in parallel arrangement. Curving filaments, sometimes with swellings, often occur. Cells often stain very weakly Gram-positive or Gram-negative with a few Gram-stain-positive spots or areas within some cells (Kopeloff's modification of the Gram stain). Cells from broth cultures containing fermentable carbohydrate usually stain Gram-negative. Cell walls contain glucose and rhamnose but no galactose. Surface colonies on blood agar are 1–4 mm and flat with interlaced filamentous rhizoid edges and small slightly raised granular centers which penetrate the agar. Cultures in broth produce slight turbidity with flocculent or granular sediment that may adhere to the tube. There is moderate growth in prereduced PY broth and heavy growth in prereduced broth containing a fermentable carbohydrate. The terminal pH in culture medium with a fermentable carbohydrate is 4.7–5.5.

Growth of most strains is stimulated by 0.02% Tween 80. The optimal temperature for growth is 37°C. The type strain grows moderately well at 30°C and poorly at 25 and 45°C.

Abundant gas is produced in PYG agar deep cultures. Urease is not produced by the type strain. H₂S is not produced in SIM medium. α-Methyl glucoside is fermented, sometimes only weakly.

Products (milliequivalents per 100 ml of culture) in PYG cultures are acetic (0.3–1.4), butyric (0.2–1.0), and lactic

(0.1–3.5) acids, occasionally with trace amounts of formic or succinic acid. Copious H_2 and moderate amounts of CO_2 are produced.

Tested strains are susceptible to chloramphenicol (12 µg/ml), clindamycin (1.6 µg/ml), erythromycin (3 µg/ml), and penicillin G (2 units/ml). Some strains are resistant to tetracycline (6 µg/ml).

Based on double diffusion in agar gel, strains of *Eubacterium saburreum* have been classified into serotypes 1, 2, and 3 (Kondo et al., 1979). The type-specific polysaccharide antigens representative of these and other groups apparently are located on the surface of the cell and contain heptose and *O*-acetyl as major constituents (Hoffman et al., 1976, 1980, 1974; Hofstad, 1972, 1975, 1977, 1978; Kondo et al., 1979; Skaug and Hofstad, 1979). Other characteristics of the species are given in Table 156.

Isolated from human dental plaque and gingival crevice.

DNA G+C content (mol%): not determined.

Type strain: ATCC 33271, CCUG 28089, CIP 105341, DSM 3986, JCM 11021, VPI 11763.

GenBank accession number (16S rRNA gene): not available.

The 16S rRNA gene sequence of the type strain is available from the Ribosomal Database Project.

35. ***Eubacterium saphenum*** corrig. Uematsu, Nakazawa, Ikeda and Hoshino 1993, 303^{VP}

sa.phen'um. L. adj. *saphenus* (probably from Gr. n. *saphenes* the plain truth) hidden; referring to the fact the organisms had been hidden in a bacterial flora.

Cells are obligately anaerobic, nonspore-forming, nonmotile, Gram-stain-positive short rods (0.5 × 1.0–1.2 µm). Cells occur singly, in pairs, and sometimes in chains. Cells from older cultures often stain Gram-negative. The growth is poor in broth media and moderately enhanced in the presence of 5% bovine serum, 0.2% lysine, or 0.2% arginine. Strictly anaerobic conditions are required for growth. After incubation of 7 d in an atmosphere of 80% N_2 , 10% H_2 , and 10% CO_2 , colonies on BHI-blood agar plates are 0.3–0.5 mm in diameter, circular, convex, and translucent. After 14 d, they are approximately 1 mm in diameter. No hemolysis is produced around colonies on BHI-blood agar plates.

Strains do not produce acid from adonitol, amygdalin, arabinose, cellobiose, erythritol, esculin, fructose, galactose, glucose, glycogen, inositol, lactose, maltose, mannose, manitol, melezitose, melibiose, raffinose, rhamnose, ribose, salicin, sorbitol, starch, sucrose, trehalose, or xylose. Moderate amounts (approx. 5 mM each) of acetate and butyrate are produced in peptone-yeast extract or PYG. Esculin and starch are not hydrolyzed, nitrate is not reduced, no liquefaction of gelatin occurs, ammonia is not produced from arginine and indole, and catalase and urease are not produced.

Isolated from human periodontal pockets.

DNA G+C content (mol%): 44–48 (HPLC).

Type strain: U 164-47, ATCC 49989.

GenBank accession number (16S rRNA gene): U65987.

36. ***Eubacterium siraeum*** Moore, Johnson and Holdeman 1976, 250^{AL}

si.rae'um. Gr. adj. *siraeum* (probably from Gr. n. *siraion* new wine boiled down) sluggish, referring to the relative inactivity of this organism in most substrates tested.

Cells are 0.5–0.6 × 1.3–3.0 µm and occur singly, in pairs, or short chains, sometimes in “V” or “flying gull” arrangements. Some strains are motile and have one or two subpolar flagella. After incubation for 5 d in RGCA, subsurface colonies are 0.5–1.0 mm in diameter, lenticular, translucent, and tan or white. The larger colonies often have a dense center. Surface colonies on BHIA-S in roll streak tubes or on blood agar plates are 0.5 mm in diameter, circular, entire, low convex, smooth, shiny, and transparent to translucent. Three of eight strains tested that grew on anaerobically incubated blood agar plates did not lyse the rabbit red blood cells. There is little growth in PY broth without fermentable carbohydrate. Cultures in PY broth with a fermentable carbohydrate are slightly turbid with abundant smooth sediment and pH of 5.3–5.8.

Most strains grow equally well at 37 and 45°C; little growth occurs at 30°C. Addition of 10–30% (v/v) rumen fluid stimulates growth of most strains. Growth is not affected by 0.02% Tween 80 and is inhibited by 20% bile. Gas production in glucose agar deep cultures is variable.

Products (milliequivalents per 100 ml of culture) in PY-cellobiose broth are acetic acid (1.3–4.1) and large amounts of ethanol. Trace amounts of lactic, butyric, or succinic acids also may be detected. Abundant H_2 (greater than 3% of the headspace gas) is produced from cellobiose, fructose, or starch. Other characteristics of the species are given in Table 156.

Isolated from human feces.

DNA G+C content (mol%): 45 (T_m).

Type strain: ATCC 29066, DSM 3996.

GenBank accession number (16S rRNA gene): L34625.

37. ***Eubacterium sulci*** (Cato, Moore and Moore 1985) Jalava and Eerola 1999, 1378^{VP} (*Fusobacterium sulci* Cato, Moore and Moore 1985, 476)

sul'ci. L. gen. n. *sulci* of a furrow, referring to its habitat, the human gingival sulcus.

Cells are Gram-stain-positive, nonmotile, nonspore-forming, obligately anaerobic, straight rods, 0.4–0.7 × 1.0–7.0 µm, with rounded ends. They occur singly, in pairs, or in short chains, often with cells of different sizes in the same chain. Surface colonies on blood agar plates are pinpoint-size to 1.00 mm, circular, entire, flat to low convex, translucent, colorless, shiny, smooth, and nonhemolytic. No internal colony structure is visible. Cultures in PYG broth have stringy or granular sediment and may be slightly turbid. After 5–7 d of incubation under CO_2/N_2 , the pH of PYG and basal medium broth cultures is 6.9–7.1; under 100% CO_2 , the pH of each is 6.0–6.2.

The optimum temperature for growth is 37°C, at which growth is only moderate at best. No growth occurs at 25 or 45°C. Growth can be stimulated by the addition of rabbit serum (10–15%) and cocarboxylase (5 µg/ml) and in an atmosphere of 10% $CO_2/90\% N_2$.

Gas is not detected in PYG deep agar cultures; trace to moderate amounts of H₂ may be produced. H₂S is not detected in sulfide-indole-motility medium. No acid is produced from adonitol, amygdalin, L-arabinose, cellobiose, dextrin, dulcitol, *meso*-erythritol, esculin, D-fructose, D-galactose, D-glucose, glycerol, glycogen, inositol, inulin, lactose, maltose, D-mannitol, D-mannose, melezitose, melibiose, pectin, raffinose, rhamnose, D-ribose, salicin, D-sorbitol, L-sorbose, starch, sucrose, trehalose, or D-xylose. Indole, acetylmethylcarbinol, catalase, lecithinase, lipase, urease, oxidase, and deoxyribonuclease are not produced. Esculin, starch, and hippurate were not hydrolyzed. Nitrate is not reduced; neither resazurin nor neutral red is reduced. There is no reaction in milk and no digestion of gelatin or chopped meat. The products of fermentation in PYG broth are moderate to large amounts of butyrate and trace to small amounts of acetate; traces of succinate are occasionally detected. Pyruvate, DL-lactate, D-gluconate, and L-threonine are utilized.

Strains are susceptible to chloramphenicol (12 µg/ml), clindamycin (1.6 µg/ml), erythromycin (3 µg/ml), penicillin (2U/ml), and tetracycline (6 µg/ml).

Isolated from the human gingival sulcus.

DNA G+C content (mol%): 39 (T_m).

Type strain: ATCC 35585, CUG 20560, VPI D45A-29A.

GenBank accession number (16S rRNA gene): AJ006963.

Further comments: *Eubacterium sulci* is closely related to *Eubacterium infirmum* and the two species may represent subspecies of the same taxon.

38. ***Eubacterium tarantellae*** corrig. Udey, Young and Sallman 1977, 407^{AL}

tar.an.tel'l. ae. N.L. n. *tarantellus*; It. n. *tarantella* a fast, whirling dance; referring to the disease symptoms of the fish from which the species was isolated.

This description is from Udey et al. (1977) and studies of the type strain (Moore and Holdeman Moore, 1986). In tissue and when initially isolated, cells are long unbranched filaments. After several transfers in the laboratory, the cells are 1.3–1.6 × 10.0–17.0 µm. No motility has been detected. Surface colonies on BHIA are 2–5 mm, flat, translucent, colorless, rhizoid, soft, and slightly mucoid, with a distinct “pinwheel” appearance. A large zone of β-hemolysis is present around colonies on sheep blood agar plates. Lecithinase is produced on EYA medium. In Brewer’s thioglycollate medium, the species grows as discrete clusters which are fluffy and filamentous. The clusters of growth often are surrounded by a slimy layer. After 48 h incubation, PY broth cultures have smooth to cottony sediment, no turbidity, and terminal pH of 5.3–5.8.

Strains grow well at temperatures between 25 and 37°C. Growth at 15 or 45°C is marginal. Cells survive for 2 weeks at 4°C, but there is no evidence of growth at this temperature. Cultures grow within 72 h in brain heart infusion broth (BHIB) adjusted to an initial pH from 5.6–8.0 but do not grow at pH extremes outside this range. The species does, however, survive for 24 h at pH 3.4 and 8.8. Growth occurs in Brewer’s thioglycollate medium with 2% (w/v) NaCl. Cells can be recovered after 24 h incubation in concentrations of NaCl up to 10% (w/v).

Deoxyribonuclease is produced. Moderate to abundant gas is produced in PYG agar deep cultures.

Products (milliequivalents per 100 ml of culture) in PYG broth are acetic (1.5–5.0) and formic (1.0–5.0) acids often with trace amounts of lactic or succinic acids. Abundant H₂ is detected in headspace gas.

Strains are sensitive (zones of inhibition surrounding the disk) to erythromycin, chloramphenicol, penicillin, tetracycline, and novobiocin (concentrations not given). Strains grow well in BHIB containing 100 µg/ml gentamicin, 100 µg/ml neomycin, or 300 units/ml polymyxin B. Vancomycin is inhibitory at 7.5 µg/ml. Blood agar with 100 µg/ml gentamicin is a highly selective isolation medium. The type strain is susceptible to chloramphenicol (12 µg/ml), clindamycin (1.6 µg/ml), erythromycin (3 µg/ml), penicillin G (2 units/ml), and tetracycline (6 µg/ml).

Not toxigenic for mice (intraperitoneal inoculation) or pathogenic for guinea pigs (intramuscular inoculation with CaCl₂). Pathogenic for channel catfish (*Ictalurus punctatus*) by intraperitoneal inoculation. Other characteristics of the species are given in Table 156.

Isolated from brains of dead or moribund striped mullet (*Mugil cephalus*) in Biscayne Bay, Florida, that have evidence of a neurological disease.

DNA G+C content (mol%): not determined.

Type strain: UM-87, ATCC 29255, DSM 3997.

GenBank accession number (16S rRNA gene): L34624.

Further comments: Henley and Lewis (1976) reported isolation of two strains with characteristics similar, but not identical to those of *Eubacterium tarantellae* from moribund fish from the Texas coast. These strains share antigens in common with *Eubacterium tarantellae* (Udey et al., 1977).

39. ***Eubacterium tenue*** (Bergey, Harrison, Breed, Hammer and Huntoon 1923) Holdeman and Moore 1970, 23^{AL} (*Bacteroides tenuis* Bergey, Harrison, Breed, Hammer and Huntoon 1923, 263)

te'nu.e. L. neut. adj. *tenue* slender (originally used with *spatuliformis* to indicate forms like slender spatulas).

The description is from study of the type and three other strains (Moore and Holdeman Moore, 1986). Cells in PYG broth cultures are 0.5–0.8 × 4.9–20.0 µm and occur singly and in pairs and short chains. Individual cells often have slightly widened and blunt ends. Cells of young cultures (exponential phase or early stationary phase of growth) of the type strain are motile by microscopic examination, but no flagella have been seen with Leifson’s flagella stain. One other strain has peritrichous flagella. Motile cells have not been seen in two strains. Surface colonies on horse blood agar (2 d) are 4–6 mm, slightly irregular with lobate to diffuse edges, flat, translucent, gray-white, smooth, and dull, with granular or mottled appearance when viewed by obliquely transmitted light. Strains are either not hemolytic or produce slight clearing of the blood beneath heavy growth. Glucose broth cultures are turbid with sediment and terminal pH of 5.5–5.9. They have a putrid odor. Growth is most rapid at 24–37°C. Growth is stimulated by 0.02% Tween 80 and inhibited by 6.5% NaCl.

Moderate to abundant gas is detected in PYG agar deep cultures. Lecithinase is produced on McClung-Toabe EYA. H₂S is produced in SIM medium. Ammonia is produced from peptone. Neutral red is reduced. Hippurate is not hydrolyzed and acetylmethylcarbinol is not produced.

Products (milliequivalents per 100 ml of culture) in PYG broth are acetate (1.0–4.7) and formate (0.4–0.8), often with small amounts of propionate, iso-butyrate, iso-valerate, iso-caproate, ethanol, propanol, iso-butanol, and butanol.

One human clinical isolate from blood is susceptible to chloramphenicol (12 g/ml), clindamycin (1.6 µg/ml), erythromycin (3 µg/ml), penicillin G (2 units/ml), and tetracycline (6 µg/ml). The type strain is nontoxic for mice (0.5 ml of 24 h chopped meat culture supernatant fluid injected intraperitoneally). Other characteristics of the species are given in Table 156.

Isolated from abscess following abortion, from knee synovial fluid, and from blood.

DNA G+C content (mol%): not determined.

Type strain: ATCC 25553, DSM 20695, JCM 6486.

GenBank accession number (16S rRNA gene): M59118.

40. **Eubacterium tortuosum** (Debonono 1912) Prévot 1938, 295^{AL} (*Bacillus tortuosus* Debonono 1912, 233)

tor.tu.ó'sum. L. neut. adj. *tortuosum* full of windings.

This description is from the study of the type and 15 other strains (Moore and Holdeman Moore, 1986). Cells in PYG broth cultures are 0.5–0.6 × 2.4–5.0 µm in long chains of 50 or more elements. Surface colonies on horse blood agar (2 d) are 0.5–4.0 mm, circular, entire to erose to diffuse, convex to umbonate, translucent, gray to white, and smooth to slightly rough. Glucose broth cultures have flocculent to gelatinous (occasionally granular) sediment, no turbidity and terminal pH of 5.3–5.6.

The temperature for optimal growth is 37–41°C. Most strains grow at 30 and 45°C, some grow at 25°C. Growth is inhibited by 20% bile but not affected by 0.02% Tween 80.

Variable amounts of gas are produced in glucose agar deep cultures. Neutral red is reduced; resazurin is not reduced. Adonitol, dextrin, dulcitol, galactose, glycerol, inulin, and sorbose are not fermented; ammonia is not produced from peptone, arginine, or threonine. Hippurate is not hydrolyzed. Little or no acetylmethylcarbinol is produced. Hydrogen sulfide is not produced in SIM medium.

Products (milliequivalents per 100 ml of culture) in PYG broth are acetic (0.05–0.45), butyric (0.3–0.8), DL-lactic (2.1–4.6), and succinic (0.06–0.5) acids, with trace to moderate amounts of formic acid. Moderate to abundant amounts of H₂ are detected in headspace gas. Pyruvate is converted primarily to acetate and butyrate. Lactate is not utilized. Threonine is not converted to propionate. Other characteristics of the species are given in Table 156.

Isolated from turkey liver granulomas, turkey enteritis, human feces, soil, and fresh water.

DNA G+C content (mol%): not determined.

Type strain: ATCC 25548, DSM 3987.

GenBank accession number (16S rRNA gene): L34683.

Further comments: *Eubacterium tortuosum* (referred to as "*Catenabacterium*," Moore and Gross, 1968) is believed to be a causative agent of turkey liver granulomas.

41. **Eubacterium uniforme** van Gylswyk and van der Toorn 1985, 324^{VP}

u.ni.for'me. L. neut. adj. *uniforme* uniform, denoting unusual uniformity among strains.

Cells are obligately anaerobic and nonmotile. The majority of cells from 16-h cultures on xylan agar stain Gram-positive. Most cells are short rods (coccioid forms are present) and have rounded or somewhat blunt ends (Figure 140). They occur singly, in pairs, and sometimes in short chains. The cells are usually about 0.4 µm wide, but some are wider (up to 0.6 µm), and the length varies from 0.6–1.5 µm. No differences in cell size occur on xylan or cellobiose agar medium. No spores are produced. After incubation for 3 d on films of xylan (3%) agar medium in roll bottles, surface colonies appear mucoid and round with smooth to wavy or irregular edges. Colony diameters vary from 2 to 8 mm. The colonies are white and show strong bluish-green iridescence when they are viewed obliquely in transmitted light. Clearings surrounding the colonies and resulting from xylan solubilization in the opaque medium vary from 15 to 25 mm in diameter. The degradation of xylan within the clearings is complete in the vicinity of the colonies. Submerged colonies are lens shaped.

Neither rumen fluid nor carbon dioxide-bicarbonate is required for growth. All strains grow well in medium which lacks added reducing agent (sulfide and cysteine) but which is nevertheless reduced with respect to resazurin. Injection of 5 ml of sterile air into 30-ml bottles containing either 4 or 10 ml of medium results in at least partial oxidation of the medium, as indicated by the color of the resazurin indicator, and causes complete inhibition of growth. The majority of strains grow at 45°C but there is no growth 22°C.

Gelatin is liquefied. Indole, α-methylindole, hydrogen sulfide, and catalase are not produced. Nitrate is not reduced. The major products of xylan fermentation are formate, acetate, lactate, and ethanol.

Isolated from the sheep rumen.

DNA G+C content (mol%): 35 (determined spectrophotometrically).

Type strain: X3C39, ATCC 35992.

GenBank accession number (16S rRNA gene): L34626.

42. **Eubacterium ventriosum** (Tissier 1908) Prévot 1938, 295^{AL} (*Bacillus ventriosus* Tissier 1908, 204)

ven.tri.ó'sum. L. neut. adj. *ventriosum* pot-bellied.

The description is from Eggerth (1935), Weinberg et al. (1937), Prévot et al. (1967) and study of the type and 20 similar strains (Moore and Holdeman Moore, 1986). Cells of the type strain are 0.8–1.3 × 1.9–5.0 µm and occur singly and in pairs and short chains of pairs. Surface colonies on blood agar are 0.5–3.0 mm, circular, entire-diffuse, convex, translucent, smooth, and shiny, with slightly mottled or granular appearance when viewed by obliquely transmitted light. Colonies in agar are 1.0–2.0 mm in diameter, lenticular, and translucent. Glucose broth cultures are turbid with smooth, ropy, or granular sediment and terminal pH of 4.6–5.4.

The optimum temperature for growth is 37°C. Strains grow well at 45°C and moderately well at 30°C. Some strains

grow at 25°C. Growth is stimulated by a fermentable carbohydrate and by Tween 80. Growth is inhibited by 6.5% NaCl. Growth and fermentation are partially inhibited by 20% bile.

Little or no gas is produced by PYG agar deep cultures. The type strain ferments pectin and galactose and weakly ferments dextrin. Adonitol, glycerol, inulin, and sorbose are not fermented. Acetyl methyl carbinol is produced. Neutral red and resazurin are reduced. Ammonia is not produced from arginine, threonine, or peptone. H₂S is not produced in SIM medium.

Products (milliequivalents per 100 ml of culture) in PYG cultures are acetic (0.1–0.5), formic (0.8–3.0), butyric (0.5–1.5), and lactic (0.8–2.7) acids; trace amounts of succinic acid may be detected. Little or no H₂ is detected. Pyruvate is partially converted to acetate and formate. Lactate, threonine, and glucose are not utilized.

The type strain is susceptible to chloramphenicol (12 µg/ml), clindamycin (1.6 µg/ml), erythromycin (3 µg/ml), penicillin G (2 units/ml), and tetracycline (6 µg/ml). Other characteristics of the species are given in Table 156. Available strains are isolated from human feces. Isolations from dog feces, mouth abscess, neck infection, purulent pleurisy, pulmonary abscesses, and material from a bronchiectasis have been reported.

DNA G+C content (mol%): not determined.

Type strain: ATCC 27560, DSM 3988.

GenBank accession number (16S rRNA gene): L34421.

Further comments: Holdeman et al. (1976) differentiated *Eubacterium ventriosum* from *Eubacterium ruminatum* on the basis of H₂ production in at least small amounts by strains of *Eubacterium ventriosum*. These authors recognized two biogroups (I and II) that differed from strains of *Eubacterium ventriosum*.

43. ***Eubacterium xylanophilum*** van Gylswyk and van der Toorn 1985, 325^{VP}

xylan.o.phil'um. N.L. n. *xylanum* xylan; Gr. part. *philos* loving; N.L. neut. adj. *xylanophilum* xylan-loving.

Cells are obligately anaerobic, nonspore-forming and motile, exhibiting a rapid corkscrew-like motion. Flagella are observed by transmission electron microscopy, but their points of insertion and their number (one or two per cell) have not been determined with certainty. After growing for 16 h on xylan agar medium, fewer than one half of the cells stain Gram-positive. The cells are straight rods or coccoid with rounded ends. They occur singly, in pairs, and sometimes in short chains. The cell width varies from 0.4–0.6 µm, and the cell length varies from 0.5–2.0 µm (sometimes up to about 3 µm). Surface colonies in roll bottles containing xylan (3%) agar medium incubated for 3 d are 2–4 mm wide, circular, entire, smooth, white, and iridescent in obliquely transmitted light. Submerged colonies are lenticular and 0.5–1 mm in diameter. Clearings due to solubilization of xylan surrounding surface colonies vary in diameter from 6 to 20 mm. Xylan is extensively degraded within the clearings.

Rumen fluid is not required for growth, but growth is slightly enhanced in the presence of carbon dioxide and bicarbonate. There is no growth at either 22 or 45°C.

Xylan and cellobiose are fermented when the inoculum for the tests is grown on xylan agar slopes. However, when the inoculum is grown on cellobiose agar slopes, esculin is also (but poorly) fermented (pH drop of 0.2–0.3 U) by all three strains. The final pH in poorly buffered medium containing xylan or cellobiose does not drop below 5.6. These bacteria utilize cellobiose but not glucose or xylose, which suggests that they may utilize xylobiose derived from xylan. Indole and α -methylindole are not produced. Gelatin is not liquefied, nitrate is not reduced, catalase is not produced, and starch is not hydrolyzed. The fermentation products are formate, acetate, and butyric acids.

Isolated from the sheep rumen.

DNA G+C content (mol%): 39 (determined spectrophotometrically).

Type strain: X6C58, ATCC 35991.

GenBank accession number (16S rRNA gene): L34628.

44. ***Eubacterium yurii*** Margaret and Krywolap 1986, 147^{VP}
yur'i.i. N.L. gen. n. *yurii* of Yuri (author).

Obligately anaerobic, nonspore-forming, straight Gram-stain-positive rods with slightly rounded ends. Individual cells are motile by means of a single subpolar flagellum. The cells form three dimensional brush-like aggregates held together by an amorphous extracellular substance. Cells from 48-h Schaedler broth cultures measure approximately 0.5 µm × 4 µm. After 48 h of incubation at 37°C on Schaedler blood agar, colonies measure 1 mm in diameter, with delicate spreading margins. Some strains exhibit a pale yellow pigment. Growth on MM10 blood agar is similar, although the colonies are smaller. Colonies do not spread on media without blood. In Schaedler broth, growth is typically as a granular sediment, with colonies adhering to the glass; the supernatant fluid remains clear; gas may be formed. Growth is poor in chopped-meat medium. Vitamin K is not required for growth.

The cultures grow well at 34–37°C but not at 25 or 40°C. All strains produce H₂S, indole, and RNase and do not hydrolyze esculin, gelatin, hippurate, or starch. Catalase and acetylmethylcarbinol are not produced. Most strains are asaccharolytic. Acid production from glucose, maltose, and sucrose and production of DNase and phosphatase is variable. In peptone-yeast extract-glucose broth, the major product is butyrate, with minor production of acetate and propionate. All strains are susceptible to penicillin, erythromycin, tetracycline, clindamycin, and chloramphenicol.

Isolated from subgingival dental plaque.

DNA G+C content (mol%): 32 (*T_m*).

Based upon production of phosphatase, saccharolytic activity, and DNA renaturation studies, three subspecies of *Eubacterium yurii* have been validly published.

44a. ***Eubacterium yurii* subsp. *yurii*** Margaret and Krywolap 1986, 148^{VP}

Phosphatase-positive; most strains are asaccharolytic; an occasional strain may produce weak acid in sucrose and may be strongly DNase-positive.

Type strain: SM14, ATCC 43714.

GenBank accession number (16S rRNA gene): L34629.

44b. **Eubacterium yurii subsp. margaretiae** Margaret and Krywopol 1986, 148^{VP}

mar.ga.re'ti.ae. N.L. gen. n. *margaretiae* of Margaret (author).

All strains are phosphatase-negative; most are asaccharolytic; some may produce weak acid in sucrose, maltose or glucose.

Type strain: SM65, ATCC 43715.

GenBank accession number (16S rRNA gene): AY533381.

44c. **Eubacterium yurii subsp. schtitka** Margaret and Krywopol 1988, 207^{VP}

schtit'ka. *schtitka* from Ukrainian n. *schtitka* brush.

Strains are phosphatase-negative, asaccharolytic, and do not stimulate bone resorption *in vitro*.

Type strain: III, ATCC 43716, SMN.

GenBank accession number (16S rRNA gene): AY533382.

Unnamed species of the genus *Eubacterium*. Characteristics of 19 groups of unnamed species of eubacteria isolated from human feces are given in Moore and Holdeman (1974) and Holdeman et al. (1976). In addition, molecular analysis of bacterial communities in the environment and associated with animals have revealed an extremely large number of cloned 16S rRNA genes that do not correspond to existing species. Some of these may be unculturable using standard culture techniques. However, experience in the oral cavity (Munson et al., 2002) suggests that the identification of isolates by 16S rRNA gene sequence analysis will reveal numerous unnamed species.

Genus II. *Acetobacterium* Balch, Schoberth, Tanner and Wolfe 1977, 360^{AL}

MARIA V. SIMANKOVA AND OLEG R. KOTSYURBENKO

A.ce.to.bac.te'ri.um. L. n. *acetum* vinegar; Gr. neut. n. *bakterion* a small rod; N.L. neut. n. *Acetobacterium* vinegar rod.

Oval-shaped, short rods. Gram-stain-positive. Motile. Endospores not formed. **Strictly anaerobic.** Optimal temperature 27–30°C for mesophilic species, 20–30°C for psychrotolerant species. Optimal pH 7.0–8.0. Colonies are convex, white, slightly yellow, or brownish, 0.6–1.0 mm in diameter. **Autotrophic** growth occurs by anaerobic oxidation of H₂ and reduction of CO₂ to acetic acid. **Chemo-organotrophic**, carrying out **homoacetogenic** fermentation of reduced substrates, such as fructose and some other monomeric sugars, as well as pyruvate, lactate, glycerol, and methanol; methyl groups of phenyl methyl ethers and betaine are converted to acetate. The acetyl-CoM pathway serves as an energy-conserving process and as a mechanism for autotrophic assimilation of carbon. Cytochromes have not been detected.

DNA G + C content (mol %): 39–45.8.

Type species: ***Acetobacterium woodii*** Balch, Schoberth, Tanner and Wolfe 1977, 360.

Further descriptive information

Oval-shaped, short rods 0.7–1.0 × 2.0–4.0 μm, single or in pairs (Figure 147). Motile by means of one or two subterminal flagella or peritrichous flagella. Swollen and elongated cells can appear under nonoptimal growth conditions. Psychrotolerant species of the genus form swollen cells at temperatures higher than optimal ones, and usually the number of the swollen cells reaches 5% of the cell number. However, at 27–30°C swollen cells of the psychrotolerant species *Acetobacterium tundrae* represent 90–95% of the cell number; the size of these cells reaches 2–3 μm in width and 10–15 μm in length (Simankova et al., 2000). At temperatures higher than 25°C, the cell size increases, but cell division does not occur. The breakage of the cell wall of swollen cells is sometimes observed, occurring when the cell content reaches a critical amount. If swollen cells grown at 25–30°C are transferred to a new fresh medium and are cultivated at 20°C, normal-sized cells develop. Analysis of the lipid complex of the cell membrane was carried out with *Acetobacterium bakii*, *Aceto-*

FIGURE 147. Micrograph of *Acetobacterium woodii*. Bar = 0.5 μm.

bacterium fimetarium, *Acetobacterium paludosum*, and *Acetobacterium tundrae*. A peculiarity of the lipid complex structure is the presence of a large amount of plasmalogens, which are detected as aldehydes released after sample processing (Kotsyurbenko et al., 1995; Simankova et al., 2000). The main components of the lipid complex of the species studied are the saturated fatty acid C_{16:0}, the unsaturated fatty acids C_{16:1Δ9} and C_{16:1Δ11}, as well as the saturated aldehyde C_{16:0}; however, the latter is absent from the lipid complex of *Acetobacterium fimetarium*.

The cell wall has a Gram-stain-positive structure and contains the more rare peptidoglycan of the cross-linkage type B (Braun and Gottschalk, 1982; Eichler and Schink, 1984), in which a L-seryl residue replaces the L-alanyl residue in position I of the peptide subunit, and the ornithinyl residues function as inter-peptide bridges (Kandler and Schoberth, 1979).

Colonies are convex, white, 0.6–1.0 mm in diameter. Some species produce slightly yellow (*Acetobacterium woodii*, *Acetobacterium carbinolicum*) or brownish (*Acetobacterium wieringae*) colonies.

The members of the genus *Acetobacterium* are metabolically versatile organisms. They are able to grow both autotrophically and chemo-organotrophically, catalyzing the formation of acetate from C₁ units as the sole or the major end product of their energy metabolism, proceeding through the acetyl-CoA (the Wood-Ljungdahl) pathway.

H₂ + CO₂. All members of the genus use H₂ as the electron donor for CO₂ reduction to acetate. Some species can also similarly utilize formate and CO, which are intermediates in acetate formation from CO₂. In the acetyl-CoA pathway, the methyl group of acetate is derived from CO₂ via formate and tetrahydrofolate-bound C₁ intermediates and is then transferred to corrinoid enzyme prior to incorporation into the methyl group of acetyl-CoA. The first step of carboxyl group synthesis is CO₂ reduction to a carbonyl group by means of a carbon monoxide dehydrogenase, the key enzyme of this metabolic pathway. It also catalyzes the acetyl-CoA formation from the carbonyl group, the methyl group of methyl-tetrahydrofolate, and coenzyme A. In the experiments with *Acetobacterium woodii*, it was found that the acetyl-CoA pathway is coupled with the generation of a primary sodium ion potential, which in turn drives ATP synthesis via Na⁺-translocating ATP synthase (Aufurich et al., 2000; Heise et al., 1992; Müller et al., 2001).

Chemo-organotrophic growth is provided by homoacetogenic fermentation of different methylated compounds, alcohols, monomeric sugars, hydroxyacids, and some other substrates.

Methyl compounds. Methanol, as well as methyl groups of phenyl methyl ethers, methyl chlorides, and betaine is converted to acetate. Methanol is converted to acetate with CO₂ as a co-substrate. The methyl group of methanol is transferred to tetrahydrofolate and is further transformed into the methyl group of the acetate, whereas the carboxyl group is derived from CO₂. Methoxylated aromatic compounds are demethylated to the corresponding phenols; the methyl residue is fermented analogously to methanol (Bache and Pfennig, 1981). o-Demethylase catalyzes the cleavage of the ether bond of phenyl methyl ethers and the transfer of the methyl group to tetrahydrofolate (Kaufmann et al., 1997; Messmer et al., 1996). *Acetobacterium woodii* dehalogenates chloromethanes (CH₂Cl₂ and CH₃Cl), converting the methyl groups to acetate in an energy-yielding reaction. It can also catalyze the reductive dechlorination of CCl₄ and its substitutive transformation to CO₂ (Egli et al., 1988; Stromeyer et al., 1991, 1992). CH₃Cl and CO₂ as a co-substrate can also be converted to acetate by "*Acetobacterium dehalogenans*" (Trauneker et al., 1991). The methyl transfer reaction is mediated by a methyl chloride dehalogenase (Messmer et al., 1996; Messmer et al., 1993; Wohlfarth and Diekert, 1997). Betaine is only demethylated to acetate and dimethylglycine (Eichler and Schink, 1984).

Alcohols. *Acetobacterium carbinolicum* is able to utilize aliphatic alcohols (C₂–C₅), which are fermented to the corresponding fatty acids and acetate (Eichler and Schink, 1984). *Acetobacterium woodii* can also convert these substrates if the bicarbonate buffer concentration is at least 100 mM; only weak growth is supported by propanol, butanol, and pentanol (Buschhorn et al., 1989).

Some species consume diols and acetoin, a component of the butanediol cycle in microorganisms. 1,2-Propanediol is

fermented to propionate and acetate by *Acetobacterium carbinolicum*, *Acetobacterium wieringae*, and *Acetobacterium woodii* (Eichler and Schink, 1984; Schink and Bomar, 1992) or to propanol, propionate, and acetate by *Acetobacterium malicum* (Tanaka and Pfennig, 1988). 2,3-Butane, as well as acetoin, is converted to acetate by *Acetobacterium carbinolicum* and *Acetobacterium woodii*. A diol dehydratase is considered to be an enzyme participating in diols cleavage. *Acetobacterium malicum*, *Acetobacterium bakii*, *Acetobacterium fimetarium*, and *Acetobacterium paludosum* can also utilize 2-methoxyethanol, converting this substrate to methanol and acetaldehyde via a diol dehydratase-analogous reaction; the latter product is then oxidized to acetate (Tanaka and Pfennig, 1988).

Sugars and hydroxyacids. One mol of fructose or any other monomeric sugar is fermented via the Embden–Meyerhof–Parnas pathway to 2 mol of pyruvate, which is further oxidized to 2 mol of acetate and 2 mol of CO₂. The latter is also reduced to acetate. Similarly, pyruvate and lactate are converted to acetate. Lactate is first oxidized to pyruvate by a lactic dehydrogenase. Malate is fermented to acetate by *Acetobacterium malicum*, *Acetobacterium bakii*, *Acetobacterium fimetarium*, and *Acetobacterium paludosum* presumably through an NAD-dependent malic enzyme (Strohäcker and Schink, 1991).

Other substrates. *Acetobacterium woodii* saturates the carbon-carbon double bond of the acrylate side chain of caffeate derivatives and converts these compounds to the corresponding hydrocaffeates (Bache and Pfennig, 1981). The process of caffeate reduction is coupled to energy conservation (Hansen et al., 1988; Tschek and Pfennig, 1984). The latter investigation of hydrogen-dependent caffeate reduction by *Acetobacterium woodii* established chemiosmotic mechanism of ATP synthesis by means of a transmembrane Na⁺ gradient generation (Imkamp and Müller, 2002).

Mandelate (phenylglycolate) is oxidized by *Acetobacterium* strain LuPhe1 via benzoyl-CoA to benzoate; carboxy carbon of mandelate serves as one-carbon substrate for acetate formation (Dorner and Schink, 1991). *Acetobacterium* strain LuPhe1 also converts 2-phenoxyethanol to phenol and acetate through acetaldehyde formation (Speranza et al., 2003).

The cytochromes have not been found in *Acetobacterium woodii* (Tschek and Pfennig, 1984), *Acetobacterium carbinolicum* (Eichler and Schink, 1984), and *Acetobacterium malicum* (Tanaka and Pfennig, 1988). Neither oxidase activity has ever been reported. Catalase and superoxide dismutase (SOD) activities were investigated in *Acetobacterium woodii*, *Acetobacterium paludosum*, and *Acetobacterium wieringae* (Brioukhanov et al., 2002). All studied species were defined as catalase-positive, but only *Acetobacterium wieringae* exhibited a high catalase activity. High specific activities of SOD were detected in *Acetobacterium woodii* and *Acetobacterium wieringae*, whereas *Acetobacterium paludosum* demonstrated a low SOD activity.

All *Acetobacterium* species are able to fix molecular nitrogen, but this process has not been studied in detail (Schink and Bomar, 1992).

The 16S rRNA gene sequence analysis shows that *Acetobacterium* species form a tight phylogenetic group exhibiting a high level (7% and higher) of sequence divergence with most closely-related species of the genus *Eubacterium* (Willems and Collins, 1996). The level of sequence similarity between species of the

genus *Acetobacterium* ranges between 96.2 and 99.4% (Simankova et al., 2000; Willems and Collins, 1996). Psychrotolerant species do not exhibit a closer phylogenetic relationship with each other than with mesophilic species. DNA–DNA hybridization experiments between *Acetobacterium* species show that hybridization levels are less than 37% for all species combinations (Simankova et al., 2000). The only exception is *Acetobacterium woodii* and *Acetobacterium carbinolicum* demonstrating 69% of DNA–DNA homology. However, 16S rRNA gene sequence analysis shows a sequence similarity of 98.4% between these species.

Streptomycin, benzylpenicillin, vancomycin, rifampin, and bacitracin completely inhibit growth of *Acetobacterium bakii*, *Acetobacterium fimetarium*, and *Acetobacterium paludosum*.

All strains of the genus *Acetobacterium* were isolated from strictly anoxic environments. Most of *Acetobacterium* species inhabit fresh water ecosystems: anoxic pond sediments, ditches, wetlands, and anoxic sewage sludge. However, *Acetobacterium woodii* strain WBI was isolated from a marine estuary, and laboratory experiments with *Acetobacterium* strains demonstrated their equally good growth in fresh water, brackish water, and salt-water medium (Schink, 1994). In recent years, it was discovered that the acetyl-CoM pathway is coupled to a chemiosmotic mechanism of ATP synthesis, namely, to the presence of sodium-proton antiporters in the cytoplasmic membrane. This finding explains the capacity of *Acetobacterium* species to well adapt to environments with periodical changes in salinity or pH, such as estuaries, soils, or sewage sludge digestors. However, *Acetobacterium* species seem to be more important for fresh water terrestrial ecosystems, where they can produce acetate from a variety of different substrates. Representatives of genus *Acetobacterium* are among the most typical microorganisms in many cold fresh water ecosystems (Kotsyurbenko et al., 1993a; Kotsyurbenko et al., 1993b; Nozhevnikova et al., 1994). All four new psychrotolerant species of homoacetogenic bacteria isolated over the last decade belong to this genus. They play an important ecological role in different cold anoxic environments as strong competitors of methanogenic archaea for hydrogen (Conrad et al., 1989; Kotsyurbenko et al., 1996), the key intermediate in the anaerobic microbial community. Under conditions of H₂ partial pressures higher than 10 Pa, psychrotolerant homoacetogens are able to outcompete methanogens owing to higher growth rates at low temperature (Kotsyurbenko et al., 2001). It can result in essential changes in the trophic structure of the microbial community and in production of acetate as one of the end products.

Enrichment and isolation procedures

Enrichment is carried out using a liquid medium and H₂:CO₂ (80:20) as gas phase. Medium contains minerals, vitamins, yeast extract, sodium sulfide as reducing agent, sodium bicarbonate (2.5 g/l) as buffer, and resazurin (Kotsyurbenko et al., 1995). The vitamin and microelement solutions described by Wolin et al. (1963) and Pfennig and Lippert (1966) are used, respectively. Yeast extract is not an obligatory requirement of any species but enhances growth yield. Methanogens can also be enriched under anoxic conditions and an atmosphere of H₂/CO₂. However, they are outgrown by faster-growing homoacetogenic bacteria when transferred repeatedly on liquid medium using tenfold serial dilutions. Moreover, methanogens can be inhibited by the addition of 50 mg/l of sodium dithionite (Balch et al., 1977) or 10–50 mM

bromoethanesulfonate (Smith and Mah, 1981). Growth of *Acetobacterium* is judged from acetate production and by observation of characteristic cell morphology under the microscope. The last positive dilution is used to inoculate roll-tubes containing H₂/CO₂ as gas phase. Colonies that developed in the roll-tubes are transferred to liquid medium and cultivated under an atmosphere of H₂/CO₂. Some species of the genus *Acetobacterium* can be enriched using selective substrates, such as methoxylated aromatic compounds (syringate, vanillate, and trimethoxycinnamate ferulate) for *Acetobacterium woodii* isolation (Bache and Pfennig, 1981), ethanol, propanol, or butanol for *Acetobacterium carbinolicum* enrichment (Eichler and Schink, 1984), and 2-methoxyethanol for *Acetobacterium malicum* isolation (Tanaka and Pfennig, 1988).

Maintenance procedures

Storage is possible anaerobically in liquid medium at 4°C, under these conditions, cells remain viable for 6 months. *Acetobacterium* may be stored after lyophilization according to the procedure for strict anaerobes (Hippe, 1991).

Differentiation of the genus *Acetobacterium* from other genera

The genus *Acetobacterium* is phylogenetically differentiated from other genera of homoacetogenic anaerobic members of the *Firmicutes* (Gram-positive bacteria with a low DNA G + C content) on the basis of oligonucleotide composition of the 16S rRNA gene. The phylogenetic relationship with the most closely related species of the genus *Eubacterium* is at the level of not more than 93% sequence similarity (Willems and Collins, 1996). *Acetobacterium* is also distinguished from other homoacetogenic anaerobic Gram-stain-positive bacteria on the basis of morphological and physiological properties. In contrast to homoacetogenic bacteria of the genus *Clostridium*, the members of the genus *Acetobacterium* do not form endospores. *Acetobacterium* differ in their cell morphology and peptidoglycan composition from the genera *Peptostreptococcus*, *Syntrophococcus*, and *Acetitomaculum*. The members of the genus *Acetobacterium* are distinguished from the only known species of the genus *Acetogenium* on the basis of their substrate spectrum, peptidoglycan composition, and inability to grow at a high temperature. The members of the genus *Acetobacterium* differ from homoacetogenic bacteria of the genus *Eubacterium* by their ability to carry out only homoacetogenic fermentation of reduced substrates.

Taxonomic comments

In the original description of the genus *Acetobacterium* it was tentatively placed in the family *Propionibacteriaceae* (Balch et al., 1977). Later, according to 16S rRNA gene sequence data, the genus *Acetobacterium* was placed in the family *Eubacteriaceae* belonging to cluster XV of the *Clostridium* subphylum of the Gram-positive bacteria (Willems and Collins, 1996). According to the 16S rRNA phylogenetic analysis presented in the roadmap to this volume (Figure 5), the genus *Acetobacterium* is a member of the family *Eubacteriaceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*.

Acknowledgements

We are grateful to N.A. Kostrikina, who took the electron micrograph presented in this description.

List of the species of the genus *Acetobacterium*1. *Acetobacterium woodii* Balch, Schoberth, Tanner and Wolfe 1977, 360^{AL}

wood'i.i. N.L. gen. n. *woodii* of Wood; named for H.G. Wood for his pioneering work on the total synthesis of acetate from CO₂ by bacteria.

Cells are oval-shaped, short rods 1.0 × 2.0 μm. Motile by means of one or two subterminal flagella. Colonies on plates are circular, convex, and white; 1 mm in diameter. Older colonies may show a slight yellow pigmentation. Optimal growth occurs at 30°C. Autotrophic growth on H₂/CO₂ and formate; acetate is formed. Methanol, 2,3-butanediol, acetoin, glycerol, ethylene glycol, lactate, pyruvate, fructose, as well as methyl groups of methoxylated aromatic compounds and betaine are fermented to acetate. Ethanol, propanol, butanol, and pentanol are utilized if medium contains at least 100 mM bicarbonate buffer. Ethanol is converted to acetate; propanol, butanol, pentanol, and 1,2-propanediol are fermented to corresponding fatty acids and acetate. Caffeate derivatives are reduced to the corresponding hydrocaffeate. Chloromethanes (CH₂Cl₂, CH₃Cl, and CCl₄) are dehalogenated; CH₂Cl₂ and CH₃Cl are then fermented to acetate, whereas CCl₄ is either reduced to CH₃Cl or transformed to CO₂.

Habitat: marine and fresh water sediments, and sewage sludge.

DNA G + C content (mol%): 39 (Bd).

Type strain: WB1, DSM 1030, ATCC 29683.

GenBank accession number (16S rRNA gene): X96954.

2. *Acetobacterium bakii* Kotsyurbenko, Simankova, Nozhevnikova, Zhilina, Bolotina, Lysenko and Osipov 1997, 242^{VP} (Effective publication: Kotsyurbenko, Simankova, Nozhevnikova, Zhilina, Bolotina, Lysenko and Osipov 1995, 33.)

ba'ki.i. N.L. gen. n. *bakii* of Bak, named for F. Bak who isolated the first psychrotolerant homoacetogenic bacterium.

Short rods, 0.9–1.5 × 1.5–2.7 μm. Motile by means of two subterminal flagella. Colonies on agar are white and 0.6–1.0 mm in diameter. Psychrotolerant. Temperature range for growth is 1–30°C, with an optimum at 20°C. Growth at pH values 5.5–8.5, with an optimum at 6.5. Autotrophic growth on H₂/CO₂, CO, and formate; acetate is formed. Fructose, lactate, malate, as well as methanol and methyl groups of vanillate and betaine are fermented to acetate. Weak growth on maltose, glucose, xylose, and 2-methoxyethanol. The main components of the lipid complex of the cell membrane are the saturated fatty acid C_{16:0}, the saturated aldehyde C_{16:0}^{*} and the unsaturated fatty acids C_{16:1Δ9}^{*}.

Isolated from anoxic sediments of a pond polluted by paper-mill wastewater.

DNA G + C content (mol%): 42.1 (T_m).

Type strain: Z-4391, DSM 8239, ATCC 51794.

GenBank accession number (16S rRNA gene): X96960.

3. *Acetobacterium carbinolicum* Eichler and Schink 1985, 375^{VP} (Effective publication: Eichler and Schink 1984, 152.)

car.bi.no'li.cum. N.L. adj. *carbinolicum* metabolizing alcohols.

Rod-shaped cells, 0.8–1.0 × 1.5–2.5 μm, with slightly pointed ends, single or in pairs. Motile. Colonies on agar are white or slightly yellow. Temperature range for growth is 15–40°C, with an optimum at 20°C. Growth at pH range 6.0–8.0, with an optimum at 7.0. Autotrophic growth on H₂/CO₂ and formate; acetate is formed. Methanol, ethanol, 2,3-butanediol, acetoin, glycerol, ethylene glycol, lactate, pyruvate, glucose, fructose, methyl groups of methoxylated aromatic compounds, and betaine are fermented to acetate. Propanol, butanol, pentanol, and 1,2-propanediol are fermented to the corresponding fatty acids and acetate. Does not require any vitamins. Sulfate, thiosulfate, elemental sulfur, and nitrate are not reduced. No cytochromes.

Isolated from anoxic freshwater mud.

DNA G + C content (mol%): 38.5.

Type strain: WoProp1, DSM 2925.

GenBank accession number (16S rRNA gene): X96956.

4. *Acetobacterium fimetarium* Kotsyurbenko, Simankova, Nozhevnikova, Zhilina, Bolotina, Lysenko and Osipov 1997, 242^{VP} (Effective publication: Kotsyurbenko, Simankova, Nozhevnikova, Zhilina, Bolotina, Lysenko and Osipov 1995, 34.)

fi.me.ta'ri.um. L. n. *fimetum* a dung-hill; N.L. neut. adj. *fimetarium* inhabiting manure.

Short rods, 0.8–1.1 × 1.5–2.6 μm. Motile by means of peritrichous flagella. Colonies on agar are white and 0.6–1.0 mm in diameter. Temperature range for growth is 1–35°C, with an optimum at 30°C. Growth at pH values 6.0–8.5, with an optimum at 7.5. Autotrophic growth on H₂/CO₂, CO, and formate with acetate production. Fructose, lactate, malate and methyl groups of vanillate and betaine are utilized for growth and fermented to acetate. 2,3-Butanediol and 2-methoxyethanol are weakly used. The main components of the lipid complex of the cell membrane are the saturated aldehyde C_{16:0} and the unsaturated fatty acids C_{16:1Δ9} and C_{16:1Δ11}^{*}.

Isolated from digested manure.

DNA G + C content (mol%): 45.8 (T_m).

Type strain: Z-4290, DSM 8238, ATCC 51795.

GenBank accession number (16S rRNA gene): X96959.

5. *Acetobacterium malicum* Tanaka and Pfennig 1990, 470^{VP} (Effective publication: Tanaka and Pfennig 1988, 186.)

ma'li.cim. N.L. neut. adj. *malicum* pertaining to malic acid.

Rod-shaped cells, 1.0–1.3 × 1.8–4.0 μm, with slightly pointed ends, single or in pairs. Motile. Colonies on agar

are white. Optimal temperature is 30°C, no growth at 16°C and 40°C. Optimal pH is 7.5–8.0, no growth at initial pH 6.0 and 9.5. Autotrophic growth on H₂/CO₂ and formate; acetate is formed. Fructose, lactate, pyruvate, malate, glycerol, acetoin, ethylene glycol, 2-methoxyethanol, 2-ethoxyethanol, as well as methyl groups of methoxylated aromatic compounds and betaine are fermented to acetate. 1,2-Propanediol is fermented to propanol, propionate, and acetate. Under optimal conditions, doubling time on 2-methoxyethanol and malate is 22 h and 7.5 h, respectively. Sulfate, sulfite, thiosulfate, elemental sulfur, and nitrate are not reduced. No cytochromes.

Isolated from anoxic freshwater sediment of a ditch.

DNA G + C content (mol%): 44.1 (Bd).

Type strain: MuME1, DSM 4132, ATCC 51201.

GenBank accession number (16S rRNA gene): X96957.

6. **Acetobacterium paludosum** Kotsyurbenko, Simankova, Nozhevnikova, Zhilina, Bolotina, Lysenko and Osipov 1997, 242^{VP} (Effective publication: Kotsyurbenko, Simankova, Nozhevnikova, Zhilina, Bolotina, Lysenko and Osipov 1995, 34.)

pa.lu.do'sum. L. neut. adj. *paludosum* inhabiting a fen.

Short rods, 0.8–1.1 × 1.3–2.9 μm. Motile by means of peritrichous flagella. Colonies in roll tube agar are white and 0.6–1.0 mm in diameter. Psychrotolerant. Temperature range for growth is 1–30°C, with an optimum at 20°C. Growth at pH values 5.0–8.0, with an optimum at 7.0. Autotrophic growth on H₂/CO₂, CO, and formate; acetate is formed. Maltose, fructose, glucose, lactate, malate, methanol, as well as methyl groups of betaine are fermented to acetate. 2-Methoxyethanol, xylose, and cellobiose are weakly used. The main components of the lipid complex of the cell membrane are the saturated fatty acid C_{16:0}, the saturated aldehyde C_{16:0'}, and the unsaturated fatty acids C_{16:1Δ9} and C_{16:1Δ11}. Habitat: anoxic freshwater sediments.

Isolated from anoxic sediments of a fen.

DNA G + C content (mol%): 41.7 (T_m).

Type strain: Z-4092, DSM 8237, ATCC 51793.

GenBank accession number (16S rRNA gene): X96958.

7. **Acetobacterium tundrae** Simankova, Kotsyurbenko, Stackebrandt, Kostrikina, Lysenko, Osipov and Nozhevnikova 2001, 793^{VP} (Effective publication: Simankova, Kotsyurbenko, Stackebrandt, Kostrikina, Lysenko, Osipov and Nozhevnikova 2000, 446.)

tun'drae. N.L. fem. gen. n. *tundrae* from the tundra (a cold treeless zone located in the north of Eurasia and North America).

Cells are short rods, 0.7–1.1 × 1.1–4.0 μm, with slightly pointed ends. Motile by means of peritrichous flagella. The irregular swollen cells 2–3 μm × 10–15 μm appear at temperatures 25–30°C as a result of a defect in cell division. Colonies in agar roll tubes are white and 1.0 mm in diameter. Psychrotolerant. Temperature range for growth is 1–30°C, with an optimum 20°C. Growth at pH values 6.0–8.0, with an optimum at 7.0. Autotrophic growth on H₂/CO₂, CO, and formate with acetate production. Maltose, mannose, fructose, glucose, xylose, pyruvate, lactate, methanol, and methyl groups of betaine are utilized for growth and fermented

to acetate. The main components of the lipid complex of the cell membrane are the saturated aldehyde C_{16:0} and the unsaturated fatty acid C_{16:1Δ9}.

Isolated from tundra soil.

DNA G + C content (mol%): 39.2 (T_m).

Type strain: Z-4493, DSM 9173.

GenBank accession number (16S rRNA gene): AJ297449.

8. **Acetobacterium wieringae** Braun and Gottschalk 1983, 438^{VP} (Effective publication: Braun and Gottschalk 1982, 374.)

wie.rin'gae. N.L. gen. n. *wieringae* of Wieringa; named for K. T. Wieringa who isolated and described *Clostridium aceticum*, the first known acetogenic bacterium.

Cells are oval-shaped, short rods 1.0 × 2.0 μm. Motile by means of one or two subterminal flagella. Colonies are circular, smooth, and brownish; 3 mm in diameter. Optimal growth occurs at temperature 30°C and pH 7.2–7.4. Autotrophic growth on H₂/CO₂ and formate; acetate is formed. Fructose, lactate, ethylene glycol, acetoin, glycerol, and ethanol are fermented to acetate. 1,2-Propanediol is fermented to acetate and propionate. Under optimal conditions, doubling time on H₂/CO₂ mixture corresponds to 10 h.

Isolated from sewage sludge.

DNA G + C content (mol%): 43 (T_m).

Type strain: C, DSM 1911, JCM 2380, ATCC 43740.

GenBank accession number (16S rDNA gene): X96955.

Other organisms

1. **"Acetobacterium dehalogenans"** Traunecker, Preuß and Diekert 1991, 417

de.ha.lo'ge.nans. N.L. adj. part. *dehalogenans* dehalogenating.

The description of this species is based on the phenotypic features and G + C content of the DNA. The data of phylogenetic analysis of the 16S rRNA gene is lacking. Cells are elongated cocci 1.1 × 1.5 μm arranged in chains. Nonmotile. Gram-stain-positive. Endospores not formed. Strictly anaerobic. Colonies are smooth, convex, and yellow, about 1 mm in diameter. Optimal growth occurs at temperature 25°C and pH 7.3–7.7. Autotrophic growth on H₂/CO₂ and CO with acetate production. Fructose, glucose, ribose, pyruvate, lactate, glycerol, as well as methyl groups of phenyl methyl ethers and methyl chloride are converted to acetate.

Isolated from a sewage digester.

DNA G + C content (mol%): 47.5 (HPLC).

Type strain: MC.

2. **"Acetobacterium psammolithicum"** Krumholz, Harris, Tay and Sufliya 1999, 2302

psam.mo.li'thi.cum. Gr. fem. n. *psammos* sand; Gr. masc. n. *lithos* stone. N.L. neut. adj. *lithicum* of stone; N.L. neut. adj. *psammolithicum* of sandstone.

The taxonomic status of this organism is uncertain because its detailed description is incomplete. Cells are elongated rods 1.1 × 1.7–3.3 μm. Flagella are not observed. Gram-stain-negative. Endospores not formed. Strictly anaerobic. The substrates, which support growth include H₂, formate, methanol, glucose, syringate, pyruvate, lactate, betaine, ethanol, propanol, glycerol, and acetoin. Accord-

ing to 16S rDNA sequence data and substrate specificity, the organism could be affiliated with the genus *Acetobacterium*. However, its morphology is not typical for the genus *Acetobacterium*: the organism was described as Gram-stain-negative, and flagella were not observed. Temperature and pH

characteristics of growth, as well as the G+C content of the DNA are lacking.

Isolated from a subsurface sandstone.

Type strain: CN-E.

Genus III. **Alkalibacter** Garnova, Zhilina, Tourova, Kostrikina and Zavarzin 2005, 983^{VP} (Effective publication: Garnova, Zhilina, Tourova, Kostrikina and Zavarzin 2004, 314)

ELENA S. GARNOVA AND TATJANA N. ZHILINA

Al.ka.li.bac'ter. Ar. def. art. al the; Ar. n. qaliy ashes of saltwort; N.L. masc. n. *bacter* (from Gr. n. *baktron*) a rod; N.L. masc. n. *Alkalibacter* alkaliphilic rod.

Rod-shaped cells, 0.5 × 1.5–2.5 μm, with **Gram-stain-positive** cell-wall structure. Nonmotile. Asporogenous. **Strictly anaerobic**, catalase negative. **Obligately alkaliphilic and halotolerant**; growth obligately depends on sodium carbonates or chlorides. **Chemoorganoheterotroph**; consumes mono- and disaccharides, sugar alcohols, and proteinaceous substrates as energy sources. Glucose is fermented to acetate, ethanol, formate, H₂, and CO₂. Requires yeast extract as a possible source of nitrogen and sulfur. Habitats are saline-carbonate lakes. The genus is monotypic.

DNA G + C content (mol%): 40.8–42.1.

Type species: **Alkalibacter saccharofermentans** Garnova, Zhilina, Tourova, Kostrikina and Zavarzin 2005, 983^{VP} (Effective publication: Garnova, Zhilina, Tourova, Kostrikina and Zavarzin 2004, 315.).

Further descriptive information

Cells are short rods with pointed ends (Figure 148). The cellular morphology varies somewhat with the age of the culture. Cells taken from the exponential growth phase usually occur singly or in pairs (Figure 148); sometimes they are at an angle to each other, or, rarely, in short chains of 3–5 cells. In the late stationary phase, most cells are swollen, irregular in shape, and arranged in chains. Cells divide by septum formation, and the cell wall has a Gram-stain-positive structure (Figure 148). Although sporulation has never been observed, cells are ther-

more resistant to pasteurization at 70°C for 50 min but not at 80°C for 10 min.

Alkalibacter possesses a remarkable adaptation to wide ranges of environmental conditions. Even though the growth optimum is narrowly defined at pH 9.0, 35°C, and 0–4% NaCl; the growth rate remains significant over broad ranges in pH (7.2–10.2), temperature (6–50°C), and salt concentration (0–10% NaCl) (Garnova et al., 2004). Thus, the organism appears to be adapted to a highly unstable environment in a cryoarid climate where seasonal rains and evaporation cause wide fluctuations in salinity and pH. Under optimal growth conditions, the generation time is 5 h.

A catalase-negative, obligate anaerobe, *Alkalibacter* does not grow under aerobic or microaerobic conditions in the presence of >0.9% O₂ in a N₂ gas phase. Growth occurs without reducing agents in the presence of glucose.

The organism is chemoorganoheterotrophic and nonhydrolytic. It utilizes the monosaccharides ribose, xylose, glucose, mannose, and fructose; the disaccharide sucrose; the sugar alcohol mannitol; and peptone and tryptone. Yeast extract is required for growth and cannot be replaced by Casamino acids. A vitamin solution is not required for growth, but it significantly improves the growth rate. Glucose is fermented to acetate, ethanol, formate, H₂, and CO₂. *Alkalibacter* is incapable of the dissimilatory reduction of sulfate, sulfite, thiosulfate, dithionite,

FIGURE 148. Morphology of *Alkalibacter saccharofermentans*. (a) Negatively stained cell. Flagella are not observed in these nonmotile bacteria. Bar = 1 μm. (b) Cells from the exponential growth phase as viewed by phase-contrast microscopy. Bar = 10 μm. (c) Thin-section demonstrates the Gram-positive type of cell wall as well as the septum formed during cell division. Bar = 0.5 μm. (Used with permission from Garnova et al., 2004, *Extremophiles* 8: 309–316.)

NO_3^- , or NO_2^- . NO_2^- completely inhibits the growth while sulfur significantly improves it. Other electron acceptors do not influence the growth rate.

Methods of isolation and cultivation of pure cultures

The type strain was isolated from an anaerobic enrichment on glucose originally inoculated with a mixture of mud and surface cyanobacterial mat from a lagoon of Lake Nizhnee Beloe (southeastern Transbaikal region, Russia). The mineral medium which was used for the enrichment culture contained (per liter): NaCl, 3.4 g; Na_2CO_3 , 4.45 g; NaHCO_3 , 5.5 g; and glucose, 5 g. Incubations were performed anaerobically under N_2 gas at pH 9.5 and 36°C. To obtain a pure culture, the enrichment culture was serially diluted in mineral medium, and colonies were isolated from the highest dilution yielding growth in the same medium containing 3% agar (w/v). The uniform colonial and cellular morphologies confirmed culture purity. After optimization of the growth conditions, the *Alkalibacter* medium contained (per liter): KH_2PO_4 , 0.2 g; MgCl_2 , 0.1 g; NH_4Cl , 0.5 g; KCl, 0.2 g; NaCl, 6.0 g; Na_2CO_3 , 15.5 g; NaHCO_3 , 3.5 g; yeast extract, 0.2 g; glucose, 5.0 g; trace element solution, 1 ml (Kevbrin and Zavarzin, 1992), vitamin solution, 10 ml (Wolin et al., 1963); and resazurin, 0.001 g. The pH was 9.0, and the gas phase was N_2 .

Maintenance procedure

The type strain remains viable when stored in *Alkalibacter* medium at +4°C and transferred every 6 months. Glycerol (15%) stocks are stored in liquid nitrogen.

Differentiation of the genus *Alkalibacter* from other genera

The genus *Alkalibacter* is differentiated from other members of the *Eubacteriaceae* by its obligate alkaliphily, dependence on Na^+ and ability to grow at high salinities (Table 157). It differs from the homoacetogenic species of the genera *Acetobacterium*

and *Eubacterium* in its inability to grow autotrophically and ferment sugars with acetate as the sole product. In addition, they have different carbohydrate specificity. *Eubacterium aggregans* (Mechichi et al., 1998) and *Eubacterium limosum* (Moore and Holdeman Moore, 1986) also produce different products from that of *Alkalibacter* when they ferment carbohydrates during chemoorganotrophic growth. *Alkalibacter* differs from the other chemoorganoheterotrophs, *Anaerofustis stercorihominis* (Finegold et al., 2004), *Eubacterium barkeri* (Moore and Holdeman Moore, 1986), *Eubacterium callanderi* (Mountfort et al., 1988), *Garciella nitratreducens* (Miranda-Tello et al., 2003), and *Pseudoramibacter alactolyticus* (Willems and Collins, 1996) in its substrate specificity and fermentation products (Table 157).

Ecophysiological features of *Alkalibacter* are consistent with its isolation from soda lakes, and it possesses some characteristics that are unusual for the other members of this family, which were isolated from sources at neutral pH. It is the first true alkaliphile in this group.

Taxonomic comments

On the basis of phylogenetic analyses of the 16S rRNA gene, *Alkalibacter* is related to cluster XV of the low G + C content Gram-positive group (Collins et al., 1994; Garnova et al., 2004). According to the 16S rRNA phylogenetic analysis presented in the roadmap to this volume (Figure 5), the genus *Alkalibacter* is a member of the family *Eubacteriaceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes* (Ludwig et al., 2009). Among the neutrophilic species of the genera *Acetobacterium*, *Anaerofustis*, *Eubacterium*, *Garciella*, and *Pseudoramibacter*, *Alkalibacter* forms (however with low bootstrap value) a separate clade together with the thermophilic thiosulfate and nitrate reductant *Garciella nitratreducens* (Figure 149) and exhibits at least 10% sequence divergence in its 16S rRNA gene from other members of this family. Together with the physiological and genotypic differences, this level of divergence supports its status as a separate genus.

List of species of the genus *Alkalibacter*

1. ***Alkalibacter saccharofermentans*** Garnova, Zhilina, Tourova, Kostrikina and Zavarzin 2005, 983^{VP} (Effective publication: Garnova, Zhilina, Tourova, Kostrikina and Zavarzin 2004, 315.) sac.cha.ro.fer.men'tans. Gr. n. *sakkharon* sugar; L. v. *fermentare* to ferment; N.L. part. adj. *saccharofermentans* sugar-fermenting.

The description for the type species is the same as given for the genus and listed in Table 157. Three strains of *Anoxynatronum saccharofermentans*, Z-7980, Z-79820, and Z-7983, have been isolated from an anaerobic microbial community decomposing cellulose (Garnova et al., 2004). While these strains have a uniform cellular morphology in

liquid medium, they form colonies that differed in shape, diameter, consistency, and edge on solid medium. All three strains possess a similar mol% G + C content (40.8–42.1) and high levels of DNA–DNA similarity (96–100%) (Tourova et al., 1999). Thus, they belong to the same species, and the morphology of the colonies is not a differentiating characteristic. Strain Z-79820 was described as the type strain.

DNA G + C content (mol%): 42.1 (T_m).

Type strain: Z-79820, DSM 14828, UNIQEM U-218, VKM B-2308.

GenBank accession number (16S rRNA gene): AY312403.

Genus IV. **Anaerofustis** Finegold, Lawson, Vaisanen, Molitoris, Song, Liu and Collins 2004, 1005^{VP} (Effective publication: Finegold, Lawson, Vaisanen, Molitoris, Song, Liu and Collins 2004, 44.)

PAUL A. LAWSON

An.a.e.ro.fus'tis. Gr. pref. *an* without; Gr. masc. n. *aer* air; L. masc. n. *fustis* stick; N.L. masc. n. *Anaerofustis* stick living without air.

Cells are rod-shaped, stain Gram-positive, and do not form spores. **Strictly anaerobic and catalase-negative**. Resistant to 20% bile. Some carbohydrates are fermented. **End products of**

metabolism from glucose peptone-yeast extract broth are acetic and butyric acids. Esculin is not hydrolyzed. **Lipase-, lecithinase-, and urease-negative**. Nitrate is not reduced to nitrite.

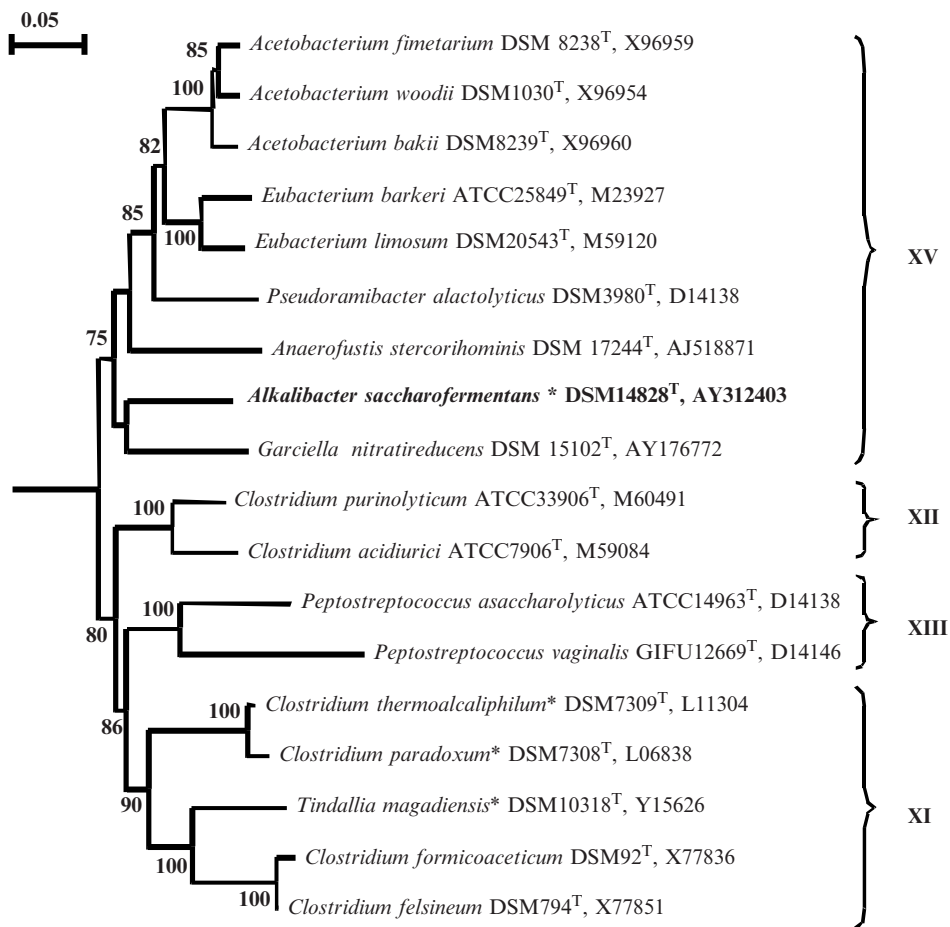

FIGURE 149. Phylogeny of *Alkalibacter saccharofermentans* and representatives of the *Eubacteriaceae* (rRNA cluster XV) and *Clostridiales* (rRNA clusters XI, XII, and XIII). Based upon the nucleotide sequence of the 16S rRNA gene, where the bar corresponds to five substitutions per 100 positions. *Bacillus subtilis* was the outgroup. Bootstrap values >75 (expressed as percentage of 100 replications) are shown at branch points. Asterisks indicate alkaliphiles.

Indole-negative. The predominant long-chain cellular fatty acids consist of a complex mixture of straight-chain saturated and monounsaturated fatty acids and dimethyl acetals (DMAs), with $C_{14:0}$, $C_{16:0}$, $C_{18:1 \text{ cis}9}$, and $C_{18:1 \text{ cis}9}$ DMA predominating.

Isolated from human feces.

DNA G+C content (mol%): 70.

Type species: Anaerofustis stercorihominis Finegold, Lawson, Vaisanen, Molitoris, Song, Liu and Collins 2004, 1005^{VP} (Effective publication: Finegold, Lawson, Vaisanen, Molitoris, Song, Liu and Collins 2004, 44.)

Further descriptive information

The genus contains only one species, *Anaerofustis stercorihominis*, and therefore the characteristics provided below refer to this species. The organism was recovered from human feces. The colonies are 1.5 mm in diameter, gray, circular, raised, smooth, with entire edges after 48 h of anaerobic incubation at 37°C. The colonies display a light yellow fluorescence under long-wave UV light. Resistant to 20% bile. Strictly anaerobic and catalase-negative. Acetic acid is produced in peptone–yeast extract broth, but in peptone–yeast extract glucose broth, acetic and butyric acids are the end products of metabolism. Grows in peptone–yeast extract broth supplemented with 1% of fructose, glucose, mannitol,

ribose, salicin, sucrose, and xylose but grows poorly with lactose, maltose, and mannose. Fructose is fermented with production of acid and gas; weak reactions occur with glucose and xylose. Lecithinase-, lipase-, and urease-negative. Cells are indole-negative, and nitrate is not reduced to nitrite. Using the commercially available API ZYM kit, weak positive reactions are obtained for esterase C4, esterase lipase C8, acid phosphatase, and naphthol-AS-BI-phosphohydrolase. Alkaline phosphatase, lipase C14, leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, α -chymotrypsin, α - and β -galactosidase, β -glucuronidase, α - and β -glucosidase, *N*-acetyl- β -glucosaminidase, α -mannosidase or α -fucosidase are not detected. The predominant long-chain cellular fatty acids are $C_{14:0}$, $C_{16:0}$, $C_{18:1 \text{ cis}9}$, and $C_{18:1 \text{ cis}9}$ DMA, together with other minor straight-chain saturated and monounsaturated fatty acids and DMAs. Resistant to colistin sulfate (10 mg) but sensitive to vancomycin (5 mg) and kanamycin (1000 mg) on the basis of disk diffusion testing.

Isolation procedures

Anaerofustis stercorihominis was recovered from a stool specimen of a 5-year 11-month-old boy with late onset autism before treatment with vancomycin. The entire stool specimen was homogenized using a sterile stainless steel blender with one to three

volumes of peptone (0.05%) added as diluent. An aliquot of the specimen (approximately 1 g) was used to make serial ten-fold dilutions in Pre Reduced Anaerobically Sterilized (PRAS) dilution blanks (Anaerobe Systems, Morgan Hill, CA, USA). Various dilutions (100 µl) were plated onto Brucella blood agar (BAP, Anaerobe Systems) and incubated anaerobically at 37°C under a gas phase comprising N₂, CO₂, and H₂ (86:7:7% by vol.).

Maintenance procedures

Strains grow well on Brucella agar base supplemented with 5% horse blood at 37°C under anaerobic conditions. For long-term preservation, strains can be maintained in the same medium containing 15–20% glycerol at –70°C or lyophilized.

Taxonomic comments

The genus *Anaerofustis* was proposed in 2004 to accommodate a phylogenetically distinct Gram-stain-positive, strictly anaerobic, catalase-negative, rod-shaped organism originating from human feces (Finegold et al., 2004). According to the 16S rRNA phylogenetic analysis presented in the roadmap to this volume (Figure 5), the genus *Anaerofustis* is a member of the family

Eubacteriaceae, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*.

Differentiation of the genus *Anaerofustis* from other genera

In addition to differentiation by 16S rRNA gene sequence analysis, *Anaerofustis stercorihominis* can be readily distinguished on the basis of biochemical, chemotaxonomic, and morphological criteria. For example, it may be differentiated from the genera *Acetobacterium* and *Eubacterium sensu stricto* by its end products of glucose fermentation. It produces acetic and butyric acids whereas *Acetobacterium* produces only acetic acid, and *Eubacterium sensu stricto* forms acetic, butyric, and lactic acids (some species may, in addition, produce formic acid) (Collins et al., 1994). Similarly the unidentified bacterium can be distinguished from *Pseudoramibacter alactolyticus* by its cellular morphology and resistance to 20% bile. *Pseudoramibacter alactolyticus* also produces rod-shaped cells that occur in pairs, resembling flying birds or Chinese characters. In addition, *Pseudoramibacter alactolyticus* produces formic, acetic, butyric, and caproic acids as end products of glucose metabolism (Moore and Holdeman Moore, 1986; Willems and Collins, 1996).

List of species of the genus *Anaerofustis*

1. ***Anaerofustis stercorihominis*** Finegold, Lawson, Vaisanen, Molitoris, Song, Liu and Collins 2004, 1005^{VP} (Effective publication: Finegold, Lawson, Vaisanen, Molitoris, Song, Liu and Collins 2004, 44.)

ster.co.ri.ho'mi.nis. L. neut. n. *stercus -oris* dung, excrements, ordure; L. gen. n. *hominis* of human; N.L. gen. n. *stercorihominis* of human feces.

Cells stain Gram-positive and consist of thin rods (0.5 × 1–3 µm). Colonies after 48 hours of anaerobic incubation at 37°C are 1.5 mm in diameter, gray, circular, raised, smooth, with entire edges. Fluoresces a light yellow under UV light. Acetic acid is produced in peptone-yeast extract broth, but

in peptone-yeast extract glucose broth, acetic and butyric acids are the end products of metabolism. Resistant to 20% bile. Grows in peptone-yeast extract broth supplemented with 1% of fructose, glucose, mannitol, ribose, salicin, sucrose, and xylose but grows poorly with lactose, maltose, and mannose.

Isolated from human feces. Habitat is not known, but this organism probably is a member of the human gut microflora. Other characteristics are as given for the genus.

DNA G+C content (mol%): 70.0 (HPLC).

Type strain: ATCC BAA-858, CCUG 47767, WAL 14563.

GenBank accession number (16S rRNA gene): AJ518871.

Genus V. ***Garciella*** Miranda-Tello, Fardeau, Sepulveda, Fernandez, Cayol, Thomas and Ollivier 2003, 1512^{VP}

ELIZABETH MIRANDA-TELLO, MARIE-LAURE FARDEAU, BERNARD OLLIVIER AND DIDIER ALAZARD

Gar.ci.el'la. L. dim. ending *-ella*; N.L. fem. n. *Garciella* named in honor of the French microbiologist Jean-Louis Garcia for his important contribution to the taxonomy of anaerobes.

Cells are **straight rods**, 0.5–0.7 µm × 1.4–2.8 µm, occurring singly or in pairs. Motile by means of one subpolar flagellum. **Terminal spores** appear in old cultures. **Gram-stain-positive. Obligately anaerobic. Moderately thermophilic and halotolerant.** The optimum growth temperature is 55°C, optimum NaCl concentration is 1%, and optimum pH is 7.5. **Chemo-organotrophic growth.** Ferments sugars. Lactate, acetate, butyrate, H₂, and CO₂ are products of glucose metabolism. **Thiosulfate is reduced to sulfide, and nitrate is reduced to ammonium.** Elemental sulfur, sulfite, sulfate, fumarate, and nitrite are not used as electron acceptors.

DNA G+C content (mol%): 30.9.

Type species: Garciella nitratireducens Miranda-Tello, Fardeau, Sepulveda, Fernandez, Cayol, Thomas and Ollivier 2003, 1512^{VP}.

Further descriptive information

Round, gray colonies (2 mm in diameter) develop in roll tubes under anaerobic conditions after 1 week of incubation at 40°C. Cells are straight rods, 0.5–0.7 µm × 1.4–2.8 µm (Figure 150) and motile by a subpolar flagellum. When grown under optimal conditions in reduced medium in the presence of air, cells form irregular gas vacuoles (Figure 150). Spores are formed in stationary phase cultures or after thermal stress (Figure 150).

FIGURE 150. Cellular morphology of *Garciella nitratreducens*. (a) Phase-contrast micrograph of cells grown in optimal conditions in reduced medium in the presence of air. Intracellular gas vacuoles are the bright bodies within some cells. Bar = 2 µm. (b) Scanning electron microscopy of cells after thermal stress, showing spherical, terminal spores, swollen sporangia (black star) and a subpolar flagellum (arrow). Bar = 1 µm. (Reprinted with permission from E. Miranda-Tello et al., 2003. *International Journal of Systematic and Evolutionary Microbiology*, 53: 1509; © International Union of Microbiological Societies.)

Garciella nitratreducens ferments cellobiose, fructose, galactose, glucose, lactose, maltose, mannose, ribose, sucrose, D-xylose, glycerol, mannitol, fumarate, lactate, malate, pyruvate, and Casamino acids. Compounds not used as energy sources include arabinose, raffinose, rhamnose, starch, cellulose, xylan, acetate, butyrate, propionate, methanol, ethanol, butanol, propanol, formate, methylamine, *p*-coumaric acid, ferulic acid, peptone, bio-Trypticase, and H₂. Thiosulfate or nitrate enhances growth. Yeast extract is required for growth and cannot be replaced by vitamins. *Garciella nitratreducens* can grow in the presence of 25 µg/ml kanamycin or chloramphenicol, 100 µg/ml ampicillin, but not in the presence of 10 µg/ml vancomycin or rifampicin.

Enrichment and isolation procedures

Garciella nitratreducens was originally enriched under anaerobic conditions from production fluids treated in an oil–water separation tank in the Gulf of Mexico using a basal medium as described by Miranda-Tello et al. (2003). Enrichments were serially diluted to extinction three times before isolation. Strains were isolated by the Hungate roll tube technique with medium solidified with 1.6% agar (Hungate, 1969). Serial dilution in roll tubes was performed twice in order to purify the culture.

Maintenance procedures

For long-term preservation, cells can be stored at –80°C in the basal medium plus 20% glycerol.

Differentiation of the genus *Garciella* from other genera

Based on 16S rRNA gene sequence analyses, *Garciella nitratreducens* is closely related to *Caloranaerobacter azorensis* (Wery

et al., 2001), *Alkalibacter saccharofermentans* (Garnova et al., 2004), and *Thermohalobacter berrensii* (Cayol et al., 2000). Characteristics differentiating *Garciella* from these genera belonging to cluster XII (*Caloranaerobacter* and *Thermohalobacter*) and cluster XV (*Alkalibacter*) within the order *Clostridiales* are presented in Table 158. *Garciella* differs in the site of isolation, cell-wall structure, and spore formation. *Caloranaerobacter* was isolated from a deep-sea hydrothermal vent in the Pacific Ocean, *Alkalibacter* was isolated from an alkaline lake with low salt concentration in Russia, whereas *Thermohalobacter* was isolated from sediments of a solar saltern in France. *Garciella* also possesses a thick, homogeneous S-layer not seen in the other genera. In contrast to *Garciella*, neither *Caloranaerobacter*, *Alkalibacter*, nor *Thermohalobacter* form endospores. *Garciella* may be also distinguished by its ability to reduce thiosulfate into sulfide, which appears to be a relatively common metabolic feature for heterotrophic anaerobes isolated from oilfield ecosystems (Ollivier and Cayol, 2005).

Taxonomic comments

The closest relatives of *Garciella* are *Caloranaerobacter*, *Alkalibacter*, and *Thermohalobacter*, with 16S rRNA gene sequence similarities of 88.7%, 88.3%, and 86.1%, respectively. They all belong to the *Clostridium* subphylum of the order *Clostridiales* (Figure 151). However, the genus *Garciella* does not possess high similarity to any of the type genera of the named families within this order. Therefore, its classification is uncertain. Detailed phylogenetic analyses presented in the roadmap to this volume of the *Clostridiales* suggest that *Garciella* may represent a deep branch associated with the *Eubacteriaceae*, while *Caloranaerobacter* and *Thermohalobacter* represent an independent lineage (Figure 5; Ludwig et al., 2009).

List of species of the genus *Garciella*

1. ***Garciella nitratireducens*** Miranda-Tello, Fardeau, Sepulveda, Fernandez, Cayol, Thomas and Ollivier 2003, 1509^{VP}.

ni.tra.ti.re.du'cens. N.L. n. *nitratum* nitrate; L. v. *reduco* to draw backwards, bring back to a state or condition; N.L. part. adj. *nitratireducens* nitrate-reducing.

The characteristics are as described for the genus. The type strain was isolated from a water separator collecting

fluids produced from different oil wells located in SAMIII oilfield, Gulf of Mexico.

DNA G+C content (mol%): 30.9 (HPLC).

Type strain: MET79, DSM 15102, CIP 107615.

GenBank accession number (16S rRNA gene): AY176772.

Genus VI. ***Pseudoramibacter*** Willems and Collins 1996, 1086^{VP}

ANNE WILLEMS AND MATTHEW D. COLLINS

Pseu.do.ra.mi.bac'ter. Gr. adj. *pseudēs* false; L. masc. n. *ramus* a branch; N.L. masc. n. *bacter* the equivalent of Gr. neut. n. *baktron* rod, staff; N.L. masc. n. *Pseudoramibacter* false branching rod.

Strictly anaerobic, catalase-negative, Gram-stain-positive, non-sporeforming rods. Nonmotile. Cells occur in pairs resembling flying birds, short-chains, clumps, or Chinese characters. Growth is stimulated by fermentable carbohydrates. **Fermentation end products are formate, acetate, butyrate, caproate and hydrogen gas. The cell-wall murein is of type A**, containing *meso*-diaminopimelic acid as the dibasic acid. *Pseudoramibacter* belongs to cluster XV of the *Clostridium* subphylum of the Gram-positive bacteria (Collins et al., 1994) together with *Acetobacterium* and *Eubacterium*.

Type species: ***Pseudoramibacter alactolyticus*** (Prévot and Taffanel 1942) Willems and Collins 1996, 1086^{VP}.

Further descriptive information

Because the genus contains only one species, all the characteristics given for the genus also describe the species *Pseudoramibacter alactolyticus*.

Phylogenetic treatment. On the basis of 16S rDNA phylogeny, *Pseudoramibacter* is closely related to the genus *Eubacterium sensu stricto* (approx. 91% sequence similarity) and the genus *Acetobacterium* (approx. 90% sequence similarity) in the *Clostridium* subphylum of the phylum *Firmicutes* (Willems and Collins, 1996).

Cell morphology. Cells grown in peptone-yeast extract-glucose (PYG) broth* (Holdeman et al., 1977) are rods 0.3–0.6 by 1.6–7.5 µm. They occur in pairs resembling flying birds, short-chains, clumps or Chinese characters (Moore and Holdeman Moore, 1986); Y-shaped forms give appearance of false branching.

Cell-wall composition. *Pseudoramibacter* has Gram-stain-positive type cell walls. Cell-wall murein is directly cross-linked with *meso*-diaminopimelic acid as the dibasic acid (Andreesen, 1992; Severin et al., 1989) (type A1γ, nomenclature of Schleifer and

Kandler, 1972). This is a significant difference with its closest phylogenetic relatives *Eubacterium sensu stricto* and *Acetobacterium* which both have mureins of type B (Andreesen, 1992; Schink and Bomar, 1992; Tanner et al., 1981).

Colonial characteristics. After 2–3 d of incubation on horse blood agar, colonies are punctate to 0.5 mm in diameter, round with an entire margin, convex to pulvinate, smooth and shiny. Smaller colonies can be translucent and larger colonies are often opaque (Moore and Holdeman Moore, 1986). Deep agar colonies are lenticular.

Nutrition and growth conditions. Optimal growth temperature is 35–37°C. Most strains grow at 30°C and some grow at 25 and 45°C. Optimal pH is between 6 and 8. Growth is stimulated by fermentable carbohydrates, but not by 0.02% Tween 80 or 5% rumen fluid and is inhibited by 20% bile. Glucose broth cultures are usually turbid with formation of granular or smooth (sometimes ropy or flocculent) sediment; occasionally sediment formation occurs without turbidity in broth cultures. The terminal pH in glucose cultures is 5.0–5.6 or, occasionally, 5.8–6.0 (Moore and Holdeman Moore, 1986).

Metabolism and metabolic pathways. *Pseudoramibacter* has a strictly anaerobic, fermentative metabolism. End products produced from PYG broth are (in milliequivalents/100 ml of culture) formate, 0.01–1.0; acetate, 0.01–0.5; butyrate, 0.1–0.5; and caproate, 0.2–2.0. Abundant hydrogen gas is produced and small amounts of caprylate may also be produced. Pyruvate is converted to acetate and formate. Lactate is not used. Threonine is not converted to propionate. In the presence of glucose and propionic acid, valeric and heptanoic acids are produced (Moore and Holdeman Moore, 1986).

Acid (pH <5.5) is produced from fructose and glucose (but weak by some strains; (Holdeman et al., 1977), but not from amygdalin, arabinose, cellobiose, dulcitol, galactose, glycerol, glycogen, inositol, inulin, lactose, maltose, mannose, melezitose (weak by some strains; Holdeman et al., 1977), melibiose, raffinose, rhamnose, ribose, salicin, sorbose, starch, sucrose, trehalose and xylose. Some strains produce acid from amygdalin, mannitol or sorbitol (pH <5.5) or from erythritol or esculin (weak reaction). Acid production from adonitol is variable (Holdeman et al., 1977; Moore and Holdeman Moore, 1986).

Resazurin is usually not reduced. The following characteristics are negative: catalase, lecithinase, lipase, hemolysis,

* Composition of PYG: 0.5 g peptone, 0.5 g trypticase, 1 g yeast extract, 0.4 ml resazurin solution (25 mg in 100 ml of distilled water), 4 ml salts solution (0.2 g CaCl₂, 0.2 g MgSO₄, 1 g K₂HPO₄, 1 g K₂HPO₄, 10 g NaHCO₃, 2 g NaCl; dissolve CaCl₂ and MgSO₄ in 300 ml distilled water; add 500 ml water and while swirling, slowly add remaining salts, when dissolved, add 200 ml distilled water and mix; store at 4°C), 100 ml distilled water, 1 ml hemin solution (dissolve 50 mg hemin in 1 ml 1 N NaOH; make to 100 ml with distilled water, autoclave for 15 min at 121°C), 0.02 ml vitamin K1 solution (Dissolve 0.15 ml of vitamin K1 in 30 ml of 95% ethanol; keep for max. 1 month, at 4°C in a brown bottle), 0.05 g cysteine-HCl H₂O, 1 g glucose; vitamin K1, hemin and cysteine are added after the medium is boiled, but before dispensing and autoclaving (Holdeman et al., 1977).

TABLE 158. Major characteristics that discriminate *Garciella nitratreducens* from *Caloranaerobacter azorensis*, *Alkalibacter saccharofermentans*, and *Thermohalobacter berrensis*^a

Characteristic	<i>Garciella nitratreducens</i> ^b	<i>Caloranaerobacter azorensis</i> ^c	<i>Alkalibacter saccharofermentans</i> ^d	<i>Thermohalobacter berrensis</i> ^e

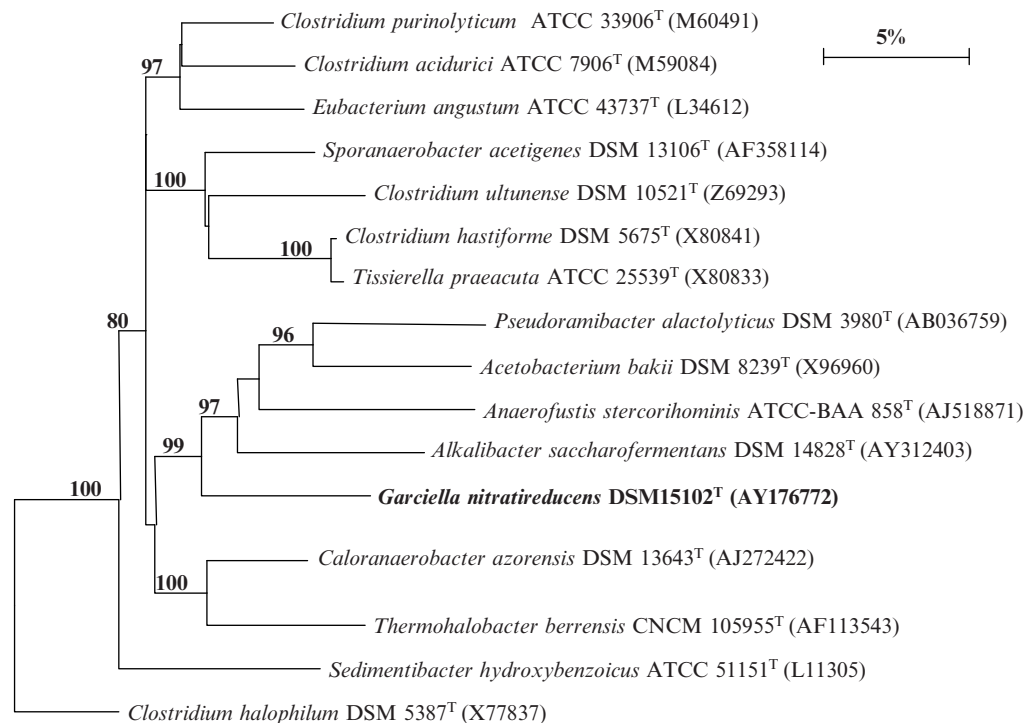

FIGURE 151. Phylogeny of *Garciella nitratreducens* and closely related members of *Clostridiales* based upon the 16S rRNA gene. A neighbor-joining dendrogram is shown with *Clostridium halophilum* as the outgroup. Bootstrap values from 100 replicates are shown at the nodes. Only values greater than 95 are reported. The bar represents 5 inferred substitutions per 100 positions.

hydrolysis of hippurate, esculin and starch, H₂S production in sulfide-indole motility medium, production of indole and acetylmethylcarbinol, digestion of meat and gelatin, and nitrate reduction. Milk is not coagulated. Some strains can grow in bile medium and some strains produce ammonia (Holdeman et al., 1977; Moore and Holdeman Moore, 1986).

Antibiotic sensitivity. Twenty-five strains of *Pseudoramibacter alactolyticus*, including the type strain, were susceptible to chloramphenicol (12 µg/ml), clindamycin (1.6 µg/ml), erythromycin

(3 µg/ml), penicillin G (2 U/ml) and tetracycline (6 µg/ml) (Moore and Holdeman Moore, 1986).

Ecology. *Pseudoramibacter alactolyticus* is a member of the normal mouth flora (Holdeman et al., 1977) and has also been identified among isolates associated with periodontitis in young adults (Moore et al., 1985; Moore et al., 1982) where *Pseudoramibacter alactolyticus* was identified in 57% of samples taken from diseased sites (Moore et al., 1985). It occurs in gingival crevices and periodontal pockets of humans with periodontal disease

(Moore and Holdeman Moore, 1986). It has been identified from infected dental root canals (Piovano, 1999; Siqueira and Rocas, 2004; Sundqvist, 1992), cases of advanced caries (Chhour et al., 2005) and in microflora of nifedipine-induced gingival overgrowth in patients with cardiovascular disorders (Nakou et al., 1998). Like several *Eubacterium* species, *Pseudoramibacter alactolyticus* is able to coaggregate with *Fusobacterium nucleatum*, another member of the human oral microflora often associated with infections. The ability to coaggregate may be important in the infection process (George and Falkler, 1992). *Pseudoramibacter alactolyticus* has also been identified in the subgingival microflora of healthy children with primary dentition (4–5-year-olds) and mixed dentition (7–8-year-olds) where it is associated with non-bleeding sites (Kamma et al., 2000b, a). It was also detected among isolates from odontogenic infections, infections associated with dental implants or saliva from healthy subjects (Downes et al., 2001).

Pseudoramibacter also occurs in various infected materials and abscesses: purulent pleurisy, jugal cellulitis, postoperative wounds, abscesses of the brain, lung, intestinal tract and mouth (Moore and Holdeman Moore, 1986).

Enrichment and isolation procedures

No specific enrichment and isolation procedures selecting for *Pseudoramibacter* have been described. These bacteria can be isolated from the gingival crevices and periodontal pockets of humans suffering from periodontitis by using standard procedures for the isolation of anaerobic bacteria (Holdeman et al., 1977).

Maintenance procedures

Cultures can be maintained using prerduced media and standard procedures for culturing anaerobic bacteria (Holdeman et al., 1977). Strains can be lyophilized for long-term preservation.

Differentiation from other Gram-stain-positive, anaerobic, nonsporeforming bacilli

Pseudoramibacter can be differentiated from its nearest phylogenetic neighbors, *Acetobacterium* and *Eubacterium sensu stricto* (comprising *Eubacterium barkeri*, *Eubacterium callanderi* and

Eubacterium limosum) by its high G+C content, its murein type, fermentation end products and its inability for autotrophic growth with H₂ and CO₂ (Table 159). Its presence in cases of advanced caries (Chhour et al., 2005) and periradicular lesions of root-filled teeth (Siqueira and Rocas, 2004) has been demonstrated with PCR and sequence analysis of 16S rRNA genes. A nested PCR test specifically targeting *Pseudoramibacter ramibacter* 16S rDNA has been used to detect the species in samples from endodontic infections (Siqueira and Rocas, 2003).

Taxonomic comments

Ramibacterium alactolyticum was described in 1942 for anaerobic, Gram-stain-positive, nonmotile, pleiomorphic, nonsporeforming rods (Prévot and Taffanel, 1942). Later two further species, *Ramibacterium pleuriticum* and *Ramibacterium dentium* were described for similar organisms (Prévot et al., 1947; Vinzent and Reynes, 1947). None of the strains used for the original descriptions of these species were preserved, but in a study of the other named strains of these species available from the Institute Pasteur, Holdeman et al. (1967) showed *Ramibacterium alactolyticum*, *Ramibacterium pleuriticum* and *Ramibacterium dentium* to form a single group. They were therefore regarded as objective synonyms with the oldest name, *Ramibacterium alactolyticum*, having priority. Strain DO-4 (= VPI 1416) was designated neotype strain (Holdeman et al., 1967).

Ramibacterium alactolyticus was later transferred to the genus *Eubacterium* as *Eubacterium alactolyticum* (Holdeman and Moore, 1970). On the basis of 16S rRNA gene sequences it was confirmed that *Eubacterium alactolyticum* was indeed phylogenetically close to the type species *Eubacterium limosum* and also to *Clostridium barkeri* and *Acetobacterium woodii* (Weizenegger et al., 1992) and along with these organisms belonged to cluster XV of the *Clostridium* subphylum of the Gram-positive bacteria (Collins et al., 1994). Analysis of additional *Acetobacterium* species and *Eubacterium callanderi*, showed that *Eubacterium alactolyticum* in fact occupies a separate position in cluster XV, and therefore it was removed from the genus *Eubacterium* and transferred to a new genus *Pseudoramibacter* as *Pseudoramibacter alactolyticus* (Willems and Collins, 1996). According to the 16S rRNA

TABLE 159. Differentiation of *Pseudoramibacter* from its nearest phylogenetic neighbors and some other genera Gram-stain-negative, nonsporeforming rods

Genus	<i>Acetobacterium</i> ^a	<i>Eubacterium sensu stricto</i> ^b	<i>Pseudoramibacter</i> ^c	<i>Lactobacillus</i> ^d	<i>Carnobacterium</i> ^d
H ₂ -CO ₂ autotrophic growth	+	v ^e	-		
Murein ^f	Type B	Type B2α	Type A1γ	Type A (Lys or Dmp or Orn)	Type A1γ
Fermentation end products from glucose	Acetate	Acetate, butyrate, lactate, formate ^g , hydrogen	Formate, acetate, butyrate, caproate, hydrogen	Lactate (homofermenters) or lactate, acetate, ethanol and CO ₂ (heterofermenters)	Lactate, acetate, ethanol and CO ₂
DNA G+C content (mol%)	39–46	45–50	61	32–55	33–37

^aData from Kotsyurbenko et al. (1995), Schink and Bomar (1992) and Tanner (1986).

^bData from Andreesen (1992), Cato et al. (1986), Moore and Holdeman Moore (1986), Mountfort et al. (1988) and Tanner et al. (1981).

^cData from Andreesen (1992), Moore and Holdeman Moore (1986) and Nakazawa and Hoshino (1994).

^dData from Hammes et al. (1992).

^ev, variable: *Eubacterium limosum* is positive, *Eubacterium barkeri* and *Eubacterium callanderi* are negative.

^fTypes as defined by Schleifer and Kandler (1972).

^gOnly produced by *Eubacterium callanderi*.

phylogenetic analysis presented in the roadmap to this volume (Figure 5), the genus *Pseudoramibacter* is a member of the family *Eubacteriaceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*.

List of species of the genus *Pseudoramibacter*

1. ***Pseudoramibacter alactolyticus*** (Prévot and Taffanel 1942) Willems and Collins 1996, 1086^{VP} (*Eubacterium alactolyticum* Prévot and Taffanel 1942) Holdeman and Moore 1970, 23^{AL}; *Ramibacterium alactolyticum* Prévot and Taffanel 1942, 261)

a.lac.to.ly'ti.cus. Gr. pref. *a* not; L. n. *lac*, *lactis* milk; N.L. adj. *lyticus* dissolving; N.L. masc. adj. *alactolyticus* not milk-digesting.

Characteristics of the species are the same as those given for the genus.

Isolated from dental callus and the gingival crevices of patients with periodontal disease, from dental root canals, and from patients with various infections, including purulent

pleurisy, jugal cellulitis, postoperative wounds, and abscesses of the brain, lung, intestinal tract, and mouth.

The type strain is ATCC 23263 and originated from purulent pleurisy. Its characteristics are the same as those of the species. This strain does not ferment adonitol, dextrin, dulcitol, galactose, glycerol, inulin, or sorbose. It does not produce ammonia from peptone, arginine, or threonine.

DNA G+C content (mol%): 61 (HPLC; Nakazawa and Hoshino, 1994).

EMBL/GenBank accession number (16S rRNA gene) for the type strain: AB036759.

Family III. *Gracilibacteraceae* fam. nov.

YONG-JIN LEE, ROB U. ONYENWOKE AND JUERGEN WIEGEL

Gra.ci.li.bac.ter.a'ce.ae. N.L. masc. n. *Gracilibacter* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Gracilibacteraceae* the *Gracilibacter* family.

Straight to curved rods that are 0.2–0.4 µm in diameter × 2.0–7.0 µm in length. Elongate infrequently up to 45 µm. Cells occur singly or form chains. Gram-positive wall structure, but stain Gram-negative. **Nonsporeforming.** Cells in old cultures become like **autoplasts** (L-shaped cells). Obligately anaerobic.

Thermotolerant. Chemoorganotrophs.

DNA G+C content (mol%): 43.

Type genus: **Gracilibacter** Lee, Romanek, Mills, Davis, Whitman and Wiegel 2006, 2092^{VP}.

Further descriptive information

The family *Gracilibacteraceae* belongs to the order *Clostridiales*. To date, it is represented by only one genus containing one species. Its closest neighbor in an inferred phylogenetic tree is *Clostridium thermosuccinogenes*, a member of the new family "*Ruminococcaceae*" (Ludwig et al., 2009). The delineation of the novel family "*Gracilibacteriaceae*" was primarily based on phylogenetic criteria and a few metabolic and physiological characteristics observed, with *Gracilibacter* as the type for the family. From the phylogenetic

analyses (Figure 6), *Gracilibacter* is distantly related to members of the *Clostridiaceae* (formerly Collins' *Clostridium* cluster I/II) and the new family "*Ruminococcaceae*" (formerly Collins' *Clostridium* cluster III). In addition to the phylogenetic evidence, *Gracilibacter* does not form endospores as tested under various conditions. The present member of the genus *Gracilibacter* is not cellulolytic, which distinguishes it from the cellulolytic species in the "*Ruminococcaceae*". The genus *Mahella* is presently not included in the family "*Gracilibacteraceae*" nor in the family "*Thermoanaerobacteraceae*" as originally suggested due to variation in its position in different phylogenetic trees (Ludwig et al., 2009).

Key to the genera of the family *Gracilibacteraceae*

1. The DNA G+C content is around 43 mol%. Growth only under anaerobic conditions. Optimal growth is at 42–47 °C. No indication of chemolithoautotrophic growth with H₂/CO₂. Indole is produced. No production of H₂S. Major branched-chain fatty acids of the lipids are C_{15:0 iso}, C_{15:0 ante}, C_{16:0 iso}, and C_{17:0 iso}.

Genus I. *Gracilibacter* Lee, Romanek, Mills, Davis, Whitman and Wiegel 2006, 2092^{VP}

YONG-JIN LEE AND JUERGEN WIEGEL

Gra.ci.li.bac'ter. L. adj. *gracilis* slender; N.L. masc. n. *bacter* equivalent of Gr. neut. n. *baktron* rod or staff; N.L. masc. n. *Gracilibacter* slender rod, referring to its cell shape.

Gram-positive cell-wall structure, but stains Gram-negative. Slightly polymorphic rods. Obligately anaerobic, chemoorganotrophic, and thermotolerant. No spores have been observed under various conditions tested. Not resistant to heating at 80 °C for 10 min.

DNA G+C content (mol%): 43.

Type species: **Gracilibacter thermotolerans** Lee, Romanek, Mills, Davis, Whitman and Wiegel 2006, 2092^{VP}.

Further descriptive information

The genus *Gracilibacter* is to date represented by only one species, and this description reflects the properties of that species. Based on an inferred phylogenetic tree, the closest cultured relative is *Clostridium thermosuccinogenes*, a member of the new family "*Ruminococcus*" (formerly *Clostridium* cluster III; Collins et al., 1994; Rainey et al., 2006; Ludwig et al., 2009). BLAST analysis yields *Clostridium pascui* (*Clostridiaceae sensu stricto*) with about 92% similarity as the taxon with the highest similarity in the 16S rRNA gene (Figure 152). Specific habitats are unknown, however, 16S rRNA genes with similar sequences have been found in various environments including hydrocarbon-degrading methanogenic consortia, rice paddy soils, oil reservoirs, and urban aerosols.

Cells are straight to curved rods, 0.2–0.4 µm × 2.0–7.0 µm, with infrequently elongated cells of up to 45 µm. Cells are either single or form chains. During the late-stationary growth phase, autoplasts (L-shaped-like cells) can occur. Endospores have not been observed. Cells are sluggishly motile or nonmotile depending upon the growth conditions. Cells have 1–5 peritrichous flagella (Figure 153).

Growth characteristics

Growth conditions. The temperature range for growth is 25–54 °C, with an optimum at 42.5–46.5 °C. Thus, the type strain is a thermotolerant anaerobe. The pH^{25°C} range for growth is 6.0–8.25 with an optimum at 6.8–7.75. The salinity range for growth is from 0–1.5% (w/v) with an optimum at 0.5%.

Saccharolytic and peptidolytic growth. *Gracilibacter thermotolerans* requires yeast extract for growth. In the presence of 0.02% yeast extract, Casamino acids, tryptone, peptone, maltose, sucrose, arabinose, fructose, galactose, glucose, mannose, xylose, mannitol, and sorbitol serve as carbon and energy sources. No growth has been observed with cellobiose, lactose, raffinose, ribose, trehalose, inositol, mannitol, xylitol, acetate, lactate, pyruvate, methanol, and carboxymethyl cellulose (1.0% w/v, CMC 7LT or 7M; Hercules) as carbon and energy

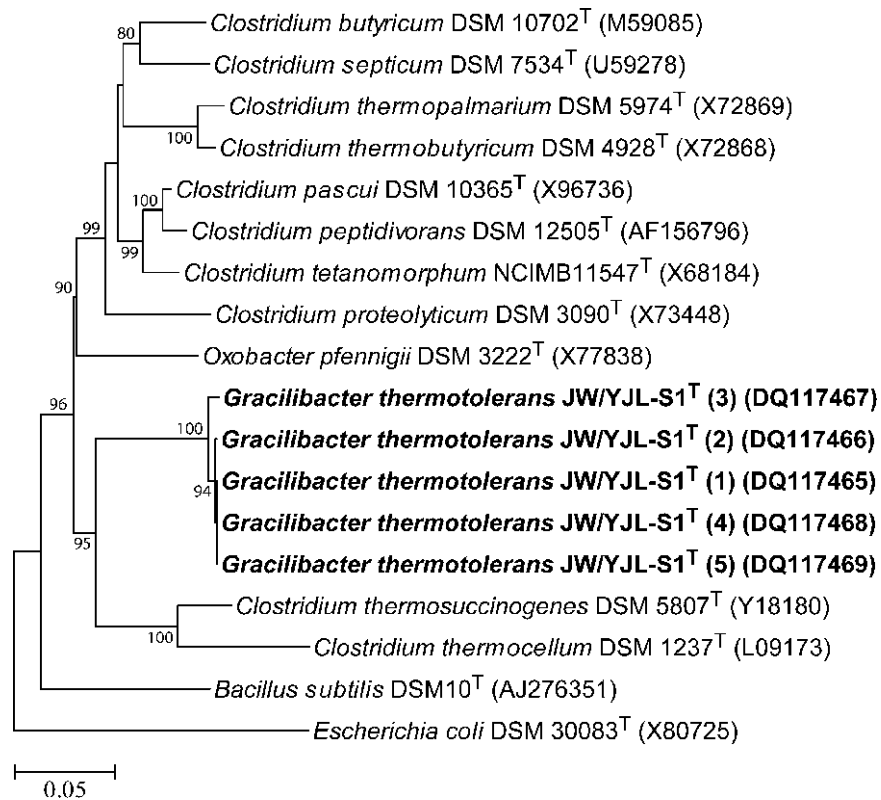

FIGURE 152. Phylogenetic dendrogram based on 16S rRNA gene sequences showing the relationship of five clones of *Gracilibacter thermotolerans* strain JW/YJL-S1^T to representatives of the *Clostridiales*. Neighbor-joining method with Jukes and Cantor distance corrections. Numbers at the nodes represent the bootstrap values (1000 replicates). Bar = 5 nucleotides substitutions per 100 nucleotides. (From Lee et al., 2006; *Int. J. Syst. Evol. Microbiol.* 56: 2089–2093. Used with permission of the publisher.)

FIGURE 153. Electron micrographs of *Gracilibacter thermotolerans* showing cells with 1–5 peritrichously inserted flagella (a) and a representative image of the cell (b). The inset in (b) shows a thin section demonstrating the Gram-positive cell-wall structure and S-layer. (From Lee et al., 2006; *Int. J. Syst. Evol. Microbiol.* 56: 2089–2093. Used with permission of the publisher.)

sources. The main fermentation end products from glucose are acetate, lactate, and ethanol. No chemolithoautotrophic growth has been detected using H_2/CO_2 (80:20, v/v). No indication of growth has been observed using Fe(III), MnO_2 , nitrate, thiosulfate, elemental sulfur, sulfate, sulfite, or fumarate as electron acceptors. The doubling time for *Gracilibacter*

thermotolerans is 3.1 h at 42 °C and pH^{25C} 6.5 with 0.3% yeast extract as the substrate.

Antibiotic resistance. Growth of *Gracilibacter thermotolerans* at pH^{25C} 6.8 and 42 °C is resistant to streptomycin at 10 μM but inhibited by 10 μM of ampicillin, chloramphenicol, erythromycin, rifampin, and tetracycline and by 100 μM streptomycin.

Enrichment and habitat

Gracilibacter thermotolerans was isolated from an enrichment in a carbonate-buffered basal medium (Widdel and Bak, 1992) supplemented with 20 mM acetate and 0.1 mM ferric citrate at pH^{25°C} 6.8 and 37 °C under anaerobic conditions (N₂, 100%). The strain also grows in a phosphate-buffered medium and classical peptone-sugar media including peptone-yeast extract, peptone-yeast extract-glucose, reinforced clostridial medium (Difco), and thioglycolate broth (Difco).

Gracilibacter thermotolerans was isolated from the uppermost sediment in a constructed wetland system at the Savannah River Site (Aiken, SC, USA). The organic substrate used for the constructed treatment wetland was composed primarily of composted stable wastes and spent brewing grains therefore, no defined habitat can be given. However, 16S rRNA genes with similar sequences have been found in various environments including hydrocarbon-degrading methanogenic consortia, rice paddy soils, oil reservoirs, and urban aerosols.

Maintenance procedures

The best method of preservation is storage in liquid nitrogen. Long-term storage is presently done as a freeze-dried culture (DSMZ). Short-term storage (up to 3 years) is performed in prerduced medium containing 12–15% (v/v) glycerol at –20 °C (for frequent sampling since the mixture stays liquid)

and –80 °C for longer and uninterrupted storage. Storage in liquid medium at room temperature is possible for several months.

Differentiation from closely related taxa

Phylogenetic analyses of its 16S rRNA genes failed to place *Gracilibacter thermotolerans* within any of the currently described families. It is outside the radiation of the *Clostridiaceae sensu stricto* as well as the “*Ruminococcaceae*” (formerly Collins’ *Clostridium* cluster III). The more complete phylogenetic analyses of the *Firmicutes* places it as a unique lineage within the *Clostridiales* (Ludwig et al., 2009) as the separate family “*Gracilibacteraceae*”. Besides the phylogenetic evidence, *Gracilibacter thermotolerans* has different physiological properties from the members of the genus *Clostridium sensu stricto* and *Oxobacter pfennigii* (genus IX in the *Clostridiaceae*). Whereas most *Clostridium* species and *Oxobacter pfennigii* form endospores, endospores have not been detected in *Gracilibacter thermotolerans*. Unlike the members of the family “*Ruminococcaceae*”, *Gracilibacter thermotolerans* is not cellulolytic, does not produce succinic acid, and does not grow above 60 °C.

Miscellaneous comments

The 16S rRNA genes of strain JW/YJL-S1^T are polymorphic. Among five clones of the 16S rRNA gene sequenced, four possessed >99% sequence similarity, while the fifth clone possessed about 2% divergence from the rest.

List of species of the genus *Gracilibacter*

1. *Gracilibacter thermotolerans* Lee, Romanek, Mills, Davis, Whitman and Wiegel 2006, 2092^{VP}

ther.mo.to'le.rans. Gr. n. *thermê* heat; L. pres. part. *tolerans* tolerating; N.L. part. adj. *thermotolerans* heat-tolerating.

Obligatory anaerobe, thermotolerant, and asporogenic (Onyenwoke et al., 2004). Endospores have not been observed by microscopy or by heat treatment (10 min. at 80 °C) under all tested growth conditions. The phospholipid fatty acid composition is dominated by C_{16:0} fatty acid (29.0%) and the branched-chained fatty acids (C_{15:0 iso}, C_{15:0}

ante⁷, and C_{17:0 iso}) which account for 39.2% of the total phospholipid fatty acids. In addition, small amounts of the unsaturated C_{16:1}, C_{17:1}, and C_{18:1} fatty acids (5.4%, 5.4%, and 2.5%, respectively) are also present. Positive for esterase, leucine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, β-galactosidase, α-glucosidase, and β-glucosidase. Produces indole, but not H₂S.

DNA G+C content (mol%): 42.8 (HPLC).

Type strain: JW/YJL-S1, ATCC BAA-1219, DSM 17427.

GenBank accession number (16S rRNA gene): DQ117465, DQ117466, DQ117467, DQ117468, DQ117469.

Family IV. *Heliobacteriaceae* Madigan 2001, 625

MARIE ASAO AND MICHAEL T. MADIGAN

He.li.o.bac.te.ri.a'ce.ae. N.L. neut. n. *Heliobacterium* type genus of the family; *-aceae* ending to denote a family; N.L. fem. pl. n. *Heliobacteriaceae* the *Heliobacterium* family.

Species of the family *Heliobacteriaceae* (the heliobacteria) are **anoxygenic phototrophs** that have **rod-shaped or spirillum-shaped cells** and multiply by **binary fission**. Rod-shaped cells are sometimes curved or twisted. In the genus *Heliophilum*, cells are straight and tapered and group together to form bundles that are motile as a unit. Currently, four genera with a total of ten species have been formally described.

Cells of heliobacteria **stain Gram-negative, although an outer membrane is lacking**. The heliobacteria form a distinct clade within the phylum *Firmicutes* (Madigan and Ormerod, 1995; Ormerod et al., 1996a; Woese et al., 1985). The closest relatives of the heliobacteria are species of *Desulfitobacterium*, chemotrophic bacteria that carry out anaerobic respiration using various electron acceptors, including sulfite, nitrate, Fe³⁺, or halogenated organic compounds (Figure 154). **Motility in the heliobacteria is by gliding or flagellar means**; if the latter, then by polar, subpolar, or peritrichous flagella.

Heliobacteria **contain bacteriochlorophyll *g*** as sole bacteriochlorophyll (Brockmann and Lipinski, 1983; Michalski et al., 1987) and diaponeurosporene (Takaichi et al., 1997) as the major carotenoid; small amounts of 8'-OH-chlorophyll *a* is also present (Amesz, 1995). Alkaliphilic species of heliobacteria contain a variety of glycosylated carotenoids (Takaichi et al., 2003). Bacteriochlorophyll *g* and 8'-OH-chlorophyll *a* are esterified with the C-15 alcohol farnesol. **The color of phototrophically grown (anoxic/light) cultures of heliobacteria is brownish-green** although cultures turn emerald green in stationary phase or if exposed to air. **Intracytoplasmic membranes of the kind observed in phototrophic purple bacteria or chlorosomes characteristic of the green sulfur or green nonsulfur bacteria are not observed** in heliobacteria (Figure 155 and Figure 156). In addition, **gas vesicles have never been found**.

Metabolism of the heliobacteria is strictly anaerobic; cells grow as **photoheterotrophs** on a limited number of organic carbon sources or **chemo-organotrophically** (in darkness) by fermentation of pyruvate or other simple organic compounds (Kimble et al., 1994). Pyruvate is used by all heliobacteria. Aerobic or microaerobic dark growth has not been observed. In addition, **photoautotrophic growth on CO₂ + H₂ or on CO₂ + H₂S has not been observed** in any species of heliobacteria, and the genome of *Heliobacterium modesticaldum* (which has been sequenced, Sattley et al., 2008) lacks genes encoding proteins of any known autotrophic pathway. Sulfide tolerance varies among heliobacteria; some species are quite sulfide sensitive whereas others are quite tolerant. However, in media containing sulfide, the **sulfide is oxidized and elemental sulfur is formed and deposited outside the cells**. Optimal pH for growth of most heliobacteria is 7, with a **pH growth range of 5.5–8**, depending on the species. Species of the genus *Heliorestis* are **alkaliphilic and show pH optima near 9** with growth occurring from pH 8–10. **Optimal temperature is 37–42 °C for most heliobacteria (52 °C for the single known thermophilic species) and 30–32 °C for alkaliphilic species**. Ammonium salts and glutamine are used as nitrogen sources by all heliobacte-

ria, and certain species can use other amino acids as well. All heliobacteria that have been tested **fix nitrogen gas** (Kimble and Madigan, 1992; Madigan, 1995). **Biotin is required** for growth by most heliobacteria, and some species also require a reduced sulfur compound (sulfide, thiosulfate, or cysteine) for biosynthetic purposes. Low levels (0.025–0.05%) of yeast extract typically stimulate growth. **Neither poly-β-hydroxybutyrate nor glycogen, common carbon storage polymers in other anoxygenic phototrophs, have been observed in heliobacteria**.

Endospores containing dipicolinic acid and elevated levels of Ca²⁺ are produced by some heliobacteria (Ormerod et al., 1996a) and this property is likely to be universal (Kimble-Long and Madigan, 2001). However, loss of the ability to form endospores in laboratory cultures is commonly observed. Heliobacteria are found **primarily in soil** (Stevenson et al., 1997) and in this regard differ significantly in their ecology from purple and green anoxygenic phototrophs. *Heliobacterium modesticaldum* is thermophilic and inhabits neutral to alkaline hot springs worldwide at temperatures below 60 °C.

Recently, two new strains of heliobacteria were isolated from alkaline soda lakes, Lake El Hamra (Wadi El Natroun, Egypt) and Soap Lake (Washington, USA) (unpublished results). Preliminary characterization of the strain isolated from soil of the shoreline of Lake El Hamra showed that this bacterium was an alkaliphilic, motile rod and clearly a member of the genus *Heliorestis* based on 16S rRNA gene analysis. However, unlike other heliobacteria, all of which utilize only a restricted set of carbon sources, the El Hamra strain photoassimilated a wide variety of carbon substrates, including several amino acids.

The heliobacterium isolated from Soap Lake was remarkable from the standpoint of its habitat and phylogeny. This organism was isolated from lake sediment at a depth of 23 m, which indicates that heliobacteria are not totally restricted to terrestrial habitats (Stevenson et al., 1997). The Soap Lake heliobacterium is an alkaliphilic, motile, curved rod. Although all of the alkaliphilic species of heliobacteria previously isolated from soda lakes are phylogenetically closely related, forming a monophyletic clade of the genus *Heliorestis* (Figure 154), the Soap Lake isolate is outside this clade, possibly representing a novel genus basal to the nonalkaliphilic heliobacteria (data not shown). These results suggest that the phylogeny of heliobacteria may be more extensive than previously acknowledged and that other aquatic heliobacteria exist.

DNA G+C content (mol %): 45–57.

Type genus: Heliobacterium Gest and Favinger 1985, 223^{VP} (Effective publication: Gest and Favinger 1983, 15.).

Further descriptive information

The family *Heliobacteriaceae* contains all of the anoxygenic phototrophic bacteria that synthesize bacteriochlorophyll *g*. This structurally and spectrally unique bacteriochlorophyll distinguishes these organisms from the purple bacteria, which

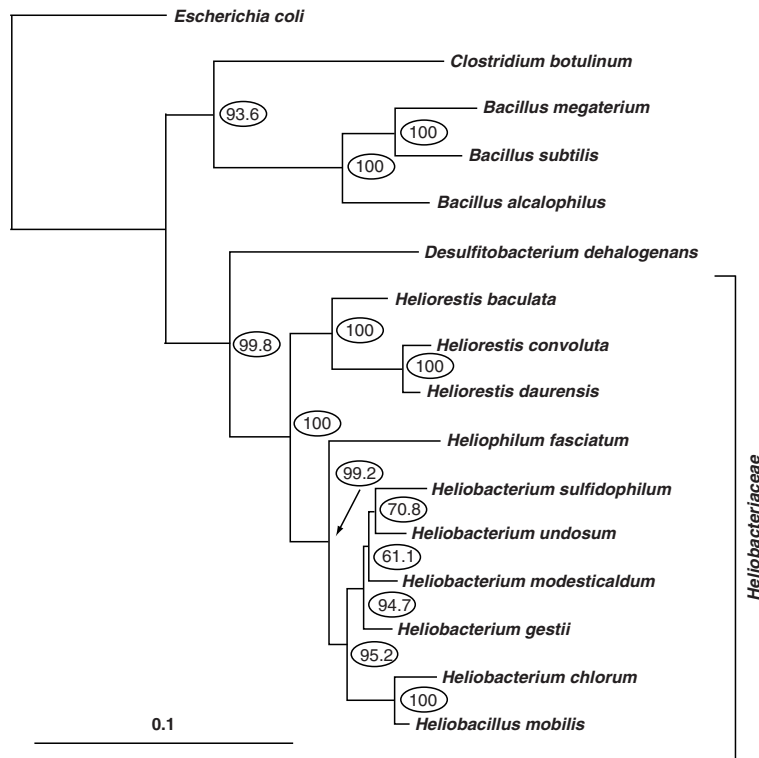

FIGURE 154. Phylogenetic tree of the family *Heliobacteriaceae* based on 16S rRNA gene sequences. 1301 nucleotide positions were compared. The tree was computed using PHYLIP version 3.66 (Felsenstein, 1989). Alignment was converted to a distance matrix using F84 algorithm (transition/transversion ratio = 2.0, empirical base frequencies) in the program DNADIST. The tree was based on the neighbor-joining method using the program NEIGHBOR. Bootstrap analysis was conducted on 1000 replications; the confidence values >50% are indicated at the nodes. The tree was rooted using *Escherichia coli* (Gamma proteobacteria) as the outgroup. All the sequences have been deposited in GenBank as follows: *Escherichia coli* (J01859), *Clostridium botulinum* (X68187), *Bacillus megaterium* (X60629), *Bacillus subtilis* (AJ276351), *Bacillus alcalophilus* (X76436), *Desulfitobacterium dehalogenans* (L28946), *Heliorestis baculata* (AF249680), *Heliorestis convoluta* (DQ266255), *Heliorestis daurensis* (AF079102), *Heliophilum fasciatum* (L36197), *Heliobacterium sulfidophilum* (AF249678), *Heliobacterium undosum* (AF249679), *Heliobacterium modesticaldum* (U14559), *Heliobacterium gestii* (L36198), *Heliobacterium chlorum* (M11212); *Heliobacillus mobilis* (U14560).

^bData obtained from Gest and Favinger (1983), Beer-Romero and Gest (1987), Beer-Romero and Madigan (1992), Kimble and Madigan (1992), Kimble et al. (1995), Ormerod et al. (1996a), Stevenson et al. (1997), Takaichi et al. (1997), Bryaniseva et al. (1999), Bryaniseva et al. (2000a, 2001a), Takaichi et al. (2003), and Asao et al. (2006).

^cHPLC analysis was not conducted in determining the type of carotenoid. Bryaniseva et al. (2000b) indicated the presence of neurosporene based on the *in vivo* absorption spectrum peak at 412 nm. However, it is likely that this is 4,4'-diaponeurosporene, as for other heliobacteria that grow at neutral pH.

^dThe standard three-letter amino acid abbreviations were used where appropriate. Nitrogen fixation was not tested for *Heliothrix baculata* and *Heliothrix dauvensis*.
^eThe standard three-letter amino acid abbreviations were used where appropriate. H₂S may exist in its anionic form (HS⁻) at high pH, in which the species of *Heliothrix* are normally cultured.

^fPhase-bright structures in the coiled cells were observed in the enrichment cultures; whether these structures were indeed endospores is unknown (Bryaniseva et al., 1999). Kimble-Long and Madigan (2001) present molecular evidence that endospore formation is a universal property of species of *Heliobacteriaceae*.

contain bacteriochlorophyll *a* or *b*, and the green sulfur (*Chlorobium* and relatives) and green nonsulfur (*Chloroflexus* and relatives) bacteria, which contain bacteriochlorophylls *c*, *d*, or *e*, or bacteriochlorophyll *c*, respectively. *In vivo* absorption spectra (performed anoxically) of heliobacteria show a major peak at 784–792 nm (depending on the species) due to absorption by bacteriochlorophyll *g* and comparatively small peaks at about 575 and 670 nm; the latter is due to a small amount of 8'-OH-chlorophyll *a* present in the reaction center. Exposure of cultures of heliobacteria to air causes the oxidation of bacteriochlorophyll *g* to chlorophyll *a*, a major increase in absorbance at 670 nm coupled to a corresponding loss of absorbance at 788 nm, and loss of cell viability. Fermentatively (anoxic/dark) grown cells of heliobacteria produce bacteriochlorophyll and carotenoids (Kimble et al., 1994), showing that pigment synthesis does not require light.

The cell wall of heliobacteria is fragile, and stationary phase cells of many species form sphaeroplasts. The peptidoglycan of the heliobacteria, which is present in cells in small amounts, contains L,L-diaminopimelic acid instead of meso-diaminopimelic acid as the diamino acid. Heliobacterial cell walls also contain a considerable amount of lipid, although this lipid is not lipopolysaccharide (Beck et al., 1990) and is not arranged in an outer membrane. Heliobacteria are unusually sensitive to penicillin; for example, growth of *Heliobacterium chlorum* is inhibited by 2 ng/ml of penicillin G, a level 1000-fold lower than the growth-inhibitory level for *Escherichia coli* (Beer-Romero et al., 1988).

The heliobacteria are differentiated from all other anoxygenic phototrophs by virtue of their production of bacteriochlorophyll *g*.

A summary of the properties of the four genera and ten species described within the family *Heliobacteriaceae* is given in Table 160.

Enrichment, isolation, and ecology

Enrichment of heliobacteria takes advantage of their ability to form endospores and their presence in soils; rice soils are particular good sources of these phototrophs (Stevenson et al., 1997). A soil sample is pasteurized (80 °C for 10 min) in a tube

of anoxically prepared growth medium (for enrichment, a medium composed of 0.25% (w/v) yeast extract at pH 7 works well), sealed under an atmosphere of N₂:CO₂ (95:5 v/v), and incubated in incandescent light (> 25 μE m⁻² s⁻¹) at 38–40 °C. It should be emphasized that all heliobacteria isolated to date are strict anaerobes. Thus, extreme care should be taken to ensure that media and growth conditions for the isolation of heliobacteria are strictly anoxic.

Successful enrichments for heliobacteria typically show a green film of cells atop the soil in the tube. This material can be removed with a sterile Pasteur pipette for streaking plates of prerduced enrichment medium (or defined media, see Kimble and Madigan, 1992; Kimble et al., 1995; Stevenson, 1997) inside an anoxic glove bag. Streaked plates are incubated inside illuminated anoxic jars (e.g., Gas-Pak jars), and green colonies with irregular edges form within 2–3 d. Higher light intensities are tolerated by heliobacteria than by purple and green bacteria (Kimble-Long and Madigan., 2002), and high light stimulates rapid enrichment. Pure cultures of heliobacteria can be obtained by repeated picking and restreaking of well-isolated colonies. Alternatively, isolated colonies can be obtained in anoxic agar dilution tubes and picked for transfer to liquid media.

In a survey of soils for the presence of heliobacteria, it was found that these phototrophs are common in rice paddy soils in both traditional rice-growing regions (such as Southeast Asia) and in modern cultivated rice fields (such as those in the southern United States). Other agricultural or garden soils only infrequently yielded heliobacteria (Stevenson et al., 1997). Aquatic habitats, with the exception of neutral to alkaline hot springs (below 70 °C) and soda lake sediments (see above), have not yielded heliobacteria. The connection between heliobacteria and rice plants suggest that a plant-bacterium association may exist, perhaps with the photoheterotrophic heliobacteria assimilating organic compounds excreted by rice plant roots and the plants benefiting from fixed nitrogen excreted by the nitrogen-fixing heliobacteria. All species of heliobacteria strongly fix molecular nitrogen, and some species contain alternative (non-molybdenum) nitrogenases (Kimble and Madigan, 1992; Madigan, 1995).

Genus I. *Heliobacterium* Gest and Favinger 1985, 223^{VP} (Effective publication: Gest and Favinger 1983, 15.)

MARIE ASAO AND MICHAEL T. MADIGAN

He.li.o.bac.te'ri.um. Gr. n. *helios* sun; Gr. neut. n. *bakterion* a small rod; N.L. neut. n. *Heliobacterium* sun bacterium.

Rod-shaped cells, slightly curved, 0.8–1 × 4–10 μm (Figure 155 and Figure 156) or **spirilla**, 1–1.2 × 4–10 μm (Figure 157). Cells lack intracytoplasmic membranes or chlorosomes, and thus electron micrographs of thin sections give no indication that the cells are phototrophic (Figure 156). Growth occurs both **photoheterotrophically (anoxic/light)** or **fermentatively (anoxic/dark)**. **Pyruvate metabolized both phototrophically and chemotrophically**. Colonies on a yeast extract/mineral salts medium (medium PYE, Kimble et al., 1995) frequently have irregular cell margins because of wavy protrusions of cell

masses in palisade formations similar to what is seen in gliding bacteria. Motility variable but usually by **polar or subpolar flagella**; *Heliobacterium chlorum* may show slow gliding movement. Some species, particularly *Heliobacterium chlorum*, lyse readily at stationary phase in rich or defined media. **One species is thermophilic**.

The major differentiating properties for species of *Heliobacterium* are listed in Table 160.

DNA G+C content (mol%): 51–57.

Type species: Heliobacterium chlorum Gest and Favinger 1985, 223^{VP} (Effective publication: Gest and Favinger 1983, 15.).

FIGURE 157. Scanning electron micrograph of cells of *Helio bacterium gestii*. Bar = 5 μ m.

Differentiation of the genus *Helio bacterium* from other genera

The genus *Helio bacterium* is differentiated from other genera by its distinct 16S rRNA gene phylogeny. In addition, species of *Helio bac-*

FIGURE 158. Phase-contrast photomicrograph of endospores produced in a culture of *Helio bacterium gestii*. Bar = 5 μ m. (Reprinted with permission from Ormerod et al., 1996a. Archives of Microbiology 165: 226–234.)

terium are motile by gliding or subpolar flagella while species of *Helio bacillus* possess peritrichous flagella, and species of *Helio philum* are motile as cell bundles that move as a unit. Its pH optimum of 7 distinguishes it from *Helio restis*, which has a pH optimum of 9.

List of species of the genus *Helio bacterium*

1. ***Helio bacterium chlorum*** Gest and Favinger 1985, 223^{VP} (Effective publication: Gest and Favinger 1983, 15.)

chlō'rum. N.L. neut. adj. *chlorum* from the Gr. adj. *chloros* green.

Cells are rod shaped; other characteristics are the same as those described for the genus. Isolated from garden soil on the campus of Indiana University, Bloomington, USA.

DNA G+C content (mol%): 52 (T_m).

Type strain: ATCC 35205, DSM 3682.

GenBank accession number (16S rRNA gene): M11212.

2. ***Helio bacterium gestii*** Ormerod, Kimble, Nesbakken, Torgersen, Woese and Madigan 1996b, 1189^{VP} (Effective publication: Ormerod, Kimble, Nesbakken, Torgersen, Woese and Madigan 1996a, 233.)

gest.i.i. N.L. gen.n. *gestii* of Gest, named for Howard Gest, an American microbiologist.

Spirillum (Figure 157) that is motile by polar or subpolar flagella. Subterminal, cylindrical endospores (Figure 158) formed in freshly isolated strains. Optimal pH is 7. Incapable of assimilatory sulfate reduction. NaCl not required and growth inhibitory above 1% (w/v). This is the only species of heliobacteria known to use sugars as carbon sources. Isolated from soil of a Thailand rice paddy.

DNA G+C content (mol%): 55.1 (T_m).

Type strain: Chainat, ATCC 43375, DSM 11169.

GenBank accession number (16S rRNA gene): AB100837, L36198.

3. ***Helio bacterium modesticatum*** Kimble, Mandelco, Woese and Madigan 1996, 1189^{VP} (Effective publication: Kimble, Mandelco, Woese and Madigan 1995, 266.)

mo.des.ti.cal'dum. L. neut. adj. *modesticum*; L. neut. adj. *caldum*; N.L. neut. adj. *modesticatum* moderately hot; named for its thermophilic character.

Cells are rod shaped or slightly curved, 0.8–1 \times 2.5–9 μ m (Figure 157). Motile by flagella or nonmotile. Forms cylindrical, subterminal endospores. Thermophilic; optimum growth temperature is 52 $^{\circ}$ C (temperature range 30–56 $^{\circ}$ C). NaCl not required for growth, and growth inhibited by 1% (w/v) NaCl. Optimal pH is 6.5. Fixes molecular nitrogen up to its maximum growth temperature. Isolated from neutral to alkaline hot spring microbial mats and volcanic soils. Type strain isolated from soil obtained near alkaline hot springs at Reykjanes, Iceland.

DNA G+C content (mol%): 54.6–55 (T_m).

Type strain: Ice1, ATCC 51547, DSM 9504.

GenBank accession number (16S rRNA gene): AB100836, U14559.

4. ***Helio bacterium sulfidophilum*** Bryantseva, Gorlenko, Tourova, Kuznetsov, Lysenko, Bykova, Gal'chenko, Mityushina and Osipov 2001b, 1^{VP} (Effective publication: Bryantseva, Gorlenko, Tourova, Kuznetsov, Lysenko, Bykova, Gal'chenko, Mityushina and Osipov 2000b, 333.)

sul.fi.do.phil.um. N.L. adj. *sulfidophilum* sulfide-loving.

Cells are rod shaped and motile by peritrichous flagella. Produces endospores. Optimal pH is 7.5, and optimal growth temperature is 35 $^{\circ}$ C. Sulfide tolerant (up to 2mM) and oxidizes sulfide to elemental sulfur. Photoheterotrophic growth on acetate, pyruvate, or lactate. Isolated from a hot spring near the Bol'shaya River, Russia.

DNA G+C content (mol%): 51.3 (T_m).

Type strain: BR4, UNIQEM 113.

GenBank accession number (16S rRNA gene): AF249678.

5. **Heliobacterium undosum** Bryantseva, Gorlenko, Tourova, Kuznetsov, Lysenko, Bykova, Gal'chenko, Mityushina and Osipov 2001b, 1^{VP} (Effective publication: Bryantseva, Gorlenko, Tourova, Kuznetsov, Lysenko, Bykova, Gal'chenko, Mityushina and Osipov 2000b, 333.)

un.do'sum. L. neut. adj. *undosum* curving.

Cells are short rods to twisted spirilla; motile by peritrichous flagella. No evidence of endospores. Optimal

pH is 7.8, and optimal growth temperature is 35 °C. Highly sulfide tolerant and oxidizes sulfide to elemental sulfur. Photoheterotrophic growth on pyruvate, lactate, or propionate. Isolated from Garginskii sulfidic hot spring, Russia.

DNA G+C content (mol%): 57.2 (T_m).

Type strain: BG29, DSM 13378, UNIQEM 114.

GenBank accession number (16S rRNA gene): AF249679.

Genus II. **Heliobacillus** Beer-Romero and Gest 1998, 627^{VP} (Effective publication: Beer-Romero and Gest 1987, 113.)

MARIE ASAO AND MICHAEL T. MADIGAN

He.li.o.ba.cil'lus. Gr. n. *helios* sun; L. dim. n. *bacillum* a small rod; N.L. masc. n. *Heliobacillus* sun rod.

Highly motile, straight rod-shaped cells containing peritrichous flagella. For other properties, see Table 160. *Heliobacillus* may be differentiated from other genera of heliobacteria by its morphology and motility. *Heliobacillus* cells are straight rods and not curved like most species of *Heliobacterium*. Cells in young

cultures are highly motile and swim much faster than cells of *Heliobacterium*.

DNA G+C content (mol%): 50.3.

Type species: **Heliobacillus mobilis** Beer-Romero and Gest 1998, 627^{VP} (Effective publication: Beer-Romero and Gest 1987, 113.).

List of species of the genus *Heliobacillus*

1. **Heliobacillus mobilis** Beer-Romero and Gest 1998, 627^{VP} (Effective publication: Beer-Romero and Gest 1987, 113.)

mo'bil.is. L. masc. adj. *mobilis* movement; named for its rapid motility.

Cells are rod-shaped, 1 × 7–10 μm, and highly motile in young cultures. Produce peritrichous flagella. Optimal pH is

7. NaCl not required. Capable of assimilatory sulfate reduction. Isolated from dry soil from Thailand.

DNA G+C content (mol%): 50.3 (T_m).

Type strain: 6, ATCC 43427, DSM 6151.

GenBank accession number (16S rRNA gene): U14560.

Genus III. **Heliophilum** Ormerod, Kimble, Nesbakken, Torgersen, Woese and Madigan 1996b, 1189^{VP} (Effective publication: Ormerod, Kimble, Nesbakken, Torgersen, Woese and Madigan 1996a, 233.)

MARIE ASAO AND MICHAEL T. MADIGAN

He.li.o'phi.lum. Gr. n. *helios* sun; *philos* loving; N.L. neut. n. *Heliophilum* sun lover.

Cells are straight rods with tapered ends and subpolar flagella. They do not exist singly but form into bundles, typically of 8–16 cells, that swim slowly as a collective unit. Entire bundles show scotophotophobic response. Heat-resistant endospores are produced in newly isolated cultures. Capable of assimilatory sulfate reduction; growth is inhibited by sulfide at levels above 0.1 mM. Biotin required. NaCl is not required for growth and is inhibitory above 1% (w/v). Other properties are described in Table 160 or are the same as those described for the family. The genus *Heliophilum* is

distinguished from other heliobacteria by its collective motility and unusual sensitivity to sulfide. Most heliobacteria are quite sulfide tolerant. However, it should be cautioned that sulfide sensitivity may be strain specific, so this trait may be of limited diagnostic value.

DNA G+C content (mol%): 51.8 (T_m).

Type species: **Heliophilum fasciatum** Ormerod, Kimble, Nesbakken, Torgersen, Woese and Madigan 1996b, 1189^{VP} (Effective publication: Ormerod, Kimble, Nesbakken, Torgersen, Woese and Madigan 1996a, 233.).

List of species of the genus *Heliophilum*

1. **Heliophilum fasciatum** Ormerod, Kimble, Nesbakken, Torgersen, Woese and Madigan 1996b, 1189^{VP} (Effective publication: Ormerod, Kimble, Nesbakken, Torgersen, Woese and Madigan 1996a, 233.)

fasc.ci.a'tum. L. neut. part. adj. *fasciatum* bundled; named for the fact that cells form into bundles that move as a unit.

The characteristics are the same as those described for the genus. Isolated from rice soil from Tanzania, continent of Africa.

DNA G+C content (mol%): 51.8 (T_m).

Type strain: Tanzania, ATCC 51790, DSM 11170.

GenBank accession number (16S rRNA gene): L36197.

Genus IV. **Heliorestis** Bryantseva, Gorlenko, Kompantseva, Achenbach and Madigan 2000c, 949^{VP} emend. Bryantseva, Gorlenko, Kompantseva, Tourova, Kuznetsov and Osipov 2000a, 289 (Effective publication: Bryantseva, Gorlenko, Kompantseva, Achenbach and Madigan 1999, 173.)

MARIE ASAO AND MICHAEL T. MADIGAN

He.li.o.res'tis. Gr. n. *helios* sun; L. fem. n. *restis* a rope; N.L. fem. n. *Heliorestis* sun rope.

Cells are coils, bent filaments, or rods. Alkaliphilic (optimum pH 8.5–9) and some species can grow at a pH as high as 10.5. No growth occurs at pH 7. Not halophilic. Sulfide tolerant, growing in media containing up to 3–10 mM sulfide. Optimal growth temperature is 30 °C; no growth above 40 °C. Obligately photoheterotrophic; chemoorganotrophy in darkness with pyruvate fermentation does not occur. Major carotenoids are OH-diaponeurosporene glucoside esters, although 4,4'-diaponeurosporene is also present as a minor component (Takaichi et al., 2003). Other proper-

ties are described in Table 160 or are the same as those described for the family. Species of *Heliorestis* are distinguished by their alkaliphily and the presence of glycosylated carotenoids.

DNA G+C content (mol%): 45.

Type species: **Heliorestis daurensis** Bryantseva, Gorlenko, Kompantseva, Achenbach and Madigan 2000c, 949^{VP} (Effective publication: Bryantseva, Gorlenko, Kompantseva, Achenbach and Madigan 1999, 173.)

List of species of the genus *Heliorestis*

1. **Heliorestis daurensis** Bryantseva, Gorlenko, Kompantseva, Achenbach and Madigan 2000c, 949^{VP} (Effective publication: Bryantseva, Gorlenko, Kompantseva, Achenbach and Madigan, 1999, 173.)

dau.ren'sis. N.L. adj. *daurensis* the name of the geographic region Dauria (Daur Steppe, Russia), from which the type strain was isolated.

Cells are 0.8–1.2 μm wide, forming a twisted or bent filament with a length up to 20 μm. Slowly motile by peritrichous flagella. Optimal growth pH is 9; pH range from 7.5–10.5. NaCl not required and growth inhibitory above 1% (w/v). Biotin required; yeast extract at 0.025–0.05% (w/v) is highly stimulatory for growth. Acetate, pyruvate, or propionate used as carbon sources in the presence of sulfide/HCO₃⁻/CO₃²⁻. Very sulfide tolerant; growth occurs in media containing up to 10 mM sulfide; sulfide is oxidized to elemental sulfur and polysulfide. Other characteristics are as described for the genus. Isolated from microbial mats on the shoreline and soils near Lake Barun Torey which is located on the Daur Steppe (South Chita region, Southeast Siberia, Russia).

DNA G+C content (mol%): 44.9 (*T_m*).

Type strain: BT-H1, ATCC 700798.

GenBank accession number (16S rRNA gene): AF079102.

2. **Heliorestis baculata** Bryantseva, Gorlenko, Kompantseva, Tourova, Kuznetsov and Osipov 2001a, 264^{VP} (Effective publication: Bryantseva, Gorlenko, Kompantseva, Tourova, Kuznetsov and Osipov 2000a, 290.)

ba.cu.la'ta. L. adj. *baculatus* rod-shaped; named for the morphological characteristic of the cells.

Cells are straight or slightly curved rods, 0.6–1 × 6–10 μm. Motile by peritrichous flagella. Optimum growth pH is 8.5–9; pH range from 8–10.2. NaCl is not required. Growth observed in media containing up to 3% (w/v) NaCl. Biotin required; low levels of yeast extract are highly stimulatory. Sodium carbonate required (optimum, 0.5–1% (w/v); range, 0.2–2%). Acetate, pyruvate, or lactate is used as carbon source in the presence of sulfide and carbonate. Growth in media containing up to 3 mM sulfide; sulfide is oxidized to

sulfur and polysulfide. Other characteristics are as described for the genus. Isolated from shoreline soil of Lake Ostozhe, located in the steppe of South Chita region (Southeast Siberia, Russia).

DNA G+C content (mol%): 45 (*T_m*).

Type strain: OS-H1, DSM 13446.

GenBank accession number (16S rRNA gene): AB100838, AF249680.

Other organisms

1. "**Heliorestis convoluta**" Asao, Jung, Achenbach and Madigan 2006, 409.

con.vo.lu'ta. L. fem. adj. *convoluta* coiled; named for the unique morphology of the cells.

Cells are 0.6 μm wide, forming a coil of variable length (Figure 159). The coil begins as a ring-shaped cell that elongates, forms a septum, but fails to divide. Motile. Optimum growth pH is 8.5–9; pH range is 8–10. NaCl is not required. Growth observed in media containing up to 3% (w/v) NaCl.

FIGURE 159. Scanning electron micrograph of *Heliorestis convoluta*. Bar = 1 μm. (Reprinted with permission from Asao et al., 2006. *Extremophiles* 10: 403–410.)

No growth factors are required. Acetate, pyruvate, propionate, or butyrate is used as carbon sources in the presence of sulfide/ $\text{HCO}_3^-/\text{CO}_3^{2-}$. Ammonia, glutamine, asparagine, yeast extract, or N_2 is used as nitrogen source. Very sulfide tolerant; growth occurs in media containing up to 10 mM sulfide; sulfide is oxidized to sulfur. Other characteristics are

as described for the genus. Isolated from shoreline soil and water of Lake El Hamra, Wadi El Natroun, Egypt.

DNA G+C content (mol%): not reported.

Type strain: HH, ATCC BAA-1281.

GenBank accession number (16S rRNA gene): DQ266255.

Family V. *Lachnospiraceae* fam. nov.

FRED A. RAINEY

*Lach.no.spi.ra'*ce.ae. N.L. masc. n. *Lachnospira* type genus of the family; -*aceae* ending to denote family; N.L. fem. pl. n. *Lachnospiraceae* the *Lachnospira* family.

The family *Lachnospiraceae* is described on the basis of phylogenetic analyses of 16S rRNA gene sequences (Figure 160); the family contains the genera *Lachnospira* (type genus), *Acetitoma-culum*, *Anaerostipes*, *Bryantella*, *Butyrivibrio*, *Catonella*, *Coprococcus*, *Dorea*, *Hespellia*, *Johnsonella*, *Lachnobacterium*, *Moryella*, *Oribacte-*

rium, *Parasporobacterium*, *Pseudobutyrvibrio*, *Roseburia*, *Shuttleworthia*, *Sporobacterium*, and *Syntrophococcus*.

The family is morphologically diverse and includes rods, vibrios, and cocci. All species are anaerobes.

Type genus: Lachnospira Bryant and Small 1956a, 24^{AL}.

Genus I. *Lachnospira* Bryant and Small 1956a, 24^{AL}

NANCY A. CORNICK AND THADDEUS B. STANTON

Lach. no. spi'ra. Gr. n. *lachnos* woolly hair, down; L. n. *spira* a coil; N.L.fem. n. *Lachnospira* named for the filamentous or "woolly" colonies formed in agar by curved or helical cells of *Lachnospira multipara*.

Straight or slightly curved rod-shaped cells. May appear helical. Single cells measure 0.35–0.6×2.0–4.0 μm. Cells occur in pairs and occasionally in long chains. Gram-stain-variable or -positive. Cells possess Gram-positive ultrastructure. **Actively motile** by monotrichous or peritrichous flagella, depending on the species. **Strictly anaerobic**. Grows at 30–45 °C. Grows in anaerobically prepared media containing rumen fluid or yeast extract, inorganic salts, and pectin or polygalacturonic acid. May also grow in a chemically defined medium. Chemo-organotrophic metabolism. **Pectinolytic**. Ferments pectin, polygalacturonic acid, fructose, and cellobiose. Acetate, formate, ethanol, and CO₂ are the major end products from polygalacturonic acid and pectin fermentation. Small amounts of H₂ may also be produced. Methanol is also produced when pectin is fermented. Succinate, butyrate, and propionate are not produced. Galacturonic acid (the monomer of polygalacturonic acid) is not fermented. Does not produce indole, catalase, or H₂S. Does not reduce nitrate. Does not hydrolyze gelatin or starch. **Indigenous to mammalian intestinal tract**. Isolated from bovine rumen contents and from swine feces and cecal contents.

Two species of *Lachnospira* have been characterized. They can be differentiated by characteristics given in Table 161.

DNA G+C content (mol%): 38–45.

Type species: Lachnospira multipara Bryant and Small 1956a, 24^{AL}.

Further descriptive information

Cell walls have a Gram-positive structure but *Lachnospira multipara* may appear to stain as Gram-negative (Cheng et al., 1979). Formerly, analysis of the 16S rRNA grouped *Lachnospira* within the XIVa cluster of the *Clostridium* subphylum, which includes several diverse Gram-positive genera (Figure 160) (Collins et al., 1994). According to the 16S rRNA phylogenetic analysis presented in the roadmap to this volume (Figure 5), the genus *Lachnospira* is a member of the family *Lachnospiraceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*. *Lachnospira multipara* and *Lachnospira pectinoschiza* form a monophyletic subset within this group and *Lachnospira pectinoschiza* shows 94% similarity to *Lachnospira multipara*. The major constituents of the peptidoglycan of *Lachnospira multipara* are muramic acid,

glucosamine, alanine, glutamic acid, and *meso*-diaminopimelic acid (Hespell et al., 1993).

Lachnospira multipara is considered one of the major pectin degraders in the rumen even though it accounts for only a small fraction of the total microflora. When cattle are fed diets rich in pectin, such as clover or fruit pulp, the population of *Lachnospira multipara* increases significantly (Bryant et al., 1960). *In vitro* incubation of *Lachnospira multipara* with clover leaflets results in extensive maceration of the clover (Cheng et al., 1979). The ecological role of *Lachnospira pectinoschiza* in the pig gastrointestinal tract is not known but presumably is involved in pectin degradation. Both species degrade pectin by using pectin methyl esterase and extracellular pectate lyase (Preston et al., 1991; Silley, 1985; Wojciechowicz et al., 1980). Polygalacturonic acid is degraded primarily to trigalacturonic acid and some digalacturonic acid by *Lachnospira multipara* and to digalacturonic acid only by *Lachnospira pectinoschiza*.

Glucose is fermented by *Lachnospira multipara* but not by *Lachnospira pectinoschiza*. Arabinose, galactose, glycerol, glycogen, maltose, mannitol, mannose, raffinose, rhamnose, ribose, salicin, sorbitol, sucrose, trehalose, amino acids, arabinogalactan, carboxymethyl cellulose, cellulose, dextrin, gum arabic, inositol, inulin, and xylan do not support growth. The major long-chain fatty acids extracted from whole cells are palmitic acid (16:0) and myristic acid (14:0) (Cornick et al., 1994).

Enrichment and isolation procedures

The isolation of *Lachnospira* requires strict anaerobic conditions and the presence of a fermentable carbohydrate in the medium. Both medium RGM (Hespell et al., 1987) and medium PF (Jensen and Canale-Parola, 1986) support heavy growth. *Lachnospira multipara* may also be grown in a defined medium (Bryant and Robinson, 1962). A semiselective medium containing energy-depleted rumen fluid and polygalacturonic acid as the sole carbon source aids in isolation, but other anaerobic bacteria that utilize pectin, such as *Butyrivibrio fibrosolvens* and *Prevotella ruminicola*, will also grow on this medium (Cornick et al., 1994). The distinctive filamentous colony morphology of *Lachnospira multipara* in agar-roll tubes aids in isolate selection.

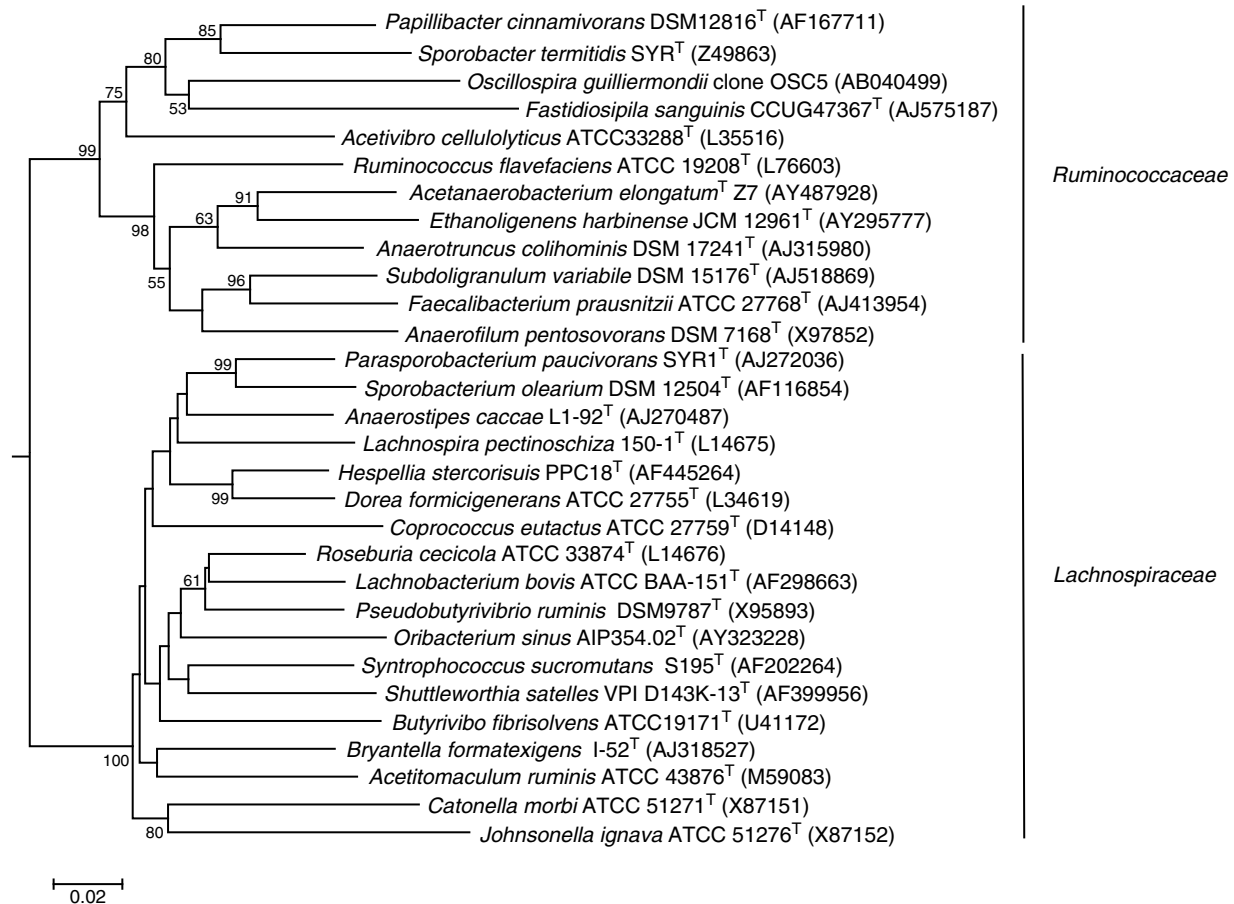

FIGURE 160. 16S rRNA gene sequence based phylogenetic analysis showing the relationships between the genera of the families *Lachnospiraceae* and *Ruminococcaceae*. Each genus is represented by the type species. The tree was reconstructed from distance matrices using the neighbor-joining method. The exception to this is the genus *Lachnospira* for which only a short and low quality sequence is available for the type species *Lachnospira multipara*. The species *Lachnospira pectinoschiza* has been used to represent this genus. The genus *Oscillospira* for which no type material exists is represented by a clone sequence from an organism with the morphological characteristics of the organism originally described as *Oscillospira guilliermondii*. The scale bar represents 2 inferred nucleotide changes per 100 nucleotides.

TABLE 161. Differentiation of *Lachnospira* species^a

Characteristic	<i>L. multipara</i>	<i>L. pectinoschiza</i>
Flagella	Monotrichous	Peritrichous
Fermentation of:		
Gluconic acid	-	+
Glucose	+	-
Lactose	-	+
Salicin	+	-
Sucrose	+	-
Esculin hydrolysis	+	-

^aSymbols: +, >85% positive; -, 0–15% positive.

Isolates that grow on polygalacturonic acid but not on glucose are suggestive of *Lachnospira pectinoschiza*.

List of species of the genus *Lachnospira*

- Lachnospira multipara*** corrig. Bryant and Small 1956a, 24^{AL} (*Lachnospira multiparus* Bryant and Small (1956a) mul.ti.par'a. L. adj. *multus* much, many; L. suff. *para* from L. v. *pario* to produce; N.L. adj. *multipara* many products produced.

Maintenance procedures

Both *Lachnospira multipara* and *Lachnospira pectinoschiza* can be frozen at -70 °C in culture broth containing 10% glycerol. *Lachnospira multipara* can also be lyophilized.

Differentiation of the genus *Lachnospira* from other genera

Lachnospira are distinguished from other genera of anaerobic, Gram-stain-positive, non-spore-forming rods primarily by their 16S rRNA sequence. DNA–DNA relative reassociation has also been used to differentiate *Lachnospira* from *Eubacterium*, *Butyrivibrio*, and *Roseburia* (Mannarelli et al., 1990b).

Further reading

Cotta, M. and R. Forster. 2000. The family *Lachnospiraceae*, including the genera *Butyrivibrio*, *Lachnospira* and *Roseburia*. In Dworin (Editor), *The Prokaryotes*, Springer-Verlag, New York.

Curved rods 0.4–0.6 × 2.0–4.0 μm in single, pairs, and occasional long chains, weakly Gram-stain-positive, monotrichous subterminal flagella. Colonies in agarose are white and filamentous in appearance. Colonies embedded

in agar are wooly in appearance. Good growth at 30–45 °C, no growth at 20 or 50 °C. Glucose, fructose, esculin, cellobiose, sucrose, and salicin are fermented. Xylose fermentation is variable, acetylmethylcarbinol may be produced. Major fermentation products from glucose are acetate, formate, ethanol, and CO₂. Minor amounts of lactate and H₂. Methanol is produced when pectin is fermented. Isolated from the bovine rumen.

DNA G+C content (mol%): 38–39 (Bd).

Type strain: D32, ATCC 19207.

GenBank accession number (16S RNA gene): L14674.

2. **Lachnospira pectinoschiza** Cornick, Jensen, Stahl, Hartman and Allison 1994, 92^{VP}

pec'ti.no.schiz.a. N.L. neut. n. *pectinum* pectin; Gr. n. *schizein* to split; N.L. fem. adj. *pectinoschiza* pectin-splitting.

Gram-stain-positive rod 0.36–0.56 × 2.4–3.1 μm in single, pairs, and long chains. Strictly anaerobic. Colonies on agar are circular, umbonate, 3–5 mm in diameter. Grows at 30–45 °C, but not at 25 or 50 °C. Ferments pectin, polygalacturonic acid,

D-gluconate, D-fructose, lactose, and cellobiose. Growth on pectin, polygalacturonic acid and D-gluconate is rapid with a doubling time of approximately 55 min. Growth is much slower on cellobiose, lactose, and D-fructose (doubling time, 4–10 h). Other carbohydrates and amino acids are not utilized. Major end products from polygalacturonic acid fermentation are formate, acetate, ethanol, and CO₂. Methanol is produced when pectin is fermented. Ethanol is the major end product when cellobiose, lactose, or fructose are utilized. Bile does not inhibit growth. Spore-like structures may be observed by electron microscopy from cells grown on egg yolk agar supplemented with polygalacturonic acid. However, cells do not survive heating at 60 °C for 5 min or exposure to 50% ethanol for 45 min. Isolated from the cecum and colon of pigs. The 16S rRNA sequence signature of *Lachnospira pectinoschiza* has also been detected in human colonic samples (Wilson and Blitchington, 1996).

DNA G+C content (mol%): 42–45 (T_m).

Type species: strain 150-1.

GenBank accession number (16S RNA gene): L14675.

Genus II. **Acetitomaculum** Greening and Leedle 1995, 879^{VP} (Effective publication: Greening and Leedle 1989, 405.)

FRED A. RAINEY

A.ceti.to.ma'cu.lum. L. n. *acetum* vinegar; L. n. *tomaculum* sausage; N.L. neut. n. *Acetitomaculum* vinegar sausage.

Curved rods, 0.8–1.0 μm in diameter and 2.0–4.0 μm in length. Occurring in singles, pairs, or small clumps. **Gram-stain-positive**. Older cultures stain Gram-stain-negative. Cells may be flagellated. **Endospores not observed**. **Obligate anaerobe**. Strains of this organism are catalase-negative. Mesophilic with growth in the temperature range 34–43 °C. Growth occurs in the pH range 6.4–7.3. Cell wall contains L-serine, D-glutamate, D-alanine, *m*-diaminopimelic acid, D-ornithine, and D-lysine. **Acetogenic, fermentative metabolism**. Ferments formate, glucose, cellobiose, fructose, and esculin to acetic acid. **Oxidizes hydrogen and reduces carbon dioxide and carbon monoxide**. Based on 16S rRNA gene sequence analysis, *Acetitomaculum* belongs to the family *Lachnospiraceae*.

DNA G+C content (mol%): 32–36 (T_m).

Type species: **Acetitomaculum ruminis** Greening and Leedle 1995, 879^{VP} (Effective publication: Greening and Leedle 1989, 405.)

Further descriptive information

The genus *Acetitomaculum* contains a single species *Acetitomaculum ruminis*, which is represented by five strains including the type strain 139B. These strains are strict anaerobes and grow only in reduced medium. All strains are curved rods and two of them show motility (strains 190A4 and 139B^T). On AC-11.1 agar, colonies of this species are 2–3 mm in diameter, opaque to translucent, circular, buff or tan in color, and have a butyrous consistency with entire margins. With the exception of strain 40C, which has a granular surface, colonies of all strains have smooth surfaces.

In the paper describing these strains, the temperature range for growth is 37–42 °C (Greening and Leedle, 1995). However, in the description of the genus and species in the same paper, the temperature range for growth is 34–43 °C with an optimum for growth of 38 °C. All of the strains grow on formate, CO,

CO₂, H₂, and glucose. In addition to these substrates, the type strain 139B grows on cellobiose, esculin, glucose, fructose, ferulic acid, and syringic acid. Strain 190A4 differs from the other four strains in its ability to grow on vanillic acid. The following substrates were not utilized by any of the strains of this species: adonitol, erythritol, glycerol, maltose, mannitol, pectin, ribose, starch, DL-alanine, betaine, methylamine, lactate, pyruvate, succinate, anisic acid, 3,4-dimethoxybenzoate, gallic acid, *p*-hydroxybenzoate, 3, 4, 5-trimethoxybenzoate, methanol, and phytic acid. Under a headspace of H₂:CO₂ in AC-11.1 medium containing 5% clarified rumen fluid (CRF), the fermentation acids include acetic, propionic, isobutyric, butyric, isovaleric, and valeric acids. The oxidation of hydrogen and reduction of carbon dioxide is according to the following equation: 4 H₂ + 2 CO₂ → CH₃COOH + 2 H₂O. The doubling times of the stains are in the range 1.6–2.8 h. Since the concentration of sulfate does not change during growth, it was considered that strains of this species do not reduce sulfate (Greening and Leedle, 1989). The ratio of serine:glutamic acid:alanine:*m*-diaminopimelic acid:ornithine:lysine was 1.0:2.6:2.3:0.4:0.1:8. The presence of both lysine and *m*-diaminopimelic acid in the cell wall differentiated this strain from other acetogenic bacteria.

Enrichment, isolation, and growth conditions

Acetitomaculum ruminis was isolated from rumen fluid recovered from a mature, rumen-fistulated Hereford crossbred steer. The isolation medium designated AC-11.1 contained (in g/l) KH₂PO₄, 0.28; K₂HPO₄, 0.94; NaCl, 0.14; KCl, 0.16; MgSO₄ · 7H₂O, 0.2; NH₄Cl, 0.5; CaCl₂ · 2H₂O, 0.001; 10 ml of trace mineral solution per liter as described by Balch et al. (1979), modified by the addition of 0.1 g of NiCl₂ · 6H₂O and 0.01 g of Na₂SeO₃; 10 ml of vitamin solution (in mg/l: sodium ascorbate, 5; biotin, 2; folic acid, 2; pyridoxine hydrochloride, 10; thiamine hydrochloride, 5; riboflavin, 5; nicotinic acid, 5; DL-

calcium pantothenate, 5; vitamin B₁₂, 0.1; *p*-aminobenzoic acid, 5; lipoic (thioctic) acid, 5; choline chloride, 5; *myo*-inositol, 5; niacinamide, 5; pyridoxal hydrochloride, 5); Na₂WO₄·2H₂O, 3 × 10⁻⁴ mM; resazurin, 0.001 g/l; yeast extract (Difco), 0.5 g/l; NaHCO₃, 6 g/l; reducing agent, 10 ml; distilled water, 660 ml; and incubated, clarified rumen fluid (Leedle and Hespell, 1980), 100 ml. The medium was boiled under a headspace of 80% N₂ and 20% CO₂ before dispensing. For enrichments, filter-sterilized 2-bromoethanesulfonic acid (sodium salt) was added to a final concentration of 50 mM. The final pH of the medium was adjusted to 7.15. For solid medium the NaHCO₃ and reducing agent were added as sterile solutions after autoclaving. Plates were poured in an anaerobic chamber with an atmosphere of 85% N₂, 10% H₂, and 5% CO₂. The strains of *Acetitomaculum* were isolated from serial dilutions of enrichment cultures using rumen fluid as the inoculum. The H₂:CO₂ enrichments incubated for 7 d were streaked on plates of AC-11.1 isolation medium and incubated at 37 °C. Colonies were picked after incubation of streak plates for 7 d. Isolates were inoculated into liquid medium under H₂:CO₂ or N₂:CO₂. Cultures showing a twofold increase in acetate production under H₂:CO₂ as compared to N₂:CO₂ were selected for further study. The organisms were routinely cultured in AC-11.1 liquid medium containing 5% CRF and an organic substrate.

Maintenance procedures

Acetitomaculum ruminis can be stored long-term lyophilized in AC-11.1 medium containing glycerol (Teather, 1982a).

Taxonomic comments

In the original description of *Acetitomaculum ruminis* the justification for the new genus was based on a comparison of the new strains to other acetogenic anaerobes (Greening and Leedle, 1989). The differences from previously described organisms included lack of endospores, Gram-stain-positive staining,

mol% G+C values, end products of fermentation and the ratio of amino acids in the cell wall. It was indicated that analysis of the 16S rRNA of the type strain 139B demonstrated a relationship to the clostridia, but no specifics were provided. Analysis of the 16S rRNA gene sequence of *Acetitomaculum ruminis* strain 139B^T (M59083) shows it to have highest similarity with the type strains of the species *Clostridium polysaccharolyticum* (91.0%), *Ruminococcus luti* (90.5%), and *Bryantella formatexigens* (90.2%). 16S rRNA gene sequence similarities to all other validly named species are below 90.0%. The species *Clostridium polysaccharolyticum* and *Ruminococcus luti* are misclassified species that are unrelated to the type strains of the genera to which they have been assigned. With 16S rRNA gene sequence similarities of 90–91%, these species would not be considered species of the genus *Acetitomaculum*. The analysis places the genus *Acetitomaculum* in the family *Lachnospiraceae*, with the most closely related genus being *Bryantella* (Figure 160.). The 16S rRNA gene sequence is only available for the type strain 139B and so the species status of the other four strains (20A, 40, 40C, and 190A4) is presently not determined. The thought that these strains are members of the same species is based on their metabolic characteristics as well as similarities in their mol% G+C values and cell-wall amino acids (Greening and Leedle, 1989).

Differentiation of the genus *Acetitomaculum* from other genera

As indicated by 16S rRNA gene sequence analysis, the closest relative of *Acetitomaculum ruminis* that is not a misclassified taxon is *Bryantella formatexigens*. *Acetitomaculum ruminis* differs from *Bryantella formatexigens* in a number of characteristics including cell shape, lack of growth on H₂:CO₂, mol% G+C content of the DNA, and the source of isolates. *Bryantella formatexigens* does not have the curved rod morphology of *Acetitomaculum ruminis* and has a DNA G+C content of 50.3 mol%, which is very different from that of the *Acetitomaculum ruminis* strains, which are in the range 32–36 mol%.

List of species of the genus *Acetitomaculum*

1. ***Acetitomaculum ruminis*** Greening and Leedle 1995, 879^{VP} (Effective publication: Greening and Leedle 1989, 405.)

ru.min.is. L. gen. n. *ruminis* of the rumen, for its source.

Colonies are convex, circular, 2–3 mm in diameter, entire, translucent, buff or tan in color, with a smooth or granular surface. Cells are curved rods. Optimum temperature for growth is 38 °C. Optimal pH for growth is 6.8. Acetogenic. Ferments formate, glucose, cellobiose, fructose, and esculin to acetic acid. Oxidizes hydrogen and reduces carbon

dioxide according to the following equation: 4 H₂ + 2 CO₂ → CH₃COOH + 2 H₂O. Grows in a mineral media with H₂ and CO₂ or organic substrate. Rumen fluid is stimulatory and may be required. The type strain was isolated from the rumen of a mature Hereford × Angus crossbred steer fed a high-forage diet.

DNA G+C content (mol%): 34.0 (T_m).

Type strain: 139B, ATCC 43876, DSM 5222, UC 12185.

GenBank accession number (16S rRNA gene): M59083.

- Genus III. ***Anaerostipes*** Schwiertz, Hold, Duncan, Gruhl, Collins, Lawson, Flint and Blaut 2002a, 1437^{VP} (Effective publication: Schwiertz, Hold, Duncan, Gruhl, Collins, Lawson, Flint and Blaut 2002b, 50.)

THE EDITORIAL BOARD

An.ae.ro.stí'pes. Gr. pref. *an* not; Gr. n. *aer* air; L. masc. n. *stipes* club of stick; *Anaerostipes* a stick not living in air.

Nonsporeforming, nonmotile rods, sometimes in chains of 2–4 cells. **Gram positive in exponential phase** but not stationary-phase cultures. Nonmotile. **Strictly anaerobic** and both catalase- and oxidase-negative. **Nonhemolytic**. Cells produce mainly acetic, lactic, and butyric acids from glucose. **Arginine dihydrolase**, phosphoam-

idase, and α -galactosidase are produced. **Gelatin and urea are not hydrolyzed; indole is not produced**. Positive for nitrate reduction.

DNA G + C content (mol%): 45.5–46.

Type species: ***Anaerostipes caccae*** Schwiertz, Hold, Duncan, Gruhl, Collins, Lawson, Flint and Blaut 2002a, 1437 (Effective

publication: Schwiertz, Hold, Duncan, Gruhl, Collins, Lawson, Flint and Blaut 2002b, 50.).

Further descriptive information

Although phenotypically similar, this new genus cannot be identified with *Eubacterium sensu stricto* with which it has 20% 16S rRNA sequence divergence. Formerly a member of the *Clostridium coccoides* group (*Clostridium* 16S rRNA cluster XIVa), it possesses no less than 10% sequence divergence with previously described species. According to the 16S rRNA phylogenetic analysis presented in the roadmap to this volume (Figure 5), the genus *Anaerostipes* is a member of the family *Lachnospiraceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*.

Cells form ropy sediment with little or no turbidity in ST medium (Schwiertz et al., 2000), and form colonies (1–3 mm in diameter) that are circular, smooth, convex, shiny, white, opaque, and nonhemolytic on Columbia blood agar and Wilkins–Chalgren agar.

Enrichment and isolation procedures

Strains L1-92^T and P2 were from human fecal samples: the former isolated as described by Barcellina et al. (2000) and the

latter as described below. In an anaerobic chamber, human feces was serially diluted (tenfold) to 10¹⁰ in Sorensen buffer (25 mM KH₂PO₄, 33 mM Na₂HPO₄·12 H₂O, 0.04% (v/v) thio-glycolic acid, 0.06% (w/v) cysteine, pH 6.8) and 1 ml aliquots were plated onto starch agar (4 g NaHCO₃, 0.348 g K₂HPO₄, 0.227 g KH₂PO₄, 0.5 g NH₄Cl, 2.25 g NaCl, 0.5 g MgCO₃·7 H₂O, 0.15 mg NaSeO₃, 2 g tryptically digested peptone from casein, 2 g yeast extract, 2 g soluble starch, 15 g agar, 1 mg resazurin, 3 ml trace element solution SL 10 (Widdel et al., 1983), and 0.5 mg cysteine HCl, at pH 7.0. Following autoclaving, 1 l of medium was supplemented with 20 ml of a filter-sterilized vitamin solution (Wolin et al., 1964). Single colonies were restreaked until pure cultures were obtained.

Maintenance procedures

Anaerostipes caccae can be grown under strictly anaerobic conditions at 37 °C either on Columbia blood agar (bioMérieux), in ST broth (Schwiertz et al., 2000), or in a medium used for culturing acetogenic bacteria (Kamlage et al., 1997). For long term storage, cultures have to be transferred every second day. Best results for long term storage can be obtained by maintaining the culture in broth medium as mentioned above.

List of species of the genus *Anaerostipes*

1. ***Anaerostipes caccae*** Schwiertz, Hold, Duncan, Gruhl, Collins, Lawson, Flint and Blaut 2002a, 1437^{VP} (Effective publication: Schwiertz, Hold, Duncan, Gruhl, Collins, Lawson, Flint and Blaut 2002b, 50.)

cac'cae. Gr. n. *kakkê* feces: N.L. gen. n. *caccae* of feces, pronounced kak'ka.

Colonies (1–3 mm in diameter) are as described for the genus. Cells are rod-shaped (0.5–0.6 µm × 2.0–4.0 µm), non-motile, Gram positive (Gram negative after 16 h), and occur in chains up to 4 cells. Strict anaerobes, they are also oxidase- and catalase-negative. Butyrate, acetate, and lactate are produced from glucose, and acetate is utilized.

Traditional tests detect acid production from D-fructose, fructooligosaccharides (FOS), D-glucose, D-galactose, inositol, maltose, D-mannose, ribose (weak), soluble starch, sucrose, L-sorbose, and sorbitol, but not from L-arabinose, cellobiose, glycerol, inulin, lactose, lactulose, melibiose, melezitose, L-rhamnose, D-trehalose, or D-xylose. Detection of acid production from salicin is variable. The API 50 system detects acid production from adonitol, D-arabitol, L-arabitol, D-arabinose, dulcitol, erythritol, galactose, D-glucose, D-fructose, inositol, D-lyxose, maltose, D-mannose, mannitol, melibiose, α-methyl-D-glucoside, N-acetylglucosamine, D-raffinose, (weak), ribose (weak), L-sorbose, sorbitol, sucrose, D-tagatose, D-turanose, and xylitol but not from amygdalin, L-arabinose, cellobiose,

D-fucose, β-gentiobiose, gluconate, glycerol, glycogen, inulin, lactose, 5-ketogluconate, melezitose, α-methyl-D-mannoside, β-methyl-D-xyloside, rhamnose, trehalose, D-xylose, or L-xylose. Acid production from arbutin, salicin, and 2-keto-gluconate as well as esculin hydrolysis is variable. The API ZYM system detects acid phosphatase and phosphoamidase activity, while the API rapid ID32A system detects arginine dihydrolase, α-galactosidase, and nitrate reductase (weak reaction) activity. Neither system detects activity for alanine arylamidase, alkaline phosphatase, arginine arylamidase, α-arabinosidase, chymotrypsin, cystine arylamidase, esterase C4, ester lipase C8, α-fucosidase, β-galactosidase, β-galactosidase-6-phosphate, α-glucosidase, β-glucosidase, β-glucuronidase, glycine arylamidase, glutamylglutamic acid arylamidase, histidine arylamidase, leucine arylamidase, leucylglycine arylamidase, lipase C14, α-mannosidase, N-acetyl-α-glucosaminidase, phenylalanine arylamidase, pyroglutamic acid arylamidase, proline arylamidase, serine arylamidase, trypsin, tyrosine arylamidase, valine arylamidase, or urease. Negative for gelatin hydrolysis and indole production.

For all other characteristics, refer to the genus description.

Source: human feces.

DNA G+C content (mol%): 45.5–46.0 (HPLC).

Type strain: L1-92, DSM 14662, JCM 13470, NCIMB 13811.

GenBank accession number (16S rRNA gene): AJ270487.

Genus IV. ***Bryantella*** Wolin, Miller, Collins and Lawson 2004, 1^{VP} (Effective publication: Wolin, Miller, Collins and Lawson 2003, 6325.)

PAUL A. LAWSON

Bry.an.tel'la. N.L. fem. n. *Bryantella* named after the American microbiologist Marvin P. Bryant in recognition of his outstanding contributions to the microbial ecology of anaerobic ecosystems.

Short, rod-shaped cells that occur in pairs and short chains. anaerobic chemo-organotroph. Catalase- and oxidase-negative. Gram-stain-positive. Nonmotile. Does not form spores. **Strictly Acid but not gas is produced from glucose.** Does not require

rumen fluid for growth. Indole-negative. Nitrate is not reduced. Acetate is the sole product of glucose fermentation when grown in the presence of high concentrations of formate. Isolated from human feces.

DNA G+C content (mol%): 50.3.

Type species: *Bryantella formatexigens* Wolin, Miller, Collins and Lawson 2004, 1^{VP} (Effective publication: Wolin, Miller, Collins and Lawson 2003, 6325.).

Further descriptive information

The genus contains only one species, *Bryantella formatexigens*, and therefore the characteristics provided below refer to this species. Cells are nonmotile, short rods that occur mainly in pairs and short chains. Strictly anaerobic chemo-organotroph. Acetate is the sole product of glucose fermentation when grown in the presence of high concentrations of formate. Glucose fermentation with low concentrations of formate yield succinate, lactate, and acetate. In the presence of 54 mM formate, it grows with added glucose, purified cabbage cellulose, stachyose, sucrose, lactose, maltose, galactose, mannose, or xylose. In the presence of formate, it does not grow with Avicel (FMC Corp.), lactate, starch, pectin, vanillate, syringate, methanol, or ethanol. It does not grow with 0.25% formate in the absence of carbohydrates. Indole-negative. Nitrate is not reduced.

Enrichment and isolation procedures

The organism was isolated from human feces using the serum bottle modification of the Hungate technique (Miller and Wolin, 1974). B1C medium was used and contained (per liter): NaHCO₃, 5.0 g; K₂HPO₄, 0.3 g; KH₂PO₄, 0.3 g; (NH₄)₂SO₄, 0.3 g; NH₄Cl, 1 g; NaCl, 0.61 g; MgSO₄·7H₂O, 0.15 g; CaCl₂·2H₂O, 80 mg; MnSO₄·H₂O, 4.5 mg; FeSO₄·7H₂O, 3.0 mg; CoSO₄·H₂O, 1.8 mg; ZnSO₄·7H₂O, 1.8 mg; CuSO₄·5H₂O, 100 µg; AlK(SO₄)₂·12H₂O, 180 µg; Na₂MoO₄·2H₂O, 100 µg; H₃BO₃, 100 µg; Na₂SeO₄, 1.9 mg; NiCl₂·6H₂O, 92 µg; nitrilotriacetic acid, 15 mg; thiamine HCl, 2.0 mg; D-pantothenic acid, 2.0 mg; nicotinamide, 2.0 mg; riboflavin, 2.0 mg; pyridoxine HCl, 2.0 mg; biotin, 10.0 mg; cyanocobalamin, 20 µg; *p*-aminobenzoic acid, 100 µg; folic acid, 50 µg; cysteine HCl, 0.5 g; rumen fluid, 100 ml; sodium acetate, 2.5 g; sodium formate, 2.5 g; trypticase, 2.0 g. WM medium was also used and contained (per liter): NaHCO₃, 3.5 g; KH₂PO₄, 0.5 g; NH₄Cl, 1 g; NaCl, 0.4 g; MgCl₂·6H₂O, 0.33 g; CaCl₂·2H₂O, 50 mg; FeCl₂·4H₂O, 1.5 mg; CoCl₂·6H₂O, 0.2 mg; ZnSO₄·7H₂O, 0.1 mg; MnCl₂·4H₂O, 0.03 mg; CuCl₂·2H₂O, 0.01 mg; Na₂MoO₄·2H₂O, 0.03 mg; H₃BO₃, 0.3 mg; Na₂SeO₄, 1.9 mg; NiCl₂·6H₂O, 0.02 mg; the same vitamins as B1C medium; cysteine HCl, 0.5 g; sodium acetate, 1.0 g; isobutyric acid, 0.54 ml; 2-methylbutyric, valeric, and isovaleric acids (0.6 ml each); casein hydrolysate, 2.0 g (Type I, No. C-9386, Sigma Chemical Co., St. Louis, MO). Resazurin (1 mg/l) was added to both media as an oxidation-reduction potential indicator. Both media were adjusted to pH 7 with NaOH prior to gassing with 100% CO₂ and the addition of NaHCO₃. After autoclaving under a CO₂ atmosphere, a sterile solution containing 0.125 g/l each of cysteine and sodium sulfide (30 µl per ml of medium) was added prior to inoculation. All incubations were performed at 37 °C.

Serial dilutions of feces in B1C medium plus 0.8% VCP (cellulose-enriched fiber from cabbage) yielded the original enrichments. After transfer to the same medium, cultures were plated

on VM medium plus 2% agar and 0.6% carboxymethylcellulose (CMC) in roll tubes. An isolated colony was transferred to B1C broth plus 0.6% CMC and replated on VM medium. Once isolated in pure culture, the organism could be grown anaerobically on blood-based agar.

Maintenance procedures

Grows well anaerobically on blood-based agar at 37 °C. For long-term preservation, strains are maintained in media containing 15–20% glycerol at –70 °C or lyophilized.

Taxonomic comments

The genus *Bryantella* was created to accommodate a phylogenetically distinct nonmotile, Gram-stain-positive, rod-shaped organism originating from human feces (Wolin et al., 2003). The genus is monospecific, and phylogenetic analyses of the 16S rRNA gene demonstrates a relationship between *Bryantella* and the *Clostridium coccooides* group (clostridial rRNA cluster XIVa; Collins et al., 1994). This diverse assortment of organisms is classified in this volume of Bergey's in the novel family *Lachnospiraceae* and includes the genera *Acetitomaculum*, *Anaerostipes*, *Bryantella*, *Butyrivibrio*, *Catonella*, *Coproccoccus*, *Dorea*, *Hespellia*, *Johnsonella*, *Lachnospira*, *Lachnobacterium*, *Moryella*, *Oribacterium*, *Parasporobacterium*, *Pseudobutyrvibrio*, *Roseburia*, *Shuttleworthia*, *Sporobacterium*, and *Syntrophococcus* in addition to many misclassified clostridial species (see treatment of the family *Lachnospiraceae* in this volume). However, *Bryantella* forms a distinct lineage within this large grouping and does not display a particularly close affinity with any of the aforementioned taxa. It is clear from phylogenetic molecular profiling studies of this large family that human feces contains additional species of *Bryantella* that remain to be isolated and described (Barcenilla et al., 2000; Hold et al., 2002; Namsolleck et al., 2004; Suau et al., 1999).

Differentiation of the genus *Bryantella* from other genera

Bryantella can be readily distinguished from its closest phylogenetic relatives by a combination of morphological, biochemical, and chemotaxonomic criteria. Its unusual homoacetogenic fermentation distinguishes it from the other members of the family *Lachnospiraceae*. Further distinctive features include the following. While the morphology of *Bryantella* somewhat resembles that of *Syntrophococcus sucromutans*, its Gram reaction is different. *Syntrophococcus sucromutans* also requires large amounts of rumen fluid for growth (Krumholz and Bryant, 1986a). *Bryantella* can be distinguished from *Clostridium* spp. and *Sporobacterium* because it does not produce endospores. Its morphology distinguishes it from *Lachnospira*. The absence of motility and butyrate as a product of the glucose fermentation distinguishes it from *Roseburia* and *Butyrivibrio*. Differences in cellular morphology and products of glucose metabolism distinguish it from *Coproccoccus* and *Ruminococcus*.

Importantly, in this diverse group of organisms, an accurate identification relies to a great extent upon molecular genetic techniques such as 16S rRNA gene sequence comparisons. Once the sole domain of specialized research facilities, these high-throughput methodologies are becoming increasingly automated, reducing costs, and making them routinely accessible. The availability of these methods facilitates more rapid and accurate identification of hitherto unknown taxa.

List of species of the genus *Bryantella*

1. ***Bryantella formatexigens*** Wolin, Miller, Collins and Lawson 2004, 1^{VP} (Effective publication: Wolin, Miller, Collins and Lawson 2003, 6325.)

for.mat.ex'i.gens. N.L. n. *formas -atis* formate; L. part. adj. *exigens* demanding; N.L. fem. part. adj. *formatexigens* formate-demanding.

Characteristics are as given for the genus with the following information. Using the commercially available API Rapid ID32A system, activity is detected for α -arabinosidase, α -galactosidase, β -galactosidase, β -galactosidase-6-phosphate, α -glucosidase, β -glucosidase, β -glucuronidase, and *N*-acetyl-

β -glucosaminidase. No activity is detected for alkaline phosphatase, arginine arylamidase, arginine dihydrolase, alanine arylamidase, α -fucosidase, glutamic acid decarboxylase, glutamyl glutamic acid arylamidase, glycine arylamidase, histidine arylamidase, leucine arylamidase, leucyl glycine arylamidase, phosphoamidase, phenylalanine arylamidase, proline arylamidase, pyroglutamic acid arylamidase, serine arylamidase, tyrosine arylamidase, or urease. Isolated from human feces.

DNA G+C content (mol%): 50.3 (HPLC).

Type species: I-52, CCUG 46960, DSM 14469.

GenBank accession number (16S rRNA gene): AJ318527.

Genus V. *Butyrivibrio* Bryant and Small 1956b, 18, emend. Moore, Johnson and Holdeman 1976, 241^{AL}

ANNE WILLEMS AND MATTHEW D. COLLINS

Bu.ty.ri.vib'ri.o. N.L. adj. *butyricus* butyric; L. v. *vibro* to vibrate; N.L. n. *Vibrio* that which vibrates, a bacterial genus name; N.L. masc. n. *Butyrivibrio* a butyric vibrio.

Gram-stain-negative, but structurally Gram-positive, non-spore-forming, strictly anaerobic straight to curved rods, 0.3–0.8 × 1.0–5.0 μ m, occurring singly or in chains or filaments that may be helical. Motile by monotrichous or lophotrichous, polar or sub-polar flagella or nonmotile. Chemo-organotrophic, fermentative metabolism with carbohydrates as the main substrates. Glucose or maltose are fermented with butyrate as a major end product.

Under some conditions some strains may produce large amounts of lactate and little butyrate. On the basis of 16S rRNA gene sequences, *Butyrivibrio* belongs to cluster XIVa of the *Clostridium* subphylum of the Gram-positive bacteria. It is not monophyletic: *Butyrivibrio fibrisolvens* strains form two distinct subgroups which correspond to different genera and *Butyrivibrio crossotus* occupies a separate position (Willems et al., 1996). *Butyrivibrio hungatei* belongs to the *Butyrivibrio fibrisolvens* subgroup that also comprises the type strain of *Butyrivibrio fibrisolvens* (Kopečný et al., 2003). According to the 16S rRNA phylogenetic analysis presented in the roadmap to this volume (Figure 5), the genus *Butyrivibrio* is a member of the family *Lachnospiraceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*. Isolated from the rumen of ruminants and in human, rabbit, and horse feces.

DNA G+C content (mol%): 36–45 mol% (T_m and HPLC).

Type species: ***Butyrivibrio fibrisolvens*** Bryant and Small 1956b, 19^{AL}.

Further descriptive information

Cell morphology. Cells are straight to curved rods with tapered or round ends. They occur singly or in short or long chains that may show helical arrangement. Pairs of cells may occur in an “S” arrangement. Cells sometimes appear as filaments. Cells of *Butyrivibrio crossotus* tend to be larger in diameter than those of *Butyrivibrio fibrisolvens* (Bryant, 1986b). Motile by means of polar or subpolar monotrichous (*Butyrivibrio fibrisolvens* and *Butyrivibrio hungatei*) or lophotrichous flagellation (*Butyrivibrio crossotus*). Often only a few cells in a culture are motile. Nonmotile strains have been reported. Flagellar filaments of *Butyrivibrio fibrisolvens* strain OR77 have been characterized biochemically and some of the genes encoding flagellins (*flaA* and *flaB*) characterized (Kalmokoff et al., 2000).

Cell-wall composition. *Butyrivibrio* strains stain Gram-negative but lack the trilamellar outer membrane structure commonly associated with Gram-negative bacteria. Some strains (including the type strain) possess an atypical, very thin Gram-positive cell-wall ultrastructure (Cheng and Costerton, 1977; Dibbayawan et al., 1985). The thin walls (approx. 12–20 nm) compared with those of normal Gram-positive walls (approx. 30–50 nm) probably account for the Gram-negative staining reactions of strains. The peptidoglycans of *Butyrivibrio* strains contain muramic acid, glucosamine, alanine, glutamic acid, and *meso*-diaminopimelic acid (Hespell et al., 1993). These components are consistent with a *meso*-diaminopimelic acid direct cross-linked structure of the A type (variation A1 γ ; Schleifer and Kandler, 1972). However, although *meso*-diaminopimelic acid is the major component involved in cross-linking, it appears that cross-linking is not extensive in many strains (Hespell et al., 1993). In addition, small amounts of glycine and aspartic acid are present in *Butyrivibrio* mureins, indicating some cross-links may involve these amino acids (Hespell et al., 1993). Further studies are needed to determine the precise structures and nature of linkages in *Butyrivibrio* peptidoglycans. Lipoteichoic acids, comprising 1,3-phosphodiester-linked polyglycerophosphate chain linked to a glycolipid, and deacylated lipoteichoic acids have been isolated from *Butyrivibrio fibrisolvens* strains (Hewitt et al., 1976).

Extracellular polysaccharides. Many *Butyrivibrio fibrisolvens* strains produce extracellular polysaccharides with rheological properties similar to those of xanthan gum (Ha et al., 1991; Wachenheim and Patterson, 1992). The structure of the exopolysaccharides of several strains has been extensively studied. In strain 49, the structure of the capsular polysaccharide consists of pentasaccharide repeating units with one of the *O*-acetyl groups substituted to *O*-3 of the 4-substituted α -D-galactopyranoside (Ferreira et al., 1995). In addition, the acid sugars 4-*O*-(1-carboxyethyl)-D-galactose and 4-*O*-(1-carboxyethyl)-L-rhamnose were reported for the first time in this strain (Stack et al., 1988b; Stack and Weisleder, 1990). In strain X6C61, the structure of the capsular polysaccharide consists of hexasaccharide repeating units with approximately 70% of *O*-acetyl groups substituted to *O*-3 of β -D-glucopyranoside

(Andersson et al., 1993). L-Iduronic acid and 6-deoxy-D-talose were identified as components of the polysaccharides of this strain (Stack, 1989; Stack et al., 1988a). In strain CF3, L-altrose was identified in the extracellular polysaccharide (Stack, 1987) that consists of pentasaccharide repeating units (Ferreira et al., 1997).

The neutral sugar composition and other compositional features of extracellular polysaccharides have been used to sort *Butyrivibrio fibrisolvens* isolates into groups (Stack, 1988). Some of these groups may be taxonomically significant, but more comparative phylogenetic data are needed to establish this clearly.

Colonial characteristics. In rumen fluid-glucose-cellobiose-agar (RGCA) roll-tubes (Bryant and Small, 1956b), surface colonies of *Butyrivibrio fibrisolvens* are usually smooth, entire, slightly convex, translucent, light brown with a diameter of 2–4 mm. Some strains have rough, more flat colonies that are paler and have filamentous margins. Deep colonies are usually lenticular or Y-shaped but some form compound lenticular colonies (Bryant, 1986b). In rumen fluid-cellulose agar, cellulolytic strains have a diverse colony morphology, varying from lens shaped over triangular to compound lenticular or rhizoidal. Zones of cellulose digestion around colonies vary from very narrow for strains with slow digestion to broad for strains with rapid and complete digestion (Bryant, 1986b).

On RGCA roll tubes, *Butyrivibrio crossotus* subsurface colonies are 0.5–1 mm in diameter, lenticular, and translucent to transparent (Bryant, 1986b). On supplemented brain heart infusion agar roll streaks of these organisms are 0.2–1 mm in diameter, circular, entire, convex, translucent to semiopaque, and smooth (Moore et al., 1976).

Nutrition and growth conditions. *Butyrivibrio* strains are strict anaerobes, occurring in the gastrointestinal system of vari-

ous domestic animals and humans. They have a fermentative metabolism and therefore growth is poor in media lacking a carbohydrate source. As fiber degraders, they are able to utilize various hemicelluloses and xylans. Most strains can degrade starch and pectines, but few strains can grow on cellulose. Most strains can ferment a variety of soluble sugars, disaccharides, or oligosaccharides to form butyrate, as well as lactate and acetate (Hespell, 1991). *Butyrivibrio* strains can use various components of plant cell walls but are also inhibited by some of these compounds. For example, growth of *Butyrivibrio fibrisolvens* strain 49 is limited by ester-linked feruloyl and *p*-coumaroyl groups. Growth limitation by phenolic acid-carbohydrate complexes varies with the ability to hydrolyze carbohydrate linkages (Akin et al., 1993).

Most *Butyrivibrio* strains can use ammonia as sole nitrogen source; many strains can also use urea. Peptides are not required but often stimulate growth on ammonia-containing media (Hespell, 1991). Strain E14 is reported to require methionine for growth (Nili and Brooker, 1995, 1997) and strain S2 requires fatty acids for growth (Hazlewood and Dawson, 1979). Growth of *Butyrivibrio fibrisolvens* strain TC33 in clarified rumen fluid with glucose is stimulated by the addition of a vitamin/casein hydrolysate mixture or yeast extract. Most rapid growth is obtained by the addition of a combination of folic acid, pyridoxamine.2HCl, and an enzymic hydrolysate of casein (Wejdemar, 1996).

Best growth temperature is 37 °C, and little or no growth occurs at 30 or 45 °C (Hespell, 1991).

Metabolism of carbohydrates. *Butyrivibrio* strains are able to metabolize a variety of carbohydrates and contribute significantly to rumen processes. Many studies have focussed on the carbohydrate metabolism of particular model strains.

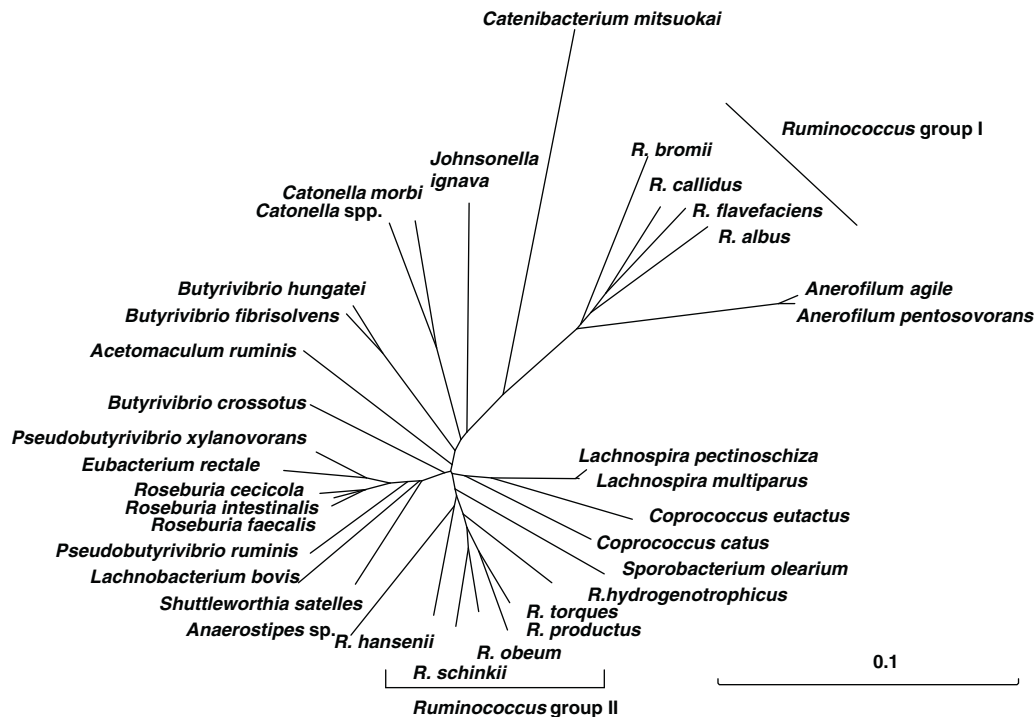

FIGURE 161. Phylogenetic position of ruminococci and coprococci among the family *Lachnospiraceae*.

In *Butyrivibrio fibrisolvens* strains ATCC 19171 and CE 51, production of cell dry matter and growth rate are higher in cultures with glucose than xylose. In the latter cultures, more carbon is converted to metabolites and less to cell material (Marounek and Petr, 1995). When provided with both glucose and xylose, *Butyrivibrio fibrisolvens* strains ATCC 19171 and 86 used both sugars simultaneously, strains X1 and CE 51 showed classical diauxic growth using glucose first, whereas strain X2D62 slowly used xylose first until depletion and then rapidly used glucose. ATP-dependent phosphorylation of glucose occurred in all these strains and, in addition, strain CE 51 also had phosphoenolpyruvate-dependent phosphorylation of glucose (Marounek and Kopečný, 1994). Strain D1 consumes glucose and xylose but has a clear preference for glucose or xylose over arabinose. It catabolizes xylose or arabinose and cellobiose, but prefers either pentose over maltose. Strain A38 showed a strong preference for disaccharides over xylose or arabinose (Strobel and Dawson, 1993). Pentose transport in strain D1 depends on a high-affinity, ATP-dependent mechanism and hexose sugars affect the use of xylose and arabinose (Strobel, 1994).

Butyrivibrio fibrisolvens strain 49 rapidly hydrolyzes starch to produce glucose, maltose, maltotriose, maltotetraose, and maltopentaose (Cotta, 1992). The α -amylase gene from strain H17c has been cloned and sequenced and the enzyme shown to be a calcium metalloenzyme (Rumbak et al., 1991).

Butyrivibrio fibrisolvens fermentation end products from glucose include formate, butyrate, acetate, and varying amounts of lactate and succinate (Holdeman et al., 1977b). However, considerable variation among strains has been reported: strains D1 and A38 were shown to produce little lactate, whereas strains 49 and nor 37 produced a lot of lactate, but this could be inhibited and butyrate would be produced instead by the presence of acetate. In the latter strains a butyryl-CoA/acetate-CoA transferase system converts butyryl-CoA into butyrate, using acetate as an acceptor. The former strains do not have this system but possess butyrate kinase instead (Diez-Gonzalez et al., 1999).

Metabolism and degradation of plant material. The role of *Butyrivibrio* in the degradation of plant material from various sources has been extensively studied because of the importance to rumen metabolism. Many studies into the solubilization of plant cell walls and the digestion cell-wall monosaccharides by co-cultures of various rumen bacteria have been published. In co-cultures, *Butyrivibrio fibrisolvens* strain D1 solubilized cell-wall carbohydrates less well than *Fibrobacter succinogenes* but did interact complementarily with this species to utilize solubilized carbohydrates and improve co-culture growth. Alfalfa hays were used to a lesser extent than ryegrass (Miron and Benghedalia, 1993a). Co-cultures of the same *Butyrivibrio fibrisolvens* strain with other ruminal bacteria are capable of degrading barley straw (Miron et al., 1994), sorghum straw (Benghedalia et al., 1993), panicum hay and vetch hay (Miron and Benghedalia, 1993c), cotton stalks (Miron and Benghedalia, 1993b), wheat straw (Miron and Benghedalia, 1992), and lucerne (Miron, 1991). In all of these reports, the role of *Butyrivibrio fibrisolvens* was mainly to use solubilized carbohydrates. Cellulose-binding proteins were eluted from a cell lysate of a *Butyrivibrio fibrisolvens* strain using SDS, but not carboxymethylcellulose (Mitsumori and Minato, 1995). In a comparative study of the use of pectin from different sources, pure cultures of *Butyrivibrio fibrisolvens* used citrus pectin best and sugar beet pectin was used better than pectin from apple

or lucerne; with mixed cultures of rumen micro-organisms, *Butyrivibrio fibrisolvens* used pectin less than *Prevotella ruminicola* and *Lachnospira multiparus* (Kasperowicz, 1994). *Butyrivibrio fibrisolvens* strain 787 grown on pectin produced significantly more acetate and less butyrate, lactate, succinate, and hydrogen than cultures grown on L-arabinose and D-glucose. Pectin-grown cells have 2-keto-3-deoxy-6-phosphogluconate aldolase and fructose-diphosphate aldolase activity but not phosphoketolase activity (Marounek and Duskova, 1999).

In a comparison of the degradation of fructan from timothy grass by rumen bacteria, *Butyrivibrio fibrisolvens* strain 3 was more effective than *Streptococcus bovis*, *Bacteroides ruminicola*, *Selenomonas ruminantium*, and two *Treponema* species (Ziolecki et al., 1992).

Metabolism and use of xylan. Xylans are hemicelluloses that constitute a major component of the ruminants diet. The xylanolytic activity of *Butyrivibrio fibrisolvens* contributes significantly to the degradation of these substrates and results in a pool of degradation intermediates including low-molecular-weight xylooligosaccharides that can be used by *Butyrivibrio fibrisolvens* and other species in the rumen microflora (Cotta, 1993; Hespell et al., 1987). For example, xylanolytic *Butyrivibrio fibrisolvens* strain H17c rapidly degrades oat spelt xylan and *Selenomonas ruminantium* strain GA 192 grown in co-culture will use the resulting xylooligosaccharides, although residual carbohydrates do remain after growth (Cotta and Zeltwanger, 1995). The ability of strain H17c to degrade various chemically and physically different xylans was studied and it was shown that the type and distribution of xylan side chains are more important for xylan utilization than the extent of water insolubility (Hespell, 1992, 1995). In strain NCFB 2249 xylanolytic enzymes were induced by xylan, xylooligosaccharides, and xylase under anaerobiosis. Highest activity was observed at pH 6.5–7 and with substrate concentrations of 2 mg/ml or higher. Enzymes involved are subject to catabolite regulation and include α -L-arabinofuranosidase, β -D-xylosidase, and xylanase. The β -xylosidase of *Butyrivibrio fibrisolvens* belongs to family 43 of a general classification of glycosyl hydrolases based on amino acid sequences and its molecular mechanism of action has been elucidated (Braun et al., 1993). In the presence of readily metabolized sugars such as glucose and arabinose, diauxic growth was observed with delayed xylanolysis (Williams and Withers, 1992a, 1992b). Xylanase genes of *Butyrivibrio fibrisolvens* were cloned, sequenced, and expressed in *Escherichia coli* (Lin and Thomson, 1991; Mannarelli et al., 1990a; Sewell et al., 1989; Utt et al., 1991). A *xynA* gene was described from strain Bu49, whereas *xynB* was described from strain H17c. Strain Bu49 harbors two enzymes with xylanase activity, XynA and a second, smaller enzyme (Hespell and Whitehead, 1990; Mannarelli et al., 1990a). The extracellular xylanase component of strain H17c is thought to be a multisubunit protein aggregate of xylanases, some with cellulase activity (Lin and Thomson, 1991). A more extensive study of the diversity and distribution of xylanase genes in *Butyrivibrio* strains revealed two gene families, *xynA* (with two subfamilies) and *xynB* and evidence that at least one additional xylanase gene family remains to be identified (Dalrymple et al., 1999).

Butyrivibrio fibrisolvens strains are able to hydrolyze ester-linked ferulic and *p*-coumaric acid, present in the arabinoxylans of dry season tropical grasses through extracellular cinnamoyl esterase activity (McSweeney et al., 1998).

About 33% of *Butyrivibrio hungatei* strains had xylanase activity (Kopečný et al., 2003).

Chemotaxonomic data. The cellular fatty acids of *Butyrivibrio fibrisolvens* have been characterized (Ifkovits and Ragheb, 1968; Miyagawa, 1982; Moore et al., 1994). *Butyrivibrio fibrisolvens* contain fatty acids of the straight-chain saturated, monounsaturated, and branched types. Moore et al. (1994) reported the major components of the type strain of *Butyrivibrio fibrisolvens* to be $C_{16:0}$ fatty acid (45%), $C_{18:1}^-$ dimethyl acetal (15%), and $C_{16:0}$ dimethyl acetal (11%). Smaller amounts of the following were also detected: $C_{12:0}$ fatty acid (1%), $C_{14:0}$ fatty acid (4%), $C_{14:0}$ dimethyl acetal (2%), $C_{16:0}$ iso fatty acid (1%), $C_{16:1}^-$ fatty acid (1%), $C_{18:1}^-$ fatty acid (2%), $C_{18:0}$ fatty acid (3%), $C_{17:1}^-$ (3%), and $C_{18:1}^-$ fatty acid or an unknown component with an equivalent chain-length of 17.834 (4%). These data are essentially consistent with the earlier findings of Ifkovits and Ragheb (1968) except the latter workers did not report the presence of large amounts of fatty aldehyde components nor did Kopečný et al. (2003). Miyagawa (1982) also detected fatty aldehydes in *Butyrivibrio* strains. In the study of Miyagawa (1982), *Butyrivibrio* strains formed two broad groups on the basis of their fatty acid profiles; group 1 contained branched-chain fatty acids and fatty aldehydes as major components, whereas group 2 had predominantly straight and monounsaturated chains. Group 1 consisted of nine strains and contained $C_{15:0}^{anteiso}$ fatty acid and $C_{15:0}^{anteiso}$ aldehyde in relatively large amounts; some strains had iso- $C_{14:0}$ aldehyde, and some had $C_{16:0}$ iso fatty acid and $C_{17:0}^{anteiso}$ fatty acid in large amounts. Group 2 consisted of 12 strains that displayed considerable variation in their fatty acids and aldehydes; for example, some strains contained $C_{16:0}$ fatty acid, $C_{18:1}$ aldehyde, and $C_{16:0}$ aldehyde, one strain had $C_{16:0}$ fatty acid, $C_{16:0}$ aldehyde, and $C_{17:0}^{iso}$ fatty acid, whereas some others had $C_{15:0}$ fatty acid, $C_{16:0}$ fatty acid, $C_{15:0}^{iso}$ fatty acid, $C_{15:0}^{iso}$ aldehyde, and/or $C_{14:0}$ fatty acid. The fatty acid compositional studies of Miyagawa (1982) revealed considerable taxonomic diversity within the *Butyrivibrio* strains examined. Marinšek-Logar et al. (2001) examined the fatty acid profiles of 45 *Butyrivibrio* strains. In the study of Marinšek-Logar et al. (2001) the *Butyrivibrio* strains fell into four major and two minor groups; the major fatty acids for the bulk of the strains were reported to be $C_{14:0}$, $C_{15:1}$, and $C_{16:1}$. These findings are at variance with earlier investigations (Miyagawa, 1982; Moore et al., 1994). *Butyrivibrio hungatei* contained relatively large amounts of $C_{16:0}^{iso}$ fatty acid (15%), $C_{16:1}$ fatty acid (13%), $C_{17:0}^{anteiso}$ fatty acid (17%), $C_{16:0}$ fatty acid (9%), $C_{16:0}^{2-OH}$ fatty acid (7%), $C_{14:0}^{2-OH}$ fatty acid (4%) and $C_{17:1}$ iso fatty acid (3%) as well as significant amounts (1–3%) of the following fatty acids: $C_{12:1}$, $C_{14:0}$ iso, $C_{14:0}$, $-C_{13:0}^{iso} 3-OH$, $C_{15:1}^{iso}$ or $C_{13:0} 3-OH$, $C_{15:1}^{anteiso}$, $C_{15:0}^{anteiso}$, $C_{15:1}^{c_{10}}$, $C_{15:0}$, $C_{14:0} 3-OH$ or $-C_{16:1}^{iso}$, $C_{17:0}$, $C_{18:1}^{iso}$, $C_{18:0}$ and $C_{19:1}^{iso}$ (Kopečný et al., 2003). No fatty acid data for *Butyrivibrio crossotus* have been reported.

Plasmids. With the aim of optimizing the activity of the rumen microflora, many studies have explored the occurrence of plasmids in *Butyrivibrio* strains and their use in developing vector systems for the transformation of rumen strains. Screening of rumen bacteria for the presence of plasmids, revealed only 0.2% of *Butyrivibrio* strains bear plasmids (Ogata et al., 1996). An earlier study, screening specifically *Butyrivibrio fibrisolvens* strains from the bovine rumen, found plasmids to be common features of these organisms, with large plasmids (250 kDa) present in all strains tested (Teather, 1982b).

A small cryptic plasmid pOM1 was characterized from strain Bu49 (Mann et al., 1986). It was later sequenced and has been used to construct an *Escherichia coli*–*Butyrivibrio fibrisolvens* shuttle vector pSMerm1 (Hefford et al., 1997). Derived from this system, plasmid pBHE can be used to characterize promoters in *Butyrivibrio* (Beard et al., 2000). Several other small cryptic plasmids have been characterized from different *Butyrivibrio* strains (Hefford et al., 1993; Kobayashi et al., 1995; Ware et al., 1992). Plasmid pRJF1 from strain OB156 was used in combination with pUC118 and pAM β 1 to construct a shuttle vector (Beard et al., 1995).

An electroporation protocol was optimized to introduce cloned genes into *Butyrivibrio fibrisolvens* (Whitehead, 1992). A conjugative transfer system has been developed using tetracycline-resistant transposon Tn916, pUB110 from *Staphylococcus aureus* and pUBLRS, a pUB110-based shuttle vector (Clark et al., 1994).

Stable transfer of a plasmid (pAM- β -1) and transposons (Tn916, Tn916- δ -E) has been shown from the nonruminal species *Enterococcus faecalis*, as well as from the ruminal species *Streptococcus bovis* to various *Butyrivibrio fibrisolvens* strains (Hespell and Whitehead, 1991b, 1991a).

Antibiotic sensitivity. *Butyrivibrio fibrisolvens* strains are resistant to high levels of nalidixic acid, a DNA gyrase inhibitor (30–500 μ g/ml) (Hespell, 1991, 1993). They are generally sensitive to many other antibiotics, especially those affecting cell-wall synthesis such as β -lactams, cephalothin, and bacitracin (Fulghum et al., 1968; Hespell et al., 1993). Five ruminal *Butyrivibrio fibrisolvens* strains were found to be very sensitive to ionophores and inhibitors of protein synthesis, except for auromycin. They were relatively insensitive to inhibitors of carbohydrate metabolism and uncouplers and sensitivity varied to salinomycin, aureomycin, and bacitracin (Marounek and Savka, 1994).

Horizontal transfer of tetracycline resistance on a chromosomal element was reported among *Butyrivibrio fibrisolvens* strains (Scott et al., 1997). Evidence supporting intergeneric exchange of tetracycline resistance genes has also been reported (Melville et al., 2001). Two types of tetracycline resistance genes are present in *Butyrivibrio fibrisolvens*: one nontransmissible with a sequence identical with that of *Streptococcus pneumoniae tet(O)* and a transmissible resistance gene, *tet(W)*, representing a new class of ribosomal protection determinants. This gene has a higher DNA GC content than other *Butyrivibrio fibrisolvens* genes and similar sequences are also present in other rumen anaerobes, suggesting recent intergeneric transfer among ruminal bacteria (Barbosa et al., 1999; Billington et al., 2002).

Tannins, as present in the leaves of sainfoin (*Onobrychis viciifolia*), inhibit growth and protease activity in *Butyrivibrio fibrisolvens* strain A38 (Jones et al., 1994).

Butyrivibrio fibrisolvens strain 49 is sensitive to the ionophore antibiotic monensin, which is used as a feed additive (Callaway et al., 1999).

Bacteriocide activity. Many *Butyrivibrio fibrisolvens* strains (over 50% of strains isolated from sheep, deer, and cattle) have bacteriocide activities, probably due to different inhibitory compounds they produce (Kalmokoff et al., 1996). The bacteriocin-like activity from strain AR10 is due to a single peptide showing no homology with previously reported bacteriocins (Kalmokoff and Teather, 1997). Strain OR79 produces a bacteriocin-like activity with a broad spectrum activity. Two very similar peptide inhibitors were isolated from spent culture liquid and partially

characterized; their genes were located. Amino acid sequence comparisons indicate these molecules represent a new type of antibiotic (Kalmokoff et al., 1999). *Butyrivibrio fibrisolvens* strain JL5 from bovine rumen produces a bacteriocin which inhibits some *Butyrivibrio fibrisolvens* but not others (Rychlik and Russell, 2002). The bacteriocin from JL5 inhibits a variety of Gram-stain-positive organisms, such as obligate amino acid-fermenting species *Clostridium sticklandii* and *Clostridium aminophilum*, and may play a role in regulating ammonia production *in vivo* (Rychlik and Russell, 2002).

Ecology. *Butyrivibrio* is a component of the normal rumen microflora in ruminants all over the world. This bacterial community is responsible for the primary degradation of raw plant material, converting it to simpler metabolites and bacterial protein that feed the animal. In the rumen ecosystem, cross-feeding between species is an important factor in the efficient degradation of plant material, as illustrated in various studies using mixed cultures (see section on degradation of plant material). Experiments using various plants have shown that *Butyrivibrio fibrisolvens* alone is unable to degrade straw extensively. In co-cultures with other ruminal bacteria it increases solubilization of cell-wall carbohydrates and significantly increases the use of arabinose, xylose, and glucose (Miron et al., 1994). In co-cultures on starch, *Selenomonas ruminantium*, a nonamylolytic species, was able to cross-feed on maltooligosaccharides produced by *Butyrivibrio fibrisolvens* (Cotta, 1992).

Genetic modification of rumen organisms opens the prospect of improving rumen fermentation and reducing economic losses of livestock industries (for reviews see Kobayashi and Onodera, 1999; Forsberg et al., 1999). A xylanase gene of *Eubacterium ruminantium* was successfully transferred to and expressed in *Butyrivibrio fibrisolvens* (Kobayashi et al., 1998). Similarly, a fungal xylanase gene has been transferred to *Butyrivibrio fibrisolvens* and its product is secreted by the bacterium, even after prolonged cultivation (Xue et al., 1997). However, *in vivo* experiments suggest that persistence in the rumen system is limited (Krause et al., 2001). Strains of *Butyrivibrio fibrisolvens* genetically modified to carry genes that detoxify fluoroacetate, a poisonous component of some trees and shrubs, have been produced and fed to sheep that subsequently suffered less toxicological symptoms when challenged with fluoroacetate (Gregg, 1995, 1998). To follow recombinant strains in the rumen, a competitive PCR assay has been tested (Kobayashi et al., 2000).

Butyrivibrio fibrisolvens may provide selenium, an important trace element for grazing ruminants, in a form utilizable by the animals by converting selenite into seleno-amino acids (Hudman and Glenn, 1985).

In a survey of 50 strains of *Butyrivibrio* of various origins, half of the strains were found to produce bacteriocins with a broad spectrum of activity. These components are thought to contribute significantly to the composition and structure of the ruminal ecosystem (Kalmokoff et al., 1996).

Butyrivibrio strains isolated from human feces are similar to *Butyrivibrio fibrisolvens* but have been placed in a separate species, *Butyrivibrio crossotus*, because they are lophotrichous, whereas *Butyrivibrio fibrisolvens* is monotrichous or occasionally has two polar flagella (Moore et al., 1976).

Enrichment and isolation procedures

A wide variety of media and growth conditions have been used for the isolation of *Butyrivibrio* strains, but no specific selective isolation or enrichment procedures have been published.

Butyrivibrio strains can be isolated by nonselective procedures in rumen fluid-glucose-cellobiose-agar (RGCA) roll-tubes among the predominant bacteria in rumen fluid (Bryant and Small, 1956b) or from human feces (Moore et al., 1976). *Butyrivibrio fibrisolvens* can be isolated from high dilutions of rumen fluid by using rumen fluid agar roll-tube media with finely ground cellulose. Small zones of cellulose digestion may be seen around colonies (Hungate, 1966; Shane et al., 1969) compared with larger zones of clearing caused by other cellulolytic bacteria (Shane et al., 1969). It can also be isolated on RGCA roll-tube medium containing 0.2% rutin as the sole energy source. Colonies from clear zones in the rutin and a yellow quercetin precipitate may form around some (Cheng et al., 1969; Leedle and Hespell, 1980). A medium containing xylan as sole carbohydrate source and nalidixic acid is suggested as selective for *Butyrivibrio fibrisolvens* because of the high resistance of some strains to this antibiotic (Hespell, 1991).

Maintenance procedures

Strains can be maintained by storage of cultures in liquid nitrogen or ultracold freezers (Hespell and Canale-Parola, 1970). Strains can also be preserved by lyophilization and storage at 4°C. For short-term storage (6–15 months) glycerol-containing cultures can be kept at –20°C (Teather, 1982a).

Differentiation of the genus *Butyrivibrio* from other genus

Butyrivibrio can be distinguished from most other genera of anaerobic bacteria on the basis of its curved rod-shaped cells, absence of spore formation, Gram-negative cell walls, its polar or subpolar flagella, and its fermentative metabolism with butyric acid as a major end product (Holdeman et al., 1977b, 1986). *Butyrivibrio fibrisolvens* can be distinguished from *Fusobacterium* species which also produce butyric acid, by its inability to produce indole, its motility, and its ability to hydrolyze esculin and ferment mannose (Holdeman et al., 1977b). A PCR assay to distinguish *Butyrivibrio* from *Pseudobutyrvibrio* has been developed (Kopečný et al., 2003; Mrázek and J. Kopečný, 2001).

Taxonomic comments

Butyrivibrio was proposed as a genus for butyric acid producing anaerobic, Gram-stain-negative, monotrichous, curved rods by Bryant and Small (1956b). Only one species, *Butyrivibrio fibrisolvens*, was proposed at the time, but the authors recognized the diversity within the genus: "Because of the variability in characteristics found between strains of this group of organisms, it will be difficult to determine what characteristics logically can be used to define natural species specific patterns". A second species, "*Butyrivibrio alacticidigenis*" was proposed later for those strains that do not produce lactate (Hungate, 1966), but this was not included in *Bergey's Manual of Determinative Bacteriology* (Bryant, 1974), nor on the Approved Lists (Skerman et al., 1980). Shane et al. (1969), in a study of cellulolytic bacteria from the rumen of sheep, described two distinct groups of curved rods within the genus *Butyrivibrio*. Their group I produced appreciable amounts of lactate and removed acetate during cellobiose

fermentation, whereas group 2 produced acetate but little or no lactate and was nutritionally more fastidious than group 1. The former group was different from “*Butyrivibrio alacticidigenis*”. In 1976, Moore et al. described a new species, *Butyrivibrio crosotus*, for isolates from human feces that resemble *Butyrivibrio fibrisolvens* but are lophotrichous.

Using DNA–DNA hybridizations, Mannarelli (1988) demonstrated a large diversity among *Butyrivibrio fibrisolvens* strains: five groups of related strains formed at least five distinct genospecies and 19 other strains (including the type strain) were not closely related to any other strain. This work was subsequently extended (Mannarelli et al., 1990b) by including more strains, also from related taxa, and three additional new *Butyrivibrio* genospecies were demonstrated. One of these groups contained the type strain of *Butyrivibrio crosotus* and strains recovered from the rumen of bison. The same strains were also studied in extracellular polysaccharide analyses and this produced groupings similar to those of DNA–DNA hybridization (Mannarelli et al., 1990b; Stack, 1988). Monoclonal antibodies have been successfully used to identify some *Butyrivibrio* strains from the rumen, but insufficient strains were included to establish the taxonomic potential of this technique inside this group (Hazlewood et al., 1986).

A phylogenetic study of the 16S rDNA genes of *Butyrivibrio* strains (Willems et al., 1996) revealed 12 rRNA types which formed three distinct lineages in cluster XIVa of the *Clostridium* subphylum as defined by Collins et al. (1994). An overview of their position is given in Figure 162 and a more detailed view of these groups is presented in Figure 163. Ribosomal RNA types 1–7 formed a first group in which rRNA type 1 (which includes the type strain of *Butyrivibrio fibrisolvens*) was the most peripheral. It showed 93–94% 16S rDNA sequence similarity with rRNA types 2–7, which showed 96–98.5% sequence similarity with each other. A second group was composed of rRNA types 8–11 which showed 98–99% 16S rDNA sequence similarity with each other and 87–88% with members of the first group. Finally, rRNA type 12, containing the type strain of *Butyrivibrio crosotus*, formed a completely separate line with 88–91% 16S rDNA sequence similarity with the first two clusters. Other studies, using 16S rDNA sequencing (Forster et al., 1996) and 16S rDNA-based hybridization probes (Forster et al., 1997), defined three further *Butyrivibrio* groups, only one of which was equivalent to one of the preceding rRNA types (type 8 = probe 49 group). Strains representing rRNA types 1, 2, 8, and 9 were previously included in DNA–DNA hybridizations (Mannarelli, 1988; Mannarelli et al., 1990b) where they formed separate genospecies. Apart from *Butyrivibrio crosotus*, in total at least 13 separate *Butyrivibrio* genotypic groups were thus reported in two distinct phylogenetic lineages. An overview of the strains that belong to each of these groups is given in Table 162. According to the 16S rRNA phylogenetic analysis presented in the roadmap to this volume (Figure 5), the genus *Butyrivibrio* is a member of the family *Lachnospiraceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*.

At about the same time, a new genus and species, *Pseudobutyrvibrio ruminis*, was described for a strain from the rumen of a cow (van Gylswyk et al., 1996). The strain was phenotypically very similar to *Butyrivibrio fibrisolvens*, but its 16S rDNA differed from that of the type strains of both *Butyrivibrio* species by at

^aData from Mannarelli (1988), Mannarelli et al. (1990b), Willems et al. (1996), Forster et al. (1997), Dalrymple et al. (1999).

^bAccording to Forster et al. (1997) this strain belongs with Mannarelli group 1.

^cDalrymple et al. (1999) demonstrated that two different strains labeled H17c appear to have been used by different research groups: the original H17c belongs to rRNA type 8, whereas another isolate, labeled H17c(SA), belongs to rRNA type 6.

least 10% and it was therefore described as a separate genus. Its closest neighbors were *Roseburia cecicola*, *Eubacterium rectale*, and *Lachnospira pectinoschiza* (van Gylswyk et al., 1996). When comparing the 16S rDNA sequence of *Pseudobutyrvibrio ruminis* with the *Butyrvibrio* rRNA types (Figure 163), it is clear that this species belongs to the second *Butyrvibrio fibrisolvens* rRNA cluster as defined by Willems et al. (1996). The type strain of *Pseudobutyrvibrio ruminis* shows 97.5–99% 16S rDNA sequence similarity with rRNA types 8–11 which make up this cluster. From this comparison and from the limited DNA–DNA hybridizations between rRNA type 8 and rRNA type 9 strains (Mannarelli, 1988), it seems justified to conclude that the second *Butyrvibrio* rRNA group could be considered as a separate genus, *Pseudobutyrvibrio*, and that rRNA types 8–11 probably represent several genospecies within *Pseudobutyrvibrio*. It is possible that one of these rRNA types is identical with *Pseudobutyrvibrio ruminis* (e.g., rRNA type 11 shows 99% 16S rDNA sequence similarity with the type strain), but this needs to be confirmed by DNA–DNA hybridizations. The genus *Butyrvibrio* should be restricted to the first *Butyrvibrio* rRNA group with *Butyrvibrio fibrisolvens* rRNA types 1–7 (with type 1 including the type strain) probably representing separate species. A new *Clostridium* species, *Clostridium proteoclasticum*, which was described for an isolate from the rumen of New Zealand cattle (Attwood et al., 1996), groups within *Butyrvibrio* rRNA group 1 (Figure 163). It is phenotypically similar to *Butyrvibrio fibrisolvens*, although it can be clearly distinguished by its low GC content of 28% (Attwood et al., 1996). On the basis of its 16S rDNA phylogeny, *Butyrvibrio crossotus* could represent a separate new genus provided sufficient additional criteria supporting its separateness becomes available.

In a study of isolates from rumen fluid of cow and sheep, together with reference strains, Kopečný et al. (2003) defined five taxa among the strains: *Butyrvibrio fibrisolvens*, *Clostridium proteoclasticum*, *Pseudobutyrvibrio ruminis* and two new species, *Butyrvibrio hungatei* and *Pseudobutyrvibrio xylanivorans*. The assignment of strains to these five taxa is based mostly on the similarity of RFLP patterns of 16S rRNA genes and fatty acid compositions. This may be insufficiently precise for definite species allocation. Indeed, using RFLP criteria several of the *Butyrvibrio* rRNA types described previously based on nearly full

gene sequence data (Willems et al., 1996) would be comprised in existing species with distinct rRNA types: rRNA type 7 (represented by Bu43) would be included in *Clostridium proteoclasticum*, rRNA types 3 (NCDO 2398) and 5 (NCDO 2434) would be included in *Butyrvibrio hungatei*, rRNA types 10 (NCDO 2397) and 11 (NCDO 2399) would be included in *Pseudobutyrvibrio xylanivorans* and rRNA type 9 (NCDO 2249) would be included in *Pseudobutyrvibrio ruminis* (Kopečný et al., 2003). From the position of these strains in the 16S rDNA phylogeny (Figure 163), it would seem that finer methods such as DNA–DNA hybridizations or phylogeny of housekeeping genes may help resolve this issue in future.

At present data allowing the phenotypic differentiation between *Pseudobutyrvibrio* and *Butyrvibrio sensu stricto* are incomplete. However, the division between both groups that has emerged from phylogenetic data appeared to be consistent with the division of *Butyrvibrio* isolates into two groups of curved rods by Shane et al. (1969). Their group 1 contains mostly strains belonging to the second *Butyrvibrio* rRNA group, equivalent to *Pseudobutyrvibrio*, whereas their group 2 comprises mostly strains of the first *Butyrvibrio* rRNA group. As mentioned previously, group 1 produces lactate and utilizes acetate during fermentation, whereas group 2 produces acetate but little or no lactate and is nutritionally more fastidious than group 1. These may be useful phenotypic features to differentiate *Butyrvibrio* from *Pseudobutyrvibrio*. An overview of phenotypic data reported for these groups is presented in Table 163. In addition, it has been suggested that the method of butyrate production, using either butyryl-CoA/acetate-CoA transferase, as in strains 49 and 37, or butyrate kinase, as in strains D1 and A38, is a phylogenetically significant characteristic (Diez-Gonzalez et al., 1999). Since on the basis of 16S rDNA sequences, the former strains may represent *Pseudobutyrvibrio* and the latter strains represent *Butyrvibrio*, this characteristic could be a potential differentiating feature between these genera, if confirmed in additional strains.

List of species of the genus *Butyrvibrio*

There are at present three species recognized within *Butyrvibrio*, *Butyrvibrio fibrisolvens*, *Butyrvibrio crossotus* and *Butyrvibrio hungatei*. However, it is now clear (see previous taxonomic comments) that the originally described species *Butyrvibrio fibrisolvens* in fact represents several species and even several genera. The phenotypic description of this species as given in the previous version of this manual (Bryant, 1986b), in fact, comprises all of these groups. However, because of lack of a recent comprehensive phenotypic study it is not possible at present to provide reliable phenotypic descriptions for more restricted genotypically defined groups, with the exception of the recently described *Butyrvibrio hungatei* (Kopečný et al., 2003). The species description of *Butyrvibrio fibrisolvens* that follow is therefore based on that in the previous version of the manual (Bryant, 1986b). It is probably based on strains of *Butyrvibrio* rRNA group 1 and on strains that would now be classified as *Pseudobutyrvibrio*.

fi.bri.sol'vens. L. n. *fibra* fiber; L. part. adj. *solvens* dissolving; N.L. part. adj. *fibrisolvens* fiber-dissolving.

Cell morphology is the same as that presented in the genus description. Cells stain Gram-negative but have a very thin cell wall with a Gram-positive ultrastructure. Colonial characteristics are as present previously. Growth in liquid glucose medium varies from a uniform turbidity to a flocculent or granular sediment. Good growth at 37°C and generally at 45°C, but slower at 30°C. No growth occurs at 22 or 50°C.

In poorly buffered glucose medium the final pH mostly ranges from 5.0–5.6.

Most strains will grow in chemically defined media containing glucose or cellobiose as the energy source, amino acid mixtures and ammonium salts as nitrogen source, minerals, B vitamins, and cysteine. Many strains will grow with

only ammonium salts as nitrogen source, but amino acid mixtures are often growth promoting. Acetate often stimulates growth, as do propionate or branched-chain volatile acids, but for some strains only. Additional properties are given in Table 163 and Table 164.

Butyrivibrio fibrisolvens is a nonpathogenic member of the normal rumen microflora.

DNA G+C content (mol%): 42 (Bd) (Mannarelli, 1988).

Type strain: ATCC 19171 (=D1).

EMBL/GenBank accession number (16S rDNA): X89970 and U41172.

2. *Butyrivibrio crossotus* Moore, Johnson and Holdeman 1976, 241^{AL}

cros.so'tus. Gr. adj. *crossotus* tasseled.

Cell morphology is the same as that presented in the genus description and colonial characteristics are as presented previously. Only a few strains grow as surface colonies on anaerobically incubated blood agar plates and no hemolysis is observed. Few strains grow on egg yolk agar and no lecithinase or lipase activity is observed. Growth is poor in peptone-yeast extract broth unless a fermentable carbohydrate is present. In maltose broth, growth is abundant with

^eCalculated from thermal melting point (Moore et al., 1976).

a smooth, flocculent, or ropy sediment and usually some uniform turbidity. Optimum growth temperature is 37 °C. Growth is slow at 30 °C and some strains may grow at 45 °C.

Metabolic properties and features differentiating *Butyrivibrio crossotus* from *Butyrivibrio fibrisolvens* are given in Table 163 and Table 164.

Butyrivibrio crossotus strains are isolated from human feces or rectal contents and are not known to be pathogenic.

DNA G+C content (mol%): 37 (T_m) (Moore et al., 1976).

Type stain: ATCC 29175 (=T9-40A).

EMBL/GenBank accession number (16S rDNA): X89981.

3. *Butyrivibrio hungatei* Kopečný, Zorec, Mrázek, Kobayashi and Marinšek-Logar 1976, 207^{VP}

hun.ga'te.i. N.L. gen. n. *hungatei* named after Robert E. Hungate, an American microbiologist who isolated similar strains in the 1960s.

Cell morphology is the same as that presented in the genus description. Motile by a single polar or subpolar flagellum. Anaerobic growth at 39 °C, but not at 25 °C. Limited growth at 45 °C. Metabolic properties and features of

Butyrivibrio hungatei are given in Table 163 and Table 164. Tryptophan, urea and gelatin are not utilized. Does not show significant fibrolytic or proteolytic activity, utilizes mainly oligo- and monosaccharides as growth substrates. Produces α -galactosidase, α -arabinosidase, phenylalanine arylamidase and leucine arylamidase. No amylase, xylanase, β -endoglucanase, laminarinase, pectin hydrolase, proteinase or Dnase activity detected. Branched chain fatty acids represent the prevailing proportion of fatty acids. In DSM medium 330 without rumen fluid, the type strain produces as major cellular fatty acids anteiso-C_{17:0} (17.4%), iso-C_{16:0} (14.5%) and C_{16:1} (13.2%) and also contains C_{16:0} 2-OH (6.9%), C_{14:0} 2-OH (4.3%) and iso-C_{17:1} (3.4%).

Butyrivibrio hungatei strains are isolated from the rumen fluid of cow and sheep where they participate in the utilization of intermediates of fibre degradation.

DNA G+C content (mol%): 44.8 (HPLC) (Moore et al., 1976).

Type stain: JK 615 (= DSM 14810 = ATCC BAA-456).

EMBL/GenBank accession number (16S rDNA): AJ428553.

Genus VI. *Catonella* Moore and Moore 1994, 189^{VP}

ANNE WILLEMS AND MATTHEW D. COLLINS

Ca.to.nel'la. N.L. fem. n. *Catonella* in honor of Elizabeth P. Cato, an American microbiologist.

Obligately anaerobic, catalase-negative, Gram-stain-negative, non-spore-forming rods. Nonmotile. End products of carbohydrate fermentation include major amounts of acetate and smaller amounts of formate and lactate. Major cellular fatty acids when grown in peptone-yeast extract-glucose broth include C_{14:0} fatty acid, C_{14:0} dimethyl acetal, and C_{16:0} fatty acid. *Catonella* is associated with periodontitis in human gingival crevices and periodontal pockets. The mol% G+C content of DNA is 34. Based on 16S rDNA sequence of its type strain, *Catonella* belongs to cluster XIVa (Collins et al., 1994) of the *Clostridium* subphylum of the Gram-positive bacteria.

Type species: *Catonella morbi* Moore and Moore 1994, 189^{VP}.

Further descriptive information

The genus contains only one species and therefore all of the characteristics provided below describe the species *Catonella morbi*.

Phylogenetic treatment. According to the 16S rRNA phylogenetic analysis presented in the roadmap to this volume (Figure 5), the genus *Catonella* is a member of the family *Lachnospiraceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*; in particular, it belongs to a subgroup with *Butyrivibrio*, *Coprococcus*, *Ruminococcus*, *Lachnospira*, and several *Eubacterium* and *Clostridium* species. Closest relatives are *Johnsonella ignava* and *Eubacterium saburreum* (approx. 85% sequence similarity) (Willems and Collins, 1995b).

Cell morphology. Cells of the type strain grown in peptone-yeast extract-glucose (PYG) broth* are 0.7–1.2 µm wide × 1.6–4.0 µm long. Central swelling may occur in media containing a fermentable carbohydrate. Cells occur in pairs and short chains (Moore and Moore, 1994).

Colonial characteristics. On blood agar, incubated for 2 d at 37 °C, colonies are 1 mm in diameter, round with an entire margin, convex, and opaque. No hemolysis on rabbit blood agar is observed and no dark pigments are produced (Moore and Moore, 1994).

Nutrition and growth conditions. Because of the human origin of the strains, cultures are grown at 37 °C. No data on minimal, maximal, or optimal growth temperatures were reported. Serum (10%, v/v) improves growth and is usually required to detect carbohydrate fermentation. Moderate turbidity with limited sediment is produced in peptone-yeast extract-serum broth and moderately heavy turbidity with a smooth sediment is produced in PYG-serum broth. The final pH of PYG-serum broth cultures is 5.0–5.6 (Moore and Moore, 1994).

Metabolism and metabolic pathways. *Catonella* has a strictly anaerobic, saccharolytic metabolism. The end products of glucose fermentation in PYG-serum broth were reported as (in milliequivalents per 100 ml of culture; mean ± standard error of mean) acetic acid, 2.2 ± 0.2; formic acid, 0.6 ± 0.1; and lactic acid, 0.4 ± 0.1. Abundant hydrogen gas is produced (Moore and Moore, 1994). Additional metabolic characteristics are presented in Table 165.

Chemotaxonomic characteristics. The cellular fatty acid composition of *Catonella morbi*, based on data for eight strains grown in 10 ml of PYG broth cultures at 37 °C, was as follows: 3% C_{12:0}, 42% C_{14:0}, 14% C_{14:0} dimethyl acetal, 2% C_{16:1-cis9}, 12% C_{16:0}, 1% C_{16:0} dimethyl acetal, 5% C_{18:1-cis9}, 4% C_{18:0} (Moore and Moore, 1994).

Antibiotic susceptibility. *Catonella morbi* is susceptible (nine strains tested) to chloramphenicol (12 µg/ml), clindamycin (1.6 µg/ml), erythromycin (3 µg/ml), penicillin G (2 U/ml), and tetracycline (6 µg/ml) (Moore and Moore, 1994).

Ecology. *Catonella morbi* occurs in human gingival crevice and periodontal pockets and is associated with adult periodontitis.

Enrichment and isolation procedures

No specific enrichment procedures for *Catonella* have been described. *Catonella* have been isolated and identified in studies of the anaerobic bacterial flora associated with human gingivitis and periodontitis (Moore et al., 1985, 1982b). In these studies, samples from supragingival plaque and periodontal pockets were taken with sterile paper tips, toothpicks, or scalers and immediately placed in prerduced, anaerobically sterilized broth under an atmosphere of CO₂ (Moore et al., 1982a). The samples were then shaken with 100-µm-diameter glass beads and dilutions were cultured in roll tubes of D4 medium with rabbit serum (Moore et

^aData taken from Moore and Moore (1994). All strains produce acid from raffinose and sucrose, hydrolyze esculin, and curd milk. No acid is produced from following substrates: erythritol, esculin, fructose, gum arabic, inulin, larch arabino-galactan, mannitol, pectin, ribose, and sorbitol. Indole and catalase are not produced; nitrate is not reduced; no lecithinase or lipase is detected on egg yolk agar; no digestion of milk or meat; no H₂S production in sulfide-indole motility medium; no growth in PYG-20% bile.

^bPercentages of strains positive.

^cA positive (acid) reaction occurs in the presence of serum (10% v/v) in the medium; usually reaction is negative in the absence of serum.

al., 1982a) and on anaerobic blood agar plates (D4 medium with 5% [v/v] rabbit blood) (Moore et al., 1985). The D4 roll tube isolation medium (Moore et al., 1982a) contained 3.7 g brain heart infusion broth base (BBL), 0.5 g yeast extract (Difco), 0.5 ml of 6% (wt/v) ammonium formate solution, 0.4 ml of resazurin (25 mg in 100 ml of distilled water), and 100 ml of distilled water. After this medium is boiled and cooled under CO₂, 0.05 g cysteine-HCl H₂O, 0.02 ml of vitamin K₁ stock solution (0.15 ml of vitamin K₁ in 30 ml of 95% ethanol; store in the dark, for maximum of 1 month under refrigeration) and 1 ml of hemin solution (50 mg hemin in 1 ml of 1 N NaOH, make to 100 ml with distilled water, autoclave 15 min, 121 °C) were added and the pH was adjusted to 7. The broth was dispensed (12 ml per tube) under an atmosphere of oxygen-free nitrogen and the stoppered tubes were autoclaved. For sample collection, agar medium in roll tubes was melted and cooled to 56 °C, 1.2 ml of serum-yeast autolysate-TPP mixture (containing 50 ml of filter-sterilized, inactivated [56 °C for 30 min], nonhemolytic rabbit serum, 50 ml of yeast autolysate [prepared by incubating 1 ounce of Fleishman's yeast powder in 100 ml of water at 56 °C for 72 h; the mixture is filtered through cheese-cloth and filters of decreasing pore size

*Composition of PYG: 0.5 g peptone, 0.5 g trypticase, 1 g yeast extract, 0.4 ml of resazurin solution (25 mg in 100 ml of distilled water), 4 ml of salts solution (0.2 g CaCl₂, 0.2 g MgSO₄, 1 g K₂HPO₄, 1 g KH₂PO₄, 10 g NaHCO₃, 2 g NaCl; dissolve CaCl₂ and MgSO₄ in 300 ml of distilled water; add 500 ml of water and, while swirling, slowly add remaining salts; when dissolved, add 200 ml of distilled water and mix; store at 4 °C), 100 ml of distilled water, 1 ml of hemin solution (dissolve

50 mg hemin in 1 ml of 1 N NaOH; make to 100 ml with distilled water; autoclave for 15 min at 121 °C), 0.02 ml of vitamin K1 solution (dissolve 0.15 ml of vitamin K1 in 30 ml of 95% ethanol; keep for maximum of 1 month, at 4 °C in a brown bottle), 0.05 g cysteine-HCl-H₂O, 1 g glucose; vitamin K1, hemin, and cysteine are added after the medium is boiled, but before dispensing and autoclaving (Holdeman et al., 1977b).

until it is sterilized by passing through a 0.2 µm pore size filter] and 0.5 ml of a thiamine pyrophosphate (TPP) stock [0.5 g of TPP in 100 ml of distilled water, filter-sterilized] was added to each tube under N₂-CO₂-H₂ (85:12:3) atmosphere. Tubes were inoculated under anaerobic gas, restoppered, spun and chilled until the agar solidified and incubated. The blood agar plates contained the same medium except that 5.2 g of brain heart infusion agar (BBL) replaced the brain heart infusion broth base and agar, 4 ml of defibrinated rabbit blood replaced the serum and no resazurin was added. The basal medium was autoclaved, cooled to 56 °C and blood, yeast autolysate, TPP, vitamin K₁, and hemin were added and plates were poured in an anaerobic atmosphere. Plates can be stored before use at room temperature under an atmosphere of 10% CO₂ and 90% H₂. After 5 d of incubation at 37 °C, colonies were randomly picked and purified. This procedure resulted in the isolation of *Catonella* as well as numerous other anaerobic bacteria of the periodontal microflora (e.g., *Bacteroides*, *Eubacterium*, *Fusobacterium*, *Selenomonas*, *Streptococcus*, *Lactobacillus* etc., which were identified using a combination of morphological, biochemical, and fatty acid characteristics (Moore et al., 1985, 1982b).

Maintenance procedures

Strains can be maintained in prerduced, anaerobically sterilized D5 broth (Moore et al., 1982a), which contains 3.7 g of brain heart infusion broth base (BBL), 0.5 g yeast extract (Difco), 0.05 ml pyruvic acid, 0.5 ml ammonium formate (6% [wt/v] in water), 0.2 g pectin, 2 ml IsoVitaleX (BBL), 1 g agar, 0.1 g KNO₃, 0.4 ml resazurin (25 mg in 100 ml of distilled water), and 100 ml of distilled water. This basal medium is boiled and cooled under CO₂ and 0.05 g cysteine-HCl-H₂O, 0.02 ml vitamin K₁ (0.15 ml vitamin K₁ in 30 ml of 95% ethanol; store in the dark, for maximum of 1 month under refrigeration) and 1 ml hemin (50 mg hemin in 1 ml of 1 N NaOH, make to 100 ml with distilled water, autoclave 15 min, 121 °C) are added. The pH is adjusted to 7.0 with 1 N NaOH and the medium (3 ml per tube) is dispensed under oxygen-free nitrogen gas and sterilized. Before use, 0.3 ml of sterile serum-yeast autolysate-TPP solution (see above) is added aseptically to each tube (Moore et al., 1982a).

For long-term storage, cultures can be preserved by lyophilization.

Differentiation of the genus saccharolytic bacilli from other genera

Catonella can readily be distinguished from most genera of Gram-stain-negative, anaerobic, saccharolytic rods (including

Bacteroides, *Prevotella*, *Oribaculum*, *Butyrivibrio*, *Ruminobacter*, *Hallela*, *Fibrobacter*, *Selenomonas*, *Pectinatus*, and *Mitsuokella*) by the G+C content of its DNA (34 mol%). It can be differentiated from other genera of Gram-stain-negative, anaerobic, saccharolytic rods with a similar G+C content by end products of glucose fermentation and by its cellular fatty acid composition (Table 166) (Moore et al., 1994; Moore and Moore, 1994).

Taxonomic comments

Catonella morbi was originally known as “*Bacteroides* D42”, one of a group of unnamed bacterial species that occur in the human gingival crevice and periodontal pockets that were first recognized and isolated at the Anaerobe Laboratory of the Virginia Polytechnic Institute and State University in Blacksburg (Moore et al., 1985, 1982b). It was formally described as *Catonella morbi*, a new genus and species of anaerobic, Gram-stain-negative, nonsporulating bacilli and therefore placed in the family *Bacteroidaceae* (Moore and Moore, 1994). Later, by 16S rDNA sequence analysis, it was shown to belong to the *Clostridium* subphylum of the Gram-positive bacteria. It is a member of *Clostridium* cluster XIVa as defined by Collins et al. (1994). This cluster consists of species from several Gram-stain-positive (*Clostridium*, *Coprococcus*, *Eubacterium*, and *Ruminococcus*) and Gram-stain-negative genera (*Butyrivibrio*, *Johnsonella*, and *Catonella*). A similar occurrence of Gram-stain-negative and Gram-stain-positive bacteria in one cluster is only observed in *Clostridium* cluster XII, which contains the Gram-stain-negative *Tissierella* (Farrow et al., 1995) and in the *Sporomusa* branch (= *Clostridium* cluster IX; Collins et al., 1994). Some of these groups, e.g., *Butyrivibrio*, are Gram-negative in traditional staining procedures, but by ultrastructural electron microscopy they were shown to possess a very thin but Gram-positive type of cell wall (Cheng and Costerton, 1977; Hespell et al., 1993). Similar observations for *Catonella* have not been reported.

List of species of the genus *Catonella*1. *Catonella morbi* Moore and Moore 1994, 189^{VP}

mor'bi. L. gen. n. *morbi* of disease, because originally the organism was isolated from diseased periodontal pockets.

The morphological and cellular characteristics are as described for the genus. Additional descriptive informa-

tion is presented in Table 165 which is based on data from Moore and Moore (1994) and Moore et al. (1994).

Isolated from gingival crevices of humans with adult periodontitis.

DNA G+C content (mol%): 34.

Type strain: ATCC 51271 (= VPI D154F-12).

GenBank accession number (16S rRNA gene): X87151.

Genus VII. *Coprococcus* Holdeman and Moore 1974, 260^{AL}

TAKAYUKI EZAKI

Co'pro.coc'cus. Gr. n. *kopros* feces; Gr. n. *kokkos* berry; N.L. masc. n. *Coprococcus* fecal coccus.

Cocci that are **Gram-stain-positive**, nonmotile, and **obligately anaerobic chemoorganotrophs**. All species in the genus are isolated from human feces (Moore and Holdeman, 1974) but rarely isolated from human clinical specimens. Strains were originally isolated on an anaerobically sterilized rumen-fluid-glucose-cellobiose agar (Holdeman et al., 1977a) roll tube. However, pure cultured strains grow on anaerobically incubated blood agar plates (supplemented with brain heart infusion agar with 5% sheep blood). Cells may occur as pairs or chains of pairs. Cells of the some species are slightly elongated, in particular, when grown in medium containing fermentable carbohydrates. **Fermentable carbohydrates** are either **required** or are **highly stimulatory for growth**. **Major fermentation products include butyric and acetic acids, with formic or propionic acid**. Characteristics to differentiate species of the genus *Coprococcus* and biochemically closely related species of the *Ruminococcus* are given in Table 167. The genus phylogenetically belongs to family *Lachnospiraceae* and the phylogenetic position within the family is shown in Figure 161 (Ezaki et al., 1994; Rainey and Janssen, 1995; Willems and Collins, 1995a). In the family *Lachnospiraceae*, members of genus *Coprococcus* are phylogenetically closely related to anaerobic curved bacteria, genus *Lachnospira* as in Figure 161.

DNA G+C content (mol%): 39–42.

Type species: *Coprococcus eutactus* Holdeman and Moore 1974, 261^{AL}.

List of species of the genus *Coprococcus*1. *Coprococcus eutactus* Holdeman and Moore 1974, 261^{AL}

eu'tac'tus. Gr. adj. *eutactos* orderly, well-disciplined (referring to the uniform reactions of the different strains).

Cells are usually round and 0.7–1.3 μm in diameter. They have abundant growth and are often elongated in a medium with fermentable carbohydrates. However, their growth is very poor or absent in peptone-yeast medium without fermentable carbohydrates.

Growth occurs equally well at 37 °C and 45 °C but growth is poor to moderate at 25 °C and 35 °C.

This species is easily recognized by its production of formic, lactic, and butyric acids from glucose (Holdeman et al., 1977a). This species is isolated from human feces. Needs anaerobically sterilized rumen-fluid-glucose-cellobiose agar for the primary isolate. Differential characteristics of the

species from other carbohydrate-requiring anaerobic cocci are given in Table 167.

DNA G+C content (mol%): 41–42.

Type strain: ATCC 27759, VPI C33-22.

GenBank accession number (16S rRNA gene): D14148.

2. *Coprococcus catus* Holdeman and Moore 1974, 263^{AL}

ca'tus. L. adj. *catus* clever, referring to unusual property of producing large quantities of both propionate and butyrate

Cells usually occur in pairs that form long chains. Coccoid and oval cells range in size from 0.8 to 1.4 μm in diameter by 1.6–1.9 μm in length Holdeman and Moore (1974). Slight and moderate growth in peptone-yeast (PY) medium. PY-fructose cultures have abundant growth. Their growth is very poor or absent in peptone-yeast medium without fermentable carbohydrates. Growth occurs well at 37 °C and

45 °C but growth is poor to moderate at 25 °C and 35 °C. This species is isolated from human feces. Need anaerobically sterilized rumen-fluid-glucose-cellobiose agar for the primary isolate.

Differential characteristics of the species from other carbohydrate-requiring anaerobic cocci are given in Table 167.

DNA G+C content (mol%): 41–42.

Type strain: ATCC 27761, VPI C6-61, NCTC 11835.

GenBank accession number (16S rRNA gene): AB038359.

3. *Coprococcus comes* Holdeman and Moore 1974, 263^{AL}

co'mes. L. n. *comes* comparison, fellow traveller (referring to the presence of the species in human feces).

Cells usually occur in pairs that form long chains. Coccoid and oval cells, 0.8–1.4 µm in diameter by 1.6–1.9 µm in length (Holdeman and Moore (1974)). Slight and moderate growth in peptone-yeast (PY) medium. PY-fructose cultures have abundant growth. Their growth is very poor or absent in peptone-yeast medium without fermentable carbohydrates. Growth occurs well at 37 °C and 45 °C but growth is poor to moderate at 25 °C and 35 °C. This species is isolated from human feces. Differential characteristics of the species from other carbohydrate-requiring anaerobic cocci are given in Table 167.

DNA G+C content (mol%): 40–41.

Type strain: ATCC 27758, VPI C1-38.

GenBank accession number (16S rRNA gene): EF031542.

Genus VIII. *Dorea* Taras, Simmering, Collins, Lawson and Blaut 2002, 426^{VP}

MICHAEL BLAUT, MATTHEW D. COLLINS AND DAVID TARAS

Do.ré.a. N.L. fem. n. *Dorea* named in honor of the French microbiologist Joel Doré, in recognition of his many contributions to gut microbiology.

Nonsporeforming, Gram-stain-positive rods. Nonmotile. **Obligately anaerobic. Chemo-organotrophic.** Major end products of glucose metabolism are **ethanol, formate, acetate, H₂, and CO₂**. Butyrate is not produced.

DNA G+C content (mol%): 40–45.6 (*T_m*).

Type species: ***Dorea formicigenerans*** (Holdeman and Moore 1974) Taras, Simmering, Collins, Lawson and Blaut 2002, 426^{VP} (*Eubacterium formicigenerans* Holdeman and Moore 1974, 274).

Further descriptive information

Dorea species generally stain Gram-positive, but some cells from old cultures may decolorize easily and give Gram-variable or negative reactions. Cells are rod-shaped; size of cells may vary considerably but are generally 0.5–0.8 by 1.0–4.5 µm and occur in pairs or chains. Strictly anaerobic, catalase- and oxidase-negative. Glucose, fructose, galactose, lactose, maltose, and some other sugars are fermented. Starch, cellulose, and gelatin are not hydrolyzed. Nitrate is not reduced. Growth is most rapid at 37 °C and pH near 7. *Dorea* species have been isolated from human feces and are inhabitants of the human gastrointestinal tract.

Enrichment and isolation procedures

Species of the genus *Dorea* found in fecal or intestinal samples can be isolated on usual complex media appropriate for culture of anaerobes using strict anoxic techniques (Hungate, 1969). Such media include blood agar plates, Wilkins–Chalgren anaerobic medium or other peptone and yeast extract containing complex media (e.g., ST medium; Schwiertz et al., 2000). Growth of *Dorea longicatena* in ST medium is supported by the addition of 0.15% agar.

Maintenance procedures

Short-term preservation is achieved by growing cultures in the above-mentioned media, storage at 4 °C up to room temperature (22 °C), and approximately weekly transfers. For long-term preservation, strains can be stored on cryogenic beads at –70 °C or lyophilized.

Procedures for testing special characters

The characteristics of *Dorea formicigenerans* were determined by Moore and Holdeman Moore (1986) using methods described in Holdeman et al. (1977b) in a basal prerduced peptone-yeast extract (PY) medium. Reactions for *Dorea longicatena* were assessed by Taras et al. (2002) with ST medium (Schwiertz et al., 2000) and in a medium used for culturing acetogenic bacteria (Kamlage et al., 1997) but modified by adding 0.5 g Proteose-Peptone No. 2 (Difco) per liter (HA medium). Growth and fermentation of substrates was monitored by changes in optical density measured at 600 nm and the pH of the medium. A pH below 5.5 and a decrease in pH of at least 0.5 pH units below the basal control ST or HA medium were scored as a positive reaction. Results were confirmed by comparison of the growth amount in carbohydrate supplemented medium and unsupplemented control medium. In addition, biochemical features were determined with the API 50 CHL system (bioMérieux). Hydrogen production was determined by gas chromatography of the headspace gas of cultures grown in tubes closed with rubber stoppers (Hartmann et al., 2000). For identification and quantification of *Dorea longicatena* in fecal samples by whole-cell *in situ* hybridization, a species-specific oligonucleotide probe (5'-CTCAGCAGTTCCAAATGC-3') targeting a hypervariable region of the 16S rRNA has been designed and validated (D. Taras and M. Blaut, unpublished).

Differentiation of the genus *Dorea* from other genera

The genus *Dorea* can be distinguished from most clostridial species and other spore-forming taxa (e.g., *Sporobacterium*) in not producing endospores, from *Lachnospira* by the absence of curved cellular shapes, from *Acetobacterium* in being nonmotile, from *Coprococcus* and *Ruminococcus* by cellular morphology and end products of glucose fermentation, and from *Roseburia* and *Butyrivibrio* in end products of glucose metabolism (i.e., not producing butyric acid) and in being nonmotile. More demanding is the differentiation from members of the genus *Eubacterium* (see also Taxonomic comments) which share, to some extent, cell mor-

phology and many biochemical characteristics with species of the genus *Dorea*. Tests which are useful in differentiating *Dorea* species from some other nonspore-forming Gram-positive rods that also fail to produce butyrate and indole are given in Table 168.

Differentiation of the species of the genus *Dorea*

Biochemical tests which may be helpful in differentiating *Dorea formicigenerans* and *Dorea longicatena* from each other are given in Table 169. Currently the most reliable means of differentiating these species is by 16S rRNA gene sequence analysis.

Taxonomic comments

The genus *Dorea* was created to accommodate the species formerly designated *Eubacterium formicigenerans* and some Gram-stain-positive, asporogenous, rod-shaped organisms isolated from human feces (Taras et al., 2002). The two currently defined *Dorea* species form a distinct subline within a suprageneric rRNA cluster referred to as the *Clostridium coccoides* group (rRNA cluster XIVa) (Collins et al., 1994). Phylogenetically, the genus *Dorea* does not display a particularly close affinity to any other taxon within this group. The two *Dorea* species display a 16S rRNA sequence divergence value of approximately 6%, which clearly shows that they are closely related, but nevertheless, different species. A tree showing the position of *Dorea* species within the *Clostridium coccoides* rRNA group is shown in Figure 164. According to the 16S rRNA phylogenetic analysis presented in the roadmap to this volume (Figure 5), the genus *Dorea* is a member of the family *Lachnospiraceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*.

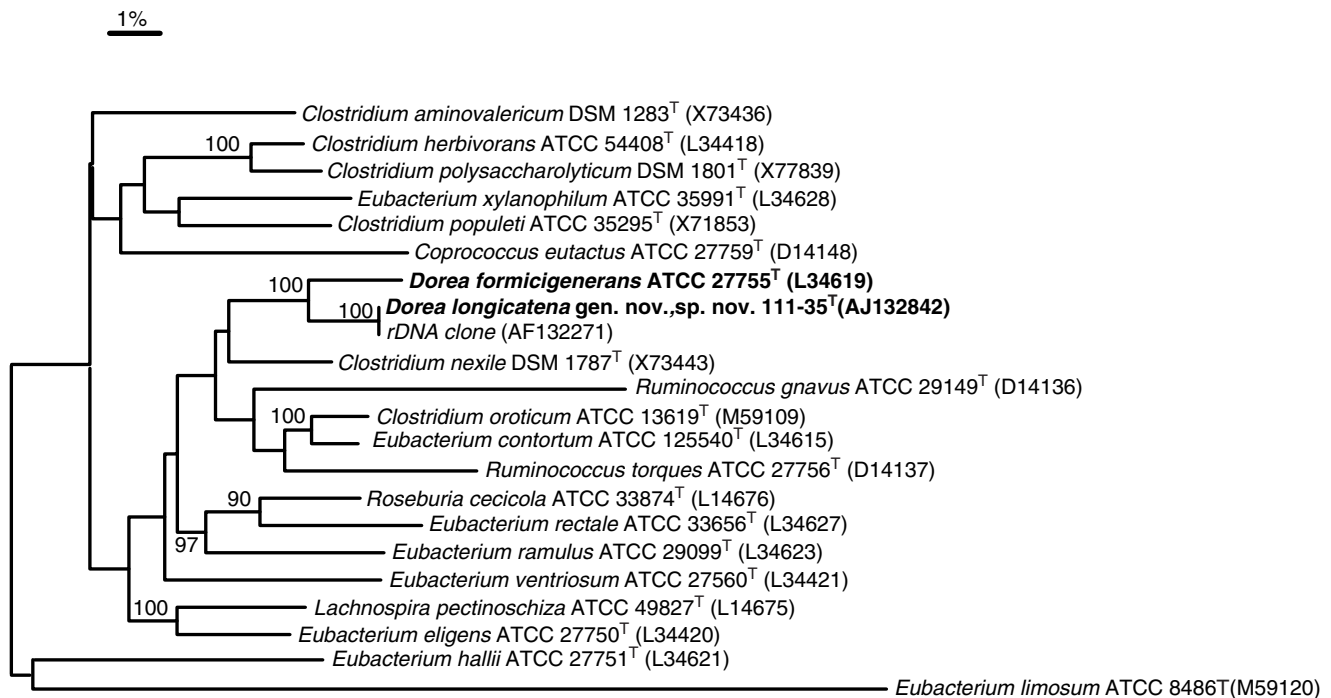

FIGURE 164. Unrooted tree showing the phylogenetic relationship of *Dorea formicigenerans* and *Dorea longicatena* with some other members of the *Clostridium coccoides* group. The tree was constructed using the neighbor-joining method and is based on a comparison of 1330 nucleotides. Bootstrap values, each expressed as a percentage of 500 replications, are given at branching points. (Reprinted with permission from Taras, D., R. Simmering, M.D. Collins, P.A. Lawson, M. Blaut. 2002. *Int. J. Syst. Evol. Microbiol.* 52: 423-428).

Before the advent of 16S rRNA gene sequencing, taxonomically the two species of the genus *Dorea* would be considered to conform to the genus *Eubacterium*, which acted as a repository for strictly anaerobic, asporogenous rod-shaped organisms. During the past decade, there have been great advances in unraveling the taxonomic complexities within the *Clostridium* subphylum of the Gram-positive bacteria, and it is universally acknowledged that the eubacteria represent a phylogenetically very heterogeneous group of organisms. There is now a growing consensus that the genus *Eubacterium sensu stricto* should be restricted to the type species *Eubacterium limosum*, and its close phylogenetic relatives (*Eubacterium barkeri*, *Eubacterium callanderi*, and *Eubacterium aggregans*) (Kageyama et al., 1999; Willems and Collins, 1996). Members of the genus *Dorea* are, however, phylogenetically far removed

from *Eubacterium limosum* and related species (approx. 20% 16S rRNA sequence divergence). Furthermore, the members of the genus *Dorea* are incompatible with the definition of *Eubacterium sensu stricto* in not producing butyrate as a major fermentation product.

It is pertinent to note that several rDNA clones derived directly from human fecal and colonic tissue samples have been shown to correspond phylogenetically to *Dorea longicatena* and *Dorea formicigenerans* (Hold et al., 2002; Suau et al., 1999). *Dorea formicigenerans*-like rDNA clones derived from the gastrointestinal tract of pigs have also been reported (Lester et al., 2002). As living organisms giving rise to these rDNA clones have not been isolated, it is not known if they correspond to *Dorea formicigenerans* or to genomically closely related species.

List of species of the genus *Dorea*

1. ***Dorea formicigenerans*** (Holdeman and Moore 1974) Taras, Simmering, Collins, Lawson and Blaut 2002, 426^{VP} (*Eubacterium formicigenerans* Holdeman and Moore 1974, 274)

for.mi.ci.ge'ne.rans. N.L. adj. *formicigenerans* formic acid producing; referring to its production of large amounts of formic acid from carbohydrate fermentation.

The description is based on that of Moore and Holdeman Moore (1986).

Cells are 0.6–1.4 wide × 0.8–4.7 μm long and occur in pairs or chains. After 5 d incubation on rumen fluid-glucose-cellobiose agar (RGCA), colonies are 0.5–1.0 mm in diameter, white to tan, circular to lenticular, and often have fuzzy edges or a woolly ball appearance. Colonies on blood agar or BHIA plates are 0.5–3.0 mm in diameter, circular to slightly irregular, entire to slightly erose, convex to umbonate, opaque, white to tan, shiny, and smooth. Some strains may show slight greening on sheep blood agar. PYG broth cultures have little or no turbidity, stringy or flocculent (occasionally smooth) sediment, and pH of 4.7–5.0 in 5 d. Growth in PY broth is increased by the presence of fermentable carbohydrate. Growth in PYG is generally not enhanced by the addition of 0.02% Tween 80 or 10% (v/v) rumen fluid. Growth is inhibited by 6.5% NaCl. Optimum growth temperature is 37 °C; most strains grow moderately well at 30 and 45 °C, but usually not at 25 °C. Moderate to abundant gas is produced in glucose agar deep cultures. Acetic, formic, lactic acids, and ethanol are the major products of glucose metabolism. Pyruvate is converted to acetate, formate, and ethanol, usually with a trace of lactate and sometimes succinate. Lactate and gluconate are not utilized. Threonine is not converted to propionate. Acid is produced from fructose, galactose, lactose, and maltose. Acid may or may not be formed from arabinose, ribose, and xylose. Acid is not produced from adonitol, amygdalin, cellobiose, cellulose, dextrin, dulcitol, erythritol, glycerol, glycogen, inositol, inulin, mannitol, mannose, melezitose, melibiose, raffinose, rhamnose, salicin, sorbitol, L-sorbose, starch, or trehalose. Hippurate hydrolysis is variable. Indole is not produced. Meat is not digested. The type strain does not produce ammonia from peptone or arginine.

DNA G + C content (mol%): 40–44 mol% (T_m).

Type strain: ATCC 27755, DSM 3992.

GenBank accession number (16S rRNA gene): L34619.

2. ***Dorea longicatena*** Taras, Simmering, Collins, Lawson and Blaut 2002, 427^{VP}

lon.gi.ca.te'na. L. adj. *longus* long; L. fem. n. *catena* chain; N.L. fem. n. *longicatena* long chain, referring to the long chains, this organism develops in culture medium.

Cells are 0.5–0.6 × 2.0–4.3 μm and occur in chains of 4–200 cells. Cells are Gram-stain-positive but sometimes in old cultures stain Gram-negative. The cell-wall murein is directly cross-linked, based upon *meso*-diaminopimelic acid (type A1γ) (Schleifer and Kandler, 1972). On Columbia blood and WCA agar, cells form opaque white colonies that are 1–3 mm in diameter, circular, convex, smooth, shiny, and sticky. Nonhemolytic. Cultures in ST medium supplemented with 0.15% agar exhibit turbidity with dense areas of fluffy, “woolly” appearance. Ethanol, formate, and acetate are the major products of glucose metabolism; H₂ is produced. Acid is produced from amygdalin, L-arabinose, L-arabitol (weak), arbutin, fructose, fructo-oligosaccharides, galactose, β-gentiobiose, D-glucosamine, inositol, inulin, lactose, lactulose, D-lyxose (weak), maltose, raffinose (weak), salicin, sorbitol, sucrose, xylitol (weak), and xylose. Acid is not produced from adonitol, DL-arginine, D-arabitol, D-arabinose, cellobiose, dulcitol, erythritol, glycerol, glycogen, methyl β-xyloside, D-fucose, L-fucose, gluconate, 2-ketogluconate, 5-ketogluconate, mannitol, mannose, melezitose, melibiose, methyl β-D-mannoside, methyl β-D-glucoside, rhamnose, ribose, sorbose, starch, trehalose, D-turanose, N-acetylglucosamine, pyruvate, or D-tagatose. Esculin and gelatin are hydrolyzed, but hippurate is not hydrolyzed. Isolated from human feces.

DNA G+C content (mol%): 43.8–45.6 (HPLC) (Mesbah and Whitman, 1989).

Type strain: 111-35, CCG 45247, DSM 13814, JCM 11232.

GenBank accession number (16S rRNA gene): AJ132842.

Genus IX. *Hespellia* Whitehead, Cotta, Collins and Lawson 2004, 244^{VP}

TERENCE R. WHITEHEAD, PAUL A. LAWSON AND MICHAEL A. COTTA

Hes.pel'li.a. N.L. fem. n. *Hespellia* named to honor the late American microbiologist Robert B. Hespell, in recognition of his many contributions to anaerobic microbiology.

Short, rod-shaped cells that occur singly and in pairs or short chains. Gram-stain-positive. Nonmotile. Does not form spores. **Strictly anaerobic and negative for catalase- and oxidase. Acid is produced from D-glucose and some other carbohydrates.** Major end products of glucose metabolism are formic, acetic, lactic, and propionic acids. **Butyric acid is not formed.** Esculin and starch are hydrolyzed, but gelatin is not. Negative for indole and does not reduce nitrate. Isolated from swine manure slurry.

DNA G + C content (mol %): 43.7–43.8.

Type species: *Hespellia stercorisuis* Whitehead, Cotta, Collins and Lawson 2004, 244^{VP}.

Further descriptive information

The genus contains two species, *Hespellia stercorisuis* and *Hespellia porcina*. Cells are nonmotile rods. After 48 h anaerobic incubation at 37 °C under a gas phase of N₂/CO₂ (80:20, v/v) on RGM-glucose-agar (Hespell et al., 1987), colonies are gray, convex, smooth, shiny, and translucent. Optimum growth temperature is 37 °C. Acid is produced from glucose; H₂ is produced. The long-chain cellular fatty acids (FAs) consist of complex mixtures of FAs and dimethylacetals (DMAs), together with small amounts of aldehydes.

Enrichment and isolation procedures

Hespellia species were recovered from a manure storage pit at a swine facility near Peoria, IL, USA. Isolations and enumerations were performed by plating serial dilutions in anaerobic buffer onto habitat-simulating media containing either 40% (v/v) substrate-depleted rumen fluid (RF medium; Dehority and Grubb, 1976; Leedle and Hespell (1980) or 80% (v/v) clarified swine manure slurry (Slurry medium, 8000 g, 20 min, 4 °C; (Cotta et al., 2003). The media used in these experiments were prepared anaerobically using the method of Hungate, as modified by Bryant (1972). The basic media contained macrominerals, microminerals, buffers, reducing agents, and other components as in the RGM medium described by Hespell et al. (Hespell et al., 1987) or anaerobic brain-heart infusion (BHI) medium described by Whitehead and Flint (1995). No additional volatile FAs were added to slurry-containing media. Glucose, xylose, cellobiose, maltose, starch (0.05%, w/v each), and peptone (0.3%, w/v) were provided as complex carbon, nitrogen, and energy sources. Plates were incubated initially at room temperature for manure slurry samples to simulate the pit environment and anaerobically in an atmosphere of 96% CO₂ and 4% H₂ (Cotta et al., 2003). The *Hespellia* isolates grew equally well at 37 °C. Single colonies were picked and repeatedly streaked out until pure cultures were obtained.

Maintenance procedures

Good growth is obtained anaerobically on RGM (Hespell et al., 1987) or BHI at 37 °C. For long-term preservation, strains are maintained in media containing 15–20% glycerol at –70 °C or lyophilized.

Taxonomic comments

The genus *Hespellia* was described in 2004 to accommodate a phylogenetically distinct catalase-negative, Gram-positive, rod-shaped bacterium originating from stored swine manure (Cotta et al., 2003; Whitehead et al., 2004). Phylogenetic analysis of the 16S rRNA gene demonstrates a relationship between *Hespellia* and the *Clostridium coccooides* group (clostridial rRNA cluster XIVa; Collins et al., 1994). This diverse assortment of organisms is classified in the novel family *Lachnospiraceae* and includes the genera *Acetitomaculum*, *Anaerostipes*, *Bryantella*, *Butyrivibrio*, *Catonella*, *Coproccoccus*, *Dorea*, *Hespellia*, *Johnsonella*, *Lachnospira*, *Lachnobacterium*, *Oribacterium*, *Parasporobacterium*, *Pseudobutyrvibrio*, *Roseburia*, *Shuttleworthia*, *Sporobacterium*, and *Syntrophococcus*, in addition to many misclassified clostridial species (see the family *Lachnospiraceae*, above). However, *Hespellia* species form a distinct lineage within this large grouping and do not display a particularly close affinity with any of the aforementioned taxa. According to the 16S rRNA phylogenetic analysis presented in the roadmap to this volume (Figure 5), the genus *Hespellia* is a member of the family *Lachnospiraceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*.

In common with many organisms in this large family, phylogenetic molecular profiling studies of both animal and human sources demonstrate that additional species of *Hespellia* remain to be isolated and described (Barcenilla et al., 2000; Hold et al., 2002; Leser et al., 2002; Namsolleck et al., 2004; Suau et al., 1999).

Differentiation of the genus *Hespellia* from other genera

Hespellia can be readily distinguished from its closest phylogenetic relatives by a combination of morphological, biochemical, and chemotaxonomic criteria. It differs phenotypically from *Eubacterium* and related species because it does not produce butyrate as a major fermentation product. *Hespellia* also differs phenotypically from all other genera within this supra-generic grouping. It can be distinguished from clostridial species and other sporeforming taxa (e.g., *Sporobacterium*) in not producing endospores, from *Lachnospira* by the absence of curved cellular shapes, from *Dorea* by hydrolyzing starch and its fermentation products, from *Coproccoccus* and *Ruminococcus* by cellular morphology and its fermentation products, and from *Roseburia* and *Butyrivibrio* by its fermentation products (i.e., no butyric acid production) and lack of motility. Based on the taxonomic and phylogenetic findings, it is evident that the isolates form a distinct group and do not display a close affinity with any recognized genus within this rRNA cluster. In this diverse group of organisms, it is clear that no one organism processes a completely unique biochemical profile; thus, an accurate identification, especially at the laboratory bench is becoming ever more reliant on molecular genetic techniques, in particular 16S rRNA gene sequence comparisons.

List of species of the genus *Hespellia*1. *Hespellia stercorisuis* Whitehead, Cotta, Collins and Lawson 2004, 244^{VP}

ster.co.ri.su'is. L. masc. n. *stercus*, -oris feces, manure; L. gen. n. *suis* of a pig; N.L. gen. n. *stercorisuis* from pig feces/manure, referring to the isolation of the type strain from swine manure.

Characteristics are as given for the genus with the following information. Cells are 0.5–1.0 × 1.5–5.0 μm and occur singly and in pairs or short chains. H₂ is formed after growth on glucose. The fermentation products following growth on BHI broth are formic, acetic, lactic, and propionic acids. Glucose, lactose, cellobiose, trehalose, amygdalin, sorbitol, maltose, mannose, sucrose, fructose, and xylose are utilized as energy sources, but not arabinose, inositol, raffinose, rhamnose, or inulin. Esculin and starch are hydrolyzed, but gelatin is not. The long-chain cellular FAs consist of complex mixtures of FAs and DMAs, together with small amounts of aldehydes; the predominant components are C_{14:0} FA, C_{16:0} FA, C_{16:1 cis9} DMA, and C_{18:1 cis11} DMA. Isolated from pig manure.

DNA G + C content (mol%): 43.7 (T_m).

Type strain: PC18, NRRL B-23456, CUG 46279, ATCC BAA-677.

GenBank accession number (16S rRNA gene): AF445264.

2. *Hespellia porcina* Whitehead, Cotta, Collins and Lawson 2004, 244^{VP}

por.ci'na. L. fem. adj. *porcina* of pigs, pertaining to pigs, referring to the isolation of the type strain from swine manure.

Characteristics are as given for the genus with the following information. Cells are 0.5–1.0 × 1.5–4.0 μm and occur singly and in pairs or short chains. H₂ is formed after growth on glucose. The fermentation products following growth on BHI broth are formic, acetic, lactic, and propionic acids. Glucose, arabinose, inositol, maltose, mannose, sucrose, fructose, and xylose are utilized as energy sources, but not amygdalin, cellobiose, lactose, raffinose, rhamnose, sorbitol, trehalose, or inulin. Esculin and starch are hydrolyzed, but gelatin is not. The long-chain cellular FAs consist of complex mixtures of FA and DMA, together with small amounts of aldehydes; the predominant components are C_{14:0} FA, C_{14:0} DMA, C_{16:0} FA, and C_{16:1 cis9} DMA. Isolated from pig manure.

DNA G + C content (mol%): 43.8 (T_m).

Type strain: PC80, NRRL B-23458, ATCC BAA-674.

GenBank accession number (16S rRNA gene): AF445239.

Genus X. *Johnsonella* Moore and Moore 1994, 190^{VP}

ANNE WILLEMS AND MATTHEW D. COLLINS

John.son.el'la. N.L. fem. n. *Johnsonella* in honor of John L. Johnson, a microbiologist from the United States.

Obligately anaerobic, catalase-negative, Gram-stain-negative, non-spore-forming rods. Nonmotile. Nonfermentative. In peptone-yeast extract-glucose broth a moderate amount of acetate and isovalerate, and traces of lactate, succinate, isobutyrate and butyrate are produced. **Major cellular fatty acids** when grown in peptone-yeast extract-glucose broth include **an unidentified compound with an equivalent chain-length of 9.740, C_{14:0} and C_{16:0} fatty acids.** *Johnsonella* is associated with gingivitis and periodontitis in human gingival crevice and periodontal pockets.

DNA G + C content (mol%): 32.

Type species: *Johnsonella ignava* Moore and Moore 1994, 190^{VP}.

Further descriptive information

The genus contains only one species and therefore all of the characteristics provided below describe the species *Johnsonella ignava*.

Phylogeny. According to the 16S rRNA phylogenetic analysis presented in the roadmap to this volume (Figure 5), the

genus *Johnsonella* is a member of the family *Lachnospiraceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*. Closest relatives are *Catonella morbi* (approx. 85% sequence similarity) and *Eubacterium saburreum* (approx. 87%) (Willems and Collins, 1995b).

Colony and cell morphology. On blood agar colonies are minute to 2 mm in diameter, round with an entire margin, low convex, white to tan, shiny, smooth and sometimes mottled. No hemolysis on rabbit blood agar is observed and no dark pigments are produced. Cells of the type strain grown in peptone-yeast extract-glucose (PYG) broth* are 0.8 μm wide by 3.7–6.4 μm long. They occur singly and in pairs; some cells display central swellings (Moore and Moore, 1994).

Growth conditions. Because of the human origin of the strains, cultures are grown at 37 °C. No data on minimal, maximal or optimal growth temperatures have been reported. In broth cultures, a small amount of granular, smooth or stringy sediment without turbidity is produced (Moore and Moore, 1994).

*Composition of PYG: 0.5 g peptone, 0.5 g trypticase, 1 g yeast extract, 0.4 ml resazurin solution (25 mg in 100 ml of distilled water), 4 ml salts solution (0.2 g CaCl₂, 0.2 g MgSO₄, 1 g K₂HPO₄, 1 g KH₂PO₄, 10 g NaHCO₃, 2 g NaCl; dissolve CaCl₂ and MgSO₄ in 300 ml distilled water; add 500 ml water and while swirling, slowly add remaining salts; when dissolved, add 200 ml distilled water and mix; store at 4 °C), 100 ml distilled water, 1 ml hemin solution (dissolve 50 mg hemin in 1 ml 1 M

NaOH; make to 100 ml with distilled water; autoclave for 15 min at 121 °C), 0.02 ml vitamin K1 solution (dissolve 0.15 ml of vitamin K1 in 30 ml of 95% ethanol; keep for max. 1 month, at 4 °C in a brown bottle), 0.05 g cysteineHCl·H₂O, 1 g glucose; vitamin K1, hemin and cysteine are added after the medium is boiled, but before dispensing and autoclaving.

Nutrition and metabolism. *Johnsonella* has a nonfermentative, nonproteolytic metabolism. Fermentation end products of PYG broth cultures are (in milliequivalents per 100 ml of culture; mean \pm standard error of mean) acetate, 0.7 ± 0.1 and isovalerate 0.2 ± 0.04 . Traces of lactate, succinate, butyrate and isobutyrate are also detected. No hydrogen gas is detectable (Moore and Moore, 1994). The following substrates are not fermented: amygdalin, arabinose, cellobiose, erythritol, esculin, fructose, glucose, glycerol, glycogen, gum arabic, inositol, lactose, larch arabinogalactan, maltose, mannitol, mannose, melezitose, melibiose, raffinose, rhamnose, ribose, salicin, sorbitol, starch, sucrose, trehalose, xylan and xylose. No H_2S production in sulfide-indole motility medium. No growth in PYG with 20% bile or in deoxycholate broth. Indole, oxidase, DNase and catalase are not produced. Lipase or lecithinase not detected on egg yolk agar. No reduction of resazurin.

Chemotaxonomic characteristics. The cellular fatty acid composition of *Johnsonella ignava*, based on data for 11 strains grown in 10 ml PYG both cultures at 37 °C included 45% of an unidentified compound with equivalent chain-length of 9.74, 8% $C_{14:0}$, 2% $C_{16:1-cis9}$, 15% $C_{16:0}$, 5% $C_{16:0}$ dimethyl acetal, 5% $C_{18:1-cis9}$, 4% $C_{18:0}$, 2% $C_{18:1-cis11}$ dimethyl acetal, 3% $C_{18:1-cis11/t9/t6}$ or an unidentified compound with ECL 17.834 and 1% iso-3-OH- $C_{17:0}$ or $C_{18:2}$ dimethyl acetal (Moore et al., 1994).

Enrichment and isolation procedures

No specific isolation procedures specific for *Johnsonella* have been described. These organisms have been isolated in studies of the anaerobic bacterial flora of gingivitis and periodontitis in children and young adults in which randomly selected strains were characterized and identified (Moore et al., 1985, 1984, 1982a). The isolation procedure and media used in these studies have been described in detail in the chapter on the genus *Catonella*.

Maintenance procedures

Strains can be maintained in prerduced, anaerobically sterilized D5-broth (Moore et al., 1982a), the composition of which

is described in the chapter on *Catonella*. Cultures can also be lyophilized for long term preservation.

Differentiation from other Gram-stain-negative anaerobic nonfermentative bacilli

Johnsonella can readily be distinguished from most genera of Gram-stain-negative, anaerobic, nonfermentative rods (including *Porphyromonas*, *Desulfomonas*, *Dialister*, and *Dichelobacter*) by the G+C content of its DNA (except for *Dialister*, the G+C content of which has not been reported), its fermentation end products in PYG broth and its fatty acid composition (Moore et al., 1994; Moore and Moore, 1994). The organism with phenotypic characteristics most similar to those of *Johnsonella* is *Tissierella praecuta*, but its fatty acid composition is clearly different since it does not contain the unidentified compound with ECL 9.74 that makes up 45% of fatty acids in *Johnsonella ignava* (Moore et al., 1994).

Taxonomic comments

Johnsonella ignava was originally known as “*Bacteroides* D19”, one of a group of unnamed bacterial species that occur in the human gingival crevice and periodontal pockets that were first recognized and isolated at the Anaerobe Laboratory of the Virginia Polytechnic Institute and State University in Blacksburg (Moore et al., 1985, 1984, 1982a). It was formally described as *Johnsonella ignava*, a new genus and species of anaerobic, Gram-stain-negative, nonsporing bacilli and therefore placed in the family *Bacteroidaceae* (Moore and Moore, 1994). Later, by 16S rDNA sequence analysis, it was shown to belong to the *Clostridium* subphylum of the *Firmicutes* (Willems and Collins, 1995b). It is a member of *Clostridium* cluster XIVa as defined by Collins et al. (1994), and has now been classified as a member of the family *Lachnospiraceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes* according to the phylogenetic outline for the this volume (Figure 5).

Type strain: ATCC 51276 (= VPI D94B-12).

EMBL accession number (16S rRNA gene): X87152.

Genus XI. *Lachnobacterium* Whitford, Yanke, Forster and Teather 2001, 1980^{VP}

FRED A. RAINEY

Lach.no.bac.te'ri.um. Gr. n. *lachnos* woolly hair, down; L. dim. n. *bakterion* a small rod; N. L. neut. n. *Lachnobacterium* woolly rod, after its colonial morphology on agar.

Long, straight rods occurring as chains or filaments. **Gram-stain-positive. Anaerobic. Spores not formed.** Products from glucose fermentation are lactic acid with very minor amounts of acetic and butyric acids.

DNA G + C content (mol%): 33.9 (HPLC).

Type species: *Lachnobacterium bovis* Whitford, Yanke, Forster and Teather 2001, 1980^{VP}.

Further descriptive information

The genus *Lachnobacterium* contains a single species *Lachnobacterium bovis* represented by four strains (Whitford et al., 2001). These organisms are anaerobes but grow weakly under aerobic conditions in liquid cultures and in agar stabs. No growth is observed on plates incubated aerobically.

The strains stain weakly Gram-positive and transmission electron microscopy shows a typical Gram-positive cell wall composed of a single layer surrounding the cytoplasmic membrane. Growth is flocculent in liquid culture, while colonies growing on agar media penetrate the surface and have a woolly morphology. The temperature range for growth is 27–42 °C with no growth occurring at 22 or 50 °C. The four strains produce acid from glucose, lactose, cellobiose, sucrose, maltose, fructose, and arabinose, but not pectin, mannitol, glycerol, galactose, starch, xylan, barley straw, or cellulose. Xylose was fermented by strain YZ 63 only. All strains produced lactic acid (71–112 mM) as the major end product when grown on glucose. Minor amounts of acetic and butyric acids are also produced (1.5–3.0 mM). The major fatty acids found in all four strains of this species are C_{16:0}, C_{16:0 DMA}, C_{18:0}, C_{18:1 cis 11 DMA}, and an unknown fatty acid with a retention time of 17.834 min. All four strains of *Lachnobacterium bovis* produce a protease-sensitive bacteriocin-like inhibitory substance (BLIS). This compound was shown to have inhibitory effects on a number of Gram-positive rumen bacteria. Compounds from the different strains of *Lachnobacterium bovis* were shown to have different target specificities. The BLIS produced by strain YZ 87^T inhibited strains YZ 39 and YZ 63 (Whitford et al., 2001).

Enrichment, isolation, and growth conditions

Lachnobacterium bovis was isolated from rumen fluid and feces of cattle. Two of the four strains (YZ 87^T and YZ 63) were isolated from rumen fluid while strains YZ 140 and YZ 39 were isolated from feces. The isolation was as described by El-Meadaway et al. (1998). For the study of the bacteriocin-like inhibitory substance the strains were grown in L10 broth (Caldwell and Bryant, 1966). Cultures were incubated at 39 °C with a H₂:CO₂ (10:90) headspace.

Taxonomic comments

16S rRNA gene sequences are available for all four strains (YZ 140, YZ 87^T, YZ 39, and YZ 63; AF298662, AF298663, AF298664,

TABLE 169. Tests differentiating *Dorea formicigenerans* and *Dorea longicatena*^a

^aSymbols: +, >85% positive; d, different strains give different reactions (16–84% positive); –, 0–15% positive; w, weak reaction.

and AF298665, respectively) and they share 100% similarity. Phylogenetic analyses show them to have highest sequence similarity to species of the genus *Roseburia* (92.5–93.4%) and the misclassified *Eubacterium rectale* (92.1%). The genus *Lachnobacterium* falls within the radiation of the genera comprising the family *Lachnospiraceae* (see Figure 160.). The majority of genera in the family *Lachnospiraceae* represent distinct lineages and their clustering with the lineages of other genera is generally not supported by bootstrap analysis. This is the case for the clustering of the genera *Lachnobacterium*, *Roseburia*, and *Pseudobutyrvibrio* (see Figure 160).

Differentiation of the genus *Lachnobacterium* from other genera

The genus *Lachnobacterium* can be differentiated from the genus *Roseburia* on the basis of differences in mol% G + C content of the DNA and the end products of glucose fermentation. *Lachnobacterium bovis* has a mol% G + C of 33.9, which is much lower than the values reported for *Roseburia* species (41–47 mol%). The major end product of glucose fermentation by *Lachnobacterium bovis* is lactic acid; only small amounts of lactate are produced by *Roseburia* species, which produce butyrate as the main end product of glucose fermentation.

List of the species of the genus *Lachnobacterium*

1. *Lachnobacterium bovis* Whitford, Yanke, Forster and Teather 2001, 1980^{VP}

bo'vis. L. n. *bos* cow; L. gen. n. *bovis* of a cow.

Straight rod-shaped cells, 2.0–3.0 μm in length and 0.6–0.75 μm in diameter. Cells occur in chains or filaments. Generally nonmotile, but rare motile cells are observed in old cultures. Colonies penetrate the agar surface and have a woolly morphology. Strains grow well overnight at 39 and 42 °C, with limited growth at 27 °C and no growth at 22 or 50 °C. Strains ferment, with acid production (final pH in parentheses), glucose (5.3), lactose (5.9), cellobiose (6.1), sucrose (5.6), maltose (6.0), fructose (6.1), and arabinose (6.1). No growth on pectin, mannitol, glycerol, galactose, starch, xylan, barley straw, or cellulose. The end products from glucose fermentation (55 mM) are lactic acid (71–112 mM) and very minor

amounts of acetic and butyric acids (1.5–3.0 mM). Positive for α-glucosidase, β-glucosidase, and α-galactosidase, but not N-acetyl-glucosaminidase, α-arabinosidase, α-fucosidase, β-galactosidase, phosphatase, arginine utilization, indole production, leucine aminopeptidase, proline aminopeptidase, pyroglutamic acid arylase, tyrosine aminopeptidase, arginine aminopeptidase, alanine aminopeptidase, histidine aminopeptidase, phenylalanine aminopeptidase, or glycine aminopeptidase. Produces a temperature-sensitive bacteriocin-like inhibitory substance. The most abundant fatty acids are C_{16:0} and isomers of C_{18:1}. The type strain was isolated from rumen fluid of a rumen-cannulated steer.

DNA G + C content (mol%): 33.9 (HPLC).

Type strain: YZ 87, ATCC BAA-151, DSM 14045, LRC 5382.

GenBank accession number (16S rRNA gene): AF298663.

Genus XII. *Moryella*. Carlier, K'ouas and Han 2007, 726^{VP}

JEAN-PHILIPPE CARLIER

Mo.ry.el'la. L. fem. dim. ending *-ella*; N.L. fem. n. *Moryella* named in honor of the French microbiologist Francine Mory.

Elongated rod with **pointed ends**, about 0.8–1.7 μm \times 0.5–0.6 μm , usually occurring singly or in pairs and occasionally in short chains. **Nonmotile**. **Gram-stain-positive**, but cells may decolorize easily. **Strictly anaerobic**. Does not form spores. **Catalase- and urease-negative**. Nitrate is not reduced. **Indole-positive** and weakly saccharolytic. Traces of gas may be produced in trypticase-glucose-yeast extract (TGY, see below) deep agar cultures. The major metabolic end products in TGY broth are **acetic, butyric, and lactic acids**. Its habitat is not known, but it is probably a resident of the human digestive tract.

DNA G + C content (mol%): 50.2.

Type species: *Moryella indoligenes* Carlier, K'ouas and Han 2007, 728^{VP}.

Further descriptive information

Morphology and ultrastructure. Cells are elongated, sometimes warped rods with pointed ends. Although they stain Gram-variable, ultrathin sections viewed by electron microscopy reveal a typical Gram-positive type of cell wall (Figure 165).

Colonial and cultural characteristics. Colonies appear on Wilkins–Chalgren blood agar (Wilkins and Chalgren, 1976) after 24–48 h of incubation. They are circular, convex, and about 0.5–1.0 mm in diameter, nonpigmented, and nonhemolytic. TGY broth cultures form a flocculent sediment with or without turbidity. Traces of gas may be detected in TGY deep agar cultures. The strains are susceptible to bile and to 1 mg kanamycin, 10 μg colistin, 5 μg vancomycin special-potency antibiotic disks (Engelkirk et al., 1992).

Nutrition and metabolism. Based on a study of three strains, glucose, galactose, maltose, and ribose fermentations are variable. Acid is not produced from raffinose, sucrose, esculin, arabinose, cellobiose, fructose, glycerol, inositol, lactose, mannitol, mannose, melezitose, melibiose, rhamnose, salicin, sorbitol,

starch, trehalose, and xylose. Esculin is not hydrolyzed. Catalase activity and nitrate and nitrite reduction are not detected. Gelatin is not liquefied, and milk is not modified. The major metabolic end products from TGY broth are acetic, butyric, and lactic acids.

Fatty acid composition. Major fatty acids from TGY broth cultures are C_{13:0 iso} 2OH (14%), C_{14:0} (47%), and C_{16:0} (9%). Percentages are mean values. The following minor fatty acids are also detected: C_{12:0}, C_{14:0 iso}, C_{15:0 iso}, C_{15:0 anteiso}, C_{16:0 iso}, C_{16:1 ω 9c}, and C_{18:0}.

Antibiotic susceptibility. The type strain is susceptible to penicillin G, ampicillin, amoxicillin, imipenem, cefalotin, cefotaxime, cefoxitin, latamoxef, and metronidazole, moderately resistant to tetracycline, and resistant to trimethoprim–sulfamethoxazole, erythromycin, and rifampin. Strains AIP241.03 and MDA2477 are resistant only to trimethoprim–sulfamethoxazole and erythromycin.

Pathogenicity. Two strains were recovered from a buttock abscess and from an intra-abdominal abscess. A third strain was from a polymicrobial thigh abscess in a man with a history of adenocarcinoma of the prostate, local radiotherapy, and complications of chronic osteomyelitis of the symphysis pubis. Bacteria similar to *Moryella indoligenes* strain MDA 2477 have been detected by terminal restriction fragment length polymorphism analyzes (T-RFLP) of symptomatic endodontic infections clinically diagnosed as acute abscesses (Sakamoto et al., 2006).

Enrichment and isolation procedures

Moryella can be isolated on Columbia or Wilkins–Chalgren sheep-blood agar after 1–2 d of incubation at 37°C. Strictly anaerobic conditions are required for growth. Good growth can be obtained in an anaerobic jar containing a mixture of H₂:CO₂:N₂ (5:5:90 by vol.).

FIGURE 165. Morphology of *Moryella indoligenes* AIP 220.04^T. Transmission electron micrographs after negative staining (a) and ultrathin sectioning (b) shows the Gram-positive type of cell wall (CW) and the cytoplasmic membrane (CM). Bars = 1 μm .

Maintenance procedures

The strain may be maintained in trypticase-glucose-yeast extract (TGY) medium consisting of: 3% (w/v) biotrypcase, 0.5% glucose, 2% yeast extract, 0.05% L-cysteine hydrochloride, and 5 mg hemin/min (Carlier et al., 2002) or in Wilkins–Chalgren Anaerobe Broth (Oxoid) under anaerobic conditions as described above. Cultures of *Moryella* will usually not survive longer than 1–2 weeks without transferring. However, it can be preserved for several years by freeze-drying or in liquid nitrogen.

Differentiation of the genus *Moryella* from other genera

Table 170 lists characteristics differentiating *Moryella* from other closely related species. The pointed ends of these rod-shaped cells, the absence of motility, and the production of indole and butyrate are the main features that distinguish the genus *Moryella* from related genera.

Taxonomic comments

Phylogenetically, the genus belongs to the *Clostridium coccooides* rRNA cluster (rRNA cluster XIVa, Collins et al., 1994) and is classified within the family *Lachnospiraceae* (Figure 166). However, it forms a distinct lineage within this phenotypically heterogeneous collection of organisms that includes sporulating and nonsporulating species. Several butyrate-producing organisms are also widely distributed within this group (Barcenilla et al., 2000). The genus *Moryella* has 16S rRNA gene sequence similarity values of approximately 91% with neighboring groups including *Clostridium clostridioforme*, *Clostridium bolteae*, and *Clostridium asparagiiforme*. However, it differs from these organisms because it is not a sporeformer and it produces butyrate. On the other hand, it is phylogenetically too distant from the butyrate-producing members of this family to belong to those genera.

List of species of the genus *Moryella*

- Moryella indoligenes***. Carlier, K'ouas and Han 2007, 728^{VP} in *dol.i'ge.nes*. N.L. n. *indolum* indole; N.L. suff. *-genes* producing from; Gr. v. *gennaio* to produce; N.L. fem. adj. *indoligenes* indole-producing.

The biochemical characteristics are as described for the genus.

Habitat: probable resident of human intestinal tract.
DNA G + C content (mol%): 50.2 (T_m).
Type strain: AIP 220.04, CCUG 52648, CIP 109174.
GenBank accession number (16S rRNA gene): DQ377947.

FIGURE 166. Phylogenetic relationships of *Moryella indoligenes*, *Oribacterium sinus*, and related genera. The neighbor-joining method was used to construct the tree from 16S rRNA genes. *Propionibacterium acnes* was the outgroup. Bootstrap confidence levels (shown as percentages above the nodes) were determined from 100 replicates. Scale bar indicates 10% difference in 16S rDNA nucleotide sequences.

Genus XIII. *Oribacterium* Carlier, K'ouas, Bonne, Lozniewski and Mory 2004, 1614^{VP}

JEAN-PHILIPPE CARLIER

O.ri.bac.te'ri.um. L. gen. n. *oris* of the mouth; N.L. neut. n. *bacterium* from Gr. dim. n. *bakterion* a small rod; N.L. neut. n. *Oribacterium* small rod from the mouth.

Elongated ovoid rods, about 1.7–2.2 μm × 0.8–1.0 μm, usually occurring singly or in pairs and occasionally in short chains. **Motile** with laterally inserted flagella. **Gram-stain-positive** but may stain Gram-negative. **Strictly anaerobic**. Does not form spores. **Catalase** is not produced. Weakly fermentative. **Abundant gas is produced** in glucose broth cultures; **nitrate reduction is negative; indole production is positive**. Major metabolic end products in trypticase-glucose-yeast extract (TGY, see below) broth are **acetic and lactic acids**. Habitat: mouth, upper respiratory tract.

DNA G + C content (mol %): 42.4.

Type species: Oribacterium sinus Carlier, K'ouas, Bonne, Lozniewski and Mory 2004, 1614^{VP}.

Further descriptive information

As seen by electron microscopy, cells possess a Gram-positive type of cell wall and 2–4 lateral flagella (Figure 167). Colonies on Wilkins–Chalgren sheep-blood agar are circular, convex, 1–1.5 mm in diameter, nonpigmented, and nonhemolytic. Strictly anaerobic. Abundant gas is produced in TGY deep agar cultures. By presumptive identification tests (Engelkirk et al.,

1992), *Oribacterium* is resistant to 1 mg kanamycin and 10 μg colistin disks, but susceptible to 5 μg vancomycin, 4 μg metronidazole, and bile disks. Catalase and nitrate reduction are negative. Indole is produced. Gelatin is not liquefied, and milk is not modified. Acid is produced from glucose, galactose, raffinose, and sucrose. Acid is not produced from esculin, arabinose, cellobiose, fructose, glycerol, inositol, lactose, maltose, mannitol, mannose, melezitose, melibiose, rhamnose, ribose, salicin, sorbitol, starch, trehalose, or xylose. Esculin is not hydrolyzed. The metabolic end products are acetic and lactic acids. Major cellular fatty acids that are present in substantial amounts are C_{14:0}, C_{15:0 anteiso}, C_{15:0}, C_{16:1 ω9c}, and C_{16:0}. Smaller amounts of C_{17:0 ante} and C_{18:1 ω9t} are also present.

Enrichment and isolation procedures

Oribacterium can be isolated on Columbia or Wilkins–Chalgren sheep-blood agar after incubating at 37 °C for 2 d. Strictly anaerobic conditions are required for growth. Good growth can be obtained in an anaerobic jar containing a mixture of H₂:CO₂:N₂ (5:5:90 by vol.).

FIGURE 167. Morphology of *Oribacterium sinus* AIP354.02^T. Transmission electron micrographs showing the (a) general morphology after negative staining and (b) ultrathin sections demonstrating the Gram-positive type of cell wall and the cytoplasmic membrane. Bars, (a) 500 nm; (b) 100 nm. (Reproduced with permission from Carlier et al., 2004. *Int. J. Syst. Evol. Microbiol.* 54: 1611–1615.)

Maintenance procedures

The strain may be maintained in trypticase-glucose-yeast extract (TGY) medium consisting of: 3% (w/v) biotrypcase, 0.5% glucose, 2% yeast extract, 0.05% L-cysteine hydrochloride, and 5 mg hemin/ml or in Wilkins–Chalgren Anaerobe Broth (Oxoid) under anaerobic conditions as described above. Cultures of *Oribacterium* will usually survive for no longer than 1–2 weeks without transferring. The organism may not survive freeze-drying procedures, but it can be preserved in liquid nitrogen for several years.

Differentiation of the genus *Oribacterium* from other genera

Oribacterium can be distinguished by its ovoid morphology, rapid motility, and ability to produce gas and indole. Other characteristics that distinguish *Oribacterium* from related organisms are listed Table 170.

Taxonomic comments

Based on 16S rRNA gene sequence analysis, the genus *Oribacterium* belongs to the family “*Lachnospiraceae*” located within the *Clostridium coccoides* rRNA cluster (cluster XIVa, (Collins et al., 1994). This cluster is a large group of disparate organisms including a large number of genera such as *Butyrivibrio*, *Clostridium*, *Lachnospira*, *Eubacterium*, *Filifactor*, *Moryella*, *Shuttleworthia*, and many other species. Among these genera, *Oribacterium* forms a distinct subcluster with several oral clones described by Munson (2002) and Paster (2001). (Figure 166). The most closely related valid species are *Shuttleworthia satelles* and *Butyrivibrio crossotus* each with less than 90% 16S rRNA gene sequence similarity.

Strictly anaerobic rods. Stains Gram-negative. Nonsporeforming. Unusual metabolism that **produces dimethyl sulfide and methanethiol** from methoxy-containing aromatic compounds and sulfide.

DNA G + C content (mol%): not reported.

Type species: Parasporobacterium paucivorans Lomans, Leijdekkers, Wesselink, Bakkes, Pol, van der Drift and Op den Camp 2004, 307^{VP} (Effective publication: Lomans, Leijdekkers, Wesselink, Bakkes, Pol, van der Drift and Op den Camp 2001, 4022.).

Further descriptive information

Syringate, 3,4,5-trimethoxybenzoate, and gallate serve as sole carbon and energy sources (Lomans et al., 2001). Growth on the methoxylated aromatic compounds, syringate and 3,4,5-trimethoxybenzoate, requires the presence of sulfide, which is methylated to methanethiol and dimethyl sulfide (Lomans et al., 2001). Sulfide is not required for growth on gallate. Acetate and butyrate are also formed. No growth was observed on 3,4-dimethoxybenzoate, 3,5-dimethoxybenzoate, vanillate, pyrogallol, phloroglucinol, benzoate, pyruvate, H₂-CO₂, methanol, malate, fructose, glucose, pectin, or glycinebetaine. Optimal growth occurs at 34–37°C, pH 6.5–7.0, and less than 1.8 g/l of NaCl.

Enrichment and isolation procedures

Parasporobacterium can be enriched in a chemostat using syringate as the sole carbon and energy source and sodium sulfide

as reducing agent and methyl-group acceptor. After inoculation with freshwater lake sediment, the chemostat is allowed to run until one morphotype predominates. A pure culture is then obtained following dilution in agar deeps.

Maintenance procedures

Stock cultures must be transferred into fresh medium once a month. Cultures can also be stored in glass ampules at –80°C under N₂/CO₂ (80/20%, v/v) after addition of glycerol (final concentration 5%).

Differentiation of the genus *Parasporobacterium* from other genera

Unlike *Parasporobacterium*, the most closely related genus, *Sporobacterium olearium*, utilizes a wider range of substrates, produces spores, and stains Gram-positive. It also only produces methanethiol from syringate plus sulfide. Unlike many related anaerobes in the *Clostridiales*, both *Parasporobacterium* and *Sporobacterium* are unable to grow with either glucose or fructose as carbon and energy sources.

Taxonomic comments

Based upon rRNA gene sequence analyses, the nearest relative of *Parasporobacterium paucivorans* is *Sporobacterium olearium* (similarity 91.8%). Both genera are members of the *Lachnospiraceae* within the *Clostridiales* (Ludwig et al., 2009).

List of species of the genus *Parasporobacterium*

1. **Parasporobacterium paucivorans** Lomans, Leijdekkers, Wesselink, Bakkes, Pol, van der Drift and Op den Camp 2004, 307^{VP} (Effective publication: Lomans, Leijdekkers, Wesselink, Bakkes, Pol, van der Drift and Op den Camp 2001, 4022.)

pau.ci.vo'rans. L. subst. *pauci* a few; L. adj. part. *vorans* devouring; N.L. neut. part. adj. *paucivorans* degrading a limited number of substrates.

Rod-shaped cells, 1.5–2 μm × 0.3–0.5 μm, form chains of two cells. They are insensitive to lysis by 0.1 g/l of SDS. In the

presence of syringate and sulfide, they form into white, deep-agar, circular colonies (1–2 mm in diameter) within 7 d.

The type strain was originally isolated from slurry of an eutrophic lake sediment (campus of the Dekkerswald Institute, Nijmegen, The Netherlands).

For all other characteristics, refer to the genus description.

DNA G + C content (mol%): not reported.

Type strain: SYR1, DSM 15970, NCCB100052.

GenBank accession number (16S rRNA gene): AJ272036.

Genus XV. **Pseudobutyrvibrio** van Gylswyk, Hippe and Rainey 1996, 561^{VP}

FRED A. RAINEY

Pseu.do.bu.ty.ri.vib.ri.o. Gr. adj. *pseudes* false; *butyrvibrio* from the genus *Butyrvibrio*; N.L. masc. n. *Pseudobutyrvibrio* not a true butyrvibrio.

Non-spore forming, Gram-stain-negative, anaerobic rods. Ferment a variety of carbohydrates. Major end products of fermentation are formate, butyrate, and lactate. The major cellular fatty acid is C_{16:0}

DNA G + C content (mol%): 40.5–42.7 (HPLC).

Type species: Pseudobutyrvibrio ruminis van Gylswyk, Hippe and Rainey 1996, 561^{VP}.

Further descriptive information

The genus *Pseudobutyrvibrio* contains two species, the type species *Pseudobutyrvibrio ruminis* (van Gylswyk et al., 1996) and an additional species *Pseudobutyrvibrio xylanivorans* (Kopečný et al., 2003). The genus was initially described on the basis of a single strain, which showed many phenotypic characters similar to those described for *Butyrvibrio fibrisolvens* but was phylogenetically distinct. The lack of xylanase activity and C₁₈ fatty acids in *Pseudobutyrvibrio ruminis* were considered differentiating characteristics when compared to *Butyrvibrio fibrisolvens* (van Gylswyk et al., 1996). However, the study of a large number of butyrate-producing rumen bacteria resulted in the description of the second species of the genus *Pseudobutyrvibrio xylanivorans* which was xylanolytic and contained C₁₈ fatty acids (Kopečný et al., 2003). Currently the two genera can be differentiated on

the basis of 16S rRNA gene sequence comparisons as well as PCR assays based on the 16S rRNA gene sequences (Mrázek and Kopečný, 2001). The type strains of *Pseudobutyrvibrio ruminis* and *Pseudobutyrvibrio xylanivorans* share 97.8% 16S rRNA gene sequence similarity. Similarity values in the range 91.2–93.1% are found to the related species of the genera *Roseburia* and *Lachnobacterium* and the misclassified *Eubacterium rectale*. The phenotypically similar species of the genus *Butyrvibrio* share <90.0% 16S rRNA gene sequence similarity with *Pseudobutyrvibrio* species. On the basis of 16S rRNA gene sequence comparisons the genus *Pseudobutyrvibrio* falls within the radiation of the family *Lachnospiraceae* (see Figure 160). The species of the genus *Pseudobutyrvibrio* can be separated on the basis of differences in their 16S rRNA gene sequences as well as enzymic activities, end products of glucose fermentation, and fatty acid profiles.

List of the species of the genus *Pseudobutyrvibrio*

1. *Pseudobutyrvibrio ruminis* van Gylswyk, Hippe and Rainey 1996, 561^{VP}

ru'mi.nis. L. neut. gen. n. *ruminis* of the rumen.

Cells are Gram-stain-negative, curved rods, often with tapering ends. Cells are 1–3 µm long and 0.3–0.5 µm in diameter. Very long cells often occur when grown on solid medium. Spores are not produced. Motile by single polar or subpolar flagellum. Colonies are 1.5–2 mm in diameter, convex, round, smooth edged, and opaque with radiating striations. Submerged colonies are lens-shaped discs with diameters of 0.5 mm. Growth occurs anaerobically at 39 °C, with little growth at 22 or 45 °C. Substrates fermented include arabinose, cellobiose, fructose, galactose, glucose, lactose, maltose, mannose, sucrose, trehalose, and xylose. Glycerol weakly fermented. Mannitol, ribose, sorbitol, soluble starch, xylan, lactate, succinate, fumarate, oxalate, pyruvate, malonate, aspartate, and glutamate do not support growth. Xylanase, amylase, proteinase, pectinase, and laminarinase activities are not detected. The end products of glucose (50 mM) fermentation are formate (29 mM), butyrate (19 mM), lactate (40 mM), and acetate (<1 mM). The major cellular fatty acid components of cells grown in DSM medium no. 330 without rumen fluid are C_{16:0} (27.6%), C_{14:0} (14.2%), C_{15:1 iso} / C_{13:0 3-OH} (12.7%), and C_{17:1 anteiso} (5.2%). Type strain was isolated from whole rumen contents of a pasture-grazing cow.

DNA G + C content (mol%): 40.5 (HPLC).

Type strain: A12-1, DSM 9787.

GenBank accession number (16S rRNA gene): X95893.

2. *Pseudobutyrvibrio xylanivorans* Kopečný, Zorec, Mrázek, Kobayashi and Marinšek-Logar 2003, 207^{VP}

xy.la.ni.vo'rans. N.L. n. *xylanum* xylan; L. part. adj. *vorans* devouring, digesting; N.L. part. adj. *xylanivorans* xylan-digesting.

Cells are Gram-stain-negative, straight to slightly curved rods 1.5–3.0 µm long and 0.4–0.6 µm in diameter. Endospores are not formed. Cells are motile by means of a single polar or subpolar flagellum. Growth occurs anaerobically at 39 °C, but not at 25 or 45 °C. No growth is observed in the presence of oxygen. Exposure of liquid cultures to air for several hours does not kill cells. Substrates that support growth of the type strain are cellobiose, esculin, glucose, lactose, maltose, mannose, melezitose, salicin, sucrose, and xylose. Tryptophan, urea, and gelatin are not utilized. The following substrates do not support growth of the type strain: glycerol, mannitol, farinose, sorbitol, rhamnose, and trehalose. Highly xylanolytic. Most strains produce amylase, proteinase, and DNase. Laminarinase is detected in some strains. Medium M10 with glucose (22 mM) is fermented to formate (15.1 mM), butyrate (17.6 mM), lactate (10.9 mM), succinate (0.3 mM), and ethanol (1.1 mM). Acetate is utilized. No growth occurs in the absence of fermentable carbohydrates. The type strain does not liquefy gelatin or produce hydrogen sulfide. Nitrate is not reduced; catalase and hydrolysis of urea are negative. The major cellular fatty acid components of the type strain grown in DSM medium no. 330 without rumen fluid are C_{16:0} (39.2%) and C_{17:1 anteiso} (6.4%), followed by C_{17:0 iso 3-OH} (3.9%) and C_{14:0} (4.3%). This species is characterized by a higher content of straight-chain cellular fatty acids and a lower content of branched-chain fatty acids. This species represents the most commonly isolated butyrate-producing anaerobic bacterium from the rumen of sheep and cow. The type strain was isolated from the rumen of a cow.

DNA G + C content (mol%): 42.1 (HPLC).

Type strain: Mz 5, DSM 14809, ATCC BAA-455.

GenBank accession number (16S rRNA gene): AJ428548.

Genus XVI. *Roseburia* Stanton and Savage 1983a, 626^{VP}

THADDEUS B. STANTON, SYLVIA H. DUNCAN AND HARRY J. FLINT

Roseburia. N.L. fem. n. *Roseburia* named in honor of Theodor Rosebury, an American microbiologist who studied and described micro-organisms indigenous to humans.

Slightly curved, rod-shaped cells ($0.5 \times 1.5\text{--}5\mu\text{m}$) occur singly and in (dividing) pairs. Nonsporulating. Gram-negative to Gram-variable staining reaction. Taxonomically grouped within cluster XIVa of the *Clostridium* subphylum on the basis of 16S rDNA sequence (see below). **Actively motile at 37 °C** by means of multiple flagella inserted along the concave side and occasionally along one end of the cell. **The flagella appear as a subterminal bundle** when cells are examined by scanning electron microscopy or phase-contrast light microscopy (Figure 168). **Strictly anaerobic**. Chemo-organotrophic. Uses the carbohydrates D-glucose, cellobiose, D-maltose, D-raffinose, sucrose, and D-xylose as carbon and energy sources. **Hydrolyzes and ferments starch**. Grows in anaerobically prepared media containing volatile fatty acids, yeast extract, trypticase peptone, inorganic salts, hemin, glucose, and vitamins, beneath 95% N₂/5% CO₂ or 100% CO₂ atmosphere. **Produces H₂, CO₂, and large amounts of butyrate from fermentation of glucose and acetate**. May produce lactate, formate, and trace amounts of ethanol. **Consumes acetate, which may be stimulatory during growth on carbohydrates. Indigenous to mammalian intestinal tract**. Catalase-negative. Isolated from mouse cecal mucosa and from human feces. Uncultured bacteria with partial 16S rDNA sequences 95–97% similar to those of *Roseburia* (GenBank nos AJ312385 and L14676) have been detected in 16S rDNA analyses of swine gastrointestinal tract samples (Leser et al., 2002) and adult human fecal samples (Hold et al., 2002). Two species of *Roseburia* have been characterized. They can be differentiated by characteristics given in Table 171.

DNA G+C content (mol%): 29–42% (T_m).

Type species: *Roseburia cecicola* Stanton and Savage 1983a, 626^{VP}.

FIGURE 168. Phase-contrast micrograph of *Roseburia cecicola* GM^T cells. Each cell has a bundle of flagella (arrow). Bar = 5 μm . (Reprinted with permission from Stanton, T.B. and D.C. Savage. 1983. Appl. Environ. Microbiol., 45: 1677–1684).

TABLE 171. Characteristics useful for differentiating *Roseburia* species^a

DNA G+C content (mol%) (T_m)	42	29–31

^aSymbols: +, >85% positive; –, 0–15% positive.

^bThe identifiable nucleotides of *Roseburia cecicola* GM^T (L14676) and *Roseburia intestinalis* LC1-82T (AJ312385) 16S rRNAs are 94.9% identical over 1357 base positions. The overall sequences would be 97.1% identical, if ambiguous nucleotides were identical.

Further descriptive information

By the Gram-staining reaction, *Roseburia* cells are Gram-stain-negative to Gram-stain-variable. *Roseburia cecicola* cells have an apparent trilaminar outer envelope, resembling that of Gram-stain-negative bacteria (*Proteobacteria*) (Stanton and Savage, 1983a). Nevertheless, analyses of *Roseburia* species 16S rDNA indicate the 16S rRNA gene has signature nucleotide bases typical of Gram-stain-positive bacteria (Martin and Savage, 1988). Comparisons of flagellin amino acid sequences indicate the *Roseburia cecicola* flagellar protein shares greatest sequence similarity with flagellins of *Bacillus*, *Clostridium*, and spirochete species (Martin and Savage, 1988; Stanton, unpublished observations). According to the 16S rRNA phylogenetic analysis presented in the roadmap to this volume (Figure 5), the genus *Roseburia* is a member of the family *Lachnospiraceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*. Phylogenetically close relatives of *Roseburia* species are strains of *Eubacterium rectale* and *Eubacterium oxidoreducens* (Figure 169), both heterogeneous taxa (Duncan et al., 2002). DNA–DNA reassociation studies would undoubtedly be useful for establishing definitive taxonomic relationships among these diverse taxa.

Enrichment and isolation procedures

Roseburia can be isolated by selecting for motile bacteria or for butyrate-forming bacteria from intestinal samples. *Roseburia cecicola* was isolated by inoculating mouse cecal tissue scrapings into one end of a capillary tube filled with sterile culture broth. After 24 h incubation at 37 °C, bacteria that had migrated through the broth were recovered from the opposite end of the capillary tube and cultured as isolated colonies in semisolid agar-containing medium. *Roseburia cecicola* strain GM was obtained from one of the colonies (Stanton and Savage, 1983b). *Roseburia intestinalis* strains were obtained from bacteria

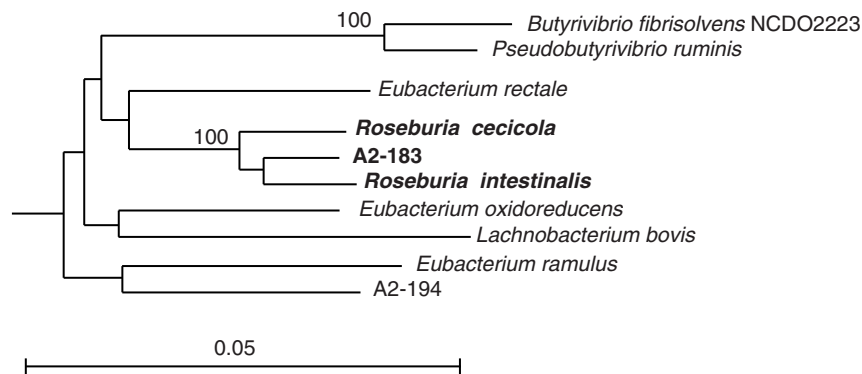

FIGURE 169. Phylogenetic tree based on 16S rDNA sequences for *Roseburia* species and their closest relatives. Sequence accession numbers are as follows: *Roseburia intestinalis* L1-82^T, AJ312385; *Roseburia cecicola* GM^T ATCC 33874, L14676; *rectale* ATCC 33656, L34627; *Eubacterium oxidoreducens* G2-2, AF202259; *Lachnospira bovis* LRC 5436, AF298665; *Eubacterium ramulus* ATCC 29099, L34623; *Pseudobutyrvibrio ruminis* pC-XS7, AF202262, *Butyrivibrio fibrisolvens* NCDO 2223, X89977; butyrate-producing human fecal bacterium *Roseburia* sp. A2-183, AJ270482; butyrate-producing human fecal bacterium *Eubacterium* sp. A2-194, AJ270473. The scale bar represents genetic distance (substitutions per nucleotide position). Bootstrap values exceeding 97% are also indicated.

forming colonies in roll tubes containing a rumen-fluid-based agar medium and inoculated with dilutions of human infant fecal homogenates. *Roseburia intestinalis* was selected after screening for strains producing large amounts of butyrate (Barcenilla et al., 2000).

Maintenance procedures

Roseburia cecicola cultures to which the cryoprotectant DMSO (final concentration, 10% v/v) has been added, can be stored frozen at -80°C for many years. *Roseburia intestinalis* cultures can be stored frozen at -20°C on rumen fluid medium containing agar (0.75% final concentration).

Differentiation of the genus *Roseburia* from other genera

Roseburia species can be differentiated from related taxa by 16S rDNA sequence analysis. *Roseburia cecicola* can be differentiated from various *Butyrivibrio*, *Lachnospira*, and *Eubacterium* strains by DNA–DNA relative reassociation (Mannarelli et al., 1991).

List of species of the genus *Roseburia*

1. *Roseburia cecicola* Stanton and Savage 1983a, 627^{VP}

ce.ci.co'la. N.L. n. *cecum* blind pouch; L.v. suff. *cola* from L. v. *colo* to dwell; N.L. n. *cecicola* cecum-dweller.

The type strain GM is the only characterized strain. Slightly curved, rod-shaped cells, $0.5\ \mu\text{m}$ in diameter and $2.5\text{--}5.0\ \mu\text{m}$ in length (Figure 168). Actively motile by means of 20–35 flagella inserted into the concave side and occasionally into the end of each cell, forming a flagellar bundle visible by phase-contrast light microscopy (Figure 168). Transmission electron micrographs of a negative stained cell and of ultrathin sections of cells have been published (Stanton and Savage, 1983a). Gram-stain-negative in staining reaction and by electron microscopy appearance. Based on phylogenetic analyses of 16S rRNA and flagellin genes, however, the species is phylogenetically associated with Gram-stain-positive genera (Collins et al., 1994; Martin and Savage, 1988; Willems et al., 1996).

Obligately anaerobic, having a fermentative type of metabolism. Nutritional requirements are undefined. Grows readily in VTY broth (Table 172). Various carbohydrates are growth substrates (Table 173) (Stanton and Savage, 1983a). GM cells constitutively produce extracellular amylase activity. Products

of glucose plus acetate metabolism are H_2 , CO_2 , *n*-butyrate, and trace amounts of ethanol (Table 174) (Stanton and Savage, 1983a). Catalase-negative.

In VTY agar medium supplemented with 0.7% Noble agar, after 48 h of incubation at 37°C , subsurface colonies are 1 mm in diameter, brownish white, lens shaped, and occasionally surrounded by gas pockets that split the agar medium. Surface colonies are white, mucoid, granular in appearance, 1.5–3 mm in diameter, and circular with smooth edges.

In assays using antibiotic disks on VTY agar medium, *Roseburia cecicola* cells are strongly inhibited by chloramphenicol, erythromycin, novobiocin, and vancomycin. Slightly to moderately sensitive to penicillin, polymyxin B, tetracycline, and neomycin. Insensitive to nalidixic acid. An uncharacterized *Roseburia* strain carries a tetracycline resistance gene, *tetW* (GenBank AJ421625).

Roseburia cecicola nonmotile strains produced by UV mutagenesis are impaired in their ability to colonize the mouse cecum in competition with other intestinal micro-organisms (Stanton and Savage, 1984).

Optimal growth (5×10^8 cells/ml; 2 h population-doubling time) at 37 °C in VTY broth (Table 172) containing glucose. Grows slowly at 30 °C but not at 22 °C or 45 °C.

Isolated from mouse cecal mucosa.

DNA G+C content (mol%): 42 (T_m).

Type strain: ATCC 33874 (strain GM).

2. **Roseburia intestinalis** Duncan, Hold, Barcenilla, Stewart and Flint 2002, 1619^{VP}

in.tes.ti.na'lis. L. adj. *intestinalis* of the intestine, the presumed habitat of the isolates.

The type strain L1-82 is one of five strains characterized. Strains initially categorized as one of 18 ribogroups of butyrate-producing bacteria based on RFLP profiles following cleavage with restriction enzyme *AluI* (Barcenilla et al., 2000). Slightly curved, rod-shaped cells, 0.4–0.5 µm in width and 1.0–5.0 µm in length. Actively motile by means of flagella inserted on the concave side of the cells. In M2GSC roll tubes surface colonies are white, mucoid, and circular with smooth edges.

p-Aminobenzoic acid		3 µg
Folic acid		5 µg
Pyridoxamine		15 µg
Culture atmosphere	95% N ₂ :5% CO ₂	100% CO ₂

^aHeat-labile medium components and glucose are filter-sterilized and added separately. Preparation of media under anaerobic conditions as described (Duncan et al., 2002; Stanton and Savage, 1983a).

Obligately anaerobic, surviving less than 2 min on exposure to air on the surface of agar plates; have a fermentative type of metabolism. Grows readily on a rumen-based medium-supplemented medium (M2GSC) and on a semidefined medium (YCFA) supplemented with glucose (Table 172). Growth is stimulated when acetate is present in the medium.

Hydrolyzes esculin. Arylamidase activity not detected. Various carbohydrates are growth substrates (Table 173). Products of glucose and acetate metabolism are H₂, CO₂, formate, butyrate, and lactate (Table 174). Catalase- and urease-negative. Strain L1-82 is tetracycline resistant.

Optimal growth occurs at 37 °C with little to no growth at 22 °C, 30 °C and slower growth at 45 °C. Isolated from a healthy infant (11 mo) fecal sample.

DNA G+C content (mol%): 29–31% (T_m).

Type strain: NCIMB 13810 (strain L1-82).

Genus XVII. *Shuttleworthia* Downes, Munson, Radford, Spratt and Wade 2002, 1473^{VP}

WILLIAM G. WADE AND JULIA DOWNES

Shuttleworthia. N.L. fem. n. *Shuttleworthia* named to honor Cyril Shuttleworth, the distinguished British microbiologist.

Slightly curved short rods which occur singly, in pairs, short chains, or diphtheroidal arrangements. Rods 0.4–0.6 µm in diameter and 1.0–2.5 µm in length. **Gram-stain-positive, non-spore-forming, and nonmotile.** Obligately **anaerobic.** Optimal growth temperature 30–37 °C. Several different colony morphologies exist.

Saccharolytic. Principal end products of glucose fermentation are acetic, butyric, and lactic acids. Growth in broth media is good and is stimulated by the presence of fermentable carbohydrates. Esculin is hydrolyzed and indole is produced. Nitrate is not reduced; arginine and urea are not hydrolyzed. Gelatin is not liquefied and H₂S and catalase are not produced. No growth in 20% bile.

Occurs in the oral cavity of man and has been isolated from periodontal pockets and subgingival plaque.

DNA G+C content (mol%): 50–51 (HPLC).

Type species: *Shuttleworthia satelles* Downes, Munson, Radford, Spratt and Wade 2002, 1474^{VP}.

Further descriptive information

The colony morphology of the type species, *Shuttleworthia satelles*, is variable with three distinct phenotypes observable. The majority of colonies are 0.7–0.9 mm in diameter, circular, entire, with a gray, low convex center surrounded by a flat, translucent margin after 5 d incubation on Fastidious Anaerobe Agar (FAA). On further incubation, smaller satellite colonies arise on the periphery or within the original colonies (Figure 170). These satellite colo-

FIGURE 170. Colony morphology of 10-d-old culture of *Shuttleworthia satelles* DSM 14600 showing satellite colonies arising within the primary colonies. Bar = 0.5 mm.

nies are 0.2–0.3 mm in diameter, convex, circular, entire, off-white, semi-opaque, and shiny. A third colony type appears as irregular, cream-colored colonies after 6 d of incubation. On subculture, the third colony type is 0.6 mm in diameter, circular, entire, high convex, cream-colored, and opaque after 5 d incubation on FAA.

The fermentation of certain sugars was the only biochemical characteristic that differed in the different colony types. Cells forming the cream-colored, high convex colonies ferment arabinose, cellobiose, melibiose, and salicin while those cells forming the gray, low convex colonies usually do not ferment these sugars.

All nine strains of *Shuttleworthia satelles* tested in the Rapid ID32A anaerobe identification kit (bioMérieux) were positive for α -galactosidase, β -galactosidase, α -glucosidase, β -glucosidase, and indole in the panel, while reactions to β -glucuronidase were weak and variable.

Enrichment and isolation procedures

Strains of *Shuttleworthia* species can be isolated on complex media appropriate for the culture of anaerobes including blood agar, enriched brain heart infusion agar, and Fastidious Anaerobe Agar (FAA) (Lab M).

Maintenance procedures

Lyophilization of cultures in the early stationary phase of growth is recommended for long term storage of most strains.

Procedures for testing special characters

The general methods described for the characterization of anaerobes in the VPI Anaerobe Laboratory Manual (Holdeman et al., 1977b) and the Wadsworth-KTL Anaerobic Laboratory Manual (Jousimies-Somer et al., 2002) are suitable for the study of members of this genus.

Differentiation of the genus *Shuttleworthia* from other genera

Characteristics that differentiate *Shuttleworthia satelles* from related taxa are shown in Table 176.

Taxonomic comments

Phylogenetic analysis of the 16S rRNA gene sequence reveals the single species of the genus, *Shuttleworthia satelles*, to be a deep-branching member of the family *Lachnospiraceae* (Figure 171), most closely related to *Eubacterium ramulus* and *Eubacterium rectale* but sharing less than 90% sequence

FIGURE 171. Phylogenetic tree based on 16S rRNA gene sequence comparisons over 1362 aligned bases showing relationships between *Shuttleworthia satelles* and related species. Tree was constructed using the neighbor-joining method following distance analysis of aligned sequences. Numbers represent bootstrap values for each branch based on data for 100 trees; only values greater than 50% are shown.

identity with these species. Bootstrap values for the tree are generally low indicating that the topology shown should be interpreted with caution.

Acknowledgements

The work reported in this chapter was funded, in part, by Wellcome Trust grant ref. 058950.

List of species of the genus *Shuttleworthia*

1. ***Shuttleworthia satelles*** Downes, Munson, Radford, Spratt and Wade 2002, 1474^{VP}
sat.ell'es. L. n. *satelles* a satellite or attendant upon a distinguished person, referring to the satelliting appearance of older cultures.

This species is the only member of the genus, thus the species description is the same as that for the genus and as

listed in Table 176. The description is based on nine strains isolated from human subgingival plaque and periodontal pockets in patients with periodontitis.

DNA G+C content (mol%): 51 (HPLC).

Type strain: CCUG 45864, DSM 14600, VPI D143K-13.

GenBank accession number (16S rRNA gene): AF399956.

Genus XVIII. *Sporobacterium* Mechichi, Labat, Garcia, Thomas and Patel 1999, 1747^{VP}

TAHAR MECHICHI AND BHARAT K. C. PATEL

Spo.ro.bac.ter'ium. Gr. n. *spora* spore; Gr. neut. dim. n. *bakterion* rod; N.L. neut. n. *Sporobacterium* spore-forming rod.

Slightly curved rods (5–10 µm × 0.4–0.8 µm). **Gram-stain-positive. Terminal spores** distend the cells. Motile by **peritrichous flagella. Strictly anaerobic. Chemo-organotrophic.** Utilizes a wide range of aromatic compounds, crotonate, and methanol. Growth occurs between 25–45 °C and at pH 6.5–8.5. Isolated from an anaerobic methanogenic waste treatment digester fed with olive mill wastewater.

DNA G+C content (mol%): 38.

Type species: ***Sporobacterium olearium*** Mechichi, Labat, Garcia, Thomas and Patel 1999, 1747^{VP}.

Further descriptive information

Aromatic compounds are structurally complex and represent one of the most diverse groups of organic substrates for micro-organisms. These compounds are widespread in the environment and are natural products of plants (Harborne, 1980), micro-organisms, and animals and are also released from industrial processes. Tarvin and Buswell (1934) were the first to show that monocyclic aromatic compounds were degraded to methane and CO₂ under anaerobic conditions. Since their findings, numerous investigations have demonstrated that aromatic compounds can be degraded to CO₂ or volatile fatty acids under anoxic conditions by sulfate-reducing, nitrate-reducing, ferric iron-reducing, photosynthetic, and fermenting bacteria. The trait of aromatic compound degradation by fermenting anaerobes can occur via ring cleavage or by the transformation of the side chains. The latter trait appears to be widely distributed in the domain *Bacteria*, but that of aromatic ring cleavage is more restricted and is only known to occur in eight genera and eleven species: *Pelobacter acidigallici*, *Pelobacter massiliensis*, *Syntrophus buswellii*, *Syntrophus gentianae*, and *Syntrophus aciditrophicus* which are members of *Deltaproteobacteria*; *Holophaga foetida*, a member of phylum *Acidobacteria*; and *Parasporobacterium paucivorans*, *Sporobacter termitidis*, *Eubacterium oxidoreducens*, *Sporotomaculum hydroxybenzoicum*, and *Sporobacterium olearum* which are members of the phylum *Firmicutes*. A few other *Eubacterium* species, *Ruminococcus schinkii* (Rieu-Lesme et al., 1996), and *Coproccoccus* species, which are also members of phylum *Firmicutes*, can

ferment aromatic compounds but can be differentiated from the latter group, as they are also able to use carbohydrates. The five aromatic-ring cleaving members of the phylum *Firmicutes* can be differentiated on a number of traits as indicated in Table 177.

Under anaerobic conditions, aromatic compounds are degraded via three different pathways, namely, the phloroglucinol pathway, the resorcinol pathway, and the benzoyl-CoA pathway. The phloroglucinol and resorcinol pathways are utilized by pure cultures of fermenting bacteria whereas the benzoyl-CoA pathway is utilized by pure cultures of fermenting bacteria or by syntrophic co-cultures. At least two different metabolic groups of bacteria that degrade aromatic compounds via the phloroglucinol pathway can be distinguished. The first group includes *Eubacterium oxidoreducens* (Krumholz and Bryant, 1986b), *Pelobacter acidigallici* (Schnell et al., 1991), and *Pelobacter massiliensis* (Schink and Pfennig, 1982), all of which degrade aromatic compounds containing two or three hydroxyl groups in the *meta*-position. Such compounds include trihydroxylated benzenes (gallate, pyrogallol, phloroglucinol, hydroxyquinone, and 2,4,6-trihydroxybenzoate) and dihydroxybenzenes (resorcinol), which are degraded to acetate or acetate and butyrate, respectively. *Eubacterium oxidoreducens* but not *Pelobacter acidigallici* or *Pelobacter massiliensis* requires hydrogen or formate for growth and utilizes quercetin. The second group, which includes *Holophaga foetida* (Liesack et al., 1994), *Sporobacter termitidis* (Grech-Mora et al., 1996), *Sporobacterium olearium* (Mechichi et al., 1999), and *Parasporobacterium paucivorans* (Lomans et al., 2001), transforms the methoxylated aromatic compounds, 3,4,5-trimethoxybenzoate, 3,4,5-trimethoxycinnamate, syringate, sinapate, and 5-hydroxyvanillate, to their corresponding hydroxylated derivatives, namely 3,4,5-trihydroxybenzoate (gallate) and trihydroxycinnamate and then to acetate and acetate and butyrate, respectively, via the phloroglucinol pathway.

Enrichment and isolation procedures

Samples from a methanogenic digester that had been fed with olive mill wastes were collected anaerobically using N₂-flushed

syringes and injected into N₂-flushed 100-ml sterile serum vials. For enrichments, a 0.5-ml sample is inoculated into 5-ml basal medium containing 5 mM syringate. The basal medium is prepared using the anaerobic techniques described by Hungate (1969) as modified for use with syringes (Macy et al., 1972; Miller and Wolin, 1974) and contains (per liter of deionized water): 1 g NH₄Cl, 0.3 g K₂HPO₄, 0.3 g KH₂PO₄, 0.6 g NaCl, 0.1 g CaCl₂·2H₂O, 0.2 g MgCl₂·6H₂O, 0.1 g KCl, 0.5 g cysteine-HCl, 1 g yeast extract (Difco), 1.5 ml trace-element solution (Widdel and Pfennig, 1981), and 1 mg resazurin. The pH is adjusted to 7.0 with 10 M KOH solution and the medium boiled under a stream of O₂-free N₂ gas and cooled to room temperature; 5 ml aliquots are dispensed into Hungate tubes under N₂:CO₂ (80:20%, v/v) and subsequently sterilized by autoclaving at 110 °C for 45 min. Prior to use, 0.2 ml 5% (w/v) NaHCO₃ and 0.05 ml 2.5% (w/v) Na₂S·9H₂O are injected from sterile stock solutions into pre-sterilized basal medium. A positive enrichment culture obtained after two weeks incubation at 37 °C is subcultured several times under the same conditions and should consist of a stable morphologically dominant microbial consortium that degrades syringate with concomitant production of acetate and butyrate. For isolation, a serial 10-fold dilution of the enrichment culture is inoculated into roll tubes containing basal medium supplemented with 5 mM syringate and 1.6% (w/v) purified agar. Several single well-isolated colonies that developed are picked and resuspended and the purification procedure repeated several times.

Maintenance procedures

Cultures can be maintained at room temperature for at least a month. Stock cultures are best stored for long term at –20 °C in anaerobic medium containing glycerol (50:50v/v).

Differentiation of the genus *Sporobacterium* from other genera

The five aromatic-ring cleaving members of the phylum *Firmicutes* can be differentiated on a number of traits as indicated in Table 177.

The common features of *Sporobacterium olearium*, *Sporobacter termitidis*, and *Parasporobacterium paucivorans* (as well as *Holophaga foetida*) are the ring cleavage of polyphenolic compounds and the production of methanethiol or dimethylsulfide. However, several metabolic differences distinguish the three strains from *Sporobacterium olearium*. *Holophaga foetida* and *Sporobacterium olearium*, but not *Sporobacter termitidis*, utilize gallate, 2,4,6-trihydroxybenzoate, pyrogallol, and phloroglucinol as carbon and energy sources. *Holophaga foetida* and *Sporobacter termitidis* produce both methanethiol and dimethylsulfide from the methoxyl group, and sulfide from cysteine in the presence of Na₂S which is used as a reducing agent in the culture media. However, *Sporobacterium olearium* produces only methanethiol and is also able to produce methanethiol from methanol. *O*-demethylation in *Parasporobacterium paucivorans* appears to be strictly sulfide or methanethiol (MT) dependent, whereas this is not

the case in *Holophaga foetida*, *Sporobacter termitidis*, and *Sporobacterium olearium*.

Taxonomic comments

Sequence analysis of 16S rDNA indicates that *Sporobacterium olearium* and *Parasporobacterium paucivorans* are phylogenetically close and are members of the family *Lachnospiraceae*, order *Clostridiales* in phylum *Firmicutes*. The vast majority of

the members of family *Lachnospiraceae* have been isolated from digestive tracts of herbivores where abundant aromatic compounds are present, but only a limited number of strains have so far been tested for their ability to ferment aromatic compounds.

Differentiation of the species of the genus *Sporobacterium*

Only one species, *Sporobacterium olearium*, is described.

List of species of the genus *Sporobacterium*

1. *Sporobacterium olearium* Mechichi, Labat, Garcia, Thomas and Patel 1999, 1747^{VP}

o.le.a'ri.um. L. adj. *olearius* of oil. N.L. neut. n. *olearium* related to olive oil.

A slightly curved rod with terminal spores. Stains Gram-stain-positive. Motile, with peritrichous flagella. Strictly anaerobic, chemo-organotrophic. Grows on crotonate, methanol, **3,4,5-trimethoxybenzoate (TMB)**, **3,4,5-trimethoxycinnamate (TMC)**, syringate, **3,4,5-trimethoxyphenylacetate (TMPA)**, **3,4,5-trimethoxyphenylpropionate (TMPP)**, ferulate, sinapate, vanillate, 3,4-dimethoxybenzoate, 2,3-dimethoxybenzoate, gallate, 2,4,6-trihydroxybenzoate, pyrogallol, phloroglycinol, and quercetin. Does not ferment benzoate, 2-, 3-,4-methoxybenzoates, 2,4-, 2,5-, 2,6-, 3,5-dimethoxybenzoates, glucose, fructose, sucrose, xylose, sorbose, galactose, *myo*-inositol, lactose, ribose, mannitol, cellobiose, formate, fumarate, pyruvate, malonate, succinate, ethanol, propanol, butanol, or grows on $H_2 + CO_2$. Yeast extract stimulates

growth, but is not required. TMB, TMC, TMPA, TMPP, syringate, sinapate, 2,3-dimethoxybenzoate, 3,4-dimethoxybenzoate, vanillate, ferulate, and methanol are fermented to acetate, butyrate, and MT. Gallate, 2,4,6-trihydroxybenzoate, pyrogallol, phloroglucinol, and crotonate are fermented to acetate and butyrate. H_2 is not required for growth but is required for complete degradation of gallate, 2,4,6-trihydroxybenzoate, pyrogallol, and phloroglucinol. Sulfate, thiosulfate, sulfite, nitrate, elemental sulfur, and fumarate are not reduced. Optimum growth temperature is between 37 and 40 °C (temperature growth range is 25–45 °C). Optimum pH for growth is 7.2 (pH growth range 6.5–8.5). Grows with NaCl concentrations 0–30 g/l but not with 35 g/l.

Habitat: anaerobic methanogenic digester fed with olive mill wastewater (Tunisia).

DNA G+C content (mol%): 38 (T_m).

Type strain: SRI, DSM 12504.

GenBank accession number: AF116854.

Genus XIX. *Syntrophococcus* Krumholz and Bryant 1986c, 489^{VP} (Effective publication: Krumholz and Bryant 1986a, 317.)

YUJI SEKIGUCHI

Syn.tro.pho.coc'cus. Gr. adj. *syn* together with; Gr. n. *trophos* one who feeds; Gr. n. *kokkos* a grain, berry; N.L. masc. n. *Syntrophococcus* coccus which feeds together with (another species).

Coccus-shaped cells. Gram-stain-negative. Nonmotile. Non-spore-forming. **Strictly anaerobic. Sugars are oxidized to acetate when an electron-accepting system is present, such as formate, methoxyl-containing benzoids, or a hydrogenotrophic methanogen.** Habitats are mesophilic, anaerobic, microbial ecosystems where complex organic matter is degraded.

DNA G+C content (mol%): 52.

Type species: ***Syntrophococcus sucromutans*** Krumholz and Bryant 1986c, 489 (Effective publication: Krumholz and Bryant 1986a, 317.)

Further descriptive information

Cells are nonmotile cocci with diameters of about 1 μ m (Krumholz and Bryant, 1986a). Gram staining is variable. Electron micrographs show a distinctly bilayered envelope, the outer membrane of which reacts with polymyxin B indicating the presence of lipids. The molar ratio of the components of the cell wall are: Glu:*m*-DAP:Ala:GluN:Mur = 1:0.95:1.65:0.9:0.85. The major cellular fatty acids are $C_{14:0}$, $C_{16:0}$, and $C_{18:0}$ (Dore and Bryant, 1989).

Comparative 16S rRNA gene sequence analysis of *Syntrophococcus* places the genus within the phylum *Firmicutes* and the family *Lachnospiraceae*.

Syntrophococcus is a strictly anaerobic chemo-organotroph that grows at mesophilic temperatures (30–44 °C) and nearly neutral pH (6.0–7.6). It grows well in a basal medium containing 30% rumen fluid, 0.5% yeast extract, and 0.5% Casitone when methoxylated benzenoids are added (Krumholz and Bryant, 1986a). This organism possesses an unusual one-carbon metabolism using sugars as electron donors and forming acetate. Formate, the methoxyl groups of benzenoids, or hydrogenotrophic methanogens serve as electron-accepting systems. Formate is reduced to acetate. The methoxyl-containing benzenoids, such as syringate, vanillin, vanillate, caffeate, ferulate, and 3,4,5-trimethoxybenzoate, are demethoxylated to the hydroxyl compounds while the methoxyl groups are utilized for concomitant acetate production. The biochemistry and metabolism of these acetogenic transformations have been studied in detail (Dore and Bryant, 1990). Lastly, hydrogenotrophic organisms such as the methanogen *Methanobrevibacter smithii*

List of species of the genus *Syntrophococcus*1. ***Syntrophococcus sucromutans*** Krumholz and Bryant 1986c, 489^{VP} (Effective publication: Krumholz and Bryant 1986a, 317.)

su.cro.mu'tans. N.L. n. *sucro* modern chemical combined form referring to all sugars; L. part. adj. *mutans* changing or converting; N.L. part. adj. *sucromutans* converting sugar.

Coccus-shaped cells. 1.0–1.3 µm in diameter, with rounded to flattened plane of division, forming short chains. Nonmotile. Does not form spores. Stains Gram-negative. Strictly anaerobic chemo-organotroph. Electron donors for growth include pyruvate, glucose, fructose, galactose, maltose, cellobiose, lactose, arabinose, maltose, ribose, xylose, salicin, and esculin. The major organic product of these carbohydrates is acetate. Compounds not used as electron donors include hydrocaffeate, gallate, protocatechuate, citrate, mannitol, fumarate, succinate, malate, aspartate, glutamate, glycine, 3-hydroxybutyrate, valine, serine, isoleucine, butyrate, pectin, and starch. Electron acceptors with the major organic products in parentheses are: formate (acetate), caffeate (hydrocaffeate), ferulate (caffeate, hydrocaffeate, acetate), syringate and 3,4,5-trimethoxybenzoate (gallate and ace-

tate), vanillin (protocatechuic aldehyde, protocatechuate, acetate), and vanillate (protocatechuate and acetate). The following compounds were not used as electron acceptors or as sole energy sources: methanol, formaldehyde, CO, ethanol, fumarate, malate, crotonate, lactate, aspartate, glutamate, glycine, valine, serine, isoleucine, 1-methoxybenzene, 4-methoxybenzoate, cinnamate, 4-hydroxycinnamate, H₂:CO₂ (4:1 v/v), and H₂:CO₂ (4:1 v/v) plus fumarate, crotonate, or caffeate. Growth also occurs with electron donors such as fructose when an H₂-CO₂-utilizing methanogen is the electron-accepting system.

Good growth occurs in an anaerobic medium containing N₂:CO₂ (4:1 v/v) gas phase, minerals, 40 mM NaHCO₃, 2 mM cysteine, 6 mM sodium formate, 6 mM fructose or xylose, 0.5% Casitone, and 30 (v/v) rumen fluid. The temperature range for growth is 30–44 °C, with an optimum at 35–42 °C. The pH range is 6.0–7.6, with an optimum of 6.4. Habitats are the rumens of hay-fed cattle.

DNA G+C content (mol%): 52 (T_m).

Type strain: S195, ATCC 43584, DSM 3224.

GenBank accession number (16S rRNA gene): AF202264, Y18191.

Family VI. **Peptococcaceae** Rogosa 1971, 235^{AL}

TAKAYUKI EZAKI

Pepto.coc.ca.ce'ae. *Peptococcus* type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Peptococcaceae* the family of *Peptococcus*.

Cocoid, curved rods, or straight rods. Motile or nonmotile; motility may be lost during cultivation. All members of the family are obligate anaerobes. Gram-positive cell-wall structure but some genera stain negative. Members of this family are chemoorganoheterotrophs, chemolithoheterotrophs or chemolithoautotrophs. Fermentative or respiratory type metabolism; some members in syntrophy with hydrogenotrophs.

Species of type genus is isolated from human intestine, vagina, and umbilicus. Most previous members of the type genus *Peptococcus* found in human and animal intestine and oral and vaginal cavities were reclassified as members of the Family XI *Incertae Sedis* as *Anaerococcus*, *Peptoniphilus*, *Fingoldia*, and *Parvimonas* (Ludwig et al., 1990; Ezaki et al., 2001). Other members of the family *Peptococcaceae* are found in various habitats including soil, terrestrial and marine sediments, sewage, or extremely thermophilic environments. Differential characteristics are given in Table 178.

Type genus: **Peptococcus** Kluyver and van Niel 1936, 400^{AL}.

Taxonomic comments

Currently, this family can be divided into at least three separate phylogenetic groups (Figure 6). The first group is comprised of *Peptococcus*, *Dehalobacter*, *Desulfitobacterium*, *Desulfonispora*, *Desulfosporosinus*, and *Syntrophobotulus*. This monophyletic group probably represents the *Peptococcaceae stricto sensu*. The second group includes *Cryptanaerobacter*, *Desulfotomaculum*, *Pelotomaculum* and *Sporotomaculum*. These genera are deep branches of the *Clostridiales* and probably represent a novel family. The last group includes only the genus *Thermincola*. Phylogenetic analyses of its relationship to the family *Peptococcaceae stricto sensu* position are ambiguous. In the absence of additional information, it was retained within this family.

Key to the genera of the family *Peptococcaceae*

Gram-stain-positive coccus, 1–2 µm in diameter. Spore formation absent. Fermentative metabolism. Optimal growth at 30–40°C in strictly anaerobic conditions. Produce caproic acid as a terminal metabolite of glucose. Found in human vagina and naval cavity. DNA G+C content is 50–51 mol% (T_m).

Genus I. *Peptococcus*

Gram-stain-positive, short rods, 1 × 2 µm. Spores not observed. Obligately anaerobic, not motile. Not fermentative, requires complex media. Phenol or 4-hydroxybenzoate required for growth. Optimal growth at 30–37°C. Isolated from a methanogenic coculture enriched from a mixture of swamp water, sewage sludge, swine waste and soil. DNA G+C content is 51 mol% (HPLC).

Genus II. *Cryptanaerobacter*

Gram-stain-negative rods, 0.5 × 2–3 µm. Spore formation absent. Obligately anaerobic flagellated bacterium. Chemolithoheterotroph, acetate is required as carbon source. Dechlorinates tetra- and trichloroethene with hydrogen as electron

donor. Grows at 25–30°C. Found in soil and sediment. DNA G+C content is 45.0–45.6 mol% (HPLC).

Genus III. *Dehalobacter*

Gram-stain-variable, curved, nonmotile rods, 0.5–0.7 × 2–5 µm. Cell wall is of Gram positive structure. Spore formation variable. Obligate anaerobe, some strains can grow under microaerophilic conditions. Fermentative and respiratory type of metabolism. Reduces halogenated alkenes and aromatic compounds, sulfite, thiosulfate, sulfur, fumarate, nitrate, various metals, and humic acids. Dechlorinates chlorophenolic compounds. Optimal growth temperature is 20–37°C. Found in soil and aquifer sediment. DNA G+C content is 45.8–48.8 mol% (T_m , HPLC).

Genus IV. *Desulfitobacterium*

Gram-stain-positive, motile rods, 0.7–1.0 × 2–5 µm. Subterminal spore formation observed. Obligate anaerobe. Fermentative metabolism. Fermentation of taurine to acetate, ammonia and thiosulfate. Optimal growth temperature is 20–37°C. Found in sewage sludge and lake sediments. DNA G+C content is 52 mol% (HPLC).

Genus V. *Desulfonispora*

Slightly curved, motile or nonmotile rods, 0.4–1.0 × 2.3–5 µm. Subterminal to terminal endospore. Obligate anaerobe. Fermentative and respiratory type of metabolism. Reduction of sulfate, thiosulfate to sulfide. Growth temperature range is 4–42°C. Found in soil and freshwater sediments. DNA G+C content is 41.6–46.9 mol% (T_m , HPLC).

Genus VI. *Desulfosporosinus*

Gram-positive cell wall structure but stains negative. Straight or curved rods, 0.3–2.5 × 2–15 µm. Central, subterminal, or terminal spores. Obligate anaerobe. Fermentative and respiratory type of metabolism. Reduction of sulfate, thiosulfate to sulfide. Growth temperature range is 30–75°C. Found in soil, freshwater and marine sediments, and hot sulfur springs. DNA G+C content is 37.5–56.3 mol% (T_m , HPLC).

Genus VII. *Desulfotomaculum*

Gram-positive cell wall structure but stains negative. Curved rods, 0.7–1.0 × 1.7–4. Central spherical endospores. Obligate anaerobe. Growth by fermentation or in syntrophy with hydrogenotrophs. Found in mesophilic or thermophilic anaerobic sludge. DNA G+C content is 52.8–53.6 mol% (T_m , HPLC).

Genus VIII. *Pelotomaculum*

Gram-positive rods, 0.6–1.0 × 1–3 µm. Central spherical endospore. Obligate anaerobe. Fermentative type of metabolism. Some organic compounds are metabolized only in syntrophy with hydrogenotrophs. Found in termite guts and anaerobic sludge. Optimal growth temperature is 30–40°C. DNA G+C content is 46.8–48.0 mol% (HPLC).

Genus IX. *Sporotomaculum*

Gram-positive cell-wall structure but stains negative. Slightly curved rods, 0.5 × 2.5–3.5 µm. Terminal spores observed. Strict anaerobe. Fermentative type of metabolism. Glycolate is oxidized

in syntrophy with hydrogenotrophs. Found in freshwater sediment. Optimal growth temperature is 15–37°C. DNA G+C content is 46.7 mol% (HPLC).

Genus X. *Syntrophobotulus*

Gram-positive rods, 0.4–0.5 × 0.6–3. Spore formation. Strict anaerobe. Chemolithotrophic growth on CO and acetate as carbon

source of the type strain. Other can grow chemolithoautotrophically with hydrogen and carbon dioxide, or chemoorganoheterotrophically linked to the reduction of metals [Fe(III), Mn(IV)] and humic acids. Optimal growth temperature is 55–60°C. Found in terrestrial hot springs. DNA G+C content is 45–48 mol% (T_m).

Genus XI. *Thermincola*

Genus I. **Peptococcus** Kluver and van Niel 1936, 400^{AL}

TAKAYUKI EZAKI

Pep.to.coc'cus. Gr. adj. *peptos* cooked, digested; Gr. n. *kokkos* a grain berry; N.L. masc. n. *Peptococcus* the digesting coccus.

Cells are Gram-stain-positive, non-spore-forming anaerobic cocci that occur singly, in pairs, and irregular mass. Chemo-organotrophs. Found in human intestine, vagina, or human umbilicus. Metabolize peptone and amino acids to acetic acid, butyric acid, isocaproic acid. Nonsaccharolytic. Cell-wall diamino acid is lysine.

DNA G+C content (mol%): 50–51 (T_m) (Ezaki et al., 1983).

Type species: **Peptococcus niger** (Hall 1930) Kluver and van Niel 1936, 400^{AL}.

Further descriptive information

Old members of the genus *Peptococcus* isolated from human intestine, vagina, or oral cavity were transferred to family *Peptostreptococaceae* fam. nov. or to family *Bacillaceae* (Ezaki et al.,

2001; Ezaki et al., 1994; Ezaki et al., 1983). *Peptococcus asacharoliticus* and *Peptococcus indolicus* reclassified as members of a new genus *Peptoniphilus*, *Peptococcus magnus* as *Finegoldia magna*, *Peptococcus prevotii* as a member of genus *Anaerococcus*, and *Peptococcus saccharolyticus* as a member of genus *Staphylococcus*.

Differentiation of the species of the genus *Peptococcus* from other genera

Differential characteristics of *Peptococcus niger* from other anaerobic cocci isolated from humans (Murdoch and Magee, 1995; Murdoch and Mitchelmore, 1991) are given in Table 179.

List of species of the genus *Peptococcus*

1. **Peptococcus niger** (Hall 1930) Kluver and van Niel 1936, 400^{AL} (“*Micrococcus niger*” Hall 1930, 409)

niger. L. adj. *niger* black.

Cells are about 0.3–1.3 µm in diameter and occur singly and in pairs, tetrads, and irregular masses. Stain Gram-stain-positive. Catalase-negative. Colonies on blood agar plate are black, minute to 0.5 mm, circular with entire margins. After several transfers, the black colonies become light gray and may not produce black color. The optimum temperature for growth is 37°C, growth may occur at 25°C

and 45°C. Carbohydrates are not fermented. Hydrogen sulfide and ammonia are produced. Metabolize peptone and amino acids to acetic, butyric, isobutyric, isovaleric, and caproic acid.

DNA G+C content (mol%): 50–51 (T_m) (Ezaki et al., 1983).

Type strain: ATCC 27731, DSM 20475, NCTC 11805, VPI 7953.

GenBank accession number (16S rDNA gene): AB036759 (VPI 7953).

Genus II. **Cryptanaerobacter** Juteau, Côté, Duckett, Beaudet, Lépine, Villemur and Bisailon 2005, 248^{VP}

PIERRE JUTEAU

Crypt.an.ae'ro.bac.ter. Gr. adj. *kryptos* hidden; Gr. pref. *an* not; Gr. n. *aer* air; *anaero* not (living) in air; N.L. masc. n. *bacter* rod; N.L. masc. n. *Cryptanaerobacter* referring to the fact that this anaerobic rod was hidden within a culture of another organism taken for pure.

Short, rod-shaped cells, 1 µm × 2 µm. **Gram-stain-positive**. Not flagellated. **Strictly anaerobic**. Sulfate, thiosulfate, nitrate, nitrite, FeCl₃, fumarate, and arsenate are not used as electron acceptors. Sulfite is not normally used even though growth stimulation has been noted in certain culture conditions.

Not fermentative. **Phenol or 4-hydroxybenzoate (4-OHB) is required for growth**. 4-OHB is believed to be an electron acceptor for anaerobic respiration. Isolated from a methanogenic consortium derived from a mixture of swamp water, sewage sludge, swine waste, and soil.

DNA G+C content (mol%): 51.

Type species: Cryptanaerobacter phenolicus Juteau, Côté, Duckett, Beaudet, Lépine, Villemur and Bisailon 2005, 249^{VP}.

Further descriptive information

Cells stain Gram-positive, and electron microscopy of thin sections reveals a typical Gram-positive cell wall. When observed by electron microscopy, cells appear particularly dark (electron-dense) (Letowski et al., 2001). The major membrane fatty acid is C_{15:0 ante}.

Colonies are obtained only in semi-solid medium (0.3% w/v agar). Colonies are 1 mm in diameter with diffuse margins and are brownish after 10 d of incubation. Growth in pure culture requires a complex medium, SBM4, composed in part of a conditioned medium. While medium conditioned by a culture of *Clostridium sporogenes* M55 (ATCC 13732, DSM 754) works best (see below), conditioned media from cultures of strain 6, the *Clostridium*-like organism from which *Cryptanaerobacter phenolicus* LR7.2 was separated, and *Enterococcus faecalis* can also be used. Optimum growth occurs under an atmosphere consisting of H₂:CO₂:N₂ (10:10:80 by vol.) at 30–37°C and pH 7.5–8.0. Growth is also possible under 100% nitrogen atmosphere or with H₂/N₂ gas mixtures (10:90, 20:80, 80:20 v/v). Even in the best culture conditions, growth is weak, and the final cell yield is ~4 × 10⁶ cells/ml.

Spores have not been observed, and both pure and co-cultures are killed when heated at 70°C for 10 minutes. However, because pasteurization was used during the enrichment of *Cryptanaerobacter phenolicus*, it is likely that cells can sporulate under certain environmental conditions that are not reproduced in pure cultures or in defined co-cultures.

An important characteristic of *Cryptanaerobacter phenolicus* is its growth dependency on phenol and 4-OHB. When phenol is

present, it is first carboxylated into 4-OHB, which is dehydroxylated into benzoate (phenol → 4-OHB → benzoate). Phenol carboxylation is a reversible reaction in which the decarboxylation is thermodynamically favored at equilibrium. The overall reaction is pulled in the direction of benzoate formation because the dehydroxylation reaction maintains a very low concentration of 4-OHB. As a consequence, when 4-OHB is given to *Cryptanaerobacter phenolicus* instead of phenol, most of it is first transformed into phenol until the 4-OHB concentration is low enough to enable the transformation of phenol (4-OHB → phenol → 4-OHB → benzoate). Phenol and 4-OHB are not a source of carbon since they are stoichiometrically transformed into benzoate, which is not further metabolized. Nevertheless, no growth is observed in the absence of phenol or 4-OHB, which means that the strain cannot grow fermentatively. Moreover, the cell yield is proportional to the concentration of these compounds up to the optimal values of 6.5 mM for 4-OHB and 3.5 mM for phenol. These observations indicate that *Cryptanaerobacter phenolicus* uses these transformations as an energy source for growth. Presumably, these transformations represent an unusual anaerobic respiration in which 4-OHB is an electron acceptor. However, neither the electron donor nor the carbon source has been identified.

Based on analysis of its 16S rRNA gene sequence, *Cryptanaerobacter* is related to the genus *Pelotomaculum* (Figure 173).

Enrichment and isolation procedures

The isolation of the type strain is quite a long story, and nearly 20 years separate the first report of the enrichment and the defining publication. The original consortium was made by mixing swamp water, sewage sludge, swine waste, and soil (Beaudet et al., 1986). Major steps toward the isolation included pasteurization of the consortium (Létourneau et al.,

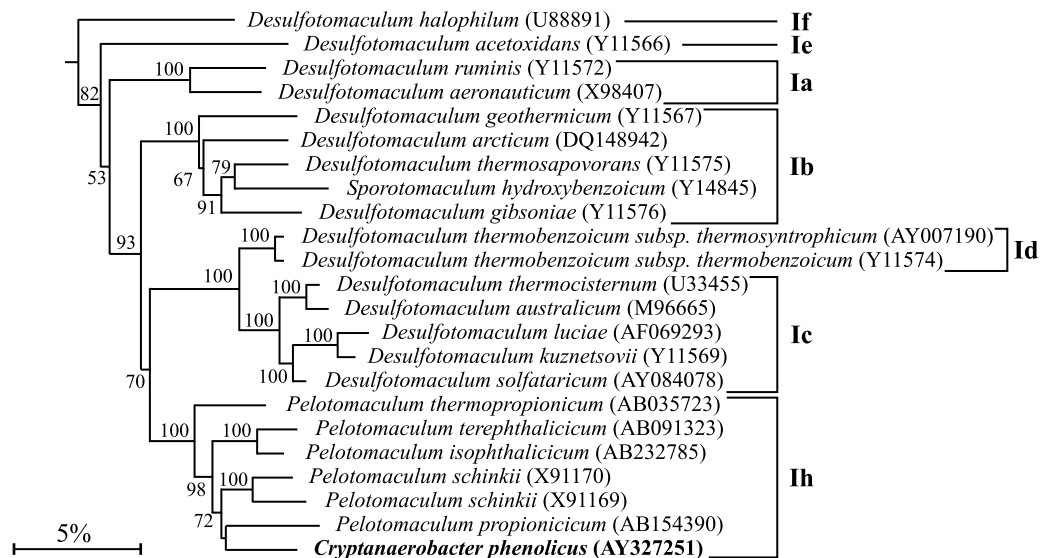

FIGURE 173. Phylogeny of *Cryptanaerobacter*. The tree shows the 16S rRNA gene sequence analysis of *Desulfotomaculum* cluster I, as first defined by Stackebrandt et al. (1997) and amended by Kuever et al. (1999) and Imachi et al. (2006). It includes all *Pelotomaculum* species, which form with *Cryptanaerobacter phenolicus* the subcluster Ih, and representatives of the other subclusters, except subcluster Ig that does not contain any validly named species. The tree was constructed by the Fitch–Margoliash method using a DNA distance matrix, itself based on the Kimura two-parameter model, with PHYLIP 3.66 package programs. One thousand bootstrap trees were generated, and bootstrap confidence levels (shown as percentages above nodes) were determined. *Bacillus subtilis* (Z99104, position 171497–173046) was used as the outgroup organism. In order to include organisms for which the available 16S rDNA sequences are shorter (particularly *Pelotomaculum schinkii*), only 1357 nucleotides (*Escherichia coli* position 124–1488) were used for *Cryptanaerobacter phenolicus* (of 1529 available). Bar = 5 nucleotide substitutions per 100 nucleotide.

1995), use of antibiotics (Li et al., 1996), separation of the two bacteria (strain 6 and strain 7) of the resulting co-culture by Percoll density-gradient centrifugation (Letowski et al., 2001), and finally the use of a mixture of fresh medium and conditioned medium from strain 6 or *Clostridium sporogenes* to obtain stable liquid cultures and colonies in soft (0.3%) agar (Juteau et al., 2005). For some time during this process, the co-culture of strains 6 and 7 was thought to be one axenic culture (Li et al., 1996).

Best growth of *Cryptanaerobacter* is obtained with a mixture of fresh and conditioned medium. The growth medium contains (per liter): yeast extract, 5 g; NaHCO₃, 1.5 g; KH₂PO₄, 0.27 g; K₂HPO₄, 0.35 g; NH₄Cl, 0.53 g; resazurin, 0.6 mg; MgCl₂·6H₂O, 0.1 g; CaCl₂·2H₂O, 77 mg; FeCl₂·4H₂O, 2 mg; pyridoxine, 0.15 mg; biotin, 30 µg; folic acid, 30 µg; riboflavin, 76 µg; thiamine, 76 µg; nicotinic acid, 76 µg; pantothenic acid, 76 µg; *p*-aminobenzoic acid, 76 µg; thioctic acid, 76 µg; vitamin B₁₂, 2 µg. The medium is made anaerobic by boiling, sparging with a H₂:CO₂:N₂ 10:10:80 (by vol.) gas mixture and adding Na₂S·9H₂O (53 mg/L). The pH is then adjusted to 7.5–7.8. The medium is then conditioned by growing *Clostridium sporogenes* M55 for 5–8 d. After growth, the culture is autoclaved, suspended solids are removed by centrifugation and filtration on cheesecloth, and the broth is sterilized by autoclaving. The final growth medium (SBM4) contains 62% of the fresh medium (prepared without Na₂S), 38% of conditioned medium, and 3 mM of 4-hydroxybenzoate.

Maintenance procedures

The type strain can be maintained at –80°C in SBM4 medium with 10% glycerol or as lyophilized culture. However, revival of preserved stock cultures can be lengthy, so the strain is also maintained by subculturing in SBM4 medium.

Differentiation of the genus *Cryptanaerobacter* from other genera

Table 180 lists physiological characteristics differentiating *Cryptanaerobacter* from its closest relatives, which are species of the genus *Pelotomaculum*. The ability to transform phenol

and 4-OHB to benzoate and the requirement of these compounds for growth are the most important distinguishing characters of *Cryptanaerobacter*. Unlike the *Pelotomaculum* species, sporulation has not been observed for *Cryptanaerobacter*. However, this criterion should not be the sole basis for differentiation because *Cryptanaerobacter* was isolated following pasteurization, suggesting that spores can be formed under certain environmental conditions. The highest 16S rRNA gene sequence similarity is with *Pelotomaculum schinkii* (94.5% over 1360 nt) and *Pelotomaculum isophthalicum* (94.3% over 1460 nt).

Taxonomic comments

At the time *Cryptanaerobacter* was described, just one species was known in the genus *Pelotomaculum*, *Pelotomaculum thermopropionicum*. It possessed only 90% 16S rRNA sequence similarity with *Cryptanaerobacter phenolicus*. Since then, other species of *Pelotomaculum* have been described which appear much more similar to *Cryptanaerobacter*. The most closely related species possesses 94.5% 16S rRNA gene sequence similarity (Figure 173). As a group, *Cryptanaerobacter* and *Pelotomaculum* form the *Desulfotomaculum* subcluster 1h, as proposed by Imachi et al. (2006). Although this group is genetically related, its unusual energy metabolism still distinguishes *Cryptanaerobacter*. The sole energy source is the transformation of 4-OHB into benzoate. In contrast, all *Pelotomaculum* species are capable of syntrophic growth by using propionate, primary alcohols, low molecular weight aromatic compounds, lactate, or other compounds in association with hydrogenotrophic methanogens. Some *Pelotomaculum* species are also capable of fermentative growth. However, none of them can use phenol or 4-OHB. While the ability of *Cryptanaerobacter* to grow syntrophically has not been tested, indirect evidence suggests that it does not. It grows under an atmosphere of 80% H₂. Within the original consortium, the transformation of phenol was insensitive to the methanogen inhibitor 2-bromoethanesulfonic acid (Bécharde et al., 1990). Given the importance of this property to classification within the genus *Pelotomaculum*, additional tests should be performed to confirm this conclusion.

TABLE 180. Characteristics differentiating *Cryptanaerobacter* from some closely related bacteria^a

	<i>Cryptanaerobacter phenolicus</i>	<i>Pelotomaculum isophthalicum</i>	<i>Pelotomaculum propionicum</i>	<i>Pelotomaculum schinkii</i>	<i>Pelotomaculum terephthalicum</i>	<i>Pelotomaculum thermopropionicum</i>

^aSymbols: +, >85% positive; –, 0–15% positive; ND, not determined.

^bNo spore has been observed and cultures are not heat resistant. However, pasteurization has been used during enrichment, which suggests that *Cryptanaerobacter phenolicus* could sporulate in nature.

^cPhenol and 4-OHB are stoichiometrically transformed into benzoate, which is not further metabolized.

^dSulfite not used in SBM4 medium. Stimulation by sulfite has been reported by Letowski et al. (2001) with another medium, but they did not confirm that the bacterium used it as an electron acceptor.

List of species of the genus *Cryptanaerobacter*

1. ***Cryptanaerobacter phenolicus*** Juteau, Côté, Duckett, Beaudet, Lépine, Villemur and Bisaillon 2005, 249^{VP}

phe.no'li.cus. N.L. n. *phenol* -olis phenol; N.L. masc. adj. *phenolicus* relating to phenol.

Since it is the only species of *Cryptanaerobacter*, all the characteristics described for the genus apply to *Cryptanaerobacter phenolicus*. None of the following compounds structurally related to 4-OHB or phenol are transformed or used for growth: 4-hydroxybenzamide, 4-hydroxysulfonic acid, 4-hydroxyacetophenone, 4-hydroxybenzoic alcohol, hydroquinone, 4-chlorophenol, 4-hydroxycinnamic acid, 4-hydroxybenzoic hydrazide, 4-hydroxybenzaldehyde, 4-hydroxyphenyl pyruvic acid, 3-(4-hydroxyphenyl) propionic acid, *p*-cresol, 3-OHB, 4-hydroxypyridine, catechol, 2-bromophenol, 2-chlorophenol, 2-fluorophenol, 2-aminophenol.

DNA G+C content (mol%): 51 (HPLC).

Type strain: LR7.2, ATCC BAA-820; DSM 15808.

GenBank accession number (16S rRNA gene): AY327251.

Acknowledgements

Most of the research that led to the isolation and description of *Cryptanaerobacter phenolicus* was directed by Dr Jean-Guy Bisaillon (now retired) at the INRS – Institut Armand-Frappier (Laval, Québec, Canada) over a 15-year period, with the technical assistance of Louis Racine. Dr Pierre Juteau, author of this text, joined them at the end. The following graduate students were also involved: Geneviève Béchar, Valérie Côté, Marie-France Duckett, Lynda Létourneau, Jaroslaw Letowski, and Tong Li. This work was supported by grants from the Natural Sciences and Engineering Research Council of Canada (NSERC) and the Fonds pour la Formation des Chercheurs et l'Aide à la Recherche (FCAR).

Cells with a diameter of 0.3–0.5 µm and 2–3 µm long are **rod-shaped with tapered ends**. Appear singly or in pairs; nonspore-forming. Cells stain Gram-negative. **Motile**, having one lateral flagellum per cell. **Strictly anaerobic**. Electron micrographs indicate that cells are surrounded by an S-layer. Cell wall contains the **peptidoglycan type A3γ**. Menaquinones and *b*-type cytochromes are present. **Mesophilic** with optimal growth 25–35°C; no growth at 37°C. **Chemolithoheterotrophic**, using dehalorespiration as method of metabolism and acetate as carbon source.

DNA G+C content (mol%): 45.

Type species: ***Dehalobacter restrictus*** Holliger, Hahn, Harmsen, Ludwig, Schumacher, Tindall, Vazquez, Weiss and Zehnder 1998a, 631^{VP} (Effective publication: Holliger, Hahn, Harmsen, Ludwig, Schumacher, Tindall, Vazquez, Weiss and Zehnder 1998b, 319.).

Further descriptive information

Phylogenetic analysis based on 16S rRNA gene sequences (Figure 6) shows that the genus *Dehalobacter* is a member of the family *Peptococcaceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*. The closest relative of the genus *Dehalobacter* is *Syntrophotobolus glycolicus* with an overall 16S rRNA sequence identity of 92.9%. Interestingly, the genus *Desulfitobacterium*, containing several species that reductively dechlorinate chlorinated compounds such as chloroethenes and chlorophenols, also affiliates with the family *Peptococcaceae* and has 16S rRNA sequence identities of 90.8% and lower compared with the genus *Dehalobacter*.

Although *Dehalobacter* cells stain Gram-negative, electron microscopy of sections did not indicate the presence of an outer membrane, but rather an S-layer. Freeze-etch preparation showed a hexagonal structure on the cell surface presumably caused by S-layer proteins. The peptidoglycan contains L-alanine, D-glutamic acid, LL-diaminopimelic acid, and glycine, and are

cross-linked between positions 3 and 4 with one glycine as inter-peptide bridge. Only some strains of the genus *Propionibacterium* have this type of peptidoglycan.

Enrichment and isolation procedures

The type strain *Dehalobacter restrictus* strain PER-K23 was isolated from a tetrachloroethene-dechlorinating packed-bed column which was filled with river Rhine sediment and ground anaerobic granular sludge from a sugar refinery. Tests with different substrates showed that hydrogen resulted in the highest dechlorination rates in batch enrichment cultures. Hydrogen-consuming dehalorespiring bacteria have to compete with methanogens and homoacetogens for the electron donor. To create advantageous conditions for tetrachloroethene-dehalorespiring bacteria and at the same time avoid too high and toxic concentrations of tetrachloroethene, a two-liquid phase system (water/hexadecane) was used. This allowed the addition of large amounts of tetrachloroethene to the batch culture with tetrachloroethene concentrations in the medium below saturation, and having a continuous supply of the aqueous phase tetrachloroethene from the "reservoir" present in the organic phase. Dechlorination was followed by monitoring chloride concentration in the specially designed medium low in chloride ions. Enrichment was obtained with serial dilutions. Colonies for pure culture isolation were only obtained if special care was taken to use soft agar at a temperature just above solidification (approx. 42°C) for agar shake production and rapid cooling of the inoculated tubes.

Maintenance procedure

No specific information on suitable procedures for the maintenance of *Dehalobacter* species is available. It may be assumed that procedures satisfactory for other strictly anaerobic bacteria will also be suitable for the maintenance of *Dehalobacter* isolates.

List of species of the genus *Dehalobacter*

1. ***Dehalobacter restrictus*** Holliger, Hahn, Harmsen, Ludwig, Schumacher, Tindall, Vazquez, Weiss and Zehnder 1998a, 631^{VP} (Effective publication: Holliger, Hahn, Harmsen, Ludwig, Schumacher, Tindall, Vazquez, Weiss and Zehnder 1998b, 319.)

re.stric'tus. L. adj. *restrictus* limited, confined, referring to the limited substrate range utilized.

Cells are rod-shaped and have tapered ends, are 0.3–0.5 µm in diameter and 2–3 µm long. They appear singly or in pairs, are motile, and nonspore-forming. Cells stain Gram-negative and are surrounded by an S-layer. Cell wall consists of type A3γ peptidoglycans (L-alanine, D-glutamic acid, LL-diaminopimelic acid, and glycine; cross-linked between positions 3 and 4 with a glycine interpeptide bridge). Menaquinones (MK-7 and MK-8 mainly, minor amounts of MK-6 and MK-9) and *b*-type cytochromes are present. Strictly anaerobic with no catalase and no superoxide dismutase.

Chemolithoheterotrophic using only H₂ as electron donor and tetra- or trichloroethene as terminal electron acceptors. *cis*-1,2-Dichloroethene as dechlorination product. Substrates such as lactate, pyruvate, propionate, butyrate, acetate, formate, succinate, fumarate, glycine, alanine, aspartate, glutamate, methanol, ethanol, propanol, glucose, fructose, xylose, glycerol, acetoin, and CO are not utilized in the presence or in the absence of tetrachloroethene. Nitrate, nitrite, fumarate, dimethyl sulfoxide, trimethylamine *N*-oxide, Fe(III), Mn(IV), sulfate, sulfite, thiosulfate, and sulfur are not reduced. Acetate serves as carbon source. Growth factors required in a defined medium are ferrous iron, thiamine, cyanocobalamin, arginine, histidine, and threonine. Optimal growth at 25–35 °C and pH 6.8–7.6.

DNA G+C content (mol%): 45.3 ± 0.3 (HPLC).

Type strain: PER-K23, DSM 9455.

GenBank accession number (16S rRNA gene): U84497.

Genus IV. *Desulfitobacterium* Utkin, Woese and Wiegel 1994, 615^{VP}

BOGUSLAW LUPA AND JUERGEN WIEGEL

De.sul.fi.to.bac.te'ri.um. L. pref. *de* from, off, away; N.L. n. *sulfis* sulfite; N.L. masc. n. *bacter* rod; N.L. neut. n. *Desulfitobacterium* rod-shaped bacterium that reduces sulfite.

Cell wall is of **Gram-positive** structure but may stain **Gram-negative or -positive** depending on the strain. Exponential-growth phase cells are **straight or curved rods**, 2–5 µm in length, depending on the species and strain. Although the physiology is obligately anaerobic; certain species tolerate microaerophilic culture conditions (< 5% air in N₂ head gas phase); **mesophilic** and **heterotrophic**. *Desulfitobacterium* species use a variety of chlorinated phenols and/or alkenes as electron acceptors during dehalorespiration (also called halorespiration or chloridogenesis). Furthermore, they reduce sulfite, thiosulfate, sulfur, fumarate (forming succinate), and nitrate, but not sulfate, in the presence of various electron donors. Yeast extract as growth supplement is required; some strains grow only using pyruvate (forming lactate + acetate + CO₂), others can utilize various sugars. Four species are validly published, *Desulfitobacterium dehalogenans*, *Desulfitobacterium chlororespirans*, *Desulfitobacterium hafniense*, and *Desulfitobacterium metallireducens*. For differentiation of the species, see Table 181.

DNA G+C content (mol%): 45–48.8.

Type species: ***Desulfitobacterium dehalogenans*** Utkin, Woese and Wiegel 1994, 615^{VP}.

Further descriptive information

Most species are motile, usually equipped with one to several terminal, rarely lateral, flagella. Most species and strains are spore-forming. Spores are located terminally or subterminally and usually appear in the late-exponential or early stationary growth phase (Bouchard et al., 1996; Christiansen et al., 1998; Finneran et al., 2002; Sanford et al., 1996; Utkin et al., 1994). The genus is recognized as one of the most important groups of anaerobic dehalogenating bacteria (Villemur et al., 2006). Members of the genus dechlorinate aromatic and

alkyl compounds, including some of the most problematic pollutants, e.g., chlorinated phenols, chlorinated ethenes, and hydroxy polychlorinated biphenyls (HOPCBs) (Christiansen and Ahring, 1996; Finneran et al., 2002; Sanford et al., 1996; Utkin et al., 1994; Wiegel et al., 1991).

Molecular investigations. The organization of the genes encoding the reductive dehalogenases has been characterized in many of species of *Desulfitobacterium*. The majority of the described chloroaromatic dehalogenases belong to the CprA family and are encoded by the *cprA* gene. These genes are usually linked to the *cprB* gene, which encodes an intrinsic membrane protein. These genes form an apparent operon *cprBA*. Usually, the *cprB* gene is upstream of *cprA*, except for *cprA₅B₅* from *Desulfitobacterium hafniense* PCP-1 (Thibodeau et al., 2004). The chloroethyl reductive dehalogenases, which constitute the PceA enzyme family, are encoded by the *pceA* genes and are located upstream to another intrinsic membrane protein encoded by the *pceB* gene. Genes of both dehalogenase families, *cprBA* and *pceAB*, are believed to be co-expressed (for a review, see Villemur et al., 2006). In addition, *Desulfitobacterium* possesses reductive dehalogenases that are not members of either family. Genomic sequencing has also identified genes with high similarity to either *cprA* and *pceA*. However, the function of these genes has not been confirmed experimentally. In all these cases, the genes are denoted as *rdhA*.

In *Desulfitobacterium dehalogenans*, *cprBA* appears to be part of a larger operon containing five additional ORFs: *cprKZEBACD*. A sixth gene, *cprT*, is located immediately upstream and is divergently transcribed (Smidt et al., 2000). CprC possesses six predicted transmembrane domains. It and CprK are involved in the regulation of *cprA* expression (Gabor et al., 2006; Pop et al., 2004, 2006). CprD, CprE, and CprT are predicted to be

TABLE 181. Comparative characteristics of the validly published *Desulfitobacterium* species

Characteristic	<i>Desulfitobacterium dehalogenans</i>	<i>Desulfitobacterium chlororespirans</i>	<i>Desulfitobacterium hafniense</i>	<i>Desulfitobacterium metallireducens</i>
Shape	Straight or slightly curved rod	Curved rod	Curved rod	Curved rod
Size (µm)	2.5–4 × 0.5–0.7	3–5 × 0.5–0.7	3.3–6 × 0.6–0.7	2–5 × 0.5
Motility	+	+	+	–
Flagella (no./position)	1–4/terminal	1–2/terminal	1–2/terminal	–
Gram stain	+	–	–	–
Spores observed	–	Terminal	Terminal	–
Colony morphology	Spherical or slightly irregular, translucent, white 2–3 mm in diameter	White, round, smooth, 1–2 mm	No growth on aerobic blood agar plates	Round, smooth, domed, white, entire
O ₂ relationship	Obligately anaerobic, slightly aerotolerant	Obligately anaerobic	Obligately anaerobic, some strains aerotolerant	Obligately anaerobic
Isolated from	Methanogenic freshwater sediment	Residential compost soil	Municipal sludge, feces	Uranium-contaminated shallow aquifer sediment
DNA G+C content (mol%)	45	48.8	47	ND
<i>Growth optima:</i>				
pH	7.5 (6.0–9.0)	6.8–7.5	7.0	7.0
Temp. (°C)	38 (13–45)	37 (15–37)	37	30 (20–37)
Electron donors ^a	H ₂ , for, lac, pyr, YE	H ₂ , for, lac, pyr, but, mal, cro, YE	H ₂ , for, cro, eth, lac, pyr, but, YE, van, syr, ver, ser	lac, for, but, eth, bOH, pyr, mal
Electron acceptors ^b	SO ₃ ²⁻ , S ₂ O ₃ ²⁻ , S, NO ₃ ⁻ , fum, HA, AQDS, IT, cys, Fe(III) PP, Se(VI), MnO ₂	SO ₃ ²⁻ , S ₂ O ₃ ²⁻ , S, Fe(III) PP, Se(VI), MnO ₂	SO ₃ ²⁻ , S ₂ O ₃ ²⁻ , NO ₃ ⁻ , fum, As(V), Fe(III), IT	Fe(III), Mn(IV), Cr(VI), AQDS, HA, S, S ₂ O ₃ ²⁻ , fum
Dechlorinated compounds ^c	CP, DCP, TCP, TeCP, PCP, BP, DBP, 2B4CP at <i>ortho</i> positions, 3Cl4HOPA, HOPCIBs, TCMP, TCHQ, PCE, 2,6DC4RPs, 2C4RPs	DCP; TCP at <i>ortho</i> positions, TBP, 3Cl4HOB, 3Cl4HOPA, TCMP, TCHQ, BXN, IXN, DBHB	PCP, TeCP, TCP at <i>ortho</i> ; DCP at <i>ortho</i> and <i>meta</i> ; 3Cl4HOPA, PCE, TCMP, TCHQ, ATIA	3Cl4HOPA, TCE, PCE
Carbon source(s) ^a	pyr, lac	pyr	pyr, trp, van, lac	lac

^aAbbreviations are: bOH, butanol; but, butyrate; cro, crotonate; eth, ethanol; for, formate; lac, lactate; mal, malate; pyr, pyruvate; ser, serine; syr, syringate; trp, tryptophan; van, vanillate; ver, verartol; YE, yeast extract.

^bAbbreviations are: AQDS, anthraquinone-2,6-disulfonate; cys, cysteate (alanine-3-sulfonate); fum, fumarate; HA, humic acid; IT, isethionate (2-hydroxyethanesulfonate); PP, pyrophosphate.

^cAbbreviations are: ATIA, 5-amino-2,4,6-triiodoisophthalic acid; BP, 2-bromophenol; BXN, bromoxynil (3,5-dibromo-4-hydroxybenzonitrile); CP, 2-chlorophenol; DBHB, 3,5-dibromo-4-hydroxybenzoate; DBP, 2,6-dibromophenol; DCP, dichlorophenol, including: 2,3-DCP; 2,4-DCP; 2,6-DCP, 3,5-DCP; HOPCIB, hydroxy polychlorinated biphenyl, including: 3,5-Cl-4-HOBP; 3,4',5-Cl-4-HOBP; 3,3',5,5'-Cl-4,4'-diHOBP; IXN, ioxynil (3,5-diiodo-4-hydroxybenzonitrile); PCE, perchloroethene (tetrachloroethene); PCP, pentachlorophenol; TBP, 2,4,6-tribromophenol; TCE, trichloroethene; TCHQ, tetrachlorohydroquinone; TCMP, 2,3,5,6-tetrachloro-4-methoxyphenol; TCP, trichlorophenol, including: 2,3,4-TCP; 2,3,6-TCP; 2,4,6-TCP; TeCP, tetrachlorophenol, including: 2,3,4,6-TCP; 2,3,4,5-TeCP; 2,3,5,6-TeCP; 2,6DCl4RPs, 2,6-dichloro-4-R-phenols, (where R is -H, -F, -Cl, -NO₂, -CO₂, or -COOCH₃); 2B4CP, 2-bromo-4-chlorophenol; 2C4RPs, 2-chloro-4-R-phenols (where R is -H, -F, -Cl, -Br, -NO₂, -CO₂, -CH₂CO₂, or -COOCH₃); 3Cl4HOPA, 3-chloro-4-hydroxyphenylacetate.

involved in proper folding of the dehalogenase and insertion of the cofactors (for a review, see Villemur et al., 2006). The reductive dehalogenase of *Desulfitobacterium chlororespirans* is encoded by an operon with the organization of *cprKBABAC*, where the individual genes are homologous to those in *Desulfitobacterium dehalogenans* (Villemur et al., 2006). *Desulfitobacterium hafniense* DCB-2 contains multiple copies of the *cpr* genes. One cluster is similar in organization to that found in *Desulfitobacterium dehalogenans*. The other gene clusters are unlinked and include *cprBA*, *cprKBA₄rdhB*, *cprKBA₂BA₃KZD*, *rdhACABCTK*, and *rdhKABC*. *Desulfitobacterium hafniense* (basonym *Desulfitobacterium frapieri*) PCP-1 harbors two dehalogenase gene clusters, *cprABA* and *cprA₃B₅*, and is thus able to dehalogenate chlorophenols substituted in both the *ortho*- and *meta*-positions. Strains, *Desulfitobacterium hafniense* TCE-1 and Y51, contain *pceABCT* gene clusters, and strain *Desulfitobacterium hafniense* PCE-S only contains the *pceAB* genes (for a review, see Villemur et al., 2006).

Enzymology. The reductive dehalogenases are indispensable for the ability of the genus *Desulfitobacterium* to respire halogenated compounds. On the basis of their substrate speci-

ficity, two groups of dehalogenases are distinguished: chlorophenol reductive dehalogenases (the *CprA* family) and chloroalkyl reductive dehalogenases (the *PceA* family). Strains which dehalogenate both chloroaromatic and chloroaliphatic compounds possess two separate enzyme systems, one for each class of substrate. The majority of the reported dehalogenases are membrane-associated. The B subunits of both types of dehalogenases contain predicted hydrophobic domains and are relatively small, with less than 100 amino acids. The A subunits do not contain transmembrane motifs, but their N-terminal amino acid sequences possess signal peptides with a TAT motif. Thus, it is likely that the dehalogenases are anchored in the membrane through the B subunits, with the A subunits on the outside of the cytoplasmic membrane facing the cell wall. All the dehalogenases tested also contain corrinoid prosthetic groups and Fe-S clusters involved in electron transport (for a review, see Villemur et al., 2006).

The *ortho*-chlorophenol reductive dehalogenase, which catalyzes the dehalogenation of 3-chloro-4-hydroxyphenylacetate (3Cl4HOPA), was purified from membrane fractions of

Desulfitobacterium dehalogenans under strictly anaerobic conditions (van de Pas et al., 1999). The enzyme has a molecular mass of 45,300, which is consistent with the removal of the 42 amino acid leader sequence from the translated polypeptide. The primary sequence and the redox properties are similar to those of the haloalkene reductive dehalogenase purified from *Dehalobacter restrictus*. *Desulfitobacterium hafniense* strains, such as strain PCP-1, which carry out the dechlorination of *ortho*-, *meta*-, and *para*-chlorosubstituted aromatic compounds, harbor separate, inducible enzyme systems for the *ortho* as well as for *meta*- and *para*-dechlorination reactions (Bouchard et al., 1996; Gauthier et al., 2006). Additional dehalogenases have been purified and characterized. A 3Cl4HOPA dehalogenase with a subunit molecular mass of 47,000 has been purified from the membrane fraction of *Desulfitobacterium hafniense* strain DCB-2 (Christiansen et al., 1998). This enzyme is inhibited by sulfite, azide, and nitrate but not by sulfate (Boyer et al., 2003). A CprA-type enzyme with a subunit molecular mass of 50,000 has also been purified from *Desulfitobacterium hafniense* strain Co23 (Löffler et al., 1996). This enzyme dechlorinates various *ortho*-chlorophenolic compounds and has a substrate specificity similar to that of the 3Cl4HOPA dehalogenase from *Desulfitobacterium dehalogenans*. *Desulfitobacterium hafniense* strain PCP-1 contains a membrane-associated CprA-type 3,5-dichlorophenol (DCP) reductive dehalogenase, with a molecular mass of 57,000 Da, which is sensitive to inhibition by 2.5 mM sulfite and 10 mM cyanide but not by sulfate and nitrate (Thibodeau et al., 2004). The phenolic hydroxyl group is required for binding of the substrate (Krasotkina et al., 2001). This strain also contains CrdA, which is a representative of a different family of reductive dehalogenases. This enzyme is an oxygen-sensitive 2,4,6-trichlorophenol (TCP) dehalogenase with a subunit molecular mass of 37,000 Da (Boyer et al., 2003).

Enzymes that dechlorinate aliphatic compounds belong to the PceA family of reductive dehalogenases and have been purified from different *Desulfitobacterium hafniense* strains. The substrate-inducible PceA derived from strain Y51 is found in the periplasm. The translation product has a molecular mass of 61,000 Da, but it is 58,000 Da after removal of the signal peptide (Suyama et al., 2002). A similar enzyme with a molecular mass of 59,000 Da was found in strain TCE-1 (van de Pas et al., 2001a). The enzyme from strain PCE-S has a molecular mass of 65,000 Da and is inhibited by sulfite (Miller et al., 1997).

The dissimilatory sulfite reductases (DsrAB) are conserved siroheme-containing enzymes (Klein et al., 2001) and catalyze the reduction of sulfite to sulfide. This enzyme is essential for sulfur respiration. In *Desulfitobacterium dehalogenans* and *Desulfitobacterium hafniense* DCB-2, it is a heterotetramer ($\alpha_2\beta_2$) encoded by *dsrAB* (Klein et al., 2001). The α -subunit contains the (Cys-X₅-Cys)-X_n-(Cys-X₃-Cys) sequence motif required for binding of the [Fe₄S₄]-siroheme cofactor (Crane et al., 1995).

Energy metabolism. *Desulfitobacterium* species are capable of dehalorespiration or halo-respiration, i.e., the process coupling reductive dechlorination (dehalogenation) with energy metabolism and growth. The term "chloridogenesis" is also proposed for this process. This term may be more accurate, because the redox state of chloride anion released during dehalorespiration does not change. Energy conservation during halo-respiration was demonstrated by growth yield studies and stoichiometric analyses (Mackiewicz and Wiegel, 1998). The reductive dechlorination

of 3Cl4HOPA is coupled with ATP synthesis and pyruvate, formate, or H₂ oxidation. During pyruvate oxidation to acetate, 1 ATP is obtained per mol of acetate through substrate level phosphorylation, and 1 ATP is obtained per chloride ion formed via chloridogenesis (dehalorespiration) and electron transport phosphorylation (Mackiewicz and Wiegel, 1998). Dehalogenation with formate as the electron donor yields only 1 ATP via electron transport phosphorylation. Chlorophenol respiration in *Desulfitobacterium dehalogenans* is not an efficient respiratory pathway since cells recover only a small fraction of the energy theoretically available (van de Pas et al., 2001c). Free energy calculations suggest that 2 ATPs could be formed per chlorine removed with H₂ as electron donor (El Fantroussi et al., 1998). However, the cell yields are consistent with only one-half of that value. Even though the efficiency is low, the haloaromatic compounds are the preferred electron acceptors. Thus, when *Desulfitobacterium dehalogenans* is provided with equimolar concentrations of various electron acceptors, 3Cl4HOPA is reduced first. As the concentration drops, it is utilized concomitantly with the other electron acceptors (Mackiewicz and Wiegel, 1998).

Genetics. Tools for gene cloning and inactivation for *Desulfitobacterium dehalogenans* have been developed, and halo-respiration-deficient mutants have been isolated (Smidt et al., 1999, 2001, 2000).

Industrial applications. Members of the genus are of industrial importance for degradation of toxic environmental pollutants. All the reported species, with the exception of *Desulfitobacterium hafniense* strain DP7 (van de Pas et al., 2001b), carry out reductive dechlorinations in bioremediation reactors (Holliger et al., 1999; Tartakovsky et al., 1999). Members of the genus also have features desired for *in situ* bioremediation, such as relatively rapid growth, broad substrate specificities for halogenated compounds (Utkin et al., 1995), and long-term survival in the environment due to spore formation (Sanford et al., 1996). In addition, some of the species respire toxic metals and metalloids, and they can use MnO₂, As(V), Fe(III) gel, Fe(III) pyrophosphate, Fe(III) citrate, Cr(VI), Se(VI), and As(V) as terminal electron acceptors (Niggemyer et al., 2001).

Desulfitobacterium dehalogenans forms a biofilm on rotating pads in a continuous flow fermenter (Knoblich, 1996; Wiegel et al., 1991). The rotating pads give this fermenter an exceptionally high surface area. Upon formation of the biofilm, the transformation rates of the chlorinated compounds are 10–20 times higher than in the batch culture. This biofilm is stable at dilution rates greater than the generation time of the bacterium and even when diluted sewage sludge contaminated with chlorophenol is used as the feedstock. This system could be used as a biofilter for bioremediation of other compounds (Knoblich and Wiegel, unpublished data; Knoblich, 1996). *Desulfitobacterium hafniense* PCP-1 was the major constituent (20%) of the microbial community in a biofilm formed in a pentachlorophenol (PCP)-degrading, methanogenic reactor and was indispensable for the efficient operation of the reactor (Lanthier et al., 2005).

Degradation of 2,4-DCP in anaerobic environments, such as methanogenic freshwater sediment, is accomplished by a consortium of at least five sequentially interacting species of bacteria and archaea. The initial step is a reductive dehalogenation catalyzed by bacteria such as *Desulfitobacterium dehalogenans*, which

forms 4-chlorophenol (4-CP). The *para*-dehalogenation of 4-CP is carried out by *Desulfitobacterium hafniense*-like strains (Christiansen and Ahring, 1996). In an enrichment from a freshwater sediment, 2,4-DCP and 4-CP dechlorination occurs in the temperature range of 18–40°C (Kohring et al., 1989b). Nitrate inhibits this process. Adding sufficient lactate to completely reduce the nitrate to N₂ and ammonia alleviates inhibition by preventing the accumulation of lethal concentrations of nitrite. Addition of sulfate to enrichments reduces the dehalogenation rate only to a small extent but strongly inhibits methanogenesis, presumably because the sulfate reducers outcompete the methanogens for H₂ (Kohring et al., 1989b).

Natural microbial communities may be adapted to utilize particular chlorophenols. Following adaptation, these communities utilize these specific chlorophenols at a high rate without a lag phase (Hale et al., 1990, 1991; Kohring et al., 1989a, 1989b; Zhang and Wiegel, 1992). However, the enrichments for specific chlorophenols are usually not adapted for utilizing other isomers of chlorophenol, presumably because a different bacterium is required to use each isomer, except when strains similar to *Desulfitobacterium hafniense* PCP-1 are present.

Desulfitobacterium hafniense strain DCB-2 reduces humic acids or their analog anthraquinone-2,6-disulfonate (AQDS). This process may be utilized to generate electricity for more than 24 h in a microbial fuel cell. H₂, formate, lactate, pyruvate, and ethanol sustain electricity generation, but not acetate, propionate, and butyrate (Milliken and May, 2007).

Enrichment and isolation procedures

The majority of strains were isolated either from methanogenic freshwater sediments, soils, compost soils, sewage sludge, aquifers, or groundwater polluted with chlorinated organic compounds or from bioreactors (El Fantroussi et al., 1998; Fetzer, 1998; Gerritse et al., 1999; Holliger et al., 1998b; Utkin et al., 1994). An exception is *Desulfitobacterium hafniense* strain DP7, which was isolated from a human fecal sample that was not contaminated with chlorinated phenolic or aliphatic compounds (van de Pas et al., 2001b). *Desulfitobacterium dehalogenans* was enriched from an apparently pristine methanogenic freshwater sediment in Sandy Creek Nature Park in Athens, GA, USA. Isolation was performed using anaerobic mineral medium supplemented with pyruvate, formate, and 3Cl4HOPA, at concentrations of 2, 2, and 1 mM, respectively. Single colonies were collected from 0.6% agar shake culture tubes and transferred to the enrichment medium supplemented with 0.1% yeast extract, 20 mM pyruvate, and 10 mM 3Cl4HOPA (Utkin et al., 1994). In the original enrichments, agar concentrations above 1% were inhibitory; however, after several years of cultivation in the laboratory, the strain adapted to form colonies on 1.5% agar plates. *Desulfitobacterium chlororespirans* was isolated from a Michigan residential compost soil based on its ability to dechlorinate 2,3-DCP. Anaerobic agar (1.5%) shake cultures that were inoculated with the secondary enrichments yielded isolated colonies. The product of 2,3-DCP dechlorination, 3-chlorophenol (3-CP), inhibited growth, and 3-chloro-4-hydroxybenzoate (3Cl4HOB) was a better substrate since its dehalogenation product 4-hydroxybenzoate (4HOB) was not inhibitory at concentrations below 20 mM (Sanford et al., 1996). *Desulfitobacterium metallireducens* was enriched from anaerobic sedi-

ment collected from the floodplain of the San Juan River at the uranium mill tailings site of the Department of Energy in Shiprock, New Mexico, USA. The enrichment medium was a defined freshwater medium that contained 10 mM lactate as the electron donor and 5 mM AQDS as the electron acceptor. Colonies were picked from agar-solidified (1.5%) medium and restreaked on solid agar slants before they were resuspended in liquid medium. The isolate was grown in medium that was supplemented with 1% yeast extract, 10 mM lactate, and 5 mM AQDS (Finneran et al., 2002).

Maintenance procedures

The anaerobic culture tubes can be stored at room temperature or at 4°C for up to 6 weeks. For longer-term storage anaerobic, 30–50% glycerol stocks are kept at –20°C (for more frequent sampling) and at –70°C (for the main stock culture). The strains in culture collections are freeze-dried.

Differentiation of the genus *Desulfitobacterium* from closely related genera

The phylogenetic analysis based on 16S rRNA gene sequences reveal that the *Desulfitobacterium* species are closely related to the *Dehalobacter–Syntrophobotulus–Desulfosporosinus* cluster (Figure 174). *Desulfosporosinus* is a novel sulfate-reducing genus (Stackebrandt et al., 1997) encompassing species recently excluded from the genus *Desulfotomaculum* (Robertson et al., 2001; Stackebrandt et al., 2003; Stackebrandt et al., 1997). Despite common morphological features of micro-organisms within the *Desulfitobacterium* and *Dehalobacter–Syntrophobotulus–Desulfosporosinus* group, the genera are readily distinguished by physiological criteria. All members of *Desulfosporosinus* reduce sulfate in the presence of lactate or pyruvate, which differentiates this group from *Desulfitobacterium* (Robertson et al., 2001; Stackebrandt et al., 2003; Stackebrandt et al., 1997; Utkin et al., 1994). *Dehalobacter* and *Syntrophobotulus*, unlike *Desulfitobacterium* and *Desulfosporosinus*, are unable to reduce sulfite, sulfate, thiosulfate, and sulfur (Friedrich et al., 1996; Holliger et al., 1998b). Species that belong to the genus *Desulfitobacterium* differ in Gram staining, motility, and/or spore formation. However, phylogenetic analyses of the 16S rRNA genes strongly support placing all *Desulfitobacterium* strains within one genus. Common physiological characteristics shared by the genus include the utilization of fumarate as an electron acceptor and ability to reduce sulfite and thiosulfate. Moreover, strains are positive for utilization of pyruvate as an electron donor, except “*Desulfitobacterium dichloroeliminans*” DCA1 (De Wilde et al., 2004), and negative for utilization of sulfate as an electron acceptor (Bouchard et al., 1996; Breitenstein et al., 2001; Christiansen and Ahring, 1996; Finneran et al., 2002; Niggemyer et al., 2001; Sanford et al., 1996, 1995; Utkin et al., 1994; van de Pas et al., 2001b).

Taxonomic comments

The genus *Desulfitobacterium* belongs to the family *Peptococcaceae*. In contrast to the type genus giving the family its name, cells of this genus (as well as some other genera in this family) are not cocci. Instead, they are rod-shaped throughout all growth phases. Similar to many other *Firmicutes*, some of the *Desulfitobacterium* species are Gram-staining negative.

same species, with *Desulfitobacterium hafniense* having seniority (Niggemyer et al., 2001).

List of species of the genus *Desulfitobacterium*

1. *Desulfitobacterium dehalogenans* Utkin, Woese and Wiegel 1994, 615^{VP}

de.ha.lo'ge.nans. L. pref. *de* off, away; Gr. n. *hals* salt, sea; F. n. *halogen* referring to the group VII elements; L. pres. part. *dehalogenans* dehalogenating, split off halogens, referring to the characteristic property of the micro-organism to dehalogenate various chlorophenolic compounds.

The description of the species is based on the type strain JW/IU-DC1^T (DSM 9161^T). Four other strains of *Desulfitobacterium dehalogenans* or *Desulfitobacterium dehalogenans*-like strains have been described, including strain PCE-1 (DSM 10344; (Gerritse et al., 1996; Villemur et al., 2006), strain KBC1 (Tsukagoshi et al., 2006; Villemur et al., 2006), strain Viet-1 (Villemur et al., 2006), and strain XZ-1 (ATCC 700041; Wiegel et al., 1999). Except for strain PCE-1, which stains Gram-negative, other strains are Gram-stain positive regardless of the growth phase. Moreover, lipopolysaccharide is absent based on absence of formation of a complex with polymyxin B (Wiegel and Quandt, 1982). Cell-wall ultrastructure is typical for Gram-positive bacteria. Exponential-phase cells are slightly curved rods, 0.5–0.7 × 2.5–6 μm. In the early stationary phase, cells are more pleomorphic, thicker, and shorter. Physiology is obligately anaerobic, heterotrophic, and mesophilic; the growth temperature range is 13–45°C, with an optimum of 37–38°C for JW/IU-DC1^T and 10–40°C with an optimum at 34°C for strain KBC1. The pH growth range is 6.0–9.2, with an optimum at 7.5. Spore formation was not observed (Utkin et al., 1994). However, major sporulation genes are present (Onyenwoke et al., 2004). *Desulfitobacterium dehalogenans* tolerates microaerophilic conditions (<0.5% v/v, air in N₂). Growth and dechlorination of 3Cl4HOPA occurs between 13–45°C and pH of 6–9, with optima at 37°C and a pH of 7.5. NaCl, 1 M but not 0.5 M, completely inhibits dechlorination of 3Cl4HOPA. In the absence of electron acceptors, pyruvate is fermented to lactate, acetate, and CO₂. In the presence of pyruvate or formate as electron donors, 3Cl4HOPA is dehalogenated to 4-hydroxyphenylacetate (4HOPA) during an anaerobic respiration that yields 1 ATP equivalent per 1 mol of 4HOPA (Mackiewicz and Wiegel, 1998). For the spectrum of dehalogenated haloaromatic compounds, see Table 181. In addition to pyruvate and formate, lactate and H₂ are electron donors for 3Cl4HOPA reduction. Arabinose, cellobiose, mannitol, raffinose, rhamnose, ribose, sucrose, xylose, ethanol, methanol, butyrate, isobutyrate, propionate, isovalerate, acetate, and formate do not support growth in anaerobic conditions in the presence of 0.1% yeast extract. The highest rate of dehalogenation is observed with 2,3-DCP, but concentrations above 2 mM are inhibitory. In contrast, 3Cl4HOB is metabolized at concentrations of

20 mM (Utkin et al., 1995; Zhang and Wiegel, 1992). Sulfur compounds are reduced to sulfide. Dissimilatory reduction of sulfate does not occur (Mackiewicz and Wiegel, 1998, 1995; Utkin et al., 1994). Reduction of nitrate with low concentrations of electron donors (e.g., <20 mM lactate) leads to accumulation of lethal concentrations of nitrite, whereas in the presence of >20 mM of lactate, nitrite is reduced to ammonia without accumulation of nitrite. Approximately 2.5 mM lactate was transformed to acetate during the reduction of 1 mM nitrate to ammonia (Knoblich, 1996; Knoblich and Wiegel, unpublished data). *Desulfitobacterium dehalogenans* reduces humic acids when either lactate or H₂ is present as an electron donor. Moreover it reduces the AQDS with lactate as an electron donor. Reducing of both chemicals is coupled to bacterial growth (Cervantes et al., 2002). Isethionate (2-hydroxyethanesulfonate) also serves as terminal electron acceptor for strain PCE-1 (Lie et al., 1999). Strain PCE-1 dehalogenates PCE and several *ortho*-chlorinated phenolic compounds (Gerritse et al., 1996).

DNA G+C content (mol%): 45.8–46 (HPLC).

Type strain: JW/IU-DC1, ATCC 51507, DSM 9161.

GenBank accession number (16S rRNA gene): L28946.

2. *Desulfitobacterium chlororespirans* Sanford, Cole, Löffler and Tiedje 2001, 793^{VP} (Effective publication: Sanford, Cole, Löffler and Tiedje 1996, 3806.)

chlor.o.respi'rans. N.L. part. adj. *chloro* referring to the group VII element chlorine; fr. L. *respirare* to blow, breathe; N.L. part. adj. *chlororespirans* breathing chlorine, referring to the characteristic of coupling oxidation of electron donors to reductive removal of chlorines from various chlorophenolic compounds via a respiratory process used for obtaining energy for growth.

Description is based on the type strain Co23^T (DSM 11544^T; Sanford et al., 1996). Exponential growth phase cells are slightly curved rods, 3–5 × 0.5–0.7 μm. Cells stain Gram-negative. Terminal spores appear in late-exponential growth phase causing swelling. Metabolism is obligately anaerobic. Colonies are round with a diameter of 1–2 mm, smooth and white on R2A agar medium (Sanford et al., 1996). The optimal temperature for growth is 37°C, and the pH range is 6.8–7.5. The strain utilizes lactate, pyruvate, H₂ + acetate, formate, butyrate, and yeast extract as electron donors, and sulfite, thiosulfate, sulfur, and *ortho*-substituted haloaromatic compounds as terminal electron acceptors (Table 181). 3Cl4HOB is the superlative substrate for dehalorespiration. The cell density increases in lactate-fed cultures in the presence of 3Cl4HOB. However, no increase in turbidity occurs with lactate alone or with lactate + sulfate. Pyruvate supports growth in the absence of an electron acceptor and is fermented stoichiometrically to acetate, CO₂, and H₂.

Compounds not utilized include: 2,4-DCP, 2,5-DCP, and PCP (Sanford et al., 1996). In addition to *ortho*-substituted haloaromatic compounds, *Desulfitobacterium chlororespirans* debrominates and deiodinates the polysubstituted herbicides, such as bromoxynil (3,5-dibromo-4-hydroxybenzotrile), ioxynil (3,5-diiodo-4-hydroxybenzotrile), and the bromoxynil metabolite 3,5-dibromo-4-hydroxybenzoate in the presence of lactate as an electron donor (Cupples et al., 2005). This strain was isolated from a Michigan residential compost soil.

DNA G + C content (mol%): 48.8 (T_m).

Type strain: Co23, ATCC 700175, DSM 11544.

GenBank accession number (16S rRNA gene): U68528.

3. **Desulfitobacterium hafniense** Christiansen and Ahring 1996, 446^{VP} emend. Niggemyer, Spring, Stackebrandt and Rosenzweig 2001, 5578.

haf.ni.en'se. L. n. *Hafnia* Copenhagen; L. suff. *-ensis* native of; L. neut. adj. *hafniense* native of Copenhagen, referring to the place of isolation.

Description of the species is based on the type strain DCB-2^T (DSM 10664^T); however, some features of other strains are indicated. Exponential growth phase cells are curved rods 2–6 × 0.5–0.8 μm and occur singly, in pairs, or in small chains. Cells are Gram staining negative (Christiansen and Ahring, 1996; Niggemyer et al., 2001), some strains stain positive (TCP-A) (Breitenstein et al., 2001) or react positively with a fluorescent probe against Gram-type-positive bacteria. The electron microscopic analysis reveals a Gram-positive type of cell wall (Bouchard et al., 1996; Gerritse et al., 1999). The cells are motile and contain one or rarely two terminal and up to six lateral flagella (strains GBFH and TCE-1). Strain PCP-1 (basonym *Desulfitobacterium frapieri* PCP-1) is nonmotile. Spores are formed and located terminally, causing the swelling of the cells; some strains (TCE-1, DP7) do not sporulate (Gerritse et al., 1999; van de Pas et al., 2001b). Growth is obligately anaerobic (Bouchard et al., 1996; Breitenstein et al., 2001; Christiansen and Ahring, 1996; Gerritse et al., 1999; Niggemyer et al., 2001). Strain GBFH is resistant to 2% air in the head space of the liquid cultures (Niggemyer et al., 2001). Optima for growth are pH 7.0 and 37°C, but growth occurs in pH range 6.5–7.5 and temperature range 23–40°C. Pyruvate, lactate, formate, fumarate, and tryptophan support growth of all strains. Butyrate, succinate, malate, and ethanol support growth of the type strain DCB-2 and strain PCP-1 (Niggemyer et al., 2001). Growth does not occur with L-arabinose, D-glucose, D-fructose, D-galactose, L-rhamnose, D-ribose, cellobiose, xylose, lactose, maltose, mannose, sucrose, raffinose, trehalose, D-mannitol, benzoate, acetate, propionate, sorbitol, salicilin, inulin, starch, glycerol, esculin, L-histidine, glutamine, L-threonine, and phenylalanine. Thiosulfate, sulfite, and Fe(III) are reduced in the presence of pyruvate as an electron donor. In addition, isethionate (2-hydroxyethanesulfonate) serves as a terminal electron acceptor (Lie et al., 1999). Sulfate is not reduced in the presence of the variety of carbon sources (Christiansen and Ahring, 1996). Strain DP7 does not carry out dechlorination of either polychlorinated ethenes or phenolic compounds (van de Pas et al., 2001b). Strain PCE-S can oxidize phenyl

methyl ethers such as vanillate, syringate, and veratrol for fumarate reduction and growth. *O*-Demethylase activity for utilization of phenyl methyl ethers is produced only when cells are growing on syringate, indicating that this enzyme might be substrate induced. PCE strongly inhibits the enzyme activity (Neumann et al., 2004).

Desulfitobacterium hafniense type strain DCB-2^T (JGI) and strain Y51 (Nonaka et al., 2006) are the only representatives of the genus with nearly completed genome sequence. Additional strains of the species include: PCP-1 (basonym *Desulfitobacterium frapieri*; DSM 12420; Bouchard et al., 1996), PCE-S (DSM 14645; Miller et al., 1997), TCE-1 (DSM 12704; Gerritse et al., 1999), TCP-A (DSM 13557; Breitenstein et al., 2001), GBFH (Niggemyer et al., 2001), DP7 (van de Pas et al., 2001b), Y51 (Suyama et al., 2001), ATIA-3 (Lecouturier et al., 2003), ATIA-6 (Lecouturier et al., 2003), and G2 (Genbank accession number for the 16S rRNA gene sequence: AF320982).

DNA G+C content (mol%): 47 (HPLC)

Type strain: DCB-2, DSM 10664.

GenBank accession number (16S rRNA gene): X94975.

4. **Desulfitobacterium metallireducens** Finneran, Forbush, Van-Praagh and Lovley 2002, 1934^{VP}

me.tal.li.re.du'cens. L. n. *metallum* metal; L. part. adj. *reducens* converting to a different state; N.L. part. adj. *metallireducens* reducing metal, referring to the ability to couple growth to respiration of several metals.

The description of the species is based on the type strain 853-15A^T (DSM 15288^T). Cells during the exponential growth-phase are nonmotile, slightly curved rods, 2–5 × 0.5 μm. In stationary phase, they become shorter and eventually “C” shaped. Stains Gram-positive in all growth phases. In micrographs of ultrathin sections, the presence of a thick peptidoglycan layer characteristic for Gram-type positive bacteria is observed. Does not form spores (Finneran et al., 2002). *Desulfitobacterium metallireducens* is not motile and does not possess flagella. It reduces metal cations and dehalogenates polychlorinated ethenes. The 3Cl4HOPA is the only haloaromatic compound utilized (Finneran et al., 2002). Optimal growth is at 30°C and pH 7.5. Electron donors for respiration include lactate, formate, ethanol, butanol, butyrate, pyruvate, and malate. Fe(III), Mn(IV), sulfur, thio-sulfate, 3Cl4HOPA, trichloroethylene, PCE, AQDS, humic acids, Cr(VI), and selenite are electron acceptors (Table 181). AQDS reduction results in an increase in cell number and accumulation of acetate from organic substrates. Good growth is also obtained with lactate and Fe(III) citrate as the electron acceptor. The strain does not utilize yeast extract, acetate, H₂, methanol, 2-propanol, benzoate, peptone, Casamino acids, isobutyrate, valerate, benzyl alcohol, salicylic acid, phenol, benzene, glucose, fructose, fumarate, glycerol, nicotinate, or caproate. Glucose, lactate, and citrate are not fermented (Finneran et al., 2002). The strain was enriched from anaerobic sediment collected from the floodplain of the San Juan River at the uranium mill tailings site of the Department of Energy in Shiprock, NM, USA.

DNA G+C content (mol%): not determined.

Type strain: 853-15A, ATCC BAA-636, DSM 15288.

GenBank accession number (16S rRNA gene): AF297871.

Other available strains

1. “**Desulfitobacterium dichloroeliminans**” Effective publication: De Wildeman, Diekert, Van Langenhove and Verstraete 2003, 5645.

The strain DCA1 is available as BCCM/LMG P-21439. Cells are motile, curved rods, $2-5 \times 0.5-0.7 \mu\text{m}$. Gram-stain-positive, spore formation does not occur. Optimal temperature and pH are $25-30^\circ\text{C}$ and $7.2-7.8$, respectively. H_2 , formate, and lactate serve as electron donors during 1,2-dichloroethane (1,2-DCA) dechlorination. Sulfite, thiosulfate, and nitrate are electron acceptors. Aerotolerant and able to survive the presence of O_2 for at least 24 h. Strain completely dechlorinates 1,2-DCA, and dichlorinated derivatives of propane and butane, but not highly chlorinated alkanes such as hexa-, penta-, and tetrachloroethanes. The mechanism of dechlorination does not rely on the reductive hydrogenolysis, rather it exclusively employs dichloroelimination of various substrates.

The process of dichloroelimination can be utilized in bioremediation, since addition of the cells to 1,2-DCA-contaminated groundwater yielded complete detoxification with high efficiency (De Wildeman et al., 2003; Maes et al., 2006). The real-time PCR quantification method in groundwater for the strain DCA1 was developed and may be useful to study the kinetics and abundance of this halo-respiring strain in the field (Van Raemdonck et al., 2006).

2. **Desulfitobacterium sp. strain RPF35Ei**

Cells are rod-shaped, $2.5-4 \times 0.3-0.5 \mu\text{m}$. The strain forms spores, oxidizes ethanol and lactate, and reduces sulfite but not sulfate. It was isolated from a sulfate-reducing fluidized-bed reactor (Kaksonen et al., 2004). Phylogenetic analyses of the 16S rRNA gene indicate that this strain may represent a novel species of this genus (Figure 174; Kaksonen et al., 2004; Villemur et al., 2006).

Genus V. **Desulfonispora** Denger, Stackebrandt and Cook 1999, 1602^{VP}

THE EDITORIAL BOARD

De.sul.fo.ni.spo'ra. N.L. pref. *desulfono* desulfonating; Gr. fem. n. *spora* spore; N.L. fem. n. *Desulfonispora* desulfonating spore (-former).

Rods with subterminal spores. Gram-stain-positive. Motile. **Strictly anaerobic. Ferments taurine to acetate, ammonia, and thiosulfate.** Oxidase negative.

DNA G+C content (mol %): 52.

Type species: **Desulfonispora thiosulfatigenes** Denger, Stackebrandt and Cook 1999, 1602^{VP}.

Further descriptive information

Phylogeny. Phylogenetic analysis of the 16S rRNA gene sequence places this genus within the family *Peptococcaceae*, of the order *Clostridiales* (Figure 6). Its closest relatives (with 86–88% sequence similarity) are *Desulfotomaculum*, *Desulfitobacterium*, *Desulfosporosinus*, and *Peptococcus*. The level of relatedness even to its closest relative (*Peptococcus niger*) is low.

Desulfonispora specializes in taurine fermentation and synthesizes thiosulfate from sulfite. This synthetic transformation is proposed to be mediated by sulfite reductase and a putative

electron transport chain containing membrane-bound cytochrome *b*. None of the other naturally occurring organosulfonates (cysteate, isethionate, and coenzyme M) are utilized for growth. Bile salts, such as taurocholate, do not support growth. Similarly, other common carbon sources, tryptone, and yeast extract do not support growth (Denger et al., 1997).

Enrichment and isolation procedures

Enrichment was performed under strictly anoxic conditions in bicarbonate-buffered, titanium(III) nitrilotriacetate-reduced mineral salts medium at pH 7.0 containing 10 mM taurine as the sole source of carbon and energy, as described by Denger et al. (1997). Incubation was at 30°C in the dark, and cultures were shaken occasionally. Subcultures of putative enrichments were isolated by the agar shake method (Pfennig, 1978).

List of species of the genus *Desulfonispora*

1. **Desulfonispora thiosulfatigenes** Denger, Stackebrandt and Cook 1999, 1602^{VP}

thi.o.sul.fa.ti'ge.nes. N.L. n. *thiosulfas* thiosulfate; N.L. suff. *genes* -producing; N.L. part. adj. *thiosulfatigenes* thiosulfate-producing.

Cells are rods ($0.7-1.0 \times 2-5 \mu\text{m}$) with subterminal spores. Motile. All are oxidase negative and most are catalase negative.

Membranes contain a high level of cytochrome *b*. Growth occurs at mesophilic temperatures with taurine consumption and concomitant production of acetate, ammonia, and thiosulfate (1:1:0.5). Sulfate, sulfite, and nitrate are not reduced.

DNA G+C content (mol %): 52 (HPLC).

Type strain: GKNTAU, ATCC 700533, DSM 11270.

GenBank accession number (16S rRNA gene): Y18214.

Genus VI. **Desulfosporosinus** Stackebrandt, Sproer, Rainey, Burghardt, Päufer and Hippe 1997, 1138^{VP} emend. Robertson, Bowman, Franzmann and Mee 2001, 139, emend. Stackebrandt, Schumann, Schüler and Hippe 2003, 1441.

HANS HIPPE AND ERKO STACKEBRANDT

De.sul.fo.spo.ro.si'nus. L. pref. *de* from; L.n. *sulfur* sulfur; Gr. n. *spora* spore; L. n. *sinus* bend; N.L. masc. n. Desulfosporosinus, a spore-forming curved (organism) that reduces sulfur compounds.

Gram-negative rods that have a multilayered cell-wall structure. Endospores present, oval and subterminal to (almost) terminal, causing the cells to swell slightly. Motile with lateral or peritrichous flagella or nonmotile. Strictly anaerobic. If determined, desulfovirodin and cytochrome c_3 absent and bisulfite reductase P582 present. Sulfate and thiosulfate are reduced to sulfide in the presence of lactate but not in the presence of acetate or fructose. Incomplete oxidation of organic compounds to acetate. Acetate is the fermentation end product. Autotrophic growth with hydrogen plus sulfate. LL-Diaminopimelic acid is the diagnostic diamino acid of peptidoglycan. Contains menaquinone with a side chain with seven isoprene units (MK-7 type) as major component. Predominant fatty acids are even-numbered, saturated and unsaturated fatty acids; significant amounts of aldehydes, detected as 1,1-dimethylacetals. Phylogenetically, a member of the *Clostridium/Bacillus* subphylum of Gram-positive bacteria.

DNA G+C content (mol%): 41.6–45.9 (T_m).

Type species: Desulfosporosinus orientis (Campbell and Postgate 1965) Stackebrandt, Sproer, Rainey, Burghardt, Päufer and Hippe 1997, 1138^{VP} (*Desulfotomaculum orientis* Campbell and Postgate 1965, 361; "*Desulfovibrio orientis*" Adams and Postgate 1959, 256).

Taxonomic comments

The type species of *Desulfosporosinus*, *Desulfosporosinus orientis*, was originally described as *Desulfovibrio orientis* (Adams and Postgate, 1959). The authors indicated in the original publication, describing strain NCIB 8323^T from soil in Singapore as a new species, that the nomenclature was not in total agreement with the taxonomic judgment of A.R. Prévot, who had also examined this strain. As Prévot found cells to contain spores, the affiliation of strain NCIB 8323^T to *Desulfovibrio* did not match the genus description. According to the classification used by Prévot (1957), it would have been classified as "*Sporovibrio orientis*". As already mentioned by Adams and Postgate (1959), *Desulfovibrio orientis* differs in morphology and physiology from other *Desulfovibrio* species, and the authors indicated that this species may phylogenetically not be related to other members of the genus.

Desulfovibrio orientis was reclassified as *Desulfotomaculum orientis* (Campbell and Postgate, 1965) and was included in the Approved Lists of Bacterial Names (Skerman et al., 1980) as one of four species of this genus. Vainshtein et al. (1995) isolated a mesophilic, spore-forming sulfate-reducer from ancient permafrost in Russia, which was classified as a strain of the species *Desulfotomaculum orientis* (DSM 8344) on the basis of phenotypic characteristics.

The reclassification of *Desulfotomaculum orientis* NCIB 8323^T (DSM 765^T) as *Desulfosporosinus orientis* was proposed in 1997 (Stackebrandt et al., 1997). The placement of strains DSM 765^T and DSM 8344 was based on phylogenetic analysis in which they formed a separate cluster from other *Desulfotomaculum*, being more closely related to members of *Desulfitobacterium* than to the other *Desulfotomaculum* species. The second species, *Desulfosporosinus meridiei*, was described for eight strains of spore-forming, sulfate-reducing bacteria isolated from a gasoline contaminated shallow aquifer in the sandy soils at Eden Hill, on the Swan Coastal Plain near Perth in the south-west of Australia (Robertson et al., 2001).

A third species has recently been transferred to the genus by reclassifying *Desulfotomaculum auripigmentum* as *Desulfosporosinus auripigmenti* (Stackebrandt et al., 2003). *Desulfotomaculum auripigmentum* ATCC 700205^T (DSM 13351^T) was originally affiliated to *Desulfotomaculum* mainly on the basis of 16S rDNA analysis (Newman et al., 1997). This nonmotile, sausage shaped, arsenate and sulfate reducing, Gram-positively staining bacterium, for which spore formation has not been reported, was placed phylogenetically adjacent to *Desulfotomaculum orientis* in the 16S rDNA dendrogram of relationship (96.2% similarity). The description by Newman et al. (1997) overlapped with the reclassification of *Desulfotomaculum orientis* as *Desulfosporosinus orientis* (Stackebrandt et al., 1997) and therefore neither of the two research groups was aware of the other group's work. In the publication of Robertson et al. (2001), *Desulfosporosinus meridiei* DSM 13257^T branched adjacent to *Desulfotomaculum auripigmentum* DSM 13351^T (97.6% 16S rRNA gene sequence similarity), but, despite the grouping of a *Desulfotomaculum* species between *Desulfosporosinus meridiei* and *Desulfosporosinus orientis*, the generic affiliation of *Desulfosporosinus auripigmentum* remained unchallenged. Morphological and physiological traits, phylogenetic position, results of DNA–DNA reassociation studies, and chemotaxonomic properties of *Desulfotomaculum auripigmentum*, including properties supplementary to the original description, led at the end to the transfer of this species to *Desulfosporosinus*.

Further descriptive information

Cell morphology. In the original description of *Desulfovibrio orientis* (Adams and Postgate, 1959) the type strain NCIB 8382^T was described as a fat rod, often slightly curved, sometimes paired or in short chains; the mean dimensions were 1.4 × 4.8 μm. Cells stained Gram-negatively and no evidence for a capsule was given. Culturing for 5 or more days (the description of Adams and Postgate, (1959), did not indicate the growth medium) contained a significant number of cells showing a

granulated cytoplasm; forms with a single central or near-central granule was sometimes seen. Figure 175 displays cells of *Desulfosporosinus orientis* DSM 765^T grown on pyruvate medium, containing these central granules. Occasionally, long filament-like cell chains are observed (Figure 176). Nonprogressive “twisting and turning” motions were sometimes seen, particularly in cells taken from colonies on agar media. Cells contained one or two polar or near-polar flagella. In contrast to the observation of Adams and Postgate (1959), Prévot reported infrequent sporulation of this strain with spores occurring central or paracentral (cited Adams and Postgate, 1959), later also detected by the latter authors. Later reports described the location of spores to be subterminal or terminal, causing the cells to swell slightly (Figure 177), and motility by peritrichous flagellation (Campbell and Postgate, 1965; Campbell and Singleton, 1986).

Strains of *Desulfosporosinus meridiei* investigated by Robertson et al. (2001) differed significantly in size; while cells of most strains are 0.7–1.1 μm in width and 2.3–4.2 μm in length, some

FIGURE 175. Sporulating cells of *Desulfosporosinus orientis* DSM 765^T grown in sulfate-limited chemostat culture with H₂ as electron donor. Bar = 10 μm. (Courtesy of H. Cypionka.)

FIGURE 176. Vegetative cells of *Desulfosporosinus orientis* DSM 765^T grown in DSMZ medium 641 with pyruvate, showing near-central granule. Bar = 10 μm.

cells measure up to 13.0 μm in length. Cells stained Gram-negatively or were Gram-variable and possessed a multilayered cell wall. Cells possessed a single lateral flagellum (only demonstrated for one strain) and were motile only in the early exponential phase of growth.

The only known strain of *Desulfosporosinus auripigmenti*, ATCC 700205^T, is a Gram-positive and nonmotile rod, 0.4 μm in width × 2.5 μm in length, with an S-layer (hexagonal surface array) attached to the thin multilayered peptidoglycan (Newman et al., 1997). Spores, originally not observed, were detected in cells (Stackebrandt et al., 2003) grown on mineral-vitamin medium no 641 (DSM catalog of strains, 2001) (Figure 177).

Morphological and cultural characteristics of species of the genus *Desulfosporosinus* and of strain DSM 8344 are listed in Table 182.

Phylogenetic position. The rationale for describing *Desulfotomaculum orientis* as the type of a new genus was based on the phylogenetic position derived from analysis of 16S rRNA gene sequences from members of *Desulfotomaculum* (Stackebrandt et al., 1997). While the majority of species formed several phylogenetic lineages, *Desulfotomaculum orientis* represented yet another lineage branching closely to the genus *Desulfitobacterium* (93.1–94.4% sequence similarity). This pattern was recovered consistently with different treeing algorithms contained in the PHYLIP package (Felsenstein, 1993), including neighbor-joining (Saitou and Nei, 1987) and maximum-parsimony analyses and the distance matrix algorithm of De Soete (1983). Most of these clusters were recovered in a high proportion of the trees generated, as demonstrated by the high bootstrap values for these groups (Figure 178).

While *Desulfosporosinus orientis* DSM 765^T (Singapore I) (GenBank accession no. Y11570) and strain DSM 7493 (Singapore II) (GenBank accession no. AJ493052) are highly related (99.5% similarity), strain DSM 8344 (GenBank accession no. Y11571) is only moderately related to the type strain (96.2% similarity). This was confirmed by DNA–DNA binding similarity values of 39% (Stackebrandt et al., 2003). Strain DSM 8344 forms a

FIGURE 177. Sporulating cells of *Desulfosporosinus auripigmenti* DSM 13351^T, grown in DSMZ medium 641. Bar = 10 μm. (Reprinted with permission from Stackebrandt et al., 2003. International Journal of Systematic and Evolutionary Microbiology 53: 1439–1443.)

FIGURE 178. Dendrogram of 16S rRNA gene sequence relationship (De Soete, 1983), displaying the phylogenetic position of species of *Desulfosporosinus* and of strain DSM 8344. Numbers at branching points refer to bootstrap values (1000 resamplings). The tree was rooted with the 16S rRNA gene sequences of *Desulfotomaculum* species. Scale bar = 2 nucleotide substitutions per 100 sequence positions. Modified from Stackebrandt et al. (2003).

cluster with *Desulfosporosinus meridiei* DSM 13257^T (GenBank accession no. AF076527) and *Desulfosporosinus auripigmenti* DSM 13351^T (GenBank accession no. AJ493051) (which share about 97.5% sequence similarity). The phylogenetic distance between the type strains of *Desulfosporosinus orientis* and *Desulfosporosinus meridiei* was confirmed by a DNA–DNA binding value of 37.7% (Robertson et al., 2001) and 54% (Stackebrandt et al., 2003), respectively, while strain DSM 765^T and *Desulfosporosinus auripigmenti* DSM 13351^T showed 30% DNA–DNA reassociation, thus confirming the status of all three species. The distinctness of the species has also been confirmed by riboprint analyses (Stackebrandt et al., 2003) and, for *Desulfosporosinus orientis* DSM 765^T and strains of *Desulfosporosinus meridiei*, by RAPD-PCR analyses (Robertson et al., 2001). As a result of the latter study the grouping of *Desulfosporosinus meridiei* strains into subclusters I–III was changed to group A (for subcluster I plus strain S4) and group B (for subcluster III plus strain S7; the latter subcluster contains the type strain).

16S rDNA sequence comparison (Robertson et al., 2000) indicated that subcluster I, containing 3 strains, was most closely related to DSM 8344 (~98.8% similarity). One representative each of subclusters I and III had a DNA–DNA similarity of 81%.

Riboprint analyses (Stackebrandt et al., 2003) showed similar *Eco*RI restriction patterns for the type strain of *Desulfosporosinus orientis* DSM 765^T and strain DSM 7439, while the type strains of *Desulfosporosinus meridiei* and *Desulfosporosinus auripigmenti* and strain DSM 8344 were characterized by individual patterns.

Chemotaxonomy. Cellular fatty acids profiles of *Desulfosporosinus orientis* are dominated by even carbon, straight chain saturated ($C_{14:0}$, $C_{16:0}$) and mono-unsaturated ($C_{16:1\ \omega 7c}$, $C_{18:1\ \omega 9c}$, $C_{18:1\ \omega 8c}$) fatty acids. In addition, significant amounts of $C_{16:0}$ dimethylacetals (8.7%) and traces of aldehydes (2.8%) were found (Table 183). The profiles of strains NCIMB 8445 (strain Singapore II) and *Desulfosporosinus* species DSM 8344 were almost identical to that of *Desulfosporosinus orientis* DSM 765^T (Hippe et al., 1995; Vainshtein et al., 1995). Neither cyclopropane fatty acids, nor iso- and anteiso fatty acids were detected. This is in contrast to the studies of Robertson et al. (2000) and Ueki and Suto (1979), who reported on the presence of these fatty acids in *Desulfosporosinus orientis*. These differences may be caused by the use of different growth media and analytical equipment.

The fatty acid profiles of strains of *Desulfosporosinus meridiei* are also dominated by even-carbon, straight-chain, saturated ($C_{14:0}$; $C_{16:0}$) and monounsaturated ($C_{16:1\ \omega 7c}$; $C_{18:1\ \omega 7c}$) fatty acids. In contrast to the finding of a significant percentage (29% in the type strain) accounting for iso- and anteiso branched fatty acids (Robertson et al., 2000), the emendation of the genus *Desulfosporosinus* (Robertson et al., 2001) indicates the presence of minor amounts of branched-chain and cyclopropane fatty acids. Major fatty acids of *Desulfosporosinus auripigmenti* DSM 13351^T are $C_{16:0}$ and the monounsaturated $C_{16:1\ \omega 7c}$ and $C_{18:1\ \omega 9c}$. Dimethylacetals (DMA), such as $C_{DMA-18:1\ \omega 9c}$, $C_{DMA-16:1\ \omega 7c}$ and $C_{DMA-18:0}$, as well as traces of $C_{17:0\ cyclo}$ occur. 10-Methyl branched fatty acids, considered chemotaxonomic markers in members of the *Desulfobacteriaceae*, and $C_{17:1\ iso\ \omega 10c}$ fatty acids, occurring in many species of the genus *Desulfovibrio* but also in *Desulfomicrobium* and in several species of *Desulfotomaculum*, are absent in strains of *Desulfosporosinus* (Hagenauer et al., 1997a; Hippe et al., 1995; Vainshtein et al., 1992).

The peptidoglycan contains LL-diaminopimelic acid (A_2pm) as the diamino acid (Table 183) This diagnostic feature has also

been found in members of the phylogenetically neighboring genus *Desulfitobacterium*, e.g., *Desulfitobacterium* species PCE1 (Gerritse et al., 1996), *Desulfitobacterium dehalogenans* DSM 9161^T, and *Desulfitobacterium hafniense* DSM 10664^T (Stackebrandt et al., 2003). Also, some species of the genus *Desulfotomaculum*, e.g., *Desulfotomaculum thermoacetoxidans* DSM 5813^T and *Desulfotomaculum thermobenzoicum* subspecies *thermobenzoicum* DSM 6193^T, contain LL-A₂pm.

Cells of *Desulfosporosinus orientis* contain spermidine and spermine as the major polyamines (Hamana, 1999). The same polyamines were detected in the phylogenetically related *Desulfitobacterium dehalogenans* but also in *Desulfotomaculum acetoxidans*. Other species of the genus *Desulfotomaculum* (*Desulfotomaculum nigrificans*, *Desulfotomaculum ruminis*, and *Desulfotomaculum thermobenzoicum*) differed from this composition (Hamana, 1999). The taxonomic significance of polyamines in Gram-positive sulfate- and sulfite-reducers needs to be placed on a broader basis by being included in a detailed study of all extant species.

The major isoprenoid quinone is a menaquinone of the MK-7 type (Collins and Widdel, 1986; Stackebrandt et al., 2003). *Desulfotomaculum auripigmenti* also contains significant amounts of MK-5, while MK-6 was found in traces in *Desulfosporosinus orientis* and *Desulfotomaculum auripigmenti* (Table 183).

Cytochromes have only been determined for *Desulfosporosinus orientis* DSM 765^T and strain DSM 8344 (Table 183). In both strains, cytochrome *b* has been found as the principal component, with traces of cytochrome *c* in strain DSM 765^T.

Physiological and metabolic properties. Oxygen is inhibitory to *Desulfosporosinus orientis* as a strictly anaerobic bacterium. Even in the absence of sulfide, survival of *Desulfosporosinus orientis* after oxygen stress induced by 3 h exposure was found to be very low (survival fraction 0.01%) compared with other sulfate-reducing bacteria (e.g., species of *Desulfovibrio*, *Desulfococcus*, and *Desulfotomaculum*) (Cypionka et al., 1985). Reducing agents even increased the oxygen toxicity. Enhanced sulfide concentrations (exceeding 2 mmol Na₂S/l) in growth media are toxic to cells of *Desulfosporosinus orientis* (Klemps et al., 1985). Growth yields of *Desulfosporosinus orientis* obtained in a sulfide-controlled continuous culture under sulfate-, hydrogen-, and nonlimited conditions were considerably higher (max. 12.4 g dry mass per mol sulfate reduced) than determined in batch culture (7.5 g per mol) (Cypionka, 1986).

Reinvestigation of physiological properties of the type strain of *Desulfosporosinus orientis* (Klemps et al., 1985) led to the unexpected finding that this species, in contrast to *Desulfotomaculum* strains, was able to grow chemoautotrophically with hydrogen, carbon dioxide, and sulfate. It was also able to grow in the absence of sulfate with formate, methanol, ethanol, lactate, pyruvate, or trimethoxybenzoate. Homoacetogenic growth on methanol and ethanol has also been reported for *Desulfosporosinus meridiei* (Robertson et al., 2001). Newman et al. (1997) report in the original description of *Desulfotomaculum auripigmentum*, that the type strain grows autotrophically on H₂ and produces acetate from organic substrates. It can thus be concluded that all species of the genus can be considered homoacetogenic bacteria.

Diazotrophic growth has been demonstrated in *Desulfosporosinus orientis* (Lespinat et al., 1985). During studies on the removal of SO₂ from flue gas by sulfate-reducing bacteria, growth of *Desulfosporosinus orientis* on H₂, CO₂, and SO₂ with the production of H₂S has been observed (Deshmane et al., 1993).

In contrast to the species *Desulfosporosinus orientis* and *Desulfosporosinus auripigmenti*, intraspecific diversity has been determined for several species. Considering the range of genomic diversity within a species, it is not surprising to find a substantial degree of intraspecific physiological diversity, as laid down in the description of the species *Desulfosporosinus meridiei* (Robertson et al., 2001). For example, nitrate reduction is variable (3 out of 7 strains, type strain negative). In the presence of sulfate and thiosulfate, the following compounds are used as carbon sources and electron donors: H₂/CO₂ + 1 mM acetate, pyruvate, lactate, ethanol, formate (3 out of 7 strains, type strain positive), caproate (1 out of 7 strains, type strain negative), caprylate (4 out of 7 strains, type strain negative), methanol (2 out of 7 strains, type strain positive), syringic acid (3 out of 7 strains, type strain positive), H₂/CO (only type strain tested), butyrate (2 out of 2 strains, including type strain), caprate (2 out of 2 strains, including type strain), and laurate (2 out of 2 strains, including type strain). The following compounds are not used as carbon sources and electron donors in the presence of sulfate and thiosulfate: acetate, propionate, fumarate, malate, benzoate, valerate (2 strains tested, including type strain), fructose (2 strains tested, including type strain) and 3,4,5-trimethoxybenzoic acid (2 strains tested, including type strain).

The following compounds are used as carbon and energy sources: in the absence of an electron acceptor (2 strains tested, including type strain): lactate, pyruvate, ethanol, methanol (1 out of 2 strains, type strain positive); perchloroethene is reduced in the presence of sulfate and pyruvate (1 strain tested).

Enrichment and isolation procedures

Procedures and media for the enrichment and isolation of sulfate-reducing, spore-forming, anaerobic bacteria, including *Desulfosporosinus orientis*, were described by Postgate (1979) and Widdel (1992). Toluene or benzoate has been used as electron donor and dithionite as reducing agent in sulfate-containing enrichment and isolation media (in agar roll tubes) for the isolation of eight strains of *Desulfosporosinus meridiei* (Robertson et al., 2000). *Desulfosporosinus auripigmenti* was enriched in a freshwater mineral medium with lactate, sulfate, and cysteine. After several transfers into medium with dibasic sodium arsenate replacing the sulfate, isolation was done by colony transfers in agar shake tubes. Reduction of arsenate was visible by formation of a yellow precipitate, As_2S_3 (Newman et al., 1997). All members of the genus grow well and sporulate in medium 641 (DSMZ Catalog of Strains, 2001) at 30°C, in which, for growth of *Desulfosporosinus meridiei*, Na-malate is replaced by 1.0 g/l Na-pyruvate.

Occasionally, *Desulfosporosinus orientis* shows very poor growth in media which have been reduced with commercial sodium sulfide. It is likely that certain impurities in the commercial Na_2S are inhibitory (Widdel and Hansen, 1992). Media which are prerduced with ascorbate and thioglycollate or reduced with sodium dithionite immediately before use may be better suited for cultivation (Widdel and Hansen, 1992).

Maintenance procedures

Vegetative cells of *Desulfosporosinus* species usually die within few days after growth has ceased, especially if grown under optimal conditions and kept at optimal temperature. The best method for maintenance is in the sporulated state. Spore formation is often induced in colonies in agar deeps. *Desulfosporosinus orientis* sporulates well if grown under sulfate limitation with hydrogen as electron donor (Cypionka and Pfennig, 1986) (Figure 175). Agar tubes with spore containing colonies may survive for several months if refrigerated. Vegetative cells of *Desulfosporosinus* can be preserved long-term by deep freezing in liquid nitrogen, using methods described for methanogens and other anaerobes (Hippe, 1991). Sporulated cultures survive freeze-drying and long-term storage after applying described methods (Hippe, 1991).

Differentiation of the genus *Desulfosporosinus* from other genera

Members of *Desulfosporosinus* can be differentiated from members of the neighboring genera *Desulfotomaculum* and *Desulfitobacterium* by the properties listed in Table 185. Analysis of 16S rRNA gene sequences is probably the most direct way to affiliate a strain to the genus. A set of signature nucleotides of 16S rRNA genes demonstrate the clear demarcation of members of *Desulfosporosinus* and *Desulfitobacterium*. (Stackebrandt et al., 2003). The phylogenetic heterogeneity of the genus *Desulfotomaculum* excluded provision of a clear-cut set of genus-specific signatures.

List of species of the genus *Desulfosporosinus*

- 1. *Desulfosporosinus orientis*** (Campbell and Postgate 1965) Stackebrandt, Sproer, Rainey, Burghardt, Päufer, and Hippe 1997, 1138^{VP} (*Desulfotomaculum orientis* Campbell and Postgate 1965, 361; “*Desulfovibrio orientis*” Adams and Postgate 1959, 256)

ori.en'tis. L. part. adj. *oriens* rising (sun), hence the orient; L. gen. n. *orientis* of the orient.

The description of *Desulfosporosinus orientis* is identical to that given by Campbell and Postgate (1965), supplemented with data from Campbell and Singleton, Jr. (1986), Klemps et al. (1985), Robertson et al. (2001), and Stackebrandt et al. (2003). Table 182, Table 183, and Table 184 list additional cultural, physiological, and chemotaxonomic properties.

Gram-negative, fat, curved rods (1.5 × 5 μm), sometimes in short chains or filamentous. Tumbling and twisting motility by means of peritrichous flagella. Spores are oval and subterminal (on rare occasions terminal), slightly swelling the cells. Sulfate, thiosulfate, sulfite, sulfur, DMSO, and Fe (III) are electron acceptors in the presence of lactate.

Mesophilic; temperature range 30–42°C. Optimal temperature between 30 and 37°C. Growth between 0 and nearly 5% NaCl.

Growth is inhibited by <0.1 μg/ml hibitane.

Major fatty acids are unsaturated ($C_{16:1\ \omega 9c}$, $C_{16:1\ \omega 7c}$, $C_{18:1\ \omega 9c}$ and $C_{18:1\ \omega 7c}$), and saturated ($C_{14:0}$ and $C_{16:0}$) fatty acids; dimethylacetals ($C_{16:0}$), and traces of aldehydes ($C_{16:0}$) are also present. Isolated from soil of a rising main at Sungei Whampoa, Rangoon Road, Singapore.

DNA G+C content (mol%): 45 (Bd)–45.9 (T_m).

GenBank accession number (16S rRNA gene): Y11570.

Type strain: Singapore I, ATCC 19365, DSM 765, NCIMB 8382, VKM B-1628.

- 2. *Desulfosporosinus auripigmenti*** corrig. (Newman, Kennedy, Coates, Ahmann, Ellis, Lovley and Morel 1997) Stackebrandt, Schumann, Schüler and Hippe 2003, 1441^{VP} (*Desulfotomaculum auripigmentum* Newman, Kennedy, Coates, Ahmann, Ellis, Lovley and Morel 1997, 387)

au.ri.pig.men'ti. L. neut. n. *aurum* gold; L. neut. n. *pigmentum* pigment; N.L. gen. n. *auripigmenti* of golden pigment, due to As_2S_3 precipitation.

The emended description of Stackebrandt et al. (2003) is based on the description of Newman et al. (1997). Table 182, Table 183, and Table 184 list additional cultural, physiological, and chemotaxonomic properties.

Gram-negative staining, nonmotile. Sausage-shaped cells 2.5 × 0.4 μm. The murein sacculus is thinner than usual for Gram-positive bacteria; a hexagonal S-layer is attached to its

^cLL-A₂pm, LL-diaminopimelic acid.

^dAs reported for *Desulfosporosinus orientis* and *Desulfosporosinus meridiei* by Robertson et al. (2001).

^eTwo out of four species tested.

cell wall. Cells occasionally form oval, subterminal to terminal spores.

Growth by oxidation of H₂, lactate, pyruvate, butyrate, ethanol, glycerol, and malate with concomitant reduction of sulfate. Incomplete oxidation, forming acetate from organic substrates. Sulfate, thiosulfate, sulfite, arsenate, and fumarate are used as electron acceptors. Temperature optimum of 25–30°C and a pH optimum of 6.4–7.0 for growth. Arsenate [As(V)] is reduced to arsenite [As(III)]. In the presence of arsenate and sulfur, arsenate is preferred as electron acceptor; golden-colored As₂S₃ precipitate is produced

The diagnostic amino acid of peptidoglycan is LL-diaminopimelic acid. MK-7 and MK-5 are the predominant iso-

prenoid quinones; MK-6 is a minor component. Major fatty acids (>5%) are unsaturated (C_{16:1 ω7c} and C_{18:1 ω9c}), and saturated (C_{16:0}) fatty acids as well as C_{DMA-16:0} (13.4%) and C_{DMA-18:1 ω9c}. Isolated from freshwater sediment samples taken from Upper Mystic Lake in Woburn, MA, USA.

DNA G+C content (mol%): 41.6% (HPLC).

Type strain: OREX-4, ATCC 700205, DSM 13351.

GenBank accession number (16S rRNA gene): AJ493051.

3. *Desulfosporosinus meridiei* Robertson, Bowman, Franzmann and Mee 2001, 139^{VP}

me.ri.di.e'i. L. n. *meridies* south; L. fem. gen. n. *meridiei* of the south, referring to its isolation in the Southern Hemisphere.

The description has been taken from Robertson et al. (2001). Table 182, Table 183, and Table 184 list additional cultural, physiological, and chemotaxonomic properties.

Gram-negative and Gram-variable curved rods with multilayered cell wall. Cells are 0.7–1.1 µm in width and generally 2.3–4.2 µm in length, cells of some strains reaching up to 13 µm in length. Cells singly or in chains of two or more cells, motile by means of a single lateral flagellum. Oval and sub-terminal endospores, sometimes causing the cells to swell.

Sulfate, sulfite, thiosulfate, elemental sulfur, DMSO, Fe(III), and nitrate (some strains) serve as electron acceptors in the presence of lactate. Manganese (IV) and arsenic (V) are not used as electron acceptors. Mesophilic, tem-

perature range for growth between 10 and 37°C, optimum at 28°C. The upper limit of salt tolerance is 4% NaCl. The predominant whole-cell fatty acids are unsaturated (C_{16:1 ω7c} and C_{18:1 ω9c}) and saturated fatty acids (C_{14:0} and C_{16:0}); minor amounts of iso- and anteiso-branched-chain fatty acids, as well as trace amounts of cyclic fatty acids (C_{17:0 cyclo} and C_{19:0 cyclo}) may occur. Isolated from a gasoline contaminated shallow aquifer in the sandy soils at Eden Hill, on the Swan Coastal Plain near Perth.

DNA G+C content (mol%): 46.8–46.9 (T_m).

Type strain: S10, ATCC BAA-275, DSM 13257, NCIMB 13706.

GenBank accession number (16S rRNA gene): AF076527.

Genus VII. *Desulfotomaculum* Campbell and Postgate 1965, 361^{AL}

JAN KUEVER AND FRED A. RAINEY

De.sul.fo.to.ma'cu.lum. L. pref. *de* from; L. n. *sulfo* sulfur; L. n. *tomaculum* a kind of sausage; N.L. neut. n. *Desulfotomaculum* a sausage-shaped sulfate reducer.

Straight or curved rod-shaped cells, 0.3–2.5 × 2.5–15 µm with rounded or pointed ends. Occur singly or in pairs. Spores oval or round, terminal to central, causing swelling of the cells. Stain Gram-positive, although often only detected by electron microscopy. Cells are motile by single polar or peritrichous flagella, but motility can be lost during cultivation. **Strict anaerobe** with a respiratory type of metabolism. **Chemo-organotrophs** or **chemoautotrophs**. Simple organic compounds are used as electron donor and carbon sources, and are either completely oxidized to CO₂ or incompletely to acetate. Some species can grow on H₂ autotrophically with CO₂ as the sole carbon source; one species can grow on CO alone. Sulfate, and usually sulfite and thiosulfate, serve as terminal electron acceptors and are reduced to H₂S. Sulfur and nitrate are not used as electron acceptors. Fermentative growth has been observed for some species. Desulfoviridin is absent. The major **menaquinone is MK-7**. Growth occurs in simple defined media containing sulfide as a reductant. Some species require vitamins or yeast extract. Some species can fix N₂. The optimum temperature range for growth is 30–37°C for mesophilic and 50–65°C for thermophilic species. The optimum pH range for growth is 6.5–7.5. Carbon monoxide dehydrogenase activity has been demonstrated for some species. *Desulfotomaculum* species are common in anoxic freshwater, brackish or marine sediments.

DNA G+C content (mol%): 37.1–56.3.

Type species: ***Desulfotomaculum nigrificans*** (Werkman and Weaver 1927) Campbell and Postgate 1965, 361^{AL} (*Clostridium nigrificans* Werkman and Weaver 1927, 63).

Further descriptive information

Many *Desulfotomaculum* strains have typical cell morphology which allows them to be distinguished from other sulfate-reducing bacteria (SRB); this is especially true for sporulating cells. Some strains form longer rods or curved cells; even clumps of cells have been observed (A. Galushko, personal communication). In the first enrichment passages, cells are often motile. After several transfers, motility may be lost.

The optimum growth temperature for mesophilic strains is usually 30–37°C and 50–65°C for thermophilic species. The

minimum temperature for mesophilic species might be lower than 10°C and the maximum temperature for thermophilic species can exceed 85°C. The pH range for growth is 5.5–8.9, with an optimum of 6.5–7.5.

Growth occurs in the presence of sulfate, sulfite, or thiosulfate as an electron acceptor. Several *Desulfotomaculum* strains can use a large variety of organic compounds as electron donor and carbon sources (see Table 186). Some strains are restricted and oxidize organic compounds incompletely to acetate; others are capable of complete oxidation even though substrates may be partially converted to acetate, depending on substrate concentration (Kuever et al., 1999). Some *Desulfotomaculum* strains can grow autotrophically with H₂ as an electron donor and CO₂ as carbon source.

In the absence of sulfate, some species can grow by fermentation of fructose, glucose, pyruvate, or lactate. Certain *Desulfotomaculum* strains can grow by homoacetogenesis and convert methanol, methoxyl groups of aromatic compounds, formate, and H₂ and CO₂ to acetate. Although growth by homoacetogenesis is weak, it allows survival in a sulfate-free habitat. Some strains reduce metal ions. In this case, growth would be linked to fermentation using certain substrates; electron transport phosphorylation is unlikely. For some strains, carbon monoxide dehydrogenase activity has been demonstrated. It can be considered that strains which show a complete substrate oxidation or autotrophic growth must have this enzyme.

Desulfotomaculum strains contain membrane-bound and soluble cytochromes of the *b* and *c* type. Desulfoviridin and desulforubidin have never been found in the genus *Desulfotomaculum*, however, the sulfite reductase P582 is present. All members of the genus investigated so far contain MK-7 as the major menaquinone (Collins and Widdel, 1986). Major cellular fatty acids of members of the genus vary between and within the phylogenetic subclusters.

Desulfotomaculum strains occur in black anoxic sediment from freshwater, brackish water, and marine habitats. Due to spore formation, they might be dominating SRB in habitats of varying redox conditions, such as groundwater, soil, or paddy fields.

Enrichment and isolation procedures

Selective enrichment of *Desulfotomaculum* species is possible from various sources using different electron donors and sulfate as the electron acceptor in simple mineral media – see *Desulfobacter* chapter in Volume 2 of the *Systematics* (Kuever et al., 2005). The formation of heat- and drought-resistant spores in *Desulfotomaculum* species allows them to survive well in oxic and varying redox regimes. Growth of nonspore-forming, sulfate-reducing bacteria can be eliminated by pasteurization at 80°C for 10–20 min. The only other spore-forming, sulfate-reducing bacteria known are *Desulfosporosinus* species and *Thermacetogenium phaeum*, but their physiological properties are much more restricted. Enrichments at elevated temperature (50–65°C) generally result in the isolation of *Desulfotomaculum* species because only a few other sulfate-reducing bacteria can grow at this higher temperature range. Isolation of pure cultures from such enrichments is achieved via the agar tube serial dilution technique as described in Volume 2 of the *Systematics* (Kuever et al., 2005). In contrast to spores, vegetative cells are very oxygen sensitive. Therefore, the addition of sodium dithionite as an additional reducing agent is helpful. After inoculation from a spore suspension, long lag phases sometimes occur. Germination times for spores can also be shortened by the addition of dithionite (10–30 mg/l medium).

Maintenance procedures

Cultures can be stored at low temperature for several months. After sporulation occurs, cultures can be stored for years. Sporulated liquid cultures can be freeze-dried and used for long term conservation. For some species, the formation of spores depends on the growth substrate. In these cases, incubation at suboptimal temperatures and the use of a substrate which allows only slow growth (e.g., acetate) can be helpful.

Differentiation of the genus *Desulfotomaculum* from other genera

Together with *Desulfosporosinus* species and *Thermacetogenium phaeum*, members of the genus *Desulfotomaculum* can be distinguished from other sulfate-reducing bacteria by their ability to form spores. A unique physiological feature of some *Desulfotomaculum* and *Desulfosporosinus* is their use of methoxylated aromatic compounds, an ability shared only by *Desulfomonile* species. A clear differentiation from other spore-forming genera is only possible by comparative 16S rRNA gene analysis.

Taxonomic comments

On the basis of the analysis of 16S rRNA gene sequence data, many of the species of the *Desulfotomaculum* have been shown to

have less 16S rRNA gene sequence similarity to each other than they do to other genera within the *Clostridiales*. Stackebrandt et al. (1997) addressed this by designating clusters Ia through Ie for the various species clusters into which the true species of the genus *Desulfotomaculum* fell. Two species were shown to fall outside the radiation of the majority of the species of the genus *Desulfotomaculum* as defined by the position of the type species *Desulfotomaculum nigrificans* and were assigned to clusters II and III (Stackebrandt et al., 1997). This resulted in the reclassification of *Desulfotomaculum orientis* as *Desulfosporosinus orientis* (Stackebrandt et al., 1997). The species *Desulfotomaculum guttoideum* was shown to be unrelated to the other species of the genus *Desulfotomaculum* and grouped with the *Clostridium* species *Clostridium sphenoides*, *Clostridium celerecrescens*, *Clostridium aerotolerans*, and *Clostridium xylanolyticum* in a cluster designated III (Stackebrandt et al., 1997). This *Desulfotomaculum* cluster III corresponds to the cluster XIVa of Collins et al. (1994). As new species have been added to the genus *Desulfotomaculum*, the clusters Ia through Ie have expanded and an additional cluster designated If is formed by the addition of the species *Desulfotomaculum alkaliphilum* and *Desulfotomaculum halophilum* (Figure 179). The bootstrap values shown in Figure 179 indicate good support for the branching patterns of the 6 *Desulfotomaculum* clusters, all being supported by values greater than 98%. As pointed out by Stackebrandt et al. (1997), each of these clusters have individual genus status on the basis of 16S rRNA gene sequence analysis and the corresponding similarity values between the sequences of the *Desulfotomaculum* species as well as between the related genera. These findings are also supported by signature sequences that have been defined for a number of the *Desulfotomaculum* species and the clusters to which they have been shown to group (Hristova et al., 2000; Stackebrandt et al., 1997). It has been reported that several *Desulfotomaculum* strains contain multiple copies of the 16S rRNA gene that show heterogeneity within the multiple copies of the 16S rRNA gene sequences (Stackebrandt et al., 1997; Tourova et al., 2001). Stackebrandt et al. (1997) also reported the presence of large inserts in the helical region 73–82/87–97 of the 16S rRNA gene. From the alignment of the 16S rRNA gene sequences of all 23 validly named species of the genus used for the construction of the phylogenetic dendrogram (Figure 179), such large inserts are found in the all nine species of clusters Ic and Id as well as *Desulfotomaculum geothermicum*. Further detailed studies of the chemotaxonomic and physiological properties of all species of the genus *Desulfotomaculum* are required before new genera can be proposed for the clusters other than cluster Ia which contains the type species of the genus *Desulfotomaculum nigrificans*.

List of species of the genus *Desulfotomaculum*

- Desulfotomaculum nigrificans*** (Werkman and Weaver 1927) Campbell and Postgate 1965, 361^{AL}. (*Clostridium nigrificans* Werkman and Weaver 1927, 63)

ni.gri'fi.cans. L. part. adj. *nigrificans* blackening.

Characteristics are summarized in Table 186. The type strain grows at 45–70°C. Can be adapted to grow slowly at 30–37°C. The original strain was isolated from spoiled canned sweet corn (Werkman and H.J. Weaver, 1927). The

deposited type strain was isolated from freshwater in Delft, Netherlands.

DNA G+C content (mol%): 48.5–49.9 (Bd, HPLC, T_m).

Type strain: strain Delft 74, ATCC 19858, ATCC 19998, DSM 574, NBRC 13698, NCIMB 8395.

GenBank accession number (16S rRNA gene): X62176.

- Desulfotomaculum acetoxidans*** Widdel and Pfennig 1977a, 306^{VP} (Effective publication: Widdel and Pfennig 1977b, 121.)

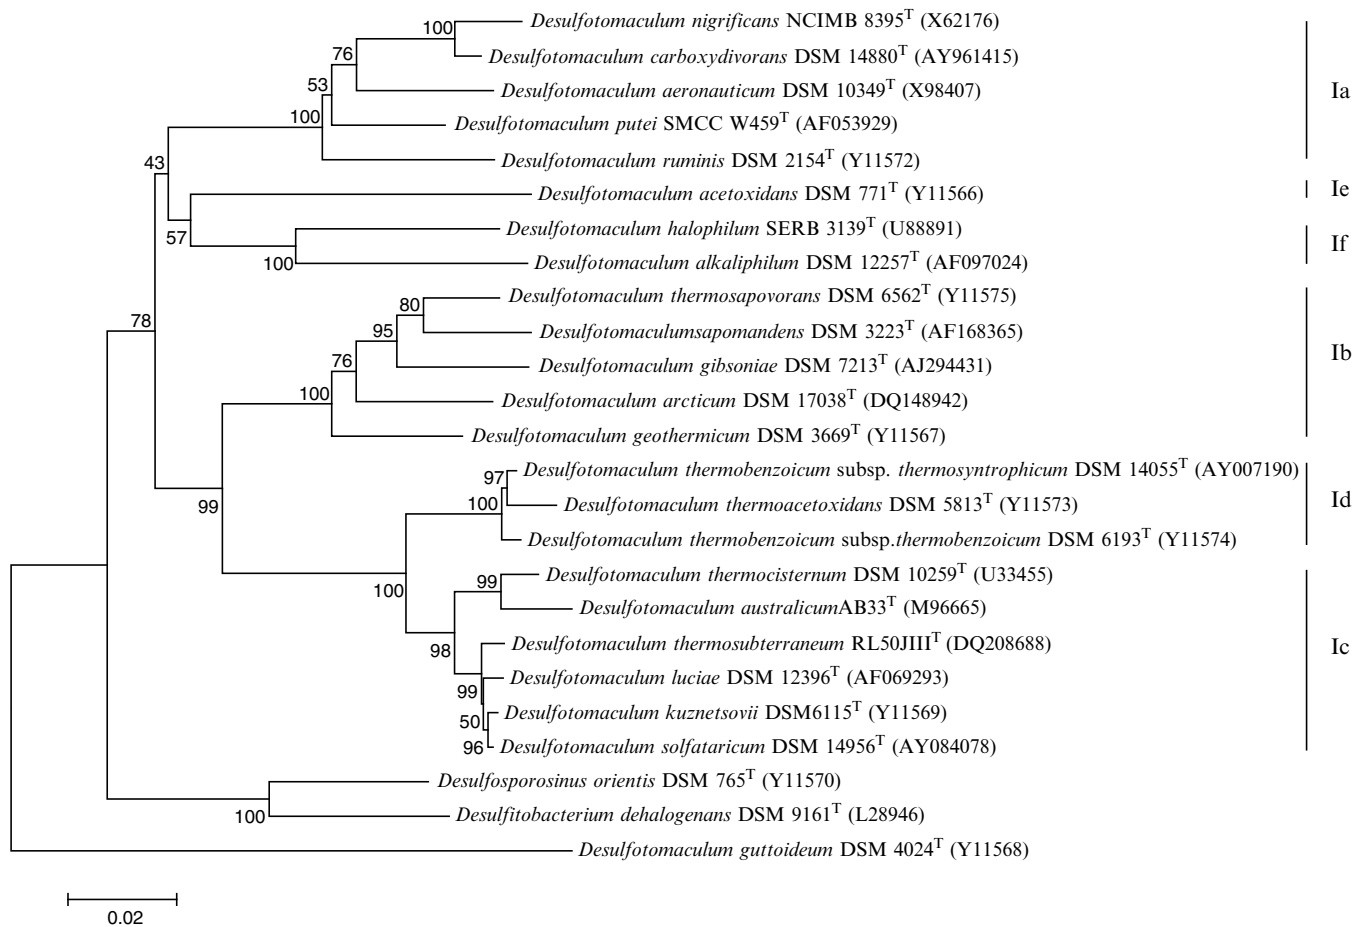

FIGURE 179. Neighbor-joining 16S rRNA gene sequence-based phylogeny of the species of the genus *Desulfotomaculum* and related genera. Numbers at branching points indicate bootstrap values from 1000 data samplings. The scale represents 2 inferred nucleotide changes per 100 nucleotides.

a.cet.o'xi.dans. L. n. *acetum* vinegar; N.L. n. *acidum aceticum* acetic acid; N.L. v. *oxido* oxidize from Gr. adj. *oxys* sour, acid; L. neut. adj. *acetoxidans* oxidizing acetic acid.

Characteristics are summarized in Table 186. The type strain grows at 20–40°C, and over a pH range of 6.6–7.6 with an optimum at 7.1. Isolated from piggery waste.

DNA G+C content (mol%): 37.5 (T_m).

Type strain: "Göttingen" 5575, ATCC 49208, DSM 771, VKM B-1644.

GenBank accession number (16S rRNA gene): Y11566.

3. ***Desulfotomaculum aeronauticum*** Hagenauer, Hippe and Rainey 1997b, 915^{VP} (Effective publication: Hagenauer, Hippe and Rainey 1997a, 70.)

ae.ro.nau'ti.cum. Gr. n. *aer* air; Gr. adj. *nautikos* nautical, concerning ship/navigation; N.L. neut. adj. *aeronauticum* navigation in air.

Characteristics are summarized in Table 186. The type strain grows at 20–42°C, and over a pH range of 6.0–9.0 with an optimum for growth at 7.0. Isolated from a corroded stringer made of aluminum alloy 2024 in the luggage area of an aircraft.

DNA G+C content (mol%): 43.8 (HPLC).

Type strain: 9, DSM 10349.

GenBank accession number (16S rRNA gene): X98407.

4. ***Desulfotomaculum alkaliphilum*** Pikuta, Lysenko, Suzina, Osipov, Kuznetsov, Tourova, Akimenko and Laurinavichius 2000, 32^{VP} al.ka.li.phi'lum N.L. fem. n. *alkali* alkali, Gr. adj. *philos* loving; N.L. neut. adj. *alkaliphilum* alkali-loving.

Characteristics are summarized in Table 186. The type strain grows at 30–60°C, and over a pH range of 8.0–9.15 with an optimum for growth at 8.7. Requires carbonate anion. Isolated from a cow/pig manure mixture at neutral pH.

DNA G+C content (mol%): 40.9 (T_m).

Type strain: S1, ATCC 700784, DSM 12257, VKM B-2192.

GenBank accession number (16S rRNA gene): AF097024.

5. ***Desulfotomaculum antarcticum*** (*ex* Iizuka, Okazaki and Seto 1969) Campbell and Singleton 1988, 220^{VP} (Effective publication: Campbell and Singleton 1986, 1202.)

ant.arc'ti.cum. N.L. adj. *antarcticum* pertaining to Antarctica.

Only a few characteristics are available and they summarized in Table 186.

TABLE 186. Characteristics differentiating the species of the genus *Desulfotomaculum*^a

Species	<i>Desulfotomaculum nigrificans</i>	<i>Desulfotomaculum neoaxialdas</i>	<i>Desulfotomaculum stercorale</i>	<i>Desulfotomaculum alkalophilum</i>	<i>Desulfotomaculum anoxicum</i>	<i>Desulfotomaculum oxicum</i>	<i>Desulfotomaculum aurivolum</i>	<i>Desulfotomaculum carboniferum</i>	<i>Desulfotomaculum acidiferrum</i>	<i>Desulfotomaculum giffordiae</i>	<i>Desulfotomaculum halophilum</i>	<i>Desulfotomaculum kuetzingii</i>

Literature	Campbell and Singleton (1986); Klempers et al. (1985); Liu et al. (1997)	Widdel and Pfennig (1977b, 1981)	Hagenauer et al. (1997a); Hippe et al.	Pikula et al. (2000)	Iizuka et al. (1969)	Vandieren et al. (2006)	Love et al. (1993b)	Parshina et al. (2005)	Dauvas et al. (1988)	Kuever et al. (1993, 1999)	Tardy-Jacquenod et al. (1998)	Nazina et al. (1989)

^aSymbols: Spore orientation: ST, subterminal; T, terminal; PC, paracentral; C, central; Motility: pc, peritrichous; sp, single or polar; Oxidation of substrate: I, incomplete; C, complete; –, positive; +, negative; (+), poorly utilized; NR, not reported.

^bTau et al. (1997) determined a cell width of 1–1.2 µm and a cell length of 3–6 µm for this species.

^cMotility was lost during cultivation.

^dSubstrate oxidation should be regarded as complete. The high substrate concentration used may result in misinterpretation.

^eOnly in the presence of acetate or yeast extract as carbon sources.

^fIn the original publication, fructose utilization without sulfate reduction is described in the text, but not listed in the table.

^gKlempers et al. (1985) observed only growth with autoclaved glucose, but not with filter-sterilized glucose.

^hDescription given in the text and table of the original publication is varying on this point.

ⁱData retrieved from whole-genome sequencing.

(1995)	Tebo and Obraztsova (1998)

DNA G+C content (mol%): unknown.

Type strain: IAM 64.

GenBank accession number (16S rRNA gene): not available.

6. **Desulfotomaculum arcticum** Vandieken, Knoblauch and Jørgensen 2006, 689^{VP}

arc'ti.cum. L. neut. adj. *arcticum* from the Arctic, referring to the place from which the strain was isolated.

Characteristics are summarized in Table 186. The type strain grows at 26–46.5°C, and over a pH range of 6.8–7.5 with an optimum for growth at 7.1–7.5. Isolated from a permanently cold fjord sediment in Svalbard.

DNA G+C content (mol%): 48.9 (T_m).

Type strain: 15, DSM 17038, JCM 12923.

GenBank accession number (16S rRNA gene): DQ148942.

7. **Desulfotomaculum australicum** Love, Patel, Nichols and Stackebrandt 1993a, 864^{VP} (Effective publication: Love, Patel, Nichols and Stackebrandt 1993b, 250.)

au.stra'li.cum. L. n. *australicum* south, pertaining to Australia.

Characteristics are summarized in Table 186. The type strain grows at 40–74°C, and over a pH range of 5.5–8.5 with an optimum for growth at 7.0–7.4. Isolated from 60°C water obtained from a depth of 914 meters in the Great Artesian Basin Australia (borehole 94).

DNA G+C content (mol%): 48.1.

Type strain: AB33, ACM 3917, DSM 11792.

GenBank accession number (16S rRNA gene): M96665.

8. **Desulfotomaculum carboxydvorans** Parshina, Sipma, Nakashimada, Henstra, Smidt, Lysenko, Lens, Lettinga and Stams 2005, 2164^{VP}

car.bo.xy.di.vor'ans. N.L. n. *carboxydum* carbon monoxide; L. part. adj. *vorans* devouring; N.L. part. adj. *carboxydvorans* carbon monoxide-digesting.

Characteristics are summarized in Table 186. The type strain grows at 30–68°C, and over a pH range of 6.0–8.0 with the optimum pH for growth at 6.8–7.2. Can grow at high concentrations of carbon monoxide (100%). Isolated from sludge from an anaerobic bioreactor treating paper mill waster water.

DNA G+C content (mol%): 45.6 (HPLC).

Type strain: CO-1-SRB, DSM 14480, VKM B-2319.

GenBank accession number (16S rRNA gene): AY961415.

9. **Desulfotomaculum geothermicum** Daumas, Cord-Ruwisch and Garcia 1990, 105^{VP} (Effective publication: Daumas, Cord-Ruwisch and Garcia 1988, 177.)

geo.ther'mi.cum. Gr. n. *gê* earth, Gr. fem. n. *therme* heat; N.L. neut. adj. *geothermicum* geothermal.

Characteristics are summarized in Table 186. The type strain grows at 37–56°C, and over a pH range of 6.0–8.0 with an optimum for growth at 7.2–7.4. Isolated from anoxic geothermal ground water (from a depth of 2500 m) used for a geothermal heating plant.

DNA G+C content (mol%): 50.4 (Bd).

Type strain: BSD, ATCC 49053, DSM 3669.

GenBank accession number (16S rRNA gene): AJ294428, X80789, Y11567.

10. **Desulfotomaculum gibsoniae** Kuever, Rainey and Hippe 1999, 1807^{VP}

gib.so'ni.ae. N.L. gen. n. *gibsoniae* of Gibson; named after Jane Gibson, a British-American microbiologist and bio-

chemist who made important contributions to the field of anaerobic degradation of aromatic compounds.

Characteristics are summarized in Table 186. Grows on a large variety of aromatic compounds including lignite monomers. The type strain grows at 20–42°C, and over a pH range of 6.0–8.0 with an optimum for growth at 6.9–7.2. Isolated from anoxic mud of a freshwater ditch.

DNA G+C content (mol%): 54.8 (T_m).

Type strain: Groll, DSM 7213.

GenBank accession number (16S rRNA gene): Y11576.

11. **Desulfotomaculum halophilum** Tardy-Jacquenod, Magot, Patel, Matheron and Caumette 1998, 337^{VP}

ha.lo'phi.lum. Gr. n. *hals*, *halos* salt; Gr. adj. *philos* loving; N.L. neut. adj. *halophilum* salt-loving.

Characteristics are summarized in Table 186. The type strain grows at 30–40°C, and over a pH range of 6.9–8.0 with an optimum for growth at 7.3. Isolated from production fluid of an oil-producing well in France.

DNA G+C content (mol%): 56.3 (HPLC).

Type strain: SEBR 3139, ATCC 700650, DSM 11559.

GenBank accession number (16S rRNA gene): U88891.

12. **Desulfotomaculum kuznetsovii** Nazina, Ivanova, Kanchaveli and Rozanova 1990, 470^{VP} (Effective publication: Nazina, Ivanova, Kanchaveli and Rozanova 1989, 662.)

kuz. net.so'vi. N.L. gen. n. *kuznetovii* of Kuznetsov, named in honor of the leading Soviet microbiologist S.I. Kuznetsov who has made a significant contribution to the study of geochemical activity of micro-organisms.

Characteristics are summarized in Table 186. The type strain grows at 50–85°C. Isolated from a water sample obtained from spontaneous effusion of a rift in the Sukhums deposit containing subsurface thermal mineral waters.

DNA G+C content (mol%): 49 (T_m).

Type strain: 17, DSM 6115, VKM B-1805.

GenBank accession number (16S rRNA gene): AJ294427, Y11569.

13. **Desulfotomaculum luciae** Liu, Karnauchow, Jarrell, Balkwill, Drake, Ringelberg, Clarno and Boone 1997, 620^{VP}

lu'ci.ae. N.L. gen. n. *luciae* of Lucia, referring to the source of the type strain, a hot spring in St Lucia.

Characteristics are summarized in Table 186. The type strain grows at 50–70°C, and over a pH range of 6.2–8.3 with an optimum for growth at 6.3–7.8. Isolated from a hot spring located on the island St. Lucia.

DNA G+C content (mol%): 51.4 (HPLC).

Type strain: SLT, ATCC 700428, DSM 12396, SMCC W644.

GenBank accession number (16S rRNA gene): AF069293.

14. **Desulfotomaculum putei** Liu, Karnauchow, Jarrell, Balkwill, Drake, Ringelberg, Clarno and Boone 1997, 619^{VP}

pu'te.i. L. gen. n. *putei* of a pit or well, referring to the source of the type strain, an exploratory gas well.

Characteristics are summarized in Table 186. The type strain grows at 40–65°C, and over a pH range of 6.0–8.4 with an optimum for growth at 7.0–7.9. Isolated from an exploratory gas well.

DNA G+C content (mol%): 47.1 (HPLC).

Type strain: TH-11, ATCC 700427, DSM 12395, SMCC W459.

GenBank accession number (16S rRNA gene): AF053929.

15. **Desulfotomaculum ruminis** (Adams and Postgate 1959) Campbell and Postgate 1965, 361^{AL}. (*Desulfovibrio orientis* Adams and Postgate 1959, 256)
ru'mi.nis. L. n. *rumen* throat, adopted for first stomach (rumen) of a ruminant; L. gen. n. *ruminis* of a rumen.
Characteristics are summarized in Table 186.
DNA G+C content (mol%): 48.5–49.9 (Bd, HPLC, T_m).
Type strain: strain DL, ATCC 23193, DSM 2154.
GenBank accession number (16S rRNA gene): AB294140, M34418, Y11572.
16. **Desulfotomaculum sapomandens** Cord-Ruwisch and Garcia 1990, 105^{VP} (Effective publication: Cord-Ruwisch and Garcia 1985, 329.)
sa.po.man'dens. L. n. *sapo* soap; L. v. *mando* to eat, to consume; N.L. part. adj. *sapomandens* eating soap.
Characteristics are summarized in Table 186. Grows on phenyl-substituted organic acids. The type strain grows at 20–43°C, and over a pH range of 6.3–8.5 with an optimum at 7.0. Isolated from oxic gasoline-contaminated soil from a gasoline station.
DNA G+C content (mol%): 48 (Bd).
Type strain: "Pato", DSM 3223.
GenBank accession number (16S rRNA gene): AF168365.
17. **Desulfotomaculum solfataricum** Goorissen, Boschker, Stams and Hansen 2003, 1227^{VP}
sol.fa.ta'ri.cum. N.L. neut. adj. *solfataricum* pertaining to solfatares, derived from solfatar (field of hot sulfur springs and fumaroles), referring to the original habitat of the organism.
Characteristics are summarized in Table 186. The type strain grows at 48–65°C, and over a pH range of 6.4–7.9 with an optimum for growth at 7.3. Isolated from hot solfataric fields in northeast Iceland.
DNA G+C content (mol%): 48.3 (method unknown).
Type strain: V21, CIP 107984, DSM 14956.
GenBank accession number (16S rRNA gene): AY084078.
18. **Desulfotomaculum thermoacetoxidans** Min and Zinder 1995, 879^{VP} (Effective publication: Min and Zinder 1990, 403.)
ther.mo.a.cet.o'xi.dans. Gr. adj. *thermos* hot; L. n. *acetum* vinegar; N.L. n. *acidum aceticum* acetic acid; N.L. v. *oxido* make oxide, oxidize; N.L. part. adj. *thermoacetoxidans* oxidizing acetate under hot conditions.
Characteristics are summarized in Table 186. The type strain grows between 45 and 65°C, and over a pH range of 6.0 to 7.5 with an optimum for growth at 6.5. Isolated from a thermophilic anaerobic digester converting cellulosic wastes to methane.
DNA G+C content (mol%): 49.7 (T_m).
Type strain: CAMZ, DSM 5813.
GenBank accession number (16S rRNA gene): Y11573.
19. **Desulfotomaculum thermobenzoicum** Tasaki, Kamagata, Nakamura and Mikami 1991b, 580^{VP} emend. Plugge, Balk and Stams 2002, 397 (Effective publication: Tasaki, Kamagata, Nakamura and Mikami 1991a, 351.)
ther.mo.ben.zo'i.cum. Gr. adj. *thermos* hot; N.L. *benzoicum* pertaining to benzoate; N.L. neut. adj. *thermobenzoicum* oxidizes benzoate under thermophilic conditions.
See following description of *Desulfotomaculum thermobenzoicum* subsp. *thermobenzoicum*.
DNA G+C content (mol%): 52.8 (HPLC).
Type strain: TSB, ATCC 49756, DSM 6193.
GenBank accession number (16S rRNA gene): Y11574.
- 19a. **Desulfotomaculum thermobenzoicum subsp. thermobenzoicum** Tasaki, Kamagata, Nakamura and Mikami 1991b, 581^{VP} emend. Plugge, Balk and Stams 2002, 397 (Effective publication: Tasaki, Kamagata, Nakamura and Mikami 1991a, 351.)
Characteristics are summarized in Table 186. The type strain grows at 40–70°C, and a pH range of 6.0–8.0 with an optimum for growth at 7.2. Isolated from sludge of a thermophilic, methanogenic reactor treating wastewater from a kraft pulp production process.
DNA G+C content (mol%): 52.8 (HPLC).
Type strain: TSB, ATCC 49756, DSM 6193.
GenBank accession number (16S rRNA gene): Y11574.
- 19b. **Desulfotomaculum thermobenzoicum subsp. thermosyntrophicum** Plugge, Balk and Stam 2002, 398^{VP}
ther.mo.syn.tro'phi.cum Gr. adj. *thermos* hot; Gr. pref. *syn* together, Gr. v. *trophein* to eat; *syntrophos* nourished together; N.L. neut. adj. *thermosyntrophicum* referring to the capacity of the organism to grow at elevated temperatures on propionate in the presence of a partner organism.
Characteristics are summarized in Table 186. Strain TPO could grow fermentatively on benzoate by an unknown pathway. Grows syntrophically on propionate in co-culture with H₂-scavenging methanogens. The type strain grows at 4–62°C, and over a pH range of 6.0–8.0 with an optimum for growth at 7.0. Isolated from granular methanogenic sludge.
DNA G+C content (mol%): 53.7 (HPLC).
Type strain: strain TPO, ATCC BAA-281, DSM 14055.
GenBank accession number (16S rRNA gene): AY007190.
20. **Desulfotomaculum thermocisternum** Nilsen, Torsvik and Lien 1996, 401^{VP}
ther.mo.cis.ter'num. Gr. adj. *thermos* hot; L. fem. n. *cisterna* reservoir; N.L. adj. *thermocisternum* hot reservoir, referring to the original habitat of the organism.
Characteristics are summarized in Table 186. The type strain grows at 41–75°C, and over a pH range of 6.2–8.9 with an optimum for growth at 6.7. Isolated from pure formation water that originated from the subterranean Brent Group oil formation 2.6 km below the sea floor of the Norwegian sector of the North Sea.
DNA G+C content (mol%): 56 (HPLC), 57 (T_m).
Type strain: ST90, DSM 10259.
GenBank accession number (16S rRNA gene): U33455.
21. **Desulfotomaculum thermosapovorans** Fardeau Ollivier, Patel, Dwivedi, Ragot and Garcia 1995, 221^{VP}
ther.mo.sa.po.vo'rans. Gr. adj. *thermos* hot; L. masc. n. *sapo* soap; L. v. *vor* to devour; N.L. part. adj. *thermosapovorans* thermophilic and soap-devouring.
Characteristics are summarized in Table 186. The type strain grows at 35–60°C. The optimum pH for growth is 7.2–7.5. Isolated from a thermophilic, anaerobic enrichment culture growing on rice hulls. The initial inoculum was a mixed compost containing rice hulls and peanut shells.
DNA G+C content (mol%): 51.2 (Bd).
Type strain: MLF, DSM 6562.

GenBank accession number (16S rRNA gene): Y11575.

22. **Desulfotomaculum thermosubterraneum** Kaksonen Spring, Schumann, Kroppenstedt and Puhakka 2006b, 2606^{VP} ther.mo.sub.ter.ra'ne.um. Gr. adj. *thermos* hot; L. neut. adj. *subterraneum* subterranean, underground, below the Earth's surface; *thermosubterraneum* thermophilic inhabitant of the Earth's subsurface.

Characteristics are summarized in Table 186. The type strain grows at 50–72°C and over a pH range of 6.4–7.8 with an optimum for growth at 7.2–7.4. Isolated from a geothermally active underground mine in Japan.

DNA G+C content (mol%): 54.4 (HPLC).

Type strain: RL50JIII, DSM 16057, JCM 13837.

GenBank accession number (16S rRNA gene): DQ208688.

Species *incertae sedis*

1. “**Desulfotomaculum reducens**” (not formally described and not validly published)
re.du'cens. L. part. adj. *reducens* converting to a different state.

Characteristics are summarized in Table 186. Incomplete description is found in Tebo and Obratzsova, (1998). Strain MI-1 grows with Cr(VI), Mn(IV) Fe(III),

and U(VI) as electron acceptors. Isolated from sediment of a shipyard located in the San Francisco Bay estuary, CA, USA.

DNA G+C content (mol%): 42 (whole-genome sequence).

Reference strain: strain MI-1 (not deposited in any service collection)

GenBank accession number (16S rRNA gene): U95951.

Genus VIII. **Pelotomaculum** Imachi, Sekiguchi, Kamagata, Hanada, Ohashi and Harada 2002, 1734^{VP} emend. deBok, Harmsen, Plugge, de Vries, Akkermans, de Vos and Stams 2005, 1702 emend. Qiu, Sekiguchi, Hanada, Imachi, Tseng, Cheng, Ohashi, Harada and Kamagata 2006a, 180

FRED A. RAINEY

Pe.lo.to.ma'cu.lum. Gr. adj. *pelos* dark-colored, hence anaerobic mud; L. neut. n. *tomaculum* sausage; N.L. neut. n. *Pelotomaculum* sausage-shaped bacteria living in anaerobic environments.

Nonmotile, sausage-shaped cells with spherical endospores. Gram reaction negative but has Gram-positive cell-wall structure. Strictly anaerobic. Mesophilic and thermophilic. Growth by syntrophy with hydrogenotrophs or by fermentation. Can use a limited number of compounds including propionate, primary alcohols, low molecular mass aromatics, or lactate in association with hydrogenotrophic methanogens. Organic compounds such as fumarate are used by some species as alternative electron acceptors. Sulfate, sulfite, thiosulfite, elemental sulfur, nitrate, and ferric ion are not reduced. The major cellular fatty acid is C_{15:0 iso}. Major quinones are MK-7, MK-7(H₄), or MK-9(H₄). Member of the family *Peptococcaceae* on the basis of 16S rRNA gene sequence comparisons (Figure 6).

DNA G+C content (mol%): 52.8–53.6.

Type species: **Pelotomaculum thermopropionicum** Imachi, Sekiguchi, Kamagata, Hanada, Ohashi and Harada 2002, 1734^{VP}.

Taxonomic comment

The genus *Pelotomaculum* comprises five species that form a phylogenetically coherent cluster within the family *Peptococcaceae*. The genus falls in a large cluster that includes the species of the genera *Desulfotomaculum* and *Sporotomaculum* (see Figure 180). The genus *Cryptanaerobacter* (Juteau et al., 2005) falls within the *Pelotomaculum* cluster and was described after the genus *Pelotomaculum* on the basis of differences in temperature optima for growth, fatty acid composition, and substrate utilization patterns. Since the description of *Cryptanaerobacter*, four additional species of the genus *Pelotomaculum* have been described and fall

on either side of the branch representing *Cryptanaerobacter phenolicus* (see Figure 180). The 16S rRNA gene sequence similarities between the species of the genus *Pelotomaculum* are in the range 92.7–97.5% and between *Pelotomaculum* species and *Cryptanaerobacter phenolicus* are 93.4–94.4%. All species of the genus are unable to reduce sulfate as is also the case with *Cryptanaerobacter phenolicus* (Juteau et al., 2005). However, the *dsrAB* genes have been found in one of the species, *Pelotomaculum propionicum* (Imachi et al., 2007). The fact that the species of the genus *Pelotomaculum* are unable to reduce sulfate differentiates them from the related *Desulfotomaculum* species in the family *Peptococcaceae*. The species of the genus are differentiated on the basis of phylogenetic position, all sharing less than 95% 16S rRNA gene sequence similarity with the exception of *Pelotomaculum isophthalicum* and *Pelotomaculum terephthalicum* which share 97.5% sequence similarity. The species *Pelotomaculum schinkii* has been shown to contain at least two copies of the 16S rRNA gene that differ in sequence 3% (de Bok et al., 2005). The species *Pelotomaculum isophthalicum* and *Pelotomaculum terephthalicum* can be differentiated on the basis that *Pelotomaculum terephthalicum* is able to grow in pure culture on crotonate, while *Pelotomaculum isophthalicum* only grows syntrophically. The species *Pelotomaculum isophthalicum*, *Pelotomaculum propionicum*, and *Pelotomaculum schinkii*, can only grow syntrophically in coculture with hydrogenotrophic methanogens. *Pelotomaculum thermopropionicum* and *Pelotomaculum terephthalicum* can grow in pure culture on a limited number of substrates. *Cryptanaerobacter phenolicus* grows in pure culture, but syntrophic growth has not been tested (Juteau et al., 2005).

FIGURE 180. 16S rRNA gene sequence based phylogeny indicating the position of the genera *Pelotomaculum* and *Sporotomaculum* within the radiation of the species of the genus *Desulfotomaculum*. The scale bar represents 2 inferred nucleotide substitutions per 100 nucleotides.

List of species of the genus *Pelotomaculum*

1. ***Pelotomaculum thermopropionicum*** Imachi, Sekiguchi, Kamagata, Hanada, Ohashi and Harada 2002, 1734^{VP}

ther.mo.pro.pi.o'ni.cum. Gr. adj. *thermos* hot; N.L. n. *propionatum* propionate; L. suff. *-icus* pertaining to; N.L. neut. adj. *thermopropionicum* thermophilic and pertaining to propionate.

Cells are 1.7–2.8 μm × 0.7–0.8 μm. Spores are spherical and central. Utilizes propionate, ethanol, lactate, ethylene glycol, 1-butanol, 1-propanol, 1-pentanol, and 1,3-propanediol in syntrophic association with hydrogenotrophic methanogens. Ferments pyruvate and fumarate in pure culture. Fumarate used as an electron acceptor in the presence of propionate, ethanol, or lactate as an electron donor. Growth occurs

0–0.4% NaCl but not at 0.5% NaCl. Growth occurs between 45–65°C, optimum 55°C. pH range for growth is 6.7–7.5, optimum 7.0. The type strain was isolated from granular sludge in a thermophilic upflow anaerobic sludge blanket reactor.

DNA G+C content (mol%): 52.8 (T_m).

Type strain: SI, DSM 13744, JCM 10971.

GenBank accession number (16S rRNA gene): AB035723.

2. ***Pelotomaculum isophthalicum*** corrig. Qiu, Sekiguchi, Hanada, Imachi, Tseng, Cheng, Ohashi, Harada and Kamagata 2006b, 2026^{VP} (Effective publication: Qiu, Sekiguchi, Hanada, Imachi, Tseng, Cheng, Ohashi, Harada and Kamagata 2006a, 181.)

i.so.phtha.li'ci.cum. N.L. neut. n. *acidum isophthalicum* isophthalic acid; L. suff. *-icus -a -um*, suffix used in adjectives with the sense of belonging to; N.L. neut. adj. *isophthalicum* referring to the substrate isophthalic acid, which can be utilized by the species.

Cells are 0.8–1.0 µm × 2.0–3.0 µm, occurring singly or in pairs. Spores are spherical and central. Mesophilic. Strictly anaerobic. The organism only shows syntrophic growth with a methanogen under anaerobic (methanogenic) conditions. In syntrophic association with hydrogenotrophic methanogens, the strain can utilize ortho-phthalate, isophthalate, terephthalate, benzoate, and 3-hydroxybenzoate. No substrates tested support growth in pure culture. The temperature range for growth is 25–45°C, optimum 37°C. Growth occurs in the pH range 6.8–7.2, optimum 7.0. Growth occurs in the presence of 0–0.5% NaCl. Growth is inhibited at 0.75% NaCl. Sulfate, sulfite, thiosulfate, nitrate, elemental sulfur, fumarate, ferric iron, and 4-hydroxybenzoate cannot be utilized as electron acceptors. The type strain was isolated from granular sludge from an upflow anaerobic sludge bed reactor treating wastewater from the manufacturing of terephthalic and isophthalic acids. This strain has been deposited in the culture collections as a co-culture with *Methanospirillum hungatei*.

DNA G+C content (mol%): not determined.

Type strain: JI, ATCC BAA-1053, JCM 12282.

GenBank accession number (16S rRNA gene): AB232785.

3. **Pelotomaculum propionicum** Imachi, Sakai, Ohashi, Harada, Hanada, Kamagata and Sekiguchi 2007, 1491^{VP}

pro.pi.o.ni'ci.cum. N.L. neut. adj. *propionicum* referring to the substrate propionic acid, which can be metabolized by the species.

Cells are Gram-positive, 1.0 µm × 2.0–4.0 µm, occurring singly or in pairs. Spores are spherical and central. Mesophilic. Strictly anaerobic. The organism only grows syntrophically on propionate with hydrogenotrophic methanogens. Does not demonstrate sulfate reduction but has *dsrAB* genes that are essential for sulfate respiration. Temperature range for growth is 25–45°C, optimum 37°C. Growth occurs in the pH range 6.5–7.5, optimum 6.5–7.2.

Growth occurs in the presence of 0–0.5% NaCl. Growth is inhibited at >1.0% NaCl. The type strain was isolated from anaerobic, mesophilic, granular sludge. This strain has been deposited in the culture collections as a co-culture with *Methanospirillum hungatei*.

DNA G+C content (mol%): not determined.

Type strain: MGP, DSM 15578, JCM 11929.

GenBank accession number (16S rRNA gene): AB154390.

4. **Pelotomaculum schinkii** de Bok, Harmsen, Plugge, de Vries, Akkermans, de Vos and Stams 2005, 1702^{VP}

schin'ki.i. N.L. gen. n. *schinkii* named after Bernhard Schink, who studied several syntrophic conversions. The first spore-forming syntrophic bacterium, *Syntrophospora bryantii*, was isolated by his group.

Cells are Gram-stain-positive, 1.0 µm × 2.0–2.5 µm. Spores are spherical in late exponential phase. Nonmotile. Strictly anaerobic. Grows syntrophically on propionate with methanogens that utilize both hydrogen and formate, such as *Methanospirillum hungatei* JF-1^T and *Methanobacterium formicum* MF^{NT}. Organic supplements not required for growth. Yeast extract (0.1%) and fumarate (10–20 mM) enhance growth. The type strain was isolated from freeze-dried granular sludge from a UASB reactor treating sugar beet waste in co-culture with *Methanospirillum hungatei* JF-1^T.

DNA G+C content (mol%): Not determined.

Type strain: HH, ATCC BAA-615, DSM 15200.

GenBank accession number (16S rRNA gene): X91169, X91170.

5. **Pelotomaculum terephthalicum** corrig. Qiu, Sekiguchi, Hanada, Imachi, Tseng, Cheng, Ohashi, Harada and Kamagata 2006b, 2026^{VP} (Effective publication: Qiu, Sekiguchi, Hanada, Imachi, Tseng, Cheng, Ohashi, Harada and Kamagata 2006a, 181.)

te.re.phtha.li'ci.cum. N.L. neut. n. *acidum terephthalicum* terephthalic acid; L. suff. *-icus -a -um*, suffix used in adjectives with the sense of belonging to; N.L. neut. adj. *terephthalicum* referring to the substrate, terephthalic acid, which can be utilized by the species.

Cells are 0.8–1.0 µm × 2.0–3.0 µm, occurring singly or in pairs. Spores are spherical and central. Mesophilic. Strictly anaerobic. Grows syntrophically and in pure culture. In syntrophic association with hydrogenotrophic methanogens, the strain can utilize terephthalate, isophthalate, benzoate, hydroquinone, 2-hydroxybenzoate, 3-hydroxybenzoate, 2,5-dihydroxybenzoate, 3-phenylpropionate, and crotonate. In pure culture ferments crotonate, hydroquinone, and 2,5-dihydroxybenzoate. The temperature range for growth is 30–40°C, optimum 37°C. Growth occurs in the pH range 6.5–7.5, optimum 7.0. Growth occurs in the presence of 0–0.5% NaCl. Growth is inhibited at >2.0% NaCl. Sulfate, sulfite, thiosulfate, nitrate, elemental sulfur, fumarate, ferric iron, and 4-hydroxybenzoate cannot be utilized as electron acceptors. The major cellular fatty acids are C_{15:0 iso} and C_{14:0}. Major quinone is MK-9 (H₄). The type strain was isolated from granular sludge from an upflow anaerobic sludge bed reactor treating wastewater from the manufacture of terephthalic and isophthalic acids.

DNA G+C content (mol%): 53.6 (HPLC).

Type strain: JT, DSM 16121, JCM 11824, NBRC 100523.

GenBank accession number (16S rRNA gene): AB091323.

Genus IX. **Sporotomaculum** Brauman, Müller, Garcia, Brune and Schink 1998, 219^{VP}

FRED A. RAINEY

Spo.ro.to.ma'cu.lum. Gr. n. *spora* spore; L. n. *tomaculum* sausage. N.L. neut. n. *Sporotomaculum* a spore-forming sausage-shaped organism.

Gram positive, strictly anaerobic. Metabolism fermentative, inorganic electron acceptors not used. Member of the family *Peptococcaceae* on the basis of 16S rRNA gene sequence comparisons (Figure 6).

DNA G+C content (mol%): 46.8–48.0.

Type species: **Sporotomaculum hydroxybenzoicum** Brauman, Müller, Garcia, Brune and Schink 1998, 219^{VP}.

Taxonomic comments

The genus *Sporotomaculum* comprises two species that fall within the radiation of a number of species of the genus *Desulfotomaculum* (see Figure 180) in the family *Peptococcaceae*. Both species of the genus *Sporotomaculum* fall within the phylogenetic cluster of the genus *Desulfotomaculum* that contains *Desulfotomaculum geothermicum*, *Desulfotomaculum arcticum*, *Desulfotomaculum gibsoniae*, *Desulfotomaculum thermosapovorans*, and *Desulfotomaculum sapomandens* (see Figure 180). The 16S rRNA gene sequence similarity values between the *Sporotomaculum* species and these related *Desulfotomaculum* species are in the range 92.3–95.2% and it is interesting to note that the two species of the genus *Sporotomacu-*

lum share the same 16S rRNA gene sequence similarity (95.2%) as *Sporotomaculum syntrophicum* and *Desulfotomaculum sapomandens*.

The genus was described based on its differentiation from *Desulfotomaculum* species due to its inability to reduce sulfate, sulfite, or thiosulfate even in the presence of added hemin or 1,4-naphthoquinone. In addition, *Sporotomaculum hydroxybenzoicum* was limited in its substrate range, using only 3-hydroxybenzoate as a sole carbon and energy source (Brauman et al., 1998). *Sporotomaculum syntrophicum* was added to the genus *Sporotomaculum* on the basis of its close phylogenetic relationship to *Sporotomaculum hydroxybenzoicum*; they share 95.2% 16S rRNA gene sequence similarity and lack the ability to reduce sulfate. The two species can be differentiated on the basis of a number of characteristics including motility (*Sporotomaculum hydroxybenzoicum* is motile). *Sporotomaculum syntrophicum* shows syntrophic growth on benzoate, crotonate, and butyrate in co-culture with *Methanospirillum hungatei*, and grows in pure culture on crotonate and benzoate. *Sporotomaculum hydroxybenzoicum* grows in pure culture and only on 3-hydroxybenzoate.

List of species of the genus *Sporotomaculum*1. **Sporotomaculum hydroxybenzoicum** Brauman, Müller, Garcia, Brune and Schink 1998, 219^{VP}

hydro.xy.ben.zo'i.cum. N.L. neut. adj. *hydroxybenzoicum* referring to hydroxybenzoic acid which is used as sole carbon and energy source.

Rod-shaped cells, 2.0–3.0 µm × 0.6–0.8 µm, motile, with pointed ends, occurring singly or in pairs. Gram positive and slightly motile in the early exponential phase. Endospores are central and spherical. Strictly anaerobic. Chemoorganoheterotroph. Grows on 3-hydroxybenzoate as sole source of carbon and energy. No growth with pyruvate, DL-lactate, succinate, fumarate, malate, citrate, valerate, pimelate, crotonate, crotonate with H₂/CO₂ atmosphere (80:20), caproate, adipate, hexanoate, heptanoate, cyclohexane carboxylate, ethanol, methanol, D-fructose, glucose, benzoate, 2-hydroxybenzoate, 4-hydroxybenzoate, 3-aminobenzoate, 4-aminobenzoate, 2,3- and 2,5-dihydroxybenzoate, α-, β-, and γ-resorcyate, protocatechuate, gallate, syringate, ferulate, caffeate, hydroxycinnamate, terephthalate, phenylacetate, 2-, 3-, and 4-chlorobenzoate, phenol, catechol, resorcinol, hydroquinone, phloroglucinol, pyrogallol, 2-, 3- and 4-cresol. 3-Hydroxybenzoate is fermented to butyrate, acetate, and CO₂. No reduction of nitrate, sulfate, thiosulfate, sulfite, ferric iron, oxygen, or fumarate. Growth requires sulfide-reduced mineral media. Addition of small amounts of dithionite shortens the lag phase. Yeast extract and tryptone stimulate growth but are not required for growth. Cytochromes not detected. The temperature range for growth is 24–37°C, optimum 30°C. pH range for growth is 6.8–8.1, optimum 7.3–7.6.

The type strain was isolated from a selective enrichment in sulfide-reduced freshwater mineral medium with 3-hydroxybenzoate as substrate using gut homogenates of soil-feeding termites (*Cubitermes speciosus*).

DNA G+C content (mol%): 48 (HPLC).

Type strain: BT, ATCC 700645, DSM 5475.

GenBank accession number (16S rRNA): Y14845.

2. **Sporotomaculum syntrophicum** Qiu, Sekiguchi, Imachi, Kamagata, Tseng, Cheng, Ohashi and Harada 2003b, 937^{VP} (Effective publication: Qiu, Sekiguchi, Imachi, Kamagata, Tseng, Cheng, Ohashi and Harada 2003a, 248.)

syn.tro'phi.cum. Gr. pref. *syn* together with; Gr. v. *trophein* nourish; N.L. suff. *icus* pertaining to; N.L. neut. adj. *syntrophicum* pertaining to syntrophic substrate utilization.

Rod-shaped cells, 1.0–2.0 µm × 0.8–1.0 µm, occurring singly or in pairs. Spores are spherical and central. Gram-stain-positive. Strictly anaerobic. Utilizes benzoate, butyrate, and crotonate in syntrophic association with hydrogenotrophic methanogens. Ferments crotonate in pure culture. Growth occurs in the presence of 0–1% NaCl but does not occur in the presence of more than 2% NaCl. The temperature range for growth is 28–45°C, optimum 35–40°C. The pH range for growth is 6.0–7.5, optimum 7.0–7.2. Sulfate, sulfite, thiosulfate, nitrate, elemental sulfur, fumarate, or ferric iron cannot be used as electron acceptors. The type strain was isolated from methanogenic sludge from a two-phase anaerobic treatment system.

DNA G+C content (mol%): 46.8 (HPLC).

Type strain: FB, DSM 14795, JCM 11495.

GenBank accession number (16S rRNA): AB076610.

Genus X. **Syntrophobotulus** Friedrich, Springer, Ludwig and Schink 1996, 1068^{VP}

BERNHARD SCHINK AND MICHAEL FRIEDRICH

Syn.tro.pho.bo'tu.us. Gr. pref. *syn* together; Gr. v. *trophein* to nourish; L. masc. n. *botulus* sausage; N.L. masc. n. *Syntrophobotulus* a syntrophic, sausage-like bacterium.

Straight to slightly curved rods. Spores formed at the cell ends. Stains Gram-stain-negative; ultrastructural analysis shows Gram-positive cell-wall architecture. **Strictly anaerobic; fermentative metabolism.** Chemo-organotrophic. Cytochromes and catalase activity absent. Isolated from sewage sludge.

DNA G+C content (mol %): 46.7 ± 0.15 % (HPLC).

Type species: **Syntrophobotulus glycolicus** Friedrich, Springer, Ludwig and Schink 1996, 1068^{VP}.

Further descriptive information

According to the 16S rRNA phylogenetic analysis presented in the roadmap to this volume (Figure 6), the genus *Syntrophobotulus* is a member of the family *Peptococcaceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*. *Desulfobacterium dehalogenans* and *Desulfotomaculum orientis* share 91.2% and 88.6% 16S rRNA sequence similarity, respectively. More distant relationships were found to other *Desulfotomaculum* species, to *Heliobacterium* sp., and to *Selenomonas* sp. (Friedrich et al., 1996).

Syntrophobotulus glycolicus was originally isolated in a defined co-culture with the methanogenic partner organism *Methanospirillum hungatei* using glycolate as the sole organic substrate (Friedrich et al., 1991). Cells are thin, slightly curved rods, 0.5 µm in diameter and 2.5–3.5 µm in length. Cells stain Gram-negative but do not form slime in the KOH-test that is typical of Gram-stain-negative bacteria. Electron microscopic examination of ultrathin sections reveals a cell-wall structure typical of Gram-positive bacteria. Oval spores are formed in ageing cultures at the cell ends. The bacterium depends on cooperation with a methanogenic or a homoacetogenic partner organism if grown on glycolate. *Syntrophobotulus glycolicus* strain FIGlyR was isolated later in pure culture with glyoxylate as the sole substrate (Friedrich and Schink, 1995).

Syntrophobotulus glycolicus is unique in its energy metabolism because it uses only glyoxylate in pure culture or glycolate in syntrophic co-culture with hydrogen-scavenging partners such as *Methanospirillum hungatei* or *Acetobacterium woodii*. Glyoxylate is condensed with acetyl-CoA to form malyl-CoA which is converted to malate in an ATP-yielding reaction. The malic enzyme converts malate to pyruvate with concomitant decarboxylation and NADP reduction, and pyruvate is oxidized to acetyl-CoA with ferredoxin as electron acceptor, thus closing the reaction cycle. Glycolate oxidation in syntrophic cultures is catalyzed by a membrane-bound glycolate dehydrogenase enzyme which forms

glyoxylate and cooperates with a membrane bound hydrogenase system. Hydrogen release from glycolate oxidation requires ATP investment via a proton-motive force (Friedrich and Schink, 1993) and glyoxylate reduction with molecular hydrogen can be coupled in membrane preparations with ATP synthesis via electron transport phosphorylation (Friedrich and Schink, 1995). Thus, during growth with glycolate in syntrophic co-culture, ATP is synthesized only by substrate level phosphorylation, and part of this energy is reinvested into a reversed electron transport driven by ATP hydrolysis, whereas during growth in pure culture on glyoxylate ATP is produced by glyoxylate dismutation to glycolate and CO₂, employing substrate-level phosphorylation and electron-transport phosphorylation (Friedrich and Schink, 1995). As a result, *Syntrophobotulus glycolicus* has become a model organism for the study of syntrophic energy metabolism because all biochemical components of this unusual energy metabolism system can be identified in cell-free extracts.

Enrichment and isolation procedures

Syntrophobotulus glycolicus was enriched with glycolate as sole carbon source under strictly anoxic conditions in bicarbonate-buffered mineral medium at pH 7.2 and 30°C. A primary co-culture contained a homoacetogenic partner bacterium which could be replaced by *Methanospirillum hungatei* to form a defined co-culture (Friedrich et al., 1991). From this co-culture, *Syntrophobotulus glycolicus* was isolated with glyoxylate as sole organic substrate.

Maintenance procedures

Pure cultures may be stored anoxically in liquid medium at 4°C in the dark. Stock cultures should be transferred every 1–2 months. For long-term preservation, a dense cell suspension of *Syntrophobotulus glycolicus* may be made in anoxic medium containing glycerol or dimethyl sulfoxide, sealed in sterile glass capillaries, and stored in liquid nitrogen.

Differentiation of the genus *Syntrophobotulus* from other genera

Syntrophobotulus glycolicus differs from all other described bacteria by its unusual energy metabolism which is based exclusively on utilization of glycolate and glyoxylate. Glyoxylate is dismutated in pure culture to glycolate and CO₂; glycolate is oxidized to CO₂ only in syntrophic co-culture with hydrogen-scavenging partner organisms.

List of species of the genus *Syntrophobotulus***1. *Syntrophobotulus glycolicus* Friedrich, Springer, Ludwig and Schink 1996, 1068^{VP}**

gly.co'li.cus. N.L. n. *acidum glycolicum* glycolic acid; N.L. masc. adj. *glycolicus* referring to glycolic acid, the key substrate of this species.

Rod-shaped bacterium, slightly curved, 0.5 µm by 2.5–3.5 µm in size, occurring typically as single cells or in short chains or small aggregates. Nonmotile. Oval spores formed

in ageing cultures at the cell ends. Cells stain Gram-stain-negative; ultrastructural analysis shows Gram-positive cell-wall architecture.

Strictly anaerobic, grow chemotrophically in pure culture by fermentative oxidation of glyoxylate. Glycolate is oxidized in syntrophic co-culture with, e.g., *Methanospirillum hungatei* or *Acetobacterium woodii* as a partner. No other organic or inorganic substrates used. Glycolic

acid is converted to carbon dioxide and hydrogen in syntrophic culture; glyoxylic acid is fermented in pure culture to carbon dioxide, hydrogen, and glycolic acid. Does not reduce sulfate, sulfite, thiosulfate, elemental sulfur, or nitrate. Cells contain menaquinones 7–10, with MK-9 as major fraction. No cytochromes present.

pH range 6.7–8.3; optimum pH 7.3. Temperature range, 15–37°C; optimum temperature 28°C. Growth optimal in

freshwater medium. Growth possible also in brackish-water medium with 110 mM NaCl and 5 mM MgCl₂; no growth in marine medium. Habitats are sewage sludge and anoxic freshwater sediments.

DNA G+C content (mol%): 46.7 ± 0.15% (HPLC).

Type strain: FIGlyR, DSM 8271.

GenBank accession number (16S rRNA gene): not available for the type strain; X99706 for strain SIGlym.

Genus XI. *Thermincola* Sokolova, Kostrikina, Chernyh, Kolganova, Tourova and Bonch-Osmolovskaya 2005, 2072^{VP}

TATYANA G. SOKOLOVA AND DARIA G. ZAVARZINA

Therm.in'co.la. Gr. adj. *thermos* hot; L. fem. n. *incola* inhabitant; N.L. fem. n. *Thermincola* inhabitant of a hot spring.

Cells are rods with **Gram-positive** type cell walls. Anaerobic thermophile **capable of chemolithotrophic growth by anaerobic CO oxidation coupled to molecular hydrogen and CO₂ production**. Does not ferment organic substrates. Found in terrestrial hot springs.

DNA G+C content (mol%): 45–48.

Type species: *Thermincola carboxydiphila* Sokolova, Kostrikina, Chernyh, Kolganova, Tourova and Bonch-Osmolovskaya 2005, 2072^{VP}.

Further descriptive information

Members of the genus *Thermincola* are geographically widespread. The type species *Thermincola carboxydiphila* was isolated from a slightly alkaline hot spring (pH 8.5, 55°C) on the bank of Bolshaya River, Baikal Lake region (Sokolova et al., 2005). The second characterized species, *Thermincola ferriacetica*, was isolated from ferric deposits at a terrestrial hot spring (pH 6.8–7.0, 65°C) of the Stolbovskie group, Kunashir Island, Kurils (Zavarzina et al., 2007). Additional isolates have been isolated from a hot spring in Iceland (personal communication from N. K. Birkland). There is also evidence that the habitat of *Thermincola* is not limited to terrestrial hot springs. Genes of 16S rRNA with high similarity to *Thermincola* have been detected in oil reservoirs by Liew and Jong (GenBank accession no. EF095439), in waste waters (personal communication from A. I. Slobodkin), and in the enrichments from a geothermally active mine in Japan (Kaksonen et al., 2006a).

Enrichment and isolation procedures

Thermincola species were enriched and isolated with anaerobically prepared media. *Thermincola carboxydiphila* was isolated in mineral carbonate-bicarbonate buffered medium (pH 9.0) under 100% CO in the gas phase. The medium was supplemented with vitamins and sodium acetate (0.2 g/l) and incubated at 55°C (Sokolova et al., 2005). For the enrichment and isolation of *Thermincola ferriacetica*, bicarbonate-CO₂ buffered medium (pH 7.0) under N₂/CO₂ (80:20 v/v) was used. The medium contained sodium acetate (20 mM) and amorphous Fe(III) oxide (90 mM) and was incubated at 60°C (Zavarzina et al., 2007). Enrichments were serially diluted in the growth medium prior to isolation of single colonies in roll tubes.

Maintenance procedures

Cultures may be stored at room temperature for 1–2 weeks, at 4°C for 3–5 months, or in liquid nitrogen.

Taxonomic comments

On the basis of 16S rRNA sequence analyses, the genus *Thermincola* is a deep lineage within the family *Peptococcaceae* in the order *Clostridiales* (Zavarzina et al., 2007) (see Figure 5 and Figure 6). *Thermincola* is currently represented by two described species, *Thermincola carboxydiphila* and *Thermincola ferriacetica*, which share 98% sequence similarity of the 16S rRNA gene and 27% DNA–DNA hybridization (Zavarzina et al., 2007). Outside the genus, the mostly closely related organism is *Pelotomaculum thermopropionicum*, with 95% similarity of its 16S rRNA gene (Imachi et al., 2002).

List of species of the genus *Thermincola*

1. *Thermincola carboxydiphila* Sokolova, Kostrikina, Chernyh, Kolganova, Tourova and Bonch-Osmolovskaya 2005, 2072^{VP} car.bo.xy.di'phi.la. N.L. neut. n. *carboxydum* carbon monoxide, Gr. adj. *philos* loving, N.L. fem. adj. *carboxydiphila* loving carbon monoxide.

Has the characteristics of the genus. Cells are straight, thick rods, with rounded ends, about 0.5 µm by 0.6–3.0 µm. Motile due to one or two lateral flagella. The temperature range for growth is 37–68°C, and the optimum is 55°C. Alkalitolerant, with a pH range for growth of 6.7–9.5 and an optimum at 8.0. The presence of 0.2 g/l of yeast extract or acetate is required

for growth with CO. Elemental sulfur, thiosulfate, sulfate, or nitrate do not stimulate the growth and are not reduced during the growth on CO. Does not grow organotrophically on peptone, yeast extract, starch, cellulose, cellobiose, sucrose, maltose, ribose, xylose, lactose, glucose, galactose, fructose, mannitol, sorbitol, pyruvate, acetate, formate, lactate, succinate, methanol, ethanol, and glycerol. H₂ + CO₂ (80/20 v/v) and H₂ or CO with ferric iron does not support growth. Does not grow on peptone, yeast extract, sucrose, pyruvate, acetate, formate, lactate, succinate, methanol, ethanol, and glycerol in the presence of elemental sulfur, sulfate, thiosulfate, or ferric

iron. Growth is inhibited by penicillin, erythromycin, streptomycin, rifampin, vancomycin, and tetracycline. Isolated from a mixture of water, mud, and cyanobacterial mat from a hot spring of the Baikal Lake region.

DNA G+C content (mol%): 45.4±1.0 (T_m).

Type strain: 2204, DSM 17129, JCM 13258, VKM B-2283.

GenBank accession number (16S rRNA gene): AY603000.

2. *Thermincola ferriacetica* Zavarzina, Sokolova, Tourova, Chernyh, Kostrikina and Bonch-Osmolovskaya 2007, 894^{VP} (Effective publication: Zavarzina, Sokolova, Tourova, Chernyh, Kostrikina and Bonch-Osmolovskaya 2007, 5.)
fer.ri.ace.ti.ca. L. n. *ferrum* iron; N.L. n. *acetis -atis* acetate; N.L. fem. n. *ferriacetica* iron oxide- and acetate-utilizing.

FIGURE 181. Morphology of *Thermincola carboxydiphila* strain 2204^T. Negative stained (a) and thin section (b) electron micrographs. Bars = 0.5 μm. (Reprinted with permission from Sokolova et al., 2005. International Journal of Systematic and Evolutionary Microbiology 55: 2069–2073.)

Thermincola ferriacetica has the characteristics of the genus. Cells are straight to slightly curved rods, 0.4–0.5 × 1.0–3.0 μm, occurring singly or in large chains (Figure 182). They exhibit a slight tumbling motility by means of 1–4 peritrichous flagella (Figure 181). Some of the cells in chains form round, clostridial-type spores that are considerably larger in diameter than the vegetative cells and located in the middle of the chain (arrows in Figure 182). Spores are exceptionally thermoresistant and survive heating at 121°C for 30 min. In roll tubes, colonies are single lens-shaped, white-cream in color, and 0.2–0.4 mm in diameter. Multiplication occurs by binary fission. Growth occurs from 45–70°C, with an optimum at 57–60°C, and in a pH range of 5.9–8.0, with an optimum at 7.0–7.1. Reduces amorphous Fe(III)-oxide by oxidation of molecular hydrogen, acetate, peptone, yeast and beef extracts, glycogen, glycolate, pyruvate, betaine, choline, *N*-acetyl-D-glucosamine and Casamino acids. No growth occurs on adonite, arginine, butyrate, citrate, formate, glutamate,

FIGURE 182. Morphology of *Thermincola ferriacetica*. Light micrographs showing the single cell morphology (a) and spore-forming chains (b, c). The arrows indicate the presence of forespores (b) and free spores (c). Bar = 5 μm. Negatively stained (d) and thin-section (e) electron micrographs. The single flagellum is apparent in (d), and the Gram-positive type cell wall is apparent in (e). Bars = 5 μm.

lactate, malate, propionate, serine, succinate, tartrate, ethanol, mannitol, methanol, propanol, L-sorbitol, L-histidine, glycerol, DL-lysine, sarcosine, tryptone, cellulose, chitin, and starch. Does not grow by fermentation of sugars, peptone, and yeast and beef extracts. With acetate, it uses amorphous Fe(III) oxide, magnetite, 2,6-anthraquinone disulfonate (AQDS), and MnO₂ as the electron acceptors, but not citrate, fumarate, sulfate, sulfite, thiosulfate, dithionite, elemental sulfur, and nitrate. With molecular hydrogen and yeast extract (0.2 g/l), it reduces Fe(III) oxide, AQDS, MnO₂, and thiosulfate. Grows chemolithoauto-

trophically with hydrogen as the energy source, Fe(III) as the electron acceptor, and CO₂ as carbon source. Yeast extract stimulates growth. Requires 0.2 g/l both of yeast extract and acetate for growth on CO. Chloramphenicol, neomycin, penicillin, kanamycin, but not polymyxin B and streptomycin, inhibit growth. The type strain was isolated from ochre deposits in a hot spring in Stolbovskiy, Kuril Islands, Russia.

DNA G+C content (mol%): 47.8±1.0 (T_m).

Type strain: Z-0001, DSM 14005, VKM B-2307.

GenBank accession number (16S rRNA gene): AY631277.

Family VII. **Peptostreptococcaceae** fam. nov.

TAKAYUKI EZAKI

Pep.to.strep.to.coc.ca'ce.ae. N.L. n. *Peptostreptococcus* a bacterial genus, the type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Peptostreptococcaceae* the family of *Peptostreptococcus*.

Obligately or facultatively anaerobic, Gram-stain-positive cocci or filamentous rods. Catalase-negative or occasionally weakly positive. Species of the genus *Filifactor* are endosporeforming. Family *Peptostreptococcaceae* contains the type genus *Peptostreptococcus*, *Filifactor*, and *Tepidibacter*. According to the 16S rRNA phylogenetic analysis presented in the roadmap to this volume (Figure 5), the genus the family *Peptostreptococcaceae* is in order

Clostridiales, class *Clostridia* in the phylum *Firmicutes*. The phylogenetic relationships among the members of the family *Peptostreptococcaceae* and closely related genera are given in Figure 183. The differential characteristics and features of the family are summarized in Table 187.

DNA G+C content (mol%): 28–43.

Type genus: **Peptostreptococcus** Kluyver and van Niel 1936.

Genus I. **Peptostreptococcus** Kluyver and van Niel 1936, 401^{AL} emend. Ezaki, Kawamura, Li, Li, Zhao and Shu 2001, 1527

TAKAYUKI EZAKI

Pep.to.strep.to.coc'cus. Gr. adj. *peptos* cooked, digested; N.L. masc. n. *Streptococcus* a bacterial genus name; N.L. masc. n. *Peptostreptococcus* the digesting streptococcus.

Non-spore-forming obligately anaerobic Gram-stain-positive cocci. Cells may occur in pairs, irregular masses, or chains. Chemo-organotrophs. The optimum temperature for growth is 37°C. Metabolize peptone and amino acids to acetic, butyric, isobutyric, caproic, and isocaproic acid (Holdeman et al., 1986). Carbohydrates are weakly fermented. Found in human intestine, vagina, and various abscesses. Diamino acid of peptidoglycan is lysine.

DNA G+C content (mol%): 34–36.

Type species: **Peptostreptococcus anaerobius** (Nativig 1905) Kluyver and van Niel 1936, 401^{AL} (*Streptococcus anaerobius* Nativig 1905, 724).

Taxonomic comments

After 16S rRNA gene sequence analysis, old members of the genus *Peptostreptococcus* were reclassified as *Anaerococcus*, *Peptoniphilus*, *Finegoldia*, *Micromonas*, *Gallicola*, *Slackia*, *Ruminococcus*, and *Atopobium*.

Nonsaccharolytic members of the genus *Peptostreptococcus* (*Peptostreptococcus asaccharolyticus*, *Peptostreptococcus harei*, *Peptostreptococcus indolicus*, *Peptostreptococcus ivorii*, and *Peptostreptococcus lacrimalis*) were reclassified as members of the genus *Peptoniphilus* (Ezaki et al., 2001). Saccharolytic members of the genus *Peptostreptococcus* (*Peptostreptococcus prevotii*, *Peptostreptococcus tetradius*, *Peptostreptococcus hydrogenalis*, *Peptostreptococcus lactolyticus*, and *Peptostreptococcus octavius*) were reclassified as members of the genus *Anaerococcus* (Ezaki et al., 2001). *Peptostreptococcus magnus* was transferred to the genus *Finegoldia*, *Peptostreptococcus micros* to the genus *Micromonas micros* (Murdoch and Shah, 1999), since renamed *Parvimonas micra* by Tindall and Euzéby (2006) because the genus name was illegitimate. *Peptostreptococcus heliotrinreducens* was transferred to the genus *Slackia* (Wade et al., 1999). *Peptostreptococcus barnesae* was transferred to the genus *Gallicola* (Ezaki et al., 2001), *Peptostreptococcus productus* to the genus *Ruminococcus* (Ezaki et al., 1994), and *Peptostreptococcus parvulus* to the genus *Atopobium* (Collins and Wallbanks, 1992).

List of species of the genus *Peptostreptococcus*

1. **Peptostreptococcus anaerobius** (Nativig 1905) Kluyver and van Niel 1936, 401^{AL} (*Streptococcus anaerobius* Nativig, 1905, 724) an.a.e.ro'bi.us. Gr. pref. *an* not; Gr. n. *aer* air; Gr. n. *bios* life; N.L. adj. *anaerobius* not living in air, anaerobic.

Nonsporeforming obligately anaerobic Gram-stain-positive cocci. Cells may occur in pairs, irregular masses, or chains. Chemo-organotrophs. The optimum temperature for growth is 37°C. Metabolizes peptone and amino acids to acetic, butyric, isobutyric, caproic, and isocaproic acid. Weak acid is produced from glucose and mannose. No acid is produced from raffinose, lactose, sucrose, mannitol, sorbitol, or arabi-

nose. Found in human intestine, vagina, and various abscesses. Differential characteristics of the *Peptostreptococcus anaerobius* from other anaerobic cocci from human sources are given in Table 188.

Peptidoglycan position 1, position 3, and interpeptide bridge are alanine, lysine, and D-aspartate. (Ezaki et al., 1983). Major cellular fatty acids are C_{18:1}, C₁₆, and C₁₈ (Ezaki et al., 1983; O'Leary and Wilkinson, 1988).

DNA G+C content (mol%): 34–36.

Type strain: ATCC 27337, CCUG 7835, CIP 104411, CIPP 4372, DSM 2949, LMG 15865, NCTC 11460, VPI 4330.

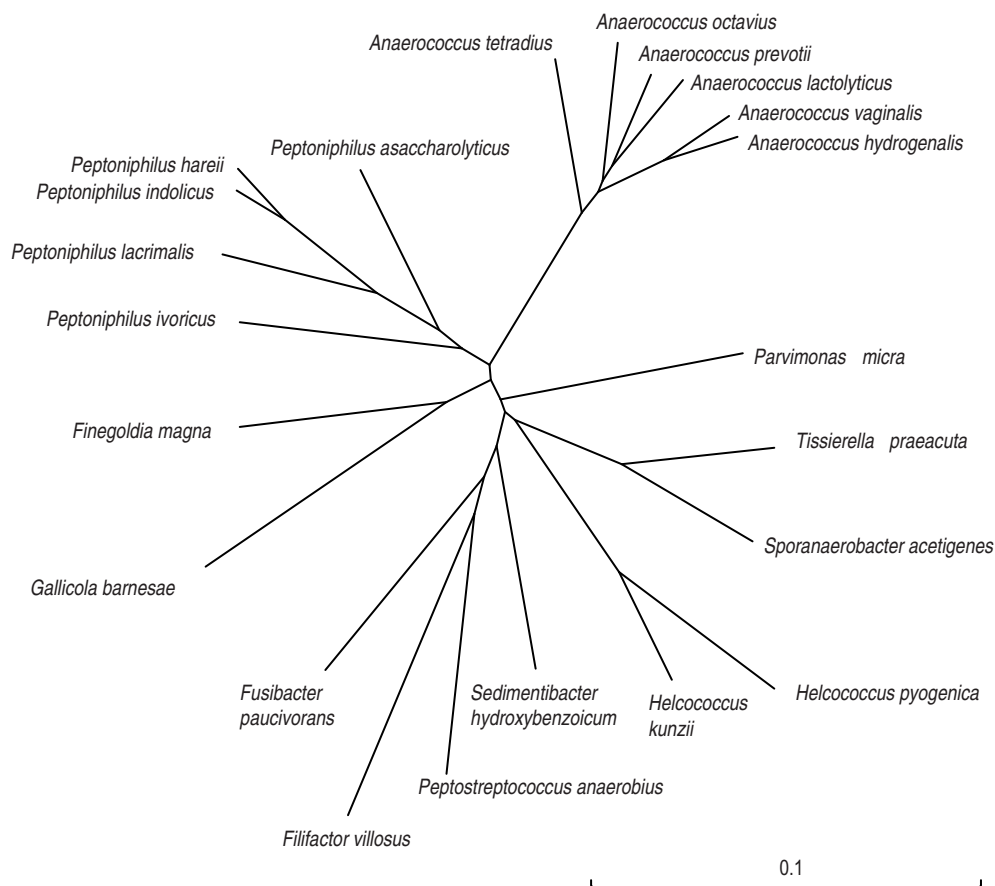

FIGURE 183. Phylogenetic relationships among type species of the family *Peptostreptococaceae* and closely related genera from *Clostridiales* families *incertae sedis* XI and XII.

GenBank accession number (16S rRNA gene): AY326462, D14150, L04168.

2. **Peptostreptococcus stomatis** Downes and Wade 2006, 753^{VP}
sto.ma'tis. N.L. gen. n. *stomatis* of the mouth from Gr. n. *stoma* mouth.

Obligately anaerobic, Gram-stain-positive cocci, 0.8×0.8–0.9 μm, occurring in pairs and short chains. After 5 d incubation on fastidious anaerobe agar (LabM) plates, colonies are 0.8–1.8 mm in diameter, circular, entire, high convex to pyramidal, opaque, shiny and cream to off-white in colour with a narrow, grey, peripheral outer ring. Moderate growth is obtained in broth media and growth is further enhanced by the addition of fermentable carbohydrates. Weakly saccharolytic and ferments fructose, glucose and maltose

weakly; arabinose, cellobiose, lactose, mannitol, mannose, melezitose, melibiose, raffinose, rhamnose, ribose, salicin, sorbitol, sucrose and trehalose are not fermented. Major amounts of acetic and isocaproic acids, minor amounts of isobutyric and isovaleric acids and trace to minor amounts of butyric acid are produced as end products of metabolism in PYG. Esculin, arginine, gelatin and urea are not hydrolyzed. Indole and catalase are not produced and nitrate is not reduced.

Source: human oral cavity infections.

DNA G+C content (mol%): 36 (HPLC).

Type strain: W2278, DSM 17678, CCUG 51858.

GenBank accession number (16S rRNA gene): DQ160208.

Genus II. **Filifactor** Collins, Lawson, Willems, Cordoba, Fernández-Garayzábal, Garcia, Cai, Hippe and Farrow 1994, 822^{VP}

JARI JALAVA AND ERKKI EEROLA

Fi.li.fac'tor. L. n. *filum* thread; L. masc. n. *factor* maker; N.L. masc. n. *Filifactor* thread-maker.

Rods, which are obligately **anaerobic** chemo-organotrophs. Cells do not have flagella. Produce **acetate** and **butyrate**.

DNA G+C content (mol%): 28–34.

Type species: Filifactor villosus Collins, Lawson, Willems, Cordoba, Fernández-Garayzábal, Garcia, Cai, Hippe and Farrow 1994, 822^{VP} (*Clostridium villosum* Love, Jones and Bailey 1979, 242).

Further descriptive information

Cells occur singly, in pairs, and occasionally in short chains or filaments. Cells have variable Gram-staining properties. Cells have rounded to tapered ends (Cato et al., 1985; Love et al., 1979). Spores may be formed. They are single, oval, and subterminal (Love et al., 1979). Cells are nonmotile, but some of the strains have been shown to have twitching or end-over-end type of motility. Colonies are small (0.5–1.0 mm) and nonhemolytic (Cato et al., 1985; Love et al., 1979).

No acid is produced from esculin, fructose, glucose, maltose, mannitol, mannose, melibiose, ribose, sucrose, or xylose. Threonine and lactate are not utilized (Cato et al., 1985; Love et al., 1979).

The 16S rRNA sequence homology between the two *Filifactor* species described thus far is 92.6 % (Jalava and Eerola, 1999).

All tested strains are susceptible to chloramphenicol (12 µg/ml) and erythromycin (3 µg/ml) and most of the strains are susceptible to penicillin (2 U/ml) (Cato et al., 1985; Love et al., 1979).

Filifactor species have been isolated from human gingival sulcus of patients with gingivitis or periodontitis, from oral cavities of cats, and from subcutaneous wound abscesses of cats. They might have a pathogenic role in mixed anaerobic infections (Cato et al., 1985; Downes et al., 2001; Love et al., 1987, 1979). Diagnostic characteristics of the two species are given in the Table 189.

Enrichment and isolation procedures

The species can be isolated and grown on sheep blood agar plates and brain heart infusion agar plates incubated anaerobically (Love et al., 1979).

Maintenance procedures

Cooked meat plus peptic digest of meat broth and cooked meat plus peptic digest of meat broth supplemented with 0.4 % glucose, 0.1 % cellobiose, 0.1 % maltose and 0.1 % starch can be used for cultivation of pure cultures (Love et al., 1979). Fastidious anaerobic agar plates with and without 7% (w/v) bovine blood have been used for cultivation of pure cultures in anaerobic conditions (Jalava and Eerola, 1999).

Taxonomic comments

The species belonging to the genus *Filifactor* are biochemically relatively inert. Also Gram-staining might give variable reactions. Because of these difficulties, proper classification of the species in the genus *Filifactor* based only on phenotypic properties is difficult. According to the 16S rRNA phylogenetic analysis presented in the roadmap to this volume (Figure 5), the genus *Filifactor* is a member of the family *Peptostreptococcaceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*.

List of species of the genus *Filifactor*

1. ***Filifactor villosus*** Collins, Lawson, Willems, Cordoba, Fernández-Garayzábal, Garcia, Cai, Hippe and Farrow 1994, 822^{VP} (*Clostridium villosum* Love, Jones and Bailey 1979, 242)

vil.lo'sus. L. adj. hairy, shaggy, rough-haired.

This description is based on studies of Love et al. (1979), comparative 16S rRNA sequence analyses by Collins et al. (1994), and the description of the *Clostridium villosum* by Cato et al. (1986) in the first edition of the Manual.

Cells are rods with parallel sides and rounded ends. Cell size is 0.6 × 4.0–6.0 µm, but up to 24- to 30-µm-long filaments are common in old cultures (24–48 h). Cells are Gram-stain-positive if cultured on agar or in broth not more than 18–24 h but after this Gram-staining gives variable or negative

reaction. Gram reaction of the old cultures (7 d) is variable and most cells are Gram-stain-negative with unstained gaps existing along cells. However, thin-section electron microscopy studies have shown that the structure of the cell wall

and the mode of the division are consistent with the Gram-positive bacteria. Cells are nonmotile and flagella have not been detected. Spores are single, oval, and subterminal, and they slightly swell the cell. Spores are not always detected but chopped meat-carbohydrate slant cultures are heat resistant (Love et al., 1979).

Young (24h) colonies on sheep blood agar and brain heart infusion agar are 0.5 mm in diameter. The diameter of the colony increases to approximately 5 mm by 3 d. Colonies are irregular, rhizoid, convex, whitish to yellow, rough, have a matt surface, adhere strongly to the medium. Colonies do not hemolyze blood (Love et al., 1979).

Cultures in chopped meat-carbohydrate (CMC) broth grow in a delicate membrane near the surface of the broth, with bacteria clumped as discrete colonies throughout the membrane; later the membrane collapses and settles to the bottom of the tube. Cultures in peptone-yeast-extracted glucose (PYG) broth have a rosy or flaky sediment and no turbidity. Growth at 37°C is stimulated by 5% horse serum. No gas is detected in PYG deep agar cultures. Ammonia is produced in chopped meat and in peptone-yeast extract broth containing 5% horse serum (SPY) cultures (Cato et al., 1986).

Products of fermentation in CMC and PY broth supplemented with 5% horse serum are acetate, butyrate, isobutyrate, formate, and isovalerate. Trace amounts of lactate, succinate, and methylmalonate may be detected. Small amounts of H₂ are produced. Pyruvate is converted to butyrate; lactate is not utilized; increased amounts of acetate and butyrate are produced in threonine cultures but propionate is not produced. Indole, lecithinase, or lipase are not produced. Esculin is not hydrolyzed. Nitrate is not reduced. There is no milk reaction and meat is not digested. Gelatin is liquefied weakly (Cato et al., 1986).

Other characteristics are given in the Table 190.

Culture supernatants are nontoxic to mice (Cato et al., 1986).

The strains are susceptible to chloramphenicol (12 µg/ml), erythromycin (3 µg/ml), penicillin (2 U/ml), amoxicillin (2.5 µg/ml), carbenicillin (100 µg/ml) and doxycycline (6 µg/ml) (Love et al., 1979).

Isolated from subcutaneous wound abscesses of cats (Love et al., 1979).

DNA G+C content (mol%): not reported.

Type strain: NCTC 11220.

EMBL/GenBank accession number (16S rRNA gene): X73452.

2. **Filifactor alocis** Jalava and Eerola 1999, 1378^{VP} (*Fusobacterium alocis* Cato, Moore and Moore 1985, 475)

a'lo.cis. Gr. n. *alox* a furrow; N.L. gen. n. *alocis* of a furrow, referring to its isolation from a crevice of the gums.

This description is based on study of Cato et al. (1985) and comparative 16S rRNA sequence analyses (Jalava and Eerola, 1999).

Cells are Gram-stain-negative, obligately anaerobic rods. The size of the cells is 0.4–0.7 × 1.5–7.0 µm. Normally they occur singly, in pairs, or sometimes in short chains and have rounded to tapered ends. Cells are nonmotile and do not have any flagella but some of the strains show slow twitching or end-over-end type of motility. Spores are not formed.

Optimal growth temperature is 37°C. Colonies are small (up to 1.0 mm), circular, entire, flat to low convex, translucent to transparent, shiny and smooth. Colonies do not produce hemolysis on blood agar plates.

Little or no gas is detected in PYG deep agar cultures. H₂ is detected in broth cultures if the growth is sufficient. Acid is not produced from adonitol, amygdalin, L-arabinose, cellobiose, dextrin, dulcitol, *meso*-erythritol, esculin, D-fructose, D-galactose, D-glucose, glycerol, glycogen, inositol, inulin, lactose, maltose, D-mannitol, D-mannose, melezitose, melibiose, pectin, raffinose, rhamnose, D(-)-ribose, salicin, D-sorbitol, L-sorbose, starch, sucrose, trehalose, or D-xylose. Esculin, starch, and hippurate are not hydrolyzed. Nitrate, resazurin, or neutral red are not reduced. Indole, acetylmethylcarbinol, catalase, lecithinase, lipase, urease, oxidase, or deoxyribonuclease are not produced. Pyruvate, DL-lactate, D-gluconate, or DL-threonine are not utilized. Milk, gelatin, or chopped meat are not digested. Small to moderate amounts of butyrate and acetate are produced in PYG broth.

Other characteristics are given in the Table 190.

The strains are susceptible to chloramphenicol (12 µg/ml), clindamycin (1.6 µg/ml), erythromycin (3 µg/ml), and tetracycline (6 µg/ml). Most of the strains are susceptible to penicillin (2 U/ml).

Isolated from human gingival sulcus of patients with gingivitis or periodontitis, from oral cavities of cats, and soft tissue infections of cats caused by contamination from oral cavities.

DNA G+C content (mol%): 34 (T_m).

Type strain: ATCC 35896.

EMBL/GenBank accession number (16S rRNA gene): AJ006962.

Genus III. **Tepidibacter** Slobodkin, Tourova, Kostrikina, Chernyh, Bonch-Osmolovskaya, Jeanthon and Jones 2003, 1133^{VP}

ALEXANDER SLOBODKIN

Te.pi.di.bac'ter. L. adj. *tepidus* warm; N.L. *bacter* masc. equivalent of Gr. neut. dim. n. *bakterion* rod; N.L. masc. n. *Tepidibacter* a warm rod.

Straight to slightly curved **rods** 0.7–0.9 µm in diameter and 3.5–6.0 µm in length. **Gram-positive type cell wall**. Cells occur singly, in pairs or in short chains and exhibit tumbling motility

due to peritrichous flagellation. **Forms** round or ovoid refractile **endospores** in terminally or subterminally swollen sporangia. **Anaerobic. Moderately thermophilic**, the temperature

range for growth is 30–60°C. Neutrophilic. Optimal growth at marine salinity. **Grows organotrophically** on a number of proteinaceous substrates and carbohydrates. Elemental sulfur may be reduced, but sulfur reduction does not stimulate growth.

DNA G+C content (mol%): 24–29 (T_m).

Type species: Tepidibacter thalassicus Slobodkin, Tourova, Kostrikina, Chernyh, Bonch-Osmolovskaya, Jeanthon and Jones 2003, 1133^{VP}.

Further descriptive information

16S rRNA gene sequence analysis places the genus *Tepidibacter* within cluster XI of the clostridia (nomenclature of Collins et al., 1994). Members of the genus *Tepidibacter* are currently represented by two species, *Tepidibacter thalassicus* and *Tepidibacter formicigenes*, which share 95% of 16S rRNA gene sequence similarity.

Both species of the genus *Tepidibacter* form terminal or sub-terminal endospores. In the late-exponential phase of growth, up to 30% of the cells contain spores.

The best growth of *Tepidibacter* can be obtained on complex proteinaceous substrates such as tryptone, casein, and peptone. *Tepidibacter thalassicus* is able to perform the Stickland reaction with alanine and proline. Carbohydrates, with an exception of starch, slightly stimulate growth of *Tepidibacter thalassicus*. Growth of *Tepidibacter formicigenes* on sugars is more efficient. Both species produce acetate and ethanol from glucose, and either H₂/CO₂, (*Tepidibacter thalassicus*) or formate (*Tepidibacter formicigenes*). External electron acceptors do not enhance growth, however, elemental sulfur can be reduced to hydrogen sulfide.

Both members of the genus *Tepidibacter* were isolated from deep-sea hydrothermal vents. *Tepidibacter thalassicus* was isolated from the outer wall of a 'black smoker' covered with the polychetous annelid *Alvinella* species (13° N hydrothermal field

on the East-Pacific Rise, depth 2650 m); *Tepidibacter formicigenes* was isolated from hydrothermal fluid (the Menez-Gwen hydrothermal site, Mid-Atlantic Ridge, depth 800–1000 m). Location of these vents, one of which is in Pacific and other in Atlantic Ocean, suggests wide geographical distribution of *Tepidibacter* in marine hydrothermal environments where they probably function as decomposers of organic matter produced by deep-sea biota.

Table 187 shows differential characteristics for *Tepidibacter* from other members of *Peptostreptococcaceae* and related genera.

Enrichment and isolation procedures

Members of the genus *Tepidibacter* have been isolated from deep-sea hydrothermal vents (Slobodkin et al., 2003; Urios et al., 2004). There are no reports that members of this genus occur in other environments. Employment of the marine anaerobic media rich in proteinaceous substrates and incubation in the temperature range of 45–55°C may favor the enrichment of *Tepidibacter* species. *Tepidibacter thalassicus* rapidly hydrolyzes casein (Hammerstein grade) that results in visual disappearance of the casein flocks and may help in the detection of growth. *Tepidibacter* forms colonies in 1.5% (w/v) agar.

Maintenance procedures

Members of the genus *Tepidibacter* may be maintained on the medium of Slobodkin et al. (2003) with peptone or casein as a substrate or on the glucose/yeast extract/peptone medium of Urios et al. (2004). Good and reproducible growth can also be obtained in liquid medium lacking sulfide as a reducing agent and prepared anaerobically (Slobodkin et al., 2003). Freeze-drying of the cultures results in good recovery. Liquid cultures may be stored at +4°C for 10–12 months without loss of viability.

List of species of the genus *Tepidibacter*

1. ***Tepidibacter thalassicus*** Slobodkin, Tourova, Kostrikina, Chernyh, Bonch-Osmolovskaya, Jeanthon and Jones 2003, 1133^{VP}

tha.las'si.cus. Gr. fem. n. *thalassa* the sea; N.L. masc. adj. *thalassicus* of the sea.

Cells are straight to slightly curved rods, 0.7–0.9 µm in diameter and 3.5–6.0 µm in length, which form round, refractile endospores in terminally swollen sporangia. Cells occur singly or in short chains and exhibit tumbling motility due to peritrichous flagellation. The temperature range for growth is 33–60°C, with an optimum at 50°C. The pH range for growth is 4.8–8.5, with an optimum at 6.5–6.8. Growth occurs at NaCl concentrations in the range 1.5–6% (w/v). Anaerobic. Substrates

utilized include casein, peptone, albumin, yeast extract, beef extract, alanine plus praline, and starch. Glucose, maltose, pyruvate, valine, and arginine slightly stimulate growth in the presence of yeast extract. Fructose, sucrose, xylose, cellobiose, L-arabinose, glycerol, sorbitol, acetate, butyrate, lactate, formate, methanol, fumarate, glycine, alanine, proline, alanine plus glycine, betaine, olive oil, xylan, carboxymethylcellulose, filter paper, chitin, keratin, and H₂/CO₂ are not utilized. The products of glucose fermentation are ethanol, acetate, and molecular hydrogen. Reduces elemental sulfur to hydrogen sulfide. Does not use nitrate, fumarate, sulfate, sulfite, thiosulfate, amorphous Fe(III) oxide, Fe(III) citrate, or oxygen as electron acceptors.

DNA G+C content (mol%): 24 (T_m).

Type strain: SC 562, DSM 15285, UNIQEM 215.

GenBank accession number (16S rRNA gene): AY158079.

2. **Tepidibacter formicigenes** Urios, Cueff, Pignet and Barbier 2004, 442^{VP}

for.mi.ci'ge.nes. N.L. adj. *formicicum* from L. n. *formica* ant; Gr. v. *gennaio* produce; N.L. adj. *formicigenes* producing formic acid.

Rod-shaped cells, 0.8 µm in diameter and 4.0 µm in length; motile by means of peritrichous flagella. Cells stain Gram-stain-positive. Forms ovoid refractile subterminal endospore. Growth occurs between 35 and 55 °C (optimum, 45 °C), between pH 5.0 and 8.0 (optimum, 6.0) and at 2–6% (w/v) sea salts (optimum, 3%). Anaerobic,

able to ferment mainly complex proteinaceous substrates and carbohydrates. Grows on glucose/yeast extract/peptone medium. Tryptone, glucose, sucrose, fructose, maltose, and pyruvate support growth in the presence of yeast extract. Poor growth on ethanol, mannose, and peptone. Cellobiose, xylose, starch, cellulose, dextran, xylan, succinate, lactate, trehalose, lactose, arabinose, galactose, ribose, rhamnose, mannitol, sorbitol, glycerol, urea, and olive oil are not utilized. The products of glucose fermentation (in decreasing order) are formate, acetate, and ethanol. Elemental sulfur, polysulfides, thiosulfate, sulfite, sulfate, nitrite, nitrate, and FeCl₃ do not enhance growth.

DNA G+C content (mol%): 29 (T_m).

Type strain: DV1184, CIP 107893, DSM 15518.

GenBank accession number (16S rRNA gene): AY245527.

Family VIII. **Ruminococcaceae** fam. nov.

FRED A. RAINEY

Ru.mi.no.coc.ca'ce.ae. N.L. masc. n. *Ruminococcus* type genus of the family; -aceae ending to denote family; N.L. fem. pl. n. *Ruminococcaceae* the *Ruminococcus* family.

The family *Ruminococcaceae* is described on the basis of phylogenetic analyses of 16S rRNA gene sequences (Figure 160); the family contains the genera *Ruminococcus* (type genus), *Acetan-aerobacterium*, *Acetivibrio*, *Anaerofilum*, *Anaerotruncus*, *Ethanoligenens*, *Faecalibacterium*, *Fastidiosipila*, *Oscillospira*, *Papillibacter*, *Sporobacter*, and *Subdoligranulum*. The genus *Ethanoligenens* was

proposed after finalization of the content of this volume and is not described here (see Xing et al., 2006).

Family is morphologically diverse and includes long thin rods, rods, cocci and pleomorphic forms. All species are obligate anaerobes.

Type genus: Ruminococcus Sijpesteijn 1948, 152^{AL}.

Genus I. **Ruminococcus** Sijpesteijn 1948, 152^{AL}

TAKAYUKI EZAKI

Ru.min.o.coc'cus. L. adj. *ruminalis* of the rumen; Gr. n. *kokkos* a grain, berry; N.L. masc. n. *Ruminococcus* *coccus* of the rumen.

Cells are coccoid, usually 0.3–1.5 × 0.7–1.8 μm. **Cells are in pairs and chains**. A few are motile with 1–3 flagella. **Gram-stain-positive cell-wall structure but many stain Gram-negative**. **Optimal temperature, 37–42°C**. **Chemo-organotrophic**. **Strictly anaerobic and require fermentable carbohydrates to grow**. Fermentation of carbohydrate yields various proportions of acetate, formate, succinate, lactate, and ethanol. **Amino acid and peptides are not fermented**. **Indole is not produced (Bryant, 1986)**. **Isolated from rumen, large bowel, or cecum of many animals and humans**. Some are isolated from human clinical specimens. Rumen fluid agar is effective to isolate and characterize strains (Holdeman et al., 1977). Some strains use cellulose on rumen fluid cellobiose agar plate (Holdeman et al., 1977) and require ammonia as a nitrogen source.

DNA G+C content (mol%): 39–47.

Type species: Ruminococcus flavefaciens Sijpesteijn 1948, 152^{AL}.

Further taxonomic comments

Species in the genus *Ruminococcus* were divided into two phylogenetically different groups within a family *Lachnospiraceae* (Figure 161). The type species of the genus *Ruminococcus*, *Ruminococcus flavefaciens*, belongs to group I *Streptococcus hansenii* Holdeman and Moore (1974) and *Peptostreptococcus productus* Prévot (1941) are reclassified to group II ruminococci (Ezaki et al., 1994). Group II ruminococci are phylogenetically close to the sugar-requiring anaerobic cocci, genus *Coproccoccus*. *Ruminococcus pasteurii* and *Ruminococcus palustris* were transferred to genus *Trichococcus* by Liu et al. (2002).

List of species of the genus *Ruminococcus*

1. **Ruminococcus flavefaciens** Sijpesteijn 1948, 152^{AL}

fla.ve.fac'i.ens. L. adj. *flavus* yellow. L. pres. part. *faciens* producing; N.L. part. adj. *flavefaciens* yellow-producing.

Strictly anaerobic, Gram-stain-positive, nonsporulating, chain-forming cocci. Cellulose and hemicellulose fermenter and pectin hydrolyzer. Catalase-negative. Nonmotile. Isolated from the rumen of many different species (Hungate, 1957). Features are listed in Table 191. Belongs to ruminococcus group I (Figure 161).

DNA G+C content (mol%): 39–44.

Type strain: Bryant C94, ATCC 19208, NCDO 2213.

GenBank accession number (16S rRNA gene): L76603.

2. **Ruminococcus albus** Hungate 1957, 307^{AL}

al'bus. L. adj. *albus* white.

Strictly anaerobic, Gram-stain-positive, nonsporulating, chain-forming cocci. Found in human feces and rumen of cattle and other animals. Cellobiose-fermenting rumen bacteria. Catalase-negative. Nonmotile. Produces more ethanol, H₂, and CO₂ than *Ruminococcus flavefaciens*. Other features are listed in Table 191. Belongs to ruminococcus group I (Figure 161). Isolated from human feces.

DNA G+C content (mol%): 42.6–45.8.

Type strain: Hungate 1957-7, ATCC 27210, DSM 20455, NCDO 2250.

GenBank accession number (16S rRNA gene): L76598.

3. **Ruminococcus bromii** Moore, Cato and Holdeman 1972, 80^{AL}

brom'i.i. L. gen. n. *bromii* of Bromius, god of alcohol.

Strictly anaerobic, Gram-stain-positive, nonsporulating, chain-forming cocci. Isolated from human feces. Cellobiose is not fermented. Catalase-negative. Nonmotile. Features are listed in Table 191. Belongs to ruminococcus group I (Figure 161).

DNA G+C content (mol%): 39–40.

Type strain: ATCC 27255, VPI 6883.

GenBank accession number (16S rRNA gene): L76600.

4. **Ruminococcus callidus** Holdeman and Moore 1974, 264^{AL}

cal'li.dus. L. adj. *callidus* clever, expert.

Strictly anaerobic, Gram-stain-positive, nonsporulating cocci. Catalase-negative. Nonmotile. Ferment cellobiose. Features are listed in Table 191. Belongs to ruminococcus group I (Figure 161). Isolated from human feces.

DNA G+C content (mol%): 43.

Type strain: ATCC 27760, VPI 57-31.

GenBank accession number (16S rRNA gene): L76596.

5. **Ruminococcus gnavus** Moore, Johnson and Holdeman 1976, 243^{AL}

gna'vus. L. adj. *gnavus* busy, active.

Strictly anaerobic, Gram-stain-positive, nonsporulating cocci. Cellobiose is not fermented. Catalase-negative. Nonmotile. Features are listed in Table 191. Belongs to ruminococcus group I. Isolated from human feces.

DNA G+C content (mol%): 43.

Type strain: ATCC 29149, VPI C7-9.

GenBank accession number (16S rRNA gene): D14136, L76597, X94967.

6. **Ruminococcus hansenii** (Holdeman and Moore 1974) Ezaki, Li, Hashimoto, Miura and Yamamoto 1994, 134^{VP} (*Streptococcus hansenii* Holdeman and Moore 1974, 266)

han.sen'i.i. N.L. gen. n. *hansenii* of Hansen named after P. Arne Hansen, a Danish-American bacteriologist.

Strictly anaerobic, Gram-stain-positive, nonsporulating cocci. Cells occur in pairs and chains. Catalase-negative. Nonmotile. Features are listed in Table 191. Belongs to ruminococcus group II (Figure 161). Isolated from human feces.

DNA G+C content (mol%): 44–45.

Type strain: ATCC 27752, CIP 104219, DSM 20583, VPI C7-24.

GenBank accession number (16S rRNA gene): D14155, M59114.

7. **Ruminococcus hydrogenotrophicus** Bernalier Willems, Leclerc, Rochet and Collins 1997, 601^{VP} (Effective publication: Bernalier Willems, Leclerc, Rochet and Collins 1996, 182.)

hy.dro.ge.no.tro'phi.cus. Gr. n. *hydor* water; Gr. n. *genus* race, offspring; N.L. n. *hydrogenum* hydrogen, that which produces water; Gr. n. *trophos* one who feeds. N.L. masc. adj. *hydrogenotrophicus* one who feeds on hydrogen, referring to the ability of the micro-organism to grow with H₂/CO₂ as energy source.

Strictly anaerobic, Gram-stain-positive, nonsporulating coccobacilli. Isolated from human feces. Features are listed in Table 191. Belongs to ruminococcus group II (Figure 161).

DNA G+C content (mol%): 45.2.

Type strain: S5a33, DSM 10507.

GenBank accession number (16S rRNA gene): X95624.

8. **Ruminococcus lactaris** Moore, Johnson and Holdeman 1976, 244^{AL}

lac.ta'ris. L. adj. *lactaris* milk-drinking.

Strictly anaerobic, Gram-stain-positive, nonsporulating cocci. Features are listed in Table 191. Belongs to ruminococcus group II (Figure 161). Isolated from human fecal samples.

DNA G+C content (mol%): 45.

Type strain: ATCC 29176, VPI X6-29.

GenBank accession number (16S rRNA gene): L76602.

9. **Ruminococcus luti** Simmering, Taras, Schwiertz, Le Blay, Gruhl, Lawson, Collins and Blaut 2002b, 1915^{VP} (Effective publication: Simmering, Taras, Schwiertz, Le Blay, Gruhl, Lawson, Collins and Blaut 2002a, 192.)

lu'ti. L. gen. neut. n. *luti* of mud (feces).

Strictly anaerobic, Gram-stain-positive, nonsporulating coccobacilli. Cells often appear in long chains, nonmotile. Catalase-negative. Features are listed in Table 191. Belongs to ruminococcus group II (Figure 161). Found in human fecal samples.

DNA G+C content (mol%): 43.3.

Type strain: BInIX, CCUG 45635, DSM 14534.

GenBank accession number (16S rRNA gene): AJ133124.

10. **Ruminococcus obeum** Moore, Johnson and Holdman 1976, 245^{AL}

o'be.um. Gr. n. *obeum* egg.

Strictly anaerobic, Gram-stain-positive, nonsporulating coccobacilli. Found in human fecal samples. Features are listed in Table 191. Belongs to ruminococcus group II (Figure 161).

DNA G+C content (mol%): 42 (T_m).

Type strain: ATCC 29174, VPI B3-21.

GenBank accession number (16S rRNA gene): L76601.

11. **Ruminococcus productus** (Prévot 1941) Ezaki, Li, Hashimoto, Miura and Yamamoto 1994, 135^{VP} (*Streptococcus productus* Prévot 1941, 105; *Peptostreptococcus productus* Smith 1957, 536)

pro.duc'tus L. adj. *productus* produced.

Strictly anaerobic, Gram-stain-positive, nonsporulating coccobacilli. Catalase-negative. Nonmotile. Isolated from human feces. Features are listed in Table 191. Belongs to ruminococcus group II (Figure 161).

DNA G+C content (mol%): 44–45.

Type strain: ATCC 27340, CCUG 9990, CCUG 10976, DSM 2950, JCM 1471, VPI 4299.

GenBank accession number (16S rRNA gene): D14144, L76595, X94966.

12. **Ruminococcus schinkii** Rieu-Lesme, Morvan, Collins, Fonty and Willems 1997, 242^{VP} (Effective publication: Rieu-Lesme, Morvan, Collins, Fonty and Willems 1996, 286.)

schink.i.i. N.L. gen. n. *schinkii* of Schink named after Bernhard Schink, a German bacteriologist.

Strictly anaerobic, Gram-stain-positive, nonsporulating coccobacilli. Cells occur in pairs or short chains. Mean size is 0.8–1.1 × 1.4–2.8 μm. Temperature range from 20 to 45°C. Optimum growth at 39°C. Isolated from human feces. Indole is not formed. Oxidase- and catalase-negative. Nitrate is not reduced. Nonmotile. Features are listed in Table 191. Belongs to ruminococcus group II (Figure 161).

DNA G+C content (mol%): 46–47.

Type strain: B, CIP 105464, DSM 10518.

GenBank accession number (16S rRNA gene): X94965.

13. **Ruminococcus torques** Holdeman and Moore 1974, 265^{AL} tor'ques. from L. n. *torquis* a twisted necklace.

Strictly anaerobic, Gram-stain-positive, nonsporulating coccobacilli. Catalase-negative. Nonmotile. Features are listed in Table 191. Belongs to ruminococcus group II (Figure 161). Isolated from human feces.

DNA G+C content (mol%): 40–42.

Type strain: ATCC 27756, VPI B2-51.

GenBank accession number (16S rRNA gene): D14137, L76604.

Genus II. *Acetanaerobacterium* Chen and Dong 2004, 2261^{VP}

XIUZHU DONG

A.cet.an.ae.ro.bac.te'ri.um. L. neut. n. *acetum* vinegar; Gr. pref. *an* not; Gr. n. *aer* air; *anaero* not (living) in air; Gr. neut. dim. n. *bakterion* small rod; N.L. neut. n. *Acetanaerobacterium* vinegar-producing anaerobic small rod.

Straight, thin rod-shaped cells. 0.2–0.4 × 4–8 μm. Gram-stain-positive. Motile. Nonspore-forming. **Obligately anaerobic. No microaerophilic or aerobic growth occurs.** Mesophilic; grows at 20–42°C. Grows at neutral pH. Chemo-organotrophic. **Oxidase and catalase are not produced.** Amino acids and peptides may serve as nitrogen sources. A variety of mono-, di-, and oligo-saccharides are fermented. Gelatin and esculin are hydrolyzed. **The major fermentation products from glucose include acetate, ethanol, hydrogen, and carbon dioxide;** lactic acid, propionate, and succinate are not produced. Sulfate is not reduced. 16S rRNA sequence analysis indicates this genus belonging to the *Clostridium leptum* rRNA subgroup (Collins et al., 1994) within the family *Clostridiaceae*. Isolated from the anaerobic sludge of paper mill waste water.

DNA G+C content (mol%): 48.6–50.4.

Type species: *Acetanaerobacterium elongatum* Chen and Dong 2004, 2261^{VP}.

Further descriptive information

The bacterium possesses one polar flagellum (Figure 184). Colonies on PYG agar are white, translucent, smooth, circular, entire, and slightly convex. They reach 1.5–3 mm in diameter after cultivation at 37°C for 72 h. Cell-wall peptidoglycan of *Acetanaerobacterium* contains LL-diaminopimelic acid. Cellular fatty acids consist mainly of iso-branched fatty acids, predominantly C_{15:0 iso} and C_{14:0 iso}.

The only species, *Acetanaerobacterium elongatum*, was isolated from anaerobic sludge of paper mill waste water. *Acetanaerobacterium elongatum* requires amino acids and peptides as the sole nitrogen sources, but not the inorganic nitrogen sources such as NH₄Cl, (NH₄)₂SO₄, (NH₄)₂HPO₄, and KNO₃. Although the genus includes only one species so far, closely related organisms have been detected by molecular techniques in a biological hydrogen production reactor (Ren et al., 2007).

Enrichment and isolation procedures

The type strain was isolated by subculturing the sludge in pre-reduced peptone-yeast extract-glucose (PYG) broth (Holdeman et al., 1977). After enrichment, the strains were isolated on PYG using the Hungate roll-tube technique.

Maintenance procedures

The type strain is maintained in PYG broth plus 50% glycerol at –80°C. Lyophilized cultures are also used.

Differentiation of the genus *Acetanaerobacterium* from other genera

Table 192 lists the characteristics that differentiate strains of *Acetanaerobacterium* from the phylogenetically related genera. They differ from *Anaerotruncus colihominis* by the latter's production of butyric acid during glucose fermentation, production of indole, and the wide pH range for growth (pH 5.5–11.0). Unlike related *Clostridium* species, *Acetanaerobacterium* strains are nonspore-forming, hydrolyze gelatin, and have different sugar

FIGURE 184. Electron micrograph of *Acetanaerobacterium elongatum* strain JCM 12359^T showing the thin-rod cell with a single polar flagellum. An unattached flagellum is also visible next to the cell shown. Transmission electron micrograph of PYG-grown cells coated with palladium/iridium alloy. Bar = 0.5 μm.

fermentation profiles. They differ from *Ruminococcus* species in their thin rod shape, different biochemical traits, and 6–11 higher mol% G+C content of their DNA. They produce a large amount of hydrogen, but no lactic acid during glucose fermentation, enabling them to be distinguished from *Anaerofilum* species. They differ from *Eubacterium siraeum* by the latter's inability to ferment glucose. *Fusobacterium prausnitzii* has a Gram-stain-negative cell wall and produces butyrate, D-lactate, and formate, but no hydrogen during glucose fermentation, enabling it to be differentiated from the *Acetanaerobacterium* strains. The 16S rRNA gene sequence of *Acetanaerobacterium elongatum* exhibits <91% similarity to other currently described species.

Taxonomic comments

Based on 16S rRNA gene sequence analysis, the genus *Acetanaerobacterium* belongs to the *Clostridium leptum* rRNA subgroup within the family *Clostridiaceae*; the closest related genera are *Clostridium*, *Ruminococcus*, *Anaerofilum*, and *Eubacterium*.

List of species of the genus *Acetanaerobacterium*

1. ***Acetanaerobacterium elongatum*** Chen and Dong 2004, 2261^{VP}
e.lon.ga'tum. L. neut. adj. *elongatum* elongated, referring to the cell shape.

Morphology and general characters are as described for the genus. Colonies on PYG agar are circular, slightly convex, white, and translucent, reaching 1.5–3 mm in diameter after 3 d incubation at 37°C. Optimal growth occurs at 37°C. The pH range for growth is 5.0–7.5 with an optimum at 6.5–7.0. Acid is produced from a few sugars, such as D-glucose, D-fructose, D-galactose, L-arabinose, D-xylose, cellobiose, D-maltose, sucrose, raffinose, inulin, and salicin. Acid is not produced from sorbose, ribose, D-lactose, mannose, melibiose, rhamnose, trehalose, starch, glycogen, amygdalin, adonitol, dulcitol, erythritol, inositol, mannitol, sorbitol, and ribitol.

No acid is produced from the following compounds: methanol, ethanol, 1-propanol, pyruvate, citrate, fumarate, malate, succinate, malonic acid, hippurate, sodium gluconate, butanedioic acid, β-hydroxybutyric acid, phenylacetic acid, cellulose, and xylan. Milk is curdled. Starch is hydrolyzed and arginine dihydrolase is produced. Urease, lecithinase, and lipase are not produced. Methyl red and Voges–Proskauer tests are negative. Nitrate is not reduced. No H₂S is produced from peptone and thiosulfate. The major cellular fatty acids are C_{15:0 iso} (43%), C_{14:0 iso} (32%), C_{15:0 ante} (6%), and C_{14:0 2OH} (8%).

DNA G+C content (mol%): 50.5 (*T_m*).

Type strain: Z7, AS 1.5012, JCM 12359.

GenBank accession number (16S rRNA gene): AY487928.

- Genus III. ***Acetivibrio*** Patel, Khan, Agnew and Colvin 1980, 184^{VP} (emend. Robinson and Ritchie 1981, 335; emend. Khan, Meek, Sowden and Colvin 1984, 420; emend. Murray 1986, 316)

FRED A. RAINEY

A.cet.i.vib.rí'o. L. n. *acetum* vinegar; N.L. masc. n. *Vibrio* genus of bacteria. N.L. masc. n. *Acetivibrio* vinegar (acetic) vibrio.

Gram-stain-negative rods or slightly curved rods. Spores are not formed. Obligate anaerobe. Chemoorganotroph. End products of fermentation include acetic acid, ethanol, H₂, and CO₂. Member of the family *Ruminococcaceae* on the basis of 16S rRNA gene sequence comparisons.

DNA G+C content (mol%): 38–44 (*T_m*/HPLC).

Type species: ***Acetivibrio cellulolyticus*** Patel, Khan, Agnew and Colvin 1980, 184^{VP}.

List of species of the genus *Acetivibrio*

1. ***Acetivibrio cellulolyticus*** Patel, Khan, Agnew and Colvin 1980, 184^{VP}
cell.u.lo.ly'ti.cus. N.L. neut. n. *cellulosum* cellulose; N.L. adj. *lyticus* able to dissolve; N.L. adj. *cellulolyticus* cellulose-dissolving.
 Cells are straight to slightly curved rods, 4.0–10.0 µm in length and 0.5–0.8 µm wide. Cells occur in chains up to 40 µm in length. Gram-stain-negative. Motile by means of a single flagellum attached to the cell about one-third of the distance from pole to pole. Exhibits tumbling motility. Colonies are 1–2 mm in diameter, cream colored, round, and raised with an undulate margin. A clear zone indicating cellulose digestion extends from the periphery of the colony on cellulose agar. Obligately anaerobic. Cellulose, cellobiose, and salicin are utilized. Temperature range for growth is 20–40°C; optimum is 35°C. pH range for growth is 6.5–7.7, optimum is pH 7.0. The type strain was isolated from a methanogenic culture from sewage sludge.
DNA G+C content (mol%): 38 (T_m).
Type strain: CD2, NRC 2248, ATCC 33288.
GenBank accession number (16S rRNA gene): L35516.
2. ***Acetivibrio cellulosolvans*** Khan, Meek, Sowden and Colvin 1984, 420^{VP}
cell.u.lo.sol'vens. L. v. *solvere* to dissolve; N.L. adj. *cellulosolvans* cellulose dissolving, indicating the ability of the organism to ferment cellulosic substrates.
 Cells are rods, 2.0–3.0 µm in length and 0.3–0.7 µm wide, Gram-stain-negative, and occur singly, in pairs, or in chains of three or more cells. No spores are detected. Cultures grown on cellobiose (72 h) or cellulose medium (2 weeks) fail to survive heating at 80°C for 10 min or exposure to 50% ethanol. Cells are nonmotile. Electron micrographs show that one end of each cell is round and uniform and the other end is rough and uneven. Cells have an outer membrane. Colonies on cellulose agar are about 2–3 mm in diameter, entire, raised, and cream colored, showing no clear zones surrounding the colonies. Obligately anaerobic. Growth in cellulose-containing broth under an N₂/CO₂ gas phase has little or no color. The optimum growth temperature is 35–37°C; no growth occurs at 20 or 45°C. The optimum pH is 6.5–7.5; no growth occurs at pH 6.0 or 8.0. Growth is supported only on cellulose, cellobiose, esculin, and salicin. Yeast extract and rumen fluid are not required for growth on these carbon sources. Bile (2% Oxgall; Difco) inhibits growth. No growth is observed on adonitol, amygdalin, arabinose, Casamino acids, casein, chopped meat broth, dulcitol, erythritol, fructose, galactose, glucose, glycerol, glycogen, inositol, inulin, lactate, lactose, maltose, mannitol, mannose, melezitose, melibiose, milk, peptone, pyruvate, raffinose, rhamnose, ribose, sorbitol, sorbose, starch, sucrose, trehalose, urea, xylose, or yeast extract. Esculin is hydrolyzed to give a positive reaction with ferric ammonium citrate. Sulfate is not reduced to sulfite, gelatin is not hydrolyzed, and catalase is not produced. Indole and nitrate reduction tests are negative. The metabolic products of cultures in basal medium containing cellobiose incubated for 4–8 d under 100% N₂ or 80% N₂/20% CO₂ are acetic acid (18 mM), ethanol (3 mM), CO₂, and H₂. Trace amounts of lactic acid also are produced. In cellulose-containing medium, glucose (8 mM) is also produced. The type strain was isolated from domestic sewage sludge.
DNA G+C content (mol%): 41 (T_m).
Type strain: BAS, NRC 2936, ATCC 35928.
GenBank accession number (16S rRNA gene): L35515.
3. ***Acetivibrio ethanolignens*** Robinson and Ritchie 1981, 335^{VP}
e.tha.nol.gig'nens. N.L. n. *ethanol* ethanol; L. part. adj. *gignens* giving birth to, producing; N.L. part. adj. *ethanolignens* producing ethanol.
 Cells are rod-shaped, 1.5–2.5 µm in length and 0.5–0.9 µm wide, Gram-stain-negative, non-spore-forming, motile, slightly curved rods, occurring singly, in pairs, and often in short chains. Flagella (10–15 per cell) are arranged linearly on the concave surface of each cell. Colonies are 0.5–1.5 mm in diameter, circular, convex, smooth, and translucent. Obligately anaerobic. Optimal temperature for growth is 37°C; no growth occurs at 15 or 45°C. Growth is enhanced by the presence of fermentable carbohydrates. Fructose, galactose, glucose, lactose, maltose, mannitol, mannose, and pyruvate are fermented. Salicin and starch are weakly fermented. Arabinose, cellobiose, esculin, glycerol, inositol, inulin, lactate, raffinose, rhamnose, ribose, sorbitol, sucrose, trehalose, and xylose are not fermented. Acetic acid and ethanol are major products of fermentation. Gelatin is hydrolyzed. Nitrate is reduced to nitrite. Cellulose is not degraded. Bile inhibits growth. The type strain was isolated from the colon of a pig with dysentery.
DNA G+C content (mol%): 40 (T_m).
Type strain: 77-6, ATCC 33324.
GenBank accession number (16S rRNA gene): not determined.
4. ***Acetivibrio multivorans*** Tanaka, Nakamura and Mikami 1992, 191^{VP} (Effective publication: Tanaka, Nakamura and Mikami 1991, 123.)
mul.ti.vo'rans. L. adj. *multus* many, numerous; L. v. *voro* to devour, eat greedily; N.L. part. adj. *multivorans* devouring many kinds of substrates.
 Cells are straight to curved rods, 0.8–3.5 µm in length and 0.5–0.9 µm wide, occurring singly or in pairs. Motile. Gram-stain-negative. Surface colonies are colorless, translucent, up to 2 mm in diameter, and circular in form with convex elevation and entire margins. Strictly anaerobic. Temperature range for growth is 20–35°C and optimal growth occurs at 30°C; no growth is observed at 15 or 40°C. pH range for growth is 7.2–8.6 and optimal growth occurs around pH 7.8; no growth is observed at pH 6.8. Cinnamate, crotonate, pyruvate, sucrose, trehalose, and other carbohydrates are utilized for growth. Cellulose is not utilized. Cinnamate is fermented to 3-phenylpropionate, benzoate, and acetate. Crotonate is fermented to butyrate and acetate. Pyruvate is fermented to lactate and acetate. Carbohydrates are fermented to ethanol, formate, and acetate. A trace amount of hydrogen is produced during growth on cinnamate. Nitrate, sulfate, and other sulfur compounds are not utilized as electron acceptors. The type strain was isolated from sludge from an oil refinery wastewater treatment facility.
DNA G+C content (mol%): 44 (HPLC).
Type strain: PeC1, DSM 6139.
GenBank accession number (16S rRNA gene): Not determined.

Genus IV. *Anaerofilum* Zellner, Stackebrandt, Nagel, Messner, Weiss and Winter 1996, 874^{VP}

FRED A. RAINEY

An.ae.ro'fi.lum. Gr. pref. *an* not; Gr. n. *aer* air; Gr. adj. *anaero* absence of air, referring to the anaerobic mode of living; L. neut. n. *filum* thread, referring to the very thin rod-shaped cells; N.L. neut. n. *Anaerofilum* anaerobic thin rods.

Thin, straight rods, 0.2–0.6 µm in diameter and 3–6 µm in length, occurring singly or in pairs. Filaments up to 30 µm observed occasionally. Spores are not formed. Cell wall contains L-glycine, D-glutamate, L-lysine, and D-alanine. Serine forms linkage in interpeptide bridge. Sphaeroplasts are formed in the stationary phase. Some strains are motile. Obligate anaerobe. Strains of this organism are catalase negative. Mesophilic with temperature range for growth between 18 and 44 °C. Chemoor-ganotrophic. Ferments mono- and disaccharides. Major end products of fermentation are lactate, acetate, ethanol, formate, 2,3-butanediol, and carbon dioxide. Sulfate is not reduced. Hydrogen and hydrogen sulfide are not produced. Found in anaerobic sewage sludge of municipal and industrial wastewater treatment plants.

DNA G+C content (mol%): 54–55 (T_m /HPLC).

Type species: *Anaerofilum pentosovorans* Zellner, Stackebrandt, Nagel, Messner, Weiss and Winter 1996, 874^{VP}.

Further descriptive information

The genus *Anaerofilum* contains two species, *Anaerofilum pentosovorans* and *Anaerofilum agile*, which are represented by the single strains Fae^T and F^T, respectively (Zellner et al., 1996). These organisms are strict anaerobes and only grow in reduced medium. Both species require 0.2% yeast extract for growth and this cannot be replaced by trypticase peptone. The species differ in their response to temperature with *Anaerofilum pentosovorans* having a broad optimal temperature for growth of 25–40 °C; *Anaerofilum agile* grows optimally at 37 °C. No growth is observed for either species below 15 °C or above 45 °C. Growth of both strains occurs in the pH range 6.5–8.0 with optimal growth at pH 7.0–7.4. Cellobiose, fructose, galactose, glucose, maltose, ribose, trehalose, and xylose act as growth substrates for both strains. Additionally, *Anaerofilum pentosovorans* can utilize arabinose, mannose, and sorbose, whereas *Anaerofilum agile* utilizes D-salicin and D-sorbitol. Lactose, melibiose, raffinose, rhamnose, sucrose, methanol, ethanol, 1-propanol, citrate, fumarate, malate, succinate, L-lactate, cellulose, starch, xylan, pectin A, L-glutamate, L-tryptophan, L-phenylalanine, L-alanine, and L-glycine are not utilized by either species. Growth of *Anaerofilum agile* on all substrates is much less than that of *Anaerofilum pentosovorans*. *Anaerofilum agile* grows very weakly on L-valine and L-isoleucine. The main products of glucose fermentation by *Anaerofilum agile* are L-(+)-lactate, acetate, formate, ethanol, and carbon dioxide. *Anaerofilum pentosovorans* ferments glucose to lactic acid [both isomers, although the L-(+)-lactate isomer is dominant], ethanol, acetate, formate, carbon dioxide, and a small amount of 2,3-butanediol. Hydrogen and hydrogen sulfide are not produced by either species. Growth of *Anaerofilum agile* is not inhibited when hydrogen is added to the gas phase of the culture vessel.

Enrichment, isolation and growth conditions

Anaerofilum pentosovorans was isolated from sludge of a Biohockreaktor at the Hoechst Chemical Company (Kelsterbach, Frankfurt, Germany), containing wastewater. The sludge was

serially diluted in 120 ml serum vials containing 20 ml pre-reduced medium with a headspace of 80% N₂ and 20% CO₂. In the only paper describing the isolation, characterization, and growth of these strains the composition of the pre-reduced medium was not given (Zellner et al., 1996). *Anaerofilum agile* was isolated from an anaerobic biofilm in a whey treatment reactor to which anaerobic sewage sludge from a municipal sewage treatment plant had been added.

The organism can be grown on DSMZ medium 119 (*Methanobacterium* medium; <http://www.dsmz.de/microorganisms/html/media/medium000119.html>).

To obtain single colonies, cultures can be streaked on agar plates of the pre-reduced medium containing 0.5% glucose and 2% agar (Oxoid). Colonies take 14 d to develop and are white and 1–2 mm in diameter with lobate margins and raised centers.

Taxonomic comments

In the initial study, this genus was shown to represent a distinct lineage close to *Fusobacterium prausnitzii* [later reclassified as *Faecalibacterium prausnitzii* (Duncan et al., 2002)] and *Ruminococcus flavefaciens* (Zellner et al., 1996). With the description in recent years of a number of new genera in this area of the *Firmicutes*, the two species of the genus *Anaerofilum* can now be considered to cluster within the family *Ruminococcaceae* with the genera *Ruminococcus*, *Acetivibrio*, *Acetanaerobacterium*, *Anaerotruncus*, *Ethanoligenens*, *Faecalibacterium*, *Fastidiosipila*, *Oscillospira*, *Papillibacter*, *Sporobacter*, and *Subdoligranulum* (see Figure 185). The two species share 98.7% 16S rRNA gene sequence similarity with each other and sequence similarities in the range 88.0–91.4% to type strains of the type species of the genera *Ruminococcus*, *Acetanaerobacterium*, *Anaerotruncus*, *Ethanoligenens*, *Faecalibacterium*, and *Subdoligranulum*, as well as the misclassified species *Clostridium methylopentosum* and *Eubacterium siraeum*. Although the highest 16S rRNA gene sequence similarities are to *Subdoligranulum variabile* and *Faecalibacterium prausnitzii*, these relationships are not supported by the bootstrap values (see Figure 185). Comparison of the *Anaerofilum pentosovorans* and *Anaerofilum agile* 16S rRNA gene sequences with the current GenBank database of 16S rRNA gene sequences shows that no further sequences of isolates of this genus are currently available. However, there are a number of environmental clone sequences (DQ011251, DQ011252, and AF150697) that cluster with these species at the 97–98% similarity level. These clone sequences originate from stratum sewage and “river snow” aggregates.

Although strains Fae^T and F^T share 98.7% 16S rRNA gene sequence similarity, they have been shown by DNA–DNA hybridization studies to share only 48% relatedness and, thus, represent distinct species (Zellner et al., 1996).

Differentiation of the genus *Anaerofilum* from other genera

Strains of the genus *Anaerofilum* can be differentiated from the most closely related genera (*Ruminococcus*, *Acetanaerobacterium*, *Anaerotruncus*, *Ethanoligenens*, *Faecalibacterium*, and *Subdoligranulum*)

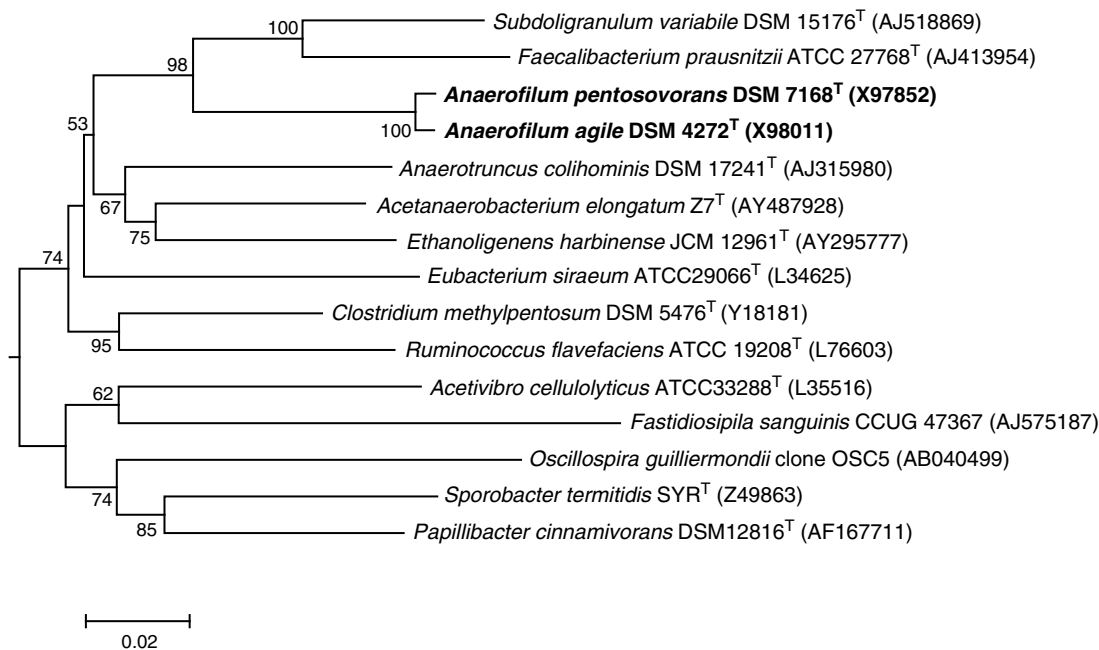

FIGURE 185. 16S rRNA gene sequence based-phylogeny showing the position of the two species of the genus *Anaerofilum* within the radiation of the family *Ruminococcaceae*. The tree was reconstructed from distance matrices using the neighbor-joining method. The genus *Oscillospira*, for which no type material exists, is represented by a clone sequence from an organism with the morphological characteristics of the organism originally described as *Oscillospira guilliermondii*. Bar = 2 inferred nucleotide changes per 100 nucleotides.

on the basis of cell morphology. The *Anaerofilum* strains are thin long rods, whereas other species of related genera are represented by rods, cocci, and pleomorphic forms. In addition, the wide range of end products of fermentation produced by

Anaerofilum strains differentiates this genus from related taxa. The end products of fermentation are lactate, acetate, formate, ethanol, and 2,3-butanediol. Related genera produce different and a less diverse range of end products of fermentation.

List of the species of the genus *Anaerofilum*

1. ***Anaerofilum pentosovorans*** Zellner, Stackebrandt, Nagel, Messner, Weiss and Winter 1996, 874^{VP}

pen.to.so'vo.rans. N.L. neut. n. *pentosum* sugar with five carbon atoms; L. v. *vorare* to eat; L. adj. *pentosovorans* fermenting pentose.

Forms thin, long, rod-shaped cells, 3–6 μm in length and 0.2–0.6 μm in diameter. Occasionally motile. Sphaeroplasts form in stationary phase. Colonies are white and translucent with lobate margins and raised centers on glucose-containing media. The type strain was isolated from an industrial wastewater bioreactor.

DNA G+C content (mol%) of the type strain: 55.0 (HPLC).

Type strain: Fae, DSM 7168.

GenBank accession number (16S rRNA gene): X97852.

2. ***Anaerofilum agile*** Zellner, Stackebrandt, Nagel, Messner, Weiss and Winter 1996, 874^{VP}

a'gi.le. L. neut. adj. *agile* rapidly moving.

Forms thin, long, rod-shaped cells 3–6 μm in length and 0.2–0.6 μm in diameter. Motile by means of peritrichous flagella. Sphaeroplasts form in stationary phase. Colonies are white, circular, slightly convex, and translucent on glucose-containing media. The type strain was isolated from an industrial wastewater bioreactor.

DNA G+C content (mol%): 54.5 (T_m).

Type strain: F, DSM 4272.

GenBank accession number (16S rRNA gene): X98011.

Genus V. ***Anaerotruncus*** Lawson, Song, Liu, Molitoris, Vaisanen, Collins and Finegold 2004, 415^{VP}

PAUL A. LAWSON

An.ae.ro.trun'cus. Gr. pref. *an* without; Gr. masc. n. *aer* air; L. masc. n. *truncus* stick; N.L. masc. n. *Anaerotruncus* a stick that lives without air.

Thin rod-shaped cells. Gram positive and sporeforming. **Strictly anaerobic and catalase negative.** Glucose is fermented. **End products of metabolism from peptone/yeast extract broth are**

acetic and butyric acids. Gelatin is not hydrolyzed. Urease negative. Nitrate is not reduced to nitrite. Indole positive. Based on 16S rRNA sequence and phylogenetic analysis, this genus

belongs to the *Clostridium leptum* rRNA super cluster (Cluster IV). Isolated from human feces and blood.

DNA G+C content (mol%): 53–54.

Type species: **Anaerotruncus colihominis** Lawson, Song, Liu, Molitoris, Vaisanen, Collins and Finegold 2004, 415^{VP}.

Further descriptive information

The genus contains only one species, *Anaerotruncus colihominis* and, therefore, the characteristics provided below refer to this species. Cells are Gram positive, thin rods of approximately 0.5 × 2–5 µm. After 48 h of anaerobic incubation at 37°C under an N₂/CO₂ (80:20, v/v) gas phase, colonies are 2–3 mm in diameter, gray, entire-edged, irregularly shaped, low pyramidal in profile, and translucent. The authors of the original description (Lawson et al., 2004) did not observe spores, but Lau et al. (2006) observed that oval, terminal spores are occasionally formed. The pH range for growth is 5.5–11, and the growth temperature range is 36–40°C. Esculin, gelatin, and urea are not hydrolyzed. It is able to grow in peptone–yeast broth supplemented with 1% glucose, fructose, mannose, or cellobiose, but does not grow in peptone–yeast broth alone or peptone–yeast broth supplemented with arabinose, inositol, lactose, maltose, mannitol, melezitose, melibiose, raffinose, rhamnose, ribose, salicin, sorbitol, starch, or xylose. With the Biolog system, N-acetyl-D-glucosamine, N-acetyl-β-D-mannosamine, arbutin, D-cellobiose, dextrin, D-fructose, D-galactose, D-galacturonic acid, α-D-glucose, maltose, maltotriose, D-mannose, methyl-3-D-glucose, methyl-β-D-glucose, methyl-β-D-galactoside, methyl-β-D-glucoside, palatinose, D-trehalose, and turanose are also used. α-Ketobutyric acid, α-ketovaleric acid, L-malic acid, pyruvic acid, and pyruvic acid methyl ester are also used. Serine, L-valine, 2'-deoxyadenosine, inosine, thymidine, and uridine are used for growth. The organism is isolated from human clinical specimens (Lau et al., 2006; Lawson et al., 2004).

Isolation procedures

Anaerotruncus colihominis was isolated from both human fecal samples and a human blood sample. Fecal samples were homogenized by using a sterile stainless steel blender with one to three volumes of peptone (0.05 %) added as diluents. An aliquot of the specimen was used to make serial tenfold

dilutions in pre-reduced, anaerobically sterilized (PRAS) dilution blanks. A 100 µl aliquot of each dilution was plated onto Brucella blood agar (Anaerobe Systems) and incubated anaerobically at 37°C under an N₂/CO₂ (80:20, v/v) gas phase (Lawson et al., 2004). The strain from blood was recovered using the BACTEC 9240 blood culture system (Becton Dickinson, MD, USA) and grown on Brucella blood agar (Lau et al., 2006).

Maintenance procedures

Strains grow well on *Brucella* blood agar base supplemented with 5% horse blood at 37°C under anaerobic conditions. For long term preservation, strains can be maintained in medium containing 15–20% glycerol at –70°C or lyophilized

Taxonomic comments

The genus *Anaerotruncus* was created to accommodate a phylogenetically distinct Gram positive, anaerobic, rod-shaped organism originating from human feces (Lawson et al., 2004). The genus is monospecific and belongs to the *Firmicutes* and, in particular, is a member within a suprageneric grouping (rRNA cluster IV, (Collins et al., 1994) that includes a diverse assortment of organisms such as *Acetanaerobacterium elongatum*, *Anaerofilum* species, *Clostridium* species, *Ethanoligenens harbinense*, *Eubacterium siraeum*, *Faecalibacterium prausnitzii*, *Ruminococcus* species, and *Subdoligranulum variable*. In this volume, it is classified with the “*Ruminococcaceae*” (Ludwig et al., 2009). *Anaerotruncus colihominis* forms a distinct lineage within this family and does not display a particularly close affinity with any of the aforementioned taxa.

Differentiation of the genus *Anaerotruncus* from other genera

In addition to differentiation by 16S rRNA gene sequence analysis, *Anaerotruncus colihominis* can be readily distinguished from its closest phylogenetic relatives *Acetanaerobacterium elongatum*, *Anaerofilum* species, *Clostridium* species, *Ethanoligenens harbinense*, *Eubacterium siraeum*, *Faecalibacterium prausnitzii*, *Ruminococcus* species, and *Subdoligranulum variable* using a combination of morphology, biochemical, and chemotaxonomic criteria (see Table 193).

List of species of the genus *Anaerotruncus*

1. **Anaerotruncus colihominis** Lawson, Song, Liu, Molitoris, Vaisanen, Collins and Finegold 2004, 415^{VP}

co.li.ho'mi.nis. L. n. *colum* colon; L. gen. n. *hominis* of humans; N.L. gen. n. *colihominis* of the gut of humans.

Cells stain Gram positive and are thin rods approximately 0.5 × 2–5 µm in size, that form oval, terminal spores. The cells are catalase negative; nitrate is not reduced to nitrite, but indole is produced. The end products of metabolism from peptone–yeast broth are acetic and butyric acids. Other characteristics are as given for the genus with the following information. With the API ZYM and Rapid ID 32A systems, acid phosphatase and indole activities are detected, but N-acetyl-β-glucosaminidase, alanine arylamidase, alkaline phosphatase, arginine arylamidase, arginine dehydrolase, α-arabinosidase, ester lipase C8, α-galactosidase, β-galactosidase, α-glucosidase, β-glucuronidase,

glutamylglutamic acid arylamidase, α-mannosidase, α-fucosidase, chymotrypsin, alanine arylamidase, leucyl glycine arylamidase, phosphoamidase, trypsin, cystine arylamidase, esterase C4, β-galactosidase-6-phosphate, glutamic acid decarboxylase, glycine arylamidase, histidine arylamidase, lipase C14, leucine arylamidase, phenylalanine arylamidase, proline arylamidase, pyroglutamic acid arylamidase, serine arylamidase, tyrosine arylamidase, and valine arylamidase activities are not detected. Cells are sensitive to vancomycin (5 mg) and kanamycin (1000 mg), but resistant to colistin sulfate (10 mg) identification discs. Isolated from human feces and blood.

DNA G+C control (mol%): 53.0–54.0 (*T_m* and HPLC).

Type strain: WAL 14565, CCUG 45055, CIP 107754, DSM 17241.

GenBank accession number (16S rRNA gene): AJ315980.

Genus VI. *Faecalibacterium* Duncan, Hold, Harmsen, Stewart and Flint 2002, 2145^{VP}

SYLVIA H. DUNCAN AND HARRY J. FLINT

Fae.ca.li.bac.te'ri.um. L. adj. *faecalis* pertaining to feces; Gr. dim. n. *bakterion* a small rod; N.L. neut. n. *Faecalibacterium* rod from feces, as this bacterium is abundant in feces, with the colon its presumed habitat.

Variable length, straight, rod-shaped cells (0.5–0.8 × 2.0–14.0 μm) mainly occur singly and sometimes seen as hourglass-shaped. Nonsporulating. Usually gives a Gram-negative staining reaction. **Cells are nonmotile.**

Strictly anaerobic. Chemo-organotrophic. Uses the carbohydrates fructose, glucose, and starch as carbon and energy sources. Strains differ in their ability to ferment cellobiose, maltose, and melezitose and fail to ferment raffinose, rhamnose, and ribose. Acetate is strongly stimulatory during growth on carbohydrates, when **net acetate utilization** is detected. Hydrogen production not detected. Grows in an anaerobically prepared medium containing volatile fatty acids, yeast extract, casein hydrolysate, inorganic salts, hemin, glucose, and vitamins at 37°C under a gas atmosphere of 100% CO₂. **Produces butyrate, formate, and D-lactate from fermentation of glucose and acetate.** Indigenous to mammalian intestinal tract. In M2GSC roll tubes colonies are 1–2 mm in diameter, circular, and entire, translucent to transparent, colorless to pale white. Catalase-negative. Isolated from human or animal feces.

DNA G+C content (mol%): 47–57 (T_m).

Type species: Faecalibacterium prausnitzii (Hauduroy, Ehringer, Urbain, Guillot and Magrou 1937) Duncan, Hold, Harmsen, Stewart and Flint 2002, 2145^{VP} (*Bacteroides prausnitzii* (*sic*) Hauduroy, Ehringer, Urbain, Guillot and Magrou 1937, 68; *Fusobacterium prausnitzii* Cato, Salmon and Moore 1974, 45).

Further descriptive information

Faecalibacterium prausnitzii cells usually give Gram-negative staining; they were formerly classified within the genus *Fusobacterium*. *Faecalibacterium prausnitzii* strains are not phylogenetically related to true *Fusobacterium* species, however, and form a distinct group within the clostridial cluster IV (also referred to as the *Clostridium leptum* cluster) (Collins et al., 1994) based on 16S rRNA sequences (Figure 186). According to the 16S rRNA phylogenetic analysis presented in the roadmap to this volume (Figure 6), the genus *Faecalibacterium* is a member of the family *Ruminococcaceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*. *Faecalibacterium prausnitzii*

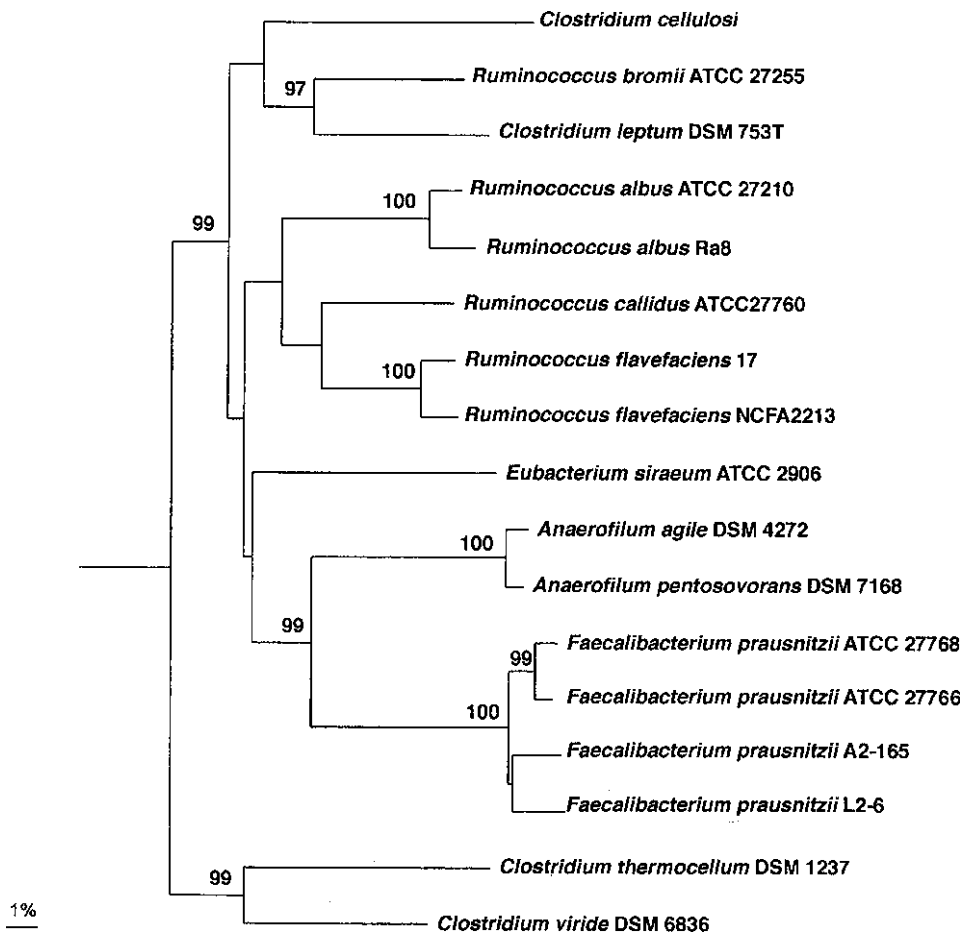

FIGURE 186. Phylogenetic relatedness of *Faecalibacterium prausnitzii* to members of the closely related cluster IV (*Clostridium leptum* group) based on a comparison of approximately 1340 nt.

comprises approximately 13% of the fecal microbiota of healthy adults when analyzed by fluorescent *in situ* hybridization (Lay et al., 2005).

Enrichment and isolation procedures

Faecalibacterium can be isolated by screening for butyrate-forming bacteria from intestinal samples. *Faecalibacterium prausnitzii* strains (A2-165 and L2-6) were obtained from colonies formed in roll tubes containing a rumen fluid-based M2GSC agar medium that were inoculated with dilutions of infant or adult human fecal homogenates maintained anaerobically. Butyrate-producing isolates belonging to ribotype 7 (i.e., those producing fragments of 797, 464, 168, and 75 bp upon *AluI* cleavage of 16S

rRNA sequences amplified with FD1 and RP2 primers) were found to correspond to *Faecalibacterium prausnitzii* (Barcenilla et al., 2000).

Maintenance procedures

Faecalibacterium prausnitzii cultures to which the cryoprotectant glycerol (final concentration, 20 %) has been added can be stored at -20°C for several years.

Differentiation of the genus *Faecalibacterium* from other closely related genera

Faecalibacterium species can be differentiated from related taxa by 16S rRNA sequence analysis (Duncan et al., 2002).

List of species of the genus *Faecalibacterium*

1. ***Faecalibacterium prausnitzii*** (Hauduroy, Ehringer, Urbain, Guillot and Magrou 1937) Duncan, Hold, Harmsen, Stewart and Flint 2002, 2145^{VP} (*Bacteroides prausnitzii* (*sic*) Hauduroy, Ehringer, Urbain, Guillot and Magrou 1937, 68; *Fusobacterium prausnitzii* Cato, Salmon and Moore 1974, 45)

praus.nit'zi.i. N.L. gen. n. *prausnitzii* of Prausnitz; named for C. Prausnitz, the bacteriologist who first isolated this organism.

Four strains have been characterized including the type strain ATCC 27768^T. All strains are nonmotile straight rods 0.5–0.8 μm in diameter and 2.0–14.0 μm in length (Figure 187). Cells give a Gram-negative staining reaction, but, based on phylogenetic analyses, the species clusters among *Firmicutes* in clostridial cluster IV (Figure 186).

Obligately anaerobic, having a fermentative type of metabolism. Various carbohydrates are growth substrates

(Table 194). Products of glucose plus acetate metabolism are butyrate, formate, and D-lactate (Table 195). Catalase-negative.

In M2GSC roll tubes colonies are 1–2 mm in diameter, circular, and entire, translucent to transparent, colorless to pale white. Isolated from animal and human fecal samples.

DNA G+C content (mol%): 47–57 (T_m).

Type strain: ATCC 27768^T.

GenBank accession numbers (16S rRNA gene): L2-6, A2-165, ATCC 27766, and ATCC 27768^T are AJ270470, AJ270469, M58682, and AJ413954, respectively.

Genus VII. *Fastidiosipila* Falsen, Collins, Welinder-Olsson, Song, Finegold and Lawson 2005, 856^{VP}

PAUL A. LAWSON

Fas.ti.di.o.si.pi'la. L. adj. *fastidiosus* fastidious; L. fem n. *pila* ball; N.L. fem. n. *fastidiosipila* a fastidious ball, because the organisms are difficult to grow.

Cells are cocci (approx. 0.5 µm diameter) that stain Gram-stain-positive and do not form spores. **Anaerobic but can grow in the presence of 2% and 6% O₂. Catalase-negative. Carbohydrates are not fermented.** Small amounts of acetic and butyric acids are detected in Fastidious Anaerobe Broth with meat granules. **Lecithinase-, lipase-, and urease-negative. Non-cellulolytic.** Cells are indole-negative and do not reduce nitrate to nitrite. Based on 16S rRNA gene sequence and phylogenetic analyses, this genus is loosely associated with *Clostridium* rRNA cluster III of the *Firmicutes*. Isolated from human blood.

DNA G+C content (mol%): 32.9.

Type species: Fastidiosipila sanguinis Falsen, Collins, Welinder-Olsson, Song, Finegold and Lawson 2005, 856^{VP}.

Further descriptive information

The genus contains only one species, *Fastidiosipila sanguinis*, and therefore the characteristics provided below refer to this species. After 48 h of anaerobic incubation at 37°C, colonies on chocolate agar and anaerobic blood agar are small, pinpoint, gray in color and non-hemolytic. Grows poorly on Fastidious Anaerobe Agar (Oxoid) and Fastidious Anaerobe Broth with meat granules. In the latter, small amounts of acetic and butyric acids are detected. Lipase, lecithinase, and urease are not produced. Gelatin is not hydrolyzed. In the API Rapid ID 32S system, activity is detected for α- and β-galactosidase; β-glucosidase; alanine, phenylalanine, and proline arylamidase; and β-mannosidase. No activity is detected for alkaline phosphatase, arginine dihydrolase, glycyl tryptophan arylamidase, pyroglutamic acid arylamidase, or urease; β-glucuronidase activity may or may not be detected. Hippurate is hydrolyzed and acetoin is not produced. In the commercially available API Rapid ID 32A kit, positive reactions are obtained for α- and β-galactosidase, α- and β-glucosidase, N-acetyl-β-glucosaminidase, alanine arylamidase (weak), arginine arylamidase, proline arylamidase, leucine arylamidase (weak), or α-fucosidase. Reactions for serine arylamidase, histi-

dine arylamidase, glycine arylamidase, and tyrosine arylamidase are either weakly positive or negative. Activity is not detected for alkaline phosphatase, α-arabinosidase, arginine dihydrolase, β-galactosidase-6-phosphate, glutamic acid decarboxylase, glutamyl glutamic acid arylamidase, β-glucuronidase, leucyl glycine arylamidase, phenylalanine arylamidase, pyroglutamic acid arylamidase, or urease. Sensitive to kanamycin (1000 mg) and vancomycin (5 mg) but resistant to colistin sulfate (10 mg) and metronidazole (5 mg) on the basis of disk diffusion testing.

Isolation procedures

Fastidiosipila sanguinis was recovered from the blood of two elderly men in Sweden. The strains were cultivated on chocolate agar (Difco) and anaerobic blood agar (Oxoid) and incubated anaerobically at 37°C under a gas phase comprising N₂/H₂/CO₂ (86:7:7% v/v). There is no selection or enrichment medium for this species. Aerotolerance was determined by incubating the organism on Brucella agar plates (Difco) with and without 5% (v/v) laked sheep blood in an atmosphere containing either 2% or 6% O₂, as described by Wexler et al. (1996).

Maintenance procedures

Grows anaerobically on chocolate agar (Difco), blood-based agars and fastidious anaerobe broth (Oxoid) with meat granules at 37°C. For long-term preservation, strains are maintained in media containing 15–20% glycerol at –70°C or lyophilized.

Taxonomic comments

The genus *Fastidiosipila* was proposed to accommodate a phylogenetically distinct nonmotile, Gram-stain-positive, coccus originating from human blood (Falsen et al., 2005). The genus is monospecific, and phylogenetic analyses of the 16S rRNA gene demonstrate it is located at the base of the clostridial rRNA cluster III of the *Firmicutes* (Collins et al., 1994). However, *Fastidiosipila* forms a distinct lineage within this grouping and does

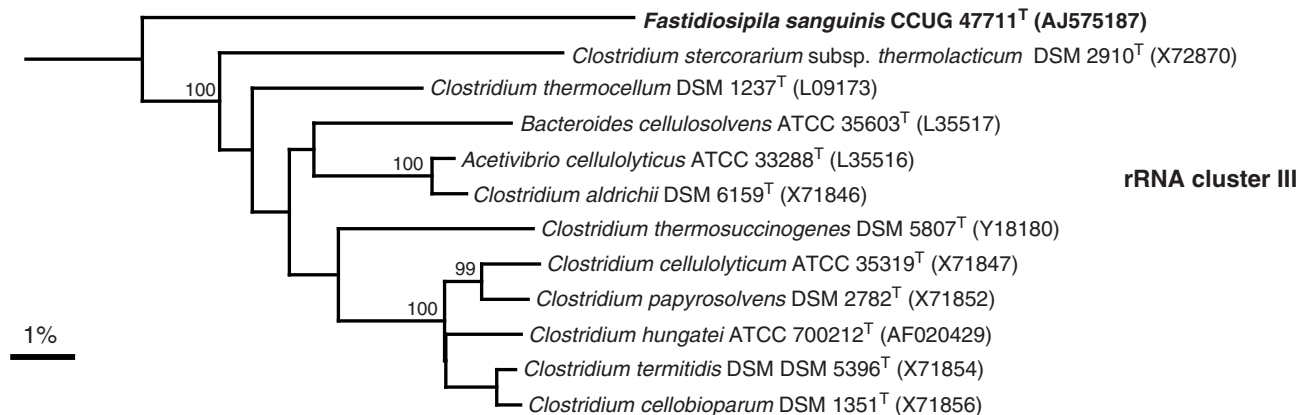

FIGURE 188. Unrooted phylogenetic tree based on 16S rRNA gene sequences showing the association of *Fastidiosipila sanguinis* with *Clostridium* rRNA cluster III. The tree was constructed using the neighbor-joining method and was based on a comparison of approximately 1330 nucleotides. Bootstrap values, expressed as a percentage of 1000 replications, are given at branching points. Scale bar = 1% sequence divergence.

not display a particularly close affinity with any of the organisms present within this cluster (see Figure 188). In the current treatment, rRNA clusters III and IV of Collins et al. (1994) are combined in the family *Ruminococcaceae* (Ludwig et al., 2009).

The anaerobic, Gram-stain-positive cocci represent a taxonomically heterogeneous group of organisms. These organisms were at one time classified in a single family, “*Peptostreptococaceae*” (Rogosa, 1974), which included the genera *Ruminococcus*, *Coprococcus*, *Sarcina*, *Peptococcus*, and *Peptostreptococcus*. During the past decade, knowledge of the phylogenetic inter-relationships of these organisms has been greatly clarified through the use of 16S rRNA gene sequencing, and it is now known that the various genera of the anaerobic Gram-positive cocci are scattered throughout the order *Clostridiales* (Collins et al., 1994; Li et al., 1994; Murdoch et al., 1997). Phylogenetically, *Peptostreptococcus anaerobius*, the type species of the genus *Peptostreptococcus*, is a member of *Clostridium* rRNA group XI (see Collins et al., (1994), for group designations) or the *Peptostreptococaceae*, whereas other peptostreptococci are found in *Clostridium* rRNA group XIII and now have been assigned to distinct genera in Family XI *Incertae Sedis* (*Anaerococcus*, *Fingoldia*, *Gallicola*, *Peptoniphilus*; Murdoch and Shah, 1999; Ezaki et al, 2001). *Sarcina ventriculi* is a member of *Clostridium* rRNA group I of the *Clostridiaceae*, coprococci are related to the members of *Clostridium* rRNA group XVI or the *Lachnospiraceae*, whereas ruminococci

are located in two different rRNA lines (Collins et al., 1994; Rainey and Janssen, 1995), now the *Ruminococcaceae* and the *Lachnospiraceae* (Ludwig et al., 2009). In addition to these changes, a plethora of novel species of strictly anaerobic, Gram-stain-positive cocci has been described (Ezaki et al., 1990; Li et al., 1994; Murdoch et al., 1997).

In addition to using classical methods in combination with 16S rRNA gene sequence analysis to aid taxonomy in the reclassification of the aforementioned taxa, culture-independent studies have shown that much new diversity remains to be discovered, especially from human sources (Namsolleck et al., 2004). The use of high-throughput methods are becoming increasingly automated, reducing costs, and making them routinely accessible; the availability of these methods facilitates more rapid and accurate identification of hitherto unknown taxa that are important components of the particular ecosystem being studied.

Differentiation of the genus *Fastidiosipila* from other genera

Fastidiosipila can be readily distinguished from its closest phylogenetic relatives by a combination of chemotaxonomic, biochemical, and morphological criteria (see Table 196). However in light of its coccal morphology it is pertinent to compare *Fastidiosipila* with other anaerobic Gram-stain-positive cocci (see Table 197).

Genus VIII. *Oscillospira* Chatton and Pérard 1913, 1159^{AL}

YOICHI KAMAGATA

Os.cil.lo.spi'ra. L. n. *oscillum* a swing; L. n. *spira* a spiral; N.L. fem. n. *Oscillospira* the oscillating spiral.

Large rods or filaments 3–6 μm in diameter and 10–40 μm in length, divided by closely spaced cross-walls into numerous disk-shaped cells. Reproduction by transverse fission. Sometimes motile by means of numerous lateral flagella. Endospores occasionally formed. **Growth in pure culture has not been reported. Found only in herbivorous animals.** *Oscillospira guilliermondii* is the only species of this genus.

Type species: *Oscillospira guilliermondii* corrig. Chatton and Pérard 1913, 1159^{AL}.

Further descriptive information

Oscillospira is a large bacterium (3–6 × 10–40 μm) often observed in the rumen contents of sheep and cattle as well as the alimentary tract of other herbivorous animals (Figure 189). *Oscillospira* is characterized as a Gram-stain-positive bacterium, with closely spaced transverse septa and endospores (Gibson, 1974; Grain and J. Senaud., 1976; Sneath, 1986; Stewart et al., 1997). Although this bacterium was first described almost a century ago (Chatton and Pérard, 1913), growth in pure culture has not been reported (Gibson, 1974; Sneath, 1986; Stewart et al., 1997), hence little is known of its ecological role and physiological properties in the intestinal tract. Clarke (1979) found that *Oscillospira* and other large bacteria attach rapidly to the cuticular surface of clover and grass leaves in the rumen suggesting that the cuticle of green leaves constitutes a specific niche for

these bacteria. Warner (1966) investigated the relation between grazing behavior and changes in rumen microbial populations in sheep and found that the population of *Oscillospira* in the rumen fluctuates and the length of the trichome also changes depending upon the amount of feed consumed. Kurihara et al. (1968) reported that the total counts of *Oscillospira* in the sheep rumen tend to decrease in the presence of ciliates. Although the number of *Oscillospira* cells is relatively low compared to other bacterial cells, they may make a significant contribution to rumen fermentation because of their large biomass, roughly equivalent to that of ruminal ciliate protozoa (Clarke, 1979; Williams and Coleman, 1997).

Recently, *Oscillospira* cells were sorted by flow cytometry based on cell size, and the 16S rRNA gene was amplified, cloned, and sequenced (Yanagita et al., 2003). The phylogenetic analysis indicates that *Oscillospira* is affiliated with the low G+C subclass of the Gram-positive bacteria (*Firmicutes*) (Figure 190). The *Oscillospira* sequences are closely affiliated with uncultured bacterial clones within the clostridial cluster IV (Collins' nomenclature) obtained from the ceca of broiler chickens and rumen contents of cows, forming a coherent group with sequence similarities of 90.2–91.1% (Yanagita et al., 2003). Interestingly, a clonal sequence from a human fecal sample also fell into this cluster, suggesting that micro-organisms within this cluster are widespread in the alimentary tracts not only of herbivores but also of omnivores. It is also distantly related to *Sporobacter termitidis* and *Papillibacter cinnaminovorans* with 86.3–88.1% sequence similarities. *Sporobacter termitidis* is, as its name indicates, an anaerobic bacterium isolated from the paunch of the wood-feeding termite *Nasutitermes lujae*. *Sporobacter termitidis* is a chemo-organotroph that grows exclusively on a limited range of methoxylated aromatic compounds including 3,4,5-trimethoxybenzoate and 3,4,5-trimethoxycinnamate, with ring cleavage and production of acetate as a major end product, suggesting that this bacterium may contribute to the degradation of lignocellulosic matter in the digestive tract of the termite (Grech-Mora et al., 1996). *Papillibacter cinnaminovorans* is a strictly anaerobic bacterium which has recently been isolated from anaerobic digester sludge and is capable of metabolizing several methoxycinnamates (Defnoul et al., 2000).

Whether or not *Oscillospira* is capable of utilizing these substrates in the rumen ecosystem is unknown. To date, all attempts to grow the flow cytometry-sorted *Oscillospira* cells anaerobically on various substrates have been unsuccessful. However, very recently emergence of *Oscillospira* was found to be dependent on the diets of its host animals (Mackie et al., 2003). For instance, distinct *Oscillospira* morphotypes were consistently observed in samples from cattle fed

FIGURE 189. Transmission electron micrograph of an *Oscillospira* cell. Bar = 1 μm.

guilliermondii have been found in the alimentary tract (mainly in the rumen or cecum) of several species of herbivorous animals. Some differ from the original description of the species in certain morphological features. An organism in the rumen of sheep that had a spherical, not an elliptical,

spore was identified as *Oscillospira guilliermondii* by Moir and Masson (1952).

DNA G+C content (mol%): not determined.

Type strain: the organism has not been cultivated.

GenBank accession number (16S rRNA gene): not available for type strain.

Genus IX. *Papillibacter* Defnoun, Labat, Ambrosio, Garcia and Patel 2000, 1227^{VP}

BHARAT K. C. PATEL

Pa.pil.li.bac'ter. L. fem. n. *papilla* teat; N.L. n. *bacter* masc. equivalent of Gr. neut. dim. n. *bakterion* rod or staff; N.L. masc. n. *Papillibacter* a rod with ends looking like a teat.

Cells are **rod-shaped** and **stain Gram-positive**. **Nonmotile**. **Nonsporulating** **Strict anaerobic**. Grows on a limited number of aromatic compounds and crotonate but not on carbohydrates, organic acids and alcohols.

Type species: *Papillibacter cinnamivorans* Defnoun, Labat, Ambrosio, Garcia and Patel 2000, 1227^{VP}.

Further descriptive information

Papillibacter utilizes a very limited range of aromatic compounds (cinnamate, 3-methoxycinnamate, and 4-methoxycinnamate) and crotonate by transforming a double bond in the C₃-aliphatic side chain without ring cleavage. Acetate and benzoate are produced from the transformation of cinnamate, acetate, and 3-methoxybenzoate from 3-methoxycinnamate transformation, acetate and 4-methoxybenzoate from 4-methoxycinnamate, and acetate and butyrate from the degradation of crotonate. Such a characteristic has not been reported for any other isolates and hence is a new physiological trait. The transformation of 3-methoxycinnamate and 4-methoxycinnamate but not 2-methoxycinnamate is also an interesting property of the isolate and suggests stereospecific selection by the species.

Enrichment and isolation procedures

The natural habitat for the genus *Papillibacter* is yet to be defined, but anaerobic digesters, which are routinely supplemented with the tannin- and aromatic-rich shea cakes, and inoculated with sludge from the pit of slaughter-houses, are considered to be ideal habitats. A 0.5-ml aliquot of the sample is inoculated into an anaerobic basal medium emended with 5 mM cinnamate to initiate enrichment. The basal medium is prepared using the anaerobic technique described by Hungate (1969) and modified for use with syringes (Macy et al., 1972; Miller and Wolin, 1974) and contains (g/l deionized water): 0.2 g K₂HPO₄; 1 g NaCl; 0.15 g CaCl₂·2H₂O; 0.4 g MgCl₂·6H₂O; 0.5 g KCl; 0.5 g cysteine-HCl; 0.5 g yeast extract; 1.5 ml trace element solution (Widdel and Pfennig, 1981), and 1 mg resazurin. The pH is adjusted to 7.0 with a 10 M NaOH solution, the medium boiled under a stream of O₂-free N₂ gas, cooled to room temperature, 5-ml aliquots dispensed into Hungate tubes under a N₂:CO₂ (80:20) gas mixture and sterilized by autoclaving at 121°C for 15 min. Prior to use, 0.2 ml 5% (w/v) NaHCO₃ and 0.05 ml 2% (w/v) Na₂S·9H₂O were injected from anaerobic sterile stock solutions into the presterilized basal medium.

A stable microbial consortium that degrades cinnamate with concomitant production of acetate and benzoate is established after 3 weeks incubation at 37°C. The consortium is then subcultured

several times under the same conditions and subsequently; serial tenfold dilutions are prepared and inoculated into roll tubes containing the basal medium supplemented with 5 mM cinnamate and

^aSymbols: +, positive; –, negative; ND, not determined.

^bSubstrates tested but not used by both strains include the following: aromatic compounds (benzoate, phenylacetate, caffeate, gallate, phloroglucinol, pyrogallol, catechol, p-coumarate, phenol, 4-hydroxybenzoate), organic acids (pyruvate), carbohydrates (glucose, fructose, ribose, xylose, maltose, galactose, lactose), and alcohols (methanol, ethanol).

1.6% (w/v) agar. Single, well-isolated colonies are picked and serially diluted in the anaerobic medium; the procedure was repeated at least three times before an isolate was deemed to be pure. The isolates fail to grow in anaerobic basal medium amended with 0.5% glucose and 0.5% Biotrypcase, which is used to check routinely for fermentative heterotrophic contaminants.

Maintenance procedures

Papillibacter cinnamivorans is maintained by subculturing once every four weeks in the anaerobic growth medium. The culture can also be stored anaerobically at -20°C in a glycerol and growth medium (50:50 v/v).

Differentiation of the genus *Papillibacter* from other genera

This trait of cinnamate transformation is common to *Syntrophus buswellii* and *Rhodopseudomonas palustris*. *Syntrophus buswellii* requires a syntrophic partner such as *Desulfovibrio vulgaris* to degrade cinnamate and produces acetate and H_2S without the accumulation of benzoate (Auburger and Winter, 1995). However, *Papillibacter* transforms cinnamate to produce acetate and benzoate, which accumulates without further degradation. *Rhodopseudomonas palustris* requires light for cinnamate degradation (Harwood and Gibson, 1988) whereas *Papillibacter* is a nonphotosynthetic bacterium.

Taxonomic comments

Analysis of 16S RNA sequence data indicates that *Papillibacter* is a member of the family *Clostridiaceae*, order *Clostridiales*, class *Clostridia*, in the phylum *Firmicutes*. The genus *Papillibacter* includes a single species, *Papillibacter cinnamivorans*. The closest phylogenetic neighbor of *Papillibacter cinnamivorans* is *Sporobacter termitidis* (Grech-Mora et al., 1996) (similarity value of 91%), and, though both transform aromatic compounds, significant differences in their traits are notable (Table 198). *Papillibacter cinnamivorans* is also phylogenetically related to the flavonoid ring-cleaving anaerobe, *Clostridium orbiscindens* (similarity value of 89%), and distantly to *Clostridium scindens* (similarity value of 85%), and *Eubacterium ramulus*, a member of the family *Eubacteriaceae*, all of which have been isolated from human gastrointestinal tracts (Schneider et al., 1999; Winter et al., 1989; Winter et al., 1991). Flavonoids are polyphenolic compounds, widely believed to have beneficial effects on human health based on their anti-inflammatory, antioxidant, vasodilatory, anticarcinogenic, and antibacterial properties. They are widely distributed in plants and over 5,000 different natural flavonoids have been described so far.

Differentiation of the species of the genus *Papillibacter*

Only one species of *Papillibacter* has been described so far.

List of species of the genus *Papillibacter*

1. ***Papillibacter cinnamivorans*** Defnoun, Labat, Ambrosio, Garcia and Patel 2000, 1227^{VP}

cin.na.mi.vo'rans. N.L. n. *cinnamum* cinnamic acid; L. part. adj. *vorans* devouring, digesting; N.L. part. adj. *cinnamivorans* referring to the ability to digest cinnamic acid.

Rod-shaped cells ($1.3\text{--}3.0 \times 0.5\text{--}0.6\ \mu\text{m}$), usually arranged singly, in pairs, or in chains. Stain Gram-stain-positive. Non-motile. Nonsporulating. Strictly anaerobic. Growth occurs at $15\text{--}40^{\circ}\text{C}$ (optimum 37°C) and at pH 6.9–8.5 (optimum pH 7.5). Chemo-organotroph. Requires yeast extract for growth and biotrypcase and casein stimulates growth. Grows

on a limited range of aromatic compounds and crotonate but not on carbohydrates, organic acids, and alcohols. Sulfate, thiosulfate, sulfite, nitrate, elemental sulfur, or fumarate are not utilized as electron acceptors. Isolated from an anaerobic digester in Burkina Faso. The digester had been inoculated with sludge from a pit of a slaughter house and had been routinely supplemented with tannin and aromatic compound containing shea cake.

DNA G+C content (mol%): 56 (HPLC).

Type strain: Strain CINI, DSM 12816, ATCC 700879.

GenBank accession number (16S rRNA gene): AF167711.

- Genus X. ***Sporobacter*** Grech-Mora, Fardeau, Patel, Ollivier, Rimbault, Prensier, Garcia and Garnier-Sillam 1996, 517^{VP}

ISABELLE GRECH-MORA, MARIE-LAURE FARDEAU, JEAN-LOUIS GARCIA AND BERNARD OLLIVIER

Spo.ro.bac'ter. Gr. n. *spora* a spore; N.L. n. *bacter* masc. equivalent of Gr. neut. dim. n. *bakterion* rod; N.L. masc. n. *Sporobacter* a spore-forming rod.

Slightly curved rods that are $0.2\text{--}0.4 \times 1\text{--}2\ \mu\text{m}$ and occur singly or in pairs. **Motile by peritrichous flagella.** Gram-stain-positive. Terminal spore swelling the sporangium. Chemo-organotrophic and **obligately anaerobic** member of the domain *Bacteria*. Yeast extract (0.01%) is required for growth. Produces methylated sulfides from methylated aromatic compounds (e.g., 3,4,5-trimethoxycinnamate) if sulfide or cysteine is present in the medium with acetate being the only volatile fatty acid produced from this metabolism. External electron acceptors are not used. **Mesophilic and neutrophilic.**

DNA G+C content (mol%): 57 (HPLC).

Type species: ***Sporobacter termitidis*** Grech-Mora, Fardeau, Patel, Ollivier, Rimbault, Prensier, Garcia and Garnier-Sillam 1996, 517^{VP}.

Further descriptive information

Sporobacter termitidis possesses peritrichous flagella (Figure 191a) and a Gram-positive type of cell wall (Figure 191b). Acetate is not only the major product of metabolism from 3,4,5-trimethoxycinnamate (TMC) but also from sinapate, syringate, and 3,4,5-trimethoxybenzoate. The amount of TMC degraded depends on the initial substrate concentration in the growth medium. For concentrations of TMC $<5.45\ \text{mM}$, the substrate is

FIGURE 191. (a) electron micrographs of *Sporobacter termitidis* negatively stained showing peritrichous flagellation. Bar = 1 μm . (b) Ultrathin section of *Sporobacter termitidis* showing the S Layer (S), and peptidoglycan (PG). Bar = 0.2 μm .

degraded into acetate (approx. 4 mol/mol of TMC). At concentrations between 5.45 and 10.82 mM, approximately 1/4 of the substrate remains unused but the amount of acetate produced per mol of TMC degraded is still approximately 4. With initial TMC concentrations higher than 10.82 mM, a greater amount of TMC remains unused and the ratio of acetate/TMC diminishes to 2.57. Initial concentrations of TMC greater than 40 mM inhibit growth of *Sporobacter termitidis* completely. Optical density increases until concentration of TMC reaches 10.82 mM ($\mu=0.027/\text{h}$). The maximum growth rate is obtained in the presence of 8.39 mM of TMC ($\mu=0.035/\text{h}$). When *Sporobacter termitidis* grows on 3,4-dimethoxycinnamate, or vanillate, acetate and catechol accumulate in the medium after 3 months of incubation. Vanillate is detected as an intermediary product from 3,4-dimethoxycinnamate metabolism. After 7 weeks of incubation, acetate and vanillate are produced from ferulate degradation, the latter being poorly used. Utilization of sulfide or cysteine as a methyl acceptor during growth on TMC results in production of dimethylsulfide (DMS), the major volatile sulfur compound, with methanethiol being an intermediate product of metabolism. However, growth on TMC also occurs in the absence of sulfide, suggesting that CO derived from the CO_2 of the medium probably acts as the methyl acceptor (Diekert and Wohlfarth, 1994). During fermentation of methoxylated aromatic substrates by *Sporobacter termitidis*, no H_2 is evolved and therefore *Sporobacter termitidis* does not possess any H_2 -evolving hydrogenase. Accordingly, no H_2 interspecies transfer can result from its association with an hydrogenotrophic methanogen (*Methanospirillum hungatei*). Mineralization of the aromatic nucleus is achieved with tri- or disubstituted compounds (TMC, sinapate, syringate, 3,4,5 trimethoxybenzoate) and not with monosubstituted methoxy aromatic compounds (ferulate, vanillate). In addition, the ring of 3,4-dimethoxycinnamate is not cleaved by *Sporobacter termitidis*, indicating that the position of methoxy substitutes on the aromatic compound is of importance for cleavage.

Enrichment and isolation procedures

Nests of the wood feeding termite, *Nasutitermes lujae* (*Termitidae*) were collected from M'Balmayo forest (Cameroon, Central Africa) and maintained at 27°C. After dipping termites in ethanol, guts were extracted and served as inoculum. Guts of 10 workers were removed with a pair of forceps and placed into a drop of 0.9 % NaCl solution. The contents were added to a

tube containing 5 ml of culture medium and transferred into an anaerobic glove box where they were homogenized. Anoxic media were prepared by using the techniques of Hungate (1969). The growth medium for enrichment, isolation, and most routine culture work contained (per liter) NH_4Cl , 1.0 g; K_2HPO_4 , 0.3 g; KH_2PO_4 , 0.3 g; $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, 0.2 g; $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$, 0.1 g; KCl, 0.1 g; $\text{CH}_3\text{COONa} \cdot 3\text{H}_2\text{O}$, 0.5 g; NaCl, 0.6 g; yeast extract (Difco), 0.5 g; resazurin, 0.001 g; cysteine-HCl, 0.5 g; and 1.5 ml of the trace element solution of Imhoff-Stuckle and Pfennig (1983) and 3,4,5-trimethoxycinnamate (TMC). The pH was adjusted to 7 with 10 M KOH. The medium was boiled under a stream of O_2 -free N_2 gas and cooled to room temperature. Five-milliliter aliquots were dispensed into Hungate tubes under a stream of $\text{N}_2\text{-CO}_2$ (4:1, v/v), and the tubes were autoclaved for 45 min at 110°C. Prior to inoculation, 0.05 ml of 2% $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$ and 0.2 ml of 10% NaHCO_3 were injected to all the anoxic media from sterile anaerobic stock solutions.

Hindgut samples were inoculated into TMC-containing (20 mM) growth medium to initiate enrichments. After several transfers, the enrichment cultures were serially diluted and pure cultures were isolated using the roll tube technique. For preparing roll tubes, the growth medium was solidified with 1.6 % (w/v) Noble agar (Difco). After incubation, colonies that developed in the roll tube containing the most diluted enrichment inoculum were picked and the process of serial dilution in roll tubes repeated at least twice to purify the cultures. Purity of the isolates was routinely checked by microscopical examination and by culturing in the growth medium lacking TMC, but containing glucose.

Differentiation of the genus *Sporobacter* from other genera

A great variety of aerobic and anaerobic bacteria are able to produce DMS from methionine degradation. DMS can also be formed from S-methylmethionine present in various terrestrial plants. Bak et al. (1992) were the first to report on the production of DMS from aromatic compound degradation by a new anaerobic strain isolated from anoxic sediments, *Holophaga foetida* (Liesack et al., 1994). This trait is similar to that observed for *Sporobacter termitidis*. However dimethylsulfide and methanethiol cannot be formed only from inorganic sulfide, but also from organic sulfide such as cysteine in *Sporobacter termitidis*. The biochemical mechanism by which the methylated sulfur compounds are formed is still unknown. Other similarities between *Holophaga foetida* and *Sporobacter termitidis* include the ability to ferment methoxylated

aromatic compounds such as 3,4,5-trimethoxybenzoate, syringate, sinapate, ferulate, but not H₂ plus CO₂, methanol or other alcohols. However, unlike *Holophaga foetida*, *Sporobacter termitidis* is a Gram-stain-positive spore-former and does not use phenolic compounds, in particular, gallate and pyrogallol, nor pyruvate, and has a G+C content of 57 mol%, which is lower than that of *Holophaga foetida* (63 mol%). Phylogenetically *Holophaga foetida* and *Sporobacter termitidis* are also different; *Holophaga foetida* is placed in family "Acidobacteriaceae" of the phylum *Acidobacteria*, whereas *Sporobacter termitidis* is clearly a member of the sub-branch of the low G+C Gram-stain-positive clostridial group in the family *Clostridiaceae*, phylum *Firmicutes*. Brauman et al. (1998) reported on *Sporotomaculum hydroxybenzoicum*, a new sporulating anaerobe isolated from the soil-feeding termite, *Cubitermes speciosus*, which ferments 3-hydroxybenzoate to acetate and butyrate. In contrast, *Sporobacter termitidis* which has been isolated from the hindgut of a wood-feeding termite, produces only acetate by cleaving the TMC aromatic ring in the absence of oxygen. *Sporobacter termitidis* clearly differs from the former as it does not ferment 3-hydroxybenzoate.

Phylogenetically, *Sporobacter termitidis* together with *Papillibacter cinnaminovorans* (Defnouv et al., 2000), its closest phylogenetic relative, are members of cluster IV of the phylum *Firmicutes* branch (Collins et al., 1994) (Figure 190). However, *Sporobacter termitidis* appears to be affiliated with, but not specifically related to, *Papillibacter cinnaminovorans* as the evolutionary distance separating them is 8%. Physiologically, *Papillibacter cinnaminovorans* is very different from *Sporobacter termitidis*. It grows on aromatic compounds (e.g., cinnamate) without the ability to cleave the aromatic ring or to demethoxylate (Defnouv et al., 2000). Acetate and benzoate are the end products of cinnamate metabolism. Phenotypically, *Sporobacter termitidis* is also distinct from *Papillibacter cinnaminovorans* (Table 198).

Taxonomic and ecological comments

Alignment of the sequence (positions 8–1542, *Escherichia coli* numbering according to Winker and Woese (1991) consisting of 1507 bases of the 16S rRNA gene of *Sporobacter termitidis* with representatives of the various phyla of domain *Bacteria*, showed that *Sporobacter termitidis*, isolated from the digestive tract of the

wood-feeding termite *Nasutitermes lujae*, was consistently placed as a member of cluster IV, in the sub-branch of the low G+C *Firmicutes* clostridial group as defined by Collins et al. (1994).

The hindgut microbial consortium of wood-feeding termites in contrast to soil-feeding termites, is inhabited by cellulose-degrading or homoacetogenic hydrogen-oxidizing bacteria such as *Clostridium termitidis* (Hethener et al., 1992), *Acetonema longum* (Kane and Breznak, 1991) and *Sporomusa termitida* (Breznak et al., 1988). The microflora therefore contributes significantly in the overall anaerobic digestion of the ingested organic plant lignocellulosic matter. However, relatively little is known about the degradation of lignin monomers and lignin-related compounds. Nevertheless, it has been suggested that microbial symbionts could play a role in the metabolism of some lignin compounds (Grasse and Noirot, 1959). Of a diverse range of available lignin-derived compounds, the fermentation of aromatic compounds in termite gut has been the most widely studied (Brauman et al., 1992; Breznak and Brune, 1994). In almost all cases studied to date, bacteria (e.g., *Sporomusa termitida*) are involved in the demethylation of methoxylated aromatic compounds (Breznak and Switzer, 1986). By using ¹⁴C-(lignin)-lignocelluloses, Butler and Buckerfield (1979) and Cookson (1988) demonstrated that the ring (nucleus) was cleaved. Cookson (1988) suggested that this degradation process could have been the result of anaerobic bacteria. A contrasting report indicated that oxic conditions are required to completely oxidize lignin-derived phenylpropanoids and other monoaromatic compounds (Brune et al., 1995). In *Nasutitermes lujae*, *Sporobacter termitidis* is a strictly anaerobic bacterium that oxidizes methoxyaromatic compounds mainly into acetate and DMS with methanethiol produced as an intermediary product of metabolism, in the presence of sulfide or cysteine. In the absence of MPN (Most Probable Number) counts, it cannot be predicted with certainty whether *Sporobacter termitidis* and other physiologically related bacteria play a major ecologically important role in the hindgut of *Nasutitermes lujae*.

List of species of the genus *Sporobacter*

1. ***Sporobacter termitidis*** Grech-Mora, Fardeau, Patel, Ollivier, Rimbault, Prensier, Garcia and Garnier-Sillam 1996, 517^{VP}

ter.mi'ti.dis. L. n. masc. *termes*, *termitis* wood-eating worm; N.L. masc. adj. *termitidis* pertaining to the termite.

cells are slightly curved rods (0.3–0.4 × 1–2 μm), occur singly or in pairs. They are not motile when viewed under a phase-contrast microscope but electron microscopy of negatively stained cells revealed the presence of peritrichous flagella (Figure 191a). Ultrathin sections reveal an atypical Gram-stain-positive cell wall composed of a thin (presumably peptidoglycan layer) and an S-layer (Figure 191b). Spores are sparse especially in liquid cultures; they are spherical to ellipsoid and slightly swell the sporangium.

Chemo-organotrophic and obligately anaerobic member of the domain *Bacteria*. Oxidizes methoxylated aromatic compounds, including 3,4,5-trimethoxycinnamate (TMC), sinapate (3,5-dimethoxy-4-hydroxycinnamate), 3,4-dimethoxycinnamate, 3,4,5-trimethoxybenzoate, ferulate, syringate (3,5-dimethoxy-4-

hydroxybenzoate), and vanillate (4-hydroxy-3-methoxy benzoate) only in the presence of yeast extract (0.01%). No growth observed with the following substrates: veratrate, isovanillate, benzoate, β-resorcyate (2,4-dihydroxybenzoate), gentisate (2,5-dihydroxybenzoate), vanillin (4-hydroxy-3-methoxybenzaldehyde), 4-hydroxybenzoate, 2,4,6-trihydroxybenzoate, protocatechuate, cinnamate, *p*-coumarate, 4-methoxycinnamate, pyrogallol, gallate, caffeate, phenol, *o*-cresol, *p*-cresol, catechol, salicin, arbutin, phloroglucinol, cyclohexanecarboxylate, hydroxycinnamate, phenylacetate (5 mM), fructose, galactose, glucose, ribose, xylose, lactose, maltose, sucrose, trehalose, mannitol, rhamnose, sorbose, melibiose, adonitol, dulcitol, sorbitol, pyruvate (20 mM), lactate, formate (10 mM), ethanol, methanol, glycerol (40 mM), and H₂/CO₂ (4:1, v/v; 2 bars). Acetate is the only end product from TMC or syringate oxidation and H₂ or CO₂ are not produced. co-culture of *Sporobacter termitidis* and the hydrogenotrophic methanogen *Methanospirillum hungatei* on methoxyaromatic compounds does not lead to

methane formation, thus indicating the absence of interspecies hydrogen transfer.

Growth requires the presence of a reducing agent in the medium such as dithionite, sulfide, or cysteine. Sulfide and cysteine act as a methyl acceptor which results in the production of dimethylsulfide (DMS) and methanethiol as an intermediary product of metabolism. Oxidation of 5.45 mM TMC led to the production of 20.25 mM acetate and 0.93 mM DMS. Nitrate, sulfur, sulfate, thiosulfate, or sulfite cannot be used as alternate electron acceptors.

Growth between 20 and 40°C with the optimum at about 35°C. The pH growth range is 5.9–8.8, and the optimum pH for growth is between 6.7 and 7.2. Growth occurs at the same rate with NaCl concentrations between 0 and 5 g/l but growth inhibition occurs at concentrations > 12.5 g/l. Isolated from the hindgut of the wood-feeding termite, *Nasutitermes lujae*.

DNA G+C content (mol%): 57 (HPLC).

Type strain: SYR^T, DSM 10068^T.

EMBL accession number (16S rRNA gene): Z49863.

Genus XI. **Subdoligranulum** Holmstrøm, Collins, Møller, Falsen and Lawson 2004, 1909^{VP} (Effective publication: Holmstrøm, Collins, Møller, Falsen and Lawson 2004, 201.)*

KIM HOLMSTRØM AND PAUL A. LAWSON

Sub.do.li.gra'nu.lum. L. adj. *subdolos* deceptive, alludes to the somewhat deceptive and unusual coccoid form; L. neut. n. *granulum* a small grain; N.L. neut. n. *Subdoligranulum* a deceptive grain.

Cells are coccoid in shape but may show some pleomorphism. Gram-stain-negative. Nonmotile and nonspore-forming. **Strictly anaerobic; no growth occurs in 2% oxygen.** Cells do not survive heating at 80°C for 10 min. **Catalase-negative.** Glucose and some other carbohydrates are fermented. **The major acid products formed in PYG broth are butyric and lactic acids** together with minor amounts of acetic and succinic acids. Cells are indole-negative and nitrate is not reduced to nitrite. **Esculin is hydrolyzed, but starch is not. Lecithinase-, urease-, and lipase-negative.** Based on 16S rRNA gene sequence and phylogenetic analysis, this genus belongs to the *Clostridium leptum* rRNA super cluster (cluster IV). Isolated from human feces. A 16S rRNA-derived probe, Svariab_645: 5'-TGCCTACTCAAGGCCAG-3', has been designed that specifically detects this genus by *in situ* hybridization to human fecal samples.

DNA G+C content (mol%): 52.2.

Type species: **Subdoligranulum variabile** Holmstrøm, Collins, Møller, Falsen and Lawson 2004, 1909^{VP} (Effective publication: Holmstrøm, Collins, Møller, Falsen and Lawson 2004, 202.).

Further descriptive information

The genus contains only one species, *Subdoligranulum variabile*, and therefore the characteristics provided below refer to this species. The organism recovered from human feces is strictly anaerobic and fails to grow in 2% or 6% (v/v) oxygen. The colonies of the isolate on Biolog Universal Anaerobe agar supplemented with 5% (v/v) defibrinated calf's blood (BUA+B) (Biolog Inc., Hayward, CA, USA) grow to approximately 1 mm in diameter after 4–5 d of strictly anaerobic incubation at 37°C. The colonies have a grayish-white appearance and are circular and concave. It is not possible to grow the strain on TPY or BHI agar. The cells are Gram-stain-negative, nonmotile, and nonspore-forming. Figure 192 shows a phase-contrast micrograph of the cells obtained from BUA+B agar. The cells have a tendency to associate in pairs or even, in some cases, triplets. The cells range in size between 0.6–2.5 µm and can be variable in shape (from circular, ellipsoid to drop-like). Growth is obtained in M2GSC broth (Barcenilla et al., 2000) and in fastidious anaerobe broth with cooked meat granules (Oxoid). TPY and BHI broths do not sustain growth. Growth on solid or liquid

medium produces *Subdoligranulum variabile* cells of similar morphology as observed when inspected by phase-contrast microscopy. The organism requires rich media for growth, and it is not possible to grow the *Subdoligranulum variabile* on defined media. The optimum growth temperature of the organism is 37°C. It fails to grow at 30°C but grows weakly at 45°C.

The major end products of glucose metabolism are butyric and lactic acids together with minor amounts of acetic and succinic acids. The organism hydrolyzes esculin but fails to hydrolyze starch. It is lecithinase, lipase, and urease-negative. Using the AN-MicroLog system, the isolate utilizes a wide range of carbohydrate substrates (N-acetyl-D-glucosamine, N-acetyl-D-mannosamine, amygdalin, arbutin, D-cellobiose, dextrin, D-fructose, L-fucose, D-galactose, D-galacturonic acid, gentiobiose, α-D-glucose, glucose-1-phosphate, glucose-6-phosphate, α-D-lactose, lactulose, maltose, maltotriose, D-mannose, D-melibiose, 3-methyl-D-glucose, α-methyl-D-galactoside, β-methyl-D-galactoside, palatinose, D-raffinose, L-rhamnose, salicin, sucrose, D-trehalose, and turanose). Using the API Rapid ID 32A kit, activity is detected for α-galactosidase, β-galactosidase, β-glucosidase, β-glucuronidase, arginine arylamidase, leucine arylamidase, and histidine arylamidase; activity for α-glucosidase is weak or negative. All other tests give negative results using this test system. Employing the API ZYM test system, the organism yields positive reactions for α-galactosidase, β-galactosidase, β-glucosidase, β-glucuronidase, with α-glucosidase displaying a weak reaction. All other tests in this kit give negative reactions. The long-chain cellular fatty acids consist primarily of the straight-chain saturated and monounsaturated types, with C_{16:0} (29.4%), C_{18:0} (10.3%), and C_{18:1 ω9c} (34.3%) predominating. Other minor components corresponded to C_{10:0 iso} (0.2%), C_{10:0} (0.4%), C_{12:0} (0.5%), C_{14:1 ω5c} (0.6%), C_{14:0} (5.5%), C_{14:0 DMA} (0.5%), C_{15:0 ante} (0.2%), C_{16:0 ALD} (2.8%), C_{15:0} (0.4%), C_{16:0 iso} (0.2%), C_{16:1 ω7c} (4.7%), C_{16:0 DMA} (4.6%), C_{17:0 iso} (0.3%), C_{17:0 ante} (0.6%), C_{17:0} (1.1%), C_{18:1 ω9c DMA} (1.7%), and C_{18:0 DMA} (0.8%).

*Parts of this chapter were published in Holmstrøm, K., M.D. Collins, T. Møller, E. Falsen and P.A. Lawson. *Subdoligranulum variabile* gen. nov., sp. nov. from human feces, *Anaerobe* 10: 197–203, © Elsevier (2004).

FIGURE 192. Phase-contrast micrograph showing the pleiomorphic morphology of *Subdoligranulum variabile*. Reprinted with permission from Holmstrøm, K., Collins, M.D., Møller, T., Falsen, E. and Lawson, P.A. *Anaerobe*, 2004, 10: 197–203.

Unpublished analyses on the prevalence of *Subdoligranulum variabile* in human fecal samples using FISH (fluorescent *in situ* hybridization) with Svriab_645 have shown a relatively high proportion of positively hybridizing cells in relation to the total number of cells in fecal samples. In order to quantify the proportion of the gut microflora corresponding to *Subdoligranulum variabile*, a screening of fecal samples from 11 different individuals was conducted using a Cy3-labeled Svriab_645 probe, a Cy5-labeled Bif-164 probe (i.e., detecting the genus *Bifidobacterium*), and a FITC-labeled Eub-338 probe (i.e., a general bacterial probe). By processing the images from the FISH-analyses, the areas covered by the Cy5-, the Cy3-, and the FITC-labeled cells, respectively, were determined. The relative proportion of bifidobacteria and *Subdoligranulum variabile* cells was calculated by dividing the area (assumed to be proportional to cell volume) of FITC-labeled cells with the area of Cy5- and Cy3-labeled cells, respectively. Svriab_645 positive cells were shown to be present in all samples with a mean proportion of 1.7% and a range of 0.3% to 4.4%. Bif-164 positive cells were present with a mean proportion of 3.0% and a range of 0–11.4%. The proportion of bifidobacteria also varied considerably from one sample to another, while the distribution of *Subdoligranulum variabile* cells was more uniform. In five samples, the numbers of *Subdoligranulum variabile* cells actually exceeded the numbers of Bif-164-positive cells. In conclusion, the new subgroup of gut bacteria represented by the Svriab_645 probe constitutes a major proportion of the bacteria in feces. In Figure 193, a black and white representation of a micrograph of a fecal sample after FISH analyses is depicted, and cells that gave strong fluorescent signal from the Cy3-labeled Svriab_645 probe are identified by white arrows.

Based on sequence comparisons between the 16S rDNA sequence of *Subdoligranulum variabile* and previously published *Clostridium leptum* subgroup associated probes (Clep866, Cvir1414, Edes635, Rbro730, Rfla729, Rcal733, and Fprau645; Lay et al., 2005), Clep866 is the only probe likely to hybridize efficiently with *Subdoligranulum variabile* cells. Therefore, the Svriab_645

FIGURE 193. *In situ* visualization of *Subdoligranulum variabile* cells (white arrows) by FISH in a human fecal sample. Notice the similar cellular morphology of putative *Subdoligranulum variabile* positive cells in these samples compared to the pleiotrophic morphology of *Subdoligranulum variabile* following *in vitro* cultivation (Figure 192).

positive cells are likely to represent a major fraction of the previously unidentified Clep866-positive cells (Lay et al., 2005).

The wide distribution of *Subdoligranulum variabile* has recently been confirmed by molecular profiling of the *Clostridium leptum* subgroup in human fecal samples. Using a combination of group specific PCR and denaturing gradient gel electrophoresis (DGGE), Shen et al. (2006) demonstrated that, in the majority of subjects sampled, approximately 6% of clones isolated within the *Clostridium leptum* group displayed high 16S rRNA sequence similarity with *Subdoligranulum variabile*. Of the remaining clones, 64% were related to *Faecalibacterium prausnitzii*, 2% to butyrate-producing bacteria, and 28% were not identified to species level. Similarly, Lay et al. (2007) employed both fluorescence-activated cell sorting (FACS) and group-specific PCR to investigate the *Clostridium leptum* subgroup. In addition to clones related to *Faecalibacterium prausnitzii* and butyrate-producing bacteria, both methodologies yielded clones that were highly related to *Subdoligranulum variabile*. These results provide additional evidence that *Subdoligranulum variabile* is an important member of the human gut community which is cultivable, well characterized, and named.

Isolation procedures

Subdoligranulum variabile was recovered from a fecal specimen of a 47 year-old female from Hørsholm, Denmark. The organism was isolated on the commercially available Biolog Universal Anaerobe agar supplemented with 5% (v/v) defibrinated calf's blood (BUA+B) (Biolog Inc., Hayward, CA, USA) and incubated anaerobically at 37°C under N₂, CO₂, and H₂ (80:10:10% [v/v]) gas phase. There is no enrichment or selective medium for this species.

Maintenance procedures

Subdoligranulum variabile can be grown in liquid medium M2GSC (including rumen fluid) prepared according to Barcenilla

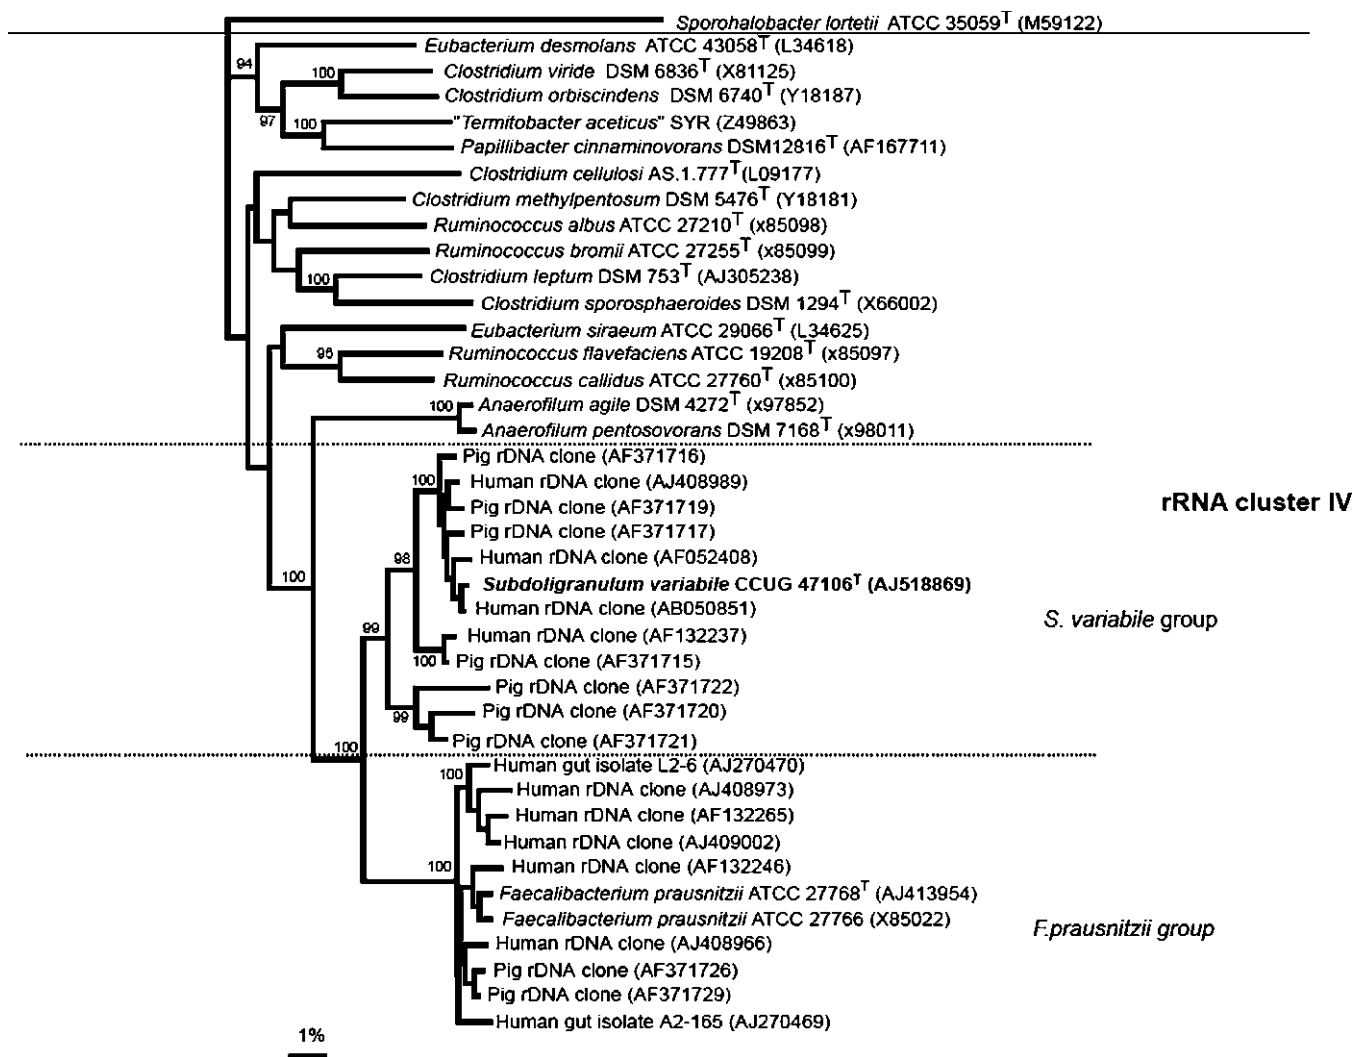

FIGURE 194. Unrooted phylogenetic tree of the 16S rRNA genes of the *Clostridium leptum* supra-generic rRNA cluster indicating the position of *Subdoligranulum variabile*. The phylogenetic tree was calculated by the neighbor-joining method. Bootstrap values greater than 90 are indicated. Bar = 1% sequence divergence.

et al. (2000) and in fastidious anaerobe broth with cooked meat granules (Oxoid). For long term preservation, strains can be maintained in media containing 15–20% glycerol at -70°C or lyophilized.

Taxonomic comments

The genus *Subdoligranulum* was created in 2004 to accommodate a phylogenetically distinct Gram-stain-negative, asporogenous, strictly anaerobic organism recovered from human feces (Holmstrøm et al., 2004). Phylogenetic analysis using 16S rDNA sequences shows that *Subdoligranulum variabile* clusters within a supra-generic grouping (rRNA cluster IV; Collins et al., 1994) that includes a diverse assortment of organisms such as *Anaerofilum* species, *Clostridium* species, *Eubacterium siraeum*, *Faecalibacterium prausnitzii*, and *Ruminococcus* species. *Subdoligranulum variabile* forms a distinct lineage within this grouping and does not display

a particularly close affinity with any of the aforementioned taxa (Figure 194). It is clear from phylogenetic molecular profiling studies of the *Clostridium leptum* group in human feces that, in addition to the diverse group of named organisms, some isolates and many cloned sequences corresponding to as yet uncultivated organisms are present. Furthermore, many of the sequences cloned from human feces possess high similarity to those cloned from other animals such as swine (Leser et al., 2002). These sequences may represent novel taxa including additional species of *Subdoligranulum*, that have not yet been described (Holmstrøm et al., 2004; Lay et al., 2007; Shen et al., 2006).

Differentiation of the genus *Subdoligranulum* from other closely related genera

In addition to differentiation by 16S rRNA gene sequence analysis, *Subdoligranulum variabile* can be readily distinguished from

TABLE 199. Characteristics differentiating the genus *Subdoligranulum* from phylogenetically closely related taxa^{a,b}

Characteristic	<i>Subdoligranulum</i>	<i>Anaerofilum</i>	<i>Clostridium cellulosi</i>	<i>Clostridium leptum</i>	<i>Clostridium sporosphaeroides</i>	<i>Eubacterium siraeum</i>	<i>Faecalibacterium</i>	<i>Ruminococcus</i>

List of species of the genus *Subdoligranulum*

1. ***Subdoligranulum variabile*** Holmstrøm, Collins, Møller, Falsen and Lawson 2004, 1909^{VP} (Effective publication: Holmstrøm, Collins, Møller, Falsen and Lawson 2004, 202.)
va.ri.a'bi.le. L. neut. adj. *variabile* because the cells are varied in shape.

Cells stain Gram-negative, are nonmotile and nonspore-forming. Colonies on BUA+B agar grow to a size of approximately 1 mm in diameter after 4-5 d incubation at 37°C and are grayish-white in appearance, circular, and concave. Cells range in size between 0.6-2.5 µm and exhibit variable forms (from circular, ellipsoid to drop-like shapes). Strictly anaerobic; no growth in 2% or 6% oxygen. Optimum growth temperature is 37°C; grows weakly at 45°C. Catalase-negative. The major products of glucose fermentation are butyric and lactic acids; small amounts of acetic and succinic acids are also formed. Using traditional methods, esculin is hydrolyzed but starch is not. Lecithinase, lipase, and urease are

not produced. Using the AN-MicroLog system, *N*-acetyl-D-glucosamine, *N*-acetyl-D-mannosamine, amygdalin, arbutin, D-cellobiose, dextrin, D-fructose, L-fucose, D-galactose, D-galacturonic acid, gentiobiose, α-D-glucose, glucose-1-phosphate, glucose-6-phosphate, α-D-lactose, lactulose, maltose, maltotriose, D-mannose, D-melibiose, 3-methyl-D-glucose, α-methyl-D-galactoside, β-methyl-D-galactoside, palatinose, D-raffinose, L-rhamnose, salicin, sucrose, D-trehalose, and turanose are utilized. *N*-acetyl-galactosamine, adonitol, D-arabitol, α-cyclodextrin, β-cyclodextrin, dulcitol, erythritol, D-gluconic acid, D-glucosaminic acid, glycerol, DL-α-glycerol phosphate, inositol, D-mannitol, melezitose, α-methyl-D-glucoside, β-methyl-D-glucoside, D-sorbitol, and stachyose are not utilized. Using the API Rapid ID 32A system, acid is not formed from mannose or raffinose. Activity is observed for α-galactosidase, β-galactosidase, β-glucosidase, β-glucuronidase, arginine arylamidase, leucine arylamidase,

and histidine arylamidase but not for alkaline phosphatase, α -arabinosidase, arginine dihydrolase, α -fucosidase, β -galactosidase-6-phosphate, *N*-acetyl- β -glucosaminidase, glutamic acid decarboxylase, glutamyl glutamic acid arylamidase, glycine arylamidase, leucyl glycine arylamidase, proline arylamidase, phenyl alanine arylamidase, pyroglutamic acid arylamidase, serine arylamidase, tyrosine arylamidase, or urease. Activity for α -glucosidase is either absent or weak. Indole is not produced and nitrate is not reduced. Using the API ZYM test system, positive reactions are observed for α -galactosidase, β -galactosidase, β -glucosidase, β -glucuronidase, and α -glucosidase (weak reaction). Alka-

line phosphatase, esterase C4, esterase lipase C8, lipase C14, valine arylamidase, cystine arylamidase, trypsin, chymotrypsin, acid phosphatase, α -fucosidase, α -mannosidase, and *N*-acetyl- β -glucosaminidase are not produced. The long-chain cellular fatty acids are mainly of the straight-chain saturated and monounsaturated types, with C_{16:0} and C_{18:1 69c} predominating; minor amounts of aldehydes and dimethyl acetals are also detected. Habitat is not known but probably resides in the human gut.

DNA G+C content (mol%): 52.2 (T_m).

Type strain: BI 114, CCUG 47106, DSM 15176.

GenBank accession number (16S rRNA gene): AJ518869.

Family IX. *Syntrophomonadaceae* Zhao, Yang, Woese and Bryant 1993a, 284^{VP}

YUJI SEKIGUCHI

Syn.tro.pho.mon.a.da'ce.ae. N.L. fem. n. *Syntrophomonas* type genus of the family; suff. *-aceae* ending to denote family; N.L. fem. pl. n. *Syntrophomonadaceae* the *Syntrophomonas* family.

Cells have various rod shapes, often curved, with or without flagella, and with or without endospores. Multiplication is by binary fission. Cells may have distinctive outer membranes or no outer membranes and stain either Gram-positive or Gram-negative. Cell walls contain muramic and *meso*-diaminopimelic acids. Poly- β -hydroxyalkanoates are the reserve material. The *Syntrophomonadaceae* are very **strict anaerobes** and heterotrophs; most of them (except for *Pelospora*) anaerobically **β -oxidize saturated fatty acids containing 4–18 straight- or branched-chained carbon atoms**, depending on the strain, in **syntrophic association with hydrogenotrophic micro-organisms** such as methanogenic archaea of the genera *Methanospirillum* and *Methanobacterium*. Organic end products from co-cultures include acetate, propionate, and other fatty acids, depending on the fatty acid energy source. Except for members of the genus *Pelospora*, strains can **grow in axenic culture without a hydrogenotrophic micro-organism with a few types of substrates, such as crotonate, trans-2-pentenoate, trans-2-hexenoate, trans-3-hexenoate, and trans, trans-2,4-hexadienoate**. These compounds are reduced to saturated fatty acids such as C₂ to C₆ fatty acids and little hydrogen (or formate) is produced. **Carbohydrates, proteinaceous materials, alcohols, or other organic compounds do not support growth of most members of the *Syntrophomonadaceae***. Members of the genus *Pelospora* do not require syntrophic association and ferment a few compounds such as glutarate. Common electron acceptors such as **fumarate, malate, nitrate, nitrite, oxygen, sulfate, sulfite, sulfur, and thiosulfate are not used**. The *Syntrophomonadaceae* may be either marine, requiring at least 1% NaCl, or freshwater, requiring considerably lower salt concentrations. Some require type B vitamins. These bacteria are present in anaerobic microbial ecosystems, such as marine and freshwater sediments, sewage digester sludge, and the rumen, where organic matter is degraded to CO₂ and CH₄. Phylogenetically, as determined by 16S rRNA gene sequencing, this family can be distinguished from other members of the phylum *Firmicutes*. The following genera belong to this family: *Syntrophomonas*, *Syntrophospora*, *Pelospora*, *Thermosyntropha*, and *Syntrophothermus*. Differentiating features for species of these taxa are presented in Table 200.

DNA G+C content (mol%): 37–48.

Type genus: ***Syntrophomonas*** McNerney, Bryant, Hespell and Costerton 1982, 267^{VP} (Effective publication: McNerney, Bryant, Hespell and Costerton 1981, 1037.) emend. Lorowitz, Zhao and Bryant 1989, 126, emend. Wu, Liu and Dong 2006, 2334.

Taxonomic comments

The family *Syntrophomonadaceae* is a phylogenetically distinct group of anaerobes that generally grows in syntrophic association with hydrogenotrophic organisms (such as methanogens) (Zhao et al., 1993a). It is one of the most deeply branching phylogenetic groups currently classified within the bacterial phylum *Firmicutes* (Figure 195 and Figure 7), and future classifications may move it to another phylum (see the road map chapter, Ludwig et al., 2009). The family encompasses physiologically

related organisms: most of the members (all known species of the genera *Syntrophomonas*, *Syntrophospora*, *Thermosyntropha*, and *Syntrophothermus*) syntrophically oxidize monocarboxylic acids with 4 (butyrate) to 18 carbons. The one exception is the genus *Pelospora* (Table 200).

While 16S rRNA gene-based phylogenetic analyses support the existence of the family *Syntrophomonadaceae sensu stricto*, many of the genera previously assigned to this family are widely dispersed and not closely related (Garrity et al., 2005). Because these organisms are only distantly related to the remainder of the *Firmicutes*, future reclassifications may necessitate the creation of more than one higher taxon, possibly even at the phylum level. Given this uncertain state of affairs, these other genera are described in subsequent chapters as “Family *incertae sedis*”. Only two genera (*Anaerobranca* and *Carboxydocella*) clearly represent lineages of the *Firmicutes* and even these genera are not closely related to each other. The remaining three groups are only distantly related. Not only can they not be assigned definitively to any of the established phyla, but they are not closely related to each other. They include the following genera. One deep lineage is represented by *Aminobacterium*, *Aminomonas*, *Anaerobaculum*, *Dethiosulfobrevibrio*, *Thermanaerovibrio*, and *Thermovirga*. The second deep lineage includes the genera *Thermaerobacter*, *Symbiobacterium*, and *Sulfobacillus* (formerly assigned to the family “*Alicyclobacillaceae*” in the class “*Bacilli*”). Lastly, *Caldicellulosiruptor* represents the final deep lineage. This genus is related to some other unclassified genera, i.e., *Tepidanaerobacter*, *Thermosediminibacter*, and *Thermovenabulum*. The genus *Thermohydrogenium* is not described in the current edition because a type strain has not been located (F. Rainey, personal communication).

Further descriptive information

The physiological properties of the *Syntrophomonadaceae sensu stricto* are quite distinctive and deserve special explanation. Under methanogenic conditions, butyrate and longer chain fatty acids are degraded by syntrophic association with two or three trophic groups of anaerobes, namely proton-reducing, syntrophic monocarboxylic-acid-oxidizing bacteria, hydrogenotrophic methanogens, and acetoclastic methanogens (Schink, 1997; Stams, 1994). Monocarboxylic acids are converted by syntrophic acid-oxidizers to acetate and H₂ (and/or formate) and these products are subsequently utilized by the latter two trophic groups to form methane. Without this food chain, acid oxidation cannot proceed because the first step of the reaction is endergonic without coupling to H₂- and acetate-consuming reactions. Of the two intermediates, H₂ is the most important intermediate and H₂ consumption makes the whole process energetically feasible (Schink and Friedrich, 1994). Hence, this mutual relationship between the substrate oxidizers and hydrogenotrophic anaerobes is called “syntrophy” and the anaerobes of the former group are often called “syntrophs”. This terminology is justified because growth of the syntrophs in their natural environments is obligately dependent on the activity of hydrogenotrophic organisms.

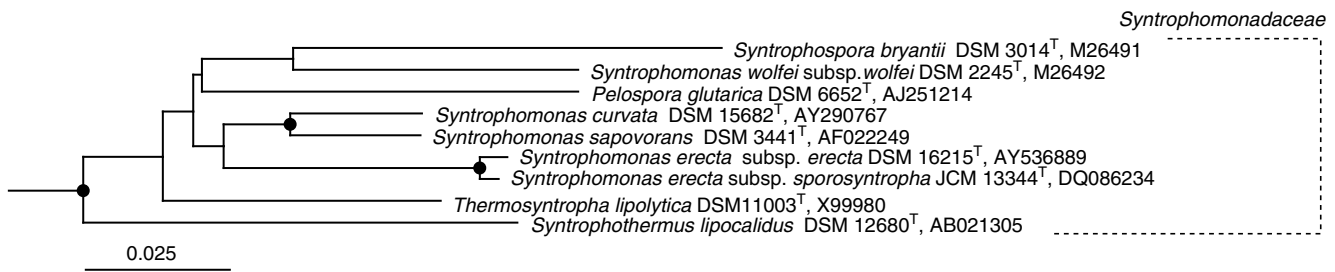

FIGURE 195. Phylogenetic neighbor-joining tree showing the relationship among the members of the family *Syntrophomonadaceae sensu stricto*. Bar = 25 nt substitutions per 1000 nt. Nodes supported by bootstrap values higher than 95 % are shown by solid circles. 16S rRNA gene sequences of some *Desulfotomaculum* species were used to root the tree.

Most of the organisms described that catalyze the syntrophic degradation of saturated fatty acids are members of this family, although a few exceptions exist, such as *Syntrophus aciditrophicus* (Jackson et al., 1999) and *Smithella propionica* (both in the *Deltaproteobacteria*) (Liu et al., 1999). The first member of the family, *Syntrophomonas wolfei*, was isolated from anaerobic digester sludge as “pure” co-cultures with either the hydrogenotrophic methanogen *Methanospirillum hungatei* or with the hydrogenotrophic sulfate-reducer *Desulfovibrio* sp. (McInerney

et al., 1981, 1979). For that reason, the syntrophic fatty-acid-oxidizing anaerobes were originally thought to be obligately syntrophic anaerobes that could grow only in co-culture with hydrogenotrophic organisms. However, *Syntrophomonas wolfei* has been grown subsequently in pure culture with crotonate (Beaty and McInerney, 1987) and most of the *Syntrophomonadaceae* are now known to grow in axenic culture without a hydrogenotroph with a few substrates such as crotonate or pentenoate plus butyrate.

Genus I. **Syntrophomonas** McInerney, Bryant, Hespell and Costerton 1982, 267^{VP}
(Effective publication: McInerney, Bryant, Hespell and Costerton 1981, 1037.) emend. Lorowitz, Zhao
and Bryant 1989, 126, emend. Wu, Liu and Dong 2006, 2334

YUJI SEKIGUCHI

Syn.tro.pho.mon'as. Gr. adj. *syn* together with; Gr. n. *trophos* one who feeds; Gr. n. *monas* a unit, monad;
N.L. fem. n. *Syntrophomonas* monad which feeds together with (another species).

Slightly helical rods, 0.5–1.0 by 2–7 μm, with slightly tapered rounded ends. Most cells occur singly or in pairs with helical chains of three or more. Multiplication is by binary fission. Cells possess 2–8 flagella (about 20 nm in diameter) that are inserted laterally in a linear fashion on the concave side of the cell, about 130 nm or more apart. Under most conditions, cells usually exhibit only sluggish twitching motility. Cells have an **unusual multilayered cell wall that stains Gram-negative**. Muramic and *meso*-diaminopimelic acids are present and the organism is susceptible to penicillin. Poly-β-hydroxybutyrate is present. Cells **β-oxidize saturated fatty acids anaerobically with protons serving as the electron acceptors in co-cultures with a hydrogenotroph**. Growth is much faster with *Methanospirillum hungatei*, which utilizes both H₂ and formate, than with methanogens such as *Methanobacterium bryantii* that utilize only H₂. In co-culture, cells produce acetate and H₂ from butyrate and longer straight-chain, even-numbered-carbon fatty acids and acetate, propionate, and H₂ from *n*-valerate and longer straight-chain, odd-numbered-carbon fatty acids. At least some strains produce acetate, isovalerate, and H₂ from iso acids such as isoheptanoate and some strains produce acetate, propionate, and H₂ from 2-methylbutyrate. It is possible, but has not yet been determined, that anteiso acids such as anteisooctanoate are degraded to acetate, anteisohexanoate, and H₂. The strains studied so far can, with considerable difficulty, be adapted to **grow slowly in axenic culture on crotonate, with acetate and butyrate as the products**.

Carbohydrates, proteinaceous materials, alcohols, and other organic compounds do not support growth. Common electron acceptors such as **fumarate, malate, nitrate, oxygen, sulfate, sulfite, sulfur, and thiosulfate are not utilized with butyrate as the electron donor**. Growth may be stimulated in co-cultures by factors in rumen fluid or mixtures of vitamins or both. Isolated as co-cultures from anaerobic ecosystems, such as aquatic sediments, sewage digester sludge, the rumen, and rice field mud, where organic matter is degraded, with CO₂ and CH₄ as major products. The temperature range for growth of co-cultures with *Methanospirillum hungatei* is in the broad mesophilic range, with an optimum of 30–37°C. Phylogenetically, as determined by 16S rRNA gene sequencing, the genus *Syntrophomonas* forms a deeply branched lineage in the bacteria related to the *Firmicutes*.

DNA G+C content (mol%): 40–47.

Type species: Syntrophomonas wolfei McInerney, Bryant, Hespell and Costerton 1982, 267^{VP} (Effective publication: McInerney, Bryant, Hespell and Costerton 1981, 1037.) emend. Lorowitz, Zhao and Bryant 1989, 126.

Further descriptive information

Cell morphology. Cells are slightly curved rods with round ends, occurring singly or in pairs (Figure 196). Tumbling motility is observed in most strains. *Syntrophomonas wolfei* strains possess 2–8 flagella that are inserted laterally in a linear fashion about 130 nm or more apart on the concave side of the cell

FIGURE 196. Phase-contrast (a) and fluorescence (b) micrograph of *Syntrophomonas wolfei* subsp. *wolfei* DSM 2245B^T (co-culture with *Methanospirillum hungatei* strain DSM 864^T) grown with butyrate (bar = 10 μm). Both micrographs show an identical field, indicating the F₄₂₀-autofluorescence of the methanogens.

(McInerney et al., 1981). *Syntrophomonas sapovorans* possesses 2–4 flagella (Roy et al., 1986). *Syntrophomonas erecta* possesses 2–5 flagella (Wu et al., 2006). Among *Syntrophomonas* strains, only “*Syntrophomonas erecta* subsp. *sporosyntropha*” is characterized as nonmotile without flagella. Spore formation is not observed in most strains of the genus *Syntrophomonas*, with the exception of the spore-forming subspecies of “*Syntrophomonas erecta* subsp. *sporosyntropha*” (Wu et al., 2006).

Cell-wall composition and chemotaxonomic data. *Syntrophomonas* strains generally have an unusual, multilayered cell wall that stains Gram-negative. A similar envelope is also seen in phylogenetically related taxa such as those in the family “*Acidaminococcaceae*”. The major membrane phospholipid fatty acids of *Syntrophomonas wolfei* are C_{16:1}, C_{16:0}, and C_{15:0} (Henson et al., 1988). Similarly, C_{14:0}, OH-C_{14:0}, C_{15:0}, C_{16:0}, C_{16:1}, and iso-C_{17:1} are the major cellular fatty acids in *Syntrophomonas curvata* and “*Syntrophomonas erecta* subsp. *erecta*” (see Table 200). Muramic acid and diaminopimelic acid have been demonstrated in *Syntrophomonas wolfei* (McInerney et al., 1981) and *Syntrophomonas erecta* (Zhang et al., 2005b).

Poly-β-hydroxyalkanoate is observed in *Syntrophomonas wolfei* (Amos and McInerney, 1989, 1991; McInerney et al., 1981) and “*Syntrophomonas erecta* subsp. *sporosyntropha*” (Wu et al., 2006).

Nutrition and growth conditions. *Syntrophomonas* strains grow on saturated fatty acids containing 4–18 carbon atoms in syntrophic association with hydrogenotrophic organisms. The range of degradable fatty acids varies with the species (see Table 200). In addition to saturated fatty acids, *Syntrophomonas wolfei* subsp. *saponavida* and *Syntrophomonas sapovorans* degrade some unsaturated fatty acids, such as oleate (*cis*-9-octadecenoate) and elaidate (*trans*-9-octadecenoate), when grown in co-culture with hydrogenotrophs (Lorowitz et al., 1989; Roy et al., 1986). Most *Syntrophomonas* strains grow in axenic culture without a hydrogenotroph with crotonate (Beaty and McInerney, 1987). *Syntrophomonas wolfei* also grows in axenic culture with some unsaturated short-chain fatty acids, such as *trans*-2-pentenoate, *trans*-2-hexenoate, *trans*-3-hexenoate, and *trans,trans*-2,4-hexadienoate (Amos and McInerney, 1990). Media supplemented with butyrate plus pentenoate or with butyrate plus dimethyl sulfoxide

(DMSO) also support growth of axenic cultures of some *Syntrophomonas* strains (Wu et al., 2006; Zhang et al., 2005b). Rumen fluid and B vitamins (thiamine, lipoic acid, biotin, and cyanocobalamin) stimulate the growth of *Syntrophomonas wolfei* in co-culture with *Methanospirillum hungatei* (McInerney et al., 1981). Axenic cultures of *Syntrophomonas wolfei* grow poorly in a defined crotonate medium in the absence of rumen fluid (Beaty and McInerney, 1990). However, addition of rumen fluid or B vitamins stimulates growth of the axenic culture as well as the co-culture (Beaty and McInerney, 1990). Iron and cobalt are required for the growth of *Syntrophomonas wolfei* in chemically defined medium (Beaty and McInerney, 1990). Amino acids and the B vitamin mixture are required for growth of *Syntrophomonas sapovorans* (Roy et al., 1986). Optimum growth temperature is 35–40°C.

Metabolism. *Syntrophomonas* strains have a unique anaerobic metabolism catalyzing β-oxidation of fatty acids (C₄–C₁₈). This reaction normally couples to the production of H₂ (and/or formate), which is subsequently consumed by partner hydrogenotrophic organisms such as methanogens. For energetic reasons, the H₂ partial pressure in cultures must be 10 to 100 Pa for β-oxidation to proceed. The partner hydrogenotrophs maintain this low partial pressure of H₂. The pathway of the β-oxidation by *Syntrophomonas wolfei* has been studied in detail (Amos and McInerney, 1993; Wofford et al., 1986). The pathway of crotonate metabolism has also been elucidated in *Syntrophomonas wolfei* (McInerney and Wofford, 1992; Sobieraj and Boone, 2002). A *c*-type cytochrome was detected in *Syntrophomonas wolfei* in pure culture with crotonate or in co-culture with methanogens, indicating the presence of an electron transport system (McInerney and Wofford, 1992).

Long-chain fatty acids (longer than C₈) are degraded by *Syntrophomonas wolfei* subsp. *saponavida*, *Syntrophomonas sapovorans*, and *Syntrophomonas curvata*. An equimolar concentration of calcium is required for the degradation of long-chain fatty acids. The degradation may involve several rounds of β-oxidation with the concomitant release of electrons as H₂, analogous to the pathway of syntrophic butyrate degradation (Sobieraj and Boone, 2002).

(2000). -, Negative; ±, weak; +/±, variable among strains; +, positive; ND, not determined.

^bStraight-chain fatty acids with C4 (butyrate) to C8 (caprylate).

Ecology. *Syntrophomonas* strains have been isolated from anaerobic digester and anaerobic wastewater treatment sludges, where methanogenic degradation of organic compounds is the dominant metabolism. Anaerobic digestion of lipids and other organic compounds, such as carbohydrates, often results in the production of large amounts of fatty acids as intermediates. *Syntrophomonas* species, like other members of the *Syntrophomonadaceae*, play an important role by scavenging these fatty acids under methanogenic conditions. Small-subunit rRNA-targeted oligonucleotide probes for members of the family *Syntrophomonadaceae* have been used for the quantification of these organisms in anaerobic digester sludge decomposing organic suspended solids (swine and cattle manure with industrial organic wastes). In these sludges, 0.2–1% of the total rRNA was attributed to members of the *Syntrophomonadaceae*, of which the majority was accounted for by *Syntrophomonas* species (Hansen et al., 1999).

Enrichment and isolation procedures

Syntrophomonas is selectively enriched using a defined anaerobic basal medium with butyrate as the sole energy source. Enrichment of *Syntrophomonas* strains with the ability to degrade long-chain fatty acids is performed with basal medium supplemented with a long-chain fatty acid and equimolar concentrations of CaCl_2 (Roy et al., 1986). Bottles or tubes (100, 50, or 10 ml vials) suitable for culturing strict anaerobes can be used. The medium is inoculated with methanogenic sludge. Enrichments are incubated in the dark at 35–40°C. After growth and methane production have been observed (1–2 weeks, or much longer in case of long-chain fatty acids), the cultures are further enriched by successive transfers. The enrichment should be stable and convert the fatty acid into acetate and methane. It should contain at least two major cell morphotypes. One is a hydrogenotrophic methanogen that can be recognized by its autofluorescence due to the abundance of co-enzyme F_{420} . The other morphotype may be *Syntrophomonas*.

For isolation of *Syntrophomonas*, roll tubes are inoculated with a mesophilic hydrogenotrophic methanogen, e.g., *Methanospirillum hungatei* cells, prior to inoculation with the enrichment culture. Pinpoint colonies are picked from the highest dilution, transferred into the liquid medium containing the substrate used for the enrichment, and incubated again.

This isolation step is repeated several times and cultures are then further purified by using the liquid basal medium containing crotonate and bromoethanesulfonate. Growth of *Syntrophomonas* occurs after a week of incubation. Three successive transfers

into the crotonate-bromoethanesulfonate liquid medium result in the disappearance of F_{420} -autofluorescent methanogens and cells in the culture are homogeneous. Then, roll tube isolation using crotonate as the sole substrate is performed. Pinpoint colonies are again picked from the highest dilution, transferred into the liquid medium containing crotonate, and incubated again. This step is repeated several times to obtain axenic cultures of *Syntrophomonas*.

Maintenance procedures

Stocks of axenic cultures may be maintained in the liquid basal medium with crotonate as the sole energy source. In the case of co-culture with methanogens, cultures may be maintained in the liquid basal medium with butyrate or longer chain fatty acids. After growth, cultures may be stored in the dark at room temperature for at least a month.

Taxonomic comments

In an earlier study (Roy et al., 1986), the genus *Syntrophomonas* was placed in the family *Bacteroidaceae*. However, comparative analyses of 16S rRNA gene sequences indicate that the genus *Syntrophomonas* encompasses physiologically and phylogenetically similar anaerobes in the deeply branching phylogenetic group (*Syntrophomonadaceae*) within the phylum *Firmicutes* (Zhao et al., 1993b). According to the 16S rRNA phylogenetic analysis presented in the roadmap to this volume (Figure 7), the genus *Syntrophomonas* is the type genus of the family *Syntrophomonadaceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*.

Differentiation of the genus *Syntrophomonas* from other genera

Characteristics that differentiate genera of the family *Syntrophomonadaceae* are listed in Table 200. The most notable features that distinguish the genus *Syntrophomonas* are: (1) they are mesophilic (optimum growth temperature of 35–40°C) anaerobes catalyzing syntrophic β -oxidation of fatty acids (C_4 – C_{18}); (2) they possess an unusual multilayered cell wall that stains Gram-negative; and (3) they do not form spores (with the exception of "*Syntrophomonas erecta* subsp. *sporosynpha*").

Differentiation of the species of the genus *Syntrophomonas*

Characteristics that differentiate species of the genus *Syntrophomonas* are also listed in Table 200. The most striking differences are found in substrate ranges. In addition, no two species of the genus possess 16S rRNA gene sequence similarities greater than 96%.

List of species of the genus *Syntrophomonas*

1. ***Syntrophomonas wolfei*** McInerney, Bryant, Hespell and Costerton 1982, 267^{VP} (Effective publication: McInerney, Bryant, Hespell and Costerton 1981, 1037.) emend. Lorowitz, Zhao and Bryant 1989, 126.

wolf'e.i. N.L. gen. n. *wolfei* of Wolfe, to honor Ralph S. Wolfe for his devotion towards the understanding of the biology of anaerobic bacteria.

Surface colonies in roll tubes of *Syntrophomonas wolfei* co-cultures with methanogens are smooth, convex, and circular

with entire edges. Colonies may be dark to black when the organisms are co-cultured with H_2 -utilizing *Desulfovibrio* species with sulfate. Grows in co-cultures with hydrogenotrophs using straight-chain fatty acids containing 4 (butyrate) to 8 (octanoate) carbon atoms as energy sources. Strains utilize isoheptanoate and some strains also use straight-chain fatty acids containing 9 (nonanoate) to 18 carbon atoms (stearate) or 2-methylbutyrate. It is not known whether some strains use anteiso or other iso fatty acids.

DNA G+C content (mol%): 45.1 (T_m).

Type strain: Göttingen G311, DSM 2245A (in co-culture with *Desulfovibrio* sp. strain G-11), DSM 2245B (in co-culture with *Methanospirillum hungatei* strain DSM 864^T).

GenBank accession number (16S rRNA gene): M26492.

1a. **Syntrophomonas wolfei subsp. wolfei** Lorowitz, Zhao and Bryant 1989, 126^{VP}

The size of the cells is in the higher range for the genus. In co-culture with hydrogenotrophs, utilizes straight-chain fatty acids with 4 (butyrate) to 8 (octanoate) carbon atoms and isoheptanoate as energy sources; in axenic culture, also uses crotonate.

DNA G+C content (mol%): 45.1 (T_m).

Type strain: Göttingen G311, DSM 2245A (in co-culture with *Desulfovibrio* sp. strain G-11), DSM 2245B (in co-culture with *Methanospirillum hungatei* strain DSM 864^T).

GenBank accession number (16S rRNA gene): M26492.

1b. **Syntrophomonas wolfei subsp. saponavida** Lorowitz, Zhao and Bryant 1989, 126^{VP}

sa.po.na.vi'da. L. n. *sapo* soap; L. adj. *avida* greedy; L. fem. adj. *saponavida* greedy for soap.

The size of the cells is in the lower range for the genus. In co-culture with hydrogenotrophs, utilizes straight-chain fatty acids with 4 (butyrate) to 18 (stearate) carbon atom as energy sources; also probably uses acids such as isoheptanoate and longer-chain iso acids. Grows on crotonate without a hydrogenotroph.

Type strain: SD2, DSM 4212 (in co-culture with *Desulfovibrio* sp. strain G-11).

2. **Syntrophomonas curvata** Zhang, Liu and Dong 2004, 972^{VP} cur.va'ta. L. fem. adj. *curvata* curved.

Cells stain Gram-negative and are curved rods, 0.5–0.7 by 2.3–4.0 μm , non-spore-forming, with 1–3 polar or subpolar flagella. Straight-chain C_4 – C_{18} fatty acids serve as substrates in co-culture with *Methanobacterium formicicum* DSM 1535^T. Even-numbered fatty acids are degraded into acetate and presumably H_2 , whereas odd-numbered ones are degraded into propionate, acetate, and H_2 . Acetate, propionate, isobutyrate, isovalerate, and benzoate do not support growth of the co-culture. Fumarate, sulfate, thiosulfate, sulfur, and nitrate cannot act as electron acceptors for butyrate oxidation. Crotonate is the only substrate tested that enables growth in axenic culture; yeast extract, tryptone, glucose, ribose, xylose, pyruvate, and fumarate do not. Cellular fatty acids comprise mainly $C_{14:0}$ (28%), $C_{15:0}$ (19%), $C_{14:0}$ 3-OH (11%), and an unknown component of ECL 14.503' (21%). Isolated from the granular sludge of an up-flow anaerobic sludge blanket (UASB) reactor treating beer wastewater in Beijing, China.

DNA G+C content (mol%): 46.6 (T_m).

Type strain: GB8-1, CGMCC 1.5010, DSM 15682.

GenBank accession number (16S rRNA gene): AY290767.

3. **Syntrophomonas erecta** Zhang, Liu and Dong 2005b, 802^{VP} e.rec'ta. L. fem. adj. *erecta* erect.

Cells are straight or slightly curved rods, 0.5–1.0 by 2.0–14.0 μm , with Gram-negative cell walls, tapered rounded ends, and 2–5 flagella, usually occurring in the subpole of

cells. Some strains form spores when co-cultured with methanogens on butyrate, but not in monoculture on crotonate. Straight-chain fatty acids with 4–8 carbon atoms serve as substrates in co-culture with *Methanospirillum hungatei* DSM 864^T. Even-numbered fatty acids are degraded into acetate and presumably H_2 , whereas odd-numbered ones are degraded into propionate, acetate, and H_2 . Straight-chain fatty acids shorter than C_4 (acetate and propionate), longer than C_8 (caprate, laurate, myristate, palmitate, stearate, oleate, linoleate, and arachidate), branched-chain fatty acids (isobutyrate and isovalerate), and benzoate do not support the co-culture. Fumarate, sulfate, thiosulfate, sulfur, and nitrate do not act as electron acceptors for butyrate oxidation. Crotonate supports growth in axenic culture, whereas butyrate plus pentenoate or butyrate plus DMSO supports growth of some strains. Yeast extract, tryptone, peptone, maltose, glucose, fructose, ribose, xylose, pentenoate, fumarate, and pyruvate alone do not support growth. The type strain can grow at pH 6.0–8.8, 25–47°C and in 0–500 mM NaCl. The cellular fatty acids of the type strain contain mainly $C_{14:0}$ (30%), $C_{16:0}$ (17%), $C_{16:1}$ $\omega 5c$ (17%), and iso- $C_{17:1}$ I (15%). LL-Diaminopimelic acid exists in the cellular peptidoglycan. Some strains contain poly- β -hydroxyalkanoate inside cells. Isolated from the granular sludge of a UASB reactor for treating bean-curd farm wastewater in Beijing, China.

DNA G+C content (mol%): 40.6–43.9 (T_m).

Type strain: GB4-38, CGMCC 1.5013, DSM 16215.

GenBank accession number (16S rRNA gene): AY536889.

3a. **"Syntrophomonas erecta subsp. erecta"** Wu, Liu and Dong 2006, 460

Cells are Gram-negative, straight rods, motile by means of 2–5 flagella. Spores are never observed. Utilizes C_4 – C_8 fatty acids as carbon and energy sources when co-cultured with methanogens. Crotonate can serve as sole carbon and energy source for the axenic culture. Utilizes pentenoate and DMSO as electron acceptors.

DNA G+C content (mol%): 43.2–43.9 (T_m).

Type strain: GB4-38, CGMCC 1.5013, DSM 16215.

GenBank accession number (16S rRNA gene): AY536889.

3b. **"Syntrophomonas erecta subsp. sporosyntropha"** Wu, Liu and Dong 2006, 460

spo.ro.syn'tro.ph.a. Gr. n. *spora* seed; Gr. adj. *syn* together with; Gr. n. *trophos* one who feeds; N.L. fem. n. *sporosyntropha* forms spores when feeds together with others.

Spores are observed in co-culture with methanogens when growing on saturated short-chain fatty acids. Spores are not formed in axenic culture during growth on crotonate. Poly- β -hydroxyalkanoate is produced when grown on crotonate, but not on butyrate or other saturated fatty acids. Utilizes DMSO as an electron acceptor. Isolated from methanogenic environments, such as river sediment, rice field mud, and UASB sludge.

DNA G+C content (mol%): 40.6–40.9 (T_m).

Type strain: 5-3-Z, CGMCC 1.5032, JCM 13344.

GenBank accession number (16S rRNA gene): DQ086234.

4. **Syntrophomonas sapovorans** Roy, Samain, Dubourguier and Albagnac 1987, 179^{VP} (Effective publication: Roy, Samain, Dubourguier and Albagnac 1986, 146.)

sa.po'vo.rans. L. n. *sapo* soap; L. v. *voro* to devour; N.L. part. adj. *sapovorans* devouring soap (i.e., long-chain fatty acids).

Cells possess 2–4 flagella. Linoleate, oleate, elaidate, and saturated linear fatty acids up to 18 carbon atoms are β -oxidized. Fatty acids are degraded to propionate, acetate, and H₂. Linolenate and branched-chain and substituted fatty acids are not used. Both amino acids and B vitamins

are required for growth. For degradation of fatty acids longer than 8 carbon atoms, calcium is required. Grows at pH 6.3–8.1 and 25–45°C, with optimum growth at pH 7.3 and 35°C.

Type strain: OM, DSM 3441 (in co-culture with *Methanospirillum hungatei* strain JF-1^T).

GenBank accession number (16S rRNA gene): AF022249.

Genus II. *Pelospora* Matthies, Springer, Ludwig and Schink 2000, 647^{VP}

BERNHARD SCHINK

Pe.lo.spo'ra. Gr. masc. n. *pelos* mud; Gr. fem. n. *spora* a seed, spore; N.L. fem. n. *Pelospora* a spore-forming bacterium originating from mud.

Strictly anaerobic bacteria forming spores. Organic substrates fermented. No reduction of external electron acceptors such as sulfate, nitrate, or Fe(III)-oxides.

Chemo-organotrophic, fermentative metabolism using few simple organic compounds as substrate. Carbohydrates not utilized. Media containing a reductant, e.g., sulfide, are necessary for growth. Catalase-negative. Isolated from sediments of limnic or marine origin.

On the basis of 16S rDNA gene sequence analysis, grouped with the family *Syntrophomonadaceae*, which is comprised of *Pelospora* and the genera *Syntrophomonas*, *Syntrophospora*, and *Thermosyntropha* within the phylum *Firmicutes* (Figure 7).

DNA G+C content (mol%): 49.0 (HPLC).

Type species: ***Pelospora glutarica*** Matthies, Springer, Ludwig and Schink 2000, 647^{VP}.

Further descriptive information

Pelospora glutarica, the only species described so far, was isolated as a glutarate-fermenting, strictly anaerobic bacterium. Its metabolism is unique because it grows only by decarboxylation of dicarboxylic acids such as glutarate, methylsuccinate, or succinate, which are converted to the corresponding monocarboxylic acids (Matthies and Schink, 1992b). Glutarate is first activated to glutaryl-CoA, oxidized to glutaconyl-CoA, and decarboxylated to crotonyl-CoA by a membrane-bound glutaconyl-CoA decarboxylase which conserves the decarboxylation energy by sodium ion transfer across the cytoplasmic membrane. The sodium ion gradient established this way drives ATP synthesis through a membrane-bound ATPase system. The resulting crotonyl-CoA is reduced to butyryl-CoA and partly isomerized to isobutyryl-CoA, and the bacterium produces a mixture of butyrate and isobutyrate as fermentation products (Matthies and Schink, 1992b). The reasons for isomerization of butyrate to isobutyrate by this bacterium are not clear. Nonetheless, this capacity allows the bacterium to convert isobutyrate to butyrate, and thus to help convert isobutyrate finally to methane and CO₂ in a methanogenic environment deprived of external electron acceptors (Matthies and Schink, 1992a). Succinate and methyl succinate are fermented to propionate or butyrate plus isobutyrate, probably through the methylmalonyl-CoA pathway described for the succinate-decarboxylating bacterium *Propionigenium modestum* (Dimroth and Schink, 1998; Hilpert et al., 1984).

No other substrates have so far been found to be utilized by *Pelospora glutarica*.

Enrichment and isolation procedures

Pelospora glutarica strains have been enriched and isolated from sediments of limnic or marine origin in simple mineral medium with glutarate as the sole source of carbon and energy. The mineral medium for enrichment must be low in phosphate (1–2 mM KPO₄) and rich in CO₂/HCO₃⁻ (>20 mM). Sulfide is usually used as a reductant. Since *Pelospora glutarica* grows with substrates that yield almost only C2 degradation intermediates, it must form pyruvate and sugars via reductive carboxylation of acetyl CoA and therefore needs carbon dioxide for this reaction. The enrichment medium used successfully for these organisms is derived from that used for the cultivation of sulfate-reducing bacteria (Widdel and Pfennig, 1981) but without sulfate, and is described in detail in the original publication (Matthies and Schink, 1992b). Two versions have been used, one for freshwater and one for marine enrichments. The respective substrates are applied in a concentration range of 10–20 mM, and inocula of at least 2–5 ml are used to secure sufficient attachment surfaces, structure-bound sulfides, and trace cosubstrates in the initial growth steps.

Maintenance procedures

Cultures are maintained either by repeated transfer at intervals of 2–3 months or by freezing in liquid nitrogen using techniques common for strictly anaerobic bacteria. No information exists about survival upon lyophilization.

Differentiation of the genus *Pelospora* from other genera

The genus *Pelospora* differs from all other strictly anaerobic bacteria in its capacity for fermentative growth with glutarate as sole source of carbon and energy, and its lack of utilization of other, more complex substrates. The type strain has been isolated in defined mineral medium with glutarate as the sole substrate and does not require complex, undefined medium additions.

Taxonomic comments

The genus *Pelospora* has been proposed as a taxonomic entity consisting of strictly anaerobic bacteria able to grow by fermentative

tative degradation of glutarate. In this, it differs from all other described genera. Although the cells stain Gram-negative, they form spores and belong to the predominantly Gram-stain-positive phylum *Firmicutes* (Figure 7). *Pelospora* groups with the genera *Syntrophomonas*, *Syntrophospora*, and *Thermosyntropha* which all have been described as syntrophically fatty-acid-oxidizing strict anaerobes. When more strains of *Pelospora* are described, the

taxonomic position of this genus and its relationship to other genera may need to be re-examined.

Further reading

List of species of the genus *Pelospora*

1. *Pelospora glutarica* Matthies, Springer, Ludwig and Schink 2000, 647^{VP}

glu.ta'ri.ca. N.L. n. *acidum glutaricum* glutaric acid; *glutarica* referring to glutarate as the key substrate of this species.

Long, rod-shaped cells, 4.5–6.5 × 0.8 μm in size, motile by one subpolar flagellum, Gram-negative staining, formation of terminal oval spores.

Chemo-organotrophic, fermentative metabolism. Contains no cytochromes. Glutarate, methylsuccinate, and succinate are the only substrates. No growth with more than 30 different substrates such as sugars, organic acids, alcohols, amino acids, primary amines, or other dicarboxylic acids

tested. Products of glutarate and methylsuccinate fermentation are butyrate, isobutyrate, and CO₂; succinate is decarboxylated to propionate.

Growth rate with glutarate at 37°C is 0.062 μ/h. Optimum pH for growth is pH 7.1–8.2; no growth below pH 6.0. Temperature optimum 37°C; no growth below 20°C or above 37°C. Growth in medium containing salt concentrations of 0.1% NaCl and 0.04% MgCl₂·6H₂O (w/v); no growth in salt-water medium at 2% NaCl and 0.3% MgCl₂·6H₂O (w/v).

Isolated from anoxic freshwater sediment.

DNA G+C content (mol%): 49.0 (HPLC).

Type strain: WoG13, ATCC BAA-162, DSM 6652.

GenBank accession number (16S rRNA gene): AJ251214.

Genus III. *Syntrophospora* Zhao, Yang, Woese and Bryant 1990, 43^{VP}

YUJI SEKIGUCHI

Syn.tro.pho.spo'ra. Gr. adj. *syn* together with; Gr. fem. n. *trophos* one who feeds; Gr. fem. n. *spora* a spore, seed; N.L. fem. n. *Syntrophospora* a spore former which feeds together with (another species).

Rod-shaped cells. Gram-stain reaction is variable. **Gram-positive cell-wall ultrastructure. Oval, terminal endospores that swell the sporangium are usually formed. Strictly anaerobic chemoorganotroph. Saturated fatty acids, butyrate, and longer chain fatty acids are utilized for growth and are β-oxidized** to acetate and H₂ or, along with odd-numbered straight-chain fatty acids, to acetate, propionate, and H₂ in syntrophic association with H₂-scavenging anaerobes. **Some strains can be adapted to grow in pure culture on crotonate** with acetate and butyrate as major products. No other organic acids, sugars, or alcohols are utilized. Sulfate, sulfur, thiosulfate, nitrate, and fumarate are not reduced. Habitats are aquatic and marine anaerobic sediments.

DNA G+C content (mol%): 37.6 (T_m).

Type species: *Syntrophospora bryantii* (Stieb and Schink 1985) Zhao, Yang, Woese and Bryant 1990, 43^{VP} (*Clostridium bryantii* Stieb and Schink 1985, 390).

Further descriptive information

Cells are slender, slightly curved, nonmotile rods with round ends, 0.4 by 3–6 μm, occurring singly or in clumps (Stieb and Schink, 1985). Gram staining is variable and electron micrographs show no indication of an outer cell membrane in sections of sporulating cells. Oval spores, 0.75 by 1.5 μm in size, are formed. Spores are heat-resistant and survive pasteurization (15 min at 80°C).

Comparative 16S rRNA gene sequence analysis of members of the genus *Syntrophospora* shows that the genus falls into the clade representing previously characterized syntrophic butyrate-degrading bacteria (i.e., the family *Syntrophomonadaceae*) (Zhao et al., 1990).

Members of the genus *Syntrophospora* are obligately anaerobic chemoorganotrophs that grow at mesophilic temperatures (28–34°C) and nearly neutral pH (6.5–7.5). In pure culture, growth is observed only with crotonate as energy source. In addition, axenic growth is also found with butyrate oxidation coupled with the reduction of pentenoate to valerate (Dong et al., 1994). In syntrophic association with hydrogen-utilizing microbes (i.e., hydrogenotrophic methanogens), only fatty acids with 4–11 carbon atoms, including 2-methylbutyrate, are utilized. The doubling time of the co-culture (with *Methanospirillum hungatei*) estimated based on acetate formation is about 72–96 h. *Syntrophospora* does not utilize oxygen, sulfate, nitrate, sulfur, thiosulfate, or fumarate as electron acceptors. The type and only species, *Syntrophospora bryantii*, can grow on butyrate with H₂- and formate-utilizing methanogens, whereas no growth is observed with methanogens that metabolize only H₂, suggesting that formate may be an important electron carrier in this organism (Dong et al., 1994; Dong and Stams, 1995; Stams and Dong, 1995).

Syntrophospora can be cultured in a defined anaerobic basal medium (Stieb and Schink, 1985) with caproate. The type strain of *Syntrophospora* was isolated from marine anoxic mud.

Enrichment and isolation procedures

Syntrophospora is selectively enriched using the defined anaerobic basal medium with caproate as the sole energy source at 28°C (Stieb and Schink, 1985). Bottles or tubes (100, 50, or 10 ml vials) may be used as culture vessels as with other strict

anaerobes. The medium is inoculated with anoxic mud. After growth and methane production have been observed (2–3 weeks), the cultures are further enriched by successive transfers. A series of transfers should be made. After several transfers, the subcultures may contain two major cell morphotypes: F_{420} -autofluorescent cells resembling hydrogenotrophic methanogens; and nonmotile spore-forming rods (*Syntrophospora*). For isolation of *Syntrophospora*, the co-culture isolation method using agar shake cultures in mineral medium containing 10 mM caproate, 20 mM sulfate, and 5 mM acetate, in which all tubes have been previously inoculated with cells of *Desulfovibrio* sp. is used. After 3 weeks of incubation, yellow, disk-shaped colonies are formed. After two subsequent dilution series in agar shake culture, the defined co-culture can be isolated.

For further isolation in pure culture, *Syntrophospora* co-culture [with methanogens (Stieb & Schink, 1985)] is grown in medium supplemented with 20 mM crotonate and 200 μ M bromoethanesulfonate (Zhao et al., 1990). After 3 weeks of incubation, growth of *Syntrophospora* is observed. Three successive transfers into the crotonate-bromoethanesulfonate liquid medium are performed to eliminate methanogens. Then, grown cells are streaked onto bottle plates containing crotonate medium. Colonies that are grayish yellow, round, and 0.5–2 mm in diameter, are formed after 7 weeks of incubation. Pinpoint colonies are again picked, transferred into the liquid medium containing crotonate, and incubated again. Consequently, pure *Syntrophospora* cells are obtained.

Maintenance procedures

Stock cultures (pure culture) may be maintained in the liquid basal medium with crotonate as the sole energy source. In case of co-cultures with *Methanospirillum hungatei*, cultures may be maintained in the liquid basal medium with butyrate. Grown

cultures may be stored in the dark at room temperature. Stock cultures are transferred monthly.

Taxonomic comments

In an earlier study (Stieb and Schink, 1985), the type species of the genus *Syntrophospora* was placed in the genus *Clostridium* as "*Clostridium bryantii*". However, comparative analyses of 16S rRNA gene sequences indicated that the species should be placed in the family *Syntrophomonadaceae* as a new genus (Zhao et al., 1990, 1993b). At present, the genus *Syntrophospora* encompasses only one species, *Syntrophospora bryantii*. According to the 16S rRNA phylogenetic analysis presented in the roadmap to this volume (Figure 7), the genus *Syntrophospora* is a member of the family *Syntrophomonadaceae*, order *Clostridiales*, class *Clostridia* in the phylum *Firmicutes*.

Differentiation of the genus *Syntrophospora* from other genera

Table 200 lists characteristics that differentiate the genus *Syntrophospora* from other related genera. Phenotypically, the most closely related genus to *Syntrophospora* is *Syntrophomonas*, since they share common physiological traits such as syntrophic growth, substrate range, and growth temperature. However, the most notable feature that distinguishes the genus *Syntrophospora* from species of the genus *Syntrophomonas* is its Gram-positive cell-wall structure with distinct spore formation. They are also closely related to each other phylogenetically: the 16S rRNA gene sequence of *Syntrophospora bryantii* is most closely related to that of *Syntrophomonas wolfei*. However, comparative 16S rRNA gene analysis indicates that no sequence similarities greater than 94 % were identified among near-full length 16S rRNA genes of other members of the family *Syntrophomonadaceae*, including members of the genus *Syntrophomonas*.

List of species of the genus *Syntrophospora*

1. ***Syntrophospora bryantii*** (Stieb and Schink 1985) Zhao, Yang, Woese and Bryant 1990, 43^{VP} (*Clostridium bryantii* Stieb and Schink 1985, 390)

bry.an'ti.i. N.L. gen. n. *bryantii* named after Marvin P. Bryant, who pioneered studies on syntrophic methanogenic associations.

Rod-shaped cells, 0.4 by 4.5–6 μ m in size with rounded end. Nonmotile, slightly curved. Gram-reaction negative to weakly positive; no outer cell membrane. Spores are terminal, oval, and 0.75 by 1.5 μ m in size. Strictly anaerobic chemoorganotroph. Fatty acids with 4–11 carbon atoms

and 2-methylbutyrate are utilized for growth and fermented to acetate and H₂ or to acetate, propionate, and H₂ in syntrophic association with hydrogen-scavenging anaerobes. No other organic acids, sugars, or alcohols are metabolized. Sulfate, sulfur, thiosulfate, nitrate, and fumarate are not reduced. Grows at pH 6.5–7.5 and 28–34°C.

DNA G+C content (mol%): 37.6 (T_m).

Type strain: CuCal, DSM 3014A (in co-culture with *Desulfovibrio* sp. strain E70), DSM 3014B (in co-culture with *Methanospirillum hungatei* strain M1h).

GenBank accession number (16S rRNA gene): M26491.

Genus IV. ***Syntrophothermus*** Sekiguchi, Kamagata, Nakamura, Ohashi and Harada 2000, 778^{VP}

YUJI SEKIGUCHI

Syn.tro.pho.ther'mus. Gr. adj. *syn* together with; Gr. fem. n. *trophos* one who feeds; Gr. adj. *thermos* hot; N.L. masc. n. *Syntrophothermus* thermophilic syntroph, referring to growth in syntrophic association with hydrogenotrophic organisms at high temperature of around 55°C.

Slightly **curved rods**, 0.4–0.5 \times 2–4 μ m that often show binary fission. **Gram-stain-negative**. Weakly motile by means of flagella. Spore formation is not observed. **Obligately anaerobic**. Fastest growth at around 55°C. Energy metabolism by reduction of pro-

tons with butyrate and higher homologs as electron donors in the presence of hydrogenotrophic microbes. Capable of growth in pure culture with crotonate.

DNA G+C content (mol%): 51 (HPLC).

Type species: Syntrophothermus lipocalidus Sekiguchi, Kamagata, Nakamura, Ohashi and Harada 2000, 778^{VP}.

Further descriptive information

Cells are slightly curved rods with round ends, occurring singly or in pairs. Tumbling motility is observed. Some flagella are seen by electron microscopy (Figure 197). Gram staining is negative, although electron micrographs show that cells possess a typical Gram-positive type cell-wall structure.

Comparative 16S rRNA gene sequence analysis of the genus *Syntrophothermus* shows that the genus falls into the clade representing previously characterized syntrophic butyrate-degrading bacteria (i.e., the family *Syntrophomonadaceae*) and that the genus is, however, phylogenetically distinct, with only a moderate relationship to the genus *Thermosyntropha*.

Syntrophothermus is an obligately anaerobic chemo-organotroph that grows at high temperatures (45–60°C) and nearly neutral pH (6.0–7.5). In pure culture, the growth is observed only with crotonate as energy source. Fermentation products from crotonate are equimolar amounts of acetate and butyrate. In syntrophic association with hydrogen-utilizing microbes (i.e., hydrogenotrophic methanogens), only fatty acids including butyrate and higher homologs are utilized. In the co-culture, fatty acids with an even number of carbon atoms are metabolized to form acetate and methane, while fatty acids having an odd number of carbon atoms are degraded to acetate, propionate, and methane. Similarly, 2-methylpropionate (isobutyrate) is degraded to form acetate and methane. In the conversion of 2-methylpropionate, butyrate can be detected as an intermediate indicating that 2-methylpropionate is isomerized to butyrate

FIGURE 197. Scanning electron micrograph of *Syntrophothermus* cells grown with crotonate in pure culture (bar = 1 µm).

in the first step of the metabolism. Other carboxylic acids, sugars, alcohols, amino acids, and aromatic hydrocarbons are not utilized either in pure culture or in co-culture with methanogens. *Syntrophothermus* does not utilize oxygen, sulfate, nitrate, sulfite, thiosulfate, fumarate, or Fe(III) as an electron acceptor.

Syntrophothermus can be cultured in a defined anaerobic basal medium (Sekiguchi et al., 2000) with crotonate. The optimum temperature for growth is 55°C. Optimal growth occurs in freshwater medium, although the genus grows in up to 1% NaCl. The growth of *Syntrophothermus* is inhibited by ampicillin, chloramphenicol, kanamycin, neomycin, rifampin, and vancomycin.

The type strain of *Syntrophothermus* was isolated from an anaerobic wastewater treatment sludge from a thermophilic (55°C) upflow anaerobic sludge blanket (UASB) reactor.

Enrichment and isolation procedures

Syntrophothermus is selectively enriched using the defined anaerobic basal medium with butyrate as the sole energy source at a high temperature (55°C). Bottles or tubes (100, 50, or 10 ml vials) can be used as culture vessels, similarly to other strict anaerobes. The medium is inoculated with anaerobic sludge. Enrichments are incubated in the dark at 55°C. After growth and methane production have been observed (1–2 weeks), the cultures are further enriched by successive transfers (1% inoculum). A series of at least five transfers should be made. The fifth enrichment may still convert butyrate into acetate and methane stably and contain at least two major cell morphotypes; one is F₄₂₀-autofluorescent cells resembling hydrogenotrophic methanogens, and the other is *Syntrophothermus*. For isolation of *Syntrophothermus*, the co-culture isolation method using roll tubes, in which all tubes were inoculated beforehand with *Methanothermobacter thermautotrophicus* cells, is used. After two weeks of incubation, white to brownish colonies 0.5–1 mm in diameter are formed. Pinpoint colonies are picked from the highest dilution, transferred into the liquid medium containing butyrate, and incubated again. This isolation step is repeated several times, and then the cultures are further purified by using the liquid basal medium containing crotonate and bromoethanesulfonate (BES). After a week of incubation, the growth of *Syntrophothermus* occurs. Three successive transfers into the crotonate-BES liquid medium results in disappearance of F₄₂₀-autofluorescent *Methanothermobacter* cells, and the cells in the culture seem to be homogeneous. When the roll tube isolation technique using crotonate as the sole substrate is used, very small colonies that are white, lens-shaped, and 0.1–0.2 mm in diameter are formed after 2 weeks of incubation. Pinpoint colonies are again picked from the highest dilution, transferred into the liquid medium containing crotonate, and incubated again. This step is repeated several times, and pure *Syntrophothermus* cells are obtained.

Maintenance procedures

Stock cultures (pure culture) may be maintained in the liquid basal medium with crotonate as the sole energy source. In case of co-culture with *Methanothermobacter thermautotrophicus*, cultures may be maintained in the liquid basal medium

with butyrate. Grown cultures are stored in the dark at room temperature for at least a month. Stock cultures are transferred monthly.

Differentiation of the genus *Syntrophothermus* from other genera

The most convincing evidence for uniqueness of the genus is based on comparative 16S rRNA gene analysis. No sequence similarities greater than 89% were identified among near-full-length 16S rRNA genes of other members of the family *Syntrophomonadaceae*. Physiologically, the genus *Syntrophothermus* represents syntrophic butyrate-degrading bacteria growing at high temperatures and nearly neutral pH; no genera

are known to show the same physiological traits. The closest genus, in terms of both phylogeny and physiology, is *Thermosyntropha*, which is also capable of degrading butyrate in syntrophy at high temperatures (Svetlitshnyi et al., 1996). However, the most striking differences between the two genera are the followings: (1) *Thermosyntropha* exhibits heterotrophic growth on substrates such as yeast extract and tryptone in addition to lipolytic growth, while *Syntrophothermus* grows only on limited fatty acids; (2) *Thermosyntropha* can grow at higher pH (growth range: 7.15–9.5) while *Syntrophothermus* is nearly neutrophilic; (3) the DNA base composition of *Syntrophothermus* is significantly higher than that of *Thermosyntropha*.

List of species of the genus *Syntrophothermus*

1. *Syntrophothermus lipocalidus* Sekiguchi, Kamagata, Nakamura, Ohashi and Harada 2000, 778^{VP}

lip.o.cal'id.us Gr. neut. *lipos* fat; L. adj. *calidus* expert; N.L. adj. *lipocalidus* fatty acid-specific, i.e., specifically utilizing fatty acids.

Cells have slightly curved rods with flagella. Gram stain negative. The dimensions of single cells are 2–4 × 0.4–0.5 μm. Weakly motile. Spores are never observed.

Strictly anaerobic chemo-organotroph. Growth occurs only in crotonate in pure culture. Saturated fatty acids with 4–10 carbon atoms are utilized in syntrophic association with hydrogenotrophic methanogens. 2-Methylpropionate is also utilized through isomerization to butyrate. Optimal growth

occurs in freshwater medium; 0.5% NaCl is slightly inhibitory for growth, and 1.5–2.0% NaCl completely inhibits the growth. Sensitive to ampicillin, chloramphenicol, kanamycin, neomycin, rifampin, and vancomycin. Cells grow between 45 and 60°C (optimum: 55°C), and pH 5.8–7.5 (optimum: 6.5–7.0). Occur in thermophilic (55°C) anaerobic wastewater treatment sludge.

DNA G+C content (mol%): 51.0 (HPLC).

Type strain: TGB-C1, DSM 12680.

GenBank accession number (16S rRNA gene): AB021305.

Note: DSM 12681 is *Syntrophothermus lipocalidus* in co-culture with *Methanothermobacter thermautotrophicus* strain ΔH.

Genus V. *Thermosyntropha* Svetlitshnyi, Rainey and Wiegel 1996, 1135^{VP}

JUERGEN WIEGEL

Ther.mo.syn.tro'pha. Gr. adj. *thermos* hot; Gr. prefix *syn* with, together; Gr. v. *trophein* to eat; Gr. masc. n. *syntrophos* foster brother or sister; N.L. fem. n. *thermosyntropha* "foster sisters liking it hot", referring to the fact that the bacterium grows at elevated temperatures on fatty acids only in syntrophic cultures with H₂-utilizing micro-organisms.

Gram-positive cell-wall type, but stains Gram-negative, slightly polymorphic rods. Obligately anaerobic, thermophilic, and heterotrophic. Members are able to utilize otherwise thermodynamically unfavorable substrates such as fatty acids in **syntrophic** cultures with H₂-utilizing sulfate-reducing bacteria or methane-producing archaea. Axenic cultures grow with crotonate or peptones as a sole carbon and energy sources.

DNA G+C content (mol%): 43–44 (HPLC).

Type species: *Thermosyntropha lipolytica* Svetlitshnyi, Rainey and Wiegel 1996, 1136^{VP}.

Further descriptive information

The genus *Thermosyntropha*, belonging to the *Syntrophomonadaceae*, is to date only represented by one species. Other similar but slightly different strains have been isolated, but have been lost before publication. The most closely related bacteria are the thermophilic neutrophile

Syntrophothermus lipocalidus, the 16S rRNA gene sequence of which possesses an evolutionary distance of 0.11–0.12 (Sekiguchi et al., 2000), and mesophilic syntrophs such as members of the genera *Syntrophospora* and *Syntrophomonas*, which, like *Thermosyntropha*, also use crotonate as the sole carbon and energy source for axenic cultures (Figure 198). So far, the only known habitats are alkaline hot springs from Lake Bogoria (Kenya). Hatamoto et al. (2007) also described thermophilic syntrophs that are able to degrade long-chain fatty acids in methanogenic sludge. Their work, using enrichments, 16S rRNA sequencing, and stable isotope analyses suggests that this phenotype may be shared by diverse bacteria from outside the *Syntrophomonadaceae* and even *Firmicutes*, taxa which remain to be isolated.

Maintenance procedures

Cultures have been successfully preserved in liquid nitrogen and upon freeze-drying. Storage for short times in 30–50%

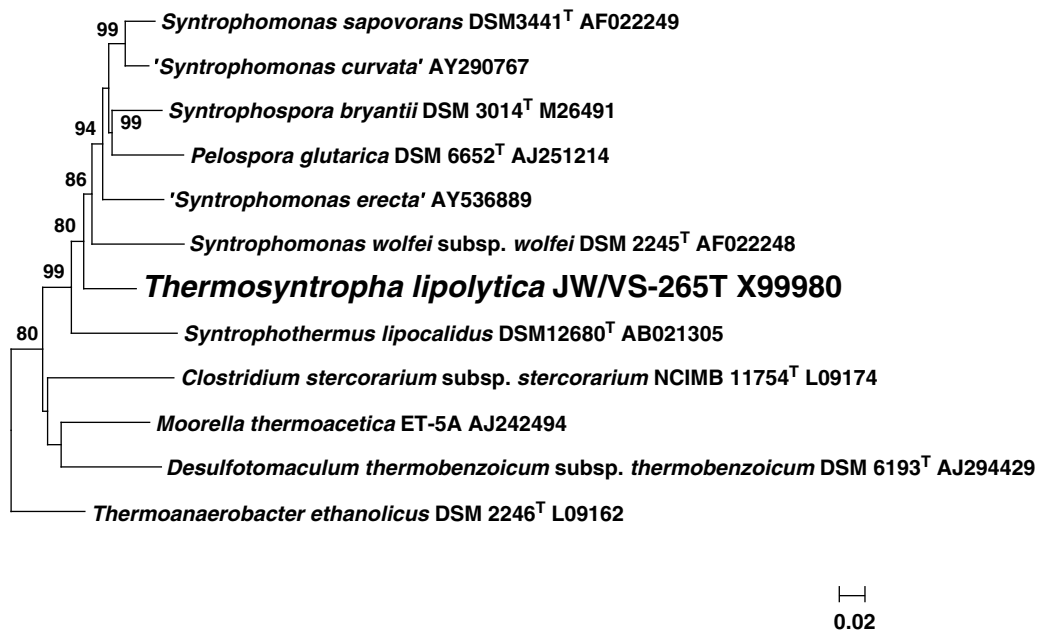

FIGURE 198. Phylogenetic dendrogram based on 16S rRNA sequence analysis demonstrating the position of *Thermosyntropha lipolytica* within the radiation of the *Syntrophomonadaceae* using *Thermoanaerobacter* (of the order “*Thermoanaerobacterales*”) as an outgroup. The 16S rRNA data used represents *Escherichia coli* DSM 30083^T nucleotide positions 1–1499. The tree was constructed using the neighbor-joining method with Jukes and Cantor distance corrections. Numbers at the nodes represent the bootstrap values (%) of 1000 replicates.

pre-reduced glycerol at -20 and -80°C has been successful. However, these cultures were lost within 4 years. Cultures growing on lipids quickly lose viability in the absence of equimolar concentrations of Ca^{2+} ions. Cultures grown on peptones remain viable at room temperature for 8–12 months if the pH at 25°C ($\text{pH}^{25^{\circ}\text{C}}$) is kept between 7.0 and 8.5.

Differentiation of the genus *Thermosyntropha* from other genera

Beside its unique position in a 16S rRNA-based phylogenetic tree, *Thermosyntropha lipolytica*, the type species of this genus, is currently the only species with a validly published name. It is an alkaliphilic thermophile that hydrolyzes long-chain (C_8 – C_{20}) fatty-acid-containing lipids in syntrophic co-culture with H_2 -utilizing methane-producing archaea or sulfate-reducing bacteria. The only other thermophilic fatty acid β -oxidizer known is *Syntrophothermus lipocalidus*, which is a neutrophile, has a much higher G+C content (51 mol% vs 43–44 mol%), cannot hydrolyze lipids such as tributyrin or olive oil, and only utilizes C_4 – C_{10} fatty acids. *Thermosyntropha* can be further distinguished from known mesophilic syntrophs by its growth temperature, pH range, rapid growth on crotonate, and substrate utilization spectrum.

Thermosyntropha also differs from many other anaerobic thermophiles in that it cannot utilize carbohydrates. Its lipolytic capability also differentiates it from other peptidolytic alkalithermophiles such as *Clostridium paradoxum*, which forms spores, and species of *Anaerobranca* and *Thermobrachium*, which form branched cells.

List of species of the genus *Thermosyntropha*

- 1. *Thermosyntropha lipolytica*** Svetlitschnyi, Rainey and Wiegel 1996, 1136^{VP}
li.po.ly'ti.ca. Gr. n. *lipos* fat; Gr. adj. *lutikos* able to loosen; N.L. fem. adj. *lipolytica* referring to the ability to hydrolyze lipids to glycerol and fatty acids.

An alkalithermophilic, lipolytic anaerobe, cells are straight, slightly curved, or polymorphic rods, 2.0 – 3.5×0.3 – $0.4 \mu\text{m}$, that stain Gram-negative. Strains grow in agar-shake-roll tubes as small (<0.5 mm diameter), lens-shaped, white colonies. During exponential growth, pairs

and chains of cells are observed. Sporulation and motility has never been observed under any conditions tested. Only the type strain is available; other strains, which were also lipolytic and peptidolytic, have been lost due to freezer malfunction.

All strains in co-culture with an H₂-utilizing organism utilize fatty acids ranging in size from butyrate (very slowly) to long-chain fatty acids such as stearate as well as the unsaturated fatty acids oleate and linoleate. Longer fatty acids such as arachidate (C_{20:0}) and behenate (C_{22:0}) do not support growth. The liberated glycerol is not metabolized in either pure or syntrophic cultures, which is unusual for lipolytic bacteria. Fatty acids are metabolized only in the presence of equimolar concentrations of Ca²⁺ ions and H₂-utilizing micro-organisms such as *Methanothermobacter thermoautotrophicus* (or its heterotypic synonym *Methanobacterium thermalcaliphilum*) and *Desulfotomaculum nigrificans* strains that are able to grow above pH 8.0. These strains must also lower the H₂ levels produced during fatty acid oxidation to concentrations rendering the fatty acid β -oxidation exothermic. Substrates such as tributyrin, trilaurin, tripalmitin, tristearin, and triolein support, in the presence of Ca²⁺ ions, growth of the methanogenic or sulfidogenic co-cultures.

Strain JW/VS-265^T contains two constitutively expressed lipases termed LipA and LipB. They possess differences in their N-terminal amino acid sequences as well as temperature optima (between 90 and 98°C) and pH optima (pH^{25°C} 9.4 and 9.6, respectively). Both enzymes hydrolyze the ester bond in positions 1 and 2, leaving the mono-substituted glycerol. In nonaqueous solutions, synthesis of various glycerides and other esters are catalyzed by these enzymes (Salameh, 2006).

Axenic growth also occurs with yeast extract. Cell yields are proportional to the concentrations of yeast extract up to 1% (w/v) and 1.4 × 10⁸ cells/ml. Yeast extract can be replaced with tryptone, Casamino acids, beef extract, heart infusion, or nutrient broth. In the presence of 0.1% yeast extract, pyruvate, ribose, and xylose support weak growth beyond that of yeast extract alone. None of the strains are able to utilize hexoses, grow chemolithoautotrophically with H₂/CO₂, or grow on fatty acids in the absence of H₂-utilizing micro-organisms.

Crotonate supports growth within 3 d, producing about 2 mol acetate and 1 mol butyrate per 2 mol crotonate. Crotonate was first observed to support axenic growth of syntrophic bacteria by Beaty and McInerney (1987). All strains are thermophilic with a growth temperature range of 50–70°C (optimum around 60–66°C). Cultures do not grow at 43 or 73°C. All isolates are moderate alkaliphiles, growing at pH^{25°C} 7.15–9.5, with optimum growth at pH^{25°C} 8.1–8.9.

NaCl concentrations above 1% (w/v) are inhibitory.

Growth of strain JW/VS265^T at pH^{25°C} 8.4 and 60°C is inhibited by 50 µg/ml ampicillin, chloramphenicol, kanamycin, neomycin, rifampin, and vancomycin.

All strains were isolated on commercial olive oil from enrichments inoculated with mixed sediment/water samples from unnamed hot springs of Lake Bogoria (Kenya) in the presence of 0.05% (w/v) yeast extract.

DNA G+C content (mol%): 43–44 (HPLC).

Type strain: JW/VS-265, ATCC 700317, DSM 11003.

GenBank accession number (16S rRNA gene): X99980.
