*This volume is dedicated to our colleagues
James T. Staley and George M. Garrity,
who retired from the Board of Trustees of Bergey's Manual Trust
during preparation of this volume.
We deeply appreciate their efforts as editors, authors and officers of the Trust.
They have devoted many years to helping
the Trust meet its objectives.*

Preface to Volume Three of the Second Edition of *Bergey's Manual of Systematic Bacteriology*

A number of important changes occurred at Bergey's Manual Trust during the preparation of this volume. In 2006, George Garrity retired from the Trust, and the Trust moved its offices from Michigan State University to the University of Georgia. We are deeply indebted to Professor Garrity, under whose supervision much of this volume was prepared. James T. Staley's wise council guided this transition until he retired from the Trust in 2008 after 32 years of service.

The officers of the Trust have also changed during this time. Barny Whitman became Treasurer and Director of the Editorial Office in 2006. Michael Goodfellow succeeded Professor Staley as Chair in 2008 and Peter Kämpfer succeeded Professor Goodfellow as Vice-Chair in 2008. The Trust was also fortunate to acquire the services of Dr Aidan Parte as Managing Editor in 2007.

Much as things have changed, prokaryotic systematics has remained a vibrant and exciting field of study, one of challenges and opportunities, great discoveries and gradual advances. To honor the leaders of our field, the Trust presented the Bergey Award in recognition of outstanding contributions to the taxonomy of prokaryotes to Jean Paul Euzéby (2005), David P. Labeda (2006), and Jürgen Wiegand (2008). In recognition of life-long contributions to the field of prokaryotic systematics, the Bergey Medal was presented to Richard W. Castenholz (2005), Kazuo Komagata (2005), Klaus P. Schaal (2006), Fergus Priest (2008), and James T. Staley (2008).

Acknowledgements

The Trust is indebted to all of the contributors and reviewers, without whom this work would not be possible. The Editors are grateful for the time and effort that each has expended on behalf of the entire scientific community. We also thank the authors for their good grace in accepting comments, criticisms, and editing of their manuscripts.

The Trust recognizes its enormous debt to Dr Aidan Parte, whose enthusiasm and professionalism have made this work possible. His expertise and good judgment have been extremely valued.

We also recognize the special efforts of Dr Jean Euzéby and Professor Aharon Oren for their assistance on the nomenclature and etymologies.

We also thank the Department of Microbiology at Michigan State University and especially Connie Williams, for her assistance in bring this volume to completion, and Walter Esselman, the Chair of the Department of Microbiology and Molecular Genetics, who facilitated our move to the University of Georgia. We thank our current copyeditors, proofreaders and other staff, including Susan Andrews, Joanne Auger, Frances Brenner, Robert Gutman, Judy Leventhal, Linda Sanders and Travis Dean, whose hard work and attention to detail have made this volume possible. Lastly, we thank the Department of Microbiology at the University of Georgia for its assistance and encouragement in thousands of ways.

William B. (Barny) Whitman

On using the *Manual*

NOEL R. KRIEG AND GEORGE M. GARRITY

Citation

The *Systematics* is a peer-reviewed collection of chapters, contributed by authors who were invited by the Trust to share their knowledge and expertise of specific taxa. Citations should refer to the author, the chapter title, and inclusive pages rather than to the Editors.

Arrangement of the Manual

As in the previous volumes of this edition, the *Manual* is arranged in phylogenetic groups based upon the analyses of the 16S rRNA presented in the introductory chapter "Revised road map to the phylum *Firmicutes*". These groups have been substantially modified since the publication of volume 1 in 2001, reflecting both the availability of more experimental data and a different method of analysis. Since volume 3 includes only the phylum *Firmicutes*, taxa are arranged by class, order, family, genus and species. Within each taxon, the nomenclatural type is presented first and indicated by a superscript T. Other taxa are presented in alphabetical order without consideration of degrees of relatedness.

Articles

Each article dealing with a bacterial genus is presented wherever possible in a definite sequence as follows:

a. Name of the genus. Accepted names are in **boldface**, followed by "defining publication(s)", i.e. the authority for the name, the year of the original description, and the page on which the taxon was named and described. The superscript AL indicates that the name was included on the Approved Lists of Bacterial Names, published in January 1980. The superscript VP indicates that the name, although not on the Approved Lists of Bacterial Names, was subsequently validly published in the *International Journal of Systematic and Evolutionary Microbiology* (or the *International Journal of Systematic Bacteriology*). Names given within quotation marks have no standing in nomenclature; as of the date of preparation of the *Manual* they had not been validly published in the *International Journal of Systematic and Evolutionary Microbiology*, although they may have been "effectively published" elsewhere. Names followed by the term "nov." are newly proposed but will not be validly published until they appear in a Validation List in the *International Journal of Systematic and Evolutionary Microbiology*. Their proposal in the *Manual* constitutes only "effective publication", not valid publication.

b. Name of author(s). The person or persons who prepared the Bergey's article are indicated. The address of each author can be found in the list of Contributors at the beginning of the *Manual*.

c. Synonyms. In some instances a list of some synonyms used in the past for the same genus is given. Other synonyms can be found in the *Index Bergeyana* or the *Supplement to the Index Bergeyana*.

d. Etymology of the name. Etymologies are provided as in previous editions, and many (but undoubtedly not all) errors have been corrected. It is often difficult, however, to determine why a particular name was chosen, or the nuance intended, if the details were not provided in the original publication. Those authors who propose new names are urged to consult a Greek and Latin authority before publishing in order to ensure grammatical correctness and also to ensure that the meaning of the name is as intended.

e. Salient features. This is a brief resume of the salient features of the taxon. The most important characteristics are given in **boldface**. The DNA G+C content is given.

f. Type species. The name of the type species of the genus is also indicated along with the defining publication(s).

g. Further descriptive information. This portion elaborates on the various features of the genus, particularly those features having significance for systematic bacteriology. The treatment serves to acquaint the reader with the overall biology of the organisms but is not meant to be a comprehensive review. The information is normally presented in the following sequence:

- Colonial morphology and pigmentation
- Growth conditions and nutrition
- Physiology and metabolism
- Genetics, plasmids, and bacteriophages
- Phylogenetic treatment
- Antigenic structure
- Pathogenicity
- Ecology

h. Enrichment and isolation. A few selected methods are presented, together with the pertinent media formulations.

i. Maintenance procedures. Methods used for maintenance of stock cultures and preservation of strains are given.

j. Procedures for testing special characters. This portion provides methodology for testing for unusual characteristics or performing tests of special importance.

k. Differentiation of the genus from other genera. Those characteristics that are especially useful for distinguishing the genus from similar or related organisms are indicated here, usually in a tabular form.

l. Taxonomic comments. This summarizes the available information related to taxonomic placement of the genus and indicates the justification for considering the genus a distinct taxon. Particular emphasis is given to the methods of molecular biology used to estimate the relatedness of the genus to other taxa, where such information is available. Taxonomic information regarding the arrangement and status of the various species within the genus follows. Where taxonomic controversy exists, the problems are delineated and the various alternative viewpoints are discussed.

m. Further reading. A list of selected references, usually of a general nature, is given to enable the reader to gain access to additional sources of information about the genus.

n. Differentiation of the species of the genus. Those characteristics that are important for distinguishing the various species within the genus are presented, usually with reference to a table summarizing the information.

o. List of species of the genus. The citation of each species is given, followed in some instances by a brief list of objective synonyms. The etymology of the specific epithet is indicated. Descriptive information for the species is usually presented in tabular form, but special information may be given in the text. Because of the emphasis on tabular data, the species descriptions are usually brief. The type strain of each species is indicated, together with the collection(s) in which it can be found. (Addresses of the various culture collections are given in the article in Volume 1 entitled *Culture Collections: An Essential Resource for Microbiology*.) The 16S rRNA gene sequence used in phylogenetic analysis and placement of the species into the taxonomic framework is given, along with the GenBank (or other database) accession number. Additional comments may be provided to point the reader to other well-characterized strains of the species and any other known DNA sequences that may be relevant.

p. Species *incertae sedis*. The List of Species may be followed in some instances by a listing of additional species under the heading “Species *Incertae Sedis*” or “Other organisms”. The taxonomic placement or status of such species is questionable, and the reasons for the uncertainty are presented.

q. References. All references given in the article are listed alphabetically at the end of the family chapter.

Tables

In each article dealing with a genus, there are generally three kinds of table: (a) those that differentiate the genus from similar or related genera, (b) those that differentiate the species within the genus, and (c) those that provide additional information about the species (such information not being particularly useful for differentiation). The meanings of symbols are as follows:

+: 90% or more of the strains are positive

d: 11–89% of the strains are positive

–: 90% or more of the strains are negative

D: different reactions occur in different taxa (e.g., species of a genus or genera of a family)

v: strain instability (NOT equivalent to “d”)

w: weak reaction.

ND, not determined or no data.

These symbols, and exceptions to their use, as well as the meaning of additional symbols, are given in footnotes to the tables.

Use of the *Manual* for determinative purposes

Many chapters have keys or tables for differentiation of the various taxa contained therein. For identification of species, it is important to read both the generic and species descriptions because characteristics listed in the generic descriptions are not usually repeated in the species descriptions.

The index is useful for locating the articles on unfamiliar taxa or in discovering the current classification of a particular taxon. Every bacterial name mentioned in the *Manual* is listed in the index. In addition, an up-to-date outline of the taxonomic framework is provided in the introductory chapter “Revised road map to the phylum *Firmicutes*”.

Errors, comments, suggestions

As in previous volumes, the editors and authors earnestly solicit the assistance of all microbiologists in the correction of possible errors in *Bergey’s Manual of Systematic Bacteriology*. Comments on the presentation will also be welcomed as well as suggestions for future editions. Correspondence should be addressed to:

Revised road map to the phylum *Firmicutes*

WOLFGANG LUDWIG, KARL-HEINZ SCHLEIFER AND WILLIAM B. WHITMAN

Starting with the Second Edition of *Bergey's Manual of Systematic Bacteriology*, the arrangement of content follows a phylogenetic framework or "road map" based largely on analyses of the nucleotide sequences of the ribosomal small-subunit rRNA rather than on phenotypic data (Garrity et al., 2005). Implicit in the use of the road map are the convictions that prokaryotes have a phylogeny and that phylogeny matters. However, the reader should be aware that phylogenies, like other experimentally derived hypotheses, are not static but may change whenever new data and/or improved methods of analysis become available (Ludwig and Klenk, 2005). Thus, the large increases in data since the publication of the taxonomic outlines in the preceding volumes have led to a re-evaluation of the road map. Not surprisingly, the taxonomic hierarchy has been modified or newly interpreted for a number of taxonomic units of the *Firmicutes*. These changes are described in the following paragraphs.

The taxonomic road map proposed in Volume 1 and updated and emended in Volume 2 was derived from phylogenetic and principal-component analyses of comprehensive datasets of small-subunit rRNA sequences. A similar approach is continued here. Since the introduction of comparative rRNA sequencing (Ludwig and Klenk, 2005; Ludwig and Schleifer, 2005), there has been a continuous debate concerning the justification and power of a single marker molecule for elucidating and establishing the phylogeny and taxonomy of organisms, respectively. Although generally well established in taxonomy, the polyphasic approach cannot be currently applied for sequence-based analyses due to the lack of adequate comprehensive datasets for alternative marker molecules. Even in the age of genomics, the datasets for non-rRNA markers are poor in comparison to more than 300,000 rRNA primary structures available in general and special databases (Cole et al., 2007; Pruesse et al., 2007). Nevertheless, the data provided by the full genome sequencing projects allow defining a small set of genes representing the conserved core of prokaryotic genomes (Cicarelli et al., 2006; Ludwig and Schleifer, 2005). Furthermore, comparative analyses of the core gene sequences globally support the small-subunit rRNA derived view of prokaryotic evolution. Although the tree topologies reconstructed from alternative markers differ in detail, the major groups (and taxa) are verified or at least not disproved (Ludwig and Schleifer, 2005). Consequently, the structuring of this volume is based on updated and curated (<http://www.arb-silva.de>; Ludwig et al., 2004) databases of processed small-subunit rRNA primary structures.

Data analysis

The current release of the integrated small-subunit rRNA database of the SILVA project (Pruesse et al., 2007) provided the basis for these phylogenetic analyses of the *Firmicutes*. The tools of the ARB software package (Ludwig et al., 2004) were used for data evaluation, optimization and phylogenetic inference. The

alignment of sequences comprising at least 1000 monomers was manually evaluated and optimized for all representatives of the phylum. Phylogenetic treeing was performed with all of the approximately 14,000 sequences from *Firmicutes* which contain at least 1400 nucleotides and an additional 1000 sequences from representatives of the other phyla and domains. For recognizing and avoiding the influences of chimeric sequences, all calculations were performed twice, once including and once excluding environmental clone data. The datasets also varied with respect to the inclusion of highly variable sequence positions, which were eliminated in some analyses (Ludwig and Klenk, 2005). The consensus tree used for evaluating or modifying the taxonomic outline was based on maximum-likelihood analyses (RAXML, implemented in the ARB package; Stamatakis et al., 2005) and further evaluated by maximum-parsimony and distance matrix analyses with the respective ARB tools (Ludwig et al., 2004). In the case that type strains were only represented by partial sequences (less than 1400 nucleotides), the respective data were inserted by a special ARB-tool allowing the optimal positioning of branches to the reference tree without admitting topology changes.

Taxonomic interpretation

The phylogenetic conclusions were used for evaluating and modifying the taxonomic outline of the *Firmicutes*. In order to ensure applicability and promote acceptance, the proposed modifications were made following a conservative procedure. The overall organization follows the type 'taxon' principle as applied in the previous volumes. Taxa defined in the outline of the preceding volumes were only unified, dissected or transferred in the cases of strong phylogenetic support. This approach is justified by the well-known low significance of local tree topologies (also called "range of unsharpness" around the nodes; Ludwig and Klenk, 2005). Thus, many of the cases of paraphyletic taxa found were maintained in the current road map if the respective (sub)-clusters rooted closely together, even if they were separated by intervening clusters representing other taxa. While reorganization of these taxa may be warranted, it was not performed in the absence of confirmatory evidence. The names of validly published but phylogenetically misplaced type strains are also generally maintained. These strains are mentioned in the context of the respective phylogenetic groups. In case of paraphyly, all concerned species or higher taxa are assigned to the respective (sub)-groups. New higher taxonomic ranks are only proposed if species or genera — previously assigned to different higher taxonomic units — are significantly unified in a monophyletic branch.

The taxonomic backbone of the *Firmicutes*

In the current treatment, the phylum *Firmicutes* contains three classes, "*Bacilli*", "*Clostridia*" and "*Erysipelotrichia*". This organization is similar to that of Garrity et al. (2005). However, the *Mollicutes*

were removed from the phylum given the general low support by alternative markers (Ludwig and Schleifer, 2005) and its unique phenotypic properties, in particular the lack of rigid cell walls (see Emended description of *Firmicutes*, this volume). The family *Erysipelotrichaceae*, which includes wall-forming Gram-positive organisms previously classified with the *Mollicutes*, was retained in the *Firmicutes* as a novel class, "*Erysipelotrichia*", and order, "*Erysipelotrichales*".

While the bipartition of the classes "*Clostridia*" and "*Bacilli*" is corroborated by the new analyses, some of the taxa previously assigned to the "*Clostridia*" tend to root outside the *Firmicutes* and may represent separate phyla. These include taxa previously classified within the "*Thermoanaerobacterales*" and

Syntrophomonadaceae (Garrity et al., 2005), which may contain a number of phylogenetic clades that are distinct at the phylum level. However, given the absence of corroboration by other phylogenetic markers for many of these assignments and a clear consensus on the definition of a phylum, these taxa were retained within the *Firmicutes* for the present.

Class "*Bacilli*"

Compared to Garrity et al. (2005), only minor restructuring of the "*Bacilli*" is indicated by this new analysis of the rRNA data. The separation into two orders, *Bacillales* and "*Lactobacillales*", is well supported (Figure 1). However, a number of paralogous

FIGURE 1. Consensus dendrogram reflecting the phylogenetic relationships of the classes "*Bacilli*" and "*Erysipelotrichia*" within the *Firmicutes*. The tree is based on maximum-likelihood analyses of a dataset comprising about 5000 almost full-length high-quality 16S rRNA sequences from representatives of the *Firmicutes* and another 1000 representing the major lines of descent of the three domains *Bacteria*, *Archaea*, and *Eucarya*. The topology was evaluated by distance matrix and maximum-parsimony analyses of the dataset. In addition, maximum-parsimony analyses of all currently available almost complete small-subunit rRNA sequences (137,400 of ARB-SILVA release 92, Prsse et al., 2007) were performed. Only alignment positions invariant in at least 50% of the included primary structures from *Firmicutes* were included for tree reconstruction. Multifurcations indicate that a common relative branching order was not significantly supported applying alternative treeing methods. The (horizontal) branch lengths indicate the significance of the respective node separation.

groups are found within the “*Bacilli*”, some of which have been reclassified.

Order *Bacillales*

The definition and taxonomic organization of the order *Bacillales* is as outlined in the previous volumes (Figure 2). Of the ten families proposed in Garrity et al. (2005), eight are retained. Upon transfer of the type genus *Caryophanon* to the *Planococcaceae*, the family *Caryophanaceae* was removed. Although the family *Caryophanaceae* Peskoff 1939^{AL} has priority over *Planococcaceae* Krassilnikov 1949^{AL}, the former is confusing because it is a misnomer, meaning ‘that which has a conspicuous nucleus’, and was based upon misinterpretation of staining results (Trentini, 1986). Similarly, upon transfer of the type genus *Turicibacter*

to the family “*Erysipelotrichaceae*”, the family “*Turicibacteraceae*” was removed. In addition, the genus *Pasteuria* was transferred out of the family “*Alicyclobacillaceae*” to the family *Pasteuriaceae*. As described below, a number of genera were also moved to families *incertae sedis* in recognition of the ambiguity of their phylogeny and taxonomic assignments.

Family *Bacillaceae*

The 16S rRNA-based phylogenetic analyses indicate that the family *Bacillaceae* is paraphyletic and composed of species misassigned to the genus *Bacillus* as well as genera misassigned to the family (Figure 2). Reclassification of some taxa is proposed to correct some of these problems. However, the complete reorganization of this old and well-abused taxon is outside the scope of this work.

FIGURE 2. Consensus dendrogram reflecting the phylogenetic relationships of the order *Bacillales* within the class “*Bacilli*”. Analyses were performed as described for Figure 1.

Genus *Bacillus*

The majority of the *Bacillus* species with validly published names are phylogenetically grouped into subclusters within this genus. However, some validly named species of *Bacillus* are not phylogenetically related to the type species, *B. subtilis*, and are more closely related to other genera. The phylogenetic subclusters within the genus *Bacillus* are:

a: *Bacillus subtilis*, *amyloliquefaciens*, *atrophaeus*, *mojavensis*, *licheniformis*, *sonorensis*, *vallismortis*, including the very likely misclassified *Paenibacillus popilliae*.

b: *Bacillus farraginis*, *fordii*, *fortis*, *lentus*, *galactosidilyticus*

c: *Bacillus asahii*, *bataviensis*, *benzoevorans*, *circulans*, *cohnii*, *firminus*, *flexus*, *fumarioli*, *infernus*, *jeotgali*, *luciferensis*, *megaterium*, *methanolicus*, *niacini*, *novalis*, *psychrosaccharolyticus*, *simplex*, *solis*, *vireti*

d: *Bacillus anthracis*, *cereus*, *mycooides*, *thuringiensis*, *weihenstephansensis*

e: *Bacillus aquimaris*, *marisflavi*

f: *Bacillus badius*, *coagulans*, *thermoamylovorans*, *acidicola*, *oleronius*, *sporothermodurans*

g: *Bacillus alcalophilus*, *arsenicoselestatensis*, *clausii*, *gibsonii*, *halodurans*, *horikoshii*, *krukwichiae*, *okhensis*, *okuhidensis*, *pseudocalcaliphilus*, *pseudofirmus*

h: *Bacillus arsenicus*, *barnaricus*, *gelatini*, *decolorationis*,

i: *Bacillus carboniphilus*, *endophyticus*, *smithii*,

j: *Bacillus pallidus*,

k: *Bacillus funiculus*, *panaciterrae*

The *Bacillus* cluster contains three additional groups of related genera: *Anoxybacillus*, *Geobacillus*, and *Saccharococcus*.

In addition to these taxa, which compose the family *Bacillaceae sensu stricto*, other phylogenetic groups have been assigned to this family (Garrity et al., 2005). Although the largest group appears to warrant elevation to a novel family, it is retained within the *Bacillaceae* in the present outline. This cluster comprises the genera *Alkalibacillus* (new; Jeon et al., 2005), *Amphibacillus*, *Cerasibacillus* (new; Nakamura et al., 2004), *Filobacillus*, *Gracilibacillus*, *Halobacillus* (new; Spring et al., 1996), *Halolactibacillus* (new; Ishikawa et al., 2005), *Lentibacillus*, *Oceanobacillus*, *Paraliobacillus*, *Paucisalibacillus* (new; Nunes et al., 2006); not described in the current volume), *Pontibacillus*, *Salibacillus* (not described in the current volume), *Tenuibacillus*, *Thalassobacillus* (new; Garcia et al., 2005), and *Virgibacillus*. The type strains of other species are positioned phylogenetically among the members of this lineage and merit taxonomical emendation: *Bacillus halophilus* and *Bacillus thermocloacae*, *Sinococcus*, and *Marinococcus*. For this reason, *Marinococcus* was transferred from the *Sporolactobacillaceae* in the current outline.

In addition, the genera *Ureibacillus*, *Marinibacillus*, *Jeotgalibacillus*, and *Exiguobacterium* were previously assigned to the *Bacillaceae* (Garrity et al., 2005). *Ureibacillus* falls within the clade represented by *Planococcaceae*, and it was reassigned to that family. *Marinibacillus* and *Jeotgalibacillus* are closely related to each other as well as to *Bacillus aminovorans*. This group is distantly related to the *Planococcaceae*, and they are also assigned to that family. Lastly, *Exiguobacterium* is not closely related to any of the described families, and it is assigned to a Family XII *Incertae Sedis* in the current road map.

Bacillus schlegelii and *Bacillus solfatarae* represent their own deeply branching lineage of the “*Bacilli*” and warrant reclassification.

Family “*Alicyclobacillaceae*”

Only the type genus *Alicyclobacillus* is retained in this family, and two genera previously classified with the *Alicyclobacillaceae* have been reclassified (Garrity et al., 2005). According to the new 16S rRNA sequence analyses, *Sulfobacillus* represents a deep branch of the “*Clostridia*”, and it is now placed within Family XVII *Incertae Sedis* of the *Clostridiales*. *Pasteuria*, which was also previously classified within this family, is an obligate parasite of invertebrates. While it can be cultivated within the body of its prey, it has not been cultured axenically. Because of the substantial phenotypic differences and low 16S rRNA sequence similarity with *Alicyclobacillus*, it is now classified within its own family, *Pasteuriaceae* (see below). Lastly, *Alicyclobacillus* possesses a moderate relationship to *Bacillus tusciae*, which could be reclassified to this family.

Family “*Listeriaceae*”

The monophyletic family “*Listeriaceae*” combines the genera *Listeria* and *Brochothrix* as in the previous outline.

Family “*Paenibacillaceae*”

The members of the family “*Paenibacillaceae*” are distributed between two phylogenetic clusters. *Paenibacillus*, *Brevibacillus*, *Cohnella* (new; Kämpfer et al., 2006) and *Thermobacillus* share a common origin and represent the first group. Some validly named *Bacillus* species are found among the *Paenibacillus* species: *Bacillus chitinolyticus*, *edaphicus*, *ehimensis*, and *mucilaginosus*. The second group comprises the genera *Aneurinibacillus*, *Ammoniphilus*, and *Oxalophagus*. Although not clearly monophyletic, these two clusters are often associated together in several types of analyses. Thus, in the absence of clear evidence for a separation, the second cluster is retained within the family. In contrast, *Thermicanus*, which was classified within this family by Garrity et al. (2005), appears to represent a novel lineage of the *Bacilli*. In recognition of its ambiguous status, it was reclassified within Family X *Incertae Sedis*.

Family *Pasteuriaceae*

This family contains *Pasteuria*, an obligate parasite of invertebrates which has not yet been cultivated outside of its host. Although this genus was previously classified within the “*Alicyclobacillaceae*”, the current analyses suggest that it is more closely associated with the “*Thermoactinomycetaceae*”. In spite of the similarities in morphology and rRNA sequences between *Pasteuria* and *Thermoactinomycetes*, these genera were not combined into a single family for two reasons. First, in the absence of an axenic culture of *Pasteuria*, additional phenotypic and genotypic evidence for combining these organisms into a single family are not available. Second, the obligately pathogenic nature of *Pasteuria* was judged to be distinctive enough to warrant a unique classification in the absence of evidence to the contrary.

Family *Planococcaceae*

The family *Planococcaceae* is a clearly monophyletic unit that contains the genera *Planococcus*, *Filibacter*, *Kurthia*, *Planomicrobium*, and *Sporosarcina* as well as three genera transferred from the *Bacillaceae* (*Jeotgalibacillus*, *Marinibacillus*, and *Ureibacillus*) and *Caryophanon*. *Caryophanon* is the only genus of the *Caryophanaceae* in

the previous outline and is transferred to the *Planococcaceae* based upon its rRNA-based phylogeny. Thus, the family *Caryophanaceae* is not used in the current outline. Again, some validly named species of *Bacillus* are found in the *Planococcaceae* radiation: *Bacillus fusiformis*, *sphaericus*, *massiliensis*, *psychrodurans*, and *psychrotolerans*.

Family “*Sporolactobacillaceae*”

Given that *Marinococcus* is transferred to the *Bacillaceae*, the family “*Sporolactobacillaceae*” is now composed of only the genus *Sporolactobacillus*. A moderate relationship to this genus is found for some validly named *Bacillus* species: *Bacillus agaradhaerens*, *clarkii*, *selenitireducens*, and *vedderis* as well as two recently described genera, *Tuberibacillus* and *Pullulanibacillus*, which are not included in this volume (Hatayama et al., 2006).

Family “*Staphylococcaceae*”

The family “*Staphylococcaceae*”, as defined in the taxonomic outline of the previous volumes, is paraphyletic (Garrity et al., 2005). Whereas the four genera *Staphylococcus*, *Jeitgaliococcus*, *Macrococcus*, and *Salinicoccus* are clearly monophyletic, the genus *Gemella* represents a separate unit paraphyletic to the first cluster. Moreover, *Gemella* is distinguished from “*Staphylococcaceae*” *stricto sensu* because it is catalase- and oxidase-negative and possesses predominantly straight-chained, saturated and monounsaturated rather than branched-chain

membrane lipids (K. Bernard, personal communication). Thus, *Gemella* is transferred to Family XI *Incertae Sedis* within the *Bacillales*.

Family “*Thermoactinomycetaceae*”

The family now contains six newly described genera in addition to the original genus *Thermoactinomyces*. The new genera are *Laceyella*, *Mechercharimyces*, *Planifilum*, *Seinonella*, *Shimazuella*, and *Thermoflavimicrobium*.

Order “*Lactobacillales*”

As in the previous outline, this order is composed of six families (Figure 3).

Family *Lactobacillaceae*

In agreement with the previous outlines, the *Lactobacillaceae* is a monophyletic group that harbors three genera: *Lactobacillus*, *Paralactobacillus*, and *Pediococcus*.

Family “*Aerococcaceae*”

Two paraphyletic groups are combined in the family “*Aerococcaceae*”. The majority of the genera are unified in a phylogenetically tight group comprising *Abiotrophia*, *Dolosicoccus*, *Eremococcus*, *Facklamia*, *Globicatella*, and *Ignavigranum*. Only the type genus *Aerococcus* represents a separate lineage.

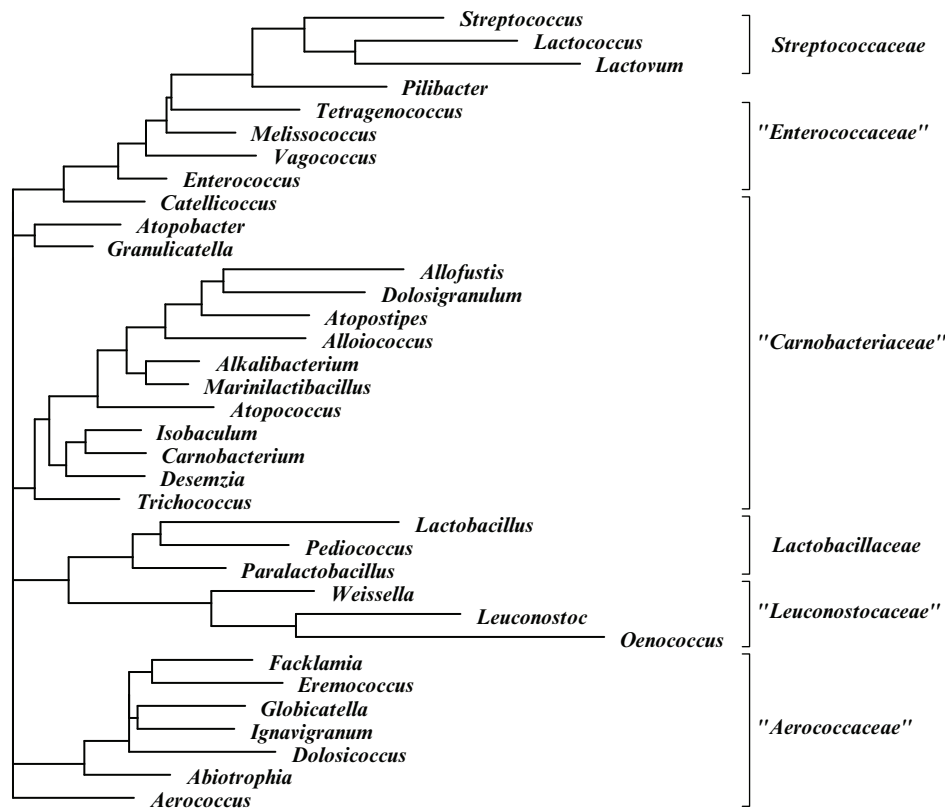

FIGURE 3. Consensus dendrogram reflecting the phylogenetic relationships of the order “*Lactobacillales*” within the class “*Bacilli*”. Analyses were performed as described for Figure 1.

Family “*Carnobacteriaceae*”

The members of the family “*Carnobacteriaceae*” are found in two paraphyletic clusters. *Carnobacterium* together with *Alkalibacterium*, *Allofustis*, *Alloiooccus*, *Atopococcus* (new; Collins et al., 2005), *Atopostipes*, *Desemzia*, *Dolosigranulum*, *Isobaculum*, *Marinilactibacillus*, and *Trichococcus* represent the most comprehensive group. *Granulicatella* and *Atopobacter* (formerly in the “*Enterococcaceae*”) are in the second group. However, the phylogenetic position of these genera remains ambiguous, and reassignment may be warranted as more information becomes available.

Family “*Enterococcaceae*”

Four genera remain within the family “*Enterococcaceae*”: *Enterococcus*, *Melissococcus*, *Tetragenococcus*, and *Vagococcus*. *Atopobacter* was transferred to the “*Carnobacteriaceae*” (see above). The recently described genus *Catelicoccus*, which is not described in this volume, phylogenetically represents a sister group to the “*Enterococcaceae*”.

Family “*Leuconostocaceae*”

No changes of the taxonomic organization are made for the “*Leuconostocaceae*”, which unifies three phylogenetically related genera: *Leuconostoc*, *Oenococcus*, and *Weissella*.

Family *Streptococcaceae*

In addition to the genera *Streptococcus* and *Lactococcus* in the previous road map, the family *Streptococcaceae* comprises a third, recently discovered, genus, *Lactovum* (Matthies et al., 2004).

Families *incertae sedis*

In the current road map, *Thermicanus*, *Gemella*, and *Exiguobacterium* have been reclassified into different families *incertae sedis* in recognition of their ambiguous taxonomic assignments (see above). The genera *Oscillospira* and *Syntrophococcus*, which were classified in this category in the previous road map (Garrity et al., 2005), have been transferred to the “*Ruminococcaceae*” and “*Lachnospiraceae*” in the *Clostridiales*, respectively (see below).

Class “*Clostridia*”

The class “*Clostridia*” is comprised of three orders, *Clostridiales*, *Halanaerobiales*, and “*Thermoanaerobacterales*”. This organization is similar to the previous roadmap (Garrity et al., 2005) and unites the orders *Clostridiales* Prevot 1953^{AL} and *Eubacteriales* Buchanan 1917^{AL}. Preference is given to *Clostridiales* because of the priority of its type genus. Moreover, because many of the species united in this group were previously classified with the genus *Clostridium*, this classification is the least likely to cause confusion. While the order *Halanaerobiales* is monophyletic, the remaining two orders are paraphyletic and each include taxa with only low similarity to the majority of the *Firmicutes* (Figure 4).

Order *Clostridiales*

In the previous road map (Garrity et al., 2005), the order *Clostridiales* was composed of eight families, many of which were paraphyletic. While it was not possible to fully address this problem, the current road map increases the number of

families to ten and notes nine additional families as *incertae sedis* (Figures 5 and 6). This is only a first step, and significant further reorganization is warranted, especially as new data and concepts are applied to these taxa.

Seven of the eight original families are retained in the current outline. However, the family “*Acidaminococcaceae*” was not used in recognition of the priority of *Veillonellaceae* 1971^{AL}. In addition, the family “*Ruminococcaceae*” is proposed to accommodate a large number of genera transferred from other families. A new family, “*Gracilibacteraceae*”, is also proposed for a newly discovered genus, *Gracilibacter*.

Family *Clostridiaceae*

The family *Clostridiaceae* comprises 13 genera in the current outline (Figure 5). Phylogenetically, these genera are distributed among three paraphyletic clusters and a fourth clade represented by a single genus, *Caminiella*. In addition, seven genera were transferred to other families. Three genera (*Aceitivibrio*, *Faecalibacterium*, and *Sporobacter*) were transferred to the newly named family “*Ruminococcaceae*” (see below), unifying phylogenetically related former members of the *Clostridiaceae* and “*Lachnospiraceae*”. The genus *Coprobaecillus* was transferred to the *Erysipelotrichaceae*. The genus *Dorea* was transferred to the “*Lachnospiraceae*”. The genus *Tepidibacter* was transferred to the “*Peptostreptococcaceae*”. Lastly, the genus *Acidaminobacter* was transferred to Family XII *Incertae Sedis*.

The first clostridial cluster is composed of the genera *Clostridium*, *Anaerobacter*, *Caloramator*, *Oxobacter*, *Sarcina*, and *Thermobrachium*. Despite intense restructuring, the genus *Clostridium* is still partly paraphyletic, comprising a large collection of validly published species and species groups. Species whose common ancestry with the type species *Clostridium butyricum* is highly supported by the rRNA data remain in this genus. They are (in alphabetical not phylogenetic order): *Clostridium absonum*, *acetobutylicum*, *acetireducens*, *acidisoli*, *akagii*, *algidicarnis*, *argentinense*, *aurantibutyricum*, *baratii*, *bejerinckii*, *botulinum*, *bowmanii*, *butyricum*, *carnis*, *cellulovorans*, *chartatabidum*, *chauvoei*, *cochlearium*, *colicanis*, *collagenovorans*, *cylindrosporium*, *diolis*, *disporicum*, *estertheticum*, *fallax*, *felsineum*, *frigoris*, *frigidicarnis*, *gasigenes*, *grantii*, *haemolyticum*, *histolyticum*, *homopropionicum*, *intestinale*, *kluyveri*, *lacusfryxellense*, *limosum*, *lundense*, *novyi*, *paraputrificum*, *pascui*, *pasteurianum*, *peptidivorans*, *perfringens*, *proteolyticum*, *puniceum*, *putrificum*, *putrefaciens*, *quinii*, *roseum*, *saccharobutylicum*, *saccharoperbutylacetonicum*, *sardiniense*, *sartagoforme*, *scatologenes*, *septicum*, *sporogenes*, *subterminale*, *tertium*, *tetani*, *tetanomorphum*, *thermopalmarium*, *thermobutyricum*, *thiosulfatireducens*, *tyrobutyricum*, *uliginosum*, and *vincentii*. Species which according to phylogenetic relationships should be assigned to other taxonomic units are mentioned below. Some species previously classified with *Eubacterium* also belong into the radiation of *Clostridium sensu stricto*: *Eubacterium budayi*, *combesii*, *moniliforme*, *nitritogenes*, and *tarantellae*.

Other genera of this clade, *Anaerobacter*, *Oxobacter*, and *Sarcina*, are partly intermixed with *Clostridium* species, indicating that further reorganization of this cluster remains to be done.

The second *Clostridiaceae* cluster comprises the genera *Alkaliphilus*, *Anoxytrichum* (new; Garnova et al., 2003), *Natronincola*, *Tindallia* as well as the *Clostridium* species *alcalibutyricum*, *felsineum*, *formicoaceticum*, and *halophilum*. The genera *Thermohalobacter*–*Caloranaerobacter* (Wery et al., 2001) represent the third cluster. *Caminiella*, represents a fourth paraphyletic lineage

FIGURE 4. Consensus dendrogram reflecting the phylogenetic relationships of the class “*Clostridia*” within the *Firmicutes*. Analyses were performed as described for Figure 1.

previously classified within this family. Based upon the rRNA analyses, reclassification of these groups into other families may be warranted.

Family “*Eubacteriaceae*”

The six genera of the family “*Eubacteriaceae*” are monophyletic. They comprise the species of *Eubacterium stricto sensu* (*Eubacterium limosum*, *aggregans*, *barkeri*, *callanderi*) as well as the genera *Acetobacterium*, *Alkalibacter*, *Anaerofustis*, *Garciella*, and *Pseudoramibacter*. It is noteworthy that *Garciella* is the only thermophile among this group, and its assignment is the least strongly supported by the rRNA analyses reported here. Other analyses suggest a closer affiliation for this genus to the thermophiles *Thermohalobacter* and *Caloranaerobacter* (*Clostridiaceae* group 3,

D. Alazard, personal communication). Therefore, reclassification may be warranted in the future. The genera *Anaerovorax* and *Mogibacterium* have been transferred to Family XIII *Incertae Sedis*. Additional *Eubacterium* species (*Eubacterium infirmum*, *minutum*, *nodatum*, and *sulci*) are closely related to these other genera.

Family “*Gracilibacteriaceae*”

The family “*Gracilibacteriaceae*” is proposed to encompass the newly described genus *Gracilibacter* (Lee et al., 2006).

Family “*Heliobacteriaceae*”

The family “*Heliobacteriaceae*” is maintained as defined in the previous volumes. It comprises four genera: *Heliobacterium*, *Heliobacillus*, *Heliophilum*, and *Heliorestis*.

FIGURE 5. Consensus dendrogram reflecting the phylogenetic relationships of the order *Clostridiales* (part one) within the class "*Clostridia*". Analyses were performed as described for Figure 1.

Family "*Lachnospiraceae*"

The family "*Lachnospiraceae*" currently comprises 19 genera. The family is monophyletic, although a number of subclusters can be recognized. The "*Lachnospiraceae*" genera are: *Acetitomaculum*, *Anaerostipes*, *Bryantella*, *Butyrivibrio*, *Catonella*, *Coprococcus*, *Dorea* (formerly in the *Clostridiaceae*), *Hespellia*, *Johnsonella*, *Lachnobacterium*, *Lachnospira*, *Moryella* (new; Carrier et al., 2007), *Oribacterium* (Carrier et al., 2004), *Parasporobacterium*, *Pseudobutyrvibrio*, *Roseoburia*, *Shuttleworthia*, *Sporobacterium*, and *Syntrophococcus* (formerly *incertae sedis* within the "*Lactobacillales*").

A number of *Clostridium* species are found within the radiation of "*Lachnospiraceae*": *Clostridium aerotolerans*, *algidixylanolyticum*, *aminophilum*, *aminovalericum*, *amygdalinum*, *bolteae*, *celerecre-scens*, *coccoides*, *colinum*, *finetarium*, *glycyrrhizinilyticum*, *hathe-wayi*, *herbivorans*, *hylemonae*, *indolis*, *lactatifermentans*, *lentocellum*, *methoxybenzovorans*, *neopropionicum*, *nexile*, *oroticum*, *piliforme*, *polysaccharolyticum*, *populeti*, *propionicum*, *proteoclasticum*, *scindens*, *sphenoides*, *saccharolyticum*, *symbiosum*, *xylanolyticum*, and *xylanovorans*. Furthermore, *Eubacterium celluloso-luens*, *eligens*, *hallii*, *ramulus*, *rectale*, *ruminantium*, *uniforme*, *ventriosum*, and *xylano-*

philum; *Ruminococcus gnavus*, *hansenii*, *hydrogenotrophicus*, *obeum*, *productus*, *schinkii*, and *torques*, as well as *Desulfotomaculum guttoideum* phylogenetically belong to this group.

Family *Peptococcaceae*

The current members of the family *Peptococcaceae* occupy two paraphyletic groups within the radiation of the *Clostridiales* (Figure 6).

The first cluster includes the genera *Peptococcus*, *Dehalobacter*, *Desulfibacter*, *Desulfitobacterium*, *Desulfonispora*, *Desulfosporosinus*, and *Syntrophobotulus*, which form a tight monophyletic group. The second group is not closely related and includes *Cryptanaerobacter*, *Desulfotomaculum*, and *Pelotomaculum* species. Given its significant relationship to these genera, *Sporotomaculum* was transferred from the family “*Thermoanaerobacteraceae*”.

FIGURE 6. Consensus dendrogram reflecting the phylogenetic relationships of the order *Clostridiales* (part two) within the class “*Clostridia*”. Analyses were performed as described for Figure 1. Family *Incertae Sedis IV* is from the “*Thermoanaerobacterales*”.

Lastly, *Thermincola* is currently classified within this group even though rRNA analyses suggest only a weak relationship to the *Peptococcaceae sensu stricto*.

Family “*Peptostreptococcaceae*”

The family “*Peptostreptococcaceae*” comprised 12 genera distributed over a number of paraphyletic groups in the original road map (Garrity et al., 2005). Most of these genera are now transferred to Family XI *Incertae Sedis* (Figure 5). The current family is greatly circumscribed and monophyletic. It includes the genera *Peptostreptococcus*, *Filifactor*, *Sporacetigenium*, and *Tepidibacter* together with a number of validly published *Clostridium* and *Eubacterium* species: *Clostridium bartlettii* (new; Song et al., 2004), *bifermentans*, *difficile*, *ghoni*, *glycolicum*, *hirononis*, *irregularis*, *litorale*, *lituseburense*, *mangenotii*, *paradoxum*, *sordellii*, *sticklandii*, and *Eubacterium tenue*, and *yurii*.

Family “*Ruminococcaceae*”

A new family is proposed for a monophyletic lineage comprising 11 genera (Figure 6). Concerning their assignment in the outline of the previous volumes, this group represents a mixture of former “*Acidaminococcaceae*”, *Clostridiaceae*, and “*Lachnospiraceae*” as well as newly described genera: *Acetanaerobacterium* (new; Chen and Dong, 2004), *Acetivibrio* (formerly in the *Clostridiaceae*), *Anaerofilum* (formerly in the “*Lachnospiraceae*”), *Anaerotruncus*, *Ethanoligenens* (new; Xing et al., 2006), *Faecalibacterium* (formerly in the *Clostridiaceae*), *Fastidiosipila*, *Oscillospira*, *Papillibacter* (formerly in the “*Acidaminococcaceae*”), the type species of the genus *Ruminococcus* (*R. flavefaciens* and the three species *Ruminococcus albus*, *bromii*, and *callidus*; the other *Ruminococcus* species remain within the family “*Lachnospiraceae*”),

Sporobacter (formerly in the *Clostridiaceae*), and *Subdoligranulum* (new; Holmstrom et al., 2004). A number of validly published *Clostridium* species belong to this lineage according to their phylogenetic relationships: *Clostridium aldricii*, *alkalicellulosi* (new; Zhilina et al., 2005), *cellobioparum*, *cellulolyticum*, *hungatei*, *josui*, *leptum*, *methylpentosum*, *orbiscindens*, *papyrosolvens*, *stercorarium*, *straminisolvens* (new; Kato et al., 2004), *termitidis*, *thermocellum*, *thermosuccinogenes*, and *viride*. *Eubacterium siraeum* also belongs to this lineage.

Family *Syntrophomonadaceae*

The genera previously assigned to the family *Syntrophomonadaceae* are widely dispersed and not closely related (Garrity et al., 2005). On the basis of the current rRNA-based phylogenetic analyses, many of these genera may not even be members of the phylum *Firmicutes*. Despite these tendencies, these taxa are maintained in the current volume owing to their taxonomic history and the lack of additional data demanding an official description of new phyla. The four very deep groups include the following: the *Syntrophomonadaceae sensu stricto* comprise the genera *Syntrophomonas*, *Pelospora*, *Syntrophospora*, *Syntrophothermus*, and *Thermosyntropha* (Figure 7). These five genera are retained within the family *Syntrophomonadaceae* in the current road map. Another lineage is represented by *Aminobacterium*, *Aminomonas*, *Anaerobaculum*, *Dethiosulfovibrio*, *Thermanaerovibrio*, and *Thermovirga* (new; Dahle et al., 2006). This group has been assigned to Family XV *Incertae Sedis* (Figure 6). The genera *Thermaerobacter* and *Sulfobacillus* (formerly assigned to the family “*Alicyclobacillaceae*” in the class *Bacilli*) share a common ancestor and represent a third deep lineage, now assigned to Family XVII *Incertae Sedis*. *Caldicellulosiruptor* represents the final deep lineage. Because of similarities to genera already classified

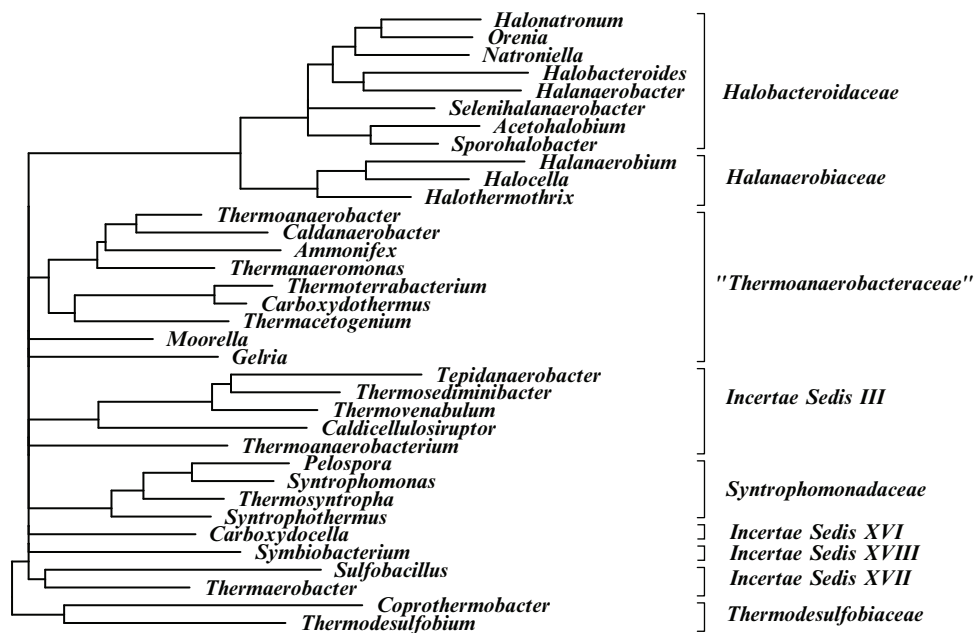

FIGURE 7. Consensus dendrogram reflecting the phylogenetic relationships of the orders *Halanaerobiales* and “*Thermoanaerobacterales*” as well as some deep branches of the *Clostridiales* within the class “*Clostridia*”. Analyses were performed as described for Figure 1.

within the “*Thermoanaerobacterales*”, it is reclassified to Family III *Incertae Sedis* within that order (Figure 7). Lastly, two genera (*Anaerobranca* and *Carboxydocella*) appear to represent lineages of the *Firmicutes*, although they are not closely related to each other. They are reclassified into Family XIV *Incertae Sedis* and Family XVI *Incertae Sedis*, respectively (Figures 5 and 7).

Family *Veillonellaceae*

The genera previously classified within the family “*Acidaminococaceae*” were reclassified into the family *Veillonellaceae* due to the priority of this name. After the transfer of the genus *Papillibacter* to the new family “*Ruminococcaceae*”, this family became monophyletic (Figure 6). The 26 genera currently harbored by the family *Veillonellaceae* are: *Acetonema*, *Acidaminococcus*, *Allisonella*, *Anaeroarcus*, *Anaeroglobus*, *Anaeromusa*, *Anaerosinus*, *Anaerovibrio*, *Centipeda*, *Dendrosporobacter*, *Dialister*, *Megasphaera*, *Mitsuokella*, *Pectinatus*, *Phascolarctobacterium*, *Propionispira*, *Propionispora*, *Quinella*, *Schwartzia*, *Selenomonas*, *Sporomusa*, *Succiniclasticum*, *Succinispira*, *Thermosinus*, *Veillonella*, and *Zymophilus*.

Families *Incertae Sedis*

Nine families *incertae sedis* were created to recognize some of the ambiguities remaining in the current classification.

Family XI *Incertae Sedis* contains a tight monophyletic cluster comprised of the genera *Anaerococcus*, *Finegoldia*, *Gallicola*, *Helcococcus*, *Parvimonas*, and *Peptoniphilus* which were transferred from the family “*Peptostreptococcaceae*”. *Soehngenia*, *Sporanaerobacter*, *Tepidimicrobium* (new; Slobodkin et al., 2006) and *Tissierella* represent four additional genera associated with this group. The genus *Tissierella* is closely related to *Clostridium hastiforme* and *ultunense*. *Sedimentibacter*, which was also previously classified within the “*Peptostreptococcaceae*”, appears to represent a separate but neighboring lineage in the phylogenetic tree. Thus, it remains classified with other genera transferred from this family in the current outline.

Family XII *Incertae Sedis* includes *Guggenheimella* (new; Wyss et al., 2005), a newly described genus that, while clearly a member of the *Clostridiales*, cannot be assigned to any of the defined families. It possesses moderate relationships to *Acidaminobacter* (previously classified with the *Clostridiaceae*) and *Fusibacter* (previously classified with the “*Peptostreptococcaceae*”).

Family XIII *Incertae Sedis* contains the genera *Anaerovorax* and *Mogibacterium*, which were transferred from the “*Eubacteriaceae*”. This group possesses a weak relationship with Family XII *Incertae Sedis*.

Family XIV *Incertae Sedis* is comprised of *Anaerobranca*, which was previously classified within the *Syntrophomonadaceae*; however, it is not closely related to any other previously described family.

Family XV *Incertae Sedis* is comprised of *Aminobacterium*, *Aminomonas*, *Anaerobaculum*, *Dethiosulfovibrio*, and *Thermanaerovibrio*. These genera form a monophyletic clade that was previously classified within the *Syntrophomonadaceae*; however, they possess only low relatedness to the type genus of that family and, thus, warrant reclassification.

Family XVI *Incertae Sedis* is comprised of *Carboxydocella*, which was previously classified within the *Syntrophomonadaceae*. Because it is not closely related to any other previously described family, it has been classified within its own group.

Family XVII *Incertae Sedis* is comprised of the genera *Sulfobacillus* and *Thermaerobacter*. Formerly classified with the “*Alicyclobacillaceae*” and *Syntrophomonadaceae*, respectively, these genera represent either a very deep group of the phylum *Firmicutes* or, perhaps, a novel phylum.

Family XVIII *Incertae Sedis* is comprised of *Symbiobacterium*. This genus also appears to represent either a very deep group of the Phylum *Firmicutes* or another novel phylum.

Family XIX *Incertae Sedis* includes *Acetoanaerobium*, whose rRNA has not been sequenced but whose phenotypic properties suggest an affiliation to this order.

Order *Halanaerobiales*

The taxonomic organization of this order remains as outlined in the previous volumes (Garrity et al., 2005). It contains two families, *Halanaerobiaceae* and *Halobacteroidaceae* (Figure 7).

Family *Halanaerobiaceae*

The monophyletic family *Halanaerobiaceae* currently is comprised of three genera, *Halanaerobium*, *Halocella*, and *Halothermothrix*.

Family *Halobacteroidaceae*

Eight genera are unified in a tight monophyletic cluster of the family *Halobacteroidaceae*. *Halobacteroides*, *Acetohalobium*, *Halanaerobacter*, *Halonatronum*, *Natroniella*, *Orenia*, *Selenihalanaerobacter*, and *Sporohalobacter* represent this family.

Order “*Thermoanaerobacterales*”

The order “*Thermoanaerobacterales*” is used in preference to “*Thermoanaerobacterales*” (Garrity et al., 2005) in recognition of the priority of *Thermoanaerobacter* over *Thermoanaerobacterium* as the type genus. As in the case of the *Syntrophomonadaceae*, the diversity within this order is very large, and some members may represent novel phyla (Mori et al., 2003); Figure 7). Therefore, reclassification within this group is expected in the near future, and the current classification is of limited biological significance.

Family “*Thermoanaerobacteraceae*”

Eight genera are currently classified within this family, but they are not closely related to each other. The type genus *Thermoanaerobacter* forms part of a monophyletic cluster comprised of *Ammonifex*, *Carboxydibrachium* (now reclassified within *Caldanaerobacter*), *Caldanaerobacter*, *Carboxydotherrmus* (previously classified within the *Peptococcaceae*), *Thermacetogenium*, and *Thermanaeromonas*. Two additional genera, *Gelbia* and *Moorella*, are neighbors of this cluster.

Family *Thermodesulfobiaceae*

A second family is comprised of the genera *Coprothermobacter* and *Thermodesulfobium*. Although not particularly closely related to each other, they are both much more distantly related to other members of the phylum *Firmicutes*.

Families *Incertae Sedis*

Family III *Incertae Sedis* contains a monophyletic cluster that is weakly related to both the “*Thermoanaerobacteraceae*” and *Syntrophomonadaceae* (Figure 7). It is comprised of the genera *Caldicellulosiruptor* (from the *Syntrophomonadaceae*), *Thermosediminibacter*,

and *Thermovenabulum*. While *Thermoanaerobacterium* is not a member of this cluster, it appears as a neighboring group in phylogenetic trees. Therefore, it is included in this family until additional analyses warrant a more informed reclassification.

Family IV *Incertae Sedis* includes the genus *Mahella*. While it possesses some relatedness to members of the “*Thermoanaerobacteraceae*” and Family III *Incertae Sedis* (above), its distinctive position in the rRNA gene tree, near the “*Ruminococcaceae*” within the *Clostridiales*, and phenotypic properties suggest that it represents a novel family (Figure 6).

Class “*Erysipelotricha*”

With the elevation of the *Mollicutes* to the phylum *Tenericutes*, the creation of a separate class within the *Firmicutes* was warranted for the family *Erysipelotrichaceae*. This new classification recognizes the low similarity of the rRNA of this group with other members of the phylum as well as the similarity in cell wall and other phenotypic features. This class comprises a single order, “*Erysipelotrichales*”, and the family *Erysipelotrichaceae*.

Family *Erysipelotrichaceae*

In comparison to the outlines of the previous volumes, the family *Erysipelotrichaceae* was extended by the inclusion of four additional genera. Besides one newly described genus (*Allobaculum*), three genera were transferred from other families. The family is now organized in eight genera: *Erysipelothrix*, *Allobaculum* (new; Greetham et al., 2004), *Bulleidia*, *Catenibacterium* (formerly in the “*Lachnospiraceae*”), *Coprobacillus* (formerly in the *Clostridia*), *Holdemania*, *Solobacterium*, and *Turicibacter* (formerly *incertae sedis* among *Bacillales*). Furthermore, a number of type species validly published as members of genera not assigned to the *Erysipelotrichaceae* should also be classified within this family. These include *Clostridium cateniformis*, *cocleatum*, *innocuum*, *ramosum*, and *spiroforme*; *Eubacterium bifforme*, *cylindroides*, *dolichum*, and *tortuosum*; *Lactobacillus cateniformis* and *vitulinus*; and *Streptococcus pleomorphus*.

Taxonomic outline of the phylum *Firmicutes*

WOLFGANG LUDWIG, KARL-HEINZ SCHLEIFER AND WILLIAM B. WHITMAN

All taxa recognized within this volume of the rank of genus and above are listed below. The nomenclatural type is listed first within each taxon followed by the remaining taxa in alphabetical order.

Phylum XIII. *Firmicutes*

Class I. “*Bacilli*”

Order I. *Bacillales*^{AL (T)}

Family I. *Bacillaceae*^{AL}

- Genus I. *Bacillus*^{AL (T)}
- Genus II. *Alkalibacillus*^{VP}
- Genus III. *Amphibacillus*^{VP}
- Genus IV. *Anoxybacillus*^{VP}
- Genus V. *Cerasibacillus*^{VP}
- Genus VI. *Filobacillus*^{VP}
- Genus VII. *Geobacillus*^{VP}
- Genus VIII. *Gracilibacillus*^{VP}
- Genus IX. *Halobacillus*^{VP}
- Genus X. *Halolactibacillus*^{VP}
- Genus XI. *Lentibacillus*^{VP}
- Genus XII. *Marinococcus*^{VP}
- Genus XIII. *Oceanobacillus*^{VP}
- Genus XIV. *Paraliobacillus*^{VP}
- Genus XV. *Pontibacillus*^{VP}
- Genus XVI. *Saccharococcus*^{VP}
- Genus XVII. *Tenuibacillus*^{VP}
- Genus XVIII. *Thalassobacillus*^{VP}
- Genus XIX. *Virgibacillus*^{VP}

Family II. “*Alicyclobacillaceae*”

- Genus I. *Alicyclobacillus*^{VP (T)}

Family III. “*Listeriaceae*”

- Genus I. *Listeria*^{AL (T)}
- Genus II. *Brochothrix*^{AL}

Family IV. “*Paenibacillaceae*”

- Genus I. *Paenibacillus*^{VP (T)}
- Genus II. *Ammoniphilus*^{VP}
- Genus III. *Aneurinibacillus*^{VP}
- Genus IV. *Brevibacillus*^{VP}
- Genus V. *Cohnella*^{VP}
- Genus VI. *Oxalophagus*^{VP}
- Genus VII. *Thermobacillus*^{VP}

Family V. *Pasteuriaceae*^{AL}

- Genus I. *Pasteuria*^{AL (T)}

Family VI. *Planococcaceae*^{AL}

- Genus I. *Planococcus*^{AL (T)}
- Genus II. *Caryophanon*^{VP}
- Genus III. *Filibacter*^{VP}
- Genus IV. *Jeotgalibacillus*^{VP}
- Genus V. *Kurthia*^{AL}
- Genus VI. *Marinibacillus*^{VP}

- Genus VII. *Planomicrobium*^{VP}

- Genus VIII. *Sporosarcina*^{AL}

- Genus IX. *Ureibacillus*^{VP}

Family VII. “*Sporolactobacillaceae*”

- Genus I. *Sporolactobacillus*^{AL (T)}

Family VIII. “*Staphylococcaceae*”

- Genus I. *Staphylococcus*^{AL (T)}
- Genus II. *Jeotgalicoccus*^{VP}
- Genus III. *Macrococcus*^{VP}
- Genus IV. *Salinicoccus*^{VP}

Family IX. “*Thermoactinomycetaceae*”

- Genus I. *Thermoactinomyces*^{AL (T)}
- Genus II. *Laceyella*^{VP}
- Genus III. *Mechercharimyces*^{VP}
- Genus IV. *Planifilum*^{VP}
- Genus V. *Seimonella*^{VP}
- Genus VI. *Shimazuella*^{VP}
- Genus VII. *Thermo flavimicrobium*^{VP}

Family X. *Incertae Sedis*

- Genus I. *Thermicanus*^{VP}

Family XI. *Incertae Sedis*

- Genus I. *Gemella*^{AL}

Family XII. *Incertae Sedis*

- Genus I. *Exiguobacterium*^{VP}

Order II. “*Lactobacillales*”

Family I. *Lactobacillaceae*^{AL}

- Genus I. *Lactobacillus*^{AL (T)}
- Genus II. *Paralactobacillus*^{VP}
- Genus III. *Pediococcus*^{AL}

Family II. “*Aerococcaceae*”

- Genus I. *Aerococcus*^{AL (T)}
- Genus II. *Abiotrophia*^{VP}
- Genus III. *Dolosicoccus*^{VP}
- Genus IV. *Eremococcus*^{VP}
- Genus V. *Facklamia*^{VP}
- Genus VI. *Globicatella*^{VP}
- Genus VII. *Ignavigranum*^{VP (T)}

Family III. “*Carnobacteriaceae*”

- Genus I. *Carnobacterium*^{VP (T)}
- Genus II. *Alkalibacterium*^{VP}
- Genus III. *Allofustis*^{VP}
- Genus IV. *Alloiococcus*^{VP}
- Genus V. *Atopobacter*^{VP}
- Genus VI. *Atopococcus*^{VP}
- Genus VII. *Atopostipes*^{VP}

- Genus VIII. *Desemzia*^{VP}
 Genus IX. *Dolosigranulum*^{VP}
 Genus X. *Granulicatella*^{VP}
 Genus XI. *Isobaculum*^{VP}
 Genus XII. *Marinilactibacillus*^{VP}
 Genus XIII. *Trichococcus*^{VP}
- Family IV. “*Enterococcaceae*”
 Genus I. *Enterococcus*^{VP (T)}
 Genus II. *Melissococcus*^{VP}
 Genus III. *Tetragenococcus*^{VP}

Phylum XIII. *Firmicutes* Gibbons and Murray 1978, 5 (*Firmacutes* [sic] Gibbons and Murray 1978, 5)

KARL-HEINZ SCHLEIFER

Fir.mi.cu'tes. L. adj. *firmus* strong, stout; L. fem. n. *cutis* skin; N.L. fem. pl. n. *Firmicutes* division with strong (and thick) skin, to indicate Gram-positive type of cell wall.

Gibbons and Murray (1978) described the division *Firmicutes* encompassing all of Gram-positive *Bacteria* ("bacteria with a Gram-positive type of cell wall"). Thus, both Gram-positive bacteria with a low DNA mol% G + C as well as Gram-positive with a high DNA mol% G + C were included in the division whereas the *Mollicutes* were placed in a separate division. In (2001), Garrity and Holt described the new phylum *Firmicutes* encompassing both Gram-positive bacteria with a low DNA mol% G + C (classes "*Clostridia*" and "*Bacilli*") and the class *Mollicutes*. However, the *Mollicutes* are phenotypically so different (no cell walls, no peptidoglycan, no muramic acid, flexible and highly pleomorphic cells) from the typical *Firmicutes* that we propose to remove them from the phylum *Firmicutes*. Moreover, comparative sequence analysis of various genes encoding conserved proteins (*atpB*, *hsp60*, *rpoB*, *rpoC*, *aspRS*, *trpRS*, *valRS*) studied so far have shown that *Mollicutes* are also phylogenetically quite distinct from typical *Firmicutes* (Ludwig and Schleifer, 2005). This was supported in a more recent study by Case et al. (2007). They found that the *Firmicutes* compared in their study formed a monophyletic group in the RpoB protein tree well-separated from the *Mollicutes*. The *Mollicutes* should be excluded from the phylum *Firmicutes* and classified in the phylum *Tenericutes* (Murray, 1984). There are only a few members of the *Firmicutes* (*Erysipelotrichaceae*) which, based on their 16S rRNA and 23S rRNA gene sequences, reveal a closer phylogenetic relatedness to *Mollicutes*. Unfortunately, there are currently no sequence data on conserved protein-coding genes available for members of *Erysipelotrichaceae*. There are also some organisms which are still listed in this volume within the phylum *Firmicutes* but they root in the 16S rRNA tree outside the *Firmicutes* and may represent separate phyla. These are members of the *Thermoanaerobacteraceae* and *Syntrophomonadaceae*.

The phylum *Firmicutes* consists of at least 26 families and 223 genera. All members possess a rigid cell wall. The members studied so far all contain muramic acid in their cell walls. Some contain a cell wall teichoic acid. Most members are Gram-positive, but there are also some that stain Gram-negative (e.g., *Veillonellaceae*, *Syntrophomonadaceae*). The phylum is phenotypically diverse. Cells may be spherical, or straight, curved, and helical rods or filaments, with or without flagella and with or without heat-resistant endospores. They are aerobes, facultative or strict anaerobes. Some members of the *Firmicutes* are thermophiles and/or halophiles. Most of them are chemo-organotrophs, a few are anoxygenic photoheterotrophs. Most grow at neutral pH, while some are acidophiles or alkaliphiles. The mol% G + C content of DNA is generally <50.

Type order: Bacillales Prévot 1953, 692.

Class I. *Bacilli* class. nov.

WOLFGANG LUDWIG, KARL-HEINZ SCHLEIFER AND WILLIAM B. WHITMAN

Ba.cil'li. N.L. masc. n. *Bacillus* type genus of the type order of the class; N.L. masc. pl. n. *Bacilli* the *Bacillus* class.

The class *Bacilli* is circumscribed for this volume on the basis of the phylogenetic analyses of the 16S rRNA sequences and includes the order *Bacillales* and its close relatives. This class

includes the orders *Bacillales* and *Lactobacillales* (ord. nov., this volume). Members of this class generally stain Gram-positive and form a Gram-positive type of cell wall. They may or may

not form endospores. Many also grow aerobically or microaerophilically. Some are facultative anaerobes.

Type order: **Bacillales** Prévot 1953, 60^{AL}.

Order I. **Bacillales** Prévot 1953, 60^{AL}

PAUL DE VOS

Ba.cil.la'les. N.L. masc. n. *Bacillus* type genus of the order; suff. *-ales* ending denoting an order; N.L. fem. pl. n. *Bacillales* the *Bacillus* order.

The delineation of the order of the *Bacillales* is based on 16S sequence analysis and consists of the families of *Bacillaceae* (which contains the type genus), *Alicyclobacillaceae* (fam. nov., this volume), *Listeriaceae* (fam. nov., this volume), *Paenibacillaceae* (fam. nov., this volume), *Pasteuriaceae*, *Planococcaceae*, *Sporolactobacillaceae* (fam. nov., this volume), *Staphylococcaceae* (fam. nov., this volume), *Thermoactinomycetaceae* (Matsuo et al., 2006), and three family *incertae sedis*. Most of the family names were not validly published, but their allocation is in agreement with the phylogenetic outline given in this volume. One of the few general characteristics of the order is the formation of **endospores** that are formed in representatives of many genera of this order, although exceptions exist. Furthermore, the cell wall stains generally **Gram-positive for young cells**. The staining is supported by the chemical composition of the cell wall. **If known**, most genera allocated to the above families have **menaquinone**

7 (MK-7) although various exceptions are found, in particular amongst the *Thermoactinomycetaceae* where menaquinones ranging from MK-6 to MK-11 have been reported.

Type genus: **Bacillus** Cohn 1872, 174^{AL}.

Family I. **Bacillaceae**

NIALL A. LOGAN AND PAUL DE VOS

Ba.cil.la'ce.ae. N.L. masc. n. *Bacillus* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Bacillaceae* the *Bacillus* family.

The family *Bacillaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA gene sequences; the family contains *Bacillus* and 18 other genera. The majority of taxa are aerobic or facultatively anaerobic chemo-organotrophic rods that possess Gram-positive type cell-wall structures and that form endospores. However, there are exceptions to all of these characteristics; the family includes strict anaerobes, autotrophs, cocci, and organisms that do not form endospores. Although the commonest Gram reaction is Gram-positive, many species of the family are Gram-variable or frankly Gram-negative. Table 1 summarizes the diversity of some routine phenotypic characters among the genera of this family.

Genus I. *Bacillus* Cohn 1872, 174^{AL}

NIALL A. LOGAN AND PAUL DE VOS

Ba.cil'lus. N.L. masc. n. *Bacillus* a rodlet.

Cells rod-shaped, straight or slightly curved, occurring singly and in pairs, some in chains, and occasionally as long filaments. Endospores are formed, no more than one to a cell; these spores are very resistant to many adverse conditions. Gram-positive, or Gram-positive only in early stages of growth, or Gram-negative. A meso-DAP direct murein cross-linkage type is commonest, but L-Lys-D-Glu, Orn-D-Glu and L-Orn-D-Asp have occasionally been reported. Motile by means of peritrichous or degenerately peritrichous flagella, or nonmotile. Aerobes or facultative anaerobes, but a few species are described as strictly anaerobic. The terminal electron acceptor is oxygen, replaceable by alternatives in some species. Most species will grow on routine media such as nutrient agar and blood agar. Colony morphology and size very variable between and within species. A wide diversity of physiological abilities is exhibited, ranging from psychrophilic to thermophilic, and acidophilic to alkaliphilic; some strains are salt tolerant and some are halophilic. Catalase is produced by most species. Oxidase-positive or -negative. Chemo-organotrophic; two species are facultative chemolithotrophs: prototrophs to auxotrophs requiring several growth factors. Mostly isolated from soil, or from environments that may have been contaminated directly or indirectly by soil, but also found in water, food and clinical specimens. The resistance of the spores to heat, radiation, disinfectants, and desiccation results in species being troublesome contaminants in operating rooms, on surgical dressings, in pharmaceutical products and in foods. Most species have little or no pathogenic potential and are rarely associated with disease in humans or other animals; an exception is *Bacillus anthracis*, the agent of anthrax; several other species may cause food poisoning and opportunistic infections, and strains of *Bacillus thuringiensis* are pathogenic to invertebrates.

DNA G + C content (mol%): 32–66 (T_m).

Type species: *Bacillus subtilis* Cohn 1872, 174^{AL}.

Further descriptive information

Phylogeny. A phylogenetic tree, based on 16S rDNA sequences, is shown in Figure 8. The tree includes 142 named *Bacillus* species as listed in this chapter (but excludes *Bacillus laevolacticus* and *Bacillus tequilensis*). *Bacillus tusciae* and *Bacillus schlegelii* lie at the edge of the tree, and their respective closest neighbors, on the basis of 16S rDNA gene sequence comparisons, are an unknown *Alicyclobacillus* species and *Aneurinibacillus*.

It is well known that 16S rDNA sequences do not always allow species to be discriminated, and that DNA–DNA hybridizations may be needed for this. However, sequences of other genes (the so-called core genes) may be more appropriate for discriminating these relatively recent branchings of the evolutionary tree that correspond to bacterial species. The ad hoc committee for the re-evaluation of the species definition in bacteriology (Stackebrandt et al., 2002) advised that genetic differences of the so-called core genes should be explored in order to come to a finer “bacterial species concept” in the future. The groupings (phylogenetic trees) that are obtained from comparisons either of sequences of

individual core genes, or of concatenated gene sequences of several core genes, need to be validated against the phylogenetic species concept (Wayne et al., 1987). Recent data (Wang et al., 2007a) clearly show that in the *Bacillus subtilis* group, within which species delineation is very difficult, core genes such as *gyrB* allow differentiation on a genetic basis. A debate began recently concerning the impact of these new findings of genome analysis on bacterial taxonomy (Buckley and Roberts, 2007). Analysis of whole-genome sequences showed that about 80% of an individual genome may be shared by all pathogenic isolates of *Streptococcus agalactiae* (Tettelin et al., 2005), indicating that in closely related strains belonging to the same species, at least, a vast amount of the genetic information is shared. The interested reader is referred to the literature (e.g., Kunin et al., 2005, 2007; Dagan and Martin, 2006).

Cell morphology. *Bacillus* cells may occur singly and in pairs, in chains (which may be of great length), and as filaments. Trichome-forming “*Arthromitus*” strains from sow bug or wood louse (*Porcellio scaber*) guts, with endospore-forming filaments over 100 μm long and up to 180 cells per filament in animals cultivated in darkness, have been identified as *Bacillus cereus* (Jorgensen et al., 1997) and similar filamentous organisms have been isolated from moths, roaches and termites (Margulis et al., 1998; see *Habitats*, below). The rod-shaped cells of *Bacillus* species are usually round-ended, but the cells of members of the *Bacillus cereus* group have often been described as squared. Cell diameters range from 0.4 to 1.8 μm and lengths from 0.9 to 10.0 μm , but the cells of a particular strain are usually quite regular in size, and individual species normally have dimensions within fairly narrow limits. For example, cells of *Bacillus pumilus* are typically 0.6–0.7 by 2.0–3.0 μm , while those of *Bacillus megaterium* are usually 1.2–1.5 by 2.0–5.0 μm . Pleomorphism, showing as cells and filaments with swollen regions, and entirely swollen cells, may be observed in cultures grown in suboptimal conditions; this is seen, for example, in cultures of *Bacillus fumarioli* grown on relatively rich media (Logan et al., 2000), and such stressed cultures sporulate poorly. *Bacillus* cytoplasm may stain uniformly or be vacuolate; vacuolation (the presence of inclusions is visible by phase-contrast microscopy as areas less refractive than spores, and in Gram-stained preparations by unstained globules) is enhanced in some species (*Bacillus cereus* and *Bacillus megaterium*, for example) by cultivation on an agar medium containing a fermentable carbohydrate such as glucose, so that copious storage material is produced.

Sporangial morphologies are characteristic of species, and so often valuable in identification (see *Life cycle*, below), but an individual strain may show some variation and produce, for example, both oval and spherical spores. The commonest spore shape is ellipsoidal or oval, but shapes range from frankly cylindrical through ellipsoidal to spherical, and irregular forms such as kidney- or banana-shaped spores may be seen in some species. The position of the spore is also characteristic; the most

FIGURE 8. Unrooted neighbor-joining phylogenetic tree of *Bacillus* species based on 16S rRNA gene sequences. Alignment of sequences was performed using CLUSTALX, BIOEDIT and TREECON. Bootstrap values above 70% are shown (based on 1000 replications) at the branch points. Sequence accession numbers for each strain are given in parentheses.

frequently observed is a subterminal placement, and position can range from central through paracentral and subterminal to terminal. An individual strain may exhibit a range of spore positions. In small sporangia it is sometimes difficult to categorize spore positions with confidence. In just over half of the validly published *Bacillus* species the spores swell the sporangia slightly or appreciably, while in the remainder sporangial swelling has not been observed, but both swollen and unswollen sporangia may be observed within a single strain. The sporangia of *Bacillus thuringiensis* are characterized by their parasporal inclusions of crystalline protein known as δ -endotoxins, which are often toxic to insects and other invertebrates. Insecticidal strains of *Bacillus sphaericus* also produce crystalline parasporal inclusions; these are less prominent than those of *Bacillus thuringiensis*, but are generally visible with the aid of a good phase-contrast microscope (Priest, 2002).

L-form *Bacillus* cells have been reported from both humans, other animals and plants. Several authors have found L-forms in the blood of normal and arthritic persons in association with erythrocytes (Bisset and Bartlett, 1978; Pease, 1970, 1974), in

other body fluids such as synovial fluids of arthritic patients (Pease, 1969), in association with neoplasms (Livingston and Alexander-Jackson, 1970), and in chickens and turkeys with infectious synovitis (Livingston and Alexander-Jackson, 1970; Roberts, 1964). As demonstrated by Bisset and Bartlett (1978), these organisms often revert to small, acid-fast diphtheroids, and on prolonged (up to 25 months) primary culture or subculture, and especially when grown in the presence of agents known to stimulate reversion of L-forms, some of them increase in size, lose their acid-fastness, and become Gram-positive endospore-forming rods. These organisms produce licheniform colonies on agar media, like the "*Bacillus endoparasiticus*" of Benedek (1955) from arthritic patients. The fully reverted isolates of Bisset and Bartlett (1978) were phenotypically similar to *Bacillus licheniformis* in other respects, and they named them "*Bacillus licheniformis* var. *endoparasiticus*."

Symbiotic associations between L-form bacteria and plants have been observed (Paton and Innes, 1991), and this has encouraged the induction and characterization of a stable L-form of *Bacillus subtilis* (Allan, 1991; Allan et al., 1993). Artifi-

cially induced symbiosis of this stable L-form of *Bacillus subtilis* in strawberry plants has been demonstrated by ELISA (Ferguson et al., 2000), and a symbiosis of the same strain in Chinese cabbage seedlings has been shown to inhibit the germination of *Botrytis cinerea* conidia (Walker et al., 2002).

Cell-wall composition. Information on murein structure is known for only about half of the valid species of *Bacillus* (Table 2), but Bacher et al. (2001) have shown that matrix-assisted laser desorption/ionization time-of-flight mass spectrometry with nano-electrospray ionization quadrupole ion-trap mass spectrometry allows the ready determination of peptidoglycan structure in *Bacillus subtilis* vegetative cells and *Bacillus megaterium* spores. The vegetative cells of the majority of *Bacillus* species that have been studied have the most common type of cross-linkage in which a peptide bond is formed between the diamino acid in position 3 of one subunit and the D-Ala in position 4 of the neighboring peptide subunit, so that no interpeptide bridge is involved. The diamino acid in most *Bacillus* species is *meso*-diaminopimelic acid (*meso*-DAP), and this cross-linkage is now usually known as DAP-direct (A1 γ in the classification of Schleifer and Kandler 1972). Where the structure is known, this cross-linkage is also typical of the examined representatives of several genera whose species were previously accommodated in *Bacillus*: *Alkalibacillus*, *Brevibacillus*, *Geobacillus*, *Gracilibacillus*, *Paenibacillus*, *Salibacillus*, and *Virgibacillus* (Table 2).

A different type of cross-linkage is found in the spherical-spored members of the genus (informally known as the *Bacillus sphaericus* group) and in other genera containing spherical-spored organisms. *Bacillus sphaericus* and its close relatives typically have the cross-linkage type A4 α (L-Lys-D-Asp or L-Lys-D-Glu), with L-Lys in position 3 of the peptide subunit with bridging to the D-Ala in position 4 of the neighboring peptide subunit by D-Asp or D-Glu. *Bacillus sphaericus* and *Bacillus fusiformis* have accordingly been transferred to the

new genus *Lysinibacillus* (Ahmed et al., 2007c), but information on the peptidoglycan structure of other potential members of this genus is awaited). Three members of the *Bacillus sphaericus* group, however, *Bacillus insolitus*, *Bacillus psychrodurans* and *Bacillus psychrotolerans*, have L-Orn in position 3 of the peptide subunit with bridging by D-Glu to the D-Ala in position 4 of the neighboring peptide subunit (type A4 β , or L-Orn-D-Glu) (Abd El-Rahman et al., 2002; Stackebrandt et al., 1987), and this structure is also found in the halophile *Filobacillus milensis* (Schlesner et al., 2001), which, although it bears spherical spores, is not related to any of the other spherical-spored groups but lies closest to *Bacillus haloalkaliphilus* (now reclassified into *Alkalibacillus*). Some spherical-spored species formerly classified in *Bacillus* have been transferred to other genera: *Bacillus globisporus*, *Bacillus pasteurii* and *Bacillus psychrophilus* have been transferred to *Sporosarcina* (Yoon et al., 2001b) and they share with the type species of that genus, *Sporosarcina ureae*, A4 α cross-linking based on L-Lys in position 3 of the peptide subunit with interpeptide bridges of D-Asp, D-Glu, L-Ala-D-Asp, or Gly-D-Glu. *Bacillus thermosphaericus*, which has been transferred to the new genus *Ureibacillus*, also has a L-Lys-D-Asp structure (Fortina et al., 2001b). Two other, monospecific, genera of spherical-spored species have been proposed (Yoon et al., 2001c): *Bacillus marinus* has been transferred to *Marinibacillus*, and *Jeotgalibacillus alimentarius* accommodates a single isolate from a traditional food; both species have a direct L-Lys cross-linkage. *meso*-DAP has been found in the peptidoglycan of spores of *Bacillus sphaericus* and *Bacillus pasteurii* (Ranftl and Kandler, 1973).

Other than the absence of DAP from the walls of *Bacillus horikoshii* (Nielsen et al., 1994), no information is available about cross-linkage in members of the phylogenetically distinct group of alkaliphilic or alkalitolerant species which contains this species and *Bacillus agaradhaerens*, *Bacillus alcalophilus*, *Bacillus clarkii*, *Bacillus clausii*, *Bacillus gibsonii*, *Bacillus*

^aData in parentheses were not obtained from the type strain of the species.

^bConfiguration not determined.

^cThis neutrophilic species is closely related to the alkaliphilic species *Bacillus cohnii* and *Bacillus halmapalus*.

^dAhmed et al. (2007c) proposed the transfer of these species to the new genus *Lysinibacillus*.

^eThe strain analyzed by Schleifer and Kandler (1972) as *Bacillus circulans* (ATCC 9966) has been reallocated to *Paenibacillus amylolyticus*.

pseudocaliphilus, *Bacillus pseudofirmus*, and *Bacillus vedderi*. The two closely related species *Bacillus cohnii* (alkaliphilic) and *Bacillus halmapalus* (alkalitolerant) do not belong in this phylogenetic group, and lie nearer to *Bacillus cereus*: the cross-linkage of *Bacillus cohnii* is L-Orn-D-Asp (Spanka and Fritze, 1993), while *Bacillus halmapalus* has been shown to lack DAP (Nielsen et al., 1994).

Other cell-wall polymers have attracted less attention than murein, and the small amounts of reported data for a few strains do not allow the taxonomic values, if any, of these components to be recognized; the subject has been reviewed by Naumova and Shashkov (1997). Teichoic acids have been found in *Bacillus coagulans*, *Bacillus licheniformis* and *Bacillus subtilis*, and teichuronic acids have been found in *Bacillus licheniformis*, *Bacillus megaterium* and *Bacillus subtilis*. Aono and Ohtani (1990) and Aono et al. (1993) found the acidic polymers teichuronic acid and teichurono-peptide in the cell walls of alkaliphilic *Bacillus* strains and suggested that these components might be important in alkaliphily as mutants deficient in them grew poorly at high pH. Fox et al. (1998) described the use of gas chromatography-mass spectrometry and liquid chromatography-mass spectrometry in the investigation of teichoic acids and teichuronic acids in *Bacillus* species.

Naumova and Shashkov (1997) also reviewed studies on sugar-phosphate polymers (found in *Bacillus pumilus* and *Bacillus subtilis*) and anionic polysaccharides (found in *Bacillus cereus* and *Bacillus megaterium*), but again the information is too sparse to reveal any taxonomic implications.

Capsules. Gram-positive bacteria may produce two kinds of capsule, composed of polyglutamic acid or polysaccharide, but their production by *Bacillus* species has not appeared to be of much taxonomic value. Although most *Bacillus subtilis* strains do not produce significant capsular material in the laboratory, the genome sequence of strain 168 indicates that this organism possesses the genes encoding both types of capsule (Foster and Popham, 2002). The production of poly- γ -glutamic acid by "*Bacillus subtilis* var. *natto*" during the stationary phase of growth is economically important in the manufacture of the fermented soybean product natto (Ueda, 1989).

The poly- γ -D-glutamic acid capsule of *Bacillus anthracis* is encoded by the three plasmid pXO2 genes *capA*, *capB*, and *capC*, and it is an important virulence factor for this organism as non-capsulate strains are avirulent (see *Pathogenicity*, below). The sequences of the enzymes encoded by the three genes suggest that they are membrane-associated (Mock and Fouet, 2001). The capsule is produced *in vivo* and when grown in appropriate conditions in the laboratory (see *Procedures for testing special characters*, below). *Bacillus anthracis* is a member of the *Bacillus cereus* group of closely related species, but none of the species besides *Bacillus anthracis* appears to produce this capsule. Although homologs of *Bacillus anthracis* virulence plasmid pXO1 genes were found in half of a set of 19 other members of the *Bacillus cereus* group in hybridization experiments, few pXO2 genes were found that hybridized with genomic DNA from the 19 *Bacillus cereus* group strains (Read et al., 2003). The capsule of *Bacillus anthracis* was reviewed by Mock and Fouet (2001). Other *Bacillus* species, outside the *Bacillus cereus* group, are known to produce poly- γ -glutamic acid. Synthesis by *Bacillus licheniformis* is carried out by a membrane-associated complex

that catalyzes glutamic acid racemization, polymerization, and membrane translocation (Gardner and Troy, 1979); as with "*Bacillus subtilis* var. *natto*", production of the capsular material is induced during the stationary phase (Foster and Popham, 2002). While D-glutamic acid is the predominant stereoisomer incorporated into the polymer, the ratio of D- and L-glutamic acids may vary according to the rate at which D-glutamic acid is being formed in the *Bacillus subtilis* cell (Aschiuchi et al., 1999), but in *Bacillus licheniformis* two glutamyl polypeptides are formed, one of each isomer, and the ratio is influenced by the concentrations of certain metal ions in the growth medium (Thorne, 1993). *Bacillus megaterium* is also known to produce poly- γ -glutamic acid, and can form a capsule comprising both polysaccharide and polypeptide, with the former at the cell poles and equators and the latter located laterally (Guex-Holzer and Tomcsik, 1956). Applications of bacterial poly- γ -glutamic acid are reviewed by Shih and Van (2001).

Carbohydrate polymers are formed by several *Bacillus* species, dextrans and levans being produced extracellularly by *Bacillus licheniformis* and *Bacillus subtilis* from sucrose (Claus and Berkeley, 1986), but true polysaccharide capsules have not been reported for *Bacillus subtilis*. The *Bacillus subtilis* genome contains two operons and some additional genes that show great similarity to capsule synthesis loci in *Staphylococcus aureus* and *Streptococcus pneumoniae*, but it is not known if they are truly genes for capsule synthesis (Foster and Popham, 2002). The extracellular polysaccharides of *Bacillus licheniformis* and *Bacillus subtilis* are of economic importance in the spoilage of bread and alcoholic beverages by "ropiness." Analysis of the polysaccharide of a *Bacillus licheniformis* from ropy cider found that it was a heteropolymer containing over 80% mannose (Larpin et al., 2002). Aubert (1951) assumed that a heteropolysaccharide of D-glucose, D-galactose and D-ribose extractable from *Bacillus megaterium* KM with hot water was probably capsular material, but Cassity and Kolodziej (1984) concluded that a heteropolysaccharide of D-glucose, D-xylose, D-galactose, and L-arabinose produced by another strain of this species was intracellular and that it was used as a source of carbon and energy during sporulation. Several polysaccharides from *Bacillus* strains have been found to cross-react with antisera to capsules from other genera: *Bacillus mycoides* with *Streptococcus pneumoniae* type III, and *Bacillus pumilus* with *Haemophilus influenzae* type b and with *Neisseria meningitidis* group A (Myerowitz et al., 1973).

Flagella. Many species of *Bacillus* are motile by means of peritrichous flagella, which are not usually numerous and may be very few in number. Flagellation has not been considered a particularly useful taxonomic character for the genus, but the presence or absence of motility continues to be indicated in most species descriptions, and it is of some value in identification. For example, *Bacillus anthracis* and *Bacillus mycoides* are nonmotile, while most *Bacillus cereus* strains are motile. The flagella of *Bacillus thuringiensis* may bind to insect cells and be important in virulence (Zhang et al., 1995). The value of H-antigens in the typing of *Bacillus cereus*, *Bacillus thuringiensis* and *Bacillus sphaericus*, and other aspects of *Bacillus* flagellar antigens, are discussed in *Antigens and vaccines*, below. The flagella of *Bacillus subtilis* are well characterized, and reviews may be found in Sonenshein et al. (1993) and in Aizawa et al. (2002).

S-layers. Surface or S-layers are two-dimensional arrays composed of protein or glycoprotein molecules. The S-layer proteins assemble themselves into very stable structures which have oblique, square or hexagonal lattice symmetries, are 5–25 nm thick, and contain pores of 2–8 nm in diameter (Sleytr et al., 2001). The phylogenetic origins of the S-layers of some *Bacillus cereus* group strains was investigated by Mignot et al. (2001), and the possession of an S-layer was found to be largely restricted to a genetically clustered subgroup of clinical and insect isolates, suggesting a role in pathogenicity and the influence of ecological pressures to maintain the layer. It has been shown that the S-layer of *Bacillus cereus* is involved in the adhesion of the organism to host cell molecules, and polymorphonuclear leukocytes, as well as enhancing the organism's radiation resistance (Kotiranta et al., 2000). However, S-layers are apparently of no value as taxonomic markers, as in some species, including *Bacillus cereus*, their presence is strain-dependent (Kotiranta et al., 1998; Sleytr et al., 2001). The S-layer of *Bacillus anthracis* is reviewed by Mock and Fouet (2001).

Colony characteristics. *Bacillus* species show a very wide range of colonial morphologies, both within and between species, and of course medium composition and other incubation conditions have a strong influence. Despite this diversity, however, *Bacillus* colonies on routine media are not generally difficult to recognize. Some species have characteristic yet seemingly infinitely variable colonial morphologies: colonies of *Bacillus cereus* and relatives are very variable, but readily recognized (Figure 9a, b, h): they are characteristically large (2–7 mm in diameter) and vary in shape from circular to irregular, with entire to undulate, crenate or fimbriate edges; they have matt or granular textures, but smooth and moist colonies are not uncommon. Although colonies of *Bacillus anthracis* and *Bacillus cereus* can be similar in appearance, those of the former are generally smaller, non-hemolytic, may show more spiking or tailing along the lines of inoculation streaks, and are very tenacious as compared with the usually more butyrous consistency of *Bacillus cereus* and *Bacillus thuringiensis* colonies, so that they may be pulled into standing peaks with a loop. The colonies of *Bacillus mycoides* differ from those of other members of the *Bacillus cereus* group; they are characteristically rhizoid or hairy-looking and adherent, and they readily cover the whole agar surface (Figure 9d).

The colonies of other species vary from moist and glossy (Figure 9c, e, f) through granular to wrinkled (Figure 9h); shapes vary from round to irregular, sometimes spreading, with entire through undulate or crenate to fimbriate edges. After 24–48 h incubation, colonial sizes of mesophilic strains typically range from 1 to 5 mm; color commonly ranges from buff or creamy-gray to off-white, but occasional strains may produce black, brown, orange, pink or yellow pigments; such pigmentation tends to be characteristic of species or subspecies. Elevations range from effuse through raised to convex. Consistency is usually butyrous, but mucoid and dry, adherent colonies are not uncommon. Hemolysis may be absent, slight or marked, partial or complete. *Bacillus subtilis* (Figure 9g) and *Bacillus licheniformis* produce similar colonies which are exceptionally variable in appearance and often appear to be mixed cultures – the colonies are irregular in shape and of moderate (2–4 mm) diameter, and range in consistency from moist and butyrous

or mucoid (with margins varying from undulate to fimbriate), through membranous with an underlying mucoid matrix (with or without mucoid beading at the surface), to a rough and crusty appearance as they dry. The “licheniform” colonies of *Bacillus licheniformis* tend to be quite adherent. Rotating and migrating microcolonies (Figure 9i), which may show spreading growth (the V morphotype, see below), were observed macroscopically in about 13% of strains received as *Bacillus circulans* (Logan et al., 1985) but this very heterogeneous species has undergone radical taxonomic revision, and organisms producing motile microcolonies are now allocated to *Paenibacillus cookii*, *Paenibacillus glucanolyticus*, *Paenibacillus lautus*, and some unidentified *Paenibacillus* species (Alexander and Priest, 1989; Logan et al., 2004a). Most of the colonial morphologies illustrated here are shown in color by Logan and Turnbull (2003).

Matsushita et al. (1998, 1999) have constructed a mathematical model to explain some of the morphological variation

FIGURE 9. Colonies of endospore-forming bacteria on blood agar [parts (a)–(c), (e)–(f), (h)] and nutrient agar [parts (d), (g), (i)] after 24–36 h at 37°C. These figures illustrate some of the diversity of colonial appearance within the genus, but the appearances shown should not be regarded as necessarily typical of the species illustrated. Bars for parts (a)–(f) and (h)–(i) = 2 mm; bar for (g) = 4 mm. (a) *Bacillus anthracis*: circular to irregular colonies with entire to undulate, crenate and fimbriate edges, and granular surface textures; (b) *Bacillus cereus*: irregular, with undulate, crenate and fimbriate edges, and matt or granular textures; (c) *Bacillus megaterium*: glossy, round to irregular colonies with entire to undulate margins; (d) *Bacillus mycoides*: rhizoid or hairy-looking, adherent colonies which may readily cover the whole agar surface; (e) *Bacillus pumilus*: wrinkled, irregular colonies with undulate margins; (f) *Bacillus sphaericus*: smooth, glossy, round to irregular colonies with entire to undulate margins; (g) *Bacillus subtilis*: irregular colonies that may give the appearance of a mixed culture. They range in consistency from moist through butyrous or mucoid to membranous, with an underlying mucoid matrix (with or without mucoid beading at the surface), and become rough and crusty in appearance as they dry. Margins vary from undulate to fimbriate; (h) *Bacillus thuringiensis*: circular to irregular colonies with entire or undulate edges, and matt to granular surface textures; (i) Motile, spreading microcolonies sometimes seen in strains that were previously assigned to *Bacillus circulans*, but which are now usually allocated to *Paenibacillus* species (see text). Photographs prepared by N. A. Logan.

FIGURE 9. (continued)

seen in colonies of *Bacillus subtilis*: it is a diffusion-reaction-type model, where colony patterns are influenced by substrate softness and nutrient concentration, and colonies comprise active and inactive cells. The active cells grow, divide and move, while inactive cells do not. Concentric ring-like colonies reflect alternate periods of advance and rest of the growing interface, which consists of the active cells. Active cells also form the tips of the growing branches of “dense branching morphology” colonies. Ben-Jacob et al. (1998) combined a detailed study of bacterial colony development with pattern-formation concepts derived from non-living systems to construct a model which suggested that cooperative cellular behavior, involving long-range chemorepulsion and short-range chemoattraction, occurs. They defined three colonial “morphotypes”: tip-splitting or branching (T), chiral (C), where the thin branches all have a same-handed twist, and vortex (V), where the tip of each branch bears a leading droplet containing many bacteria. The T morphotype is seen in *Paenibacillus dendritiformis*, the C morphotype particularly where a rapid growth transition from the T type occurs on softer agar (the reverse transition, C to T, occurring on harder agar), and the V morphotype is characteristic of some *Paenibacillus* strains formerly classified as *Bacillus circulans*. Stecchini et al. (2001) found that the radial growth rate of *Bacillus cereus* colonies diminished as the agar content increased, and that colony density decreased during the incubation period, being lowest at the lower agar concentrations because the liquid film was thicker. Delprato et al. (2001) found that the bacteria in the central regions of *Bacillus subtilis* colonies migrated to the colony edge and formed a ring pattern following exposure of the whole colony to UV radiation, and that cells grew both inwards and outwards when the irradiation ceased; they proposed a diffusion-reaction model in which the radiation initiates a waste-limited chemotaxis.

Sporulation is strongly associated with the spatial development of the bacterial community; in *Bacillus subtilis* biofilms, sporulating aerial structures (primitive fruiting bodies) may be formed by motile cells that align themselves to form chains of attached cells (Branda et al., 2001). *Bacillus subtilis* uses an elaborate peptide quorum-sensing system to choose between the competent (i.e., for exogenous DNA uptake) state and the sporulation process, and sporulation occurs only poorly at low cell densities, even if the cells are starved (Miller and Bassler, 2001). To explain differences in the architectures of colonies grown from vegetative cells and those grown from spores, characterized by different glycocalyx wetting angles, Puzyr et al. (2002) suggested that germinating spores and vegetative cells of *Bacillus subtilis* adopt different strategies of substrate colonization.

Life cycle. Cohn (1876), Koch (1876) and Tyndall (1877) independently discovered that certain bacteria could spend part of their lives as the dormant cellular structures now known as endospores. The first two of these authors recognized the significance of these structures in the epidemiology of anthrax, and Koch’s study of the life history of *Bacillus anthracis* proved the germ theory of disease and so marked the genesis of clinical bacteriology. Although Pasteur (1870) had previously figured endospores in a work on silkworm diseases, he did not clearly attribute the longevity of the pathogens to their spores.

The ability to form endospores in aerobic conditions has been a defining character of the genus *Bacillus* since the 1920s, and has been applied in all editions of the *Manual*.

Spore formation is most important in identification to genus level. Before attempting to identify to species level it is important to establish that the isolate really is an aerobic endospore-former, and that other inclusions are not being mistaken for spores.

Endospores are so named because they are formed intracellularly, and they differ from their parent vegetative cells in many ways: they are optically refractile, and are highly resistant to chemical and physical stresses that are lethal to vegetative cells. These properties are conferred by the spores’ special chemical composition and ultrastructure, and much effort has been expended over many years in order to elucidate the processes of spore formation and germination, and the molecular mechanisms that make endospores the hardiest form of life known on Earth. Although endospores are to be found in other genera, *Clostridium* for example, it is the spores of *Bacillus subtilis* that have been the most intensively studied, especially those of strain 168.

Under suitable nutritional, temperature, pH, gaseous and other conditions, *Bacillus* cells will grow and divide by binary fission, with the dividing septum traversing the middle of the cell. Depending on species, strain, and cultural conditions, daughter cells may separate so that the culture appears to be composed of single cells and pairs of dividing cells when viewed by phase-contrast microscopy. In other cases, daughter cells may remain attached to each other, so that chains of cells are seen. Filaments may also be observed, and these can often be symptomatic of a stressed culture. An organism that exists predominantly as regular rods in optimal growth conditions may produce swollen, pleomorphic, unhealthy-looking cells when stressed.

Endospores are formed at the end of the exponential growth phase, and at least two kinds of environmental factors have been implicated in the induction of sporulation. One trigger for sporulation is nutritional deprivation, for example when an actively growing culture is transferred from a rich to a poor growth medium. Many other factors are known to affect endospore formation, including growth temperature, environmental pH, aeration, presence of certain minerals, and carbon, nitrogen and phosphorus sources and their concentrations. Another influence is population density: as the mass of a culture increases, there is an extracellular accumulation of a secreted peptide (competence and sporulation factor, or CSF), which acts as an autoinducer for quorum sensing (Miller and Bassler, 2001). When this peptide reaches a concentration that relates to a particular cell density, high intracellular levels of CSF lead to an increase of the phosphorylated form of a response regulator (SpoOA), which leads to derepression of various stationary-phase genes, some of which are needed for sporulation (Sonenshein, 2000). Studies of *Bacillus subtilis* biofilms have shown that the cells do not behave as strictly unicellular organisms, but that sporulation is also tightly linked with the spatial development of the microbial community. Motile cells may form aligned chains of attached cells that produce aerial structures; these can be seen as primitive fruiting bodies, as they are the preferred sites of sporulation (Branda et al., 2001).

Sporulation is closely tied to the cell cycle, and a round of DNA replication must be initiated as a prerequisite for the sporulation pathway being activated (Michael, 2001). The cell division of vegetative growth is symmetrical, and yields two similar cells. During sporulation, however, cell division is asymmetrical and two quite different kinds of cells, the small forespore and the larger mother cell, are produced, each with its own copy of the chromosome. The two different kinds of division are believed to use essentially the same protein machinery (Errington, 2001). At the commencement of sporulation, the chromosomes form an elongated structure called the axial filament, with migration of a specific region of the chromosomes towards the poles, and polar septation bisects one end of this filament so that only part of the nucleoid lies within the forespore; the remainder of the chromosome is then transferred into the forespore from the mother cell (Errington, 2001; Levin and Grossman, 1998). The process of sporulation may be divided into seven morphologically recognizable stages following vegetative growth: I, pre-septation, with the DNA forming the axial filament; II, asymmetric septation, the membrane of the developing spore surrounds the spore protoplast and becomes detached from the membrane of the mother cell; III, the forespore so formed becomes surrounded by the cytoplasm of the mother cell and so is contained within two membranes of opposing polarity; IV, spore cortex formation commences, with a primordial cell wall being laid down between the membranes, next to the forespore inner membrane; the cortex (a thicker layer of electron-transparent peptidoglycan, unique to bacterial endospores) is laid down on the outside of this primordial cell wall; an exosporium, a thin and delicate proteinaceous outermost covering, may be formed at this stage; V, proteinaceous spore coats are synthesized and begin to be deposited outside the cortex; VI, the spore matures, and acquires its refractility and heat resistance; VII, the sporangium lyses and releases the mature spore (Foster, 1994). In a laboratory culture of *Bacillus subtilis*, the whole process of sporulation may take about 8 h. The genetics of sporulation are reviewed by Piggot and Losick (2002).

Endospores are metabolically extremely dormant and do not contain ATP; this dormancy is the key to their resistance to many agents, including heat, radiation and chemicals, and their survival over long periods. Spore structure, resistance and germination are reviewed by Atrih and Foster (2001). The spore cortex is essential for spore dehydration (10–30% of the water content of the vegetative cell) and so for the maintenance of dormancy, and for the spore's heat resistance; the temperature of sporulation influences the mature spore's heat resistance (Nicholson et al., 2000). The mechanisms of spore resistance to chemical agents and radiation are not well understood, but saturation of the chromosome by protective small acid-soluble proteins (SASPs) is believed to play a part, while the spore coats are believed to prevent access of peptidoglycan-lytic enzymes to the spore cortex, and are also known to protect from hydrogen peroxide and UV radiation (Riesenman and Nicholson, 2000); coat assembly and composition are reviewed by Takamatsu and Watabe (2002). SASPs appear to be more important than the low core water content in protecting DNA from heat and oxidative damage (Setlow, 1995). Spore core and coat proteins are reviewed by Driks

(2002). Pyridine-2,6-dicarboxylic acid (dipicolinic acid; DPA) is a unique and quantitatively important spore component (comprising 5–14% of the spore dry weight), and Ca^{2+} and other divalent cations are chelated by it, but precisely how it contributes to spore resistance is unclear (Slieman and Nicholson, 2001). DPA may be used as a marker for detecting the presence of spores by Curie-point pyrolysis mass spectrometry and by Fourier-transform infrared spectroscopy (Goodacre et al., 2000). Mechanisms of spore resistance have been reviewed by Nicholson et al. (2000) in the contexts of survival both in extreme terrestrial conditions and during travel through extraterrestrial environments. The function of the exosporium is not known; the exosporium of *Bacillus cereus* has been characterized by Charlton et al. (1999).

Conversion from the dormant spore to vegetative cell involves the three steps: activation, germination, and outgrowth. Dormancy may be broken by heat treatment at a time and sublethal temperature appropriate to the organism concerned, and by ageing at low temperatures, but endospores of many species do not require such activation. The heat treatment procedure used to assist the isolation of *Bacillus* species, by destruction of all kinds of vegetative cells, is often effective in activation (see *Enrichment and isolation procedures*, below). Following dormancy, with or without activation, the spore may encounter conditions that trigger germination; the cortex is rapidly hydrolyzed, SASPs are quickly degraded, and refractility is lost in a matter of minutes. The germinated spore protoplast then outgrows: it visibly swells owing to water uptake, biosynthesis recommences (taking advantage of the nutrients released by germination as well as those available in its new environment), and a new vegetative cell emerges from the broken spore coat; another period of vegetative reproduction ensues. It seems remarkable that a metabolically dormant spore can monitor its external environment in order to trigger germination within seconds in suitable conditions, and that this triggering mechanism can escape the constraints of dormancy while being resistant to damaging agents. Germination can be induced by exposure to nutrients such as amino acids and sugars, by mixtures of these, by non-nutrients such as dodecylamine, and by enzymes and high hydrostatic pressure; for many species, L-alanine is an important germinant, while D-alanine can bind at the same site as L-alanine and acts as a competitive inhibitor (Foster and Johnstone, 1990; Johnstone, 1994). The mechanism of germination has been most studied for *Bacillus megaterium*. Although spore structure is very similar between species, and cortex peptidoglycan structure is highly conserved (Atrih and Foster, 2001), there are many different germinant receptor specificities; nonetheless, the underlying mechanism of germination may be universal (Foster and Johnstone, 1990). Recent developments in the understanding of spore germination process and the spore components required for it are reviewed by Moir et al. (2002) and Paidhungat and Setlow (2002).

Various aspects of spores have been considered as taxonomic characters. Spore antigens are considered under *Antigens and vaccines*, below. The spore coat may open by splitting polarly, equatorially, transversely, or by expansion with the halves of the coat at each end of the outgrowing cell, or by the coat lysing. Small-celled organisms such as *Bacillus subtilis* tend

to leave well-defined spore coat residues, while large-celled species such as *Bacillus cereus* and *Bacillus megaterium* may not. Lamana (1940a, 1954) studied modes of spore germination for nine species and found it to be of potential value for differentiation between the small-celled species and between this group and the large-celled species, but, with two exceptions (Burdon, 1956; Gould, 1962), little further attention has been paid to this character.

Bradley and Franklin (1958) showed that most of the 20 species they studied could be distinguished by electron microscopy of carbon replicas of spore surface patterns. Bulla et al. (1969) found that scanning electron microscopy gave inadequate resolution for such studies, but Murphy and Campbell (1969) achieved good resolution of *Bacillus polymyxa* spores by this method, and Gray and Hull (1971) considered this approach to be promising in the study of the *Bacillus circulans* complex. Later authors have sometimes described spore surface structure in proposals for new species, but too few such descriptions are available to judge the taxonomic value of spore surface characteristics across the genus.

Electron microscopy has revealed sword-shaped appendages radiating from one end of the exosporium of the spores of two phylloplane strains of *Bacillus cereus* (Mizuki et al., 1998). The proteinaceous spore appendages of 10 *Bacillus cereus* strains isolated from food-borne illness outbreaks and food industry sources showed some antigenic relationship, but when subjected to SDS-PAGE analysis none showed identical patterns (Stalheim and Granum, 2001). Smirnova et al. (1991) found that hemagglutination patterns of fimbriated *Bacillus thuringiensis* spores correlated with the subspecies of the strains rather than with their flagellar serovars. Song et al. (2000) reported that under strictly standardized growth conditions, spore fatty acid profiles, like those of vegetative cells, are stable and potentially of taxonomic value.

The microscopic morphologies of *Bacillus* species, especially of their sporangia, are well established as valuable characters. Smith et al. (1946, 1952) and Gordon et al. (1973) used cell size, appearance of cytoplasm and sporangial morphology as the basis of their division of the genus into three groups of species, and this arrangement still correlates quite well with the present classification of the aerobic endospore-formers. Sporangial morphology, and cell size, shape and cytoplasmic appearance, remain useful characters in polyphasic taxonomic studies, and sporangial characters are particularly valuable in identification. Spore shapes vary from cylindrical (Figure 10a) through ellipsoidal (Figure 10b–e, g) to spherical (Figure 10f); bean- or kidney-shaped, curved-cylindrical, and pear-shaped spores are also seen occasionally. Spores may be terminally (Figure 10f), subterminally (Figure 10a–g), paracentrally (Figure 10b, d, e, g) or centrally (Figure 10f) positioned within sporangia and may distend them (Figure 10c–f). Despite within-species and within-strain variation, sporangial morphologies tend to be characteristic of species, and for some species may allow tentative identification by the experienced worker. Routine recognition of *Bacillus thuringiensis* is largely dependent on observation of its cuboid or diamond-shaped parasporal crystals in sporangia (Figure 10h).

Nutrition and growth conditions. Despite the very wide diversity of the genus, most *Bacillus* species will grow well on routine media such as nutrient agar or trypticase soy agar, and most will grow on blood agar. However, some isolates, particularly those from nutritionally poor environments, may grow poorly if at all on these standard media and so require weaker formulations; for example, strains of *Bacillus thuringiensis* (Forsyth and Logan, 2000) isolated from Antarctic soils required *Bacillus fumarioli* agar or a half-strength formulation of this medium for reliable cultivation, and they would not grow consistently on trypticase soy agar.

FIGURE 10. Photomicrographs of *Bacillus* species viewed by phase-contrast microscopy. Bars = 2 μm . (a) *Bacillus pumilus*: slender cells with cylindrical, subterminal spores, not swelling the sporangia; (b) *Bacillus cereus*: broad cells with ellipsoidal, paracentral and subterminal spores, not swelling the sporangia and showing some poly- β -hydroxybutyrate inclusions, which are smaller and less phase-bright than the spores; (c) *Bacillus circulans*:

(continued)

FIGURE 10. (continued) ellipsoidal, subterminal spores, swelling the sporangia; (d) *Bacillus licheniformis*: some chaining of cells evident; ellipsoidal, central and subterminal spores, not swelling the sporangia; (e) *Bacillus megaterium*: broad cells with ellipsoidal to spherical, subterminal and terminal spores, not swelling the sporangia, and showing poly- β -hydroxybutyrate inclusions, which are smaller and mostly less phase-bright than the spores; (f) *Bacillus sphaericus*: spherical, terminal spores, swelling the sporangia; (g) *Bacillus subtilis*: ellipsoidal, central, paracentral and subterminal spores, not swelling the sporangia; (h) *Bacillus thuringiensis*: broad cells with ellipsoidal, subterminal spores, not swelling the sporangia, and showing parasporal crystals of insecticidal toxin, which are less phase-bright than the spores. Photomicrographs prepared by N. A. Logan.

In the First Edition of this *Manual*, Claus and Berkeley (1986) listed five of their 34 valid species that would not grow on nutrient agar. Three of these (*Bacillus larvae*, *Bacillus lentimorbus* and *Bacillus popilliae*) have been transferred to *Paenibacillus*, and one (*Bacillus pasteurii*) has been transferred to *Sporosarcina*, leaving *Bacillus fastidiosus* as the only exception. However, of the 68 *Bacillus* species newly described or validated in the two decades following the preparation of the First Edition of this *Manual*, some 24 grow poorly or not at all on nutrient agar because of its neutral pH, and/or insufficient salinity, or because it is nutritionally too weak or too rich. *Bacillus benzoevorans* does not grow on peptone or tryptone media, but may be cultivated on yeast extract media containing sodium acetate or benzoate (Pichinoty et al., 1984). *Bacillus fastidiosus* strains usually need allantoic acid, allantoin or uric acid as sole carbon, nitrogen and energy sources, but some strains will grow on certain peptones, especially at high concentrations. *Bacillus laevolacticus* requires glucose or other carbohydrate for growth (Andersch et al., 1994). *Bacillus psychrodurans* and *Bacillus psychrotolerans* do not grow, or grow only weakly, on nutrient agar or in nutrient broth, and require a rich medium such as casein-peptone soymeal-peptone agar (Abd El-Rahman et al., 2002). *Bacillus sporothermodurans* also grows weakly on nutrient agar but grows on Brain heart Infusion Agar or in nutrient agar supplemented with vitamin B₁₂ (Pettersson et al., 1996). Both *Bacillus fumarioli* and *Bacillus naganensis* are moderately acidophilic, and will not grow at pH 7.0 (Logan et al., 2000; Tomimura et al., 1990); also, *Bacillus fumarioli* sporulates poorly on trypticase soy agar even when adjusted to its optimum pH of 5.5, and requires a weaker medium such as *Bacillus fumarioli* agar or half-strength *Bacillus fumarioli* agar. *Bacillus aeolius*, *Bacillus halodenitrificans*, *Bacillus halophilus*, *Bacillus horti* (the type strain) and *Bacillus jeotgali* do not grow in routine media without added NaCl (Denariuz et al., 1989; Gugliandolo et al., 2003a; Ventosa et al., 1989; Yoon et al., 2001a; Yumoto et al., 1998). The majority of *Bacillus* species that do not grow on routine media, however, are alkaliphiles: *Bacillus alcalophilus*, *Bacillus agaradhaerens*, *Bacillus clarkii*, *Bacillus cohnii*, *Bacillus krukwichiae*, *Bacillus pseudoalcalophilus*, *Bacillus pseudofirmus*; *Bacillus haloalkaliphilus* (which also needs NaCl; now reclassified in *Alkalibacillus*), *Bacillus thermo-cloacae* and *Bacillus vedderi* will not grow at pH 7.0 (Agnew et al., 1995; Demharter and Hensel, 1989b; Fritze, 1996a; Nielsen et al., 1995a; Spanka and Fritze, 1993; Yumoto et al., 2003), while the alkalitolerant organisms *Bacillus clausii*, *Bacillus gibsonii*, *Bacillus halmapalus*, *Bacillus horikoshii* and *Bacillus okuhidensis*, will all grow at pH 7.0. The two arsenate- and selenate-reducing species *Bacillus arseniciselenatis* and *Bacillus selenitireducens* are both obligately alkaliphilic and halophilic (Switzer Blum et al., 1998). Table 6 shows differential characters of species with pH optima for growth of 8 or above.

Chemically defined media have been developed for several species, often with the optimization of industrial processes in mind. Minimal growth requirements have been established for rather few species, may be influenced by environmental conditions, and further emphasize the diversity of the genus.

Most species will use glucose and/or other fermentable carbohydrates as sole sources of carbon and energy. Patterns of acid production from, or assimilation of, carbon substrates are of great value in the characterization and identification of *Bacillus*

species (Logan, 2002), but some species do not appear to utilize carbohydrates at all. *Bacillus azotoformans* uses a range of organic acids as carbon sources and does not attack carbohydrates; *Bacillus badius* and *Bacillus benzoevorans* assimilate certain amino acids and organic acids and do not produce acid from glucose and other carbohydrates. As indicated above, *Bacillus fastidiosus* usually uses allantoic acid, allantoin or uric acid as its sole carbon and energy source. The spherical-spored species *Bacillus fusiformis*, *Bacillus neidei*, *Bacillus pycnus*, *Bacillus silvestris* and *Bacillus sphaericus* do not produce acid or gas from D-glucose or other carbohydrates; *Bacillus fusiformis* utilizes acetate, citrate, formate, lactate and succinate. *Bacillus carboniphilus*, *Bacillus insolitus*, *Bacillus sivalis* and *Bacillus thermocloacae* do not produce acid or gas from glucose or a range of other carbohydrates; the growth of *Bacillus carboniphilus* is promoted by activated carbon and graphite. *Bacillus schlegelii* and *Bacillus tusciae* will grow chemolithoautotrophically, using H₂ as electron donor and CO₂ as carbon source, and for the former species CO will satisfy both requirements. When growing chemoorganoheterotrophically, *Bacillus schlegelii* utilizes acetate, butyrate, fumarate, propionate, succinate, phenol, 1-propanol and a small number of amino acids, and *Bacillus tusciae* uses a few alcohols, amino acids and organic acids, as their sole carbon sources, but neither species metabolizes carbohydrates. *Bacillus methanolicus* can grow on methanol, and some strains will also grow on ethanol.

Bacillus subtilis is attracted by many sugars (Ordal et al., 1979); following the genome sequencing of this species, its carbohydrate uptake and metabolism have been reviewed by Deutscher et al. (2002). In a theoretical analysis of metabolic fluxes, the capacity of *Bacillus licheniformis* for the production of certain industrial enzymes was found to be affected by the carbon sources used (Calik and Özdamar, 2001).

Bacillus species may use inorganic and organic sources of nitrogen. Many species will utilize an ammonium salt as their sole nitrogen source, amino acids are widely utilized, and strains of some species can use urea. The two facultative autotrophs *Bacillus schlegelii* and *Bacillus tusciae* can utilize ammonium ions, asparagine and urea as sole nitrogen sources. In the presence of molybdate, *Bacillus niacini* can use nicotinate as its sole source of carbon, nitrogen and energy. A soil isolate identified as *Bacillus coagulans* was found to use pyridine as sole carbon, nitrogen and energy source (Uma and Sandhya, 1997). Strains of *Bacillus pumilus* resistant to and able to utilize cyanide have been isolated (1983; Meyers et al., 1991; Skowronski and Strobel, 1969) and a cyanide-degrading enzyme purified and characterized (Meyers et al., 1991, 1993). In studies of the chemotaxis and motility of *Bacillus subtilis*, all 20 common amino acids have been found to attract the organism (Garrity and Ordal, 1995). Leucine, threonine and valine were found to be essential for growth and emetic toxin production by *Bacillus cereus* (Agata et al., 1999). Although Achouak et al. (1999) concluded that nitrogen fixation among aerobic endospore-formers is restricted to certain species of *Paenibacillus*, nitrogen fixation has been demonstrated in several *Bacillus* isolates from soil, including strains of *Bacillus azotoformans*, *Bacillus cereus*, *Bacillus licheniformis*, *Bacillus megaterium* (Rózycki et al., 1999) and *Bacillus sphaericus*. Some *Bacillus* species may stimulate the nitrogen-fixing activities of unrelated organisms, and so perhaps benefit from the nitrogen so fixed: a *Bacillus firmus* strain growing in association

with a strain of *Klebsiella terrigena* was found to increase nitrogen fixation by the latter, probably owing to the protection of nitrogenase by the phenolic compounds it excreted (Zlotnikov et al., 2001); a *Bacillus cereus* strain was found to stimulate nodulation in legumes, so enhancing nitrogen fixation by bradyrhizobia (Vessey and Buss, 2002).

Little comprehensive information is available on the vitamin requirements of individual *Bacillus* species. Many do not require such growth factors, but yeast extract will often stimulate better growth. Adams and Stokes (1968) studied the requirements of the psychrophiles *Bacillus insolitus* and *Bacillus psychrosaccharolyticus*: the former required biotin and thiamine, while the latter needed niacin and thiamine, and biotin was essential or stimulator, depending upon the strain. Among spherical-spored species, *Bacillus neidei* and *Bacillus sphaericus* require both biotin and thiamin for growth, but *Bacillus pycnus* does not. In the presence of molybdate, *Bacillus niacini* can use nicotinate (niacin) as sole source of carbon, nitrogen and energy. *Bacillus sporothermodurans* and *Bacillus subterraneus* require biotin and thiamin for growth, but neither require cystine. For some species, such as *Bacillus thermoamylovorans*, vitamins and nucleic acid derivatives will stimulate growth, but are not essential.

Growth temperature ranges vary appreciably between the strains of species, and maxima and minima may be extended beyond the usual limits of a species for strains found in unusually hot or cold environments. Isolates of *Bacillus licheniformis* and *Bacillus megaterium* from an Antarctic geothermal lake, for example, were found to have maxima of 68 °C and 63 °C, 13 °C and 18 °C, respectively, higher than the previously published limits for these species (Llarch et al., 1997). The vast majority of established species are mesophiles, with optima between 25 °C and 40 °C and typically around 30 °C, minima in the range 5–20 °C, and maxima of 35–55 °C. Several species, *Bacillus coagulans*, *Bacillus fumarioli*, *Bacillus infernus*, *Bacillus methanolicus*, *Bacillus okuhidensis*, *Bacillus smithii*, *Bacillus thermoamylovorans* and *Bacillus tusciae*, have higher growth temperature optima, ranging from 40 °C to 55 °C and above, with minima in the range 25–40 °C and maxima of 55–65 °C, and may be regarded as only moderately thermophilic. With minimum temperatures for growth of 37 °C and above, optima in the range 55–70 °C and maxima of 65–75 °C, *Bacillus schlegelii* and *Bacillus thermocloacae* may be regarded as true thermophiles. *Bacillus psychrodurans*, *Bacillus psychrosaccharolyticus*, and *Bacillus psychrotolerans* grow and sporulate around 0 °C and have maximum growth temperatures between 30 °C and 35 °C, while *Bacillus insolitus*, with a maximum growth temperature of 25 °C, an optimum of 20 °C and a minimum below 0 °C, is a true psychophile. Growth temperature ranges and optima are given for most species in the *List of species of the genus*, below, and the differential characters of species with optimum temperatures of 50 °C and above are shown in Table 8.

Although aerobic growth has long been a defining character of members of the genus, some 20 species are facultatively anaerobic, and the definition was undermined by the discoveries of *Bacillus infernus* and *Bacillus arseniciselenatis*, which are strictly anaerobic (Boone et al., 1995; Switzer Blum et al., 1998). Nitrate respiration is a common property in the genus. Although *Bacillus subtilis* has long been regarded as a strict aerobe, which will like many *Bacillus* species, however, grow anaerobically using nitrate or nitrite as an electron acceptor, it has

recently been shown to grow by fermentation in the absence of electron acceptors (Clements et al., 2002; Nakano and Zuber, 2002) (see *Metabolism* and *metabolic pathways*, below).

Survival. Spores are readily formed by strains of many species, but it is a mistake to assume that a primary culture or subculture in or on a routine growth medium will automatically yield spores if stored on the bench or in the incubator. *Bacillus* strains will not sporulate under all cultural conditions, and if conditions are not suitable for sporulation the culture may die (see *Life cycle*, above). Most strains will sporulate if grown for a few days on a routine, solid growth medium supplemented with 5 mg/l manganese sulfate; failure to sporulate on such a medium may be addressed by cultivating on a nutritionally weaker, manganese-supplemented, medium. Repeated subculture of a strain sometimes leads to the production of fewer spores or the complete loss of ability to sporulate; some strains, however, appear able to survive for long periods in refrigerated cultures, even though they have not sporulated.

It is best to grow the organism on nutrient agar containing manganese for a few days, and refrigerate when microscopy shows that most cells have sporulated. For most species sporulated cultures, sealed after incubation, can survive in a refrigerator for many years.

Metabolism and metabolic pathways. The majority of information on the metabolism and biochemistry of *Bacillus* species relates to *Bacillus subtilis* alone or to comparisons of this with other species, and further valuable information has been forthcoming from studies aimed at the optimization of various industrial processes employing several other aerobic endospore-forming species.

It is now established that *Bacillus subtilis*, which was long regarded as a strict aerobe, is capable of growing anaerobically, not only with nitrate as electron acceptor but also by fermentation in the absence of electron acceptors. This species and its close relatives apparently cannot use other electron acceptors such as dimethyl sulfoxide, fumarate and trimethylamine N-oxide, and have been considered to lie in an intermediate position between the true facultative anaerobes now allocated to *Paenibacillus* and the aerobes of the *Bacillus sphaericus* group (Priest, 1993), which are strictly oxidative. *Bacillus cereus*, *Bacillus licheniformis* and *Bacillus thuringiensis* can ferment carbohydrates in the absence of exogenous electron acceptors, and many *Bacillus* species can use nitrate as an electron acceptor in the absence of oxygen, but several species such as *Bacillus megaterium* and *Bacillus pumilus* are unable to do this. *Bacillus subtilis* uses pyruvate dehydrogenase for conversion of pyruvate to acetyl-coenzyme A in anaerobic as well as in aerobic conditions and fermentation is stimulated by pyruvate. The fermentation is of the mixed acid-butanediol type, and products include acetate, acetoin, 2,3 butanediol, ethanol and lactate (Nakano et al., 1997); *Bacillus licheniformis* also carries out a mixed acid fermentation (Shariati et al., 1995). During nitrate respiration, *Bacillus subtilis* reduces nitrate to nitrite and ammonium, and, unlike the denitrifier *Bacillus licheniformis*, it does not produce the gaseous products NO, N₂O and N₂ (Nakano and Zuber, 2002). A homolog of the *Bacillus subtilis* gene encoding membrane-bound respiratory nitrate reductase is found in *Bacillus anthracis* (Nakano and Zuber, 2002). *Bacillus licheniformis* shows poor anaerobic growth on fumarate, but it can

grow in the presence of arginine using the arginine deiminase pathway (Maghnoij et al., 1998); *Bacillus cereus* also possesses genes for this pathway but *Bacillus anthracis* does not (Ivanova et al., 2003; Read et al., 2003). In the First Edition of this Manual (Claus and Berkeley, 1986), ability to grow and sporulate in air was implicit in the definition of *Bacillus*, but the proposals of the species *Bacillus infernus* and *Bacillus arseniciselenatis*, which are strictly anaerobic, undermine this long-held element of the genus definition. *Bacillus arseniciselenatis* and *Bacillus selenitireducens* are two alkaliphiles isolated from a lakewater containing unusually high levels of arsenic, and they will grow by respiratory (dissimilatory) reduction of As(V) to As(III) (arsenate to arsenite) and oxidation of lactate to acetate and CO₂. The former will also grow by dissimilatory reduction of Se(VI) to Se(IV) (selenate to selenite) and the latter will reduce Se(IV) to Se(0), so that co-cultures will reduce selenate to elemental selenium (Switzer Blum et al., 1998). Such organisms or their enzymes are of interest for the bioremediation of environments contaminated with toxic oxyanions of arsenic and selenium. Lindblow-Kull et al. (1982) isolated a *Bacillus* strain from the seeds of the selenium-accumulating plant *Astragalus crotalariae*. It grew optimally in the presence of 3–100 mM selenite in nutrient broth, giving a strong red color owing to elemental selenium, and growth also occurred with selenate or tellurate. *Bacillus infernus*, a strict anaerobe, was isolated from a deep terrestrial subsurface environment and it can use Fe³⁺ and MnO₂, as well as trimethylamine N-oxide and nitrate, as electron acceptors (Boone et al., 1995), while *Bacillus subterraneus*, which is a facultative anaerobe isolated from a deep subsurface thermal aquifer, also uses Fe³⁺ and MnO₂, as well as fumarate, nitrate and nitrite as electron acceptors (Kanso et al., 2002).

The respiratory cytochromes and other heme proteins of *Bacillus subtilis* and relatives have been reviewed by von Wachenfeldt and Hederstedt (2002).

The natural habitat of *Bacillus subtilis* is soil, which contains a wide range of carbohydrates and polysaccharides from microorganisms, plants and animals, and so it can utilize a wide range of such substrates and possesses a large number of enzymes which degrade polysaccharides. Carbohydrates are taken into the cell by a range of means, including ATP-binding cassette (ABC) transporters and phosphotransferase systems (PTS); there are 77 putative ABC transporters and at least 16 PTS sugar transporters encoded in the genome (Kunst et al., 1997); 75 ABC transporter/ATP-binding proteins are encoded by the *Bacillus halodurans* genome (Takami et al., 2000). ABC transporters are important in Gram-positive organisms, given their single-membrane cell envelope, as they allow them to escape the toxic actions of many compounds. *Bacillus anthracis* has reduced numbers of PTS and other types of sugar transporters and lacks pathways for catabolism of several sugars compared with *Bacillus subtilis* (Read et al., 2003). Carbohydrate uptake and metabolism in *Bacillus subtilis* has been reviewed by Deutscher et al. (2002) and the regulation of carbon catabolism in *Bacillus* species was reviewed by Stulke and Hillen (2000).

Because many *Bacillus* species grow aerobically and produce acid from carbohydrates by oxidation rather than fermentation, they normally produce smaller amounts of acid from carbohydrates in comparison with most *Paenibacillus* species. Also, because the ammonia they produce from peptones may

neutralize the small amount of acid produced, it is necessary to use a medium of low protein to carbohydrate ratio, and a sensitive indicator such as phenol red in order to detect acid production.

Most members of the *Bacillus sphaericus* group will not use carbohydrates as carbon or energy sources, and use certain organic acids and amino acids instead.

The genome of *Bacillus subtilis* encodes an Embden–Meyerhof–Parnas glycolytic pathway, coupled to a functional tri-carboxylic acid (Krebs) cycle (Kunst et al., 1997), and the *Bacillus halodurans* genome is little different to that of *Bacillus subtilis* in this respect (Takami et al., 2000). *Bacillus subtilis* appears to have no glyoxylate shunt, but some *Bacillus* species, including *Bacillus halodurans* and *Bacillus anthracis*, produce glyoxylate shunt (or bypass) enzymes and/or have genes encoding components of this shunt, which allows acetate or fatty acids to be used as sole sources of carbon (Sonenshein, 2002). Inactivating mutations in the Krebs cycle genes of *Bacillus subtilis* cause defects in sporulation, and although most such defects are attributable to the conventional roles of the affected enzymes, other defects cannot be explained in this way and their mechanisms are unclear (Sonenshein, 2002). It appears that some Krebs cycle proteins may have regulatory as well as enzymic activities: the E2 subunit of the pyruvate dehydrogenase complex of *Bacillus thuringiensis* can bind to DNA, and in so doing has been implicated in regulation of the expression of a gene for toxin production (Walter and Aronson, 1999).

Bacillus subtilis can use ammonium, nitrate, amino acids, some purines, urea, uric acid, allantoin, and peptides as sole nitrogen sources. Glutamine, followed by arginine, is the best source for rapid growth. In order to utilize the nitrogen compounds that permit optimal growth rates, this organism, like other Gram-positive bacteria, regulates nitrogen metabolism genes by mechanisms very different to the pathway found in enteric bacteria. *Bacillus subtilis* controls gene expression in response to nitrogen availability with the three proteins GlnR, TnrA and CodY. Also, although σ^{54} factors were initially believed to be present only in Gram-negative bacteria, the *Bacillus subtilis* *sigL* regulon was found to contain a homolog of σ^{54} , and is now known to contain genes involved in carbon and nitrogen source utilization (Fisher and Débarbouillé, 2002). *Bacillus subtilis* also possesses many genes involved in the degradation of opines and related molecules derived from plants (Kunst et al., 1997). Although *Bacillus subtilis*, *Bacillus anthracis*, *Bacillus cereus* and *Bacillus halodurans* have broad similarities in their metabolisms, *Bacillus anthracis* and *Bacillus cereus* have greater capacities for the utilization of amino acids and peptides. *Bacillus anthracis* and *Bacillus cereus* have wider ranges of coding sequences for secreted proteases, 48 and 51 respectively, compared with *Bacillus subtilis*, which has only 30, and wider ranges of peptidases too (Ivanova et al., 2003). The *Bacillus anthracis* genome also encodes 17 ABC-type peptide binding proteins, has nine homologs of the BrnQ branched chain amino-acid transporter, and has six LysE/Rht amino-acid efflux systems, whereas *Bacillus subtilis* has only four, two and two respectively. *Bacillus anthracis* and *Bacillus cereus* thus appear to be adapted to protein-rich environments such as animal matter (Ivanova et al., 2003; Read et al., 2003). *Bacillus* proteases are of considerable economic value, especially as detergent additives, are intensely studied with a view to enhancing their behaviors in industrial processes,

and the search for new strains producing enzymes with novel properties continues (Outtrup and Jørgensen, 2002).

Although iron is an essential nutrient for most organisms, free iron availability is severely restricted in neutral, aerobic environments, including animal tissues, owing to its insolubility in such conditions. Bacteria secrete siderophores into their environments in order to chelate iron, and the ferri-siderophore complexes can then be assimilated. *Bacillus subtilis* regulates iron uptake by members of the ferric uptake regulator (Fur) family of proteins, and possesses three such homologs, Fur, PerR (peroxide stress response) and Zur (zinc uptake regulation). The *Bacillus subtilis* homolog BsuFur shows only 33% sequence similarity to *Escherichia coli* Fur (EcoFur) and, unlike EcoFur, it does not respond to Mn(II) *in vivo* (Herbig and Helmann, 2002). *Bacillus anthracis* has a wider range of iron-acquisition genes than does *Bacillus subtilis*; it possesses 15 ABC uptake systems for iron siderophores or chelates, and two clusters of genes for the biosynthesis of siderophores. There are in the sequence of *Bacillus anthracis* two genes involved in the synthesis of an aerobactin-like siderophore that are not found in the sequenced strains of *Bacillus subtilis* and *Bacillus cereus* (Read et al., 2003). *Bacillus anthracis* carries genes for two sphere-like proteins which have internal cavities and act as ferritins, and so are involved in iron uptake and regulation; the immunogenicities of these proteins make them of interest in the development of new anthrax vaccines (Papinutto et al., 2002). *Bacillus cereus* can use hemoglobin, heme and heme-albumin complex as its iron sources, but does not appear to use other iron-binding proteins such as lactoferrin and transferrin; it does not digest these two proteins, but it will digest heme-protein complexes to elicit release of heme which may then be captured as an iron source (Sato et al., 1999).

Halophilic species and some alkaliphilic *Bacillus* strains have obligate requirements for Na⁺. The strain of the alkaliphile *Bacillus halodurans* that was subjected to complete genome sequencing requires Na⁺ for growth in alkaline conditions, where the environmental sodium ions are essential for solute transport through the cytoplasmic membrane. ATP metabolism through the action of ATPases is considered to be important in generating a proton-motive force across the cytoplasmic membrane by extrusion of H⁺; *Bacillus halodurans* possesses genes for four types of ATPases which are well conserved between the genome of this species and *Bacillus subtilis* (Takami et al., 2000). The *Bacillus halodurans* genome was also found to carry protein coding sequences that are candidates for Na⁺/H⁺ antiporter genes, at least some of which are involved in halotolerance and alkali-tolerance and allow the organism to maintain an intracellular pH lower than the environmental pH (Takami et al., 2000). The *Bacillus subtilis* 168 genome possesses a single ABC-type putative Na⁺ efflux system (Saier et al., 2002).

The abilities of some *Bacillus* strains to metabolize and transform complex organic compounds are of interest in both bioremediation and pharmaceutical production, and studies of isolates from special environments and searches for activities of potential value in biotechnological applications have revealed a number of unfamiliar substrates.

Reports of *Bacillus* strains or their enzymes capable of metabolizing environmental pollutants include: a *Bacillus* sp. capable of oxidizing H₂S in chicken feces (Nakada and Ohta, 1998); a *Bacillus sphaericus* isolate from agricultural soil which oxidizes

p-nitrophenol (Kadiyala et al., 1998); the naphthalene-degrading "*Bacillus naphthovorans*" from oil-contaminated tropical marine sediments (Zhuang et al., 2002; a *Bacillus* sp. that can utilize dimethylphthalate as sole carbon source (Niazi et al., 2001); a *Bacillus* sp. capable of using 4-chlorobiphenyl as sole carbon source, metabolizing it to 4-chlorobenzoic acid (Säägaa et al., 1998); and an engineered *Bacillus megaterium* cytochrome P450 that degrades polycyclic aromatic hydrocarbons (Carmichael and Wong, 2001).

The uricase of *Bacillus fastidiosus* catalyzes the oxidation of uric acid into the more soluble allantoin, and conjugates of this enzyme with soluble polymers to reduce antigenicity are of value in the therapy of gout, and of hyperuricemias associated with blood malignancies and chemotherapy (Schiavon et al., 2000). Some strains of *Bacillus cereus*, *Bacillus megaterium* and *Bacillus sphaericus* are capable of biotransformations of inexpensive natural steroidal substrates into high-value therapeutic compounds (Manosroi et al., 1999; Wadhwa and Smith, 2000). A *Bacillus subtilis* isolate from soil has been reported to produce the aroma compound vanillin by degradation of the phenylpropanoid isoeugenol, which it could use as sole carbon source (Shimoni et al., 2000). Decarboxylation of the abundant ferulic acid into the useful aromatic compound 4-vinylguaiaicol has been described for *Bacillus pumilus* (Lee et al., 1998), while another strain of this species has been reported to be able to use phenols and cresols as sole carbon sources (Günther et al., 1995).

Genetics. Aerobic endospore-formers have been and continue to be important in many fields of basic research, and long-term studies of the sporulation process in *Bacillus subtilis* have led to its being probably the best understood developmental system. Although endospores are to be found in other genera, it is the spores of *Bacillus subtilis* that have been the most intensively studied, especially those of strain 168. Burkholder and Giles (1947) produced auxotrophic mutants of the Marburg (i.e., type) strain by exposure to UV light and X-rays in the 1940s, and their tryptophan auxotrophic strain 168 was chosen by Spizizen (1958) as the recipient in his demonstration of transformation of this species by bacterial DNA in the 1950s. Because studies on individual genes and gene products have been performed mainly on *Bacillus subtilis*, and to a lesser extent on pathogenic members of the *Bacillus cereus* group, such properties have as yet made little contribution to our understanding of the phylogeny of the genus *Bacillus*, but this will of course change as more species have their genomes sequenced (Stackebrandt and Swiderski, 2002).

The same laboratory strain, *Bacillus subtilis* 168, was also the first *Bacillus*, indeed the first Gram-positive bacterium, to have its genome sequenced (Kunst et al., 1997), and the implications of this knowledge in our understanding of the cellular architecture, chromosomal replication, cellular division, metabolism and metabolic regulation, macromolecular synthesis, adaptation and differentiation of this organism have been reviewed by Sohenshein et al. (2002). As these authors observe, it has become clear from comparisons with the genome sequences of other organisms that the proteins of macromolecular synthesis, and the enzymes of biosynthesis and biodegradation, are widely conserved among prokaryotes, but that Gram-positive and Gram-negative organisms regulate gene expression and the activities of their gene products somewhat differently. The *Bacillus*

subtilis genome is similar in size to that of *Escherichia coli*, and these two organisms have orthologous counterpart genes representing about one-quarter of their genomes (Kunst et al., 1997). The same authors found that of the 450 genes encoded by *Mycoplasma genitalium*, some 300 had products similar to proteins of *Bacillus subtilis*, and this is particular of interest given the belief that mycoplasmas are derived from Gram-positive bacteria.

Subsequent to this pioneering work on the *Bacillus subtilis* genome, those of three other *Bacillus* species, *Bacillus halodurans*, *Bacillus anthracis* and *Bacillus cereus*, have been sequenced (Ivanova et al., 2003; Read et al., 2003; Takami et al., 2000), so that comparisons can be made and both common and specific features of these organisms (a soil bacterium, an alkaliphile, a pathogen of humans and other animals, and an opportunistic pathogen, respectively) can be identified.

The genome of *Bacillus subtilis* has 4,214,810 bp comprising 4,100 protein-coding sequences (CDSs); although the mean mol% G+C is 43.5 for this organism, the ratio varies greatly throughout the chromosome. There are many gene duplications, including rRNA genes, and a particularly conspicuous duplication is a 190 bp element that is repeated 10 times, with five repeats lying each side of the origin of replication; similar sequences have been found in the closely related species *Bacillus licheniformis* (Kunst et al., 1997). The genome of *Bacillus halodurans* has 4,202,353 bp containing 4,066 predicted CDSs, its mean mol% G+C is 43.7, and 16S rDNA sequence analysis shows it to be a close relative of *Bacillus subtilis*. The principal apparent difference between the two organisms is the alkaliphily of *Bacillus halodurans*, and so it was naturally of interest to identify differences between the genomes and to try and correlate these with phenotype. Both genomes showed substantial conservation of a common region comprising, amongst others, the functions of cell division, DNA replication, RNA modification, nucleotide and nucleic acid metabolism, metabolism of enzymes and prosthetic groups, glycolytic pathways and the TCA cycle, protein secretion, motility and chemotaxis (Takami et al., 2000). *Bacillus halodurans* was found to carry 112 CDSs which showed similarity with transposases or recombinases from other prokaryotes, indicating their important evolutionary roles in horizontal gene transfer. *Bacillus subtilis*, on the other hand, has only ten transposons and transposon-related proteins (Takami et al., 2000). However, the genome of *Bacillus subtilis* was found to contain at least 10 prophages or remnants of prophages, which suggest that horizontal gene transfer by bacteriophages may have played an important part in the evolution of this organism (Kunst et al., 1997); *Bacillus halodurans*, on the other hand, has no intact prophage. The σ factors required for sporulation are well conserved between the two genomes, but of 11 σ factors belonging to the extracytoplasmic function (ECF) only one is found in *Bacillus subtilis* and 10 are unknown outside *Bacillus halodurans*; these unique σ factors may play parts in alkaliphily given the roles of ECF σ factors in the control of specific molecule or ion uptake or secretion, or of various extracellular stress signals (Takami et al., 2000). Other differences between the organisms concern genes affecting competence, the control of sporulation, and cell-wall components. The last of these includes teichuronopeptide (a compound known to contribute to alkaliphily) in *Bacillus halodurans*, and the genome of this organism also possesses five candidates for Na⁺/H⁺ antiporter genes that may relate to its haloduric and alkaliphilic phenotype.

The chromosomes of *Bacillus anthracis* and *Bacillus subtilis* encode similar sporulation machineries, and metabolic and transport genes, and both encode numbers of predicted drug efflux pumps common in soil bacteria. Particular differences include the extended capacity of *Bacillus anthracis* for amino acid and peptide utilization, including more peptide binding proteins, secreted proteases and peptidases, and amino-acid efflux systems, and *Bacillus cereus* is likewise well equipped with proteolytic enzymes, peptide and amino acid transporters and amino-acid degradation pathways (Ivanova et al., 2003). These may correlate with their being adapted to protein-rich environments, and they have lesser capacities than *Bacillus subtilis* for sugar utilization. *Bacillus subtilis* carries 41 genes for degradation of carbohydrate polymers, whereas *Bacillus anthracis* has 15 and *Bacillus cereus* only 14 (Ivanova et al., 2003). The *Bacillus anthracis* genome encodes several detoxification functions for which homologs are not apparent in *Bacillus subtilis*; one of these is cytoplasmic Cu-Zn superoxide dismutase (SodC) which counteracts nitric oxide-mediated killing in the macrophage and has an important role in several other intracellular bacteria.

Bacillus anthracis has 5,227,293 bp and 5,508 CDSs (5,503,799 bp and 5,838 CDSs when the virulence plasmids are included), while *Bacillus cereus* carries 5,426,909 bp and 5,366 CDSs. It is well established that the genes on its virulence plasmids are essential to the virulence of *Bacillus anthracis*, as strains cured of one or both plasmids are avirulent. Study of the genome sequence shows that this organism has chromosomally encoded proteins, including hemolysins, phospholipases and iron-acquisition proteins which might contribute to pathogenicity, and surface proteins which might have potentials as drug and vaccine targets. Nearly all of these potential virulence factors and surface proteins have homologs in *Bacillus cereus*, even the sequenced *Bacillus cereus* strain which is considered to be non-pathogenic (Ivanova et al., 2003), underlining yet again the well-established close relationship between these two organisms (Turnbull et al., 2002). The chromosome of *Bacillus anthracis* carries most of its housekeeping functions, and these mostly have homologs in the sequence of *Bacillus cereus*, while the two virulence plasmids pXO1 (toxic complex) and pXO2 (capsule) carry transposons, and genes of unknown function in addition to the key virulence determinants. *Bacillus anthracis* also chromosomally encodes proteins with homology to virulence factors of *Listeria monocytogenes*, and these may be significant for intracellular survival, multiplication and escape (Read et al., 2003). The genes for a complex of three non-hemolytic enterotoxins and two channel-forming hemolysins that have roles in the pathogenicities of *Bacillus cereus* and *Bacillus thuringiensis* have homologs in *Bacillus anthracis*. *Bacillus anthracis* also carries two (and *Bacillus cereus* three) homologs of *Bacillus thuringiensis* immune inhibitor A protease which has a role in virulence to insects, and both it and *Bacillus cereus* encode a homolog of the metalloprotease enhancin which boosts viral infectivity in insect guts. It has been suggested that these genes may be evidence that the *Bacillus cereus* group had an insect-infecting ancestor, and their possession of genes for chitinolytic enzymes is consistent with this idea (Ivanova et al., 2003; Read et al., 2003).

Comparative genome hybridization of 19 *Bacillus cereus* and *Bacillus thuringiensis* strains against a *Bacillus anthracis* microarray revealed 66–92% homology of chromosomal genes, and several major differences between *Bacillus anthracis* and *Bacillus cereus*

reflect altered gene expression as opposed to gene gains or losses. In the *Bacillus cereus* and *Bacillus thuringiensis* strains were very few homologs of genes found on the virulence plasmid pXO2, but about half of the 19 strains carried homologs of genes (but not of the anthrax toxin genes) found in the virulence plasmid pXO1. There are many mobility genes on pXO1 (Okinaka et al., 1999), and plasmid transfer is known to occur within the *Bacillus cereus* group, but there is little localized variation in the G+C and dinucleotide contents of the *Bacillus anthracis* chromosome and virulence plasmids which suggests that most of the genes are native to this group of species (Read et al., 2003).

The great phylogenetic heterogeneity of *Bacillus sensu lato* was long evident from its wide mol% G+C range of 43–68 (Claus and Berkeley, 1986), and this heterogeneity has clearly been demonstrated by the 16S rRNA and rDNA sequence analyses that have followed. The impact of such analyses on the taxonomy of *Bacillus sensu lato* is discussed in *Taxonomic comments* (below) and in Stackebrandt and Swiderski (2002). Although 16S rDNA sequence comparisons are valuable in the determination of approximate phylogenetic relationships at the generic level and higher, they are not appropriate for the classification of strains at the species level (Stackebrandt and Goebel, 1994). Xu and Cote (2003) compared the sequences of the 16S–23S internal transcribed spacer region (ITS) of representatives of 27 *Bacillus* species and 19 strains representing five other endospore-forming genera. Although they found general agreement with polyphasic taxonomies incorporating 16S rDNA sequence comparisons, they also found support for the division of *Bacillus* into further new genera, and revealed unexpected groupings. For example, *Bacillus coagulans* was found to lie nearer to *Geobacillus* strains than to the other *Bacillus* species, *Bacillus laevolacticus* grouped with *Virgibacillus pantothenicus*, and *Bacillus badius* with *Marinibacillus marinus*, yet *Bacillus circulans* remained ungrouped (Xu and Cote, 2003). The ITS region is hypervariable in comparison with the more conserved 16S rRNA coding region, and ITS-PCR fingerprints have been used to investigate the relationships of members of the genus. Daffonchio et al. (1998a) were able to separate several species of *Bacillus* by this approach, but distinctions of very closely related species were not possible, and single-strand conformation polymorphism analysis was used to distinguish members of the “*Bacillus subtilis* group,” while *Bacillus mycoides* could be separated from *Bacillus cereus*/*Bacillus thuringiensis* by restriction analysis. When ITS-PCR, analysis of the regions between tRNA genes (tDNA-PCR), and RAPD were applied to *Bacillus licheniformis* the 10 strains studied fell into two clusters by all three fingerprinting methods. With *Bacillus cereus*, on the other hand, it was found that ITS-PCR and tDNA-PCR gave virtually identical profiles among the 21 strains, but that these strains showed great diversity in RAPD analysis and in plasmid profiles (Daffonchio et al., 1998b). Part of the ITS region has been used as a probe for the detection of *Bacillus sporothermodurans* (de Silva et al., 1998).

De Vos (2002) reviewed several other approaches to the analysis of nucleic acids that cover a wide range of taxonomic levels, and these are summarized here. As direct sequencing of 16S rDNA is still relatively expensive and not available to all microbiologists, indirect, fast and less expensive methods such as ARDRA, to characterize the 16S rDNA part of the ribosomal operon via restriction analysis, have offered a good alternative

for sequencing aerobic endospore-forming bacteria (Heyndrickx et al., 1996c; Logan et al., 2000). This method also has the advantages that both computerized interpretation of the data and database construction are possible.

Because *Bacillus sensu lato* members contain 9–12 rRNA operons (e.g., Johansen et al., 1996; Okamoto et al., 1993), ribotyping of the aerobic spore-formers has been considered as a potentially useful approach to unravel their taxonomic structure. At present, the number of studies in which ribotyping has been used to characterize members of *Bacillus* is rather limited, and published reports deal mainly with intraspecific variation. In these studies the investigators try to find a correlation between the intraspecific distribution of ribopatterning in correlation with, for example, (i) food poisoning with *Bacillus licheniformis* (Salkinoja-Salonen et al., 1999), (ii) toxin production by members of the *Bacillus cereus* group, including strains of *Bacillus cereus* from food poisoning incidents (Pirttijärvi et al., 1999), (iii) tracing of certain *Bacillus thuringiensis* types (Akhurst et al., 1997) and (iv) differentiation between toxic and non-toxic *Bacillus sphaericus* strains (Aquino de Muro et al., 1992).

Although comparative data with other fine DNA fingerprinting methods are somewhat scarce for representatives of *Bacillus*, at least one study has revealed that randomly amplified polymorphic DNA (RAPD) analysis is only slightly more discriminative than the automated ribotyping (riboprinting) for *Bacillus cereus* isolates (Andersson et al., 1999a).

Denaturing-gradient gel electrophoresis (DGGE) and temperature-gradient gel electrophoresis (TGGE) are based on similar principles, and allow discrimination at the subspecies level and often at the strain level (De Vos, 2002). As patterns from both techniques can be obtained after amplification of target DNA taken from non-purified biological material such as soil or water samples, the methods allow visualization of the genetic biodiversity, including the non-cultivable bacterial components of biotopes. Comparison of the sequences of the dominant bands visualized by these approaches with databases such as EMBL may be indicative for the dominant bacterial component of the biotope under study. Using TGGE, for example, an unknown group of *Bacillus* members has been discovered as the main bacterial component in Drentse grassland in the Netherlands (Felske et al., 1998; Felske et al., 1999).

As identical 16S rDNA sequences do not guarantee species identity (Fox et al., 1992), DNA:DNA hybridizations are needed when 16S rDNA sequences between strains show 97% similarity or more with existing taxa. The study of DNA relatedness by different techniques has been widely applied to *Bacillus*, but only two methods are currently used for species delineation within the genus: the liquid renaturation method (De Ley et al., 1970, or a variant) and the later microplate method of Ezaki et al. (1989). Data obtained by both methods have been evaluated and compared (Goris et al., 1998). Neither of these methods allows the determination of ΔT_m (thermostability (expressed as ΔT_m)) of the hybrid, but differences in ΔT_m between the hybrid and the homologous duplex are important and can be decisive for taxonomic conclusions (Grimont et al., 1982).

Several typing methods are based on indirect comparative analysis of nucleic acid characteristics, and were originally developed for the discrimination of species, subspecies and even strains for epidemiological studies. Restriction Fragment Length Polymorphism (RFLP) analysis of whole bacterial

genomes yielded very complex patterns of DNA fragments that are difficult to compare because of their smear-like appearance. The use of restriction enzymes that cut infrequently drastically reduces the number of the DNA fragments, the high molecular mass of which required the development of a specific technique known as pulsed field gel electrophoresis (PFGE) for the satisfactory separation of fragments on agarose gels. The method has been applied to differentiate between strains of *Bacillus sphaericus* (Zahner et al., 1998), and between very closely related species such as *Bacillus anthracis*, *Bacillus cereus*, *Bacillus mycoides* and *Bacillus thuringiensis* (Carlson et al., 1994; Harrell et al., 1995; Helgason et al., 2000; Liu et al., 1997). The last two of these studies dealt with infrequently reported clinical infections by *Bacillus cereus*.

Several other genomic typing techniques overcome the problem of interpreting complex banding patterns by visualizing only selected parts of bacterial genomes that have been amplified using the PCR. The banding patterns obtained using RAPD, in which oligonucleotides of about 10–20bp are used as primers, are not always very reproducible, so that databases are of limited use and data exchanged between laboratories have to be interpreted with great care. Nonetheless, RAPD has been applied to the discrimination of *Bacillus thuringiensis* (Brousseau et al., 1993), *Bacillus sphaericus* (Woodburn et al., 1995) and thermophilic (now mostly assigned to *Geobacillus*) and mesophilic *Bacillus* members (Ronimus et al., 1997). A second group of PCR-based typing methods uses repetitive element primers and so is known as rep-PCR. It is based upon the observation that repetitive elements are dispersed throughout genomes of bacteria, and consensus motifs deduced from the sequence of these repetitive elements can be used as primers. The electrophoretic patterns revealed allow discrimination at the within-species level and sometimes at the strain level, and have been used to investigate the genetic diversity of novel species (Heyrman et al., 2003a; Heyrman et al., 2003b; Heyrman et al., 2004; Logan et al., 2002b), to unravel the genetic diversity of *Bacillus sphaericus* (da Silva et al., 1999; Miteva et al., 1999), and to demonstrate the presence of the thermoresistant organism *Bacillus sporothermodurans* in UHT treated milk (Klijn et al., 1997). Amplified Fragment Length Polymorphism (AFLP) is based upon a specific combination of PCR and restriction methodologies (Zabeau and Vos, 1993), and although much more complex than RAPD and Rep-PCR methods, it is also much more reproducible. It has been used in epidemiological studies of *Bacillus cereus* (Mantynen and Lindstrom, 1998; Ripabelli et al., 2000; Schraft et al., 1996) and for the genetic comparison of *Bacillus anthracis* and its closest relatives (Jackson et al., 1999; Keim et al., 1997; Turnbull et al., 2002). Further molecular characterization showed that variable number tandem repeats (VNTR), which are short, tandemly repeated sequences which undergo very rapid mutational change, were responsible for the variations seen by AFLP. Multiple-locus VNTR analysis (MVLA) thus offers greater discriminatory power than AFLP and should be useful for investigating the ecology and epidemiology of anthrax (Turnbull et al., 2002).

Hansen et al. (2001) developed a PCR assay for the detection of members of the *Bacillus cereus* group, using a 16S rRNA probe. Real-time PCR assays, which use primer and fluorescently labeled gene probe systems to allow the rapid and sensitive detection of genes specific for *Bacillus anthracis*, have been developed

in several laboratories. Makino and Cheun (2003) described an assay that targeted genes for capsule and PA and allowed a single spore to be detected in 100l of air in 1 h. Drego et al. (2002) outlined an assay targeting fragments of a chromosomal gene (*rpo*) for detecting the organism in clinical samples. Hoffmaster et al. (2002) evaluated and validated a three-target assay, with primers for capsule, PA and *rpo*, in order to test suspect isolates and to screen environmental samples during the outbreak that followed the 2001 bioterrorist attack in the USA, and a similar approach was evaluated by Ellerbrok et al. (2002).

Antigens and vaccines. Despite the promising findings of some early studies of somatic and spore antigens from a range of species (Doak and Lamanna, 1948; Lamanna, 1940a, c, 1942), of flagellar, somatic and spore antigens of *Bacillus* (now *Paenibacillus*) *polymyxa* (Davies, 1951), and the potential taxonomic value of spore precipitinogens reported by Norris and Wolf (1961) following an extension of Davies' work to a wider range of species, serological studies have been taken little further for classification and identification of members of this genus. Paradoxically, however, although the *Bacillus cereus* group appeared to one of the least tractable in these early studies, where species-specific antigens were sought, the H-antigens of *Bacillus cereus* and *Bacillus thuringiensis* are now used with considerable success for typing purposes; *Bacillus anthracis* does not possess H-antigens as it is nonmotile. Smith et al. (1952) reviewed the earliest work, following their own disappointing results with antisera to vegetative cells of a range of species, and Berkeley et al. (1984) reviewed the application of serological methods to the identification of *Bacillus* species.

Somatic antigens have been little used for the identification of *Bacillus* strains. Investigations into the O-antigens of a *Bacillus cereus* and *Bacillus licheniformis* (Norris and Wolf, 1961) found them too strain-specific to be of taxonomic value. (Walker and Wolf, 1971) and Wolf and Sharp (1981) found the O-antigens of *Bacillus* (now *Geobacillus*) *stearothermophilus* to show some correlation with the three biochemical and physiological subgroups of this species that they recognized. Serotyping of *Bacillus thuringiensis* strains has been attempted on the basis of extracellular heat-stable somatic antigens (HSSAs; Ueda et al., 1989; Ohba et al., 1992), by observing the formation of immunoprecipitation haloes around colonies on antiserum-agar plates; they found a lack of correlation with H-antigen serogroups, while field isolates showed little HSSA variation within a single H-serovar. Concerns about the potential of *Bacillus anthracis* as a biological weapon have emphasized the need for a rapid method for the identification of *Bacillus anthracis* and diagnosis of anthrax. Polyclonal antibodies lack the desired specificity, because they react with other members of the *Bacillus cereus* group. Phillips and Ezzell (1999) were able to identify *Bacillus anthracis* by raising polyclonal antibodies against extracted vegetative cell antigens, absorbing with *Bacillus cereus* and *Bacillus thuringiensis*, and detecting reactions by immunofluorescence or immunoblotting. A monoclonal antibody specific to the *Bacillus anthracis* cell-wall polysaccharide antigen is effective in identification (Ezzell and Welkos, 1999), but this antigen may be masked *in vivo* by the organism's poly- γ -D-glutamic acid capsule. De et al. (2002) therefore developed a two-component direct fluorescent-antibody assay that allows rapid, sensitive and specific detection of the cell wall and capsule of *Bacillus anthracis* in clinical specimens.

Flagellar antigens have been more widely used in *Bacillus* typing than any other kind of antigen, as they provide the highest strain specificity, and valuable serotyping schemes have been developed for *Bacillus thuringiensis* and *Bacillus cereus*. High frequencies of H-antigen sharing between *Bacillus cereus* and *Bacillus thuringiensis* have been reported; in one study of *Bacillus cereus* strains from soils, phylloplanes and animal feces the seropositivity of the isolates with *Bacillus thuringiensis* H-antisera was 60–77% (Shisa et al., 2002). The common flagellar antigen of *Bacillus cereus* has been shown by SDS-PAGE and immunoblot assay to be due to a 61-kDa protein, and monoclonal antibody studies showed that the common antigenic epitope of the 61-kDa protein also exists in the flagella of *Bacillus thuringiensis* (Murakami et al., 1993).

Sixty-nine serotypes and 13 subantigenic groups of *Bacillus thuringiensis* have been recognized, giving 82 serovars (Lecadet et al., 1999). New strains of the species are screened by reference H-antisera and antisera are prepared against any strains that do not agglutinate. New antisera are then screened with all the known H-antigens, and a new serovar is recognized if cross-reactions do not occur or if new subfactors can be demonstrated by the antiserum-saturation technique (de Barjac, 1981). New serovars are registered at the International Entomopathogenic *Bacillus* Centre (IEBC) Collection at the Institute Pasteur, Paris, France; this laboratory was the international reference for *Bacillus thuringiensis* since 1965. Distinct serovars of *Bacillus thuringiensis* are given names and abbreviations, such as finitimus (FIN, H-antigen 2), sotto (SOT, H4a4b), tolworthi (TOL, H9) and pirenaica (PIR, H57). The first two of these two names were formerly used as the specific epithets of distinct species (Gordon et al., 1973). Although these serovar names have often been informally regarded as subspecific epithets, they do not represent validated subspecies of *Bacillus thuringiensis* and should instead be regarded as varieties. These varieties do not, unfortunately, show much correlation with toxicity to invertebrates; for example, serovar morisoni (MOR, H8a8b) includes strains pathogenic to mosquitoes (Diptera), Coleoptera and Lepidoptera (Lecadet et al., 1999), while the invertebrate toxicity, if any, of many serovars (especially the recently recognized ones) is unknown.

A strain differentiation system for *Bacillus cereus* based on H-antigens is available at the Food Hygiene Laboratory, Central Public Health Laboratory, Colindale, London, UK, for investigations of food-poisoning outbreaks or other *Bacillus cereus*-associated clinical problems (Kramer and Gilbert, 1992). This system was developed by Taylor and Gilbert (1975) for the investigation of food poisoning outbreaks and recognized 18 serovars, but many strains from outbreaks were untypable (Gilbert and Parry, 1977). Terayama et al. (1978) extended the system and recognized further serovars in foods. Some of the serotypes show some correlation with pathogenicity and biotype; the distinction is not absolute, however, and it is probable that some organisms can produce both diarrheal and emetic toxins. Serovar 1, 3, 5 and 8 strains comprise a biotype distinguishable from other *Bacillus cereus* serovars and untypable strains, and these former four serovars have often been isolated in connection with cases of the emetic form of food poisoning (Logan and Berkeley, 1984; Logan et al., 1979), a form especially associated with cooked rice. Gilbert and Parry (1977) found that strains of serovar 1 are found more frequently in cooked rice than in

uncooked rice, while strains of serovar 17 are commoner in uncooked rice than they are in cooked rice; they later showed that serovar 1 strains form more heat resistant spores than do serovar 17 strains (Parry and Gilbert, 1980).

Flagellar serotyping was developed for *Bacillus sphaericus* (de Barjac et al., 1985) independently of the recognition of DNA relatedness groups, so that the DNA relatedness group IIA (see *Bacillus sphaericus* in *List of Species*, below), the group in which the mosquitocidal strains of this species lie, is divided into 9 non-consecutively numbered serovars. The serotyping scheme for *Bacillus sphaericus* shows good agreement with a phage typing scheme (Yousten, 1984) for this species, but, as with *Bacillus thuringiensis*, the types do not always concur with pathogenicity (Priest, 2002).

The study of H-antigens of *Bacillus subtilis* (Simon et al., 1977) by agglutination tests was complicated by the tendency of the cells to clump spontaneously, and so double-diffusion in agar or complement fixation methods were applied. At least five distinct serovars were recognized, and although cross-reactions made the establishment of a practical serotyping scheme difficult, this approach was considered to be potentially useful in taxonomic studies.

As spores are so characteristic of the genus *Bacillus*, it is not surprising that their antigens have attracted much interest. Early workers (reviewed by Norris, 1962) recognized: (i) that any attempt to use living spores as antigens might be complicated by their germination in the host animal, giving rise to antisera against vegetative cells as well as spores; (ii) the need for a rapid method to overcome any problems of germination during the agglutination test itself; (iii) the tendency of spores to auto-agglutinate owing to their hydrophobic surfaces; and (iv) the need to remove vegetative cell debris from spore suspensions—by using media promoting complete sporulation, or by autolysis with lysozyme or thiomersalate, or by autoclaving. Once these problems are overcome, spore antigens can be useful for serological identification, and a revival of interest has been stimulated by the need to detect the spores of *Bacillus anthracis* in the contexts of biowarfare and bioterrorism (Iqbal et al., 2000). Several antigens common to endospores from different genera may be found on the exosporium, and an antibody to one of these antigens also reacted with vegetative cells of *Bacillus cereus* and *Clostridium sporogenes* (Quinlan and Foegeding, 1997).

Lamana (1940c) was able to differentiate between spores of several of the small-celled species by their antigens, but again was less successful with the large-celled species (Lamana, 1940b), and Lamana and Eisler (1960) were unable to separate *Bacillus anthracis* from *Bacillus cereus* using spore agglutinogens. Norris and Wolf (1961) reported a similar picture from their study of spore agglutinogens, but found that spore precipitinogens were of some taxonomic value, and the latter observation was confirmed for the *Bacillus circulans* complex by Wolf and Chowhury (1971a). Walker and Wolf (1971) found that spore agglutinogens supported the main biochemical subdivisions of their *Bacillus* (now *Geobacillus*) *stearothermophilus* strains, but could not detect spore precipitinogens. Smirnova et al. (1991) considered that hemagglutination patterns of fimbriated *Bacillus thuringiensis* spores might be of taxonomic value.

In order to circumvent cell-clumping problems, Kim and Goepfert (1972) developed a fluorescent antibody technique for confirming identifications of *Bacillus cereus* from food

poisoning cases, but could not distinguish between spores of this species and *Bacillus thuringiensis*; it has subsequently been recognized that strains of the latter species may also cause food poisoning (Damgaard et al., 1997). Phillips and Martin (1983a, b) used radiolabeled polyclonal antibody to probe for *Bacillus anthracis* spores attached to solid supports. Spores would not attach reliably to microtiter plates, but although attachment to glass slides was better, the background signal in the immunoradiometric assay (IRMA) was higher; the best sensitivity was achieved with an indirect assay, but specificity was only moderate. Fluorescein-conjugated polyclonal antibodies to *Bacillus anthracis* spore surface antigens were found to cross-react with spores of several other *Bacillus* species, but these cross-reactions could be absorbed with strains of *Bacillus cereus*; however, spores of the Vollum strain (=type strain) did not react with antibodies to spores of most of the other strains of *Bacillus anthracis* tested (Phillips and Martin, 1988). A monoclonal antibody to viable and heat-killed spores of *Bacillus anthracis* was used in an immunofluorescence assay and achieved higher specificity but lower sensitivity than the IRMA approaches, but the epitope recognized by the antibody appeared to be unstable in spores stored for long periods (Phillips et al., 1988).

Anthrax vaccine The Sterne attenuated live spore vaccine, based on a toxigenic but non-capsulate strain, was introduced for animal vaccination in the late 1930s and spores of this strain remain in use as the basis of livestock vaccines in most parts of the world today. As this vaccine can show some slight virulence for certain animals, it is not considered suitable for human protection in the West, but live spore preparations are used in China and Russia. The former USSR vaccine was developed in the 1930s and 1940s, and licensed for administration by injection in 1959. It was based on two avirulent, non-capsulate *Bacillus anthracis* strains TI-I and 3, which were derived from virulent agents at the Sanitary-Technical Institute (STI), in Kirov (now Viatka). It was reported that in 30 years of use no adverse effects were associated with this vaccine, and so reconsideration of the suitability of live spore vaccines for human use has been suggested (Shiyakhov and Rubinstein, 1994). The UK vaccine is an alum-precipitated culture filtrate of the Sterne strain; it was first formulated in 1954, introduced for workers at risk in 1965, and licensed for human use in 1979. The current human vaccine in the USA is an aluminum hydroxide-adsorbed vaccine strain culture filtrate containing a relatively high proportion of protective antigen (PA) and relatively low amounts of lethal factor and edema factor; it was licensed in 1972 (Turnbull, 2000). Concerns about the lack of efficacy and safety data on the long-established UK and US vaccines, especially following the Sverdlovsk incident, and allegations that anthrax vaccination contributed to Gulf War syndrome in military personnel, have led to demands for new vaccines that would necessarily undergo stricter testing than was customary in the past. Favored active ingredients of these next-generation vaccines are whole-length recombinant PA or a mutant (non-toxic) portion of this molecule (Turnbull, 2000).

Antibiotic sensitivity. Most strains of *Bacillus anthracis* are susceptible to penicillin, there being few authenticated reports of resistant isolates (Lalitha and Thomas, 1997); consequently this antibiotic has been the mainstay of treatment and there have been few studies on the organism's sensitivity to other antibiotics. Mild and uncomplicated cutaneous infections may

be treated with oral penicillin V, but the treatment usually recommended is intramuscular procaine penicillin or benzyl penicillin (penicillin G). In severe cases, and gastrointestinal and inhalational infections, the recommended therapy has been penicillin G by slow intravenous injection or infusion until the fever subsides, followed by intramuscular procaine penicillin; the organism is normally susceptible to streptomycin, which may act synergistically with penicillin (Turnbull et al., 1998). The use of an adequate dose of penicillin is important, as Lightfoot et al. (1990) found that strains grown in the presence of subinhibitory concentrations of flucloxacillin *in vitro* became resistant to penicillin and amoxicillin. The study of Lightfoot et al. (1990) on 70 strains, and that of Doganay and Aydin (1991) on 22 isolates, found that most strains were sensitive to penicillins, with minimal inhibitory concentrations of 0.03 mg/l or less; however, the former authors found that two resistant isolates from a fatal case of inhalational infection had MICs in excess of 0.25 mg/l. *Bacillus anthracis* is resistant to many cephalosporins. Coker et al. (2002) found that of 25 genetically diverse, mainly animal and human isolates from around the world, five strains were resistant to the "second generation" cephalosporin cefuroxime, and 19 strains showed intermediate susceptibility to this agent; all strains were sensitive to the "first generation" cephalosporin cephalexin, and to the "second generation" cefaclor, and three were resistant to penicillin but were negative for β -lactamase production. Mohammed et al. (2002) studied 50 historical isolates from humans and animals and 15 clinical isolates from the 2001 bioterrorist attack in the USA; the majority of their strains could be regarded as nonsusceptible to the "third generation" cephalosporin ceftriaxone, and three strains were resistant to penicillin. Genomic sequence data indicate that *Bacillus anthracis* possesses two β -lactamases: a potential penicillinase (class A) and a cephalosporinase (class B) which is expressed (Bell et al., 2002). Tetracyclines, chloramphenicol, gentamicin and erythromycin are suitable for the treatment of patients allergic to penicillin; tests in primates showed doxycycline to be effective, a finding confirmed by Coker et al. (2002), and indicated the suitability of ciprofloxacin (Turnbull et al., 1998). Mohammed et al. (2002) found that most of their strains showed only intermediate susceptibility to erythromycin. Esel et al. (2003) found that ciprofloxacin and the newer quinolone gatifloxacin had a good *in vitro* activity against 40 human isolates collected in Turkey, but that for another new quinolone, levofloxacin, it was observed that minimum inhibitory concentrations were high for 10 strains. Because human cases tend to be sporadic, clinical experience of alternative treatment strategies was sparse until the bioterrorist attack occurred in the US in late 2001. The potential and actual use of *Bacillus anthracis* as a bioweapon has also emphasized the need for post-exposure prophylaxis; recommendations include ciprofloxacin or doxycycline, with amoxicillin as an option for the treatment of children and pregnant or lactating women, given the potential toxicity of quinolones and tetracyclines; however, β -lactams do not penetrate macrophages well, and these are the sites of spore germination (Bell et al., 2002). Combination therapy, begun early, with a fluoroquinolone such as ciprofloxacin and at least one other antibiotic to which the organism is sensitive, appears to improve survival (Jernigan et al., 2001). Following the 2001 outbreak in the US, the recommendation for initial treatment of inhalational anthrax is ciprofloxacin or doxycycline

along with one or more agents to which the organism is normally sensitive; given supportive sensitivity testing, a penicillin may be used to complete treatment. The same approach is recommended for cutaneous infections (Bell et al., 2002). Doxycycline does not penetrate the central nervous system well, and so is not appropriate for the treatment of meningitis.

Despite the well-established importance of *Bacillus cereus* as an opportunistic pathogen, there have been rather few studies of its antibiotic sensitivity, and most information has to be gleaned from the reports of individual cases or outbreaks. *Bacillus cereus* and *Bacillus thuringiensis* produce a broad spectrum β -lactamase and are thus resistant to penicillin, ampicillin, and cephalosporins; they are also resistant to trimethoprim. An *in vitro* study of 54 isolates from blood cultures by disk diffusion assay found that all strains were susceptible to imipenem and vancomycin and that most were sensitive to chloramphenicol, ciprofloxacin, erythromycin and gentamicin (with 2, 2, 6 and 7% strains, respectively, showing moderate or intermediate sensitivities), while 22 and 37% of strains showed only moderate or intermediate susceptibilities to clindamycin and tetracycline, respectively (Weber et al., 1988); in the same study, microdilution tests showed susceptibility to imipenem, vancomycin, chloramphenicol, gentamicin and ciprofloxacin with MICs of 0.25–4, 0.25–2, 2.0–4.0, 0.25–2 and 0.25–1.0 mg/l, respectively. A plasmid carrying resistance to tetracycline in *Bacillus cereus* has been transferred to a strain of *Bacillus subtilis* and stably maintained (Bernhard et al., 1978).

Although strains are almost always susceptible to clindamycin, erythromycin, chloramphenicol, vancomycin, and the aminoglycosides and are usually sensitive to tetracycline and sulfonamides, there have been several reports of treatment failures with some of these drugs: a fulminant meningitis which did not respond to chloramphenicol (Marshman et al., 2000); a fulminant infection in a neonate which was refractory to treatment that included vancomycin, gentamicin, imipenem, clindamycin, and ciprofloxacin (Tuladhar et al., 2000); failure of vancomycin to eliminate the organism from cerebrospinal fluid in association with a fluid shunt infection (Berner et al., 1997); persistent bacteremias with strains showing resistance to vancomycin in two hemodialysis patients (A. von Gottberg and W. van Nierop, personal communication). Oral ciprofloxacin has been used successfully in the treatment of *Bacillus cereus* wound infections. Clindamycin with gentamicin, given early, appears to be the best treatment for ophthalmic infections caused by *Bacillus cereus*, and experiments with rabbits suggest that intravitreal corticosteroids and antibiotics may be effective in such cases (Liu et al., 2000).

Information is sparse on treatment of infections with other *Bacillus* species. Gentamicin was effective in treating a case of *Bacillus licheniformis* ophthalmitis and cephalosporin was effective against *Bacillus licheniformis* bacteremia/septicemia. Resistance to macrolides appears to occur naturally in *Bacillus licheniformis* (Docherty et al., 1981). *Bacillus subtilis* endocarditis in a drug abuser was successfully treated with cephalosporin, and gentamicin was successful against a *Bacillus subtilis* septicemia. Penicillin, or its derivatives, or cephalosporins probably form the best first choices for treatment of infections attributed to other *Bacillus* species. In the study by Weber et al. (1988), isolates of *Bacillus megaterium* (13 strains), *Bacillus pumilus* (4), *Bacillus subtilis* (4), *Bacillus circulans* (3), *Bacillus amyloliquefaciens* (2)

and *Bacillus licheniformis* (1), along with five strains of *Bacillus* (now *Paenibacillus*) *polymyxa* and three unidentified strains from blood cultures, over 95% of isolates were susceptible to imipenem, ciprofloxacin and vancomycin; while between 75% and 90% were susceptible to penicillins, cephalosporins and chloramphenicol. Isolates of "*Bacillus polymyxa*" and *Bacillus circulans* were more likely to be resistant to the penicillins and cephalosporins than strains of the other species – it is possible that some or all of the strains identified as *Bacillus circulans* might now be accommodated in *Paenibacillus*, along with "*Bacillus polymyxa*." An infection of a human bite wound with an organism identified as *Bacillus circulans* did not respond to treatment with amoxycillin and flucloxacillin, but was resolved with clindamycin (Goudswaard et al., 1995). A recurrent septicemia with *Bacillus subtilis* in an immunocompromised patient yielded two isolates, both of which could be recovered from the probiotic preparation that the patient had been taking; one isolate was resistant to penicillin, erythromycin, rifampin and novobiocin, while the other was sensitive to rifampin and novobiocin but resistant to chloramphenicol (Oggioni et al., 1998).

A strain of *Bacillus circulans* showing vancomycin resistance has been isolated from an Italian clinical specimen (Ligozzi et al., 1998). Vancomycin resistance was reported for a strain of *Bacillus* (now *Paenibacillus*) *popilliae* in 1965, and isolates of this species dating back to 1945 have been shown to carry a *vanA*- and *vanB*-like gene, that is to say a gene resembling those responsible for high-level vancomycin resistance in enterococci. Vancomycin-resistant enterococci (VRE) were first reported in 1986, and so it has been suggested that the resistance genes in *Bacillus popilliae* and VRE may share a common ancestor, or even that the gene in *Bacillus popilliae* itself may have been the precursor of those in VRE; *Bacillus popilliae* has been used for over 50 years as a biopesticide, and no other potential source of *vanA* and *vanB* has been identified (Rippere et al., 1998). Of two South African vancomycin-resistant clinical isolates, one was identified as *Paenibacillus thiaminolyticus* and the other was unidentified but considered to be related to *Bacillus lentus* (Forsyth and Logan, unpublished); the latter was isolated from a case of neonatal sepsis, and has been shown to have inducible resistance to vancomycin and teicoplanin; this is in contrast to the *Bacillus circulans* and *Paenibacillus thiaminolyticus* isolates mentioned above, in which expression of resistance was found to be constitutive (A. von Gottberg and W. van Nierop, personal communication).

Isolates of novel *Bacillus* species from pristine Antarctic environments showed sensitivity to: ampicillin, chloramphenicol, colistin sulfate, kanamycin, nalidixic acid (*Bacillus fumarioli* resistant), nitrofurantoin, streptomycin and tetracycline (Logan et al., 2000, 2002b, and unpublished information).

Pathogenicity. The majority of *Bacillus* species apparently have little or no pathogenic potential and are rarely associated with disease in humans or other animals. The principal exceptions to this are *Bacillus anthracis* (anthrax), *Bacillus cereus* (food poisoning and opportunistic infections), and *Bacillus thuringiensis* (pathogenic to invertebrates), but a number of other species, particularly *Bacillus licheniformis*, have been implicated in food poisoning and other human and animal infections. The resistance of the spores to heat, radiation, disinfectants, and desiccation also results in *Bacillus* species being troublesome contaminants in the operating room, on surgical dressings, in pharmaceutical products and in foods.

***Bacillus anthracis*.** Anthrax is primarily a disease of herbivores, and before an effective veterinary vaccine became available in the late 1930s, it was one of the foremost causes worldwide of mortality in cattle, sheep, goats, and horses. In 1945 an outbreak in Iraq killed 1 m sheep. The development and application of veterinary and human vaccines together with improvements in factory hygiene and sterilization procedures for imported animal products, and the increased use of man-made alternatives to animal hides or hair, have resulted over the past half century in a marked decline in the incidence of the disease in both animals and humans. Nevertheless, the disease continues to be endemic in several countries of Africa, Asia, and central and southern Europe, particularly those that lack an efficient vaccination policy, and nonendemic regions must be constantly on the alert for the arrival of *Bacillus anthracis* in imported products of animal origin. Sites where these materials were formerly handled, such as disused tanneries, may be sources of infection when they are disturbed during redevelopment. Likewise, anthrax carcasses can remain infectious for many years, even when buried with quicklime. The cycle of infection is as follows: the spores are ingested by a grazing animal and may gain access to the lymphatics, and so to the spleen, though abrasions in the alimentary canal; following several days of the organism multiplying and producing toxin in the spleen, the animal suffers a sudden and fatal septicemia and collapses; hemorrhagic exudates escape from the mouth, nose and anus and contaminate the soil, where the vegetative cells sporulate in the air. The spores remain viable in soil for many years and their persistence does not depend on animal reservoirs, so that *Bacillus anthracis* is exceedingly difficult to eradicate from an endemic area. *Bacillus anthracis* continues to be generally regarded as an obligate pathogen. Its continued existence in the ecosystem appears to depend on a periodic multiplication phase within an animal host, with its environmental presence reflecting contamination from an animal source at some time (Lindeque and Turnbull, 1994); however, some authorities believe that self-maintenance may occur within certain soil environments (Cherkasskiy, 1999). Direct animal-to-animal transmission within a species (that is to say, excluding carnivorous scavenging of meat from anthrax carcasses) is very rare.

Bacillus anthracis has long been considered a potential agent for biological warfare or bioterrorism. It is believed its first use was against livestock during World War I (Barnaby, 2002; Christopher et al., 1997). It has been included in various development and offensive programmes in several countries since (Alibek, 1999; Barnaby, 2002; Mangold and Goldberg, 1999; Mikkola et al., 2000; Zilinskas, 1997) and it has also been used in terrorist attacks (Christopher et al., 1997; Lane and Fauci, 2001; Takahashi et al., 2004). In public consciousness, *Bacillus anthracis* is associated more with warfare and terrorism than with a disease of herbivores, and it is feared accordingly. Apart from artificial attacks, humans almost invariably contract anthrax directly or indirectly from animals. It is a point-source type of disease, and direct human-to-human transmission is exceedingly rare. Circumstantial evidence shows that humans are moderately resistant to anthrax as compared with obligate herbivores; infectious doses in the human inhalational and intestinal forms are generally very high (LD_{50} 2,500 to 55,000 spores). Naturally acquired human anthrax may result from close contact with infected animals or their carcasses after death from the disease, or be

acquired by those employed in processing wool, hair, hides, bones, or other animal products. Most cases (about 99%) are cutaneous infections, but *Bacillus anthracis* meningitis and gastrointestinal anthrax are occasionally reported. In industrial settings, inhalation of spore-laden dust may also occur; anthrax weapons are normally intended to cause the inhalational form, but are likely to cause cutaneous cases as well. There have been a few reports of laboratory-acquired infections, none of them recent (Collins, 1988), but a major outbreak of anthrax occurred in April 1979 in the city of Sverdlovsk (now Yekaterinburg) in the Urals as a result of the accidental release of spores from a military production facility; 77 cases were recorded and 66 patients died (Meselson et al., 1994).

Cutaneous infection occurs through a break in the skin, and as *Bacillus anthracis* is not invasive the lesions generally occur on exposed regions of the body; this includes the eyelids. Before the availability of antibiotics and vaccines, 10–20% of untreated cases of cutaneous anthrax were fatal, and the rare fatalities seen today are due to obstruction of the airways by the edema that accompanies lesions on the face or neck, and sequelae of secondary cellulitis or meningitis. Inhalational anthrax cases are more often fatal, because they go unrecognized until too late for effective therapy, but undiagnosed, low-grade infections with recovery may occur. The number of recorded cases of inhalational anthrax is lower than might be expected from the high profile given to this condition. In the 20th century there were just 18 reported cases (two of them laboratory-acquired) in the USA, 16 (88.9%) fatal (Brachman and Kaufmann, 1998); figures in the UK showed a similar picture. In 11 confirmed cases of inhalational anthrax that followed a bioterrorist attack, in which spores were delivered in mailed letters and packages, early recognition and treatment helped a survival level of 55% to be achieved (Bell et al., 2002; Jernigan et al., 2001). Oropharyngeal and gastrointestinal anthrax are not uncommon in regions of the world where animal anthrax is endemic and socio-economic conditions are poor, and people eat the meat of animals that have died suddenly; such cases are greatly underreported (Anonymous, 1994; Dietvorst, 1996). Gastrointestinal infections are mainly characterized by gastroenteritis, and asymptomatic infections and symptomatic infections with recovery are not uncommon (CDC, 2000). The symptoms of oropharyngeal infections are fever, toxemia, inflammatory lesions in the oral cavity and oropharynx, cervical lymph node enlargement, and edema, and there is a high case-fatality rate (Sirisanthana and Brown, 2002). Meningitis can develop from any of the forms of anthrax. The emergence of clinical signs is rapidly followed by unconsciousness, and the prognosis is poor. Outbreaks of primary anthrax meningoencephalitis have been reported from India and elsewhere (George et al., 1994; Kwong et al., 1997).

Infection occurs when endospores enter the body from the environment, and the spore is the primary infectious form of the organism (Hanna and Ireland, 1999). Spores are rapidly phagocytosed by macrophages, some of which undergo lysis, and in cases of inhalational anthrax the surviving macrophages are carried towards the mediastinal lymph nodes by the lymphatics. Phagocytosed spores may not germinate for up to 60 d, and so incubation of the inhalational form of the disease may take between 2 d and 6–8 weeks; this latency does not appear to occur in the cutaneous form of the disease. By analogy with

other *Bacillus* species, germination is presumed to be triggered by a specific chemical germinant, but this remains unidentified. In several *Bacillus* species L-alanine is a germinant, and its binding to a receptor causes loss of spore refractility and resistance, the cortex swells, and metabolic activity commences; triggering of the germinant receptor is believed to activate endogenous proteolytic activity which converts the proenzyme of a germination-specific cortex-lytic enzyme to its active form which allows hydrolysis of the cortex, uptake of water, and all the other events associated with germination. The elevated CO₂ level and body temperature of the host cause the organism to transcriptionally activate the capsule and toxin genes. These genes are carried on two plasmids: plasmid pXO1 encodes the toxin genes, and plasmid pXO2 encodes the capsule genes; loss of either plasmid effectively renders the organism avirulent. Spores germinating in the presence of serum and elevated levels of CO₂ release blebs of capsular material through openings in the spore surface; the capsule of poly- γ -D-glutamic acid is purported to resist phagocytosis by virtue of its negative charge (Ezzell and Welkos, 1999). The anthrax toxin complex comprises three components: edema factor (EF), protective antigen (PA), and lethal factor (LF), none of which is toxic alone; EF and LF are active in binary combinations with PA and have different activities. PA molecules bind to molecules of a particular host cell membrane protein (anthrax toxin receptor or ATR; Bradley et al., 2001) and form ring-shaped prepores of heptameric oligomers (aggregates of seven); PA is then cleaved and so activated by a furin-like protease on the surface of the cell under attack. An active PA heptamer can then bind one or more molecules of EF, LF or both. The complex passes into the cell by receptor-mediated endocytosis and into an acidified endosome; following conformational change of the heptamer in the low-pH environment, the complex escapes directly to the cytosol by insertion of the heptamer into the endosomal membrane. The PA-EF binary toxin interacts with the abundant host protein calmodulin (CaM; the major intracellular calcium receptor) and becomes an active adenylyl cyclase in most cell types; this elevates levels of the secretagogue cAMP and leads to hypovolaemic shock. The crystal structure of EF in complex with CaM has been elucidated (Drum et al., 2002). The PA-LF binary toxin is a zinc metalloprotease which cleaves members of the mitogen-activated protein kinase kinase family, so affecting certain signaling pathways, and levels of shock-inducing cytokines. This toxin primarily affects macrophages, and removal of macrophages from mice using silica renders them insensitive to the toxin (Hanna, 1999); however, the process which leads to macrophage lysis is unclear (Pannifer et al., 2001). The importance of any interaction between EF and LF awaits clarification. The molecular pathogenesis of infection with *Bacillus anthracis* was reviewed by Little and Ivins (1999).

Bacillus cereus. *Bacillus cereus* is next in importance to *Bacillus anthracis* as a pathogen of humans (and other animals), causing food-borne illness and opportunistic infections, and its ubiquity ensures that cases are not uncommon. In relation to food-borne illness, *Bacillus cereus* is the etiological agent of two distinct food poisoning syndromes (Kramer and Gilbert, 1992): (i) the diarrheal-type, characterized by abdominal pain with diarrhea 8–16 h after ingestion of the contaminated food and associated with a diversity of foods from meats and vegetable dishes to pastas, desserts, cakes, sauces, and milk, and (ii) the

emetic-type characterized by nausea and vomiting 1–5 h after eating the offending food, predominantly oriental rice dishes, although occasionally other foods such as pasteurized cream, milk pudding, pastas, and reconstituted formulas have been implicated. One outbreak followed the mere handling of contaminated rice in a children's craft activity (Briley et al., 2001), and fulminant liver failure associated with the emetic toxin has been reported (Mahler et al., 1997). Both syndromes arise as a direct result of the fact that *Bacillus cereus* spores can survive normal cooking procedures. Under improper storage conditions after cooking, the spores germinate and the vegetative cells multiply. In diarrheal illness, the toxin(s) responsible are produced by organisms in the small intestine (infective doses 10⁴–10⁹ cells per gram of food), while the emetic toxin is preformed and ingested in food (about 10⁵–10⁸ cells per gram in order to produce sufficient toxin). Variations in infective dose of the diarrheal illness will reflect the proportion of ingested cells that are sporulated, and so can survive the acid barrier of the stomach. The capacity of the strain concerned to produce toxin(s) will, of course, influence the infective or intoxicating dose in both types of illness. It is likely that cases showing both diarrheal and emetic symptoms are caused by organisms producing both diarrheal and emetic toxins. Strains of *Bacillus thuringiensis*, which are close relatives of *Bacillus cereus*, may also produce the diarrheal toxin, and *Bacillus thuringiensis* has indeed been implicated in cases of gastroenteritis (Dangaard et al., 1997); strains of this species commonly carry genes for *Bacillus cereus* enterotoxins (Rivera et al., 2000) and Fletcher and Logan (1999) found that strains of both *Bacillus mycoides* and *Bacillus thuringiensis* were positive in commercial tests for enterotoxin and in a cytotoxicity assay. Cases of illness caused by *Bacillus thuringiensis* may have been diagnosed as caused by *Bacillus cereus*, as the former may not produce its characteristic insecticidal toxin crystals when incubated at 37 °C, owing to the loss of the plasmids carrying the toxin genes (Granum, 2002). The safety of using *Bacillus thuringiensis* as a biopesticide on crop plants has been reviewed by Bishop (2002); Bishop et al. (1999) found that the main pesticide strains that they assayed produced low titers of enterotoxin.

The toxigenic basis of *Bacillus cereus* food poisoning and other *Bacillus cereus* infections has begun to be elucidated, and a complex picture is emerging (Beecher, 2001; Granum, 2002). *Bacillus cereus* is known to produce six toxins, four of which are enterotoxins, and the emetic toxin. The enterotoxins are (i) Hemolysin BL (Hbl), a 3-component proteinaceous toxin which also has dermonecrotic and vascular permeability activities, and causes fluid accumulation in ligated rabbit ileal loops; Hbl is produced by about 60% of strains tested (Granum, 2002), and it has been suggested that is a primary virulence factor in *Bacillus cereus* diarrhea, but the mechanism of its enterotoxic activity is unclear (Granum, 2002); (ii) Non-hemolytic enterotoxin (Nhe) is another 3-component proteinaceous toxin which is produced by most strains tested (Granum, 2002), and whose components show some similarities to Hbl; (iii) and (iv) Enterotoxin T (BceT) and Enterotoxin FM (EntFM) are single-component proteinaceous toxins whose roles and characteristics are not known; also, Cytotoxin K (CytK) is similar to the β -toxin of *Clostridium perfringens* and was associated with a French outbreak of necrotic enteritis in which three people died (Lund et al., 2000). The genetics of toxin production are summarized by Granum (2002).

The emetic toxin, cereulide, is a dodecadepsipeptide comprising a ring of four amino- and/or oxy-acids: [D-O-Leu-D-Ala-L-O-Val-L-Val] thrice repeated; chemically speaking, it is closely related to the potassium ionophore valinomycin (Agata et al., 1994). It is resistant to heat, pH and proteolysis, but it is not antigenic (Kramer and Gilbert, 1989). Cereulide is probably an enzymically synthesized peptide rather than a direct genetic product; it is produced in larger amounts at lower incubation temperatures, its production does not appear to be connected with sporulation (Finlay et al., 2000), and it is produced in aerobic, and microaerobic, but not in anaerobic conditions (Finlay et al., 2002). Its mechanism of action is unknown, but it has been shown to stimulate the vagus afferent through binding to the 5-HT₃ receptor (Agata et al., 1995). The earliest detection system for emetic toxin involved monkey-feeding tests (Logan et al., 1979), but a semi-automated metabolic staining assay has now been developed (Finlay et al., 1999).

Bacillus cereus is also a destructive ocular pathogen. Endophthalmitis may follow penetrating trauma of the eye, intraocular surgery, or hematogenous spread, and it may evolve very rapidly. Loss both of vision and the eye is likely if appropriate treatment is instituted too late (Das et al., 2001; Davey and Tauber, 1987). *Bacillus cereus* keratitis associated with contact lens wear has also been reported (Pinna et al., 2001) Other *Bacillus cereus* infections occur mainly, though not exclusively, in persons predisposed by neoplastic disease, immunosuppression, alcoholism and other drug abuse, or some other underlying condition, and fatalities occasionally result. Reported conditions include bacteremia, septicemia, fulminant sepsis with hemolysis, meningitis, brain hemorrhage, ventricular shunt infections, infections associated with central venous catheters, endocarditis, pseudomembranous tracheobronchitis, pneumonia, empyema, pleurisy, lung abscess, brain abscess, osteomyelitis, salpingitis, urinary tract infection, dermatolymphangioadenitis associated with filarial lymphedema, and primary cutaneous infections. Wound infections, mostly in otherwise healthy persons, have been reported following surgery, road traffic and other accidents, scalds, burns, plaster fixation, drug injection (including a case associated with contaminated heroin; (Dancer et al., 2002) and close-range gunshot and nail bomb injuries; some became necrotic and gangrenous. A fatal inflammation was caused by a blank firearm injury; blank cartridge propellants are commonly contaminated with the organism (Rothschild and Leisenfeld, 1996). Neonates also appear to be particularly susceptible to *Bacillus cereus*, especially with umbilical stump infections; respiratory tract infections associated with contaminated ventilation systems have also occurred (Van Der Zwet et al., 2000). Other infections reported in neonates include intestinal perforation, meningoencephalitis, and bacteremia refractory to therapy. There have been reports of wound, burn, and ocular infections with *Bacillus thuringiensis* (Damgaard et al., 1997), but there is as yet no evidence of infections associated with the use of this organism as an insecticide.

Bacillus cereus also causes infections in domestic animals. It is a well-recognized agent of mastitis and abortion in cattle, and can cause these conditions in other livestock (Blowey and Edmondson, 1995).

Other species. Reports of infections with non-*Bacillus cereus* group species are comparatively rare, but very diverse (Berkeley and Logan, 1997; Logan, 1988), and there have been several hospital pseudoepidemics associated with contaminated blood

culture systems. *Bacillus licheniformis* has been reported from ventriculitis following the removal of a meningioma, cerebral abscess after penetrating orbital injury, septicemia following arteriography, bacteremia associated with indwelling central venous catheters (Blue et al., 1995), bacteremia during pregnancy with eclampsia and acute fibrinolysis, peritonitis in a CAPD patient and in a patient with volvulus and small-bowel perforation, ophthalmitis, and corneal ulcer after trauma. There have also been reports of L-form organisms, phenotypically similar to *Bacillus licheniformis*, occurring in blood and other body fluids of patients with arthritis, patients with neoplasms, clinically normal persons, and in association with infectious synovitis in birds (see *Cell morphology*, above). Although some authors have claimed a relationship between these organisms and diseases with postulated immunological elements, and higher isolations from the synovial fluids and membranes of arthritic patients have been reported, Bartlett and Bisset (1981) were unable to confirm the latter association. *Bacillus licheniformis* can cause food-borne diarrheal illness, and has been associated with an infant fatality (Mikkola et al., 2000). A toxin possibly associated with *Bacillus licheniformis* food poisoning has been identified (Mikkola et al., 2000), and toxigenic strains of *Bacillus pumilus* have been isolated in association with food-borne illness and from clinical and environmental specimens (Suominen et al., 2001). *Bacillus licheniformis* is frequently associated with bovine abortion and has been reproduced by experimental infection of cows, which demonstrated the tropism of the organism for the bovine placenta (Agerholm et al., 1997); this species has also been associated with abortion in water buffalo (Galiero and De Carlo, 1998), and is occasionally associated with bovine mastitis (Blowey and Edmondson, 1995). Many of these types of *Bacillus licheniformis* and *Bacillus cereus* infections are associated with wet and dirty conditions during winter housing, particularly when the animals lie in spilled silage (Blowey and Edmondson, 1995); in one outbreak, a water tank contaminated with *Bacillus licheniformis* was implicated (Parvanta, 2000).

The name *Bacillus subtilis* was often used to mean any aerobic, endospore-forming organism, but since 1970 there have been reports of infection in which identification of this species appears to have been made accurately. They include bacteremias associated with immunosuppression, surgical intervention, neoplastic disease, and trauma (de Boer and Diderichsen, 1991); other cases associated with neoplastic disease include: fatal pneumonia and bacteremia, a septicemia and an infection of a necrotic axillary tumour in breast cancer patients; breast prosthesis and ventriculo-atrial shunt infections; endocarditis in a drug abuser; meningitis following a head injury; cholangitis associated with kidney and liver disease; and isolations from dermatolymphangioadenitis associated with filarial lymphedema (Olszewski et al., 1999), and from surgical wound-drainage sites. *Bacillus subtilis* has also been associated with cases of bovine mastitis and of ovine abortion (Logan, 1988).

Bacillus subtilis has been implicated in food-borne illness: vomiting has been the commonest symptom, but with accompanying diarrhea frequently reported, the onset periods have been short (ranging from 10 min to 14 h; median 2.5 h), the bacterial loads of the organism were high (10^5 – 10^9 c.f.u./g), and the implicated foods were often prepared dishes in which meat or fish were served with cereal-based components such as bread, pastry, rice or stuffing (Kramer and Gilbert, 1989).

A probiotic preparation labeled as containing strains *Bacillus subtilis* led to a fatal septicemia in an immunocompromised patient (Oggioni et al., 1998); subsequently, the organisms concerned were identified as *Bacillus clausii* (Spinosa et al., 2000). These authors reported another *Bacillus clausii* infection, cholangitis in polycystic kidney disease in a 15-year-old French boy who had undergone renal transplant. The original authors (Wallet et al., 1996) had identified the organism as *Bacillus subtilis*; their patient had not been taking a probiotic preparation and the source of the infecting *Bacillus clausii* was unclear (Spinosa et al., 2000).

Organisms identified as *Bacillus circulans* have been isolated from cases of meningitis, a cerebrospinal fluid shunt infection, endocarditis, a wound infection in a cancer patient, a bite wound, and endophthalmitis (Tandon et al., 2001). Roy et al. (1997) reported epidemic endophthalmitis associated with isolates identified as *Bacillus circulans* that contaminated a product used during cataract surgery. It must be noted, however, that many isolates previously identified as *Bacillus circulans* might have been misallocated (see comments on *Bacillus circulans* in the *List of species*, below). *Bacillus coagulans* has been isolated from corneal infection, bacteremia and bovine abortion. *Bacillus pumilus* has been found in cases of pustule and rectal fistula infection, and in association with bovine mastitis. *Bacillus sphaericus* has been implicated in a fatal lung pseudotumour, and meningitis. Among 18 cancer patients with 24 bacteremic episodes, Banerjee et al. (1988) isolated *Bacillus cereus* (eight cases), *Bacillus circulans* (3), *Bacillus subtilis* (2), *Bacillus coagulans* (1), *Bacillus licheniformis* (1), *Bacillus pumilus* (1), *Bacillus sphaericus* (1) and six unidentified aerobic endospore-formers.

Fish. There have been several reports of *Bacillus* infections among farmed fish. *Bacillus mycoides* was isolated from necrotic muscular lesions in channel catfish (*Ictalurus punctatus*) during an epizootic in a commercial pond in Alabama, USA, and similar lesions could be reproduced by subcutaneous injection of the isolate (Goodwin et al., 1994). An unidentified aerobic endospore-former was associated with a septicemic condition affecting a variety of widely cultivated freshwater fish in Nigeria, and its etiological role was confirmed by reinfection trials (Oladosu et al., 1994). Ferguson et al. (2001) isolated an unidentified *Bacillus* from a severe multi-focal, necrotizing and granulomatous infection of the intensively reared catfish *Pangasius hypophthalmus* in the Mekong delta; the condition was reproduced experimentally, but subsequently the pathogenicity of this organism has not been demonstrable (M. Crumlish, personal communication).

Insect pathogens. *Bacillus thuringiensis* strains produce crystalline, proteinaceous, parasporal bodies within the sporangia (Figure 10h), and the insecticidal activities of many of these δ -endotoxins have made the organism (often referred to as Bt) one of the most widely produced and studied bacteria in biotechnology. The δ -endotoxins are produced as the organism begins to sporulate (in most cases; Sekar, 1988), and may represent up to 30% of sporangial dry weight by the completion of sporulation (Baum and Malvar, 1995). The δ -endotoxin genes are designated with the “cry” prefix to indicate that their product proteins are crystalline; they are nearly always located on large conjugative plasmids (Aronson, 1993), and transposons and insertion elements have been found associated with them.

During infection, plasmids may be transferred between strains by conjugation (Thomas et al., 2000). There are over 80 different classes and subclasses of Cry proteins, representing at least four distinct protein families, and they have their own nomenclatural system (Crickmore et al., 1998). Related proteins are produced by *Clostridium bifementans* (Barloy et al., 1996) and *Paenibacillus popilliae* (Zhang et al., 1997). Some strains of Bt which are active against Diptera produce structurally unrelated crystalline proteins known as Cyt toxins (Ellar, 1997). The full list of Cry and Cyt toxins is maintained at: http://www.biols.susx.ac.uk/Home/Neil_Crickmore/Bt/. An individual sporangium may carry a single type of insecticidal crystal protein, or several different types, comprising one or more parasporal bodies. Despite the name, the targets of insecticidal crystal proteins are not restricted to insects such as Lepidoptera (butterflies and moths), Coleoptera (beetles) and Diptera (flies); some mites, nematodes, flatworms and protozoa are also susceptible (Feitelson et al., 1992). The protein structure and mode of action of the δ -endotoxins remain subjects of intensive study, which has been reviewed by Ellar (1997), Schnepf et al. (1998) and Aronson and Shai (2001). The δ -endotoxins have three-domain structures (Groschulski et al., 1995; Li et al., 1991), with molecular masses usually of around 70 kDa or 130–140 kDa. Their phylogenetic relationships have been investigated by Bravo (1997). Domain I forms pores in susceptible gut epithelia, while Domain II has receptor-binding properties which influence the toxin's spectrum of activity (reviewed by Dean et al., 1996). Several roles have been suggested for Domain III; it is believed to play a part in receptor binding – perhaps an initial and reversible binding which is followed by an irreversible interaction mediated by Domain II (Lee et al., 1999b). An aminopeptidase N (Knight et al., 1994) and a cadherin-like glycoprotein (Vadlamudi et al., 1995; Vladmudi et al., 1995) have been identified as δ -endotoxin-binding proteins in insect larval gut epithelia.

The ingested protoxin dissolves in the alkaline midgut of a susceptible insect larva and undergoes proteolytic activation. Binding to the specific receptor on the brush-border cell is followed by insertion into the membrane to form a pore (Knowles, 1994) through which small molecules and ions can pass, so that water is taken up by osmosis and the cells swell and lyse (Ellar, 1997). It has been suggested that the concomitant fall in midgut pH is followed by spore germination and a fatal septicemia, while the micro-organism benefits from the nutrients so liberated (Ellar, 1990). With neutral or acidic guts, proteolytic nicking may allow protoxin solubilization (Carroll et al., 1997), and pore characteristics may vary with pH (Schwarz et al., 1993). The applications and development of Bt pesticides, and their safety, have been reviewed by Bishop (2002), while Van Rie (2002) has reviewed the development of transgenic crop plants.

Bacillus sphaericus has been divided into six taxa on the basis of DNA relatedness, supported by other molecular studies, and some strains belonging to group IIA (Rippere et al., 1997) are pathogenic to mosquitoes and have been exploited for biological control purposes. The parasporal crystal proteins synthesized by pathogenic strains of *Bacillus sphaericus* share no homology with those produced by *Bacillus thuringiensis* (Baumann et al., 1991; Charles et al., 1996; Porter et al., 1993). Early isolates, recovered in California, had mosquitocidal activities too low to be of practical use (Kellen et al., 1965), but further isolates,

strain numbers 1,593 from Indonesia, 2,362 from Nigeria and 2,297 from Sri Lanka, showed toxicities high enough to be of value in vector control programmes (reviewed by Baumann et al., 1991; Charles et al., 1996). These later, highly toxic, strains all produced parasporal toxin crystals which were absent from the earlier, poorly toxic, isolates. The crystals, although smaller than those seen in *Bacillus thuringiensis*, are visible by phase-contrast microscopy (Priest, 2002). Screening programmes around the world have yielded over 560 further mosquitocidal isolates, and these are held by the International Entomopathogenic *Bacillus* Centre at the Institute Pasteur, Paris. Toxicity for different species of mosquito vary: there is no activity against *Aedes aegypti*; other *Aedes* species are moderately susceptible; intermediate activity against *Anopheles* species has attracted interest for malaria control; high activity against *Culex quinquefasciatus* is used to combat Japanese encephalitis and filariasis (Priest, 2002). Insects other than mosquitoes, and mammals, are unaffected by the toxins.

In all cases, it is the mosquito larvae that are attacked. As they feed, they ingest the spore/crystal complex, and symptoms follow rapidly; the spores then germinate so that the organism can take advantage of the rich nutrient supply. The parasporal crystal produced by high-toxicity strains of *Bacillus sphaericus* lies within the exosporium and is a binary toxin (Bin) reminiscent of cholera and diphtheria toxins. Its *bin* genes are highly conserved, only four variants being known (Priest, 2002). When ingested by a mosquito larva the component polypeptides, BinA and BinB, dissolve in the alkaline conditions of the midgut; BinA is slowly reduced from 42 kDa to an active form of about 39 kDa by host proteases, while BinB is more rapidly reduced from 51 kDa to an active form of about 43 kDa (Aly et al., 1989; Broadwell and Baumann, 1987). The exact mechanism of toxicity is not clear, but it is known that BinB is responsible for specific binding while BinA effects channel formation (Priest, 2002). Following mitochondrial swelling, large vacuoles appear in cells of the gastric caecum and posterior midgut (Davidson, 1981), peristalsis stops, and the larvae may die within 6 h. The Mtx1 protein, which is formed within the vegetative cells, is responsible for the toxicity of some strains that lack parasporal crystals. This protein of about 100 kDa is broken into subunits of 27 kDa and 70 kDa which respectively resemble an ADP-ribosylating toxin and a glycoprotein-binding protein (Hazes and Read, 1995; Thanabalu et al., 1993). Although highly toxic to a wide range of mosquitoes, it is not highly expressed and is subject to proteolytic attack within the bacterium (Ahmed et al., 1995; Wati et al., 1997). Other mosquitocidal toxin genes include *mtx2* (Liu et al., 1996) and *mtx3* (Thanabalu and Porter, 1996), whose related products act by pore formation. As some isolates that lack all the toxins described above show weak pathogenicity, it is likely that further toxins await discovery (Priest, 2002).

Ecology. Most *Bacillus* species are saprophytes widely distributed in the natural environment, but some species are opportunistic or obligate pathogens of animals, including humans, other mammals, and insects. *Bacillus anthracis* is, to all intents and purposes, an obligate pathogen of animals and humans. The habitats of most species are soils of all kinds, ranging from acid through neutral to alkaline, hot to cold, and fertile to desert, and the water columns and bottom deposits of fresh and marine waters. Their endospores readily survive distribution in soils, dusts and aerosols from these natural environments to a

wide variety of other habitats, and Nicholson et al. (2000) has considered the roles of *Bacillus* spores in the natural environment. Some species appear to be ubiquitous contaminants of man, other animals, their foodstuffs, water and environments, natural, domestic, industrial and hospital. Their wide distribution is in part owing to the extraordinary longevity of their endospores, which show much greater resistance to physical and chemical agents, such as heat, cold, desiccation, radiation, disinfectants, antibiotics and other toxic agents, than their counterpart vegetative cells. Endospores are typically more resistant to heat than vegetative cells by a factor of 10^5 or more, while resistance to UV and ionizing radiation may be 100-fold or more. If protected from radiation, spores may survive for very long periods. Striking claims include the isolation of a viable strain of *Bacillus sphaericus* from an extinct bee preserved in 25- to 40-million-year-old amber (Cano and Borucki, 1995), and the recovery of an aerobic endospore-former related to *Salibacillus* and *Virgibacillus* from a water droplet trapped in a Permian salt crystal for an estimated 250 million years (Vreeland et al., 2000); the latter report has been contested on account of the apparent modernity of its DNA (Graur and Pupko, 2001; Nickle et al., 2002), and both isolations need to be confirmed by independent laboratories. *Bacillus infernus* was isolated from Triassic shales, lying at depths of around 2.7 km below the land surface, that may have been hydrologically isolated for 140 million years, and although they have not been demonstrated for this organism, endospores are likely to have contributed to its survival (Boone et al., 1995). Another organism from a deep subsurface environment is *Bacillus subterraneus*, which was isolated from the Great Artesian Basin of Australia, a thermal aquifer up to 2 km deep (Kanso et al., 2002); spores have not been demonstrated for this species either.

The commonly isolated species, such as *Bacillus subtilis* and *Bacillus cereus* are very widely distributed worldwide; *Bacillus thuringiensis* has been isolated from all continents, including Antarctica (Forsyth and Logan, 2000); as well as being a common organism in the natural environment and foods, *Bacillus cereus* frequently contaminates domestic kitchen environments (Beumer and Kusumaningrum, 2003). In studies of indoor and outdoor air and dusts, *Bacillus* species commonly dominate the cultivable flora or form a large part of it (Aldagal and Fung, 1993; Andersson et al., 1999b; Dutkiewicz et al., 2001; Marafie and Ashkanani, 1991; Schaffer and Lighthart, 1997; Venkateswaran et al., 2001), and honeybees have been found to scavenge airborne spores electrostatically (Lighthart et al., 2000). The presence of *Bacillus fumarioli* strains showing similar phenotypic behavior and substantial genotypic similarity from Candlemas Island in the South Sandwich archipelago and from volcanoes some 5600 km distant on continental Antarctica, is most convincingly explained by their carriage in the air as free spores or spores attached to plant propagules, as no birds are known to visit the latter sites (Logan et al., 2000). Strains indistinguishable from these Antarctic isolates have been cultivated from gelatin production plants in Belgium, France and the USA (De Clerck et al., 2004a).

Bacillus species are often isolated following heat treatment of specimens in order to select for spores, and presence of spores in a particular environment does not necessarily indicate that the organism is metabolically active there; however, it is reasonable to assume that large numbers of endospores in a given environment

reflects former or current activity of vegetative *Bacillus* cells there. Indeed, the ease with which strains of a close relative of *Bacillus pumilus* and strains of *Bacillus thuringiensis* have been isolated from pristine environments along the Victoria Land coast of Antarctica (Forsyth and Logan, 2000; and unpublished observations) cannot easily be explained as widespread and chance contamination with endospores from another source; the organisms almost certainly undergo some multiplication in those environments. *Bacillus fumarioli* was found as both spores and vegetative cells at geothermal sites in Antarctica where soil temperatures ranged from 3.4°C to 62.5°C; the proportions of sporulated cells tended to be higher at the temperature extremes and lower at temperatures approaching the optimum growth temperature (50°C) of the organism (Logan et al., 2000). Isolation of organisms showing special adaptations to the environments in which they are found, such as acidophily, alkaliphily, halophily, psychrophily, and thermophily, suggests that these organisms must be metabolically active in these niches, but it tells us little about the importances of their roles in the ecosystems, and nothing about their interactions with other members of the flora. *Bacillus thermantarcticus*, which warrants transfer to *Geobacillus* (see *Species Incertae Sedis*, below), was also found in the geothermal soil of Cryptogam Ridge, Mount Melbourne, Antarctica (Nicolaus et al., 1996), a site from which *Bacillus fumarioli* was isolated (Logan et al., 2000).

Many *Bacillus* species will degrade biopolymers, with versatilities varying according to species, and it is therefore assumed that they have important roles in the biological cycling of carbon and nitrogen; it is further assumed that their activities in food spoilage and biodegradation reflect the contamination of these materials by endospores derived from dusts and other vehicles. Valid though these assumptions may be, the ever-increasing diversity of known *Bacillus* species and their apparent primary habitats implies that such generalizations may deserve reconsideration in some cases, and that certain species may have quite specialized activities.

Habitats. Although isolates of many of the established species have been derived from soil, or from environments that may have been contaminated directly or indirectly by soil, the range of isolation sources is very wide, and includes, in addition to temperate, acidic, neutral and alkaline soils, fresh and marine waters, foods and clinical specimens: air (*Bacillus carboniphilus*), arsenic-rich sediments (*Bacillus arseniciselenatis*, *Bacillus selenitireducens*) and arsenic-contaminated mud and water (*Bacillus indicus*, *Bacillus macyae*), bauxite-processing waste (*Bacillus vedderi*), brine (*Bacillus haloalkaliphilus*), compost (*Bacillus circulans*, *Bacillus coagulans*, *Bacillus licheniformis*, *Bacillus sphaericus*, *Bacillus subtilis*), emperor moth caterpillars ("phane"; *Bacillus cereus*, *Bacillus circulans*, *Bacillus licheniformis*, *Bacillus megaterium*, *Bacillus mycoides*, *Bacillus pumilus*, *Bacillus subtilis*), feathers (*Bacillus cereus*, *Bacillus licheniformis*, *Bacillus pumilus*, *Bacillus subtilis*), feces (*Bacillus alkalophilus*, *Bacillus badius*, *Bacillus cohnii*, *Bacillus flexus*, *Bacillus halodurans*, *Bacillus megaterium*, *Bacillus pseudofirmus*), geothermally heated soils (*Bacillus fumarioli*, *Bacillus luciferensis*, *Bacillus schlegelii*), honey bee and greater wax moth frass (*Bacillus cereus*, *Bacillus megaterium*, *Bacillus sphaericus*), inner tissues of plants (*Bacillus amyloliquefaciens*, *Bacillus cereus*, *Bacillus endophyticus*, *Bacillus insolitus*, *Bacillus licheniformis*, *Bacillus megaterium*, *Bacillus pumilus*, *Bacillus subtilis*), invertebrates (*Bacillus oleronius*, *Bacillus sphaericus*, *Bacillus*

thuringiensis), leather (*Bacillus cereus*, *Bacillus firmus*, *Bacillus licheniformis*, *Bacillus megaterium*, *Bacillus pumilus*, *Bacillus sphaericus*, *Bacillus subtilis*), milk (*Bacillus cereus*, *Bacillus coagulans*, *Bacillus licheniformis*, *Bacillus smithii*, *Bacillus sporothermodurans*, *Bacillus weihenstephanensis*), naturally heated waters (*Bacillus methanolicus*, *Bacillus okuhidensis*), poultry litter and manure (*Bacillus cereus*, *Bacillus fastidiosus*, *Bacillus halodurans*, *Bacillus pumilus*, *Bacillus subtilis*), paper and paperboard (*Bacillus amyloliquefaciens*, *Bacillus cereus*, *Bacillus circulans*, *Bacillus coagulans*, *Bacillus firmus*, *Bacillus flexus*, *Bacillus halodurans*, *Bacillus licheniformis*, *Bacillus megaterium*, *Bacillus mycoides*, *Bacillus pumilus*, *Bacillus sphaericus*, *Bacillus subtilis*, *Bacillus thuringiensis*), recycled paper pulp (*Bacillus pumilus*), seaweed (*Bacillus algicola*), saline and hypersaline environments (*Bacillus alcalophilus*, *Bacillus firmus*, *Bacillus halodenitrificans*, *Bacillus halophilus*, *Bacillus megaterium*), sewage and wastewater treatment processes (*Bacillus funiculus*, *Bacillus thermocloacae*), sheep fleece (*Bacillus cereus*, *Bacillus thuringiensis*), silage (*Bacillus coagulans*, *Bacillus soralis*), soda lakes (*Bacillus agaradhaerens*, *Bacillus cohnii*, *Bacillus pseudofirmus*, *Bacillus vedderi*), solfatara (*Bacillus tusciae*), gemstones (*Bacillus badius*, *Bacillus cereus*, *Bacillus circulans*, *Bacillus coagulans*, *Bacillus firmus*, *Bacillus lentus*, *Bacillus licheniformis*, *Bacillus mycoides*, *Bacillus subtilis*; Khan et al., 2001), stone surfaces of ancient monuments (*Bacillus licheniformis*, *Bacillus megaterium*, *Bacillus mycoides*, *Bacillus subtilis*; Turtura et al., 2000), subterranean soil and water (*Bacillus infernus*, *Bacillus subterraneus*), and wall paintings (*Bacillus decolorationis*, Heyrman et al., 2003a; *Bacillus barbaricus*, Taubel et al., 2003).

Most species of *Bacillus* are heterotrophic organisms that have been isolated on complex organic media. Relatively few attempts have been made to isolate aerobic endospore-formers which can utilize inorganic sources of carbon and energy, or to demonstrate that established heterotrophic species are capable of facultative autotrophy. The two thermophiles *Bacillus schlegelii* and *Bacillus tusciae* remain the only species in the genus shown to be facultatively chemolithoautotrophic. Nitrogen fixation is well established for certain species in *Paenibacillus* (*Paenibacillus azotofixans*, *Paenibacillus macerans*, *Paenibacillus polymyxa*), but less is known about *Bacillus* species utilizing atmospheric nitrogen; although *Bacillus edaphicus* and *Bacillus mucilaginosus* were isolated on nitrogen-free media, these species are actually members of *Paenibacillus* (see *Species Incertae Sedis*, below). However, several studies have demonstrated nitrogen fixation by strains of *Bacillus cereus*, *Bacillus licheniformis*, *Bacillus megaterium*, *Bacillus sphaericus*, and unidentified strains (some of which may have been *Paenibacillus* species) isolated from rhizospheres and phylloplanes, and from endophytic sites and mycorrhizae (Rózycki et al., 1999). A comparative phylogenetic study, however, concluded that nitrogen fixation among aerobic endospore-formers is restricted to certain species of *Paenibacillus* (Achouak et al., 1999). Nitrogen-fixing *Bacillus* and *Paenibacillus* growing in the rhizosphere may help to promote plant growth; other ways in which aerobic endospore-formers may promote the growth of plants include (Chanway, 2002): the production of phytohormones, increasing nutrient availability (to the plant or to other, nitrogen-fixing, bacteria; Zlotnikov et al., 2001), the suppression of ethylene production by the plant in its rhizosphere, interactions with symbiotic bacteria and fungi (Medina et al., 2003), enhancement of root nodulation, and biological control of plant pathogens by various mechanisms including

the production of antibiotics. In one study, *Bacillus subtilis* and *Bacillus mycoides* were found to dominate the rhizosphere of tea bushes (Pandey and Palni, 1997), a strain of the latter species having antifungal activity. Epiphytic *Bacillus* strains can have protective roles in the phyllosphere (Collins and Jacobsen, 2003; Jock et al., 2002). Representatives of several species, including *Bacillus amyloliquefaciens*, *Bacillus cereus*, *Bacillus endophyticus*, *Bacillus insolitus*, *Bacillus licheniformis*, *Bacillus megaterium*, *Bacillus pumilus* and *Bacillus subtilis*, have been isolated from the inner tissues of healthy plants, including cotton, grape, pea, spruce and sweet corn, and some strains appear to have important roles in growth promotion and plant protection (Reva et al., 2002). These endophytes and epiphytes can have potential as agents for the biocontrol of plant diseases, and their spores offer advantages in the formulation of such preparations (Emmert and Handelsman, 1999). Hosford (1982) and Leary et al. (1986), on the other hand, reported *Bacillus* species showing pathogenicity for plants.

Bacillus species are known to have roles in the postharvest processing and flavor development of cocoa (Schwan et al., 1995), coffee (Silva et al., 2000), tobacco (English et al., 1967) and vanilla (Röling et al., 2001), in the production of natural fibers and other vegetable products, in several traditional fermented foods based on leaves and seeds (and poultry eggs) (often dominated by *Bacillus subtilis*; Wang and Fung, 1996; Beaumont, 2002; Sarkar et al., 2002), and in composting (Blanc et al., 1999; Strom, 1985).

Bacillus species may cause deterioration of hides intended for leather production (Birbir and Ilgaz, 1996). Keratinolytic strains of *Bacillus cereus*, *Bacillus licheniformis*, *Bacillus pumilus*, *Bacillus subtilis* and of unidentified *Bacillus* species have roles in the degradation of feathers in poultry waste and may be found in the plumage of many bird species (Burt and Ichida, 1999; Kim et al., 2001). *Bacillus* species also play a part in the degradation of chitin. This activity has been demonstrated for strains of *Bacillus circulans*, *Bacillus coagulans*, *Bacillus lentus*, *Bacillus licheniformis*, *Bacillus megaterium*, *Bacillus pumilus* and *Bacillus thuringiensis* (Clements et al., 2002), and strains of *Bacillus amyloliquefaciens*, *Bacillus cereus*, *Bacillus megaterium*, *Bacillus sphaericus* and *Bacillus subtilis* which utilize the chitin in crustacean wastes have been isolated (Sabry, 1992; Wang and Hwang, 2001). The value of chitinolysis to insect-pathogenic strains of *Bacillus thuringiensis* is evident, and an exochitinase from a strain of "*B. thuringiensis* subsp. *pakistanii*" was found to be toxic to *Aedes aegypti* larvae (Thanthiankul et al., 2002). Chitinases from a soil isolate of *Bacillus amyloliquefaciens* have been found to have antifungal properties (Wang et al., 2002). (The two species *Bacillus chitinolyticus* and *Bacillus himensis*, which were isolated using a chitin medium, are members of *Paenibacillus*).

Strains of several *Bacillus* species have been found to accumulate metal ions non-enzymically by adsorption to their cell surfaces and this can be of importance in waste treatment and natural environments: *Bacillus licheniformis* cells can accumulate cerium, cobalt and copper ions from aqueous and simulated waste solutions (Hafez et al., 2002), *Bacillus subtilis* may accumulate aluminum, cadmium, iron and zinc, and aluminosilicates (Urrutia and Beveridge, 1995), and an unidentified *Bacillus* strain bound chromium, copper and lead ions (Nourbakhsh et al., 2002). *Bacillus megaterium* biomass was found to bioreduce ions of the precious metals gold, palladium, platinum, rhodium

and silver (Lin et al., 2001). *Bacillus arseniciselenatis* and *Bacillus selenitireducens* can use oxyanions of the two highly toxic elements arsenic and selenium as terminal electron acceptors in anaerobic respiration, and the environmental impact of such activity is becoming appreciated (Stolz and Oremland, 1999).

The trichome-forming bacteria "*Anisomitus*", "*Arthromitus*", "*Entomitus*", "*Coleomitus*", "*Metabacterium*", and "*Sporospirillum*", which occur in the alimentary tracts of animals, and which have been reported to form endospores, were listed as *Genera Incertae Sedis* in the First Edition of this *Manual* (Claus and Berkeley, 1986). Since that time, molecular methods have allowed considerable progress to be made in the taxonomy of some of these organisms. A cultivable "*Arthromitus*" strain from sow bug or wood louse (*Porcellio scaber*) has been identified as *Bacillus cereus*, and similar organisms have been isolated from moths, roaches and termites (Jorgensen et al., 1997; Margulis et al., 1998). *Bacillus oleronius* was first isolated from the hindgut of the termite *Reticulitermes santonensis*, and cellulolytic strains of the *Bacillus cereus* group and *Bacillus megaterium* have been found in the gut of another termite, *Zootermopsis angusticollis* (Wenzel et al., 2002). An "*Arthromitus*"-like endospore has been reported from a Miocene termite preserved in amber (Wier et al., 2002). On the other hand, several nonculturable, segmented, filamentous bacteria from chickens, mice, rats and trout have been shown to represent a distinct subline of the *Clostridium* subphylum, which has been proposed as "*Candidatus Arthromitus*" (Snel et al., 1995; Urdaci et al., 2001). Strains of "*Metabacterium polyspora*" from guinea pig cecum are closely related to the extremely large, viviparous, intestinal symbionts of the surgeonfish, *Epulopiscium* species, and also belong to the *Clostridium* subphylum (Angert et al., 1996).

Cellular fatty acids. This approach was recently reviewed by Kämpfer (2002). On the basis of the fatty acid compositions of 19 *Bacillus sensu lato* species Kaneda (1977) recognized six groups (A-F). All except group D were found to contain major amounts of branched chain acids, while within groups A-C only insignificant amounts (<3%) of unsaturated fatty acids were found; these latter three groups could be separated on the basis of their predominant fatty acids. Group A contained species now allocated to *Bacillus* (*Bacillus circulans*, *Bacillus licheniformis*, *Bacillus megaterium*, *Bacillus pumilus* and *Bacillus subtilis*), *Brevibacillus* and *Paenibacillus* and contained C_{14:0 anteiso} (26–60%) and C_{15:0 iso} (13–30%) acids, with chain lengths of 14–17. Among group B strains, now all allocated to *Paenibacillus*, C_{15:0 anteiso} acid predominated (39–62%), with chain lengths between 14 and 17. In group C species, now accommodated in *Geobacillus*, C_{15:0 iso} acid was predominant. In group D, now *Alicyclobacillus*, a unique fatty acid pattern with up to 70% cyclohexane fatty acids of chain length 17–19 was found. Group E comprised members of the *Bacillus cereus* group of species which, unlike the other groups, always had small proportions (7–12%) of unsaturated fatty acids present; the predominant fatty acids (19–21%) were of the C_{15:0 iso} type. The psychrophiles *Bacillus* (now *Sporosarcina*) *globosporus* and *Bacillus insolitus* formed group F and contained large proportions (17–28%) of unsaturated fatty acids, and the predominant branched-chain fatty acids in these two species were C_{15:0 anteiso} acids. The work of Kaneda was largely confirmed, and was supplemented, by the comprehensive study of Kämpfer (1994). For many species of *Bacillus sensu stricto* (but excluding *Bacillusadius*, the *Bacillus cereus* group, *Bacillus circulans*,

Bacillus coagulans, *Bacillus simplex* and *Bacillus smithii*) profiles (with ranges as percentage of total given in parentheses) were $C_{15:0 \text{ anteiso}}$ (25–66%), $C_{15:0 \text{ iso}}$ (22–47%), and $C_{17:0 \text{ anteiso}}$ (2–12%). For the *Bacillus cereus* group (*Bacillus anthracis*, *Bacillus cereus*, *Bacillus mycoides*, *Bacillus pseudomycooides*, *B. thuringiensis*), levels of $C_{15:0 \text{ anteiso}}$ were lower (3–7%), and amounts of unsaturated fatty acids were generally higher (> 10%). *Bacillus smithii* and *Bacillus coagulans* showed higher amounts of $C_{17:0 \text{ anteiso}}$ (17–42%) and lower amounts of $C_{15:0 \text{ anteiso}}$ and $C_{15:0 \text{ iso}}$, and they also form a separate lineage within the *Bacillus* rRNA group. Other findings were low amounts of $C_{15:0 \text{ anteiso}}$ (<10%) and relatively high amounts of unsaturated acids in *Bacillus badius*, and very low amounts of $C_{15:0 \text{ iso}}$ in *Bacillus circulans*. These results indicated that the *Bacillus* rRNA group is still heterogeneous, and it was predicted that further taxonomic rearrangements would follow (Kämpfer, 2002).

With the division of *Bacillus sensu lato* into several phylogenetically distinct genera, the re-evaluation of the ability of fatty acid data to differentiate taxa has become possible. Numerical analyses of fatty acid data have shown that, in terms of level of taxonomic resolution, profiles vary largely within the species (Kämpfer, 1994). Although *Bacillus* species often cannot be differentiated by fatty acid analysis, especially in cases when large numbers of strains are examined, distinction of individual species, or even subspecies in certain cases, can be possible if small numbers of strains are studied (because possible intraspecific variation is not detected and hence cannot influence the interpretation of the results), or if genomically well-characterized groups of strains such as *Bacillus cereus* and its relatives are being investigated. Thus, given highly standardized growth conditions to achieve reproducible results, and a reliable database containing information on genomically homogeneous strains, fatty acid patterns can be used for *Bacillus* species identification. Also, whole-cell fatty acid analysis is valuable as a rapid and fairly inexpensive screening and identification method as part of polyphasic taxonomic studies (Kämpfer, 2002).

A GLC system developed for the identification of bacteria and yeasts by fatty acid methyl ester (FAME) analysis is marketed as the Microbial Identification System (MIDI, Newark, DE, USA). It requires highly standardized cultivation and extraction procedures and provides a species-specific fatty acid database. Fatty acid peaks can be named by comparing retention times with those of a known mixture, but definitive identification can be made only by mass spectrometry. Species identification within *Bacillus* is not always possible by this approach, and additional phenotypic and/or genotypic characterization is often necessary (Kämpfer, 2002).

Sodium-Dodecylsulfate-Polyacrylamide Gel Electrophoresis (SDS-PAGE) of whole-cell proteins. Whole-cell protein patterning (SDS-PAGE) is a rapid and cost-effective method for the comparison of large groups of bacteria, and is a valuable initial step in polyphasic characterization. It requires highly standardized conditions of growth, combined with a rigorously standardized procedure for analysis, and normalization of the data for computer-assisted comparison of the results. Normalization between different electrophoretic runs can be achieved by the inclusion of a carefully chosen bacterial pattern in which a protein extract of a standard organism is loaded into the outer lanes and the central lane of the gel. If a molecular mass marker is loaded as well, the molecular mass of the protein

bands can be estimated easily. This method was reviewed by De Vos (2002). It has made important contributions to polyphasic taxonomic studies within *Bacillus* (De Clerck and De Vos, 2002) and to the recognition of novel *Bacillus* species such as *Bacillus fumarioli*, *Bacillus luciferensis* and *Bacillus shackletonii* (Logan et al., 2000, 2002b, 2004b).

Whole-cell spectrometric analysis. A variety of instrument-based physico-chemical techniques for whole-cell analysis, including pyrolysis mass spectrometry (PyMS), matrix-assisted laser desorption-ionization time-of-flight mass spectrometry (MALDI-TOF-MS) and Fourier transform infrared spectrometry (FT-IR), have been applied to *Bacillus*. These “fingerprinting” methods require expensive instruments and complex data handling, but offer simple sample preparation, speed of analysis, high throughput, and low processing costs, and they yield data that can discriminate at genus, species and strain level. They can be valuable in polyphasic taxonomic studies, but better long-term reproducibility of spectra is required for the building of databases for routine identification applications. These approaches are reviewed by Magee and Goodacre (2002).

Bacteriophage. The potential for phage typing of *Bacillus* species has been little investigated. The γ phage has long been used as a specific test for identifying *Bacillus anthracis*, but preparations of this phage are not widely available, and the specific molecular tests for this species now exist. Ackermann et al. (1995) developed phage typing schemes for *Bacillus subtilis* and *Bacillus thuringiensis*. They examined 200 *Bacillus subtilis* strains and were able to distinguish 29 phagovars using 10 phages; with 500 strains of *Bacillus thuringiensis*, 10 phages allowed the recognition of 25 phagovars, but the phagovars showed no correlation with H-serovars. Pantasicaldas et al. (1992) investigated the population dynamics of *Bacillus subtilis* and its phages in soil.

Enrichment and isolation procedures

Detection of *Bacillus* strains by cultivation and isolation relies mainly upon resistance of their endospores to heat (and to other conditions) which are lethal to vegetative cells of most kinds of bacteria. Only endospores and extremely thermophilic, non-spore-forming bacteria are able to survive the heat treatment, so that subsequent aerobic culture at lower temperatures yields only isolates germinating from the surviving spores. Such an approach may also heat-activate the spores and so enhance their germination. However, an obvious disadvantage is that vegetative cells of *Bacillus* will be lost along with the other, non-spore-forming bacteria; as a result, it will not be known whether the isolation of a *Bacillus* strain from a particular habitat reflects its multiplication in and colonization of that niche, or mere survival of a dormant, contaminant spore. Furthermore, spores formed in natural environments may have heat sensitivities that are different to those formed in laboratory cultures, spores may be present in very small numbers or even absent, and heat treatment may be mutagenic. It is therefore valuable to reserve part of the specimen or sample for cultivation from an unheated control preparation for study in parallel with the heat-treated sample. With many environments this will allow isolates arising from vegetative cells to be obtained – problems of heavy bacterial load can, of course, be addressed by dilution of the sample. Repeated and consistent isolations of similar strains from heat-treated samples taken from pristine or sparsely populated

environments would suggest that the organisms must be colonizing the habitat rather than just be reflecting heavy contamination, and it seems likely that populations of *Bacillus* strains in many habitats will exist as both vegetative and sporulated cells (see the comments on *Bacillus fumarioli* in the *Ecology* section of *Further descriptive information*, above). Notwithstanding this, it is clear that spores may be carried for long distances by water or the air, and locally large numbers of spores may be regularly deposited in sites that are apparently unsuitable for their germination and continued development; it is well known, for example, that thermophilic endospore-formers may easily be isolated from cold environments (Marchant et al., 2002).

Heat treatment may vary from 60 °C to 80 °C for 10 min or longer; 80 °C for 10 min is widely used. The given time allows for a period of heat penetration of the sample followed by a sufficient holding period at temperature; this assumes that the specimen is in an aqueous suspension in a water bath, and is adequately immersed. Solid samples may be emulsified in sterile, deionized water, 1:2 (w/v) prior to heating; the unheated control is prepared in the same way, but is unheated, or else the suspension intended for heating may be sampled for cultivation prior to heating. Direct plate cultures are made on appropriate solid media by spreading up to 250 µl volumes from undiluted, and 10-, 100- and 1000-fold dilutions of the treated sample.

Enrichment culture of samples from habitats expected to be sparsely populated with bacteria can be done by heat-treating suspensions in a suitable broth medium (perhaps 1–5 g of soil in 10 ml broth, for example), then incubating them and streak-diluting onto solid media as soon as they show signs of turbidity, with further subcultures from the reincubated broths being made at intervals thereafter. This approach, using different incubation temperatures and a range of pH, and with paired cultures from samples that had not been subjected to heat treatment, yielded a variety of isolates from pristine soils (Logan et al., 2000). Broths for particular kinds of organisms (nitrogen-free broths – in flasks so as to give a large broth surface/air interface – to isolate nitrogen fixers, for example) can be made selective or elective as desired.

Using a disinfectant to inactivate vegetative cells is for most such agents constrained by the difficulty of removing or neutralizing the agent prior to cultivation. Ethanol, however, may easily be removed by evaporation, and it does not have the potentially mutagenic effect of heat treatment. Filter-sterilized 95–100% ethanol is added to a final concentration of 1:1 (v/v) and held for 30–60 min at room temperature. The ethanol must first be filter-sterilized, because some commercial batches may be contaminated with spores.

For soil and certain other kinds of samples, desiccation by air drying will destroy many vegetative cells, but inactivation of cyst-forming bacteria such as *Azotobacter* may require an extended period of drying.

Although useful for the detection and isolation of well-represented species, the approaches outlined above are rather crude for the isolation of organisms present only in relatively small numbers, and for the slow-growing, less vigorous types. Methods that have been described for the isolation of individual species are outlined below. For isolation of species from clinical cases, most strains will survive carriage in freshly collected specimens or in a standard transport medium (for safety concerning

Bacillus anthracis, see below); heat treatment is not appropriate for fresh clinical specimens, where spores are usually sparse or absent. All the clinically significant isolates reported to date are of species that grow, and often sporulate, on routine laboratory media at 37 °C. It seems unlikely that many clinically important, but more fastidious, strains are being missed for the want of special collection, media or growth conditions.

Safety. With the exception of *Bacillus anthracis*, species of aerobic endospore-forming bacteria that may be isolated from clinical specimens can be handled safely on the open bench, and no special precautions are required for specimen collection. Isolation and presumptive identification of *Bacillus anthracis* can be performed safely in the routine clinical microbiology laboratory, provided that normal good laboratory practice is observed; vaccination is not required for minimal handling of the organism. If aerosols are likely to be generated, the work should be performed in a safety cabinet. Anthrax is not highly contagious; cutaneous anthrax is readily treated and is only life-threatening in exceptional cases, and the infectious doses in the human inhalation and intestinal forms (also treatable if recognized) are generally very high ($LD_{50} > 10,000$ spores). Precautions, therefore, need to be sensible, not extreme. When collecting specimens related to suspected anthrax, disposable gloves, disposable apron or overalls, and boots which can be disinfected after use should be worn; for dusty samples that might contain many spores, the use of head-gear and dust masks should be considered. Discard disposable items into suitable containers for autoclaving followed by incineration. Non-autoclavable items should be immersed overnight in 10% formalin (5% formaldehyde solution). Glutaraldehyde (5%) is also effective. Items that cannot be immersed should be bagged and sent for formaldehyde fumigation. Ethylene oxide and hydrogen peroxide vapor are also effective fumigants, but the latter is inappropriate if organic matter is being treated. The best disinfectant for specimen spillages is again formalin; where this is considered impractical, 10% hypochlorite solution can be used, although its limitations should be appreciated; it is rapidly neutralized by organic matter, and it corrodes metals. Other strong oxidizing agents, such as hydrogen peroxide (5%) and peracetic acid (1%) are also effective but with the same organic matter limitations. Specimen collection and handling from humans and animals is described by Logan and Turnbull (2003), Logan et al. (2007) and Turnbull et al. (1998); non-clinical materials associated with attempts at deliberate release of the organism as a weapon may be very hazardous and no attempt to sample or process them should be made without the appropriate instructions from the correct authorities.

Bacillus aeolius was isolated from a 45 °C water sample collected from a shallow (15 m depth) marine hot spring, by aerobic enrichment in marine broth at 65 °C for 3 d, followed by plating on marine agar (Gugliandolo et al., 2003a).

Bacillus agaradhaerens, *Bacillus alcalophilus* and other alkaliphiles. These may be isolated by direct plating of heat-treated samples onto alkaline nutrient media, or by enrichment for 1 or more days in alkaline liquid nutrient media, with shaking, at the chosen incubation temperature, followed by plating. Media may be adjusted to a pH between 8.6 and 11.0, by using sodium hydrogen carbonate, sodium carbonate, sodium sesquicarbonate, trisodium phosphate or sodium perborate. A modification (Grant and Tindall, 1980) of the widely used medium of

Horikoshi (1971) is: glucose, 10.0 g; peptone, 5.0 g; yeast extract, 5.0 g; KH_2PO_4 , 1.0 g; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.2 g; distilled water 900 ml. Agar is added at the recommended concentration if a solid medium is required. After autoclaving, 100 ml of 20% (w/v) $\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$, which has been sterilized by autoclaving separately, is added (at 60 °C if the medium contains agar); the final pH of the medium is 10.5, and the concentration of the Na_2CO_3 solution can be reduced to give lower pH values. Other carbon sources, such as starch, may be substituted for the glucose. Most alkaliphilic *Bacillus* species require Na^+ ions for growth, germination and sporulation (Horikoshi, 1998). Optimal growth of *Bacillus agaradhaerens* is at pH 10.0 or above, no growth occurs at pH 7.0, and up to 16% NaCl is tolerated; optimal growth of *Bacillus alcalophilus* is about pH 10.0, no growth occurs at pH 7.0, and 5–8% NaCl is tolerated (Nielsen et al., 1995a).

Bacillus algicola was isolated from 5 g seaweed allowed to decay in 200 ml sterilized natural sea water for 2 months at 22 °C, supplemented with and aqueous ethanol extract of a protein inhibitor of endo(1→3)- β -D-glucanases (Yermakova et al., 2002). 0.1 ml of suspension was then plated onto plates of Marine Agar 2216 (Difco) and on plates of medium B (peptone, 2.0 g; casein hydrolysate, 2.0 g; yeast extract, 1.0 g; glucose, 1.0 g; KH_2PO_4 , 0.02 g; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.05 g; agar, 15 g; natural sea water, 500 ml; distilled water at pH 7.5–7.8, 500 ml), which was also used as the maintenance medium.

Bacillus amyloliquefaciens. This organism has been isolated from a wide range of environments, including industrial amylase fermentations, foods and soil. It is phenotypically similar to *Bacillus subtilis*. Welker and Campbell (1967) isolated strains of this organism from commercial α -amylase concentrates as follows: 1 ml or 0.5 g of α -amylase concentrate is placed in a tube containing 5 ml of sterile distilled water and heated at 80 °C for 10 min.; the heated suspension is then streaked onto plates of tryptose blood agar base containing 1% starch; after incubation at 37 °C for 18–20 h, colonies showing wide haloes of starch hydrolysis are purified by restreaking on fresh plates of the same medium. The screening method of Effio et al. (2000), which uses dye-linked starch to reveal colonies of amylolytic bacteria, may also be of value.

Bacillus anthracis. For isolation of this organism from old carcasses, animal products or environmental specimens, the organisms will mostly be present as spores. The heat treatment recommended for isolating this species is 62.5 °C for 15 min; this will both heat-shock the spores to enhance germination, and effectively destroy nonspore-forming contaminants [solid samples should first be emulsified in sterile, deionized water, 1:2 (w/v)]. Direct plate cultures are made on blood, nutrient, or, selective agars, as appropriate, by spreading up to 250 μl volumes from undiluted, and 10- and 100-fold dilutions of the treated sample. There is no effective enrichment method for *Bacillus anthracis* in old animal specimens or environmental samples; isolation from these is best done with polymyxin-lysozyme EDTA-thallos acetate (PLET) agar (Knisely, 1966). Aliquots (250 μl) of the undiluted and 1:10 and 1:100 dilutions of heat-treated suspension of the specimen are spread across PLET plates which are read after incubation for 36–40 h at 37 °C. Roughly circular, creamy-white colonies, 1–3 mm diameter, with a ground-glass texture must be distinguished from those of other members of the *Bacillus cereus* group; they are subcultured on (i), blood agar plates to test for γ phage and penicillin susceptibility, and for

hemolysis, and (ii), directly or subsequently in blood to look for capsule production using M'Fadyean's stain. PCR-based methods are being used increasingly for confirming the identity of isolates (Turnbull et al., 1998).

Bacillus aquimaris and *Bacillus marisflavi* were isolated from sea water of a tidal flat by dilution plating onto marine agar (Yoon et al., 2003a).

Bacillus arseniciselenatis. The only reported isolate of this organism was isolated from the arsenic-rich sediment of Mono Lake, California. Lake sediment (15 ml) was added to 45 ml supplemented, autoclaved lake water and sealed under N_2 in a 160 ml serum bottle. Supplements were 10 mM sodium lactate, 10 mM Na_2SeO_4 , 0.5 g yeast extract, in 1 l lake water, with 2.5% cysteine-sulfide reducing agent. The slurry was incubated statically in the dark at 20 °C for 18 d, by which time red deposits of elemental selenium were evident. A 1.0 ml aliquot was transferred to a smaller serum bottle containing 20 ml of the supplemented lake water and incubated in the same way for 1 week. A stable enrichment culture was achieved by weekly transfers into 10 ml medium in anaerobic, crimp-sealed test tubes for over 1 year. Manipulation was done in an anaerobic glove box using standard anaerobic methods. The enrichment was streaked onto solidified supplemented lake water medium and the plates incubated under N_2 for 1 week, after which red colonies were seen. Colonies were inoculated into further sealed test tubes of supplemented lake water, and non-spore-forming organisms were destroyed by heat treatment at 70 °C for 20 min (Switzer Blum et al., 1998).

Bacillus asahii was cultivated from soil using PY-1 medium (peptone, 8 g; yeast extract, 3 g; agar, if required, 15 g, distilled water, 1 l).

Bacillus atrophaeus is essentially a variant of *Bacillus subtilis* which forms a soluble black pigment on media containing utilizable carbohydrates. Most strains have been isolated from soil. No method for its specific enrichment or selective isolation are known to the authors, but its pigment formation is evidently of value in its recognition on plate cultures; it forms bluish-black colonies on glycerol-glutamate agar (Arai and Mikami, 1972).

Bacillus azotoformans. For selective isolation, soil samples are heat-treated (80 °C, 10 min) in peptone broth, and incubated under an atmosphere of pure N_2O at 32 °C; gassy and foaming cultures are subcultured several times in fresh medium under the same conditions. Pure cultures are obtained by streak plating from the enrichment cultures onto the same medium solidified with agar, and incubating at 32 °C in air (Pichinoty et al., 1976). The enrichment medium contains: peptone, 10 g; $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$, 3.6 g; KH_2PO_4 , 1.0 g; NH_4Cl , 0.5 g; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.03 g; trace elements solution (Pichinoty et al., 1977), 0.2 ml; distilled water, 1 l; adjust pH to 7.0 and autoclave at 121 °C for 15 min.

Bacillus badius. No methods for the specific enrichment or selective isolation of this species are known to the authors.

Bacillus barbaricus was isolated from samples of an experimental wall painting by suspending in sterile saline, shaking for 1 h, then plating dilutions onto PYES agar and incubating at room temperature. PYES agar contained: peptone from casein, 3 g; yeast extract, 3 g; disodium succinate, 2.3 g; agar to solidify; distilled water, 1 l; pH 7.2 (Taubel et al., 2003).

Bacillus bataviensis was isolated from soil by plating two dilution series, one unheated and the other heated at 80 °C for

15 min, onto 35 different agar media, most of which were mineral media with different complex components as sole carbon sources (Felske et al., 1999; Heyrman et al., 2004).

Bacillus benzoovorans was originally isolated by aerobic enrichment culture of heat-treated soil samples at 32 °C for a week in a minimal medium containing benzoate, *p*-hydroxybenzoate or cyclohexane carboxylate as carbon and energy sources (Pichinoty, 1983). The enrichment medium comprises: Na₂HPO₄·12H₂O, 3.575 g; KH₂PO₄, 0.98 g; MgSO₄·7H₂O, 0.03 g; NH₄Cl, 0.5 g; trace element solution (Pichinoty et al., 1977), 0.2 ml; benzoate, *p*-hydroxybenzoate or cyclohexane carboxylate, 2 g; yeast extract (except in case of *p*-hydroxybenzoate), 0.1 g; distilled water to 1 l; pH adjusted to 7.0 with NaOH.

Bacillus carboniphilus was isolated from the air using a otherwise nonpermissive medium which had been spotted with sterilized graphite suspension (Fujita et al., 1996). The basal medium was Penassay Broth (Bacto Antibiotic Medium 3; Difco), the potassium and sodium levels of which were stressful to the organism: beef extract, 1.5 g; yeast extract, 1.5 g; peptone, 5.0 g; glucose, 1.0 g; NaCl, 3.5 g; K₂HPO₄, 3.68 g; KH₂PO₄, 1.32 g; agar 15 g; distilled water, 1 l. 200 µl of a thick suspension of graphite in 1% Triton X-100, sterilized by heating for 1 min at about 700 °C on a gas burner, was spotted on the surface of each agar plate, and plates were incubated at 44 °C for 48–96 h. Colonies appearing around the graphite spots were purified by streaking on trypticase soy agar plates.

Bacillus cereus. With food specimens submitted for the investigation of food-poisoning incidents, heating part of the specimen at 62.5 °C for 15 min will both heat-shock the spores and effectively destroy nonspore-forming contaminants [solid samples should first be emulsified in sterile, deionized water, 1:2 (w/v)]. The other part of the specimen is cultivated without heat treatment in case spores are very heat-sensitive, or absent. Direct plate cultures are made on blood, nutrient, or selective agars, as appropriate, by spreading up to 250 µl volumes from undiluted, and 10-, 100- and 1000-fold dilutions of the treated sample. Heat treatment is not suitable for human specimens where spores are usually sparse or absent. Enrichment procedures are generally inappropriate for isolations from clinical specimens, but when searching for *Bacillus cereus* in stools ≥3 d after a food-poisoning episode, nutrient or tryptic soy broth with polymyxin (100,000 U/l) may be added to the heat-treated specimen. Several media have been designed for isolation, identification and enumeration of *Bacillus cereus*. They exploit the organism's egg-yolk reaction positivity and acid-from-mannitol negativity; pyruvate and polymyxin may be included for selectivity. Three satisfactory formulations are MEYP (Mannitol, Egg Yolk, Polymyxin B agar), PEMBA (Polymyxin B, Egg yolk, Mannitol, Bromthymol blue Agar) and BCM (*Bacillus cereus* Medium) (van Netten and Kramer, 1992).

Bacillus circulans. Although several methods for isolating this organism have been described (Claus and Berkeley, 1986), recent developments in the taxonomy of this species (which had long been known as a complex of species) indicate that very few of the strains that have been allocated to this taxon on the basis of phenotypic properties are actually closely related to the type strain. It is not possible, therefore, to recommend a method for its specific isolation.

Bacillus clarkii. Optimal growth of this alkaliphilic organism is above pH 10.0, no growth occurs at pH 7.0, and up to 16% NaCl

is tolerated (Nielsen et al., 1995a); see *Bacillus agaradhaerens*, *Bacillus alcalophilus* and other alkaliphiles.

Bacillus clausii. Optimal growth of this alkalitolerant organism is above pH 8.0, good growth occurs at pH 7.0, and 8–10% NaCl is tolerated (Nielsen et al., 1995a); see *Bacillus agaradhaerens*, *Bacillus alcalophilus* and other alkaliphiles.

Bacillus coagulans. Methods for the specific isolation of this species are based upon its thermotolerance and acid tolerance; it may be isolated from soil and other sources by enriching and then subculturing at pH 5.5–6.0 with incubation at around 50 °C. Allen (1953) used an enrichment medium of glucose, 10 g; yeast extract, 5.0 g; distilled water to 1 l, adjusted with lactic acid to pH 5.5 and autoclaved at 121 °C for 15 min.; flasks containing 200 ml are inoculated with 1 ml of heat-treated suspension of soil or other material and incubated for 24 h at 50 °C; 0.1 ml aliquots are then transferred to fresh medium and incubated for 24 h at 50 °C; loopfuls are streaked onto nutrient agar and incubated at 45 °C for 48 h. Small, round, whitish, opaque or opalescent colonies are likely to be *Bacillus coagulans*. A similar approach was used by Emberger (1970): heat-treated soil samples were incubated anaerobically at 54 °C in nutrient broth which had been supplemented with 1% (w/v) glucose and adjusted to pH 6.0. Loopfuls were then streaked onto plates of the same medium solidified with agar and incubated aerobically at 45 °C; this yielded colonies of *Bacillus coagulans* and *Bacillus licheniformis*.

Bacillus cohnii. Samples of alkaline or possibly alkaline soil from horse meadows, and from horse feces that have been lying for some time, or other potential sources, are heat treated at 80 °C for 10 min and 1–2 drop inocula are added to nutrient broth which has been adjusted to pH 9.7 by adding sodium sesquicarbonate (Na₂CO₃) to a final concentration of 0.1 mol/l (Spanka and Fritze, 1993). Cultures are incubated aerobically at 45 °C for 1–2 d, and streaked onto plates of the same medium solidified with agar, with incubation at 45 °C or 28–30 °C for 2–7 d. Small, cream-white, seldom-occurring colonies are picked for purification.

Bacillus decolorationis was isolated from scrapings of biofilms on ancient mural paintings by homogenizing the samples in physiological water, preparing a dilution series, and then plating on five different media: (i) trypticase soy broth (BBL) solidified with Bacto agar (Difco); (ii) the aforementioned trypticase soy agar supplemented with 10% NaCl; (iii) R2A agar (Difco); (iv) R2A agar supplemented with 10% NaCl; (v) starch-casein medium, which contained starch, 10 g; casein, 0.3 g; KNO₃, 2 g; K₂HPO₄, 2 g; NaCl, 2 g; MgSO₄·7H₂O, 0.05 g; CaCO₃, 0.02 g; FeSO₄·7H₂O, 0.01 g; agar, 20 g; water, 1 l. All media were supplemented with 0.03% cycloheximide to inhibit fungal growth. Plates were incubated aerobically at 28 °C for 3 weeks (Heyrman et al., 1999).

Bacillus drementensis – see *Bacillus bataviensis*.

Bacillus endophyticus. Strains of this species were isolated from the inner tissues of healthy cotton plants (Reva et al., 2002). Pieces of stem about 1 cm in diameter were flamed with ethanol and the outer layers removed with a sterile scalpel; slices of inner stem were placed on nutrient agar plates and incubated for 48 h at 30 °C. Bacterial growth associated with the stems was then purified by repeated streak cultivation on plates of the same medium.

Bacillus farraginis, *Bacillus fordii* and *Bacillus fortis* were isolated from samples of raw milk, feed concentrate and green fodder,

and samples taken from milking apparatus, by heat treating at 100 °C for 30 min followed by plating on brain heart infusion (Oxoid) supplemented with bacteriological agar no. 1 (Oxoid) and filter-sterilized vitamin B₁₂ (1 mg/l) (Sigma).

Bacillus fastidiosus uses uric acid, allantoin and allantoic acid as sole carbon, nitrogen and energy sources, and this property may be used in its enrichment and isolation. The method of Fahmy (personal communication to Claus and Berkeley, 1986) uses the following enrichment medium: K₂HPO₄, 0.8 g; KH₂PO₄, 0.2 g; MgSO₄·7H₂O, 0.5 g; CaCl₂·2H₂O, 0.05 g; FeSO₄·7H₂O, 0.015 g; MnSO₄·H₂O, 0.01 g; uric acid, 10 g; distilled water to 1 l. The pH is not adjusted. 300 ml Erlenmeyer flasks containing 30 ml of this medium are inoculated with 5 ml of a soil suspension in water that has been heat treated for 5 min at 80 °C, and the inoculated flasks are shaken at 30 °C for 24 h. One milliliter quantities are transferred to fresh flasks of medium for further incubation under the same conditions. Loopfuls, or 0.1 ml quantities, of serial dilutions of the enrichment culture are streaked or spread on plates of the following medium: a layer of the medium described above, from which the uric acid has been omitted but which has been solidified with agar, is overlaid with uric acid agar; the latter is prepared by sterilizing a 3% (w/v) agar solution and a 2% (w/v) uric acid suspension separately and then combining equal parts and pouring to a depth of about 3 mm. Colonies of uric acid-degrading organisms produce clear haloes in the milky layer of uric acid agar, owing to utilization of the acid and its solubilization in the rising pH caused by splitting of the urea that is formed from the uric acid. *Bacillus fastidiosus* colonies usually show rhizoid outgrowths on this medium. Suspect colonies are suspended in nutrient broth and streaked on uric acid agar and nutrient agar; isolates developing only on the former medium are likely to be this species, and they may be purified on plates of the mineral agar to which 2% (w/v) allantoin has been added before autoclaving.

Bacillus firmus. Methods for isolating members of this species complex, particularly pigmented organisms from salt marshes and marine environments, have been described (Claus and Berkeley, 1986), but none of them are specific, and recent developments in the taxonomy of the group have revealed that few authentic strains of *Bacillus firmus* originate from salty environments or are strongly pigmented; most strains have been isolated from soil, as laboratory contaminants, and as contaminants of food and pharmaceutical production environments. Until the species is more tightly defined, it is not possible to recommend a method for its specific isolation.

Bacillus flexus was revived by Priest et al. (1988) to accommodate two strains that showed low DNA homology to *Bacillus megaterium* but which showed phenotypic similarity to that species. No method has been described for its specific isolation.

Bacillus fordii and *Bacillus fortis* – see *Bacillus faraginis*.

Bacillus fumarioli. Strains of this species were isolated from soil samples that were collected from geothermal sites in the Antarctic and transported and stored both chilled and frozen. 1 g quantities of soil are added to 9 ml *Bacillus fumarioli* broth (BFB) in duplicate at pH 5.5, and one of each pair is heat treated at 80 °C for 10 min to kill vegetative cells. Broths are incubated at 50 °C in air (bottles loose-capped), and subcultured by streaking onto *Bacillus fumarioli* agar (BFA, which is BFB containing 5 mg/l MnSO₄·4H₂O, to enhance sporulation, and 18 g/l agar) and incubated at 50 °C (with the plates in loosely closed polythene

bags to avoid drying-out) for 1–2 d (Logan et al., 2000). BFB is an adaptation of medium B of Nicolaus et al. (1998) and contains yeast extract, 4 g; (NH₄)₂SO₄, 2 g; KH₂PO₄, 3 g and 4 ml each of solutions A and B in distilled water, 1 l; adjust to pH 5.5. Solution A: (NH₄)₂SO₄, 12.5 g; MgSO₄·7H₂O, 5.0 g; distilled water, 100 ml; Solution B, CaCl₂·2H₂O, 6.25 g; distilled water, 100 ml. Growth and sporulation may be enhanced by enriching and subculturing on 1/2 BFB and 1/2 BFA, in both of which all components excepting the water, and the agar in the latter, are reduced by half. Using the same medium and conditions, further isolates have been obtained from gelatin production plants in France, Belgium and the USA (De Clerck et al., 2004a).

Bacillus funiculus was described on the basis of a single isolate from a domestic wastewater treatment tank (Ajithkumar et al., 2001). Water from a sludge-circulating tank was diluted to 10⁴ in 0.5% NaCl solution and plated onto the following medium: nutrient broth (Oxoid CM-1), 4 g; potato starch, 5 g; glucose, 8 g; NaCl, 5 g; yeast extract, 0.5 g; agar, 15 g; distilled water, 1 l. Plates were incubated at 32 °C for 24 h, and then at 20 °C for 1 week, and colonies of this species were white, opaque, round and umbonate.

Bacillus fusiformis was revived for four strains, three of which were urease-positive, that had been assigned to *Bacillus sphaericus*. No method for its specific enrichment or isolation have been described, but urease positivity may be of value when screening colonies from *Bacillus sphaericus* isolations (see below); however, other spherical-spored organisms, including mosquito pathogenic strains of *Bacillus sphaericus* (Krych et al., 1980) and *Sporosarcina psychrophila* (formerly *Bacillus psychrophilus*), are also urease-positive.

Bacillus galactosidilyticus. Two strains of this species were isolated from raw milk after a heat treatment of 80 °C for 10 min in one case, and 100 °C for 30 min in the other, in order to pasteurize the samples and activate any endospores present; samples were then plated on brain heart infusion (BHI) (Oxoid) solidified with Bacteriological Agar no. 1 (15 g/l) (Oxoid) and supplemented with filter-sterilized vitamin B₁₂ (1 mg/l), incubating at 37 °C for 48 h (Heyndrickx et al., 2004).

Bacillus gelatini. Strains were isolated from samples of gelatin batches from a gelatin production plant by enrichment of 30 g of sample in 70 ml Trypticase Soy Broth (Oxoid) at 45 °C and 55 °C for 24 h, and plating on Trypticase Soy Agar (Oxoid) and Brain heart Infusion Agar (BBL), supplemented with 1 mg vitamin B₁₂/l and Nutrient Agar supplemented with 1.2% gelatin at 45 °C and 55 °C (De Clerck et al., 2004c).

Bacillus gibsonii. Optimal growth of this alkalitolerant organism is about pH 8.0, growth occurs at pH 7.0, and up to 9% NaCl is tolerated (Nielsen et al., 1995a); see *Bacillus agaradhaerens*, *Bacillus alcalophilus* and other alkaliphiles.

Bacillus halmaphus. Optimal growth of this alkalitolerant organism is about pH 8.0, and good growth occurs at pH 7.0, but 5% NaCl is not tolerated (Nielsen et al., 1995a); see *Bacillus agaradhaerens*, *Bacillus alcalophilus* and other alkaliphiles.

Bacillus halodurans. Optimal growth of this alkaliphilic organism is pH 9.0–10.0, most strains grow at pH 7.0, and good growth is obtained at up to 12% NaCl (Nielsen et al., 1995a); see *Bacillus agaradhaerens*, *Bacillus alcalophilus* and other alkaliphiles.

Bacillus halophilus. This species is based upon one strain isolated from rotting wood on a seashore (Ventosa et al., 1989) by enrichment in Sehgal and Gibbons complex medium

(Onishi et al., 1980): NaCl, 234 g; vitamin-free Casamino acids (Difco), 7.5 g; yeast extract, 10 g; sodium citrate, 3 g; KCl, 2 g; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 2 g; $\text{FeCl}_3 \cdot n\text{H}_2\text{O}$, 2.3 mg; distilled water 1 l; pH 6.6), followed by inoculation onto 15% (w/v) salt MH medium: yeast extract, 10 g; proteose peptone, 5 g; glucose, 1 g; agar, 20 g; 15% (w/v) NaCl solution 1 l.

Bacillus horikoshii. Optimal growth of this alkalitolerant organism is about pH 8.0, growth occurs at pH 7.0, and 8–9% NaCl is tolerated (Nielsen et al., 1995a); see *Bacillus agaradhaerens*, *Bacillus alcalophilus* and other alcaliphiles.

Bacillus horti. This species is based upon two strains isolated from garden soil in Japan using an alkaline peptone-yeast extract agar (Yumoto et al., 1998); details of sample preparation and inoculation were not reported. The isolation medium comprised: peptone, 8 g; yeast extract, 3 g; K_2HPO_4 , 1 g; $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, 10 mg; EDTA, 3.5 mg; $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$, 3 mg; $\text{Co}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$, 2 mg; $\text{MnSO}_4 \cdot n\text{H}_2\text{O}$, 2 mg; $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, 1 mg; H_3BO_3 , 1 mg; agar, 15 g; $\text{NaHCO}_3/\text{Na}_2\text{CO}_3$ buffer (100 mM; pH 10) in deionized water, 1 l.

Bacillus hwajinpoensis was isolated from sea water of the East Sea in Korea by dilution plating onto marine agar (Yoon et al., 2004b).

Bacillus indicus was isolated from a sand sample from an arsenic-contaminated aquifer by cultivation on nutrient agar containing 5% sodium arsenate. Nutrient agar without sodium arsenate was used for growth and maintenance.

Bacillus infernus. This anaerobic species was isolated from shale taken from a depth of about 2.7 km below the land surface, where conditions were estimated to be anoxic, thermic (60 °C), and brackish (1.2% NaCl). Core sample material was placed in an inert atmosphere, pared to remove potential surface contamination, and transferred to the laboratory on ice. Enrichment was done by adding 50 mg pieces of rock to MSA medium (Boone et al., 1995) and incubating for 40 d at 50 °C in pure nitrogen at pH 8.2. The medium comprised: yeast extract, 0.5 g; peptone, 0.5 g; NaCl, 10 g; NaOH, 4 g; NH_4Cl , 1 g; $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, 1 g; K_2HPO_4 , 0.4 g; $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$, 0.4 g; $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$, 250 mg; disodium EDTA $\cdot 2\text{H}_2\text{O}$, 5 mg; $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$, 1.5 mg; resazurin, 1 mg; $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$, 1 mg; $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, 1 mg; ZnCl_2 , 1 mg; $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$, 0.4 mg; $\text{Na}_2\text{WO}_4 \cdot 2\text{H}_2\text{O}$, 0.3 mg; $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$, 0.2 mg; $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$, 0.2 mg; H_2SeO_3 , 0.1 mg; H_3BO_3 , 0.1 mg; $\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$, 0.1 mg; 20 mM formate, 20 mM acetate, 20 mM MnO_2 (MnO_2 prepared by mixing a 9.5% KMnO_4 solution with an equal volume of a 17.8% $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$ solution) in deionized water, 1 l. Ingredients excepting sulfide were added together and solution equilibrated under pure N_2 ; the medium was dispensed into bottles sealed to exclude air. Sulfide was added from O_2 -free stock solution 1 h before use. The enrichment culture was serially diluted and inoculated onto MSA medium lacking the NaCl, but solidified with 18 g agar per liter, in roll tubes. Pinpoint colonies became visible in the zones of clearing of the MnO_2 in 3–4 weeks, and they were picked, suspended in MSA medium, serially diluted and reinoculated into the roll tube medium to purify.

Bacillus insolitus. This psychrophilic organism, along with other organisms, was isolated from marshy and normal soil by enrichment in trypticase soy broth at 0 °C for 2 weeks; cultures showing turbidity were streaked on trypticase soy agar and incubated at 0 °C for 2 weeks, and isolates were purified on nutrient agar (Larkin and Stokes, 1966). Cells of this species appear

coccoid when grown on nutrient agar, but rod-shaped on richer media such as trypticase soy agar (Larkin and Stokes, 1967).

Bacillus jeotgali. Strains of this species were isolated by dilution plating of jeotgal, a Korean traditional fermented seafood, on trypticase soy agar supplemented with artificial sea water (per liter: NaCl, 24 g; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 7 g; $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, 5.3 g; KCl, 0.7 g; CaCl_2 , 0.1 g) at pH 7.5 and incubated at 30 °C. Colonies were cream-yellow or light orange-yellow, smooth, flat and irregular (Yoon et al., 2001a).

Bacillus krukwichiae was isolated from garden soil contaminated with aromatic compounds. Soil samples were added to alkaline mineral basal salt medium (AMBS) and incubated aerobically for 48 h at 30 °C; 0.5 ml amounts were transferred to fresh medium and incubated for 24 h, then plated onto ABMS agar plates, purified five times, and maintained on peptone-yeast extract-alkaline (PYA) agar at 27 °C. AMBS contained: yeast extract, 0.2 g; hydroxybenzoate, 3 g; NH_4NO_3 , 2.5 g; K_2HPO_4 , 1.5 g; Na_2HPO_4 , 1.5 g; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.5 g; $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$, 20 mg; $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, 10 mg; $\text{MnSO}_4 \cdot n\text{H}_2\text{O}$, 1 mg; $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$, 0.5 mg; Na_2CO_3 , 10 g; distilled water, 1 l; pH 10. PYA agar contained: peptone, 8 g; yeast extract, 3 g; K_2HPO_4 , 1 g; $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, 10 mg; EDTA, 3.5 mg; $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$, 3 mg; $\text{Co}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$, 2 mg; $\text{MnSO}_4 \cdot n\text{H}_2\text{O}$, 2 mg; $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, 1 mg; H_3BO_3 , 1 mg; $\text{NaHCO}_3/\text{Na}_2\text{CO}_3$ buffer (100 mM in deionized water; pH 10), 1 l (Yumoto et al., 2003).

Bacillus lentus. Gibson originally isolated this species from soil by plating dilutions of soil suspensions on nutrient agar supplemented with 10% urea (peptone, 10 g; meat extract, 10 g; agar, 15 g; distilled water to 1 l; adjusted to pH 7.0–7.5 and autoclaved at 121 °C for 15 min; 100 g crystalline urea is added to molten agar immediately before use and steamed for 10 min prior to cooling and pouring) and incubating at 25 °C. However, recent work on the taxonomy of the species (Logan and De Vos, unpublished observations) has revealed that few authentic strains of *Bacillus lentus* are available for study and that many unrelated strains have been assigned to the species. Until the species is more tightly defined, it is not possible to recommend a method for its specific isolation.

Bacillus licheniformis. Strains of this species may be obtained from soil by anaerobic enrichment in peptone-meat extract- KNO_3 medium (Claus, 1965): soil suspensions are heat treated at 80 °C for 10 min, and 2 ml quantities are added to glass-stoppered bottles of a medium containing peptone, 5 g; meat extract, 3 g; KNO_3 , 80 g; distilled water 1 l; pH 7.0. The bottles are filled completely, without trapping bubbles of air, and incubated at 40–45 °C for 48 h, whereupon most will show turbidity and gas production. Loopfuls are streaked onto plates of glucose mineral base agar: glucose, 10 g; $(\text{NH}_4)_2\text{SO}_4$, 1 g; K_2HPO_4 , 0.8 g; KH_2PO_4 , 0.2 g; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.5 g; $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$, 0.05 g; $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, 0.01 g; agar, 12 g; distilled water to 1 l; adjust to pH 6.8. Colonies are often reddish and have lobes and mounds of slime.

Bacillus luciferensis. Strains of this species were isolated from soil samples that were collected from a geothermal site on Candlemas Island, South Sandwich archipelago, and transported and stored both chilled and frozen. 1 g quantities of soil were added to 9 ml trypticase soy broths in duplicate at pH 6.5 and one of each pair was heat treated at 80 °C for 10 min to kill vegetative cells. Spread plates were inoculated with 0.1 ml soil suspension on trypticase soy agar at pH 6.5 (containing 5 mg/l

MnSO₄ to enhance sporulation) and incubated at 30 °C. The suspensions remaining were incubated at the same temperature in a waterbath, and streaked onto the solid medium as soon as they became turbid (Logan et al., 2000).

Bacillus macyae was isolated from arsenic-contaminated mud from a gold mine, as described by Santini et al. (2002). The medium for *Bacillus macyae* is NaCl, 1.2 g; KCl, 0.3 g; NH₄Cl, 0.3 g; KH₂PO₄, 0.2 g; Na₂SO₄, 0.3 g; MgCl₂·6H₂O, 0.4 g; CaCl₂·2H₂O, 0.15 g; NaHCO₃, 0.6 g; trace element solution with 5.2 g/l Na₂-EDTA and pH 6.5, 1.00 ml; resazurin, 0.5 mg; yeast extract, 0.8 g; Na-lactate, 1.1 g; KNO₃, 0.5 g; distilled water 1000.00 ml. Prepare the medium anaerobically under 100% N₂. Add sodium lactate (10 mM; electron donor) and sodium nitrate (or sodium arsenate; electron acceptors) to 5 mM from sterile, anaerobic stock solutions. Adjust final medium pH to 7.4–7.8. The trace element solution contains: HCl (25%; 7.7 M); FeCl₂·4H₂O, 1.5 g; CoCl₂·6H₂O, 190 mg; MnCl₂·4H₂O, 100 mg; ZnCl₂, 70 mg; H₃BO₃, 6 mg; Na₂MoO₄·2H₂O, 36 mg; CuCl₂·2H₂O, 2 mg; NiCl₂·6H₂O, 24 mg; distilled water, 990 ml; dissolve the FeCl₂ in the HCl, then dilute in water, add and dissolve other salts, and make up to 1 l. Incubate at 28 °C.

Bacillus marisflavi – see *Bacillus aquimaris*.

Bacillus megaterium. The method of Claus (1965) may be used to isolate strains of this species from soil. Plate 0.1 ml volumes of dilutions of heat-treated soil suspensions on glucose mineral base agar: glucose, 10 g; (NH₄)₂SO₄ or KNO₃, 1 g; K₂HPO₄, 0.8 g; KH₂PO₄, 0.2 g; MgSO₄·7H₂O, 0.5 g; CaSO₄·2H₂O, 0.05 g; FeSO₄·7H₂O, 0.01 g; agar, 12 g; distilled water to 1 l; adjust to pH 7.0. Plates are incubated at 30 °C. On the nitrate medium, white, round, smooth and shiny colonies 1–3 mm in diameter may develop in 36–48 h. On the ammonium medium (necessary, because not all strains can use nitrate), a variety of colonies may develop in 24–36 h, but colonies of *Bacillus megaterium* can be detected by their appearance. Suspect colonies from either medium should be observed microscopically for the typically large cells of this species, then purified on nutrient agar or trypticase soy agar.

Bacillus methanolicus. Dijkhuizen et al. (1988) isolated their thermotolerant, methanol-utilizing strains using the following enrichment medium: filter-sterilized methanol to 50 mMol; yeast extract, 0.5 g; Casamino acids, 0.5 g; peptone, 0.5 g; (NH₄)₂SO₄, 1.5 g; K₂HPO₄, 4.65 g; NaH₂PO₄·H₂O, 1.5 g; MgSO₄·7H₂O, 0.2 g; trace element solution, 0.2 ml; vitamin solution, 1 ml; distilled water, 1 l; the medium was adjusted to pH 7.0. The trace element solution contained: EDTA, 50 g; ZnSO₄·7H₂O, 22 g; CaCl₂, 5.54 g; MnCl₂·4H₂O, 5.06 g; FeSO₄·7H₂O, 4.99 g; (NH₄)₆Mo₇O₂₄·4H₂O, 1.10 g; CuSO₄·5H₂O, 1.57 g; CoCl₂·6H₂O, 1.61 g; distilled water, 1 l; pH adjusted to 6.0 with KOH. The vitamin solution contained biotin, 100 mg; thiamin, HCl, 100 mg; riboflavin, 100 mg; pyridoxalphosphate, 100 mg; pantothenate, 100 mg; nicotinic acid amide, 100 mg; *p*-aminobenzoic acid, 20 mg; folic acid, 10 mg; vitamin B12, 10 mg; lipoic acid, 10 mg; distilled water, 1 l. To conical flasks containing 25 ml of the medium, 1–5 ml of liquid samples or 1–5 g of soil samples (both previously heat treated at 80 °C for 10 min, the soil samples suspended in 5 ml mineral medium) were added, and incubated at 50–55 °C. Dense growth usually appeared within 72 h, and this was subcultured onto methanol agar plates (the enrichment medium solidified with 1.5% agar), which were incubated at 50 °C. Colonies were transferred to the liquid medium after 24 h incubation. Cells apparently lysed rapidly on plates, and

so repeated transfers (about 10) to liquid culture, followed by plating, were used to select variants less susceptible to lysing on solid medium. Cultures were then serially diluted in mineral medium and plated on methanol agar.

Bacillus mojavenis. This species is phenotypically virtually indistinguishable from *Bacillus subtilis*. Original strains were isolated from desert soil using a non-specific method for *Bacillus* species (see *Bacillus subtilis*, below), and the emerging colonies screened for the *Bacillus subtilis* phenotype (Roberts et al., 1994). See also *Bacillus subtilis*.

Bacillus mycoides. Strains of this species are readily isolated from a wide variety of sources, including soil, and are easily recognized by the characteristic rhizoid morphologies of their colonies (Figure 9d). Small drops of heat-treated or untreated soil suspensions (or soil crumbs, or appropriate preparations of other source material) are placed in the centers of nutrient or trypticase soy agar plates and incubated at 28 °C. A *Bacillus mycoides* colony will develop as rhizoid growth which may spread to cover the agar surface within 2–3 d of incubation. Purification is best attempted by subculturing from the outer edge of the colony, and is aided by suspending growth (which may be quite adherent) in a nutrient broth, shaking vigorously, and then serially diluting prior to plating.

Bacillus naganensis. The single original strain of this species was isolated on a medium containing colored starch and pullulan, designed to screen for organisms producing α-amylases and pullulanases (Tomimura et al., 1990). The initial screening medium contained: tryptone, 2 g; (NH₄)₂SO₄, 1 g; KH₂PO₄, 0.3 g; MgSO₄·7H₂O, 0.2 g; CaCl₂·2H₂O, 0.2 g; FeSO₄·7H₂O, 0.01 g; MnCl₂·4H₂O, 0.001 g; agar, 20 g; soluble starch, 10 g; blue-colored soluble starch (Rinderknecht et al., 1967), 3 g; red-colored pullulan, 7.5 g; distilled water to 1 l; adjust to pH 4.0 using 0.2 N sulfuric acid. The colored pullulan was prepared by dissolving 100 g pullulan in 2 l distilled water, heating to 50 °C and adding 10 g Brilliant Red and 100 ml of 10% Na₃PO₄; after 75 min incubation the product was precipitated with 1600 ml 99.5% ethanol, collected by decantation, washed twice with 60% ethanol, washed once with 99.5% ethanol, and air-dried (Tomimura et al., 1990). A 2 g portion of soil sample was suspended in 10 ml water and a 0.1 ml volume spread onto the screening medium and incubated at 30 °C. Discrete colonies surrounded by blue zones (indicating pullulan, but not starch, hydrolysis), were subcultured onto a variant of the screening medium in which amylopectin (10 g/l) replaced the starches and pullulan; following incubation, pullulanase producing colonies were revealed by the dark blue zones surrounding them, against a light-purple background, when exposed to iodine vapor.

Bacillus nealsonii was isolated from a spacecraft-assembly plant by exposing 2.5 × 5 cm (0.05–0.08 cm thick) stainless steel witness plates, which had been cleaned by ultrasonication and solvent treatment, then sterilized by heating at 175 °C for 2 h, on 2-m-high stands for 9 months. Each plate was placed in 30 ml sterile phosphate-buffered rinse solution (pH 7.2) and sonicated (25 kHz, 0.35 W/cm²) for 2 min. Each rinse was divided into two equal parts and one was heat treated at 80 °C for 15 min, the other not. Total aerobic counts were determined in tryptic soy agar pour plates, incubated at 32 °C for 3–7 d (Venkateswaran et al., 2003).

Bacillus neidei. This species contains soil isolates previously allocated to *Bacillus sphaericus*, and is distinguished from that

species by a small number of phenotypic characters. Unlike *Bacillus sphaericus*, it has a requirement for cystine (Nakamura et al., 2002). No method for its specific enrichment or isolation has been described. See *Bacillus sphaericus*.

Bacillus niacini. Strains of this and other nicotinate-utilizing species were recognized by their production of blue or brown haloes on nicotinate medium. About 1 g of sample, which may have been heat treated (60 °C or 80 °C for 10 min), was suspended in 20 ml nicotinate medium (Nagel and Andreesen, 1989) and in 20 ml of the same medium supplemented with 0.05% yeast extract. This medium comprised: nicotinic acid or 6-hydroxynicotinic acid, 40 mM; CaCl₂, 0.18 mM; MnSO₄, 0.14 mM; MgSO₄, 2.0 mM; NH₄Cl, 5.6 mM; NaCl, 0.85 mM; FeSO₄, 0.036 mM; potassium phosphate buffer (0.6 M, pH 7.5), 5 ml; Tris/HCl (1.0 M, pH 7.5), 100 ml; trace element solution, 1 ml; filter-sterilized vitamin solution, 5 ml; distilled water to 1 l; pH adjusted to 7.5. After 3–5 d incubation at 30 °C on a rotary shaker, aliquots are plated onto nicotinate-yeast extract medium solidified with agar. The trace element solution contained: HCl (25% = 7.7 M), 12.5 ml; FeSO₄·7H₂O, 2.1 g; H₃BO₃, 0.03 g; MnCl₂·4H₂O, 0.1 g; CoCl₂·6H₂O, 0.19 g; NiCl₂·6H₂O, 0.024 g; CuCl₂·2H₂O, 0.002 g; ZnSO₄·7H₂O, 0.144 g; Na₂MoO₄·2H₂O, 0.036 g; distilled water, 987 ml; autoclaved in sealed bottles with about 1/3 head space of air. The vitamin solution comprised: lipoic acid, 60 mg; *p*-aminobenzoic acid, 50 mg; calcium-D-pantothenate, 50 mg; cyanocobalamin, 50 mg; nicotinic acid, 50 mg; riboflavin, 50 mg; thiamine hydrochloride, 50 mg; biotin, 20 mg; folic acid, 20 mg; pyridoxal hydrochloride, 10 mg; distilled water, 1 l. Colonies with blue or brown haloes were streaked on the same medium to purify, then single colonies were suspended in saline and plated onto tryptone-yeast extract-succinate medium (tryptone, 10 g; yeast extract, 5 g; disodium succinate, 2 g; agar, 20 g; distilled water, 1 l; pH 7.5) or other complex medium, allowed to sporulate, and subjected to heat treatment then further cultivation on the same medium (Nagel and Andreesen, 1991).

Bacillus novalis – see *Bacillus bataviensis*.

Bacillus odyseyi. The description of this species (La Duc et al., 2004) indicates that the two isolates were isolated from two spa waters in Japan; one at 59 °C and pH 6.4 and the other at 51 °C and pH 8.1; both isolates showed optimal growth between 45 °C and 50 °C at pH 10.5 in heart infusion broth.

Bacillus okuhidensis. The description of this species (Li et al., 2002) indicates that the two isolates were isolated from two spa waters in Japan; one at 59 °C and pH 6.4 and the other at 51 °C and pH 8.1; both isolates showed optimal growth between 45 °C and 50 °C at pH 10.5 in heart infusion broth.

Bacillus oleronius. The original isolate of this species was cultivated from the hindgut contents of a termite (*Reticulitermes santonensis*) using the following enrichment medium: yeast extract, 1 g; vitamin and trace element solution (Balch et al., 1979), 10 ml; distilled water, 1 l; NaCl, 24.1 mM; KCl, 21.5 mM; K₂HPO₄, 10.8 mM; KH₂PO₄, 6.9 mM; MgSO₄·5.3 mM; CaCl₂, 0.53 mM; adjusted to pH 7.2; after sterilization 1 mM of each of the following aromatic substrates were added: benzoic acid, coumaric acid, ferulic acid, 4-hydroxybenzoic acid and vanillic acid. After enrichment, the organism was maintained on trypticase soy agar, with monthly transfers. Further strains of this species have been isolated from animal feed concentrate, raw milk and dairy plant using a method devised for the isolation of *Bacillus sporothermodurans* (Scheldeman et al., 2002): samples

were heat treated for 30 min at 100 °C, followed by plating on brain heart infusion broth solidified with bacteriological agar and supplemented with vitamin B₁₂ (1 mg/l, filter-sterilized); plates were incubated for 48 h at 37 and 55 °C, but 37 °C is the optimal temperature for growth and isolation of this species.

Bacillus pseudocalophilus. Optimal growth of this alkaliphilic organism is about pH 10.0, no growth occurs at pH 7.0, and up to 10% NaCl is tolerated (Nielsen et al., 1995a); see *Bacillus agaradhaerens*, *Bacillus alcalophilus* and other alkaliphiles.

Bacillus pseudofirmus. Optimal growth of this alkaliphilic organism is about pH 9.0, most strains do not grow at pH 7.0, and 16–17% NaCl is tolerated (Nielsen et al., 1995a); see *Bacillus agaradhaerens*, *Bacillus alcalophilus* and other alkaliphiles.

Bacillus pseudomycooides is indistinguishable from *Bacillus mycooides* by conventional characters, and will probably be isolated along with strains of that species. It was proposed on the basis of differences in fatty acid composition and DNA relatedness between strains of *Bacillus mycooides* (Nakamura, 1998). See *Bacillus mycooides*.

Bacillus psychrosaccharolyticus. This psychrophilic organism was isolated by the same methods as were used for *Bacillus insolitus*. Cells of this species appear granular when grown on nutrient agar and lightly stained, and are larger and vacuolate when grown on glucose agar (Larkin and Stokes, 1967).

Bacillus pumilus. There is no specific method of enrichment or isolation of this species that is known to the authors; however, Knight and Proom (1950) found that when their suspensions of soil in distilled water were incubated at 37 °C for 3 d, then plated on nutrient agar and incubated at 37 °C, the mixed collection of colonies arising included strains of this species.

Bacillus pycnus. Like *Bacillus neidei*, this species contains soil isolates previously allocated to *Bacillus sphaericus*, and is distinguished from that species by a small number of phenotypic characters. Unlike *Bacillus sphaericus*, it does not have a requirement for biotin and thiamin (Nakamura et al., 2002). No method for its specific enrichment or isolation has been described. See *Bacillus sphaericus*.

Bacillus schlegelii. Aragno (1978) isolated this thermophilic, hydrogen-oxidizing organism by adding superficial samples (0.5 g) of sediment from a eutrophic lake in Switzerland to 100 ml bottles containing 20 ml of a basal mineral medium and Bonjour et al. (1988) made further isolations from the same lake, from air and from geothermal sites in Iceland and Italy using this three-part medium: Solution I: Na₂HPO₄·2H₂O, 4.5 g; KH₂PO₄, 1.5 g; NH₄Cl, 1 g; MgSO₄·7H₂O, 0.2 g; trace elements solution, 1 ml; distilled water, 1 l; Solution II: CaCl₂·2H₂O, 100 mg; ferric ammonium citrate, 50 mg; distilled water, 100 ml; Solution III: NaHCO₃, 5 g; distilled water, 100 ml; the three solutions were autoclaved separately and mixed in the proportions I, 1 l; II, 10 ml; III, 10 ml after cooling; pH 7.0. The trace elements solution contained: H₃BO₃, 300 mg; CoCl₂·6H₂O, 200 mg; ZnSO₄·7H₂O, 100 mg; MnCl₂·4H₂O, 30 mg; Na₂MoO₄·2H₂O, 30 mg; NiCl₂·6H₂O, 20 mg; CuCl₂·2H₂O, 10 mg; distilled water, 1 l. Cultures were incubated in desiccators at 65 °C under an atmosphere of 0.05 atm O₂ + 0.1 atm CO₂ + 0.45 atm H₂ (partial pressure measured at room temperature). Dense growth was apparent after 4 d, and it was twice subcultured in fresh medium using loopful inocula. Pure cultures were obtained by streaking on plates of the same medium solidified with agar and incubating in the same conditions as before.

Further strains have been obtained by Krüger and Meyer (1984) from sludge samples of a sugar factory settling pond, by, and by Hudson et al. (1988) from geothermally heated Antarctic soil. Krüger and Meyer used carbon monoxide as the sole carbon and energy source for enrichment, and cultivated at 65 °C in the mineral medium of Meyer and Schlegel (1983) under an atmosphere of (v/v) 5% CO₂, 35% CO and 60% air. After 1 week of incubation, positive enrichments were serially subcultured in fresh medium using a 10% inoculum. Hudson et al. (1988) isolated their strain from a soil sample taken from Mount Erebus, Antarctica. The temperature of the sample site was 37 °C, and the sample was kept unfrozen; 1 g was added to 100 ml of a thio-sulfate medium: Na₂S₂O₃, 10 g; NaHCO₃, 2 g; NaNO₃, 0.689 g; NH₄Cl, 0.4 g; Na₂HPO₄, 0.111 g; KNO₃, 0.103 g; MgSO₄·7H₂O, 0.1 g; CaSO₄·2H₂O, 0.06 g; NaCl, 0.008 g; nitrilotriacetic acid, 0.1 g; (also, for later work, yeast extract, 0.1 g); phenol red, 0.024 g; distilled water to 1 l; pH 7.0. Trace elements and ferric chloride, and vitamins were also added. Incubation was at 60 °C, and growth was evident from a fall in pH shown by the phenol red indicator. pure cultures were obtained by streaking on the same medium (without yeast extract) solidified with agar.

Bacillus selenitireducens. The single reported strain of this medium was isolated using the same method employed for *Bacillus arseniciselenatis* (see above), but it was found not to use selenate as the electron acceptor and could use arsenate in the lake water medium or selenite instead (Switzer Blum et al., 1998).

Bacillus shackletonii – see *Bacillus luciferensis*.

Bacillus silvestris. The single strain upon which this species is based was isolated from a 10 g sample of beech forest soil by storing it in humid conditions and incubating at 40 °C for 15 min followed by suspension in 100 ml of a germination solution comprising: malt extract, 1 g; glucose, 0.4 g; yeast extract, 0.4 g; CaCO₃, 0.2 g; L-asparagine, 1 g; distilled water, 1 l; filter-sterilized cycloheximide solution (0.1 g in 10 ml water) was added after cooling to room temperature (Rheims et al., 1999). Dilutions in the germination medium were prepared to 10⁻³ and this final dilution was stirred at room temperature for 15 min and then aliquots of 100 µl were streak diluted on various media and incubated at different temperatures. The strain was isolated on a plate of tryptic soy broth supplemented with 0.3% yeast extract and solidified with agar; incubation was at 25 °C for 1 d.

Bacillus simplex. This species is based on two soil isolates received as “*Bacillus simplex*” and “*Bacillus teres*” (Priest et al., 1988), and no method for isolating strains of the species is known to the authors.

Bacillus siralis. The original strain of this species was isolated from silage by heat treating the sample at 100 °C for 60 min and plating onto brain heart infusion (BHI) agar (de Silva et al., 1998). Pettersson et al. (2000) made further isolations by suspending 1 g of lyophilized silage in 1 ml sterile water, heating at 100 °C for 90 min, then diluting to 10⁻² in sterile water; 50 ml aliquots were spread on plates of BHI agar and on plates of the following medium: yeast extract, 0.5 g; salts solution, 1 ml; nutrient agar, 100 ml. The salts solution comprised: MgCl₂, 1 × 10⁻³ M; CaCl₂, 7 × 10⁻⁴ M; MnCl₂, 5 × 10⁻⁵ M. Plates were incubated at 24–48 h at 37 °C, and colonies resembling those of the original isolate were purified on plates of the supplemented nutrient agar.

Bacillus smithii. This species contains isolates from evaporated milk, canned foods, cheese, and sugar beet juice extrac-

tion plant which were previously assigned to *Bacillus coagulans*; no methods for its specific enrichment or isolation are known to the authors – see *Bacillus coagulans*.

Bacillus soli – see *Bacillus bataviensis*.

Bacillus sonorensis. This species is phenotypically similar to *Bacillus licheniformis*, although yellow/cream pigmentation has been given as a distinguishing character, and colonies are bright yellow on a medium containing glucose 40 g; neopeptone, 10 g; agar 15 g, distilled water, 1 l; pH 5.6; whereas those of *Bacillus licheniformis* are cream (Palmisano et al., 2001). Original strains were isolated from desert soil using a general method for *Bacillus* species (see *Bacillus subtilis* below).

Bacillus sphaericus. Members of this species and closely related, spherical-spored organisms may be enriched using a method described by Beijerinck and Minkman (1910): 10–20 g of casein or its sodium salt is added to 1 l tap water, and the medium is dispensed in 30 ml quantities in 300 ml Erlenmeyer flasks; about 1 g of soil is added to each and the suspensions are heated to boiling, cooled and then incubated at 37 °C for 3 d. Spherical-spored organisms will usually predominate in the resulting mixture of sporulating organisms. The flasks are heated to 80 °C for 5 min and loopfuls are streaked on plates of nutrient agar at pH 7.0 and incubated at 30 °C; colonies yielding sporangia swollen with spherical spores are further purified. Massie et al. (1985) described a medium containing sodium acetate as the only major source of carbon, for isolating *Bacillus sphaericus* from soil: Na₂HPO₄·12H₂O, 11.2 g; KH₂PO₄, 2.4 g; (NH₄)₂SO₄, 2.0 g; MgSO₄·7H₂O, 50 mg; MnCl₂·4H₂O, 4 mg; FeSO₄·7H₂O, 2.8 mg; sodium acetate·3H₂O, 5.0 g; trisodium citrate·2H₂O, 20 mg; distilled water to 1 l; pH 7.2. The basal medium, without salts of Mg²⁺, Mn²⁺ and Fe²⁺ and the carbon source, was autoclaved for 10 min at 121 °C. The salts were dissolved together at ×50 strength in 0.005 M-H₂SO₄ and autoclaved separately. The carbon source was autoclaved separately as a 25% w/v aqueous solution. The medium was solidified with agar. The medium was used unsupplemented or else it was supplemented with (per liter): glutamate, 1 g; thiamine, 10 mg; biotin 0.001 mg; in the combinations: biotin plus thiamine, thiamine plus glutamate, glutamate alone. The medium was also prepared with the acetate concentration doubled, and this version also used supplemented or unsupplemented. About 1 g moist soil was suspended in 5 ml sterile water and heated at 60 °C for 30 min; 50 ml medium in a 250 ml flask was inoculated with 1 g soil suspension and incubated at 30 °C with shaking; the next day, a loopful of culture was streaked onto solid medium, of the same composition as that in the original flask, and incubated at 30 °C.

Strains of the species pathogenic to mosquito larvae may be naturally resistant to chloramphenicol and streptomycin (Burke and McDonald, 1983) and a selective, differential medium containing streptomycin has been described by Hertlein et al. (1979). The BATS medium of Yousten et al. (1985) uses arginine as the sole carbon and nitrogen source and uses streptomycin as the selective agent; it was found to inhibit the growth of 68% the nonpathogenic *Bacillus sphaericus* strains tested: Na₂HPO₄, 5.57 g; KH₂PO₄, 2.4 g; MgSO₄·7H₂O, 50 mg; MnCl₂·4H₂O, 4 mg; FeSO₄·7H₂O, 2.8 mg; CaCl₂·2H₂O, 1.5 mg; L-arginine, 5 g; thiamine, 20 mg; biotin, 2 µg; streptomycin sulfate, 100 mg; agar, 20 g; distilled water, 1 l. The arginine, thiamine, biotin and streptomycin are prepared as a filter-sterilized stock solution. The Mg²⁺, Mn²⁺, Fe²⁺ and Ca²⁺ salts are prepared as an acidified

[0.03% (v/v) concentration of H_2SO_4], autoclaved stock solution. Stock solutions are added to the autoclaved phosphate salts-agar medium when it has cooled to 50 °C after autoclaving.

Bacillus sporothermodurans. Strains of this species are characterized by their highly heat-resistant spores (HHRS), and they were first detected in ultrahigh-temperature (UHT) treated milk which is heated to 135–142 °C for a few seconds; further strains were isolated from silage. The organism has been sought in milk, feed and silage by heating samples to 100 °C for 60 min, plating onto brain heart infusion (BHI) agar, and incubating at 37 °C for 2 d. Colonies resembling *Bacillus sporothermodurans* are selected and purified by streaking on plates of BHI agar or nutrient agar which have been supplemented with 1 mg per liter of vitamin B_{12} (Pettersson et al., 1996). The approach described is not specific for this species, and a range of other HHRS is likely to be isolated. Further strains of this species have been isolated from raw, UHT and sterilized milks, animal feed concentrate, and soy meal using the following method (Scheldeman et al., 2002): samples were heat treated for 30 min at 100 °C, followed by plating on brain heart infusion broth solidified with bacteriological agar and supplemented with vitamin B_{12} (1 mg/l, filter-sterilized); plates were incubated for 48 h at 20, 37 and 55 °C, but 37 °C is the optimal temperature for growth and isolation of this species.

Bacillus subterraneus. The single isolate of this species was cultivated from deep subterranean thermal water (71 °C, pH 7.8) collected in a sterile glass container from a bore well tapping the Great Artesian Basin of Australia; the containers were completely filled and sealed with air-proof enclosures. For enrichment, 1 ml of water was injected into 10 ml of metal reduction (MR) medium, supplemented with 0.016 g iron oxide, in Hungate tubes and incubated at 40 °C for 1 week (Kanso et al., 2002). MR medium was prepared as follows: yeast extract, 2 g; NH_4Cl , 1 g; $\text{K}_2\text{HPO}_4 \cdot 3\text{H}_2\text{O}$, 0.08 g; $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, 4.5 g; $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$, 0.375 g; NaCl, 20 g; vitamin solution (Patel et al., 1985), 10 ml; trace element solution, 1 ml; distilled water to 1 l. The trace element solution contained: nitrilotriacetic acid neutralized to pH 6.5 with KOH, 12.5 g; $\text{FeCl}_3 \cdot 4\text{H}_2\text{O}$, 0.2 g; $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$, 0.01 g; $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$, 0.017 g; $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$, 0.1 g; ZnCl_2 , 0.1 g; CuCl_2 , 0.02 g; H_3BO_3 , 0.01 g; $\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$, 0.01 g; NaCl, 1.0 g; Na_2SeO_3 , 0.02 g; distilled water, 1 l. The medium was boiled and then cooled under a stream of oxygen-free N_2 gas to about 50 °C, 3.6 g of NaHCO_3 were added, and the pH adjusted to 7.1; 10 ml aliquots were dispensed under N_2 into Hungate tubes (Hungate, 1969), and this gas phase was subsequently replaced with N_2/CO_2 (80:20) and the medium autoclaved at 121 °C for 15 min. The enrichment culture that developed could reduce Fe(III), and nitrate (20 mM) was used as an alternative electron acceptor; serially diluted enrichments in MR medium with nitrate were purified on plates of the same medium solidified with 2% agar and incubated at 40 °C for 1 week.

Bacillus subtilis. This species is readily isolated from dried grass, and has long been known as the “hay bacillus.” Zopf (1885) recommended the following method: hay is soaked in water for 4 h at 36 °C, using as small a volume of water as possible, and the fluid is decanted and diluted to a specific gravity of 1.004; the pH is adjusted to 7.0 and 500 ml of the suspension is transferred to a sterile 1-l Erlenmeyer flask, which is plugged with cotton wool and then boiled for 1 h. The flask is incubated at 36 °C for about 28 h, and the pellicle that usually forms will

often be found to yield only *Bacillus subtilis*. Knight and Proom (1950) added air-dried soil to 10 ml of nutrient broth to a give total volume of 15 ml, shook the vessel well, plated loopfuls of the suspension on nutrient agar, and then incubated at 37 °C for 2 d; the resulting flora was predominantly *Bacillus subtilis*. Roberts and Cohan (1995) and their colleagues isolated the *Bacillus subtilis* strains which they subsequently allocated to *Bacillus mojavensis*, *Bacillus vallismortis* and *Bacillus subtilis* subsp. *spizizenii* (and close relatives of *Bacillus licheniformis* allocated to *Bacillus sonorensis*) by suspending 1 g quantities of desert soils in 5 ml amounts of sterile water, heat-treating suspensions at 80 °C for 10 min, vortex mixing for 1 min and allowing to settle for a further minute, then plating 50–100 μl onto tryptone blood agar base plates and incubating at 37 °C for 48 h (F.M. Cohan, personal communication).

Bacillus thermoamylovorans. The single original strain of this species was isolated from palm wine (Combet-Blanc et al., 1995) using Hungate’s anaerobic methods (Hungate, 1969; Macy et al., 1972; Miller and Wolin, 1974). Palm wine, 10 ml; 10% NaHCO_3 , 1 ml; 2% $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$, 0.2 ml were added to a 60 ml serum bottle containing 20 ml of basal medium supplemented with 0.3% glucose. Bottles were incubated at 50 °C for 24 h, and then a 1-ml sample was transferred to a fresh serum bottle of basal medium. This step was twice repeated. A pure culture was obtained by the roll-tube method of Hungate, using Hungate tubes containing 4.5 ml of basal medium supplemented with 0.3% glucose. Basal medium contained: yeast extract, 5 g; Biotrypcase (bioMérieux), 5 g; KH_2PO_4 , 1 g; NH_4Cl , 1 g; $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, 0.4 g; $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, 5 mg; mineral solution, 25 ml; trace element solution, 1 ml; Tween 80, 1 ml; distilled water, 1 l; pH adjusted to 7.5 with 10 M KOH. The mineral solution contained: KH_2PO_4 , 6 g; $(\text{NH}_4)_2\text{SO}_4$, 6 g; NaCl, 12 g; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 2.6 g; $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$, 0.16 g; distilled water, 1 l. The trace element solution contained: nitrilotriacetic acid (neutralized to pH 6.5 with KOH), 1.5 g; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 3 g; $\text{MnSO}_4 \cdot 2\text{H}_2\text{O}$, 0.5 g; NaCl, 1 g; $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, 0.1 g; CoCl_2 or CoSO_4 , 0.1 g; $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$, 0.1 g; ZnSO_4 , 0.1 g; $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, 0.01 g; $\text{AlK}(\text{SO}_4)_2$, 0.1 g; H_3BO_3 , 0.01 g; $\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$, 0.01 g; distilled water, 1 l; pH adjusted to 7.0 with KOH. The medium was boiled, and cooled under a stream of O_2 -free N_2 at room temperature, distributed into serum bottles and Hungate tubes, and autoclaved at 110 °C for 45 min. Energy sources were injected into the bottles and tubes from separately sterilized stock solutions.

Bacillus thermocloacae. Strains of this species were isolated from an aerobic culture at 60 °C of municipal sewage sludge in a laboratory fermenter (Demharther and Hensel, 1989b). Samples were taken from the fermenter, homogenized, diluted and plated on Ottow’s (1974) medium (glucose, 1.0 g; peptone, 7.5 g; meat extract, 5.0 g; yeast extract, 2.5 g; Casamino acids, 2.5 g; NaCl, 5.0 g; agar, 13 g; tap water, 1 l; pH 7.2–7.4.) supplemented with 100 ml per liter of aqueous sludge extract, adjusted to a final pH of 8.5, and incubated for 3–4 d at 60 °C.

Bacillus thuringiensis. The isolation of *Bacillus thuringiensis* from environmental samples can be very laborious. After heat treatment and plate cultivation, it requires the microscopic examination of material from all colonies with *Bacillus cereus*-type morphologies for the parasporal crystals characteristic of *Bacillus thuringiensis*. Therefore, several methods have been devised in order to increase the proportion of such colonies which are *Bacillus thuringiensis*. Travers et al. (1987) described

a method which uses acetate to inhibit germination of *Bacillus thuringiensis* spores, followed by heat to kill germinated cells of other spore-formers and cells of non-spore-forming bacteria: L broth (tryptone, 10g; yeast extract, 5g; NaCl, 5g; distilled water, 1l) is buffered with 0.25 M sodium acetate. 0.5 g of sample is added to 10 ml of this broth in a 125 ml triple-baffled flask, and the flask is shaken at 250 r.p.m. at 30 °C for 4 h. A sample of this suspension is then heat treated for 3 min at 80 °C in a flow-through heat treater, and used to inoculate plates of L agar (as L broth, but solidified with agar; sodium acetate is not included). Carozzi et al. (1991) used a similar approach, but with heat treatment at 65 °C for 10 min. Johnson and Bishop (1996) enriched *Bacillus thuringiensis* in penicillin broth, followed by plating on penicillin agar, and found their method to be superior to those of Travers et al. (1987) and Carozzi et al. (1991): 0.25 g of sample is placed in a tube containing 2 ml of nutrient broth which has been supplemented with 1 ml/l CCY salts and 20 IU/ml penicillin G. The CCY salts solution (to aid sporulation) contains: acid casein hydrolysate, 1g/l; enzymic casein hydrolysate, 1g; glycerol, 0.6g; enzymic yeast extract, 0.4g; glutamine, 20mg; distilled water, 1l; and the following salts: K_2HPO_4 , 26 mM; KH_2PO_4 , 13 mM; $MgCl_2 \cdot 6H_2O$, 0.5 mM; $CaCl_2 \cdot 6H_2O$, 0.2 mM; $FeCl_3 \cdot 6H_2O$, 0.05 mM; $ZnCl_2$, 0.05 mM; $MnCl_2 \cdot 4H_2O$, 0.01 mM. The suspension is heat-shocked at 70 °C for 10 min and then added to 50 ml of the same medium in a 250 ml flask. The flask is shaken at 200 r.p.m. at 30 °C until sporulation is complete. The suspension is centrifuged at 3,600 r.p.m. for 1 h, and the pellet resuspended in 2 ml of fresh medium and the heat treatment and shaking procedure repeated; serial dilutions of the suspension are then inoculated onto plates of the supplemented nutrient broth which has been solidified with agar, and incubated at 30 °C until sporulation is complete (as judged by microscopy), and observed for the characteristic sporangial morphology of *Bacillus thuringiensis*. Forsyth and Logan (2000) found that a penicillin-based method was unsuitable for the isolation of *Bacillus thuringiensis* from Antarctic soils, as their isolates from these environments showed some penicillin sensitivity. Heat treatment and enrichment in BFB (see *Bacillus fumarioli*, above), followed by plating from turbid enrichments onto BFA and observation for parasporal crystals gave best results; over all the samples studied, however, acetate selection methods gave yields no better than the BFB method (Logan and Grieg, unpublished observations).

Bacillus tusciae. Strains of this hydrogen-oxidizing thermoacidophile were isolated from ponds in a geothermally heated area in Italy (Bonjour and Aragno, 1984). The enrichment medium was the mineral medium used by Bonjour et al. (1988) (see *Bacillus schlegelii*, above): 0.5g per liter of $NaHCO_3$ were added for autotrophic growth, and the medium was acidified to pH 3.5 using 5 M HCl. About 1g amounts of pond sediment mixed with overlying water were added to 20 ml of medium in 100 ml Pyrex screw-capped bottles, and cultures were incubated in desiccators under a gas mixture of 0.05 atm O_2 + 0.1 atm CO_2 + 0.45 H_2 (partial pressures measured at room temperature; the reduced total pressure of 0.6 atm allowed incubation at high temperatures without overpressure) for 5 d at 55 °C. For isolation, cultures were subcultured by streaking onto plates of the same medium solidified with agar and incubated under the same conditions as for enrichment.

Bacillus vallismortis. This species is phenotypically virtually indistinguishable from *Bacillus subtilis*, and original strains were isolated from desert soil using a non-specific method for *Bacillus* species (see *Bacillus subtilis*, above).

Bacillus vedderi. Samples of mud from a bauxite-processing red mud tailing pond were inoculated into alkaline oxalate medium and incubated at room temperature or 45 °C for 2 weeks (Agnew et al., 1995). Bottles showing turbidity were subcultured into bottles of fresh medium which, once turbid, were subcultured by streaking on plates of the same medium solidified with 2% (w/v) agar. Isolates were routinely grown at 37 °C. The alkaline oxalate medium comprised: Na_2CO_3 , 2.65 g; $(NH_4)_2SO_4$, 1g; K_2HPO_4 , 0.17g; $MgSO_4$, 0.15g; distilled water, 1l; pH adjusted to 10.5 with 5 M NaOH before autoclaving. After cooling, the following additions were made from sterile stock solutions to the final concentrations shown: sodium oxalate, 0.67% (w/v); yeast extract, 0.1% (w/v); mineral solution, 0.2% (v/v). The mineral solution contained: nitrilotriacetic acid, 1.5g; $MgSO_4 \cdot 7H_2O$, 3g; $MnSO_4 \cdot 2H_2O$, 0.5g; NaCl, 1g; $FeSO_4 \cdot 7H_2O$, 0.1g; $CaCl_2 \cdot 2H_2O$, 0.1g; $CoCl_2$, 0.1g; $ZnSO_4$, 0.1g; $CuSO_4 \cdot 5H_2O$, 0.01g; $AlK(SO_4)_2$, 0.01g; H_3BO_3 , 0.01g; $Na_2MoO_4 \cdot 2H_2O$, 0.01g; distilled water, 1l.

Bacillus vietnamensis was isolated from *nuoc mam* (Vietnamese fish sauce); trypticase soy agar was used as basal and maintenance medium.

Bacillus vireti – see *Bacillus bataviensis*.

Bacillus weihenstephanensis. This species is phenotypically similar to *Bacillus cereus* and only distinguishable from it by ability to grow at 7 °C, inability to grow at 43 °C, and by certain 16S rDNA signature sequences (Lechner et al., 1998), but not all psychrotolerant organisms resembling *Bacillus cereus* are *Bacillus weihenstephanensis*. Strains were isolated from German dairies by plating pasteurized milk samples on plate count agar and incubating at 7 ± 0.5 °C for 10–16 d. Psychrotolerance was confirmed by inoculating purified colonies into liquid culture of plate count medium and incubating at 7 ± 0.5 °C with agitation until growth was visible. Plate count medium contained: peptone, 5g; yeast extract, 2.5g; glucose, 1g; distilled water, 1l; pH, 7.0.

Maintenance procedures

Bacillus strains may be preserved on slopes of a suitable growth medium that encourages sporulation, such as nutrient agar or trypticase soy agar containing 5 mg/l of $MnSO_4 \cdot 7H_2O$. Slopes should be checked microscopically for spores before sealing, to prevent drying out, and storage in a refrigerator; on such sealed slopes the spores should remain viable for many years. For longer-term preservation, lyophilization and liquid nitrogen may be used, as long as cryoprotectants are added.

Procedures for testing special characters

Introduction. The ubiquity and huge diversity of *Bacillus* species presents a huge diagnostic challenge. In the First Edition of this *Manual*, the genus *Bacillus* was essentially defined as: “aerobic, endospore-forming, Gram-positive rod-shaped bacteria,” and the methods of Gordon et al. (1973) could confidently be recommended for identification of the majority of the 34 valid species (five further species were added in proof) listed by Claus and Berkeley (1986). The scheme of Smith et al. (1952) split the species into three groups according to their sporangial

morphologies, and then further divided them by biochemical and physiological tests, and this system culminated in the monograph of Gordon et al. (1973). This approach was effective for some years, but *Bacillus* identification was still generally perceived as complicated, the chief difficulties being the need for special media, and between-strain variation. Much of the latter was a reflection of unsatisfactory taxonomy, but, as the studies of Logan and Berkeley (1981) revealed, test inconsistency exacerbated the problems. Logan and Berkeley (1984) addressed these problems with a large database for 38 clearly defined taxa (species) using miniaturized tests in the API 20E and 50CHB Systems (bioMérieux, Marcy l'Etoile, France), and this scheme, with updates, remains in common use. Since the development of the Gordon et al. and Logan and Berkeley schemes, the genus has been radically changed, and the task of identification made more complicated, by: (i) the proposal of many new species (frequently from exotic habitats, and often primarily on the basis of molecular analyses), (ii) the allocation of strict anaerobes (*Bacillus arseniciselenatis*, *Bacillus infernus*) and organisms in which spores have not been observed (*Bacillus infernus*, *Bacillus thermoamylovorans*) to the genus, and (iii) the transfer of many species to the new genera, *Alicyclobacillus*, *Aneurinibacillus*, *Brevibacillus*, *Geobacillus*, *Gracilibacillus*, *Marinibacillus*, *Paenibacillus*, *Salibacillus* (now merged with *Virgibacillus*), *Ureibacillus* and *Virgibacillus*, and to the long-established genus *Sporosarcina*.

Unfortunately, taxonomic progress has not revealed readily determinable features characteristic of each genus. Also, many recently described species represent genomic groups disclosed by DNA–DNA pairing experiments, and routine phenotypic characters for distinguishing some of them are very few and of unproven value. Furthermore, several recently described species were proposed on the basis of very few strains so that the within-species diversities of such taxa, and so their true boundaries, remain unknown. It is clear, therefore, that the identification of *Bacillus* species has become increasingly difficult since the publication of the schemes of Gordon et al. and Logan and Berkeley, a period during which demands to identify such organisms have greatly increased, especially in the medical and biotechnological fields.

The identification scheme of Gordon et al. (1973) embraced 18 species, only half of which now remain in *Bacillus*. The genus now contains 90 species, and encompasses acidophiles, alkaliphiles, neutrophiles, halophiles, mesophiles, psychrophiles and thermophiles, in addition to the largely neutrophilic and mesophilic species studied by Gordon et al. (1973), so that their methods can no longer be expected, even with substantial modifications and an expanded database, to allow recognition of all the species now allocated to the genus. Identification of *Bacillus* species with routine phenotypic tests must therefore call upon a variety of characterization methods, and a unified approach is no longer possible. Despite this, the traditional characterization tests used by Gordon et al. retain their place in *Bacillus* identification, because the most commonly encountered species are still distinguishable by these methods.

Fritze (2002) recommended a stepwise approach to identification of the aerobic endospore-formers: (i) differential cultivation at a range of temperature (say 5, 30 and 55 °C) and pH conditions (say pH 4.5, 7–7.2 and 9) [to which we may add salt concentrations appropriate to halotolerant and halophilic organisms], (ii) selection of spores by heat treatment or alcohol

treatment (the latter being preferred, because not all spores are sufficiently heat-resistant to survive the former procedure), and (iii) characterization using the appropriate media and incubation temperatures.

Reva et al. (2001) described a phenotypic identification scheme for aerobic endospore-formers based on 115 characters and a key. Their database included just 69 strains of validly published *Bacillus* species, with numbers of representatives of each species ranging from one for *Bacillusadius*, *Bacillus mycoides*, *Bacillus lentus* and *Bacillus thuringiensis* to 27 for *Bacillus subtilis*. Four of the 13 *Bacillus* species they included were not represented by their type strains. They also included strains of two *Brevibacillus* species, four *Paenibacillus* species and one *Virgibacillus* species. Identification schemes are naturally limited by their databases, and schemes based on keys are prone to failure with atypical isolates. The strengths and weaknesses of the Reva et al. (2001) scheme can only be revealed by usage; the characters they employed were investigated by the traditional procedures described by Gordon et al. (1973) and Claus and Berkeley (1986), and the discriminative efficiencies they calculated for these characters might be valuable in the construction of “home-grown” identification systems.

Reference strains. In the following accounts of media and methods, the above-mentioned constraints must be borne in mind, and it is recommended that the original and emended descriptions of the more recently described species are consulted wherever possible, and that cultures of those organisms are obtained for comparison. It should also be remembered that 16S rDNA sequencing is not always reliable as a stand-alone tool for identification, and that a polyphasic taxonomic approach is advisable for the identification of some of the more rarely encountered species and the confident recognition of new taxa. It must be appreciated that the species descriptions given in the text and tables below are largely lifted from authors' descriptions of their proposed species, and that a number of such descriptions were based upon few strains, so that within-species diversities in such cases are unknown. Characterization methods and their interpretation vary, and typographic errors in the compilation of descriptions are bound to occur (several being encountered in the preparation of this review), so original descriptions should never be relied upon entirely. Nomenclatural types exist for a good reason and are usually easily available; there is no substitute for direct laboratory comparisons with authentic reference strains. However, collections of *Bacillus* species in laboratories around the world harbor many misnamed strains. This is not necessarily a reflection on the competence of those assembling the collections; it is more a symptom of the unsatisfactory state of the classification of the organisms at the time the cultures were acquired, and this underlies the difficulty that many bacteriologists frequently encounter with *Bacillus* identification.

Unfortunately, several of the groups whose taxonomies are the most complex are the ones whose members are frequently submitted to reference laboratories. Such organisms are frequently included in the databases of commercial kits, but it can be difficult to obtain sufficient authentic strains of some these species to allow a satisfactory database entry to be made. Ideally, an entry in the database should reflect at least ten representative strains of the species, but for some taxa, and particularly for the new species which have been based upon just one strain or very

few strains, this can be impossible. It can also be a problem for some of the older-established species, such as *Bacillus circulans* and *Bacillus lentus*, as the representative strains found in culture collections around the world are sometimes the widely dispersed subcultures of a few original isolates. These problems emphasize the importance of basing proposals for new taxa on adequate numbers of strains to reflect the diversities of the taxa.

A further problem has emerged with the splitting of well-established (but not necessarily homogeneous) species or groups into large numbers of new taxa over a short period. *Bacillus circulans* was long referred to as a complex rather than a species, but the revision of the taxonomy of this group, and consequent proposals for several new species to be derived from it, have led to difficulties in identification. Although the proposals were mostly based upon polyphasic taxonomic studies, initial recognition of the new taxa depended largely upon DNA relatedness data. A DNA:DNA reassociation study of *Bacillus circulans* strains yielded *Bacillus circulans sensu stricto*, *Bacillus amylobiticus*, *Bacillus lautus*, *Bacillus pabuli* and *Bacillus validus* and evidence for the existence of five other species (Nakamura, 1984a; Nakamura and Swezey, 1983). *Bacillus amylobiticus*, *Bacillus lautus*, *Bacillus pabuli* and *Bacillus validus* are now accommodated in *Paenibacillus*, and these species and *Bacillus circulans* are difficult to distinguish using routine phenotypic tests.

Such radical taxonomic revisions have left many culture collections worldwide with few representatives of *Bacillus circulans sensu stricto*, but with numerous misnamed strains of this species, which may or may not belong to one of the newly proposed taxa. The curators will normally not be able to know which are which without considerable expenditure in scholarship and experimental work, and in many cases a collection will hold only one authentic strain, the type strain, of a species - be it an old or new species.

When attempting to construct an identification scheme for *Bacillus* the implication of such rapid taxonomic progress is huge. Accessing authentic strains of many species, even well-established ones, may require much time and effort, and for several of them the strains available may be too few to allow the diversities of the taxa to be adequately reflected in the identification scheme. Smith et al. (1952) and Gordon et al. (1973) showed commendable restraint in their concept of a bacterial species, saying in the latter monograph: "When only a few strains of a group are available, as often happens, their species descriptions must remain tentative until verified by the study of more strains". Just as taxonomists can only be as good as their culture collections, so identification systems can only be as good as their databases.

Although many new characterization methods have been developed over the last 30 years, the principle of identification remains the same; identifications cannot be achieved, strictly speaking; the best that can be done is to seek the taxon to which the unknown strain probably belongs. The outcome is expressed as a probability and, as with the classification upon which the scheme is based, the answer cannot be final (Logan, 2002). It should not be assumed that, because traditional approaches for identifying *Bacillus* are perceived as being difficult and unreliable, any newer approach is likely to be superior regardless of the size and quality of its database; whatever characterization method is used, considerable amounts of time, money and expertise need to be invested in the construction of

reliable and detailed databases, which must be founded upon wide diversities of authentic reference strains.

Standardization. Whatever methods are used to generate the characters upon which identifications are based, standardization of methodologies and inclusion of reference strains is crucial. The methods used to generate the characters included in species descriptions have not usually been standardized between laboratories, and the test results shown in differentiation tables often include information lifted from the literature, so that data are often not comparable. As the number of valid *Bacillus* species increases, the task of studying related and reference organisms in parallel becomes more demanding for classification and identification work, and authors may be tempted to lean ever more heavily on data presented in the literature. In addition, standardization of methodologies for many phenotypic tests is inherently impossible between those organisms whose temperatures and pH ranges for growth do not overlap. Miniaturized versions of traditional biochemical tests (API kits, VITEK cards, and Biolog plates) offer standardized methods for a range of biochemical characters; the first named offers some versatility in temperature and pH, while the last named can be incubated at a range of temperatures.

Media. The most widely used solid media for cultivating neutrophilic *Bacillus* species are nutrient agar and trypticase soy agar; these media may be adjusted to higher or lower pH for cultivating alcaliphiles and acidiphiles, and NaCl may be added for the cultivation of halophiles. Sporangial morphology remains an important character, and although many strains will sporulate on these media within a few days of incubation, the addition of 5 mg/l of $MnSO_4 \cdot xH_2O$ is recommended for encouraging sporulation. Gordon et al. (1973) recommended soil extract agar to encourage sporulation for the purpose of strain maintenance, but this approach is unnecessarily laborious as the addition of manganese ions appears to serve just as well. Rich media such as blood agar may not yield sporulated cells and the culture might die without sporulating. Many of the more recently described *Bacillus* species have been found in unusual environments and/or have been isolated and studied using special media; these media are described in the descriptions of these species (see below). Most of the media (or revisions described by Claus and Berkeley, 1986) used by Gordon et al. (1973) for separation of the nine species that they listed, and which remain in the genus, are given below. Other media employed by Gordon et al., such as litmus milk, are not listed because they gave very poorly reproducible results (Logan and Berkeley, 1981) and/or are now rarely used for some other reason.

Anaerobic agar. Trypticase (trypsin hydrolysate of casein), 20 g; glucose, 10 g; NaCl, 5 g; sodium thioglycolate (mercaptoacetic acid, sodium salt), 2 g; sodium formaldehydesulfoxylate (hydroxymethanesulfinic acid, monosodium salt dihydrate), 1 g; agar 15 g; distilled water, 1 l; pH 7.2. Distribute into 15 mm diameter glass tubes to 75 mm depth and autoclave at 121 °C for 20 min. Several commercial preparations are available. (Note: Gordon et al. omitted the indicator and glucose from the usual formulation of this medium).

Citrate and propionate utilization media. Trisodium citrate $\cdot 2H_2O$, 1 g (or sodium propionate, 2 g); $MgSO_4 \cdot 7H_2O$, 1.2 g; $(NH_4)_2HPO_4$, 0.5 g; KCl, 1 g; trace element solution, 40 ml; phenol red (0.04% w/v solution), 20 ml; agar, 15 g; distilled water, 920 ml; pH 6.8;

distribute in tubes, autoclave at 121 °C for 20 min and set as slopes. Trace element solution: ethylenediaminetetraacetate, 500 mg; FeSO₄·7H₂O, 200 mg; H₃BO₃, 30 mg; CoCl₂·6H₂O, 20 mg; ZnSO₄·7H₂O, 10 mg; MnCl₂·4H₂O, 3 mg; Na₂MoO₄·2H₂O, 3 mg; NiCl₂·6H₂O, 2 mg; CuCl₂·2H₂O, 1 mg; distilled water, 1 l.

Egg-yolk reaction medium. Tryptone (trypsin hydrolysate of casein), 10 g; Na₂HPO₄, 5 g; KH₂PO₄, 1 g; NaCl, 2 g; MgSO₄·7H₂O, 0.1 g; glucose, 2 g; distilled water, 1 l; pH 7.6; autoclave at 121 °C for 20 min. Add sterile, commercially prepared egg-yolk emulsion (at the concentration recommended by the manufacturer), or 1.5 ml egg yolk (aseptically aspirated from a hen's egg) to 100 ml of basal medium and allow to stand overnight in a refrigerator. Dispense the supernatant in 2.5 ml amounts; basal medium without yolk is similarly dispensed. Modern practice replaces this medium with egg-yolk agar, without a noticeable difference in sensitivity: add 10 ml commercially prepared egg-yolk emulsion to 90 ml molten nutrient agar held at 45–50 °C; mix and pour as plates.

Glucose agar. D-Glucose, anhydrous, 10 g; nutrient agar, 1 l; pH 6.8; mix thoroughly and autoclave at 115 °C for 20 min.

Medium for acid production from carbohydrates. Basal medium: (NH₄)₂HPO₄, 1 g; KCl, 0.2 g; MgSO₄·7H₂O, 0.2 g; yeast extract, 0.2 g; agar 15 g; distilled water, 1 l; adjust to pH 7.0; bromcresol purple (0.04% w/v solution), 15 ml; autoclave at 121 °C for 20 min. Aqueous solutions (10% w/v) of carbohydrates are filter-sterilized or may be autoclaved at 121 °C for 20 min. Gordon et al. (1973) used L-arabinose, D-glucose, D-mannitol and D-xylose, but on the basis of API 50CHB tests (see *Miniaturized biochemical test systems*, below) the following other carbohydrates may be valuable for differentiation of certain species: N-acetylglucosamine, D-mannose, D-tagatose, galactose, gluconate, glycerol, glycogen, inulin, melezitose, methyl α-D-mannoside, β-methylxyloside, salicin and starch. Aseptically add carbohydrate solution to molten base to a final concentration of 0.5% w/v, and set the medium as slopes. Media for testing acidophilic and alkaliphilic strains are described in *Methods*, pH below.

Milk agar. Skim milk powder, 5 g in 50 ml of distilled water; agar, 1 g in 50 ml of distilled water. Autoclave separately at 121 °C for 20 min, cool to 45 °C, mix, and pour into Petri dishes. Dry the surfaces of the plates before use.

Nitrate broth. Peptone (trypsin hydrolysate of meat), 5 g; beef extract, 3 g; KNO₃, 1 g; distilled water, 1 l; pH 7.0. Distribute into test tubes containing inverted Durham's tubes, and autoclave at 121 °C for 20 min.

Gelatin medium. Gelatin, 120 g; distilled water, 1 l; pH 7.0; autoclave at 121 °C for 20 min; distribute in test tubes. Alternatively, tubes of commercially prepared nutrient gelatin may be used, or plates of nutrient agar supplemented with 0.4% gelatin.

Phenylalanine agar. NaCl, 5 g; yeast extract, 3 g; DL-phenylalanine, 2 g; Na₂HPO₄, 1 g; agar, 12 g; distilled water, 1 l; pH 7.3; distribute in tubes, autoclave at 121 °C for 20 min and set as slopes. Claus and Berkeley (1986) favored the commercially prepared product available from BBL (www.voightglobal.com).

Resistance to lysozyme medium. Prepare a solution of lysozyme containing 10,000 enzyme units/ml in distilled water and sterilize it by filtration. Add 1 ml of this medium to 99 ml sterile nutrient broth and distribute the mixture in 2.5 ml amounts.

Sabouraud dextrose broth. Neopeptone (enzyme digest of casein and meat), 10 g; D-glucose, 40 g; agar, 15 g; distilled water, 1 l; pH 5.7; dispense into test tubes, sterilize by autoclaving at 121 °C for 20 min, and set as slopes. The broth is prepared by reducing the glucose content to 20 g, omitting the agar, and distributing in tubes.

Sodium chloride media. Tubes of nutrient broth are prepared with 0, 5, 7 and 10% (w/v) NaCl.

Starch agar. Suspend 1 g of potato starch in 10 ml cold distilled water and mix with 100 ml nutrient agar. Autoclave at 121 °C for 20 min, cool to 45 °C, mix thoroughly, and pour into Petri dishes.

Tyrosine agar. L-tyrosine, 0.5 g; distilled water, 10 ml; autoclave at 121 °C for 20 min. Mix aseptically with 100 ml sterile, molten nutrient agar, cool to about 50 °C and pour into Petri dishes, taking care to achieve a uniform distribution of the tyrosine crystals. Dry plates before use.

Voges – Proskauer broth. Proteose peptone (enzyme digest of meat), 7 g; glucose, 5 g; NaCl, 5 g; distilled water, 1 l; pH 6.5; dispense 5 ml amounts into 20 mm test tubes and sterilize by autoclaving at 115 °C for 20 min.

Methods. Current schemes for identifying *Bacillus* species may be roughly divided into four categories according to the kinds of characters they use: (i) traditional biochemical, morphological and physiological characters, (ii) miniaturized versions of traditional biochemical tests (API kits, VITEK cards, and Biolog plates), (iii) chemotaxonomic characters [such as fatty acid methyl ester (FAME) profiles, and pyrolysis mass spectrometry], and (iv) genomic characters (ribotyping, and nucleic acid probes). However, as early as the work of Smith et al. (1952) it was becoming clear that no one phenotypic technique would be suitable for identifying all *Bacillus* species. The problems have mounted up as further species from extreme environments have subsequently been proposed, and the potentials of chemotaxonomic analyses and studies of nucleic acids have therefore been investigated. The sections that follow outline these approaches and summarize their current contributions to identification for *Bacillus* and its relatives. However, it is impossible to devise standard conditions to accommodate the growth of strains of all species for chemotaxonomic work, and it remains unknown to the taxonomist if differences between taxa are consequences of genetic or environmental factors. The need to substantiate each characterization method by other techniques (be they phenotypic or genotypic) has become increasingly important as new techniques emerge. This need is satisfied by the polyphasic approach now usual for the better classification studies, and the same approach may sometimes be necessary in order to identify strains from some of the less familiar species.

Sporulation and microscopic appearance. Before attempting to identify to species level it is important to establish that the isolate really is an aerobic endospore-former. Isolates of large, aerobic Gram-positive rods have often been submitted to reference laboratories as *Bacillus* species, even though sporulation had not been observed, or because PHB granules or other storage inclusions had been mistaken for spores. It should also be borne in mind that *Bacillus* species do not always stain Gram-positive. See *Media* (above) for comments on suitable sporulation media; cultures grown on rich media may lyse and die

rather than sporulate. Sporulation has not been observed in several recently described species (*Bacillus infernus*, *Bacillus thermoamylovorans*), but the potential to form endospores may be detected using a PCR method based upon certain genes for sporulation (Brill and Wiegel, 1997).

A Gram-stained smear showing cells with unstained areas suggestive of spores can be stripped of oil with acetone/alcohol, washed, and then stained for spores. Spores are stained in heat-fixed smears by flooding with 10% aqueous malachite green for up to 45 min. (without heating), followed by washing and counterstaining with 0.5% aqueous safranin for 30 s; spores are green within pink/red cells at 1000× magnification. Phase-contrast (at 1000× magnification) should be used if available, as it is superior to spore-staining and more convenient. Spores are larger, more phase-bright, and more regular in shape, size and position than other kinds of inclusion such as polyhydroxybutyrate (PHB) granules (Figure 10e), and sporangial appearance is valuable in identification (Figure 10). Members of the *Bacillus cereus* group and *Bacillus megaterium* will produce large amounts of storage material when grown on carbohydrate media such as glucose agar, but on routine media this vacuolate or foamy appearance is rarely sufficiently pronounced to cause confusion (Figure 10e).

General morphology should be studied in relatively young (18–24 h at 30 °C) cultures grown in nutrient broths aerated by shaking. Morphologies of cells raised on nutrient agar plates or slopes may be heterogeneous owing to varying conditions of oxygen supply within colonies. Wet preparations may be viewed by phase-contrast microscopy at 1000× magnification, and observed for cell size (diameter), shape, shapes of ends of cells (rounded, squared, tapered), chains, filaments, and motility; for cells grown on glucose agar observe for storage inclusions (use the type strains of *Bacillus cereus* and *Bacillus subtilis* as positive and negative controls, respectively). Study cultures grown for 24 h and up to 7 d on medium supplemented with 5 mg/l MnSO₄ for spores: observe for spore shape (spherical, cylindrical, ellipsoidal), position (central or paracentral, subterminal, terminal), presence of parasporal bodies (use the type strain of *Bacillus thuringiensis* as positive control), and for swelling of the sporangium. Cells in wet preparations may be immobilized by coating clean slides with a thin (0.5 mm) layer of sterile 2% water agar; a drop of turbid suspension of the organism is placed on the solidified agar, overlaid with a coverslip, and viewed by phase-contrast microscopy in the normal way.

Capsule formation by *Bacillus anthracis*. The capsule of virulent *Bacillus anthracis* can be demonstrated on nutrient agar containing 0.7% sodium bicarbonate incubated overnight under 5–7% CO₂ (candle jars perform well). Colonies of the capsulated *Bacillus anthracis* appear mucoid, and the capsule can be visualized by staining smears with M'Fadyean's polychrome methylene blue or India ink, or by indirect fluorescent antibody staining (Logan and Turnbull, 2003). More simply, 2.5 ml of blood (defibrinated horse blood seems best; horse or fetal calf serum are quite good) can be inoculated with a pinhead quantity of growth from the suspect colony, incubated statically for 6–18 h at 37 °C, and M'Fadyean stained. The M'Fadyean stain is preferable to other capsule staining methods, as it is more specific for *Bacillus anthracis* capsules. As *Bacillus anthracis* is suspected, safety precautions must be taken throughout capsule staining procedures; all materials coming into contact with the specimen, including spent reagents and rinsings, must either be discarded

into a disinfectant effective against endospores or autoclaved. For the M'Fadyean stain, make a thin smear from the specimen, and also from a positive control, on a clean slide and allow to dry. Fix by immersion in 95% or absolute alcohol for 30–60 s. Put a large drop (approx. 50 µl) of polychrome methylene blue (M'Fadyean stain) on the smear and ensure all the smear is covered by spreading the stain with an inoculating loop ("flooding" the slide is wasteful, unnecessary and ecologically undesirable). Leave for one minute and wash the stain off with water (into 10% hypochlorite solution). Blot the slide and allow to dry. At 100–400× magnification, the organisms can be seen as fine short threads; at 1,000× magnification (oil immersion), if virulent *Bacillus anthracis* is present, the capsule should be seen as a clearly demarcated zone around the blue-black, often square-ended rods which lie in short chains of two to a few cells in number. The positive control can be prepared by culturing a virulent strain in defibrinated horse blood as described above. For India ink negative-staining, place a large loopful of undiluted India ink on a cleaned slide, and mix in a small portion of the bacterial colony or a small loopful of the deposit from a centrifuged liquid culture. Drop a cleaned cover glass on, avoiding air bubbles, and press firmly between two sheets of blotting paper. When examined at 1000× under oil, the capsules appear as haloes around the highly refractive outlines of the bacterial cells. When capsules are absent, the ink particles directly abut the cell wall, and the cells are not easily seen. Phase-contrast is superior to bright-field microscopy, as the bacterial cells can be seen clearly in all cases.

Gamma phage sensitivity of *Bacillus anthracis*. Schuch et al. (2002) found that the PlyG lysin of γ phage may be used to detect *Bacillus anthracis* by luminescence, and that the same lysin could kill vegetative cells and germinating spores. blood agar plates to test for γ phage and penicillin susceptibility. Enquiries about gamma phage and indirect fluorescent antibody capsule staining should be addressed to the Diagnostics Systems Division, USAMRIID, Fort Detrick, Frederick, MD 21702-5011, USA.

Incubation temperature and time. Select an incubation temperature that matches the optimum growth temperature of the organism(s) as closely as is practical. Convenient temperatures are 20 °C for psychrophiles, 30 °C for mesophiles, and 45, 50 or 55 °C for strains growing up to 55–65 °C. Claus and Berkeley (1986) suggested that the incubation temperature should lie 10–15 °C below the maximum growth temperature, and this remains sound advice; however, it should be noted that some new isolates of well-established species and strains of certain more recently described species may have unusually narrow or wide growth temperature ranges, so that this rule of thumb can be difficult to apply. Although Gordon et al. (1973) stipulated incubation periods of up to 14 d for many tests, most strains will have realized their potentials on these test media within 7 d.

pH. The media and the methods used by Gordon et al. (1973), and presented here in updated form, were mainly developed for mesophilic, neutrophilic species. They will not be applicable to acidophilic and alkaliphilic organisms. Certain media and methods may be adapted by adjusting the acidity as far as pH 6 for moderate acidophiles; for tests based upon acid production from carbohydrates, an indicator with a lower end point such as bromcresol purple will need to be selected (see Logan et al., 2000, and *Miniaturized biochemical test systems*, below).

For alkaliphilic organisms, the methods described by Fritze et al. (1990) may be recommended: the alkalinity of the casein, gelatin, nitrate and phenylalanine media, and media for determining growth temperatures and salt tolerance may be raised as far as pH 9.5–10 by adding 100 ml/1 l M sodium sesquicarbonate after autoclaving; the phenylalanine medium is prepared with only 50 ml/1 l M sodium sesquicarbonate, and it and the nitrate reduction medium should be acidified at the time of reading the results. Acid production from carbohydrates may be detected by using thymol blue in the following basal medium: K_2HPO_4 , 7 g; NaCl, 5 g; KH_2PO_4 , 2 g; $(NH_4)_2SO_4$, 1 g; $MgSO_4 \cdot 7H_2O$, 0.1 g; vitamin solution, 1 ml; distilled water, 1 l; adjust to pH 8.9–9.1 with NaOH. The vitamin solution contained: pyridoxine HCl, 100 mg; *p*-aminobenzoic acid, 50 mg; calcium *D*-pantothenate, 50 mg; nicotinic acid, 50 mg; riboflavin, 50 mg; thiamin HCl, 50 mg; *D*-biotin, 20 mg; folic acid, 20 mg; vitamin B12, 1 mg; distilled water, 1 l. The same basal medium, containing glucose as the carbon source and with pH adjusted with sodium sesquicarbonate, is used to test for ability to grow in neutral and alkaline conditions. Other tests useful for characterizing alkaliphiles are: diaminopimelic acid in cell walls, glucuronidase, pullulanase, Tween hydrolysis, and urease. The presence of diaminopimelic acid in cell walls is tested as follows: hydrolyze 1 mg dried cells with 1 ml 6 N HCl in a sealed, hard-glass tube held at 100 °C for 18 h; cool; filter the sample through paper and wash with 1 ml H_2O ; remove HCl by drying 2–3 consecutive times under reduced pressure at 40 °C on a rotary evaporator; take up residue with 0.3 ml H_2O and spot 5 ml onto a cellulose-coated (microcrystalline) thin layer chromatography plate; separate the amino acids using the solvent mixture methanol-water-10 N HCl-pyridine (80:17.5:2.5:10, by volume), and detect them using acetic ninhydrin spray (0.1% w/v) followed by heating at 100 °C for 2 min. DAP spots are olive green fading to yellow, while other amino acids give purple spots. β -glucuronidase is detected by 4-methyl-umbelliferone glucuronide (MUG) agar: tryptose, 20 g; NaCl, 5 g; cysteine · HCl, 1 g; agar, 12 g; distilled water, 1 l; pH 9.7; autoclave and hold molten at 45–50 °C; dissolve MUG in warm water and filter through a 0.22 μ m membrane or autoclave the solution; add this solution to the agar base at 100 μ g/ml and distribute in microtiter plate wells; when solidified, stab inoculate the wells and seal the microtiter plate with plate tape; observe after overnight incubation for fluorescence at about 366 nm. For pullulanase, add 0.3% (w/v) pullulan to a minimal medium at pH 9.7, and supplement with sterile solutions of peptone (0.5%), yeast extract (0.05%), and vitamin supplements; inoculate, incubate and reveal the reaction as for starch hydrolysis (below). For hydrolysis of Tween 20, 40 and 60, use the following medium: peptone, 10 g; NaCl, 5 g; $CaCl_2 \cdot H_2O$, 0.1 g; agar, 11 g; water, 1 l; pH 9.7; autoclave at 121 °C for 20 min and cool to 45–50 °C; add Tween to final concentration of 1% and pour plates; inoculate as single streaks, incubate up to 7 d, and observe for opaque halo. For urease detection, strains are cultivated on slopes of nutrient agar and growth is washed off at 3 and 7 d with 2 ml distilled water into a test tube; a drop of phenol red indicator is added and the reaction brought to pH 7 with dilute HCl; the suspension is equally divided and one tube has 0.1 g crystalline urea added (the other tube is a negative control) and allowed to stand; an alkaline reaction demonstrates the presence of urease. Nielsen et al. (1995a) determined carbohydrate utilization

profiles of alkaliphiles using the API 50CH gallery (see *Mimiatized biochemical test systems*, below).

Salinity. Halotolerant and halophilic organisms may be tested in the Gordon et al. (1973) media, but supplemented with up to 10% NaCl; reactions of these salt-loving organisms in routine tests may often be very weak. Alternatively, media prepared in a marine broth or marine salts base may be used. Halophiles may often also be alkaliphilic.

Traditional characterization tests. *Bacillus cereus*, *Bacillus circulans*, *Bacillus coagulans*, *Bacillus firmus*, *Bacillus licheniformis*, *Bacillus megaterium*, *Bacillus pumilus*, *Bacillus sphaericus* and *Bacillus subtilis* are the only species listed and distinguished by Gordon et al. (1973) that remain in *Bacillus* after later taxonomic revisions, and the tests outlined below are still valuable for distinguishing between these commonly encountered species.

Inocula. Use 1 drop inocula of overnight (for mesophiles at 30 °C) nutrient broth cultures delivered with Pasteur pipettes for liquid and sloped media. For plate media, use the same culture, but apply the inoculum with a moderate sized (2–3 mm outside diameter) loop.

Maximum and minimum growth temperatures. Use slopes of nutrient agar or some other suitable growth medium for the organism, immerse bottles to their necks in a waterbath at the chosen temperature and allow to equilibrate prior to inoculation. Intervals of 5 °C are recommended. Take care to maintain the water levels in the waterbaths throughout the test. Observe for growth after 3 d for temperatures of 55 °C or higher, after 5 d at 30–50 °C, after 14 d at 20 and 25 °C, and after 21 d for temperatures below 20 °C.

Acid production from carbohydrates. Inoculate, incubate, and observe for growth and acid production (shown by the indicator passing from mauve through gray to yellow) for up to 14 d. Use the type strain of *Bacillus subtilis* as positive control and the type strain of *Bacillus sphaericus* as negative control for L-arabinose, *D*-glucose, *D*-mannitol and *D*-xylose.

Anaerobic growth. Inoculate a tube of anaerobic agar with a small loopful of broth culture by stabbing to the bottom of the tube, or use a Pasteur pipette to seed molten medium held at about 40 °C and then allow the agar to solidify. Incubate mesophiles for 3–7 d. Use the type strains of *Bacillus cereus* and *Bacillus megaterium* as positive and negative controls, respectively.

Casein decomposition. Inoculate plates of milk agar with one-streak inocula, incubate, and observe for zones of clearing around the growth over 7 d and up to 14 d. At the termination of the test, scrape growth aside with a loop and observe for weak reactions which may have occurred beneath the colony. Use the type strains of *Bacillus megaterium* and *Paenibacillus macerans* as positive and negative controls, respectively.

Citrate and propionate utilization. Inoculate slants of the citrate and propionate utilization media and incubate for up to 7 d. Observe for a red (alkaline) reaction which indicates utilization of the substrate as sole carbon source. Use the type strains of *Bacillus subtilis* and *Bacillus badius* as positive and negative controls for citrate, and the type strains of *Bacillus licheniformis* and *Bacillus subtilis* as positive and negative controls for propionate, respectively.

Egg-yolk reaction medium. Inoculate into an egg-yolk broth and a control broth lacking egg yolk, incubate for up to 7 d, observing the egg-yolk broth at 1 or 2-d intervals for a heavy white precipitate in or on the surface of the medium. If using plates of egg-yolk agar, apply one-streak inocula, incubate as for tubes, and observe for a zone of whitish opacity in the medium around the growth. Use the type strains of *Bacillus cereus* and *Bacillus megaterium* as positive and negative controls, respectively.

Gelatin hydrolysis. Inoculate tubes of nutrient gelatin and incubate at 28 °C; at 2- to 3-d intervals, for up to 4 weeks, hold the tubes at 20 °C for 4 h and observe for liquefaction. If using plate medium, inoculate with a single streak and incubate for 3–5 d, scrape some growth aside with a loop to reveal weak reactions which may have occurred beneath the colony, then flood the plate with 10 ml of 1 N H₂SO₄ saturated with Na₂SO₄; unchanged gelatin forms an opaque precipitate within 1 h, and a clear zone indicates hydrolysis. Use the type strains of *Bacillus cereus* and *Bacillus coagulans* as positive and negative controls, respectively.

Growth at pH 5.7 in Sabouraud media. Inoculate a slope of Sabouraud dextrose agar and a tube of Sabouraud dextrose broth, and a tube of nutrient broth as a control, incubate, and observe for growth in either or both Sabouraud media for up to 14 d. Use the type strains of *Bacillus cereus* and *Bacillus badius* as positive and negative controls, respectively.

Nitrate reduction. Inoculate nitrate broths and incubate. After 3 and 7 d, observe for gas in the Durham tube, indicating reduction of nitrate through nitrite to nitrogen gas), and touch a loopful of culture onto a strip of potassium iodide/starch paper which has been moistened with a few drops of 1 N hydrochloric acid and observe for a purple color which indicates the presence of nitrite. Strains negative at 7 d are tested at 14 d by mixing 1 ml culture with 3 drops of each of: (i) sulfanilic acid, 0.8 g; 5 N acetic acid (glacial acetic acid and water 1:2.5), 100 ml; (ii) dimethyl- α -naphthylamine, 0.6 ml; acetic acid, 100 ml. A red or yellow (=high concentration) color indicates the presence of nitrite. If still negative, add 4–5 mg zinc dust to the tube; if a red color develops (owing to reduction of nitrate to nitrite by the zinc) it indicates the absence of nitrate reduction by the organism, and confirms that rapid reduction of nitrate to nitrogen gas (not trapped by the Durham tube) has not occurred within the first 3 d of incubation. Use the type strains of *Bacillus cereus* and *Bacillus megaterium* as positive and negative controls, respectively.

Phenylalanine deamination. Inoculate duplicate slopes of phenylalanine agar and incubate for 7 d. Pipette 4–5 drops of 10% (w/v) ferric chloride solution over the slope and observe for a green color beneath the growth; this indicates the formation of phenylpyruvic acid from the phenylalanine. If negative, the second tube is tested after 14 d further incubation. Use the type strains of *Bacillus megaterium* and *Bacillus cereus* as positive and negative controls, respectively.

Resistance to lysozyme. Lightly inoculate a tube of resistance-to-lysozyme medium and a control tube of 2.5 ml nutrient broth and incubate. Observe for growth or its absence in the lysozyme medium after 7–14 d. Use the type strains of *Bacillus cereus* and *Bacillus megaterium* as positive and negative controls, respectively.

Sodium chloride tolerance. Lightly inoculate NaCl broths, incubate at a slant in order to enhance aeration, and observe for growth after 7 and 14 d.

Starch hydrolysis. Inoculate duplicate plates of starch agar and incubate. At 3 and 5 d scrape some growth aside with a loop to reveal weak reactions which may have occurred beneath the colony and flood the plates with 95% ethanol in order to make the unchanged starch turn white and opaque; observe for a clear zone around and under the growth which indicates starch hydrolysis. Use the type strains of *Bacillus cereus* and *Bacillus sphaericus* as positive and negative controls, respectively.

Tyrosine decomposition. Use one-streak inocula on plates of tyrosine agar and incubate; protect from drying during incubation. Observe for clearing of the tyrosine crystals around and below the growth after 7 and 14 d. Use the type strains of *Bacillus cereus* and *Bacillus sphaericus* as positive and negative controls, respectively.

Voges–Proskauer reaction. Inoculate Voges–Proskauer broths in triplicate and test for acetyl methyl carbinol production after incubation for 3, 5 and 7 d by adding 3 ml of 40% (w/v) NaOH to the culture and adding 0.5–1 mg creatine. Vortex mix to aerate and observe for the production of a red color after 30–60 min at room temperature. Use the type strains of *Bacillus cereus* and *Bacillus megaterium* as positive and negative controls, respectively.

Chemotaxonomic characters. Chemotaxonomic fingerprinting techniques applied to aerobic endospore-formers include FAME profiling (Kämpfer, 2002), polyacrylamide gel electrophoresis (PAGE) analysis (De Vos, 2002), pyrolysis mass spectrometry, and Fourier-transform infra-red spectroscopy (Magee and Goodacre, 2002). Only one of these approaches, FAME analysis, is supported by a commercially available database for routine identification. Fatty acid analysis can play a very useful part in polyphasic taxonomic studies of *Bacillus*. However, fatty acid profiles across the aerobic endospore-forming genera do not, given frequent and considerable within-species heterogeneity, form the basis of a reliable, stand-alone identification scheme (Kämpfer, 1994, 2002). A further difficulty is the need for a standardized media and incubation temperature for preparing isolates for FAME analysis, making databases for acidophiles, alkaliphiles, neutrophiles, mesophiles, psychrophiles and thermophiles incompatible. The commercially available Microbial Identification System software (MIDI, Newark, Delaware, USA) includes a FAME database for the identification of aerobic endospore-formers. Although it cannot be expected to give an accurate or reliable identification with every isolate, it is certainly a valuable screening tool when used with caution.

Serology. See *Antigenic structure* in *Further descriptive information*, above.

Genotypic methods. As with other groups of bacteria, studies of 16S rDNA and of DNA have very valuable applications in the classification of aerobic endospore-formers (De Vos, 2002). Nucleic acid fingerprinting techniques are also of great potential for typing work, of course. A good example is the ability to differentiate *Bacillus anthracis* strains by amplified fragment length polymorphism (AFLP) analysis (Keim et al., 1997) on account of variable number tandem repeats (VNTR; Keim et al., 2000; Turnbull et al., 2002), as the distinction of isolates

of this species for epidemiological or strategic purposes has long been a challenge. AFLP also shows promise for the epidemiological typing of *Bacillus cereus* (Ripabelli et al., 2000).

At present, however, nucleic acid analyses are not entirely suitable for the routine identification of aerobic endospore-formers; their value in classification does not necessarily make them suitable as routine diagnostic tools at the species level. Amplified rDNA restriction analysis (ARDRA), for example, has been and continues to be exceptionally effective in the classification of *Bacillus* (Logan et al., 2000). It is a very powerful technique for recognizing new taxa and can be used to screen large numbers of strains much faster than is reasonably possible with 16S rDNA sequencing, but it is not always capable of distinguishing closely related species (Logan et al., 2002b). Sequencing of 16S rDNA is not always capable of resolving species either; not only are the sequences within and adjacent to this gene almost identical among *Bacillus anthracis*, *Bacillus cereus* and *Bacillus thuringiensis*, but the variable sites within these sequences can differ among multiple rRNA cistrons within a single strain (Turnbull et al., 2002).

Other fingerprinting methods such as ribotyping, which is commercially available, are presently limited by the appropriateness of the restriction enzymes they use, and by the sizes of the databases available to those developing them – both in terms of the numbers of species included and of the numbers of authentic strains representing those species.

The use of gene probes in conjunction with the PCR, to allow rapid and sensitive detection, is covered in *Genetics*, above.

Miniaturized biochemical test systems. Over 50 years after Smith et al. (1946) published their first identification scheme, the most widely used commercially available methods for identifying members of the genus *Bacillus* and its relatives are still based upon miniaturized developments of traditional, routine biochemical tests: the API 20E and 50CHB Systems (bioMérieux, Marcy l'Etoile, France), the VITEK System (bioMérieux, Hazelwood, Missouri, USA) and Biolog (Biolog Inc., Hayward, California, USA) (Logan et al., 2000).

The API 20E/50CHB kits contain miniaturized and standardized versions of conventional biochemical tests, the API 50CHB comprising 48 tests for acid production from carbohydrates, esculin hydrolysis, and a negative control. They can be used for distinguishing between a number of well-established *Bacillus* species, can also recognize biotypes within the *Bacillus cereus* group (Logan et al., 1979) and may be used for the presumptive distinction of *Bacillus anthracis* from other members of the *Bacillus cereus* group within 48 h. The overall findings of an international reproducibility trial employing code-numbered *Bacillus sensu lato* strains showed that better test reproducibility could be achieved with API tests than with the conventional tests of Gordon et al. (1973), even when the latter had been carefully standardized by the Subcommittee on the Taxonomy of the Genus *Bacillus* of the International Committee on Systematic Bacteriology (Logan and Berkeley, 1981). API tests have proved valuable in the characterization of several novel species of aerobic endospore-formers (Heyndrickx et al., 1998, 1999; Heyrman et al., 2003a, b, 2004; Logan et al., 2000, 2002b, 2004b). The API 50CH gallery offers some flexibility in incubation temperature and in pH and salinity of the suspension medium. Deinhard et al. (1987a) used an ammonium salts-yeast extract medium at pH 4, with bromphenol blue as indicator, to investigate acid production from carbohydrates in

the API 50CH gallery by strains of *Bacillus* (now *Alicyclobacillus acidoterrestis*, and Logan et al. (2000) used a similar medium at pH 6 with 0.033% bromocresol purple as indicator to characterize strains of *Bacillus fumarioli*: KH_2PO_4 , 3 g; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.5 g; $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$, 0.25 g; $(\text{NH}_4)_2\text{SO}_4$, 0.2; yeast extract, 0.5 g; trace element solution, 1 ml; bromocresol purple, 0.33 g; distilled water, 1 l; pH 6.0. Trace element solution contained: $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, 0.05 g; $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$, 0.05 g; $\text{MnSO}_4 \cdot 3\text{H}_2\text{O}$, 0.05 g; distilled water, 100 ml; 0.1 M H_2SO_4 , 1 ml. Nielsen et al. (1995a) used the 50CH gallery for testing carbohydrate utilization by alkaliphilic *Bacillus* species. Heyrman et al. (2003b) added up to 10% NaCl to the API 50CHB suspension medium in order to detect acid production by strains of halotolerant and halophilic *Bacillus* and *Virgibacillus* strains.

The Vitek system arose from the Auto Microbial System (AMS) which was used for the direct identification of microbes from urine samples (Aldridge et al., 1977) and which led from the Microbial Load Monitor (MLM), which was an instrumental system developed for NASA in the 1960s for the detection of specific micro-organisms in a space-craft environment. bioMérieux offers a *Bacillus* card for the VITEK automated identification system; identifications are automatically attempted hourly between 6 h of incubation and the final reading at 15 h.

As many new species have been proposed since the API and Vitek schemes were established, updated databases are being prepared following the study of a large number of strains which have been carefully authenticated by polyphasic taxonomic study. Biolog also offers a database for the aerobic endospore-forming bacteria. The Biolog system is based on carbon source utilization patterns, indicated by the reduction of a tetrazolium dye, using a 96-well MicroPlate that is inoculated with a standardized suspension of a pure culture and incubated as appropriate. Unlike the API 50CH, the system is based on the process of metabolism itself rather than the release of metabolic by-products such as acid. For *Bacillus* identification the first release of the Biolog Gram-positive panel was dogged by problems of false positive results (Baillie et al., 1995), and this problem has been addressed by using a more viscous suspension medium to reduce flocculation and pellicle formation. The MicroPlates can be read after 4–6 h incubation, then reincubated for a further 12–18 h if an acceptable similarity threshold has not been reached.

The effectiveness of such kits can vary with the genera and species of aerobic endospore formers concerned, but they are improving with continuing development and expanding databases (Logan, 2002), and many of the characters they test are valuable in polyphasic taxonomic studies. It is stressed that their use for identification should always be preceded by the basic characterization tests, especially endospore formation, described above.

Differentiation from closely related taxa

The 142 species of *Bacillus* present such a wide diversity of routine phenotypic features that there are no characters that reliably allow distinction of *Bacillus* species from members of the other 18 genera in the family *Bacillaceae*, or from some genera of aerobic endospore-forming bacteria in other families. Table 1 summarizes some routine phenotypic characters that may be of value for differentiating between members of the family.

Taxonomic comments

Ferdinand Cohn established the genus *Bacillus* in 1872 to include the three species of rod-shaped bacteria, *Bacillus subtilis* (type species), *Bacillus anthracis* and *Bacillus ulna*, without taking motility or sporulation into account. Ehrenberg had described *Vibrio subtilis* in 1835, and “subtilis” is one of the earliest bacterial species epithets still in use. Davaine (1868) had proposed the genus *Bacteridium* to accommodate the nonmotile organism that causes anthrax. Cohn illustrated spores, and in later publications he discussed the resistance of spores and their significance in anthrax epidemiology, but Winter (1880) was the first to include “propagation through spores” in the description of the genus, and Prazmowski (1880) was the first to use sporulation as a differential (i.e., taxonomic) characteristic; he proposed the genus name *Clostridium* for organisms that differed from *Bacillus* in having spindle-shaped sporangia. At this time some workers still believed that all bacteria existed in several morphological and physiological forms, and that classification of the “fission fungi” was of no scientific value – Buchner (1882) claimed that shaking cultures of *Bacillus subtilis* at different temperatures could yield *Bacillus anthracis*!

The definition of the genus *Bacillus* as rod-shaped, aerobic or facultatively anaerobic organisms forming resistant endospores has been used for many years, and it remains of practical value despite the proposal of the strictly anaerobic species *Bacillus infernus* (Boone et al., 1995), *Bacillus arsenicoselenatis* and *Bacillus selenitireducens* (Switzer Blum et al., 1998). However, it was not until the 1880s that the name *Bacillus* and sporulation were brought together, and not until 1920 that aerobic growth became a defining character. From the 1880s to the 1900s *Bacillus* was variously used to contain rod-shaped organisms, all the rods except those in *Clostridium*, all the spore-formers, only those spore-formers producing unswollen sporangia, all motile rods, peritrichously flagellate rods (a classification that became the best-established in the American literature up to 1920), and nonmotile spore-formers with unswollen sporangia. The term *Bacillus* has thus been used in two senses: as a genus name, and, as “bacillus,” as a general reference to shape; unfortunately the latter remains the most widely accepted definition of the term, especially by medical bacteriologists. As early as 1913, Vuillemin (1913) considered the name *Bacillus* so vulgarized by its various applications that it should lose nomenclatural status.

Although some took physiological characters as well as morphological ones into account in their classifications, it was not until the Committee of the Society of American Bacteriologists on Characterization and Classification of Bacterial Types reported in the early volumes of the *Journal of Bacteriology* (Winslow et al., 1917, 1920), that satisfactory and largely uncontested definitions of the bacterial groups emerged. The family *Bacillaceae* was defined as “Rods producing endospores, usually Gram-positive. Flagella when present peritrichic. Often decompose protein media actively through the agency of enzymes” and *Bacillus* was described as “Aerobic forms. Mostly saprophytes. Liquefy gelatin. Often occur in long threads and form rhizoid colonies. Form of rod usually not greatly changed at sporulation”. The Committee also used the requirement of oxygen and sporangial shape for differentiation between *Bacillus* and *Clostridium*, the other genus in the family *Bacillaceae*, and this description was applied in the first and second editions of *Bergey’s Manual of Determinative Bacteriology* (Bergey et al., 1923,

1925). So, as noted by Gordon (1981), the definition of the genus *Bacillus* as aerobic endospore-forming rods had become widely established by the 1920s.

Identification remained difficult, however, and the early editions of *Bergey’s Manual* were not practical bench books for many taxa. Although the commonest spore-forming bacteria were accurately described in papers published early in the 20th century, Ford and his coworkers found that identification of their fresh isolates from milk remained difficult. This stimulated an extensive investigation of many strains from various environments in order to test the classification devised for the milk strains (Laubach et al., 1916; Lawrence and Ford, 1916), and 26 species were recognized – four of them new.

In 1937 it was agreed that “the genus *Bacillus* should be so defined as to exclude bacterial species which do not produce endospores” (Nomenclature Committee of the International Society for Microbiology, 1937; St. John-Brooks and Breed, 1937), over 100 years after Ehrenberg first described what is now the type species of the genus.

Some late-19th century classification schemes excluded motile organisms from *Bacillus*, and so abandoned *Bacillus subtilis* as the type species of the genus. Although other schemes retained *Bacillus subtilis*, in the late 1890s and early 1900s some confusion was emerging about the identity of the type. When describing *Bacillus cereus*, Frankland and Frankland (1887) noted its similarity both to *Bacillus anthracis* and a culture of *Bacillus subtilis* received from Koch. That could not have been *Bacillus subtilis* as recognized nowadays, and two very different type strains seemed to exist: one bore small spores and germinated equatorially, and the other formed much larger spores with germination occurring at the pole. The former was a strain from the University of Marburg and the latter was the Michigan type originating from the laboratory of Koch in 1888, and then maintained at the University of Michigan.

Following studies of strains from various culture collections, and after finding that the small-spored type tended to overgrow the large-spored type in cultures that mimicked the methods used by Cohn and other earlier workers, Conn (1930) suggested that the Marburg type should be called *Bacillus subtilis* Cohn. The Nomenclature Committee of the International Society for Microbiology sought the opinions of its members (Breed and St. John-Brooks, 1935), and in 1936, at the Second International Congress for Microbiology in London, the Marburg strain of *Bacillus subtilis* was officially adopted as the generic type (Nomenclature Committee of the International Society for Microbiology, 1937; St. John-Brooks and Breed, 1937).

With the resolution of the type strain controversy, the discovery that many pathogenic “*Bacillus subtilis*” strains were in fact *Bacillus cereus* stimulated a large taxonomic study of the genus (Clark, 1937) followed by a grouping of the mesophilic species in the form of a diagnostic key (Smith and Clark, 1937). In another study with a key, Gibson and Topping (1938) considered the *Bacillus circulans* and *Bacillus fusiformis* groups to be species complexes exhibiting several variations, and the problems so presented remain incompletely resolved to this day. Smith’s team meticulously characterized their cultures and then emphasized the similarities rather than the differences between their strains, so “lumping” their taxa rather than splitting them. In a report published a decade after the study began (Smith et al., 1946), they recognized three groups of species: Group

One comprised those with oval to cylindrical spores without definite swelling of the sporangia, and included the *Bacillus cereus* and *Bacillus subtilis* groups, *Bacillus pumilus*, *Bacillus lentus*, *Bacillus megaterium* and *Bacillus firmus*. Group Two contained those with oval spores and swollen sporangia, and included *Bacillus alvei*, *Bacillus brevis*, *Bacillus circulans*, *Bacillus laterosporus*, *Bacillus macerans* and *Bacillus polymyxa*. Group Three consisted of *Bacillus pasteurii* and *Bacillus sphaericus*, both of which produced round spores with distinct swelling of the sporangia. The first truly workable diagnostic key designed for *Bacillus* identification emerged as a result of this work and appeared in the 6th edition of *Bergey's Manual* (Breed et al., 1948). The effectiveness of the scheme was demonstrated by Knight and Proom (1950); in their study of 296 strains all but 51 could be allocated to the species or groups previously described.

Smith et al. (1952) published a revision of their 1946 report, another classic example of painstaking and objective work. It was based on the study of 1134 strains, and such were the problems of synonymy in the genus that although 491 of these had 158 species names on receipt, all but 20 could be assigned to only 19 species. The classification outlined was used in the 7th edition of *Bergey's Manual* (Breed et al., 1957) and was adopted by most bacteriologists working with *Bacillus*. The designation of *Bacillus anthracis* as a variety of *Bacillus cereus* resulted in much controversy, but Smith et al. (1946, 1952) cited several reports on the loss of pathogenicity by *Bacillus anthracis* and considered such strains to be indistinguishable from *Bacillus cereus*. These studies from Smith's laboratory shaped the future of *Bacillus* taxonomy, and various research groups began applying existing techniques and new methods to the taxonomy of the genus *Bacillus*.

Numerical taxonomic methods were first applied to *Bacillus* by Sneath, 1962) using the data of Smith et al. (1952), and a phenogram was constructed which "largely agreed" with the 1952 classification. Although current classifications were criticized by Bonde (1975) on the grounds that their systems depended more on laboratory culture collection strains than on fresh isolates, his own classification generally agreed with that of Gordon et al. (1973).

During the 1970s several new approaches to characterization such as serology, enzyme and other molecular studies, and pyrolysis gas-liquid chromatography (Oxborrow et al., 1977) began to emerge as potentially useful taxonomic tools in bacterial taxonomy as a whole but despite this, the taxonomy of *Bacillus* remained relatively untouched, with few new species or subspecies being described and names validated. With *Bacillus* the emphasis during this time was on facilitating the identification of members of the genus.

One of the most influential and significant studies of the genus *Bacillus* was published in by Gordon et al. (1973), 1,134 strains were included in a classification which formed the basis for the *Bacillus* section in the Eighth Edition of *Bergey's Manual* (Gibson and Gordon, 1974) but numerical methods were not used in the analysis. The classification was very similar to that proposed by Smith et al. (1946, 1952), the main difference being that subgrouping was not attempted and the species were arranged as a spectrum of morphological characteristics. Given the period at which the work was done, it is surprising that numerical analysis was not attempted, and so the success of the arrangement that was made is all the more impressive. The characterization tests applied by Gordon et al. (1973) were

used by the International Committee on Systematic Bacteriology Subcommittee on the Taxonomy of the Genus *Bacillus* as standard methods, but international reproducibility trials found that, even in the hands of *Bacillus* experts, the miniaturized, highly standardized tests in the API System gave more rapid and consistent results (Logan and Berkeley, 1981). The increasing incidence of *Bacillus* isolations from clinical environments emphasized the need for a rapid identification scheme, which could only follow an improved taxonomy of the genus. Consequently, Logan and Berkeley (1984) developed a *Bacillus* identification scheme based upon API tests.

It was also the classification of Gordon et al. (1973) with support from the work of Logan and Berkeley (1981) that formed the basis of the list of *Bacillus* included in the Approved Lists of Bacterial Names published by the International Committee of Systematic Bacteriology (Skerman et al., 1980). These lists marked a new starting date for bacterial nomenclature, the previous date being that of Linnaeus' monumental classification work, *Species Plantarum*, which was published in 1753. Since that time, many synonyms had been inadvertently been proposed, and the number of *Bacillus* species described fluctuated greatly through the eight editions of *Bergey's Manual*, ranging from a peak of 146 species in 1939 to the smallest number of 22 in 1974 (a further 26 appeared as *species incertae sedis*, and many of these were represented by very few strains).

The need for subdividing *Bacillus* had long been recognized from its DNA base composition range of 32–69 mol% G + C and the arrangements that had emerged from numerical taxonomies of phenotypic data (Logan, 1994). Early phylogenetic studies based on 16S rRNA cataloging (e.g., Fox et al., 1977, 1981; Stackebrandt et al., 1987) confirmed the evolutionary heterogeneity of *Bacillus*, and were found to be entirely consistent with the distribution of murein types among the species (Stackebrandt et al., 1987), but it was considered too early to split *Bacillus* to provide a more "natural" classification, as very few species had yet been analyzed by 16S rRNA cataloging or full sequence comparative studies. The genus was thus still kept as one taxonomic entity in *Bergey's Manual of Systematic Bacteriology* (Claus and Berkeley, 1986).

Ash et al. (1991) recognized five phylogenetically distinct clusters among 51 type strains of *Bacillus* species on the basis of 16S rRNA sequence similarities. Rössler et al. (1991) published the results of a similar study in the same year, finding four major clusters which showed high correlation with those described by Ash et al. A weakness of both studies was their reliance upon single (type) strains of each species, so that within-species diversities were not indicated and the authenticities of the strains were not controlled. Indeed, in the Ash et al. study, *Bacillus acidoterrestris* and *Bacillus lautus* were misplaced owing, presumably, to contaminants (Heyndrickx et al., 1996b; Wisotzkey et al., 1992). A sixth rRNA group containing *Bacillus alcalophilus* was recognized by Nielsen et al. (1994) but insufficient phenotypic and genotypic data were available to allow the proposal of a new genus.

With the accumulation of further 16S rRNA (rDNA) sequence data, *Bacillus* has been divided into more manageable and better-defined groups. So far, nine new genera have been established. However, this taxonomic progress has not revealed readily determinable features characteristic of each genus, and they show wide ranges of sporangial morphologies and phenotypic test patterns.

The proposal of *Alicyclobacillus* (Wisotzkey et al., 1992) initiated the splitting of the genus *Bacillus* and extensive reclassification ensued. *Alicyclobacillus* contains 19 species of thermoacidophiles, including organisms formerly called *Bacillus acidocaldarius* (Darland and Brock, 1971), *Bacillus acidoterrestris* (Deinhard et al., 1987a) and *Bacillus cycloheptanicus* (Deinhard et al., 1987b). These organisms exhibit ω -alicyclic fatty acids as the major natural membranous lipid components, a phenotypic trait not found in other *Bacillus* species.

Ash et al. (1993) proposed the genus *Paenibacillus* to encompass their previously described Group 3 (Ash et al., 1991) as they considered these organisms to be phylogenetically "so removed" from the cluster which contained *Bacillus subtilis* as to warrant such an action. Data from their 1991 publication were used along with previously published phenotypic characters, and a gene probe based on 16S rRNA. *Paenibacillus* contains 95 species and includes organisms formerly called *Bacillus alginolyticus* (Nakamura, 1987), *Bacillus alvei* (Cheshire and Cheyne, 1885), *Bacillus amylolyticus* (Nakamura, 1984a), *Bacillus chondroitinus* (Nakamura, 1987), *Bacillus curdlanolyticus* (Kanzawa et al., 1995), *Bacillus glucanolyticus* (Alexander and Priest, 1989), *Bacillus gordonae* (Pichinoty et al., 1986), a synonym of *Bacillus validus*, now *Paenibacillus validus* (Heyndrickx et al., 1995), *Bacillus kobensis* (Kanzawa et al., 1995), *Bacillus larvae* (White, 1906) and *Bacillus pulvifaciens* (Nakamura, 1984c) (now both subspecies of *Paenibacillus larvae* (Heyndrickx et al., 1996c), *Bacillus lautus* (Nakamura, 1984a), *Bacillus lentimorbus* (Dutky, 1940), *Bacillus macerans* (Schardinger, 1905), *Bacillus macquariensis* (Marshall and Ohye, 1966), *Bacillus pabuli* (Nakamura, 1984a), *Bacillus peoriae* (Montefusco et al., 1993), *Bacillus polymyxa* (Prazmowski, 1880), *Bacillus popilliae* (Dutky, 1940), *Bacillus thiaminolyticus* (Nakamura, 1990) and *Bacillus validus* (Nakamura, 1984a). It was perhaps surprising to find that *Bacillus circulans sensu stricto* was recovered within the cluster containing *Bacillus subtilis*, as it is phenotypically similar to *Paenibacillus polymyxa* and *Paenibacillus macerans*; however, strains originally named *Bacillus amylolyticus*, *Bacillus pabuli* and *Bacillus validus* had been members of the *Bacillus circulans* "complex" (Gibson and Topping, 1938) until these three species were revived by Nakamura (1984c). Another member of this complex, *Bacillus lautus*, was also revived by Nakamura (1984c) and later transferred to *Paenibacillus* (Heyndrickx et al., 1996c). Unfortunately, there is no phenotypic character which might allow the differentiation of the genus *Paenibacillus* from other genera of aerobic endospore-forming genera, and so the taxonomic gain in phylogenetic accuracy was not accompanied by easier routine identification.

Following 16S rRNA gene sequence analyses of type strains of species closely related to *Bacillus brevis* and *Bacillus aneurinolyticus* Shida et al. (1996) recognized two distinct clusters and proposed the *Bacillus brevis* cluster as a new genus *Brevibacillus* and the *Bacillus aneurinolyticus* cluster as *Aneurinibacillus*. *Brevibacillus* (Shida et al., 1996), contains the 10 species formerly known as *Bacillus agri* (Nakamura, 1993), *Bacillus borstelensis* (Shida et al., 1995), *Bacillus brevis* (Migula, 1900), *Bacillus centrosporus* (Nakamura, 1993), *Bacillus choshimensis* (Takagi et al., 1993), *Bacillus formosus* (Shida et al., 1995), *Bacillus laterosporus* (Laubach et al., 1916), *Bacillus parabravis* (Takagi et al., 1993), *Bacillus reuszeri* (Shida et al., 1996) and *Bacillus thermoruber* (Manachini et al., 1985). *Bacillus galactophilus* (Takagi et al., 1993) is a synonym of *Bacillus agri* (Shida et al., 1994). *Aneurinibacillus* (Shida et al., 1996) emend. Heyndrickx et al. (1997) accommodates the three species *Bacillus aneurinolyti-*

cus (Shida et al., 1994), *Bacillus migulanus* (Takagi et al., 1993), and *Bacillus thermoaerophilus* (MeierStaufer et al., 1996).

Subsequent developments included proposals for three genera of halotolerant and halophilic species: *Virgibacillus* (Heyndrickx et al., 1998) containing *Bacillus pantothenicus* (Proom and Knight, 1950); *Gracilibacillus* (Wainø et al., 1999) containing *Bacillus dipsosauri* (Lawson et al., 1996); *Salibacillus* (Wainø et al., 1999) containing *Bacillus marismortui* (Arahal et al., 1999, 2000) and *Bacillus salexigens* (Garabito et al., 1997).

It is possible that the boundaries between some of the new genera, in terms of 16S rDNA sequence differences, may become obscured as and when further species are discovered; indeed, Heyrman et al. (2003b) transferred the species of *Salibacillus* to *Virgibacillus*.

Several of the familiar *Bacillus* thermophiles comprise a distinct evolutionary line, and so the genus *Geobacillus* (Nazina et al., 2001) accommodates species formerly called *Bacillus kaustophilus* (Priest et al., 1988), *Bacillus stearoaerophilus* (Donk, 1920), *Bacillus thermocatenulatus* (Golovacheva et al., 1975), *Bacillus thermodenitrificans* (Manachini et al., 2000), *Bacillus thermoglucosidasius* (Suzuki et al., 1983) and *Bacillus thermoleovorans* (Zarilla and Perry, 1987). However, the longer-established species in this genus await polyphasic taxonomic study and circumscription, as many misnamed strains are known to exist in collections.

The thermophilic, round-spored, organism *Bacillus thermosphaericus* (Andersson et al., 1996) has been accommodated within the new genus *Ureibacillus* (Fortina et al., 2001b). Several other round-spored species, *Bacillus globisporus* (Larkin and Stokes, 1967), *Bacillus pasteurii* (Chester, 1898) and *Bacillus psychrophilus* (Nakamura, 1984b), have been transferred (Yoon et al., 2001b) to *Sporosarcina* (Kluyver and van Neil, 1936) which was established to accommodate the motile, spore-forming coccus *Sporosarcina ureae* (Beijerinck, 1901). As this proposal placed spore-forming rods and cocci in the same genus, the definition of *Sporosarcina* had to be emended. Two further new genera of round-spored organisms were subsequently proposed to accommodate single species, but they were only represented by single strains in the study concerned: *Jeotgalibacillus alimentarius* (Yoon et al., 2001c), and *Marinibacillus* to which *Bacillus marinus* was transferred (Yoon et al., 2001c).

Bacillus continues to accommodate the best-known species such as *Bacillus subtilis* (the type species), *Bacillus anthracis*, *Bacillus cereus*, *Bacillus licheniformis*, *Bacillus megaterium*, *Bacillus pumilus*, *Bacillus sphaericus* and *Bacillus thuringiensis*. It still remains a large genus, with 90 species (May 2004), since losses of species to other genera have been balanced by proposals for new *Bacillus* species. Seventy-one of the present members of *Bacillus* were proposed after the treatment of the genus for the first edition of the *Systematics* was compiled, and of the 34 species described in that edition, only 18 remain in *Bacillus*.

Members of the *Bacillus cereus* group, *Bacillus anthracis* *Bacillus cereus* *Bacillus thuringiensis*, are really pathovars of a single species (Turnbull et al., 2002), and yet the phylogenetic and phenetic distinction of this group probably support generic status. The internal division of the different 16S rRNA groups within the genus *Bacillus sensu lato* is presently far from clear. Many of its species fall into several apparently distinct rRNA sequence groups such as the "*Bacillus subtilis* group", the "*Bacillus cereus* group", and the "*Bacillus sphaericus* group", but although such divisions may also be phenotypically distinguishable, intermediate organisms may make satisfactory subdivision difficult.

Numerous *Bacillus* species mentioned in the literature over the years are not now recognized because of synonymy, incomplete characterization, or the lack of type strains, or even the complete loss of original isolates. Some invalid names persist, however, and can cause much confusion. Good examples are “*Bacillus subtilis* var. *niger*” and “*Bacillus globigii*”. Strains bearing these names are used for sterilization control and other purposes, but the names themselves are invalid. Most of these currently used strains may be regarded as *Bacillus subtilis*, and are listed as such in the catalogues of several culture collections; all three names may appear on the packaging of the commercially available biological indicator products that use them. *Bacillus subtilis* var. *niger* is a name that was applied to strains that produce a distinctive black pigment, hence their popularity as biological indicators. However, N. R. Smith’s strain 1221A of *Bacillus subtilis* var. *niger*, which is a standard strain for sterility testing, is noted for its red pigment, and is also known as *Bacillus globigii*. Gordon et al. (1973) found their strains labeled as *Bacillus globigii* were *Bacillus circulans* (*sensu lato*), *Bacillus licheniformis*, *Bacillus pumilus* or *Bacillus subtilis* var. *niger*, and they commented: “strains of *Bacillus subtilis*, *Bacillus pumilus* and *Bacillus circulans* labeled *Bacillus globigii* are extant, and some have been widely distributed. As a result, the name *Bacillus globigii* is meaningless”.

New species and subspecies of aerobic endospore formers are regularly described: 182 new species were proposed between the publication of the First Edition of this *Manual* in 1986 and the time of preparing the present edition (May 2004); of these, 121 were initially assigned to *Bacillus*, 43 were then transferred to new genera, and three others await transfer (these are *Bacillus edaphicus* and *Bacillus mucilaginosus*, which belong in *Paenibacillus*, and *Bacillus thermantarcticus*, which belongs in *Geobacillus*). The remaining new species were distributed among the 11 new genera mentioned in the preceding sentence and ten further new genera; 15 of the new genera contain a single species. During that period only six proposals for merging species (Heyndrickx et al., 1996a; Heyndrickx et al., 1995; Rosado et al., 1997; Shida et al., 1994; Sunna et al., 1997b), and one proposal for merging genera (Heyrman et al., 2003b) had been made. At the time of writing there are 440 valid species of aerobic endospore-formers among 47 genera. Unfortunately, new taxa have often been proposed on the basis of very few strains (48 of the present *Bacillus* species are based upon the study of a single strain, and nine on the basis of only two strains), so that their within-species variations are unknown. It is of small comfort that the proportion of new *Bacillus* species proposed on the basis of a single isolate is, at 33%, less than the proportion of single-isolate taxa described for prokaryotes overall between 1990 and 2000 (Christensen et al., 2001).

Another regrettable circumstance is that many recently described species of *Bacillus*, and species of the genera recently derived from it, represent genomic groups disclosed by DNA–DNA pairing experiments, and routine phenotypic characters for distinguishing some of them are very few and of unproven value. An extreme example of this kind of problem is the splitting of strains of *Bacillus subtilis* into two subspecies and three new species: *Bacillus atrophaeus* (Nakamura, 1989), *Bacillus mojavensis* (Roberts et al., 1994), *Bacillus vallismortis* (Roberts et al., 1996), *Bacillus subtilis* subsp. *spizizenii* (Nakamura et al., 1999) and *Bacillus subtilis* subsp. *subtilis*. These proposals were based principally upon DNA relatedness studies (the 70% relatedness threshold for species being rigorously applied),

with distinctions between these “cryptic” individual taxa being supported by a miscellany of approaches which included small differences in fatty acid compositions, multilocus enzyme electrophoresis, restriction digest analysis of selected genes, and transformation resistance. The only distinctive phenotypic character cited among these proposals was the production of brown pigment by *Bacillus atrophaeus* on media containing tyrosine, and so the recognition of the four new taxa appears to be of little practical value.

It is known (Fox et al., 1992; Stackebrandt and Goebel, 1994) that rDNA sequence analysis alone does not allow unequivocal differentiation at the species or finer taxonomic levels, and may even lead to completely mistaken conclusions on the exact phylogenetic positions of certain strains (Clayton et al., 1995), especially when taxa are proposed on the basis of lone strains. Christensen et al. (2001) proposed an addition to Recommendation 30b of the *Bacteriological Code* (1990 Revision), which advises that proposals for new taxa be based upon at least five strains from different sources, and that descriptions be based upon comparative studies including reference strains. Adoption of this suggestion, and its application by reviewers of proposals for new taxa, would do much to improve the practical usefulness of future developments in *Bacillus* taxonomy.

An important proposal, published at the time that this account was going to press, was for the transfer of *Bacillus sphaericus* and *Bacillus fusiformis* to the new genus *Lysinibacillus* (Ahmed et al., 2007c). Other transfers of species listed below include a proposal by Jeon et al. (2005b) for *Bacillus haloalkaliphilus* to be reclassified in a new genus *Alkalibacillus*, and a proposal by Hatayama et al. (2006) for the transfer of *Bacillus laevolacticus* to *Sporolactobacillus*, and the reclassification of *Bacillus halophilus* as *Salimicrobium halophilum* (Yoon et al., 2007b) and *Bacillus arvi*, *Bacillus arenosi* and *Bacillus neidei* into a new genus, *Viridibacillus* (Albert et al., 2007).

It is clear that the taxonomic reshuffling of the genus has not yet come to an end. Furthermore, none of the other new genera of aerobic endospore formers, *Sulfobacillus*, *Amphibacillus*, *Halobacillus*, *Ammoniphilus*, *Thermobacillus*, *Filobacillus*, *Oceanobacillus*, *Lentibacillus*, *Paraliobacillus*, *Cerasibacillus*, *Halolactibacillus*, *Pontibacillus*, *Tenuibacillus*, *Salinibacillus*, *Pullulanibacillus*, *Tuberibacillus*, *Caldalkalibacillus*, *Ornithinibacillus*, *Paucisalibacillus*, *Vulcanibacillus*, *Pelagibacillus*, and *Piscibacillus* (Golovacheva and Karavaiko, 1978; Hatayama et al., 2006; Ishikawa et al., 2002; Ishikawa et al., 2005; Kim et al., 2007b; L’Haridon et al., 2006; Lim et al., 2005b; Lu et al., 2001; Mayr et al., 2006; Nakamura et al., 2004b; Niimura et al., 1990; Nunes et al., 2006; Ren and Zhou, 2005a, b; Schlesner et al., 2001; Spring et al., 1996; Tanasupawat et al., 2007; Touzel et al., 2000; Xue et al., 2006; Yoon et al., 2002; Zaitsev et al., 1998) contain species formerly assigned to *Bacillus*. “*Bacillus flavothermus*” is accommodated in *Anoxybacillus* as *Anoxybacillus flavithermus* (Pikuta et al., 2000a).

Differentiation of the species of the genus *Bacillus*

Differential characteristics of the species of the genus *Bacillus* are shown in Table 3, and additional data are shown in Table 4.

List of species of the genus *Bacillus**

1. ***Bacillus subtilis*** (Ehrenberg 1835) Cohn 1872, 174^{AL}. *Nom. cons.* Nomencl. Comm. Intern. Soc. Microbiol. 1937, 28; Opin. A. Jud. Comm. 1955, 39 (*Vibrio subtilis* Ehrenberg 1835, 279.)

sub'ti.lis. L. adj. *subtilis* slender.

Aerobic, Gram-positive, motile rods, forming ellipsoidal to cylindrical spores which lie centrally, paracentrally and subterminally in unswollen sporangia (Figure 10g). Cells grown on glucose agar stain evenly. Cells 0.7–0.8 by 2.0–3.0 µm, occurring singly and in pairs, seldom in chains. Colonial morphology is exceptionally variable, within and between strains, and may give the appearance of a mixed culture. Colonies are round to irregular in shape and of moderate (2–4 mm) diameter, with margins varying from undulate to fimbriate; they become opaque, with surfaces that are dull and which may become wrinkled; color is whitish, and may become creamy or brown; textures range from moist and butyrous or mucoid, through membranous with an underlying mucoid matrix, with or without mucoid beading at the surface, to rough and crusty as they dry (Figure 9g). Pigments, varying from cream through yellow, orange, pink and red, to brown or black, may be formed on potato or agar media containing glucose; strains forming brown or black pigment were often formerly called "*Bacillus subtilis* var. *aterrimus*." Strains forming brownish-black pigment on tyrosine (and so often evident on the crude media available to earlier workers), and often formerly called "*Bacillus subtilis* var. *niger*," have been split from *Bacillus subtilis* as *Bacillus atrophaeus*.

Optimum growth temperature 28–30 °C, with minimum of 5–20 °C and maximum of 45–55 °C. Growth occurs between pH 5.5 and 8.5, but limits have not been recorded. Some restricted anaerobic growth may occur in complex media with glucose or (less effectively) nitrate. Growth occurs on minimal medium with glucose and an ammonium salt as sole sources of carbon and nitrogen. Grows in presence of up to 7% NaCl, some strains will tolerate 10% NaCl. Catalase-positive, oxidase variable. Casein, esculin, gelatin and starch are hydrolyzed, phenylalanine and urea are not hydrolyzed. Pectin and polysaccharides of plant tissues are decomposed. Dextran and levan are formed extracellularly from sucrose. Citrate is utilized as sole carbon source by most strains; propionate is not utilized. Nitrate is reduced to nitrite. Voges–Proskauer-positive. Acid without gas is produced from glucose and from a wide range of other carbohydrates.

The practical values of the distinction of the subspecies of *Bacillus subtilis* and of the species *Bacillus mojavensis* and *Bacillus vallismortis* are questionable. The distinction of

Bacillus atrophaeus from the *Bacillus subtilis* subspecies and from *Bacillus mojavensis* and *Bacillus vallismortis* is dependent upon brownish-black pigment production on tyrosine agar by strains of *Bacillus atrophaeus*. See Table 5.

Endospores are very widespread in soil, dust and on vegetation, and in many other environments. The vegetative organisms participate in the early stages of the breakdown of organic matter. Causative agent of ropy (slimy) bread.

- 1a. ***Bacillus subtilis* subsp. *subtilis*** Nakamura, Roberts and Cohan 1999, 1214^{VP}

Description is that given above for the species.

Phenotypically similar to *Bacillus atrophaeus* and distinguishable from that species only by the pigmentation of the latter. Not distinguishable from *Bacillus mojavensis*, *Bacillus subtilis* subsp. *spizizenii* and *Bacillus vallismortis* by conventional phenotypic tests.

DNA G + C content (mol%): 41.5–47.5 (T_m) for 31 strains, 41.8–46.3 (Bd) for 34 strains, and 42.9 (T_m) for the type strain.

Type strain: ATCC 6051, IAM 12118, CCM 2216, DSM 10, IFO 12210, NCIMB 3610, NCTC 3610, NRRL NRS-744.

EMBL/GenBank accession (16S rRNA gene): AB042061 (IAM 12118).

Additional remarks: Strains designated by Gibson (1944) and Smith et al. (1946) as synonyms of *Bacillus subtilis* included *Bacillus aterrimus*, *Bacillus mesentericus*, *Bacillus natto*, *Bacillus niger*, *Bacillus nigrificans* and *Bacillus panis*. "*Bacillus natto*" is a name given to *Bacillus subtilis* strains associated with natto, a Japanese food made by fermenting soybeans with these organisms. Strains formerly designated "*Bacillus amyloliquefaciens*" or "*Bacillus subtilis* var. *amyloliquefaciens*" are now accommodated within *Bacillus amyloliquefaciens*.

- 1b. ***Bacillus subtilis* subsp. *spizizenii*** Nakamura, Roberts and Cohan 1999, 1214^{VL}

spi.zi.ze'ni.i. L. gen. n. *spizizenii* named after the American bacteriologist J. Spizizen.

Phenotypically indistinguishable from *Bacillus subtilis* subsp. *subtilis*, and separated from that taxon only by DNA relatedness values of 58–68% with 12 strains of that subspecies, by the presence of ribitol in the cell wall, and by transformation studies.

The type strain was isolated from Tunisian soil.

Type strain: NRRL B-23049, DSM 15029, LMG 19156, KCTC 3705.

EMBL/GenBank accession number (16S rRNA gene): AF074970 (NRRL B-23049).

2. ***Bacillus aeolius*** Gugliandolo, Maugeri, Caccamo and Stackebrandt 2003b, 1701^{VP} (Effective publication: Gugliandolo, Maugeri, Caccamo and Stackebrandt 2003a, 175.)

ae.o'li.us. L. adj. *aeolius* pertaining to the Eolian Island (Insulae Aeoliae) where the organism was isolated from a shallow marine hydrothermal vent.

Aerobic, Gram-positive, motile rods, 0.5 µm by 2.0 µm, forming terminal, oval endospores. Description is based upon a single isolate. Catalase-negative, oxidase-positive. Growth

*Type strains distributed by international culture collections may be subjected to quality control, and the user should establish whether or not this is the case. The type strain accession numbers shown for *Bacillus* species were chosen to give an acceptable geographic spread. Sometimes more than one 16S rRNA gene sequence is available from EMBL/GenBank for different subcultures of the same type strain; we indicate alongside the EMBL/GenBank accession number which sequence has been used to construct the tree (Figure 8). Other sequences may or may not be reliable and users of these should check carefully.

(2004); Santini et al. (2004); Scheldeman et al. (2004); Suresh et al. (2004).

^cSee Table 5 for a comparison of the subspecies of *Bacillus subtilis* and the closely related species *Bacillus subtilis*, *Bacillus atrophaeus*, *Bacillus mojavensis* and *Bacillus vallismortis*, and the species *Bacillus amyloliquefaciens*, *Bacillus licheniformis*, *Bacillus pumilus*, and *Bacillus sonorensis*.

^dSee Table 6 for a comparison of alkaliphilic species: *Bacillus agaradhaerens*, *Bacillus alcalophilus*, *Bacillus algicola*, *Bacillus arseniciselenatis*, *Bacillus clarkii*, *Bacillus cohnii*, *Bacillus halodurans*, *Bacillus horti*, *Bacillus krulwichiae*, *Bacillus okuhidensis*, *Bacillus pseudoalcaliphilus*, *Bacillus pseudofirmus*, *Bacillus selenitireducens*, *Bacillus thermocloacae*, *Bacillus vedderi*.

^eSee Table 7 for comparison of the closely related species *Bacillus anthracis*, *Bacillus cereus*, *Bacillus mycoides*, *Bacillus pseudomycoloides*, *Bacillus thuringiensis*, and *Bacillus weihenstephanensis*.

^fSee Table 8 for comparison of the thermophilic species (optimum growth at 50 °C or above): *Bacillus aeolius*, *Bacillus fumarioli*, *Bacillus infernus*, *Bacillus methanolicus*, *Bacillus schlegelii*, *Bacillus thermoamylovorans*, *Bacillus thermocloacae*, and *Bacillus tusciae*.

^gSee Table 9 for comparison of the neutrophilic, non-thermophilic species that form spherical spores: *Bacillus fusiformis*, *Bacillus insolitus*, *Bacillus neidei*, *Bacillus psychrodurans*, *Bacillus psychrotolerans*, *Bacillus pycnus*, and *Bacillus sphaericus*.

^hPigmentation: *Bacillus subtilis* may form pigments, varying from cream through yellow, orange, pink and red, to brown or black, on potato or agar media containing glucose, and strains forming brown or black pigment were often formerly called “*Bacillus subtilis* var. *aterrimus*”; *Bacillus algicola* produces semitransparent, creamy, slightly yellowish colonies; *Bacillus aquimaris* colonies are pale orange-yellow; *Bacillus arseniciselenatis* and *Bacillus selenitireducens* will produce red colonies, owing to elemental selenium precipitation, on selenium oxide media; *Bacillus atrophaeus* forms a dark brownish-black soluble pigment in 2–6 d on media containing tyrosine or other organic nitrogen source; *Bacillus carboniphilus* produces grayish yellow pigment on nutrient agar and brownish red pigment on trypto-soya agar; some strains of *Bacillus cereus* may produce a yellowish-green fluorescent pigment on various media, some strains may produce a pinkish brown diffusible pigment on nutrient agar, and on starch-containing media containing sufficient iron some strains produce the red pigment pulcherrimin; *Bacillus clarkii* colonies may be cream-white to pale yellow in color, and one of the three strains described produces dark yellow colonies with age; *Bacillus endophyticus* colonies may be white or pink-red, even on the same plate, and media containing ampicillin and lysozyme commonly yield red colonies; colonies of *Bacillus fastidiosus* on uric acid medium may become yellowish; *Bacillus firmus* colonies are creamy-yellow to pale orangey-brown after 3 d on TSA at 30 °C; *Bacillus gibsonii* colonies are yellow; *Bacillus indicus* colonies are yellowish-orange; *Bacillus hwaijinpoensis* colonies are light yellow; *Bacillus jeot-gali* colonies are cream-yellow to light orange-yellow; many strains of *Bacillus licheniformis* can produce red pigment (assumed to be pulcherrimin) on carbohydrate media containing sufficient iron, and colonies on glycerol/glutamate medium are reddish-brown; *Bacillus marisflavi* colonies are pale yellow; *Bacillus megaterium* colonies may become yellow and then brown or black on long incubation; *Bacillus pseudofirmus* colonies are yellow; *Bacillus sonorensis* colonies are yellowish-cream on routine media, and bright yellow on pH 5.6 agar; *Bacillus subterraneus* colonies are dark yellow to orange on tryptic soy agar.

ⁱCitrate test results may vary according to the test method used; Gordon et al. (1973) found citrate utilization to be a variable property among 23 strains of *Bacillus anthracis*, while Logan and Berkeley (1984) and Logan et al. (1985) obtained negative results for 37 strains using the API 20E test method. For *Bacillus badius*, Gordon et al. (1973) obtained negative results with two strains, while Logan and Berkeley (1984) obtained positive results for two strains using the API 20E test method.

^jStrains of *Bacillus cereus* of serovars 1, 3, 5, and 8, which are particularly associated with outbreaks of emetic-type food poisoning, do not produce acid from salicin and starch, whereas strains of *Bacillus cereus* of other serotypes are usually positive for these reactions. See Table 7.

^kFor *Bacillus fumarioli*, acid production from carbohydrates is tested at pH 6 – see Logan et al. (2000) and *Testing for special characters*.

^lGordon et al. (1973) found the Voges–Proskauer reaction to be negative for 60 strains of *Bacillus megaterium*, while Logan and Berkeley (1984) obtained positive results for all but one of 33 strains using the API 20E test method.

^mAcid production from carbohydrates by *Bacillus naganensis* is slow, and shows only after extended (>14 d) incubation.

ⁿThe published description of *Bacillus pseudomycoloides* (Nakamura, 1998) records that 7% salt is tolerated, but the differentiation table in that publication indicates the opposite result.

^oSpores of *Bacillus psychrodurans* and *Bacillus psychrotolerans* are rarely formed; on casein-peptone soymeal-peptone agar spores are predominantly spherical, but on marine agar they are predominantly ellipsoidal.

^pMosquitocidal strains of *Bacillus sphaericus* produce parasporal toxin crystals which are smaller than those produced by *Bacillus thuringiensis*, but which are nonetheless visible by phase-contrast microscopy.

^qGrowth occurs within the range pH 7.2–9.5 in media adjusted with NaOH and HCl, but not in media where the pH is adjusted using buffered systems as described by Nielsen et al. (1995a).

^rNegative when incubated at 30 °C, but may become positive slowly when incubated at 40 °C.

^sGrowth is poor in the absence of NaCl.

^aSymbols: +, >85% positive; d, different strains give different reactions (16–84% positive); –, 0–15% positive; w, weak reaction; nd, no data are available.

^bCompiled from Claus and Berkeley (1986), Priest et al. (1987), Nakamura (1989), Roberts et al. (1994, 1996), Nakamura et al. (1999), and Palmisano et al. (2001).

^cThe subspecies of *Bacillus subtilis* are not distinguishable by routine phenotypic tests.

^d*Bacillus subtilis* may form pigments, varying from cream through yellow, orange, pink and red, to brown or black, on potato or agar media containing glucose; strains forming brown or black pigment were often formerly called “*Bacillus subtilis* var. *aterrimus*.”

^eColonies are yellowish-cream on routine media, and bright yellow on pH 5.6 agar.

^fThis species accommodates strains forming brownish-black pigment on tyrosine (and so often evident on the crude media available to earlier workers), and often formerly called “*Bacillus subtilis* var. *niger*.”

temperature range is 37–65 °C, with an optimum growth temperature of 55 °C. pH range for growth 7–9, with an optimum of pH 8.0. Grows in the range 0.5–5% NaCl, with an optimum of 2% NaCl. Acid is produced from glucose and a wide range of other carbohydrates. The following may be utilized as carbon sources: arabinose, *N*-acetylglucosamine, citrate, glucose, gluconate, malate, maltose, mannitol, mannose, phenylacetate. Produces acetoin but not H₂S or indole. Nitrate is not reduced. Casein, gelatin and starch are hydrolyzed, but esculin and urea are not. Arginine dihydrolase, and lysine and ornithine decarboxylases negative. Exopolysaccharides are produced in mineral medium supplemented with sucrose. See Table 8.

Source: a shallow marine hydrothermal vent, Vulcano Island, Eolian Islands, Italy.

DNA G + C content (mol%): 40.8 (*T_m*) (for methods, see Maugeri et al., 2001).

Type strain: 4-1, DSM 15804, and CIP 107628.

EMBL/GenBank accession number (16S rRNA gene): AJ504797 (4-1).

3. **Bacillus agaradhaerens** Nielsen, Fritze and Priest 1995b, 879^{VP} (Effective publication: Nielsen, Fritze and Priest 1995a, 1758.)

a.gar.ad'hae.rens. Malayan n. *agar* gelling polysaccharide from brown algae; L. adj. *adhaerens* adherent; N.L. adj. *agar-adhaerens* adhering to the agar.

Strictly alkaliphilic organisms forming ellipsoidal spores which lie subterminally in swollen sporangia. Cells 0.5–0.6 by 2.0–5.0 μm. Colonies are adherent, white and rhizoid with filamentous margins. Growth temperature range 10–45 °C. Optimal growth at pH 10.0 or above; no growth at pH 7.0. Grows (sometimes only weakly) in presence of up to 16% NaCl. Nitrate is reduced to nitrite. Casein, cellulose, gelatin, starch, Tween 40 and xylan are hydrolyzed. Tween 60 is hydrolyzed by most strains. Hippurate, 4-methylumbelliferone glucuronide, Tween 20 and 80 are not hydrolyzed; phenylalanine is not deaminated. Glucose and a range of other carbohydrates can be utilized as sole sources of carbon. See Table 6.

Source: soil.

DNA G + C content (mol%): 39.3–39.5 (HPLC).

Type strain: PN-105, ATCC 700163, DSM 8721, LMG 17948.

EMBL/GenBank accession number (16S rRNA gene): X76445 (DSM 8721).

4. **Bacillus alcalophilus** Vedder 1934, 141^{AL} (emend. Nielsen, Fritze and Priest 1995a, 1758.)

al.cal.o.phil'us. N.L. *alcali* En. alkali from the Arabic *al the*; *qaliy* soda ash; Gr. adj. *philos* loving; N.L. adj. *alcalophilus* liking alkaline (media).

Alkaliphilic organisms forming ellipsoidal spores which lie subterminally in unswollen sporangia. Cells 0.5–0.7 by 3.0–5.0 μm. Colonies are white, circular, smooth and shiny, sometimes with darker centers. Growth temperature range 10–40 °C. Optimal growth at pH 9.0–10.0; no growth at pH 7.0. Maximum NaCl concentration tolerated ranges from less than 5% up to 8%. Nitrate is usually not reduced to nitrite. Casein, gelatin, pullulan, starch, and Tween 40 and 60 are hydrolyzed. Hippurate, 4-methylumbelliferone glucuronide, Tween 20 (usually) and 80 are not hydrolyzed; phenylalanine is not deaminated. Glucose and a range of other carbohydrates can be utilized as sole sources of carbon. See Table 6.

Source: a variety of materials after enrichment at pH 10.

DNA G + C content (mol%): 36.2–38.4 (HPLC analysis) and 37.0 (*T_m*), 36.7 (Bd) for the type strain.

Type strain: Vedder 1, ATCC 27647, DSM 485, JCM 5262, LMG 17938, NCIMB 10436.

EMBL/GenBank accession number (16S rRNA gene): X76436 (DSM 485).

5. **Bacillus algicola** Ivanova, Alexeeva, Zhukova, Gorshkova, Buljan, Nicolau, Mikhailov and Christen 2004b, 1425^{VP} (Effective publication: Ivanova, Alexeeva, Zhukova, Gorshkova, Buljan, Nicolau, Mikhailov and Christen 2004a, 304.)

al.gi'co.la. L. fem. n. *alga-ae*, *alga*; L. suff. *-cola* (from L. masc. n. *incola-ae* inhabitant, dweller); N.L. masc. n. *algicola* algae-dweller.

Gram-positive cells (0.5–0.9 μm in diameter and 1.8–5.0 μm long) are aerobic, filamentous with “cross-like” branching, and produce subterminally located ellipsoidal spores (0.5–0.7 μm by 0.7–1.0 μm). Description is based upon a single isolate. Colonies are semitransparent, creamy, and slightly yellowish in color. Growth occurs between 10 °C and 45 °C with optimum at 28–30 °C. No growth is detected at 4 °C and at 50 °C. Alkalitolerant, growing at pH 7–10. Growth occurs at 0–3% NaCl. Anaerobic growth and oxidase are negative. Catalase and nitrate reduction are weak. Urea, alginate, starch, and gelatin are hydrolyzed. Do not decompose agar and casein. According to Biolog, utilizes dextrin, cellobiose, D-fructose, α-D-glucose, maltose, D-mannose, sucrose, D-trehalose, pyruvic acid methyl ester, β-hydroxybutyric acid, α-ketobutyric acid, inosine, uridine, thymidine, glycerol, and DL-α-glycerol phosphate. The predominant cellular fatty acids are C_{14:0 iso}⁷, C_{15:0 iso}⁷, C_{15:0 anteiso}⁷, C_{16:0 iso}⁷, and C_{17:0 anteiso}⁷. See Table 6.

Source: degraded thallus of brown alga *Fucus evanescens* collected from Kraternaya Bight, Pacific Ocean.

DNA G + C content (mol%): 37.4 (*T_m*).

Type strain: KMM 3737, CIP 107850.

GenBank/EMBL accession number (16S rRNA gene): AY228462 (KMM 3737).

6. **Bacillus amyloliquefaciens** Priest, Goodfellow, Shute and Berkeley 1987, 69^{VP}

am.yl.o.li.que.fac'i.ens. L. n. *amyllum* starch; L. part. adj. *liquefaciens* dissolving; N.L. part. adj. *amyloliquefaciens* starch-digesting.

Strictly aerobic, Gram-positive, motile rods, 0.7–0.9 by 1.8–3.0 μm, often occurring in chains, and forming ellipsoidal spores (0.6–0.8 by 1.0–1.4 μm) which lie centrally, paracentrally and subterminally in unswollen sporangia. No growth below 15 °C or above 50 °C; optimum growth temperature 30–40 °C. Casein, elastin, esculin, gelatin, starch and Tween 20, 40 and 60 are degraded, but adenine, cellulose, guanine, hypoxanthine, pectin, testosterone, tyrosine, urea and xanthine are not. Nitrate is reduced to nitrite. Voges–Proskauer-positive. Citrate is utilized as sole carbon source, propionate is not. Growth occurs in presence of 5% NaCl, and most strains tolerate 10% NaCl. Acid without gas is produced from glucose and a range of other carbohydrates. This species is important as a source of α-amylase and protease for industrial applications. See Table 5.

Source: soil and industrial amylase fermentations.

^aSymbols: +, >85% positive; d, different strains give different reactions (16-84% positive); -, 0-15% positive; v, variation within strains; w, weak reaction; d/w, d, different strains give different reactions, but positive reactions are weak; nd, no data are available.

^bCompiled from Claus and Berkeley (1986), Demharter and Hensel (1989b); Spanka and Fritze (1993); Agnew et al. (1995); Nielsen et al. (1995a); Fritze (1996a); Yumoto et al. (1998, 2003); Switzer Blum et al. (2001); Li et al. (2002); Ivanova et al. (2004a).

^c*Bacillus algicola* produces semitransparent, creamy, slightly yellowish colonies; *Bacillus arseniciselenatis* and *Bacillus selenitireducens* will produce red colonies, owing to elemental selenium precipitation, on selenium oxide media; *Bacillus clarkii* colonies may be cream-white to pale yellow in color, and one of the three strains described produces dark yellow colonies with age; *Bacillus pseudofirmus* colonies are yellow.

^d*Bacillus arseniciselenatis* does not grow aerobically; *Bacillus selenitireducens* grows weakly in microaerobic conditions.

DNA G + C content (mol%): 44.35 ± 0.38 (T_m) for eight strains; 44.2 ± 0.7 (Bd) with a range of 44–46; the mol% G + C of the type strain is 44.6.

Type strain: Fukumoto strain F, ATCC 23350, DSM 7, LMG 9814, NCIMB 12077, NRRL B-14393.

EMBL/GenBank accession number (16S rRNA gene): X60605 (ATCC 23350).

7. *Bacillus anthracis* Cohn 1872, 177^{AL}

an'thra.cis. Gr. n. *anthrax* charcoal, a carbuncle; N.L. n. *anthrax* the disease anthrax; N.L. gen. n. *anthracis* of anthrax.

Phenotypically similar to *Bacillus cereus* (see below and Table 7) except in the characters undernoted. Colonies of *Bacillus anthracis* (Figure 9a) are similar to those of *Bacillus cereus*, but those of the former are generally smaller, non-hemolytic, may show more spiking or tailing along the lines of inoculation streaks, and are very tenacious as compared with the usually more butyrous consistency of *Bacillus cereus* and *Bacillus thuringiensis* colonies, so that they may be pulled into standing peaks with a loop. Nonmotile. Usually susceptible to penicillin. Susceptible to gamma phage (see Logan and Turnbull, 2003; Logan et al., 2007). Produces a glutamyl-polypeptide capsule *in vivo* and when grown on nutrient agar containing 0.7% sodium bicarbonate incubated overnight under 5–7% CO₂. Colonies of the capsulate *Bacillus anthracis* appear mucoid, and the capsule can be visualized by staining smears with M'Fadyean's polychrome

methylene blue or India Ink (Turnbull et al., 1998). An isolate showing the characteristic phenotype but unable to produce capsules may be an avirulent form lacking either or both capsule or toxin genes (Turnbull et al., 1992). Virulent and avirulent strains may be distinguished from other members of the *Bacillus cereus* group using tests in the API System (Logan et al., 1985). Virulence genes are carried by plasmids pX01 (toxins) and pX02 (capsule); these plasmids may be transmissible to other members of the *Bacillus cereus* group (Turnbull et al., 2002). Primer sequences are now available for confirming the presence of the toxin and capsule genes, and hence the virulence of an isolate. Genetically very closely related to *Bacillus cereus* and other members of the *Bacillus cereus* group (Turnbull, 1999); *Bacillus anthracis* may be distinguished from other members of the *Bacillus cereus* group by amplified fragment length polymorphism (AFLP) analysis (Keim et al., 2000; Turnbull et al., 2002). A 277bp DNA sequence (Ba813) has been described as a specific chromosomal marker for *Bacillus anthracis* and in combination with sequencing of parts of *lef* and *cap* genes its sequence allows the identification of virulent strains (application note 209 of Pyrosequencing AB). Isolates of *Bacillus anthracis* show considerable molecular homogeneity, and the species may derive from a relatively recent common ancestor.

Causative agent of the disease anthrax in herbivorous and other animals and man. Widely studied and developed

TABLE 7. Differentiation of *Bacillus cereus* from closely related *Bacillus* species^{a,b}.

^bCompiled from Gordon et al. (1973); Logan and Berkeley (1984); Logan et al. (1985); Claus and Berkeley (1986); Lechner et al. (1998); Nakamura (1998).

^cStrains of *Bacillus cereus* of serovars 1, 3, 5 and 8, which are particularly associated with outbreaks of emetic-type food poisoning.

^dCitrate test results may vary according to the test method used; Gordon et al. (1973) found citrate utilization to be a variable property among 23 strains of *Bacillus anthracis*, while Logan and Berkeley (1984) and Logan et al. (1985) obtained negative results for 37 strains using the API 20E test method.

as a biological weapon. Generally considered to be an obligate pathogen; if it ever multiplies in the environment, it probably only does so rarely. Spores remain viable in soil for many years and their persistence does not depend on animal reservoirs.

Source: blood of animals and humans suffering from anthrax, from anthrax carcasses, and from animal products and soil contaminated with spores of the organism.

DNA G + C content (mol%): 32.2–33.9 (T_m) for five strains, and 33.2 (T_m) for the type strain.

Type strain: Vollum strain, ATCC 14578, NCIB 9377, NCTC 10340.

The 16S rRNA (or rDNA) gene sequence of the type strain is not available in the EMBL/GenBank database. However, 16S rDNA sequences of 98 strains of this species in EMBL are nearly all identical. Accession number AF176321 corresponds with the strain "Sterne."

8. **Bacillus aquimaris** Yoon, Kim, Kang, Oh and Park 2003a, 1301^{VP}
a.qui.ma'ris. L. n. *aqua* water; L. gen. n. *maris* of the sea; N.L. gen. n. *aquimaris* of the water of the sea.

Aerobic, Gram-variable rods, 0.5–0.7 by 1.2–3.5 μm , motile by means of peritrichous flagella. Description is based on a single isolate. Ellipsoidal endospores are borne centrally in large, swollen sporangia. Colonies are pale orange-yellow, circular to slightly irregular, slightly raised, and 2–4 mm in diameter after 3 d at 30 °C on marine agar. Optimal growth temperature is 30–37 °C. Growth occurs at 10 and 44 °C, but not at 4 or above 45 °C. Optimal growth pH is 6.0–7.0, and no growth is observed at pH 9.0 or 4.5. Optimal growth occurs in the presence of 2–5% (w/v) NaCl. Growth is poor in the absence of NaCl, but occurs in the presence of up to 18% (w/v) NaCl. Catalase-positive, oxidase- and urease-negative. Casein, starch and Tween 80 are hydrolyzed. Esculin, hypoxanthine, tyrosine and xanthine are not hydrolyzed. Acid is produced from D-fructose, D-glucose, glycogen, 5-ketogluconate, maltose, D-ribose, starch, sucrose and D-trehalose. The cell-wall peptidoglycan contains *meso*-diaminopimelic acid. The predominant menaquinone is MK-7. The major fatty acids are $C_{15:0 \text{ iso}}$ and $C_{15:0 \text{ anteiso}}$.

Source: sea water of a tidal flat of the Yellow Sea in Korea.

DNA G + C content (mol%) of the type strain is: 38 (HPLC).

Type strain: TF-12, JCM 11545, KCCM 41589.

GenBank accession number (16S rRNA gene): AF483625 (TF-12).

9. **Bacillus arseniciselenatis** (nom. corrig. *Bacillus arsenicoselenatis* [sic]) Switzer Blum, Burns Bindi, Buzzelli, Stolz and Oremland 2001, 793^{VP} (Effective publication: Switzer Blum, Burns Bindi, Buzzelli, Stolz and Oremland 1998, 28.)
ar.se.ni.ci.se.le.na'tis. L. n. *arsenicum* arsenic; N.L. n. *selenas-atris* selenate; N.L. gen. n. *arseniciselenatis* of arsenic (and) selenate.

Strictly anaerobic, nonmotile, spore-forming, Gram-positive rods which show respiratory growth with Se(VI) (selenate), As(V) (arsenate), Fe(III), nitrate and fumarate as electron acceptors. Cells are 0.5–1.0 by 3–10 μm . Description is based upon a single strain. Catalase- and oxidase-positive. Colonies are formed on lactate/selenate/

yeast extract-supplemented lakewater medium incubated anaerobically at 20 °C. Grows fermentatively on fructose. Uses lactate, malate, fructose, starch and citrate as electron donors. Moderately halophilic, with optimum salinity of 60 g/l NaCl, and a requirement for NaCl for growth. Moderately alkaliphilic, with optimum growth in the range pH 8.5–10. See Table 6.

Source: arsenic-rich sediment of Mono Lake, California.

DNA G + C content (mol%) of the type strain: 40.0% (T_m).

Type strain: E1H, ATCC 700614, DSM 15340.

EMBL/GenBank accession number (16S rRNA gene): AF064705 (E1H).

10. **Bacillus asahii** Yumoto, Hirota, Yamaga, Nodasaka, Kawasaki, Matsuyama and Nakajima 2004c, 1999^{VP}
as.a.hi'i. N.L. gen. n. *asahii* of Asahi; named after Asahi Kasei Co., a researcher from which isolated the bacterium.

Cells are Gram-positive peritrichously flagellated straight rods (1.4–3.0 \times 0.4–0.8 μm) and produce terminally or centrally located ellipsoidal spores. Description is based upon a single isolate. Utilizes butyrate as carbon source for growth. Spores do not cause swelling of sporangium. Colonies are circular and white. Catalase and oxidase reactions are positive. Nitrate reduction to nitrite is weakly positive. Negative for indole production, Voges–Proskauer test, methyl red test, growth on MacConkey agar and H_2S production. Trypsin, esterase (C4) and esterase/lipase (C8) are positive. Alkaline phosphatase, valine arylamidase, cystine arylamidase, chymotrypsin, acid phosphatase, β -glucosidase, β -glucosidase and N-acetyl- β -glucosaminidase are negative. Growth occurs at pH 6–9; growth at pH 5 is variable. Growth occurs at 0–1% NaCl but not at 2% NaCl. Growth occurs at 15–45 °C, but not above 50 °C. No acid is produced carbohydrates. Hydrolysis of casein, DNA, and Tween 20, 40 and 60 is observed but hydrolysis of gelatin is not. Hydrolysis of starch is weak. $C_{15:0 \text{ iso}}$ (39.0%) and $C_{15:0 \text{ anteiso}}$ (27.8%) represent the main fatty acids produced during growth in PY-1 medium.

Source: a soil sample obtained from Tagata-gun, Shizuoka, Japan.

DNA G + C content (mol%): 39.4 (HPLC).

Type strain: FERM BP-4493, MA001, JCM 12112, NCIMB 13969, CIP 108638.

GenBank/EMBL accession number (16S rRNA gene): AB109209 (FERM BP-4493).

11. **Bacillus atrophaeus** Nakamura 1989, 299^{VP}
a.tro.phae'us. L. adj. *ater* black; Gr adj. *phaeus* brown; N.L. adj. *atrophaeus* dark brown.

Aerobic, Gram-positive, motile rods, forming ellipsoidal spores which lie centrally or paracentrally in unswollen sporangia. Cells 0.5–1.0 by 2.0–4.0 μm , occurring singly and in short chains. Colonies are opaque, smooth circular and entire and up to 2 mm in diameter after 2 d at 28 °C, and form a dark brownish-black soluble pigment in 2–6 d on media containing tyrosine or other organic nitrogen source. Optimum growth temperature 28–30 °C, with minimum of 5–10 °C and maximum of 50–55 °C. Catalase-positive, oxidase-negative.

Includes strains formerly called "*Bacillus subtilis* var. *niger*"; some strains so designated are used for autoclave

sterility testing. Phenotypically distinguishable from *Bacillus mojavensis*, *Bacillus subtilis* subsp. *spizizenii* and *Bacillus subtilis* subsp. *subtilis* only by pigment production and a negative oxidase reaction. Phenotypically indistinguishable from *Bacillus vallismortis*. See Table 5.

Source: isolated mainly from soil.

DNA G + C content (mol%): 41.0–43.0 (Bd).

Type strain: NRRL NRS-213, ATCC 49337, DSM 7264, JCM 9070, LMG 17795, NCIMB 12899.

EMBL/GenBank accession number (16S rRNA gene): AB021181 (JCM 9070).

12. ***Bacillus azotoformans*** Pichinoty, de Barjac, Mandel and Aselineau 1983, 660^{VP}

a.zo.to.for'mans. Fr. n. *azote* nitrogen; L. part. adj. *formans* forming; N.L. part. adj. *azotoformans* nitrogen-forming.

Gram-negative, peritrichously motile rods (0.5–0.8 µm by 3–7 µm), forming ellipsoidal, subterminal and terminal spores which swell the sporangia. Nitrate, nitrite and nitrous oxide are denitrified with the production of N₂. For anaerobic growth, nitrate, nitrite, nitrous oxide, tetrathionate and fumarate act as terminal electron acceptors. Growth requirements are complex; non-fermentative, carbohydrates are not attacked, a range of organic acids is utilized as carbon sources. Colonies circular and partially translucent, with entire margins, on yeast extract agar. Oxidase-positive, catalase-negative. Gelatin, starch and Tween 80 not hydrolyzed. Maximum growth temperature 42–46 °C.

Source: garden soil by enrichment culture in peptone broth under N₂O.

DNA G + C content (mol%): 39.0–43.9 (mean of 39.8 for 17 strains) (Bd) and 39.0 for the type strain.

Type strain: Pichinoty 1, ATCC 29788, NRRL B-14310, DSM 1046, LMG 9581, NCIMB 11859.

EMBL/GenBank accession number (16S rRNA gene): D78309 (DSM 1046). This sequence seems to be somewhat more reliable than the one reported for ATCC 29788. Both sequences differ and contain inadequately determined bases.

13. ***Bacillus badius*** Batchelor 1919, 23^{AL}

ba.di'us. L. adj. *badius* chestnut brown.

Aerobic, Gram-positive, motile rods, cells 0.8–1.2 by 2.5–5.0 µm, occurring singly and in pairs and chains, forming ellipsoidal spores which are located subterminally, and sometimes paracentrally or terminally, and which do not swell the sporangia. Growth occurs between 15 °C and 50 °C, with the optimum around 30 °C. Catalase-positive. Casein and gelatin are hydrolyzed; starch is not hydrolyzed. Tyrosine is degraded. Grows in presence of up to 7% NaCl. Citrate may be utilized as sole carbon source. Nitrate is not reduced. Acid is not produced from glucose and other carbohydrates. Assimilates certain amino acids and organic acids.

Source: feces, dust, marine sources, foods, antacids and gelatin production plant.

DNA G + C content (mol%): 43.8 (*T_m*) and 43.5 (Bd) for the type strain.

Type strain: ATCC 14574, DSM 23, LMG 7122, NCIMB 9364, NRRL NRS-663, IAM 11059.

EMBL/GenBank accession number (16S rRNA gene): X77790 (ATCC 14574).

14. ***Bacillus barbaricus*** Taubel, Kämpfer, Buczolits, Lubitz and Busse 2003, 729^{VP}

bar.ba'ri.cus. L. adj. *barbaricus* strange, foreign, referring to the strange behavior towards growth at different pH levels.

Facultatively anaerobic, Gram-positive, nonmotile rods, 0.5 µm wide and 4–5 µm long. Oval endospores are borne subterminally in swollen sporangia. Colonies are brownish, opaque, circular, flat and 3–7 mm in diameter when grown on peptone-yeast extract-succinate (PYES) agar. Catalase-positive, oxidase- and urease-negative. Nitrate is not reduced. Indole and H₂S are not produced. Alkalitolerant; growth is weak at pH 6.0, but strong at pH 7.2, 8.0 and 9.5 in PYES medium adjusted with HCl or NaOH before autoclaving, but no growth in buffered media at pH 7.0–11.0. Good growth occurs at temperatures ranging from 18 °C to 37 °C, with no growth at 4 or 47 °C. Weak growth occurs in presence of 2% NaCl, and no growth in 5% NaCl. Hippurate is decomposed. Esculin is not hydrolyzed. Citrate is not utilized. Acid is produced from D-glucose, N-acetylglucosamine, maltose, trehalose, starch and glycogen. Acid production is variable from D-fructose (type strain weakly positive), galactose, methyl-D-glucoside, lactose, sucrose and D-turanose (type strain negative). The cell-wall diamino acid is diaminopimelic acid and MK-7 is the predominant menaquinone. The polar lipid profile is composed of the major compounds phosphatidylethanolamine, phosphatidylglycerol and diphosphatidylglycerol. The fatty acid profile consists of the predominant compounds C_{15:0 anteiso} and C_{15:0 iso}; C_{14:0 iso} and C_{16:0 iso} are present in moderate amounts.

Source: an experimental wall painting exposed in the Virgillkapelle in Vienna, Austria.

DNA G + C content (mol%): not reported.

Type strain: V2-BIII-A2, DSM 14730, CCM 4982.

EMBL/GenBank accession number (16S rRNA gene): AJ422145 (V2-BIII-A2).

15. ***Bacillus bataviensis*** Heyrman, Vanparys, Logan, Balcaen, Rodríguez-Díaz, Felske and De Vos 2004, 55^{VP}

ba.ta.vi.en'sis. L. adj. *bataviensis* pertaining to Batavia, the name with which Julius Caesar described The Netherlands.

Facultatively anaerobic, Gram-positive or Gram-variable (at 24 h), motile, slightly tapered rods, 0.7–1.2 µm in diameter, occurring singly, and in pairs and short chains. Endospores are mainly ellipsoidal but may be spherical, and lie centrally, paracentrally and occasionally subterminally in slightly swollen sporangia. Colonies on TSA are butyrous, cream-colored, and produce a soft-brown pigment that diffuses in the agar; they are slightly raised and umbonate, have regular margins and smooth or rough, eggshell-textured surfaces. The optimum temperature for growth is 30 °C, and the maximum growth temperature lies between 50 °C and 55 °C. The optimum pH for growth is 7.0–8.0, and the pH range for growth is from 4.0–6.0 to 9.5–10.0. Casein is not hydrolyzed. In the API 20E strip, *o*-nitrophenyl-β-D-galactopyranoside hydrolysis is positive, gelatin is hydrolyzed by most strains, and nitrate reduction is positive; Voges-Proskauer reaction is negative, and reactions for arginine dihydrolase (one strain positive), lysine decarboxylase, ornithine decarboxylase, citrate uti-

lization, hydrogen sulfide production, urease, tryptophan deaminase, indole production are negative. Hydrolysis of esculin is positive. Acid without gas is produced from the following carbohydrates in the API 50 CH gallery using the CHB suspension medium: *N*-acetyl-D-glucosamine, D-cellobiose, D-fructose, galactose, β -gentiobiose, D-glucose, glycerol (weak), lactose, maltose, D-mannitol, D-mannose, D-melezitose, raffinose, ribose (weak), salicin (weak), D-trehalose and D-turanose. The following reactions are variable between strains and, when positive, are usually weak: amygdalin, arbutin, L-fucose, inulin, D-melibiose, starch and sucrose; type strain is positive but weak for: arbutin, L-fucose, inulin, D-melibiose, methyl α -D-glucoside, methyl α -D-mannoside and sucrose. The major cellular fatty acids are C_{15:0 iso} and C_{15:0 anteiso}, present at a level of about 37 and 21%, respectively, while C_{16:1 ω 11c} accounts for about 11% of the total fatty acids.

Source: soil in the Drentse A agricultural research area, The Netherlands.

DNA G + C content (mol%): 39.6–40.1 (type strain 40.1) (HPLC).

Type strain: LMG 21833, DSM 15601.

EMBL/GenBank accession number (16S rRNA gene): AJ542508 (LMG 21833).

16. **Bacillus benzoovorans** Pichinoty, Asselineau and Mandel 1987, 179^{VP} (Effective publication: Pichinoty, Asselineau and Mandel 1984, 215.)

ben.zo.e.vor'ans. L. part. adj. *acidum benzoicum*. benzoic acid; L. *vorans* devouring; N.L. part. adj. *benzoovorans* devourer of benzoic acid.

Prototrophic, facultatively anaerobic, Gram-variable, large (1.8 μ m diameter) filaments and rods which use aromatic acids and phenols, but not carbohydrates and amino acids (except glycine) as carbon and energy sources. Do not grow in media containing only peptone or tryptone; grow rapidly in media containing yeast extract and sodium acetate or benzoate. Filamentous growth on solid and in stationary liquid media, with motile rods appearing in shaken liquid culture. Form ellipsoidal spores which do not swell the sporangia. Colonies circular, flat, off-white and opaque with matt surface. Nitrate, but not nitrite, reduced. Optimum growth temperature 32 °C; maximum 39–45 °C.

Source: pasteurized soil by aerobic enrichment in minimal medium containing benzoate, *p*-hydroxybenzoate or cyclohexane carboxylate.

DNA G + C content (mol%) of the type strain: 41.3% (T_m).

Type strain: Pichinoty strain B1, ATCC 49005, DSM 5391, LMG 20225, NCIMB 12555, NRRL B-14535, CCM 3364.

EMBL/GenBank accession number (16S rRNA gene): X60611 (NCIMB 12555).

17. **Bacillus carboniphilus** Fujita, Shida, Takagi, Kunugita, Pankrushina and Matsushashi 1996, 118^{VP}

car.bo.ni'phi.lus. L. n. *carbo* coal, carbon; Gr adj. *philos* loving; N.L. adj. *carboniphilus* carbon-loving.

Aerobic, Gram-positive, peritrichously motile rods, forming ellipsoidal spores which lie centrally or terminally in unswollen sporangia. Cells 0.5–0.9 by 3.0–5.0 μ m. Growth promoted by activated carbon and graphite. Colonies on

nutrient agar are circular, flat, smooth, and grayish yellow; brown-red pigment is produced on trypto-soya agar. Growth temperature range 17–47 °C. Strictly aerobic; nitrate not reduced. Grows in presence of 7% NaCl. Catalase- and oxidase-positive; casein, gelatin, hippurate, starch and Tween 80 are hydrolyzed. Acid and gas are not produced from glucose and a range of other carbohydrates.

Source: air, using antibiotic-containing medium spotted with sterile graphite.

DNA G + C content (mol%): 37.8–38.1 (T_m), and 37.9 for the type strain.

Type strain: strain Matsushashi Kasumi 6, JCM 9731, ATCC 700100, LMG 18001, NCIMB 13460.

EMBL/GenBank accession number (16S rRNA gene): AB021182 (JCM 9731).

18. **Bacillus cereus** Frankland and Frankland 1887, 257^{AL} ce're.us. L. adj. *cereus* waxen, wax-colored.

Facultatively anaerobic, Gram-positive, usually motile rods 1.0–1.2 by 3.0–5.0 μ m, occurring singly and in pairs and long chains, and forming ellipsoidal, sometimes cylindrical, subterminal, sometimes paracentral, spores which do not swell the sporangia (Figure 10b); spores may lie obliquely in the sporangia. Cells grown on glucose agar produce large amounts of storage material, giving a vacuolate or foamy appearance. Colonies are very variable in appearance, but nevertheless distinctive and readily recognized: they are characteristically large (2–7 mm in diameter) and vary in shape from circular to irregular, with entire to undulate, crenate or fimbriate edges; they usually have matt or granular textures, but smooth and moist colonies are not uncommon (Figure 9b). Colonies are usually whitish to cream in color, but some strains may produce a pinkish brown pigment, and some strains produce a yellow diffusible pigment or a yellowish-green fluorescent pigment. Fresh plate cultures commonly have a “mousy” smell. Minimum temperature for growth is usually 10–20 °C, and the maximum 40–45 °C, with the optimum about 37 °C. Psychrotolerant strains growing at 6 °C have been isolated. Egg yolk reaction is positive. Catalase-positive, oxidase-negative. Casein, gelatin and starch are hydrolyzed. Voges–Proskauer-positive. Citrate is utilized as sole carbon source. Nitrate is reduced by most strains. Tyrosine is decomposed. Phenylalanine is not deaminated. Resistant to 0.001% lysozyme. Acid without gas is produced from glucose and a limited range of other carbohydrates. Most strains produce acid from salicin and starch, but strains of serovars 1, 3, 5 and 8 (which include strains associated with emetic food poisoning) do not produce acid from these substrates. Extracellular products include hemolysins, enterotoxins, heat-stable emetic toxin, cytotoxin, proteolytic enzymes and phospholipase; psychrotolerant strains may produce toxins (Stenfors and Granum, 2001).

Bacillus cereus has been divided into serovars on the basis of H-antigens (Kramer and Gilbert, 1992); 42 serovars are presently recognized (Ripabelli et al., 2000). Plasmid banding patterns and amplified fragment length polymorphism analysis may be of value in distinguishing between strains of the same serotype (Nishikawa et al., 1996; Ripabelli et al., 2000).

Endospores are very widespread in soil, in milk and other foods, and in many other environments. The vegeta-

tive organisms may multiply readily in a variety of foods and may cause diarrheal and emetic food poisoning syndromes. Growth in milk may result in "bitty cream defect". Occasionally causes opportunistic infections in man and other animals. Certain endospore-forming, trichome-forming bacteria that occur in the alimentary tracts of animals, some of which have been called "*Arthromitus*", have been identified as *Bacillus cereus*; see *Cell morphology* and *Habitats*, in *Further descriptive information*, above.

DNA G + C content (mol%): 31.7–40.1 (T_m) for 11 strains, 34.7–38.0 (Bd), and 35.7 (T_m), 36.2 (Bd) for the type strain.

Type strain: ATCC 14579, DSM 31, JCM 2152, LMG 6923, NCIMB 9373, NRRL B-3711, IAM 12605.

EMBL/GenBank accession number (16S rRNA gene): D16266 (IAM 12605).

Additional remarks: Phenotypically similar to other members of the *Bacillus cereus* group: *Bacillus anthracis*, *Bacillus mycoides*, *Bacillus thuringiensis* and *Bacillus weihenstephanensis*. For distinguishing characters see the individual species descriptions and Table 7. Another member of the group, *Bacillus pseudomycoloides*, is separated from *Bacillus cereus* only by DNA relatedness and some differences in fatty acid composition. Genetic evidence supports the recognition of members of the *Bacillus cereus* group as one species, given that differentiation often relies on the presence of virulence characters which are carried by extrachromosomal mobile genetic elements (Turnbull et al., 2002), but practical considerations argue against such a move.

19. ***Bacillus circulans*** Jordan 1890, 821^{AL}

circulans. L. part. adj. *circulans* circling.

For many years this species accommodated a wide variety of phenotypically unrelated strains. It was referred to by Gibson and Topping (1938) as a complex rather than a species, and later investigators agreed with this description. Strains were frequently allocated to this species on account of their distinctive motile microcolonies (Figure 9i); however, Jordan named his isolate for the circular motion that he saw in the interior of colonies observed under low magnification, rather than because of motile microcolonies. Jordan's original strain is considered lost, but Ford's isolate 26, that he believed to be of the same species as Jordan's strain, is available. Smith and Clark (1938) observed the rotary motion within the colonies of Ford's strain and noted also the production of motile microcolonies. Despite a few discrepancies between Jordan's and Ford's descriptions of their strains, Smith et al. (1952) considered that Ford's strain 26 could be accepted as authentic and this became the type strain. The production of motile microcolonies is more characteristic of strains now allocated to *Paenibacillus* (see *Further descriptive information, Colony characteristics*, above).

Further grounds for the allocation of later isolates to this species were the production of sporangia swollen by subterminal to terminal ellipsoidal spores, and their being very active in the production of acid from a very wide range of carbohydrates. DNA relatedness studies revealed at least 10 homology groups among strains labeled *Bacillus circulans*, and it became clear that the phenotypic and genotypic heterogeneity of the complex had resulted from the allo-

cation of unrelated strains to the species (Nakamura and Swezey, 1983). This work led to the allocation of members of several of the homology groups to new or revived species which were subsequently assigned to *Paenibacillus*: *Paenibacillus amylolyticus*, *Paenibacillus lautus*, *Paenibacillus pabuli* and *Paenibacillus validus*. A further group of strains previously assigned to *Bacillus circulans* was proposed as the new species *Bacillus* (now *Paenibacillus*) *glucanolyticus* on the basis of a numerical taxonomic study (Alexander and Priest, 1989). However, many misnamed strains remain allocated to *Bacillus circulans* and await reallocation, and authentic strains of this species are in the minority in most collections.

The description which follows is based upon the type strain and several other strains which have been shown by amplified rDNA restriction analysis, polyacrylamide gel electrophoresis of whole-cell proteins, and various phenotypic characters (De Vos, Logan and colleagues, unpublished data) to be closely related to the type strain. Phylogenetic studies indicate that *Bacillus circulans*, *Bacillus firmus* and *Bacillus lentus* are related.

Facultatively anaerobic, motile, straight, round-ended, occasionally slightly tapered and curved rods 0.6–0.8 µm in diameter, appearing singly or in pairs and occasionally short chains. Endospores are ellipsoidal and lie terminally or subterminally in swollen sporangia (Figure 9c). Colonies grown for 2 d on TSA at 30 °C are 1–3 mm in diameter, opaque, cream-colored, slightly convex, with eggshell surface textures and irregular margins that may spike along the streak lines. Optimum temperature lies between 30 °C and 37 °C; maximum temperature for growth lies between 50 °C and 55 °C. The optimum pH for growth is 7.0. Minimum pH for growth lies between 4.0 and 5.0. The maximum pH lies between 9 and 10. Casein and starch are weakly hydrolyzed. In the API 20E strip, *o*-nitrophenyl-β-D-galactopyranoside hydrolysis is positive and urease production, hydrolysis of gelatin and nitrate reduction are occasionally positive. Arginine dihydrolase, lysine decarboxylase and ornithine decarboxylase production, citrate utilization, hydrogen sulfide, tryptophan deaminase and indole production and Voges-Proskauer reaction are negative. In the API 50CH gallery using the CHB suspension medium, hydrolysis of esculin is positive, and acid without gas is produced from a very wide range of carbohydrates: Production of acid without gas is variable for: adonitol, D-arabitol, 2-keto- and 5-keto-D-glucuronate, rhamnose and ribose; the type strain is positive for adonitol, rhamnose and ribose. Acid production is negative for the following substrates: D-arabinose, dulcitol, erythritol, D-fucose, L-fucose, L-sorbose, D-tagatose and L-xylose. In the variable results, the type strain scores positive for: adonitol, rhamnose and ribose. Occasional strains may produce acid without gas from D-lyxose.

Source: sewage, soil, food and infant bile.

DNA G + C content (mol%): 35.7 (T_m), 36.2 (Bd) for the type strain.

Type strain: ATCC 4513, DSM 11, JCM 2504, LMG 13261, IAM 12462.

EMBL/GenBank accession number (16S rRNA gene): D78312 (IAM 12462).

20. ***Bacillus clarkii*** Nielsen, Fritze and Priest 1995b, 879^{VP} (Ef-

fective publication: Nielsen, Fritze and Priest 1995a, 1758.)
 clar'ki.i. N.L. gen. n. *clarkii* of Clark, named after the American bacteriologist Francis E. Clark.

Strictly alkaliphilic and moderately halophilic organisms forming ellipsoidal spores which lie subterminally. The sporangia of the type strain are distinctly swollen, those of the other two strains characterized by Nielsen et al. were not swollen. Cells 0.6–0.7 by 2.0–5.0 µm. Colonies are circular and smooth, creamy-white to pale yellow or (with age) dark yellow, and with entire margins. Growth temperature range 15–45 °C. Optimal growth at pH 10.0 or above; no growth at pH 7.0. Grows in presence of up to 16% NaCl; unable to grow in the absence of sodium ions. Nitrate is reduced to nitrite. Casein, hippurate, gelatin, and Tween 40 and 60 are hydrolyzed. Pullulan, starch, and Tween 20 and 80 are not hydrolyzed; phenylalanine is not deaminated. See Table 6.

Source: mud and soil.

DNA G + C content (mol%): 42.4–43.0 (HPLC analysis).

Type strain: PN-102, ATCC 700162, DSM 8720, LMG 17947.

EMBL/GenBank accession number (16S rRNA gene): X76444 (DSM 8720).

21. **Bacillus clausii** Nielsen, Fritze and Priest 1995b, 879^{VP} (Effective publication: Nielsen, Fritze and Priest 1995a, 1759.)
 clau'si.i. N.L. gen. n. *clausii* of Claus, named after the German bacteriologist Dieter Claus.

Alkalitolerant organisms forming ellipsoidal spores which lie paracentrally to subterminally in sporangia which may be slightly swollen. Cells 0.5–0.7 by 2.0–4.0 µm. Colonies are white and filamentous with filamentous margins. Growth temperature range 15–50 °C. Optimal growth at pH 8.0; good growth at pH 7.0. Grows in presence of up to 8–10% NaCl. Nitrate is reduced to nitrite. Casein, gelatin and starch are hydrolyzed. Hippurate, pullulan, and Tween 20, 40, 60 and 80 are not hydrolyzed; phenylalanine is not deaminated. Glucose and a wide range of other carbohydrates can be utilized as sole sources of carbon. Strains in this species were formerly assigned to *Bacillus lentus* type II by Gordon and Hyde (1982).

Source: clay and soil.

DNA G + C content (mol%): 42.8–45.5 (HPLC analysis).

Type strain: PN-23, ATCC 700160, DSM 8716, LMG 17945, NCIMB 10309.

EMBL/GenBank accession number (16S rRNA gene): X76440 (DSM 8716).

22. **Bacillus coagulans** Hammer 1915, 119^{AL}

co.a'gu.lans. L. part. adj. *coagulans* curdling, coagulating.

Moderately thermophilic, aciduric, facultatively anaerobic, Gram-positive, motile rods. The cell diameter is 0.6–1.0 µm. Spores are ellipsoidal but sometimes appear spherical; they lie subterminally and occasionally paracentrally or terminally in slightly swollen sporangia; some strains do not sporulate readily. After 2 d incubation on TSA at 40 °C, colonies are <1 to 3 mm in diameter, white, convex with entire margins and smooth surfaces; they become cream-colored with age. Growth occurs at 30 °C, the optimum growth temperature lies between 40 °C and 57 °C, and the maximum temperature for growth lies between 57 °C and 61 °C. The optimum

pH for growth is 7.0; cells are able to grow at pH 4 and the maximum pH for growth lies between 10.5 and 11. Does not grow in presence of 5% NaCl. Minimal nutritional requirements are variable, and may include several amino acids and vitamins. Catalase-positive. Starch is hydrolyzed. Tyrosine is not decomposed. Casein is not hydrolyzed. In the API 20E strip, strains give variable results for arginine dihydrolase, gelatin liquefaction (type strain positive), nitrate reduction, ONPG (type strain positive) and the Voges–Proskauer test (type strain weak positive); all the strains are negative for lysine decarboxylase and ornithine decarboxylase reactions, citrate utilization, hydrogen sulfide production, urease, tryptophan deaminase, and indole production. In the API 50CH gallery using the CHB suspension medium, hydrolysis of esculin is variable (most strains positive), and acid without gas is produced from the following carbohydrates by more than 85% of strains: D-galactose, D-fructose, D-glucose, glycerol, maltose, D-mannose, D-melibiose, N-acetylglucosamine, starch and D-trehalose. Acid production from the other substrates varies between strains (see Tables 3 and 4, and De Clerck et al., 2004b).

Bacillus coagulans is economically important as a food spoilage agent, as a producer of commercially valuable products such as lactic acid, thermostable enzymes, and the antimicrobial peptide coagulin, and as a probiotic for chickens and piglets, but several taxonomic studies revealed considerable diversity within the species. De Clerck et al. (2004b) carried out a polyphasic taxonomic study of 30 strains, and found that although individual characterization methods revealed subgroups of strains, these intra-species groupings were not sufficiently consistent among the different methods to support the proposal of subspecies, nor were there any features to suggest such a division, and DNA–DNA relatedness data and 16S rDNA sequence comparisons upheld the accommodation of all the strains in one species.

Source: soil, canned foods, tomato juice, gelatin, milk, medical preparations and silage.

DNA G + C content (mol%): 44.3–50.3 (T_m) for seven strains, 45.4–56.0 (Bd) for three strains, and 47.4 (HPLC), 47.1 (T_m), 44.5 (Bd) for the type strain.

Type strain: ATCC 7050, DSM 1, JCM 2257, LMG 6326, NCIMB 9365, NRRL NRS-609, IAM 12463.

EMBL/GenBank accession number (16S rRNA gene): D16267 (IAM 12463).

23. **Bacillus cohnii** Spanka and Fritze 1993, 155^{VP}

coh'nii. N.L. gen. n. *cohnii* of Cohn; named after the German bacteriologist Ferdinand Cohn.

Alkaliphilic, Gram-positive, peritrichously motile rods, forming ellipsoidal spores which lie subterminally to terminally in swollen sporangia. In the cell wall, diaminopimelic acid is replaced by ornithine, and aspartic acid forms the interpeptide bridge. Colonies are creamy white, and 1–2 mm in diameter after 2 d at 45 °C. Growth temperature range 10–47 °C. Growth in presence of 5% but not 10% NaCl. Grows at pH 9.7. Nitrate is reduced. Catalase- and oxidase-positive. Gelatin, hippurate, starch and Tween 60 are hydrolyzed; hydrolysis of casein, pullulan and Tween 80

usually positive. Urea is not hydrolyzed, phenylalanine is not deaminated. See Table 6.

Source: soil and feces.

DNA G + C content (mol%): 33.9–35.0, and that of the type strain is 34.6 (T_m).

Type strain: RSH, ATCC 51227, DSM 6307, LMG 16678, IFO 15565.

EMBL/GenBank accession number (16S rRNA gene): X76437 (DSM 6307).

24. **Bacillus decolorationis** Heyrman, Balcaen, Rodríguez-Díaz, Logan, Swings and De Vos 2003a, 462^{VP}

de.co.lo.ra.ti.on'is. L. gen. n. *decolorationis* of discoloration.

Aerobic, Gram-variable, motile, rods and coccoid rods, 0.5–0.8 µm wide and 1.0–4.0 µm long, that occur singly, in pairs or short chains. Spores are produced slowly and in small numbers in culture; they are ellipsoidal, sometimes nearly spherical, central to subterminal and swell the sporangia slightly. Colonies on TSA are cream-colored to beige, circular with a smooth to slightly irregular margin, low-convex with a glistening and rough surface. Oxidase- and catalase-positive. The temperature range for growth is 5–40 °C with optimal growth at 25–37 °C. The NaCl concentration for growth is 0–10% (w/v), with an optimum of 4–7% (w/v). Casein hydrolysis is positive within 4 d incubation. In the API 20E strip, conversion of nitrates to nitrite and dinitrogen is positive and gelatin hydrolysis occurs with or without added salt, but only with large inocula. Reactions are negative for arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, citrate utilization, hydrogen sulfide production, urease, tryptophan deaminase, indole production and Voges–Proskauer. The ONPG reaction is negative without added NaCl and variable (type strain positive) when supplemented with 7% NaCl. Acid is produced weakly and without gas from the following carbohydrates in the API 50 CH gallery using the CHB suspension medium supplemented with 7% NaCl: cellobiose, D-fructose, gentiobiose, D-glucose, 5-keto-D-gluconate, maltose, D-mannose, N-acetylglucosamine, ribose, salicin, sucrose and trehalose. Esculin hydrolysis is positive with or without added NaCl. Results are variable amongst strains for weak acid production from arbutin, galactose, glycerol, lactose and D-mannitol; type strain is positive for arbutin, glycerol and D-mannitol. The major fatty acid is C_{15:0 anteiso}, present at about 68%; C_{17:0 anteiso} accounts for about 11% of the total.

Source: mural paintings, discolored by microbial growths.

DNA G + C content (mol%) of the type strain: 39.8 (HPLC).

Type strain: LMG 19507, DSM 14890.

EMBL/GenBank accession number (16S rRNA gene): AJ315075 (LMG 19507).

25. **Bacillus drentensis** Heyrman, Vanparys, Logan, Balcaen, Rodríguez-Díaz, Felske and De Vos 2004, 56^{VP}

dren.ten'sis. N.L. adj. *drentensis* of Drente, a province in The Netherlands.

Facultatively anaerobic, Gram-positive or Gram-variable, motile, tapered rods, 1.5–3.5 µm in diameter, occurring singly and in pairs. Cells show pleomorphism (narrow and broad cells, the latter showing swellings) and produce intracellular storage products (possibly PHB) on TSA. Endospores

are spherical or ellipsoidal and lie in paracentral or occasionally subterminal positions in swollen sporangia. Colonies are slightly convex with regular margins when small, and sometimes wrinkled with irregular margins and prominent centers when larger. Colonies are cream-colored and produce a brownish soluble pigment; consistency is butyrous, with an eggshell-like surface texture. The optimum temperature for growth is 30 °C, and the maximum growth temperature lies between 50 °C and 55 °C. The optimum pH for growth is 7.0–8.0, and growth occurs from pH 5.5–6.0 to 9.5–10.0. Casein is not hydrolyzed. In the API 20E strip, *o*-nitrophenyl-β-D-galactopyranoside hydrolysis is positive, Voges–Proskauer reaction is variable (most strains negative, positive strains weak), and nitrate reduction is variable; reactions for arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, citrate utilization, hydrogen sulfide production, urease, tryptophan deaminase, indole production and gelatin hydrolysis are negative. Hydrolysis of esculin is positive. Acid without gas is produced from the following carbohydrates in the API 50 CH gallery using the CHB suspension medium: N-acetyl-D-glucosamine, D-fructose, D-glucose (some strains, including the type strain, weak), lactose, maltose, D-melibiose and salicin (some strains, including the type strain, weak). The following reactions are variable between strains and, when positive, are usually weak: amygdalin, arbutin, galactose, gluconate, inulin, D-mannose, D-melezitose, α-methyl-D-glucoside, raffinose, ribose, starch, sucrose, D-trehalose, D-turanose and D-xylose; type strain is positive for inulin, D-mannose, D-melezitose, sucrose and weak for raffinose, ribose, starch and D-turanose. The major cellular fatty acids are C_{15:0 iso} and C_{15:0 anteiso}, present at a level of about 32 and 22%, respectively, while C_{16:1 ω11c} accounts for about 13% of the total fatty acids.

Source: soil in the Drentse an agricultural research area, The Netherlands.

DNA G + C content (mol%): 39.3–39.4 (HPLC) and 39.4 for the type strain.

Type strain: LMG 21831, DSM 15600.

EMBL/GenBank accession number (16S rRNA gene): AJ542506 (LMG 21831).

26. **Bacillus endophyticus** Reva, Smirnov, Pettersson and Priest 2002, 106^{VP}

en.do.phy'ti.cus. Gr. *endo* within; Gr. n. *phyton* plant.; L. masc. suff. *-icus* adjectival suffix used with the sense of belonging to; N.L. adj. *endophyticus* within plant; originally isolated from plant tissues.

Strictly aerobic, Gram-positive, nonmotile rods, forming ellipsoidal spores which lie subterminally or terminally in unswollen sporangia. Cells 0.5–1.5 by 2.5–3.5 µm, occurring singly and in short or long chains, the latter appearing filamentous. Vacuoles are formed in the cytoplasm of cells grown on media containing 2% glucose. Colonies are circular, 1–3 mm in diameter, with entire or slightly indented margins, and may be slimy or rough; they are usually white, but pink and red pigmentation is occasionally seen. Growth temperature range 10–45 °C; optimum about 28 °C. Grows in presence of 10% NaCl. Nitrate is not reduced to nitrite. Catalase- and oxidase-positive. Casein, gelatin, starch and urea are not hydrolyzed. Acid

without gas produced from D-glucose and a range of other carbohydrates. Citrate and gluconate are utilized; acetate, propionate and tartrate are not.

Source: inner tissues of healthy cotton plants.

DNA G + C content (mol%): not reported.

Type strain: 2DT, ATCC 29604, NRRL NRS-1705, LMG 7124, NCIMB 11326, CIP 106778, JCM 9331.

EMBL/GenBank accession number (16S rRNA gene): AF295302 (2DT).

27. **Bacillus farraginis** Scheldeman, Rodríguez-Díaz, Goris, Pil, De Clerck, Herman, De Vos, Logan and Heyndrickx 2004, 1362^{VP} far.ra.gin'is. L. gen. fem. n. *farraginis* from mixed fodder for cattle, referring to feed concentrate for dairy cattle as the principal isolation source.

Cells are long, straight, round-ended, motile, strictly aerobic, Gram-negative rods, occurring singly, in pairs or filaments. Cell diameter is 0.5–0.8 µm and cell length 1.2–4 µm. Spores are ellipsoidal and occur paracentrally or subterminally in occasionally slightly swollen sporangia. Colonies grown for 3 d at 30 °C on nutrient agar are cream-colored or translucent, slightly raised, with irregular margins and granular, glossy surfaces. Colony diameter is no greater than 1 mm. Good growth occurs at 30 and 45 °C and weak growth occurs at 20 °C. Some strains are capable of growth at pH 9 but none grows at pH 5. Growth is not inhibited by 7% (w/v) NaCl. Hydrolysis of starch and casein is not observed within 7 d of incubation at 30 °C, and growth in casein agar is poor or negative. Catalase- and oxidase are positive. All strains are unreactive in the API 20E and API 50CHB test kits. In the Biotype100 kit using the Biotype 2 medium, nearly all strains (>83%) belonging to the species are able to use the following substrates as sole carbon sources: 4-aminobutyrate, 5-aminovalerate, D- and L-alanine, fumarate, L-glutamate, glutarate, L-histidine, 3-hydroxybutyrate, 2-oxoglutarate, D- and L-malate, DL-lactate, L-proline, putrescine, succinate, L-tryptophan and L-tyrosine. Many strains (>45%) are able to use L-aspartate, dulcitol, *m*-hydroxybenzoate, malonate, D-mannitol, D-ribose and D-sorbitol. Other substrates are used less frequently (17–44%): L-arabinose, D-galactose, gentisate, D-glucuronate, *p*-hydroxybenzoate, *myo*-inositol and α -L-rhamnose.

The type strain utilizes the following substrates as sole carbon sources: 4-aminobutyrate, 5-aminovalerate, D- and L-alanine, L-aspartate, dulcitol, fumarate, D-glucosamine, L-glutamate, glutarate, histamine, L-histidine, *m*-hydroxybenzoate, 3-hydroxybutyrate, 2-oxoglutarate, D- and L-malate, malonate, DL-lactate, L-proline, putrescine, D-ribose, D-sorbitol, succinate, *meso*-tartrate, L-tryptophan and L-tyrosine. The major cellular fatty acids (>5% of total cellular fatty acids) are C_{15:0 iso}, C_{15:0 anteiso}, C_{17:0 anteiso}, C_{16:0 iso} and C_{16:1 ω _{7c}} alcohol.

Source: cattle feed concentrate, milking clusters, hay, silage, grass, lucerne and green fodder.

DNA G + C content (mol%): 43.7 (HPLC).

Type strain: R-6540, MB 1885, LMG 22081, DSM 16013.

GenBank/EMBL accession number (16S rRNA gene): AY443034 (R-6540).

28. **Bacillus fastidiosus** den Dooren de Jong 1929, 344^{AL}

fas.tid'i.os.us. L. adj. *fastidiosus* disdainful, fastidious.

Strictly aerobic rods about 1.3 µm in diameter, forming ellipsoidal spores which usually lie centrally, paracentrally and subterminally, occasionally terminally, in unswollen sporangia. Colonies on 1% uric acid agar become opaque and are usually unpigmented but may become yellowish; margins are often ragged and have hair-like outgrowths, or the colonies may be rhizoid. Colonies are surrounded by zones of clearing and the reaction becomes strongly alkaline. Growth occurs at 10 °C and 40 °C, but not at 5 °C or 50 °C. Does not grow at pH 6.8 or below. Grows in presence of 5% NaCl. Grows on allantoinic acid, allantoin or uric acid as sole carbon, nitrogen and energy sources. Some strains will grow on certain peptones, especially at high concentrations. Growth factors not required, Nitrate is not reduced to nitrite. Catalase- and oxidase-positive. Urea is hydrolyzed; casein, gelatin and starch are not hydrolyzed. Acid and gas are not produced from D-glucose and other carbohydrates; there is no growth in the media used to test these characters. Citrate and propionate are not utilized.

Source: soil and poultry litter.

DNA G + C content (mol%): 34.3–35.1 (*T_m*) for 17 strains, and 35.1 (*T_m*), 35.1 (Bd) for the type strain.

Type strain: Delft LMD 29-14, ATCC 29604, DSM 91, LMG 7124, NCIMB 11326, NRRL NRS-1705, KCTC 3393.

EMBL/GenBank accession number (16S rRNA gene): X60615 (DSM 91).

29. **Bacillus firmus** Bredemann and Werner in Werner 1933, 446^{AL} fir'mus. L. adj. *firmus* strong, firm.

This species has for long been genetically heterogeneous, and many strains have been incorrectly assigned to it. Strains received as *Bacillus firmus* show phenotypic profiles that appear to overlap with those of strains assigned to *Bacillus lentus*, so that Gordon et al. (1977) raised the question of whether *Bacillus firmus*–*Bacillus lentus* represented a single species or a series of strains.

The description which follows is based upon the type strain and 17 other strains which have been shown by amplified rDNA restriction analysis, polyacrylamide gel electrophoresis of whole-cell proteins, and various phenotypic characters (De Vos, Logan and colleagues, unpublished data) to be closely related to the type strain. Phylogenetic studies indicate that *Bacillus circulans*, *Bacillus firmus* and *Bacillus lentus* are related.

Facultatively anaerobic, straight, round-ended, motile rods, 0.8–0.9 µm in diameter, that occur singly, in pairs, or occasionally as short chains. Endospores are ellipsoidal or cylindrical, lie subterminally, paracentrally or centrally, and may swell the sporangia slightly. Colonies grown for 3 d on TSA at 30 °C are 1–12 mm in diameter, creamy-yellow to pale orangey-brown in color, are of butyrous consistency, have margins that vary from entire to finely rhizoidal and surface appearances that are egg-shell to glossy, sometimes with granular or zoned areas in center. Maximum growth temperature is 40–50 °C, the optimum temperature lies between 30 °C and 40 °C, and growth occurs at 20 °C. The optimum pH for growth is 7.0–9.0; the minimum is 6.0–7.0, and the maximum lies between 11 and 11.5. Grows in presence of 7% NaCl. Catalase-positive. Casein is weakly

hydrolyzed and a pale to dark honey-brown diffusible pigment is produced on it. Starch is hydrolyzed, but strength of reaction varies among strains. Citrate and propionate are not utilized. In the API 20E strip, gelatin is partially or completely hydrolyzed by most strains and nitrates are totally or partially reduced. *o*-nitrophenyl- β -D-galactopyranoside is not hydrolyzed, arginine dihydrolase, lysine decarboxylase and ornithine decarboxylase are not produced, citrate is not utilized, hydrogen sulfide, urease, tryptophan deaminase and indole are not produced and Voges–Proskauer reaction is negative. In the API 50CH gallery using the CHB suspension medium, hydrolysis of esculin is variable and acid without gas is positive or weakly positive from the following carbohydrates: D-glucose, maltose, mannitol, starch and sucrose. In the API Biotype 100 kit the following substrates are utilized as sole carbon sources: D- and L-alanine, D-gluconate, D-glucosamine, α -D-glucose, L-glutamate, glycerol, 2-oxoglutarate, DL-lactate, L-malate, maltose, maltotriose, D-mannitol, N-acetyl-D-glucosamine, L-proline, sucrose, L-serine, succinate and D-trehalose. The type strain and some other strains are positive or weak for: glycerol, N-acetylglucosamine and D-trehalose.

According to their patterns of acid production from other carbohydrates, and use of other substrates as sole carbon sources, 2 bioypes may be recognized, with Biovar 1 containing the type strain; Biovar 2 strains may represent a distinct species and are distinct from Biovar 1 strains in their slightly stronger acid production from the above-mentioned carbohydrates and their acid production from: D-fructose, glycogen and, although variable among Biovar 2 strains, D-xylose. Only Biovar 2 strains are able to utilize: *cis*-aconitate, citrate, β -D-fructose, DL-glycerate, 2-keto-D-gluconate, maltitol, 3-methyl-D-glucopyranose, methyl α -D-glucopyranoside, tricarballylate, trigonelline, L-tryptophan and D-xylose. In assimilation tests giving variable results, the type strain is positive for: L-histidine and 3-hydroxybutyrate.

Source: soil and other environments.

DNA G + C content (mol%): 41.4 (T_m), 40.7 (Bd).

Type strain: ATCC 14575, DSM 12, JCM 2512 (D78314), LMG 7125, NCIMB 9366 NRRL B-14307, IAM 12464.

EMBL/GenBank accession number (16S rRNA gene): D16268 (IAM 12464).

30. **Bacillus flexus** (*ex* Batchelor 1919) Priest, Goodfellow and Todd 1989, 93^{VP} (Effective publication: Priest, Goodfellow and Todd 1988, 1878.)

flexus. L. adj. *flexus* flexible.

Strictly aerobic, Gram-variable rods, forming ellipsoidal spores which lie centrally or paracentrally in unswollen sporangia. Description is based upon two strains. Mean cell width 0.9 μ m. Colonies are opaque and smooth. Growth occurs at 17–37 °C, but not at 5 °C or 50 °C. Grows between pH 4.5 and 9.5. Grows in presence of 10% NaCl. Nitrate is not reduced to nitrite. Oxidase-positive. Casein, elastin, gelatin, pullulan, starch and urea are hydrolyzed; esculin is not. Acid without gas is produced from D-glucose and a range of other carbohydrates; acid is not produced from pentoses. Acetate, citrate, formate and succinate are utilized; gluconate, lactate and malonate are not.

Source: feces and soil.

DNA G + C content (mol%): 35 and 36 (T_m) for two strains.

Type strain: ATCC 49095, DSM 1320, LMG 11155, NCIMB 13366, NRRL NRS-665, IFO 15715.

EMBL/GenBank accession number (16S rRNA gene): AB021185 (IFO 15715).

31. **Bacillus fordii** Scheldeman, Rodríguez-Díaz, Goris, Pil, De Clerck, Herman, De Vos, Logan and Heyndrickx 2004, 1363^{VP} for 'di.i. N.L. gen. n. fordii named after W. W. Ford, an American microbiologist working on aerobic spore-forming bacteria at the beginning of the twentieth century.

Cells are long, straight, round-ended, motile, strictly aerobic, Gram-negative rods, occurring singly or in pairs. Cell diameter is 0.6–0.8 μ m and length 1.6–3.5 μ m. Spores are ellipsoidal and occur paracentrally or subterminally in, occasionally, slightly swollen sporangia. Colonies grown on nutrient agar at 30 °C for 3 d are cream-colored, raised, with entire margins and smooth glossy surfaces. Their maximum diameter is 2 mm. Good growth occurs at 30 and 45 °C and weak growth occurs at 20 °C. Growth occurs at pH 9 and some strains grow at pH 5. Growth is not inhibited by 7% (w/v) NaCl. Hydrolysis of starch and casein is not observed within 7 d of incubation at 30 °C. Growth on casein agar is colored faint pink. Catalase and oxidase are positive. All strains are unreactive in the API 20E and API 50CHB test kits. In the Biotype100 kit using the Biotype 2 medium, all strains show very good production of biomass using malonate and L-tyrosine as sole carbon sources. Variable results with good production of biomass are obtained for L-histidine, 2-oxoglutarate, glutarate, DL-lactate, 5-aminovalerate and L-tryptophan. All or most strains are capable of weak growth from the following carbon sources: esculin, gentisate, protocatechuate, *meso*-tartrate, D-glucosamine, DL-glycerate, quinate, ethanolamine, D-gluconate, *p*-hydroxybenzoate, hydroxyquinoline β -glucuronide and 2- and 5-keto-D-gluconate. Growth occurs seldom and weakly from the following substrates: adonitol, L-alanine, L-arabinose, L-arabitol, benzoate, fumarate, D-galacturonate, D-gluconate, α -D-glucose, histamine, 3-hydroxybutyrate, D-lyxose, D-malate, methyl α -galactopyranoside, methyl β -D-glucopyranoside, N-acetyl D-glucosamine, phenylacetate, propionate, putrescine, D-raffinose, D-ribose, D-saccharate, L-sorbose, succinate, D-tagatose, L-tartrate, tricarballylate, trigonelline and D-xylose.

Where results are variable, the type strain uses the following substrates: esculin, 5-aminovalerate, L-arabinose, benzoate, ethanolamine, D-galacturonate, gentisate, D-gluconate, glutarate, DL-glycerate, histamine, *p*-hydroxybenzoate, 3-hydroxybutyrate, hydroxyquinoline- β -glucuronide, 2- and 5-keto-D-gluconate, 2-oxoglutarate, DL-lactate, D-lyxose, N-acetyl D-glucosamine, phenylacetate, protocatechuate, putrescine, quinate, D-raffinose, *meso*-tartrate, tricarballylate, L-tryptophan and D-xylose. The major cellular fatty acids (>5% of total cellular fatty acids) are C_{15:0} iso^o, C_{15:0} anteiso^o, C_{17:0} anteiso^o, C_{16:1} ω 11^c and C_{17:0} iso^o.

Source: cattle feed concentrate, milking clusters, filter cloths, and raw milk.

DNA G + C content (mol%): 41.9 (HPLC).

Type strain: R-7190, MB 1878, LMG 22080, DSM 16014.

GenBank/EMBL accession number (16S rRNA gene): AY443034 (R-7190).

32. **Bacillus fortis** Scheldeman, Rodríguez-Díaz, Goris, Pil, De Clerck, Herman, De Vos, Logan and Heyndrickx 2004, 1362^{VP} for'tis. L. adj. *fortis* strong, referring to the fact that the strains were isolated after heat treatment for 30 min at 100 °C.

Cells are straight, round-ended, motile, strictly aerobic, Gram-negative rods, occurring singly or in pairs. Cell diameter is 0.6–0.8 µm and length 1.0–3.5 µm. Spores are oval and occur centrally or paracentrally in slightly swollen sporangia. Colonies grown on nutrient agar at 30 °C for 3 d are cream-colored, raised with entire margins and smooth, glossy surfaces. Their maximum diameter is 1 mm. Good growth occurs at 30 and 45 °C and weak growth occurs at 20 °C. Growth does not occur at pH 9 or 5. Growth is not inhibited by 7% (w/v) NaCl. Hydrolysis of starch and casein is not observed within 7 d of incubation at 30 °C, and growth on casein agar is poor or negative. Catalase and oxidase are positive. All strains are unreactive in the API 20E and API 50CHB test kits. In the Biotype 100 kit using the Biotype 2 medium, strains use L-tryptophan and L-histidine as sole carbon sources. Most strains (>50%) use the following substrates as sole carbon sources: 4-aminobutyrate, 5-aminovalerate, esculin, ethanolamine, glutarate, hydroxyquinoline β-glucuronide, 2-oxoglutarate, DL-lactate, malonate, phenylacetate, L-proline, putrescine, D-ribose and L-tyrosine. Some strains (<50%) use the following substrates: citrate, erythritol, D-gluconate, D-glucosamine, α-D-glucose, L-glutamate, DL-glycerate, histamine, *m*-hydroxybenzoate, 2- and 5-keto-D-gluconate, L- and D-malate, α-D-melibiose, protocatechuate, L-sorbose and L-tartrate. Where results are variable, the type strain uses the following substrates: esculin, D-gluconate, D-glucosamine, D-glucuronate, DL-glycerate, hydroxyquinoline-β-glucuronide, 2-oxoglutarate, 2- and 5-keto-D-gluconate, DL-lactate, malonate, phenylacetate, protocatechuate, L-tartrate and L-tyrosine. The major cellular fatty acids (>5% of total cellular fatty acids) are C_{15:0 iso}, C_{15:0 anteiso}, C_{16:0 iso}, C_{15:0} and C_{17:0 anteiso}.

Source: cattle feed concentrate, milking clusters, soy, and raw milk.

DNA G + C content (mol %): 44.3 (HPLC).

Type strain: R-6514, LMG 22079, DSM 16012.

GenBank/EMBL accession number (16S rRNA gene): AY443034 (R-6514).

33. **Bacillus fumarioli** Logan, Lebbe, Hoste, Goris, Forsyth, Heyndrickx, Murray, Syme, Wynn-Williams and De Vos 2000, 1751^{VP}

fum.a.rio'li. nemt. L. gen. n. *fumariolum* a smoke hole; L. gen. n. *fumarioli* of a smoke hole, whence fumarole, a hole emitting gases in a volcanic area.

Moderately thermoacidophilic and strictly aerobic, feebly motile, Gram-positive organisms growing and sporulating best at pH 5.5 and 50 °C on nutrient-weak media such as BFA (Logan et al., 2000) and BFA at half nutrient-strength, but also growing and sporulating weakly on trypticase soy agar containing 5 mg/l MnSO₄. Colonies 3–10 mm in diameter, low convex, circular and slightly irregular, glossy, creamy-brown, and butyrous. Spores ellipsoidal to cylindrical, lying paracentrally and subterminally, and not swelling

the sporangia. Temperature limits for growth: 25–30 °C and 55 °C; optimum temperature is about 50 °C. Limits of pH for growth: 4–5 and 6–6.5. Catalase-positive. Nitrate is not reduced. Gelatin is hydrolyzed, but esculin and casein are not. Acid without gas produced from D-fructose, D-glucose, mannitol, D-mannose, N-acetylglucosamine (weak), sucrose, D-trehalose (weak). Acid production from galactose, glycerol, lactose, maltose, D-melibiose, D-melezitose, methyl-α-D-glucoside, D-raffinose, ribose and D-turanose varies between strains. See Table 8.

Source: geothermal soils and active and inactive fumaroles in continental and maritime Antarctica, and from gelatin production plants in Belgium, France, and the USA.

DNA G + C content (mol %): 40.7% (T_m).

Type strain: Logan B1801, LMG 19448 (replaces LMG 17489), NCIMB 13771, KCTC 3851.

EMBL/GenBank accession number (16S rRNA gene): AJ250056 (LMG 17489).

34. **Bacillus funiculus** Ajithkumar, Ajithkumar, Iriye and Sakai 2002, 1143^{VP}

fu.ni'cu.lus. L. masc. n. *funiculus* string, rope; referring to the filamentous appearance of the cells.

Aerobic, Gram-variable, motile rods 0.8–2.0 by 4.0–6.0 µm, which form filamentous trichomes by cellular binding. Description is based upon a single isolate. Ellipsoidal spores lie centrally in unswollen sporangia. On prolonged incubation heat-resistant, spore-like resting cells, which outgrow by budding, are formed. Colonies are round, opaque, and off-white to colorless. Growth temperature range 20–40 °C, optimum about 30 °C. The pH range for growth is 5.0–9.0 with optimum at 7.0–8.0. Catalase-positive, oxidase-negative. Voges–Proskauer reaction is positive. Citrate utilization negative. Nitrate is reduced to nitrite. Esculin, starch and urea are hydrolyzed; casein, gelatin and Tween 80 are not hydrolyzed. Acid without gas is produced from glucose. Glucose and a range of other carbohydrates are utilized as sole carbon sources.

Source: activated sewage sludge.

DNA G + C content (mol %): 37.2 (HPLC).

Type strain: NAF001, DSM 15141, JCM 11201, CIP 107128, KCTC 3796.

EMBL/GenBank accession number (16S rRNA gene): AB049195 (NAF001).

35. **Bacillus fusiformis** (ex Smith, Gordon and Clark 1946) comb. nov. *Bacillus sphaericus* var. *fusiformis* Smith, Gordon and Clark 1946), Priest, Goodfellow and Todd 1989, 93^{VP} (Effective publication: Priest, Goodfellow and Todd 1988, 1878.)

fus.i.form'is. L. n. *fusus* spindle; L. suff. *-formis* of the shape of; N.L. adj. *fusiformis* spindle-shaped.

Strictly aerobic, Gram-variable rods, forming spherical spores which lie centrally or terminally in swollen sporangia. Mean cell width ≤0.9 µm. Colonies are opaque and smooth. Growth occurs at 17–37 °C, but not at 5 °C or 50 °C. Grows between pH 6.0 and 9.5. Growth in presence of 2–5% NaCl varies. Nitrate is not reduced to nitrite. Casein and gelatin are hydrolyzed; urea hydrolysis varies; esculin is not hydrolyzed. Acid and gas are not produced from D-glucose or other carbohydrates. Acetate, citrate, formate, lactate and

^cFor *Bacillus fumarioli*, acid production from carbohydrates is tested at pH 6 - see Logan et al. (2000) and *Testing for special characters*.

succinate are utilized; gluconate and malonate utilization varies between strains.

Phenotypically similar to *Bacillus sphaericus*, and according to Priest et al. (1988) distinguishable from that organism by urease positivity, ability to grow in presence of 7% NaCl, and sensitivity to 1 µg/ml tetracycline; however, the data reported in that study indicated that only three of the four strains assigned to this species were urease-positive, and only one strain could grow at 2 or 5% NaCl. In a study of 12 strains belonging to the *Bacillus fusiformis* DNA homology group (Krych et al., 1980), all strains could grow in 7% NaCl and only one strain failed to degrade urea, but members of other *Bacillus sphaericus* homology groups were also positive for these characters. See Table 9.

Ahmed et al. (2007c) proposed the transfer of this species to the new genus *Lysinibacillus*.

Source: soil.

DNA G + C content (mol%): 35–36 (T_m).

Type strain: ATCC 7055, DSM 2898, LMG 9816, NRRL NRS-350, IFO 15717.

EMBL/GenBank accession number (16S rRNA gene): AJ310083 (DSM 2898).

36. ***Bacillus galactosidilyticus*** Heyndrickx, Logan, Lebbe, Rodríguez-Díaz, Forsyth, Goris, Scheldeman and De Vos 2004, 619^{VP}

ga.lac.to.si.di.ly'ti.cus N.L. neut. n. *galactosidum* galactoside, N.L. adj. *lyticus* lysing, dissolving; N.L. adj. *galactosidilyticus* referring to positive ONPG test revealing β-galactosidase activity.

Facultatively anaerobic, Gram-positive or Gram-variable, small, plump, round-ended rods 0.7–0.9 µm by 2–5 µm, with tumbling motility, occurring singly and in pairs, and occasionally in short chains. Ellipsoidal endospores are borne in central, paracentral and subterminal positions within slightly swollen sporangia. After 2 d on TSA, the creamy or off-white colonies have opaque centers and are approximately 1 mm in diameter, smooth, flat and butyrous; the margins are usually irregular with pointed projections that may spread and become rhizoid in older cultures. Catalase-positive. Growth occurs at 30 and 40 °C but not at 50 °C. Alkalitolerant; growth occurs between pH 6 and 10.5, but not at pH 5 or below. Casein hydrolysis is very weak. In the API 20E strip, *o*-nitrophenyl-β-D-galactopyranoside is hydrolyzed, nitrate is reduced to nitrite, urease production is variable (type strain is negative), arginine dihydrolase, lysine decarboxylase and ornithine decarboxylase are negative, citrate is not utilized, hydrogen sulfide is not produced, the Voges–Proskauer reaction is negative, indole is not produced, and gelatin is not hydrolyzed. Hydrolysis of esculin is positive. In the API 50 CHB gallery, acid without gas is produced, often weakly, from N-acetylglucosamine, D-fructose and D-glucose. Acid production from the following carbohydrates is variable, and when positive is usually very weak: amygdalin, L-arabinose, arbutin, D-cellobiose, galactose, gentiobiose, inulin, lactose, maltose, mannitol, D-mannose, D-melezitose, D-melibiose, methyl-D-glucoside, D-raffinose, rhamnose, ribose, salicin, starch, sucrose, D-trehalose, D-turanose and D-xylose; the type strain is positive for arbutin, D-cellobiose, D-melibiose, D-melezitose, D-raffinose, starch, sucrose and D-trehalose.

The major cellular fatty acids are: C_{15:0 anteiso} (33% of total), C_{16:0} (27%), C_{15:0 iso} (13%) and C_{14:0} (8%).

Source: raw milk, partially decomposed wheat grain and infant bile.

DNA G + C content (mol%): 35.7–38.2 (HPLC), and for the type strain is 37.7.

Type strain: LMG 17892, DSM 15595.

EMBL/GenBank accession number (16S rRNA gene): AJ535638 (LMG 17892).

37. ***Bacillus gelatini*** De Clerck, Rodríguez-Díaz, Vanhoutte, Heyrman, Logan and De Vos 2004c, 944^{VP}

ge.la.ti'ni. N.L. gen. neut. n. *gelatini* from gelatin.

Strictly aerobic, Gram-variable, feebly motile, round-ended, straight rods, 0.5–0.9 µm by 4–10 µm, which form long chains and occasionally appear singly. Endospores are oval, lie paracentrally and subterminally, and do not swell the sporangia. Colonies on TSA incubated at 30 °C for 4 d are smooth, cream-colored but darker in the center, have slightly irregular borders, and are waxy in appearance, with eggshell-textured surfaces. Colonies are slightly convex, but older colonies are flatter with concave, transparent centers, and diameters range from 1 to 4 mm. The maximum temperature for growth lies between 58 °C and 60 °C and the optimum temperature lies between 40 °C and 50 °C. Good growth occurs at pH 5–8; the minimum pH for growth is 4–5 and the maximum is 9–10. Good growth occurs in nutrient broth with 15% NaCl added. Catalase-positive, oxidase-negative. Casein is hydrolyzed. In the API 20E strip, hydrolysis of gelatin is positive. All the strains are negative for *o*-nitrophenyl-β-D-galactopyranoside hydrolysis, arginine dihydrolase, lysine decarboxylase and ornithine decarboxylase reactions, citrate utilization, hydrogen sulfide production, urease, tryptophan deaminase, indole production, Voges–Proskauer reaction, and nitrate reduction. In the API 50CH gallery using the CHB suspension medium, hydrolysis of esculin is positive, and acid without gas is produced, often weakly, from the following carbohydrates: D-fructose, D-glucose, glycerol, mannitol, D-mannose, D-trehalose and D-xylose. Most strains show a very weak production of acid from N-acetylglucosamine, maltose, and ribose. The more reactive strains may also produce acid from D-cellobiose, D-galactose, 5-keto-D-gluconate, D-melezitose, *meso*-inositol, methyl D-glucoside and D-turanose. The major cellular fatty acids are C_{15:0 iso}, C_{17:0 iso} and C_{17:0 anteiso} (respectively representing about 60, 13 and 10% of total fatty acid). The following fatty acids are present in smaller amounts: C_{15:0 anteiso}, C_{16:0 iso} and C_{16:0} (respectively representing about 9, 4 and 2% of total fatty acid).

Source: gelatin production plants.

DNA G + C content (mol%): 41.5% (HPLC).

Type strain: LMG 21880, DSM 15865.

EMBL/GenBank accession number (16S rRNA gene): AJ551329 (LMG 21880).

^bCompiled from Larkin and Stokes (1967); Schenk and Aragno (1979); Logan and Berkeley (1984); Claus and Berkeley (1986); Priest et al. (1988); Fritze (1996a); Rheims et al. (1999); Abd El-Rahman et al. (2002); Nakamura et al. (2002); Priest (2002); La Duc et al. (2004).

^cSpores of *Bacillus psychrodurans* and *Bacillus psychrotolerans* are rarely formed; on casein-peptone soymeal-peptone agar spores are predominantly spherical, but on marine agar they are predominantly ellipsoidal.

^dMosquitocidal strains of *Bacillus sphaericus* produce parasporal toxin crystals which are smaller than those produced by *Bacillus thuringiensis*, but which are nonetheless visible by phase-contrast microscopy.

Alkalitolerant organisms forming ellipsoidal spores which lie subterminally and, in ageing cultures paracentrally and occasionally laterally, in unswollen sporangia. Cells 0.6–1.0 by 2.0–3.0 µm. Colonies are, yellow, smooth, shiny and circular. Growth temperature range 10–30–37 °C. Optimal growth at pH 8.0; growth occurs at pH 7.0. Grows in presence of up to 9–12% NaCl. Nitrate

reduction varies between strains. Casein, and gelatin are hydrolyzed. Hippurate, pullulan, starch and Tween 20 are not hydrolyzed; phenylalanine is not deaminated. Glucose and a range of other carbohydrates can be utilized as sole sources of carbon.

Source: soil.

DNA G + C content (mol%): 40.6–41.7 (HPLC analysis).

Type strain: Nielsen PN-109, ATCC 700164, DSM 8722, LMG 17949.

EMBL/GenBank accession number (16S rRNA gene): X76446 (DSM 8722).

39. **Bacillus halmopalus** Nielsen, Fritze and Priest 1995b, 879^{VP} (Effective publication: Nielsen, Fritze and Priest 1995a, 1759.)

hal.ma'pa.lus. Gr. n. *halme* brine; Gr adj. *hapolos* delicate; N.L. adj. *halmopalus* sensitive to brine.

Alkalitolerant organisms forming ellipsoidal spores which lie paracentrally to subterminally in unswollen sporangia. Description is based upon two isolates. Cells 0.6–1.0 by 3.0–4.0 µm. Colonies are small, circular, shiny and creamy-white with entire margins. Growth temperature range 10–40 °C. Optimal growth at pH 8.0; growth occurs at pH 7.0. No growth in presence of 5% NaCl. Nitrate is not reduced. Casein, gelatin, hippurate, pullulan and starch are hydrolyzed. Tween 20, 40, 60 and 80 are not hydrolyzed; phenylalanine is not deaminated. Glucose and a narrow range of other carbohydrates can be utilized as sole sources of carbon. It is distinguished from *Bacillus horikoshii* by its larger cell size, lower salt tolerance, and DNA relatedness.

Source: soil.

DNA G + C content (mol%): 38.6 (HPLC analysis).

Type strain: Nielsen PN-118, ATCC 700165, DSM 8723, LMG 17950.

EMBL/GenBank accession number (16S rRNA gene): X76447 (DSM 8723).

40. **Bacillus halodurans** Nielsen, Fritze and Priest 1995b, 879^{VP} (Effective publication: Nielsen, Fritze and Priest 1995a, 1759.)

ha.lo.du'rans. Gr. n. *hals* salt; L. pres. part. *durans* enduring; N.L. adj. *halodurans* salt-enduring.

Alkaliphilic and moderately halotolerant organisms forming ellipsoidal spores which lie subterminally in slightly swollen sporangia. Cells 0.5–0.6 by 3.0–4.0 µm, and occur in long chains even when sporulated. Colonies are white and circular with slightly filamentous margins. Growth temperature range 15–55 °C. Optimal growth at pH 9–10; most strains grow at pH 7.0. Growth in presence of up to 12% NaCl. Most strains do not reduce nitrate. Casein, gelatin pullulan, starch, and Tween 40 and 60 are hydrolyzed, but most strains do not hydrolyze Tween 20, and Tween 80 is not hydrolyzed. Most strains do not hydrolyze hippurate. Phenylalanine is not deaminated. Glucose and a wide range of other carbohydrates can be utilized as sole sources of carbon. The type strain was previously named "*Bacillus alcalophilus* subsp. *halodurans*" (Boyer et al., 1973). Strains in this species were formerly assigned to *Bacillus lentus* type III by Gordon and Hyde (1982). See Table 6.

Source: soil.

DNA G + C content (mol%) ranges from 42.1–43.9 (HPLC).

Type strain: PN-80, ATCC 27557, DSM 497, LMG 7121, NRRL B-3881.

EMBL/GenBank accession number (16S rRNA gene): AJ302709 (DSM 497).

41. **Bacillus halophilus** Ventosa, García, Kamekura, Onishi and Ruiz-Berraquero 1990a, 105^{VP} (Effective publication: Ventosa, García, Kamekura, Onishi and Ruiz-Berraquero 1989, 164.)

hal.o.phi'lus. Gr. n. *hals* salt; Gr. adj. *philos* loving; N.L. adj. *halophilus* salt-loving.

Halophilic, strictly aerobic, Gram-positive, motile rods, 0.5–1.0 by 2.5–9.0 µm, occurring singly and in pairs or chains, and forming ellipsoidal spores which lie centrally in unswollen sporangia. Description is based upon a single isolate. Colonies on 15% NaCl medium are circular, smooth, entire, opaque and unpigmented. Grows at between 3% and 30% total salts with optimal growth at about 15% salts. Growth occurs between 15 °C and 50 °C, and is optimal at 37 °C. The pH range for growth is 6.0–8.0, with the optimum at 7.0. Catalase- and oxidase-positive. Chemo-organotroph. Acid is produced without gas from glucose and a range of other carbohydrates. Nitrate is not reduced. Esculin, DNA and urea are hydrolyzed; casein, gelatin, starch and tyrosine are not. Negative for arginine dihydrolase, lysine and ornithine decarboxylases, Voges–Proskauer, and indole. Utilizes a range of amino acids, carbohydrates and organic acids as sole carbon and energy sources, and utilizes a small range of amino acids as sole carbon, nitrogen and energy sources.

Source: rotting wood on seashore.

DNA G + C content (mol%): 51.5 (T_m).

Type strain: Kamekura N23–2, ATCC 49085, DSM 4771, LMG 17942, KCTC 3566.

EMBL/GenBank accession number (16S rRNA gene): AB021188 (DSM 4771).

42. **Bacillus horikoshii** Nielsen, Fritze and Priest 1995b, 879^{VP} (Effective publication: Nielsen, Fritze and Priest 1995a, 1760.)

ho.ri.ko'shi.i. N.L. gen. n. *horikoshii* of Horikoshi; named after the Japanese microbiologist Koki Horikoshi.

Alkalitolerant organisms forming ellipsoidal spores which lie subterminally in sporangia which may be slightly swollen. Cells 0.6–0.7 by 2.0–4.0 µm. Colonies are small, circular, shiny and creamy-white with entire margins. Growth temperature range 10–40 °C. Optimal growth at pH 8.0; growth occurs at pH 7.0. 8–9% NaCl is tolerated. Nitrate is not reduced. Casein, gelatin, hippurate, pullulan, starch and Tween 80 are hydrolyzed. Tween 40 and 60 are hydrolyzed by most strains. Tween 20 is not hydrolyzed; phenylalanine is not deaminated. Glucose and a narrow range of other carbohydrates can be utilized as sole sources of carbon. Distinguished from *Bacillus halmopalus* by having a smaller cell size, higher salt tolerance, and by DNA relatedness.

Source: soil.

DNA G + C content (mol%): 41.1–42.0 (HPLC).

Type strain: Nielsen PN-121, ATCC 700161, DSM 8719, LMG 17946.

EMBL/GenBank accession number (16S rRNA gene): AB043865 (DSM 8719).

43. **Bacillus horti** Yumoto, Yamazaki, Sawabe, Nakano, Kawasaki, Ezura and Shinano 1998, 570^{VP}

hor'ti. L. masc. n. *hortus* garden; L. gen. n. *horti* from the garden.

Alkaliphilic, strictly aerobic, Gram-negative, motile rods, 0.6–0.8 by 1.5–6.0 µm, forming ellipsoidal, subterminal spores in swollen sporangia. Description is based upon two isolates. Colonies on complex medium at pH 10 are white. Grow occurs at pH 7, with optimum growth at pH 8–10. Grows in presence of 3–11% NaCl but not at 12% NaCl. Growth occurs between 15 °C and 40 °C; no growth at 10 and 45 °C. Catalase- and oxidase-positive. Nitrate is reduced to nitrite, *o*-nitrophenyl-β-D-galactopyranoside is hydrolyzed and H₂S is produced at pH 7. Acid is produced without gas from glucose and a narrow range of other carbohydrates. Casein, gelatin, starch and DNA are hydrolyzed; Tween 20, 40, 60 and 80 and urea are not. See Table 6.

Source: garden soil in Japan.

DNA G + C content (mol%): 40.9% for the type strain and 40.2 for another strain (HPLC).

Type strain: K13, ATCC 700778, DSM 12751, JCM 9943, LMG 18497.

EMBL/GenBank accession number (16S rRNA gene): D87035 (K13).

44. **Bacillus hwajinpoensis** Yoon, Kim, Kang, Oh and Park 2004b, 807^{VP}

hwa.jin.po.en'sis. N.L. adj. *hwajinpoensis* of Hwajinpo, a beach of the East Sea in Korea, where the type strain was isolated.

Aerobic, nonmotile rods, 1.0–1.3 µm in diameter and 2.5–4.0 µm long. Gram-positive, but Gram-variable in older cultures. Description is based on a single isolate. Ellipsoidal endospores are borne centrally or terminally in swollen sporangia. Colonies are smooth, circular to slightly irregular, slightly raised, light yellow in color and 2–4 mm in diameter after 3 d cultivation at 30 °C on marine agar. Optimum growth temperature is 30–35 °C. Growth occurs at 10 and 40 °C but not at 4 °C or above 41 °C. Optimum pH for growth is 6.0–7.0. Growth is observed at pH 5.0, but not at pH 4.5. NaCl is required for growth. Optimal growth occurs in the presence of 2–5% NaCl. Growth occurs in the presence of 19% NaCl but is inhibited by 20% NaCl. No anaerobic growth on marine agar. Esculin is hydrolyzed. Hypoxanthine, tyrosine, urea and xanthine are not hydrolyzed. Acid is produced from D-mannitol and stachyose. Cell-wall peptidoglycan contains *meso*-diaminopimelic acid. Predominant menaquinone is MK-7. Major fatty acid is C_{15:0 anteiso}.

Source: sea water of the East Sea in Korea.

DNA G + C content (mol%): 40.9 (HPLC).

Type strain: SW-72, KCCM 41641, JCM 11807.

EMBL/GenBank accession number (16S rRNA gene): AF541966 (SW-72).

45. **Bacillus indicus** Suresh, Prabakaran, Sengupta and Shivaji 2004, 1374^{VP}

in'di.cus. L. masc. adj. *indicus* pertaining to India, Indian.

Cells are aerobic, Gram-positive, nonmotile rods measuring approximately 0.9–1.2 µm wide and 3.3–5.3 µm long. Description is based upon a single isolate. Produces subterminal endospores in a slightly swollen sporangium. Colonies on nutrient agar are yellowish-orange pigmented, circular, raised, smooth, convex and 3.0–4.0 mm in diameter. The pigment in acetone exhibits three absorption maxima at 404, 428 and 451 nm, characteristic of carotenoids. Grows in the range of 15–37 °C (optimum 30 °C) but not at 40 °C. Grows between pH 6 and 7 and tolerates up to 2.0% (w/v) NaCl. Positive for catalase, gelatinase, amylase, arginine dihydrolase and esculin. Does not hydrolyze Tween 20 or urea. Does not reduce nitrate to nitrite and is negative for indole production, Voges–Proskauer test and citrate utilization. Utilizes D-cellobiose, *meso*-erythritol, inositol, lactose, D-melibiose, D-maltose, D-mannose, sucrose, L-rhamnose, D-ribose, raffinose, L-arginine, L-tryptophan and L-tyrosine as sole carbon sources. The major fatty acids are C_{14:0 iso} (10.9%), C_{15:0 iso} (33.5%), C_{15:0 anteiso} (19.3%), C_{16:0 iso} (11.0%), C_{16:0} (5.9%) and C_{17:0 iso} (10.8%). The main proportion of the polar lipids consists of phosphatidylglycerol, diphosphatidylglycerol and phosphatidylethanolamine. The major respiratory quinone is MK-7. The cell wall is an A4β-murein with ornithine as the diamino acid and aspartic acid as the interpeptide bridge.

Source: sand of an arsenic-contaminated aquifer in West Bengal, India.

DNA G + C content (mol%): 41.2 (*T_m*).

Type strain: Sd/3, MTCC 4374, DSM 15820.

GenBank/EMBL accession number (16S rRNA gene): AJ583158 (Sd/3).

46. **Bacillus infernus** Boone, Liu, Zhao, Balkwill, Drake, Stevens and Aldrich 1995, 447^{VP}

in.fer'nus. N.L. adj. *infernus* that which comes from below (the ground).

Strictly anaerobic, thermophilic, nonmotile rods 0.7–0.8 by 4–8 µm. Cell-wall morphology is Gram-positive but the Gram reaction is ambiguous. Endospores not observed, but their presence has been inferred from the survival of heat-treated cultures. Growth occurs at 45–60 °C but not at 40 or 65 °C; optimum temperature for growth is about 61 °C. Optimum pH for growth is about 7.3; grows well at pH 8.1 but does not grow at pH 9.2. The type strain is halotolerant; other strains have not been tested for this property. Grows fermentatively with glucose as substrate, but not with a range of other carbohydrates, alcohols and organic acids. Respiratory growth uses formate or lactate as electron donors and MnO₂, Fe³⁺, trimethylamine oxide, and nitrate as electron acceptors. Nitrate is reduced to nitrite but not to ammonia or dinitrogen. Sulfate and thiosulfate are not reduced. Casein, gelatin and starch are not hydrolyzed. See Table 8.

Source: a shale core taken from 2.7 km below the land surface in the Taylorsville Triassic Basin in Virginia, USA.

DNA G + C content (mol%): not reported.

Type strain: Boone TH-23, DSM 10277, SMCC/W 479.

EMBL/GenBank accession number (16S rRNA gene): U20385 (Boone TH-23).

47. **Bacillus insolitus** Larkin and Stokes 1967, 891^{AL}

in.so.li'tus. L. adj. *insolitus* unusual.

Strictly aerobic, Gram-positive, nonmotile cocci and motile rods and coccoid rods 1.0–1.5 by 1.6–2.7 µm on nutrient agar, and 0.7–0.9 by 2.4–5.3 µm on trypticase soy agar, occurring singly and in pairs. Description is based upon two isolates. Spores vary in shape from spherical to cylindrical, and from 0.7 to 1.4 µm in diameter, depending on the growth medium; terminal ellipsoidal and cylindrical spores are formed in rod-shaped cells. Sporangia are not appreciably swollen. Motile at 5 °C and 20 °C by one polar and one subpolar flagellum. Colonies on nutrient agar are small, soft, off-white and irregular. Optimum growth temperature about 20 °C, minimum below 0 °C, maximum 25 °C; sporulates and germinates at 0 °C. Tolerance of 2% NaCl varies; 4% NaCl is not tolerated. Catalase- and oxidase-positive. Gelatin and starch are not hydrolyzed; one of the two strains hydrolyzes urea (Logan and Berkeley, 1984). No growth on milk agar. Nitrate is not reduced to nitrite. Citrate not utilized as sole carbon source. No acid or gas produced from glucose or a range of other carbohydrates. See Table 9.

Source: normal and marshy soil.

DNA G + C content (mol%): 35.9 (T_m), 36.1 (Bd) for the type strain and 41.0 (T_m) for another strain.

Type strain: W 16B, ATCC 23299, DSM 5, LMG 17757, NCIMB 11433, KCTC 3737.

EMBL/GenBank accession number (16S rRNA gene): X60642 (DSM 5). This sequence displays 41 nucleotides as N-hits, indicating the weak quality of the sequence analysis. A further partial sequence of ATCC 23299 is available under accession number AF478084.

48. **Bacillus jeotgali** Yoon, Kang, Lee, Kho, Choi, Kang and Park 2001a, 1091^{VP}

je.ot.ga'li. N.L. gen. n. *jeotgali* of jeotgal, Korean traditional fermented seafood.

Facultatively anaerobic, Gram-variable, motile rods 0.8–1.1 by 4.0–6.0 µm, forming ellipsoidal spores in swollen sporangia. Description is based upon two isolates. Colonies are cream-yellow or light orange-yellow, smooth and flat with irregular margins. Growth occurs at 10 and 45 °C but not at 55 °C; optimum growth temperature 30–35 °C. Growth occurs at pH 7.0–8.0. Tolerates up to 13% NaCl. Growth poor on nutrient agar and trypticase soy agar without added salts. Catalase-positive, oxidase-negative. Esculin, gelatin, starch and urea are hydrolyzed; casein, hypoxanthine, tyrosine and xanthine are not hydrolyzed. Acid without gas is produced from glucose and a narrow range of other carbohydrates.

Source: jeotgal, a Korean traditional fermented seafood.

DNA G + C content (mol%): 41.0 (HPLC).

Type strain: YKJ-10, AF221061, JCM 10885, CIP 107104, KCCM 41040.

EMBL/GenBank accession number (16S rRNA gene): AF221061 (YKJ-10).

49. **Bacillus krulwichiae** Yumoto, Yamaga, Sogabe, Nodasaka, Matsuyama, Nakajima and Suemori 2003, 1534^{VP}

krul.wich.i'ae. N.L. fem. gen. n. *krulwichiae* of Krulwich; named after American microbiologist Terry A. Krulwich who made fundamental contributions to the study of alkaliphilic bacteria.

Alkaliphilic, facultatively anaerobic, Gram-positive, peritrichously flagellated straight rods, 0.5–0.7 by 1.5–2.6 µm. Ellipsoidal endospores are borne subterminally and do not cause swelling of sporangia. Description is based on two isolates. Colonies are circular and colorless. Catalase and oxidase reactions are positive. Negative for indole production, ONPG hydrolysis, and H₂S production. Growth occurs at pH 8–10, but no growth occurs at pH 7. Grows in presence of 14% NaCl, but not at higher concentrations. Nitrate is reduced to nitrite. Acid, but no gas, is produced from D-xylose, D-glucose, D-fructose, D-galactose, D-ribose, maltose, sucrose, trehalose, glycerol and mannitol when grown at pH 10. Positive for hydrolysis of starch, DNA, hippurate and Tween 20, 40, 60 and 80. Hydrolysis of casein and gelatin is variable among strains. Utilizes benzoate and m-hydroxybenzoate as sole carbon sources. The major isoprenoid quinones are menaquinone-5, -6 and -7. The main fatty acids produced during growth in an alkaline medium (pH 10) are C_{15:0 iso} (17.1–19.2%) and C_{15:0 anteiso} (45.6–49.0%). See Table 6.

Source: a soil sample obtained from Tsukuba, Ibaraki, Japan.

DNA G + C content (mol%): 40.6–41.5 (HPLC).

Type strain: AM31D, IAM 15000, NCIMB 13904, JCM 11691.

EMBL/GenBank accession number (16S rRNA gene): AB086897 (AM31D).

50. **Bacillus lentus** Gibson 1935, 364^{AL}

len'tus. L. adj. *lentus* slow.

As with *Bacillus firmus*, strains allocated to this species are genetically heterogeneous, and many strains have been incorrectly assigned to it. Strains received as *Bacillus lentus* show phenotypic profiles that appear to overlap with those of strains assigned to *Bacillus firmus*, so that Gordon et al. (1977) raised the question of whether *Bacillus firmus-Bacillus lentus* represented a single species or a series of strains.

The description which follows is based upon the type strain and a small number of other strains which have been shown by amplified rDNA restriction analysis, polyacrylamide gel electrophoresis of whole-cell proteins, and various phenotypic characters (Logan, De Vos and colleagues, unpublished data) to be closely related to the type strain. Phylogenetic studies indicate that *Bacillus circulans*, *Bacillus firmus* and *Bacillus lentus* are related.

Strictly aerobic, Gram-positive, straight or slightly curved, round-ended, motile rods 0.7–0.8 µm in diameter that occur singly, in pairs and occasionally in short chains. Endospores are ellipsoidal, lie subterminally or paracentrally, and may swell the sporangia slightly. After 2 d on TSA at 30 °C, colonies are 1–2 mm in diameter, whitish, opaque and flat, with glossy surfaces and entire margins. Optimum growth temperature is 30 °C, minimum temperature is 10 °C and maximum lies below 40 °C. The optimum pH is 8.0; the minimum pH lies between 5.0 and 6.0 and the maximum between 9.5 and 10. Catalase-positive. Grows in presence of 5% NaCl. Starch hydrolysis is positive but casein is not hydrolyzed. In the API 20E strip, *o*-nitrophenyl-β-D-

galactopyranoside hydrolysis, urease production and nitrate reduction are positive. Citrate utilization is variable. Arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, hydrogen sulfide production, tryptophan deaminase, indole production, gelatin hydrolysis, and Voges–Proskauer reaction are negative. Acid without gas is produced, often weakly, from D-glucose and from a wider range of other carbohydrates than is attacked by strains of *Bacillus firmus*. In the API 50CH gallery using the CHB suspension medium, hydrolysis of esculin is positive, and production of acid without gas is positive for lactose, N-acetylglucosamine, sucrose, and D-trehalose. Acid production is weak or positive for amygdalin, L-arabinose, arbutin, D-cellobiose, D-fructose, galactose, gentiobiose, D-glucose, maltose, mannitol, D-mannose, D-melezitose, D-melibiose, methyl-xyloside, D-raffinose, rhamnose, ribose, salicin, starch and D-xylose. In the API Biotype 100 kit, hydroxyquinoline- β -glucuronide is hydrolyzed and D-glucosamine, D-glucuronate and 2-keto-D-glucuronate are assimilated.

Source: soil.

DNA G + C content (mol%): 36.3 (T_m), 36.4 (Bd).

Type strain: ATCC 10840, AF478107, DSM 9, JCM 2511, LMG 16798, NCIMB 8773.

EMBL/GenBank accession number (16S rRNA gene): AB021189 (NCIMB 8773).

51. ***Bacillus licheniformis*** (Weigmann 1898) Chester 1901, 287^{AL} (*Clostridium licheniforme* Weigmann 1898, 822)

li.che.ni.for'mis. Gr. n. *lichen* lichen; L. adj. suff. *-formis* -like, in the shape of; N.L. adj. *licheniformis* lichen-shaped.

Facultatively anaerobic, Gram-positive, motile rods, forming ellipsoidal to cylindrical spores which lie centrally, paracentrally and subterminally in unswollen sporangia (Figure 10d). Cells grown on glucose agar stain evenly. Cells 0.6–0.8 by 1.5–3.0 μm , occurring singly and in pairs, and chains. Colonial morphology is variable, within and between strains, and, as with *Bacillus subtilis*, may give the appearance of a mixed culture. Colonies are round to irregular in shape and of moderate (2–4 mm) diameter, with margins varying from undulate to fimbriate; they become opaque, with surfaces that are dull and which may become wrinkled; color is whitish, and may become creamy or brown (perhaps red on carbohydrate media containing sufficient iron); textures range from moist and butyrous or mucoid, through membranous with an underlying mucoid matrix, with or without mucoid beading at the surface, to rough and crusty as they dry; these “licheniform” colonies tend to be quite adherent to the agar. Minimum growth temperature 15 °C, maximum 50–55 °C; an isolate from a geothermal environment with a maximum growth temperature of 68 °C has been reported (Llarch et al., 1997). Growth occurs at pH 5.7 and 6.8, but limits have not been reported. Grows in presence of up to 7% NaCl. Catalase-positive, oxidase variable. Casein, esculin, gelatin and starch are hydrolyzed; occasional strains will hydrolyze urea; phenylalanine is not deaminated. Usually arginine dihydrolase-positive. Pectin and polysaccharides of plant tissues are decomposed. Dextran and levan are formed extracellularly from sucrose. Citrate and propionate are utilized as sole carbon sources by most strains. Nitrate is reduced to nitrite.

Voges–Proskauer-positive. Acid without gas is produced from glucose and from a wide range of other carbohydrates.

Widely distributed in soil and many other environments, including milk and other foods, and clinical and veterinary specimens. Vegetative growth may occur readily in foods held at 30–50 °C. Occasionally reported as an opportunistic pathogen in man and other animals, and as a cause of food poisoning.

DNA G + C content (mol%): 42.9–49.9 (T_m) for 12 strains, 44.9–46.4 (Bd) for 19 strains, and 46.4 (T_m), 44.7 (Bd) for the type strain.

Type strain: ATCC 14580, CCM 2145, DSM 13, LMG 12363, IFO 12200, NCIMB 9375.

EMBL/GenBank accession number (16S rRNA gene): X68416 (DSM 13).

Additional remarks: Gibson (1944) considered *Bacillus globigii* to be a synonym of *Bacillus licheniformis*, but as Gordon et al. (1973) pointed out, strains of *Bacillus circulans*, *Bacillus pumilus* and *Bacillus subtilis* labeled *Bacillus globigii* have been widely circulated, so that the name is meaningless. Strains named *Bacillus globigii* were formerly popular for tracing studies, including those associated with the development of biological weapons.

52. ***Bacillus luciferensis*** Logan, Lebbe, Verhelst, Goris, Forsyth, Rodríguez-Díaz, Heyndrickx and De Vos 2002b, 1988^{VP}

lu.cif.er.en'sis. N.L. adj. *luciferensis* referring to Lucifer Hill, a volcano on Candlemas Island, South Sandwich Islands, the soil of which yielded the organism.

Motile rods (0.4–0.8 by 3–6 μm) occurring singly and in pairs and showing pleomorphism. Gram-positive, but becoming Gram-negative within 24 h of culture at 30 °C. Ellipsoidal endospores lie subterminally and occasionally terminally, and may swell the sporangia slightly. Colonies are 1–5 mm in diameter, creamy-gray, raised, translucent, glossy, moist and loosely butyrous, with irregular margins and surfaces. The growth temperature range lies between 15–20 °C and 35–45 °C, with an optimum of 30 °C. The pH range for growth is from 5.5–6.0 to 8.0–8.5, with an optimum of 7.0. Organisms are facultatively anaerobic and weakly catalase-positive. Esculin and gelatin are hydrolyzed, casein is weakly hydrolyzed. Nitrate is not reduced. Acid without gas is produced from glucose and a range of other carbohydrates. The major cellular fatty acids are C_{15:0}^{anteiso} and C_{15:0}^{iso} (representing about 25% and 50% of total fatty acid, respectively).

Source: geothermal soil taken from an active fumarole on Lucifer Hill, a volcano on Candlemas Island, South Sandwich archipelago.

DNA G + C content (mol%): 33.0 (T_m) for the type strain.

Type strain: Logan SSI061, LMG 18422, CIP 107105.

EMBL/GenBank accession number (16S rRNA gene): AJ419629 (LMG 18422).

53. ***Bacillus macyae*** Santini, Streimann and vanden Hoven 2004, 2244^{VP}

ma.cy'ae. N.L. fem. gen. n. *macyae* of Macy, named after the late Joan M. Macy, La Trobe University, Australia, in tribute to her research in the area of environmental microbiology.

Cells are Gram-positive, motile rods (2.5–3 µm long and 0.6 µm wide) and produce subterminally located ellipsoidal spores. Spores do not cause swelling of sporangia. Colonies are round and white. Catalase reaction is positive and oxidase is negative. Strict anaerobe that respire with arsenate and nitrate as terminal electron acceptors. Arsenate is reduced to arsenite and nitrate to nitrite. The electron donors used for anaerobic respiration are acetate, lactate, pyruvate, succinate, malate, glutamate and hydrogen (with acetate as carbon source). Growth occurs at 28–37 °C, pH 7–8.4 and 0.12–3% NaCl.

Source: arsenic-contaminated mud from a gold mine in Bendigo, Victoria, Australia.

DNA G + C content (mol%): 37 (HPLC).

Type strain: JMM-4, DSM 16346, JCM 12340.

GenBank/EMBL accession number (16S rRNA gene): AY032601 (JMM-4).

54. **Bacillus marisflavi** Yoon, Kim, Kang, Oh and Park 2003a, 1301^{VP}

ma.ris fla'vi. L. gen. neut. n. *maris* of the sea; L. masc. adj. *flavus* yellow; N.L. gen. masc. n. *marisflavi* of the Yellow Sea.

Aerobic rods, 0.6–0.8 µm by 1.5–3.5 µm, motile by means of a single polar flagellum. Gram-positive, but Gram-variable in older cultures. Description is based on a single isolate. Ellipsoidal endospores lie centrally or subterminally in swollen sporangia. Colonies are pale yellow, smooth, circular to slightly irregular, slightly raised, and 2–4 mm in diameter after 3 d at 30 °C on marine agar. Optimal growth temperature is 30–37 °C. Growth occurs at 10 and 47 °C, but not at 4 or above 48 °C. Optimal growth pH is 6.0–8.0. Growth is observed at pH 4.5, but not at pH 4.0. Growth occurs in the presence of 0–16% (w/v) NaCl, and optimal growth occurs at 2–5% (w/v) NaCl. Catalase-positive, oxidase- and urease-negative. Esculin and casein are hydrolyzed. Hypoxanthine, starch, Tween 80, tyrosine and xanthine are not hydrolyzed. Acid is produced from arbutin, D-cellobiose, D-fructose, gentiobiose, D-glucose, glycerol, maltose, D-mannitol, D-mannose, melibiose, methyl-D-mannoside, D-ribose, salicin, stachyose, sucrose, D-trehalose and D-xylose and produced weakly from D-galactose and D-raffinose. The cell-wall peptidoglycan contains *meso*-diaminopimelic acid. The predominant menaquinone is MK-7. The major fatty acids are C_{15:0 anteiso} and C_{15:0 iso}.

Source: sea water of a tidal flat of the Yellow Sea in Korea.

DNA G + C content (mol%): 49 (HPLC).

Type strain: TF-11, KCCM 41588, JCM 11544.

EMBL/GenBank accession number (16S rRNA gene): AF483624 (TF-11).

55. **Bacillus megaterium** de Bary 1884, 499^{AL}

me.ga.te'ri.um. Gr. adj. *mega* large; Gr. n. *teras, teratis* monster, beast; N.L. n. *megaterium* big beast.

Aerobic, Gram-positive, motile rods, large cells 1.2–1.5 by 2.0–5.0 µm, occurring singly and in pairs and chains, forming ellipsoidal and sometimes spherical spores which are located centrally, paracentrally or subterminally, and which do not swell the sporangia (Figure 10e). Cells grown on glucose agar produce large amounts of storage material, giving a vacuolate or foamy appearance. Colonies are glossy, round

to irregular, and have entire to undulate margins (Figure 9c). Minimum temperature for growth 3–15 °C, maximum 35–45 °C, with the optimum around 30 °C. The temperature range of a water isolate from an Antarctic geothermal island was 17–63 °C, with an optimum of 60 °C (Llarch et al., 1997). Catalase-positive. Casein, gelatin and starch are hydrolyzed. Phenylalanine is deaminated by most strains; tyrosine degradation is variable. Most strains grow in presence of 7% NaCl, but none grow at 10% NaCl. Citrate is utilized as sole carbon source. Most strains do not reduce nitrate. Acid without gas is produced from glucose and a wide range of other carbohydrates.

Source: soil, cow feces, foods and clinical specimens.

DNA G + C content (mol%): 37.0–38.1 (T_m) for 12 strains, and 37.2 (T_m) for the type strain.

Type strain: ATCC 14581, CCM 2007, DSM 32, NCIMB 9376, NCTC 10342, LMG 7127, IAM 13418.

EMBL/GenBank accession number (16S rRNA gene): D16273 (IAM 13418).

Additional remarks: Gordon et al. (1973) found that their 60 cultures of *Bacillus megaterium* formed two merging aggregates of strains, and Hunger and Claus (1981) recognized three DNA relatedness groups among 21 strains labeled as *Bacillus megaterium*, with the type strain lying within relatedness group A; Priest et al. (1988) revived the names *Bacillus simplex* for strains of DNA relatedness group B and *Bacillus flexus* for two strains which showed low homology with these two relatedness groups.

56. **Bacillus methanolicus** Arfman, Dijkhuizen, Kirchhof, Ludwig, Schleifer, Bulygina, Chumakov, Govorhukina, Trotsenko, White and Sharp 1992, 444^{VP}

me.tha'noli.cus. N.L. n. *methanol* methanol; L. masc. suff. *-icus* adjectival suffix used with the sense of belonging to; N.L. masc. adj. *methanolicus* relating to methanol.

Methylophilic, thermotolerant, strictly aerobic, non-motile, Gram-positive rods, usually occurring singly. Filamentous cells may be seen, especially in older cultures. Ellipsoidal endospores lie centrally to subterminally and swell the sporangia. Grows on methanol, some strains also grow on ethanol. Colonies on tryptone soya agar are circular, and usually have rough surfaces and crenated, undulating margins. The growth temperature range lies between 35 °C and 60 °C, with an optimum of 55 °C. Catalase- and oxidase-positive. Casein and hippurate are not hydrolyzed; starch hydrolysis varies between strains. Nitrate is not reduced. Acid without gas is produced from glucose and a narrow range of other carbohydrates. See Table 8.

Source: soil, aerobic (and thermophilic) wastewater treatment systems and volcanic hot springs.

DNA G + C content (mol%): 48–50 (T_m).

Type strain: Dijkhuizen PB1, NCIMB 13113, LMG 16799, KCTC 3735.

EMBL/GenBank accession number (16S rRNA gene): X64465; this is for strain C1 (=NCIMB 13114) which is not the type strain.

57. **Bacillus mojaviensis** Roberts, Nakamura and Cohan 1994, 263^{VP}

mo.ha'ven'sis. N.L. masc. adj. *mojavensis* from the Mojave Desert.

Aerobic, Gram-positive, motile rods, forming ellipsoidal spores which lie centrally or paracentrally in unswollen sporangia. Cells 0.5–1.0 by 2.0–4.0 µm, occurring singly and in short chains. Colonies are opaque, smooth, circular and entire and 1.0–2.0 mm in diameter after 2 d at 28 °C. Optimum growth temperature 28–30 °C, with minimum of 5–10 °C and maximum of 50–55 °C. Catalase-positive, oxidase-positive. Casein, gelatin and starch are hydrolyzed; Tween 80, tyrosine and urea are not. Nitrate is reduced to nitrite. Acid without gas is produced from glucose and a range of other carbohydrates.

Phenotypically indistinguishable from *Bacillus subtilis* subsp. *subtilis* and *Bacillus subtilis* subsp. *spizizenii* and distinguished from those organisms principally by DNA relatedness and resistance to transformation. Phenotypically indistinguishable from *Bacillus vallismortis*, and distinguished from that organism by DNA relatedness, restriction digestion analysis, and fatty acid analysis.

Phenotypically distinguishable from *Bacillus atrophaeus* only by failure to produce dark brown pigmented colonies on media containing tyrosine or other organic nitrogen source.

Source: desert soils.

DNA G + C content (mol%): 43.0 (T_m).

Type strain: Cohan RO-H-1, ATCC 51516, NRRLB-14698, DSM 9205, LMG 17797, NCIMB 13391, IFO 15718.

EMBL/GenBank accession number (16S rRNA gene): AB021191 (IFO 15718).

58. ***Bacillus mycoides*** Flügge 1886, 324^{AL}

my.co.i'des. Gr. n. *myces* fungus; Gr. *eidus* form, form, shape; N.L. adj. *mycoides* fungus-like.

Facultatively anaerobic, Gram-positive, nonmotile organisms forming ellipsoidal spores which lie paracentrally to subterminally in unswollen sporangia. Cells 1.0–1.2 by 3.0–5.0 µm, occurring singly and in chains. Cells grown on glucose agar produce large amounts of storage material, giving a vacuolate or foamy appearance. Colonies are white to cream, opaque, and characteristically rhizoid; this ability to form rhizoid colonies may be lost. Minimum growth temperature 10–15 °C, maximum 35–40 °C. Grows at pH 5.7, and in 0.001% lysozyme. Ability to grow in presence of 7% NaCl varies between strains. Catalase-positive, oxidase-negative. Lecithinase and Voges–Proskauer reactions are positive. Citrate utilization variable; propionate not utilized. Nitrate reduction is variable. Casein and starch are hydrolyzed; decomposition of tyrosine variable. Acid without gas is produced from glucose and a limited range of other carbohydrates.

Phenotypically similar to other members of the *Bacillus cereus* group: *Bacillus anthracis*, *Bacillus cereus*, *Bacillus thuringiensis* and *Bacillus weihenstephanensis*. *Bacillus mycoides* is distinguished by its characteristic rhizoid colonies (Figure 9d) and absence of motility. Smith et al. (1952) and Gordon et al. (1973) considered *Bacillus mycoides* to be a variety of *Bacillus cereus*. For distinguishing characters within the *Bacillus cereus* group, see the individual species descriptions and Table 7. Those strains which have been proposed as *Bacillus pseudomycoides* can only be separated from *Bacillus mycoides* by DNA relatedness and some differences in fatty acid composition.

Source: mainly from soil.

DNA G + C content (mol%): 32.5–38.4 (T_m) for nine strains, 35.2–39.0 (Bd) for four strains, and 34.2 (T_m), 34.1 (Bd) for the type strain.

Type strain: ATCC 6942, DSM 2048, LMG 7128, NRRLB-14811, NRS 273, NCIMB 13305, KCTC 3453.

EMBL/GenBank accession number (16S rRNA gene): AB021192 (ATCC 6462).

59. ***Bacillus naganoensis*** Tomimura, Zeman, Frankiewicz and Teague 1990, 124^{VP}

na.ga.no.en'sis. N.L. masc. adj. *naganoensis* of the Japanese Prefecture Nagano.

Aerobic, moderately acidophilic, Gram-positive, nonmotile rods, forming ellipsoidal spores which lie subterminally in swollen sporangia. Description is based upon a single isolate. Cells are 0.5–1.0 by 2.1–10.0 µm, have rounded or square ends, and occur singly or in chains. Colonies are opaque, smooth, glistening, circular and entire, and reach 2.0–3.0 mm in diameter. Optimum growth temperature 28–33 °C, with minimum above 20 °C and maximum below 45 °C. The pH range for growth is about 4.0–6.0. Catalase-positive. A thermostable pullulanase is produced. Casein, gelatin and starch are hydrolyzed. Hippurate and tyrosine are not decomposed. Citrate and propionate are not utilized as sole sources of carbon. Nitrate is not reduced. Acid without gas is produced from glucose and a small range of other carbohydrates after extended (>14 d) incubation. Not pathogenic to mice.

Source: soil by selection using a pullulan-containing medium.

DNA G + C content (mol%): 45 ± 2 (T_m).

Type strain: ATCC 53909, DSM 10191, LMG 12887, KCTC 3742.

EMBL/GenBank accession number (16S rRNA gene): AB021193 (ATCC 53909).

Additional remark: this species has recently (Hatayama et al., 2006) been classified as *Pullulanibacillus naganoensis*.

60. ***Bacillus nealsonii*** Venkateswaran, Kempf, Chen, Satomi, Nicholson and Kern 2003, 171^{VP}

neal'son.i.i. N.L. gen. n. *nealsonii* referring to Kenneth H. Nealson, an American microbiologist.

Facultatively anaerobic, Gram-positive, motile rods 1.0 by 4.0–5.0 µm. The ellipsoidal spores are 0.5 by 1.0 µm, and bear an additional extraneous layer similar to an exosporium. Description is based upon a single isolate. Young colonies on TSA are 3–4 mm in diameter, irregular, rough and umbonate with undulate or lobate edges and are of a beige color. Sodium ions are not essential for growth; up to 8% NaCl is tolerated. Growth occurs at pH 6–10, with an optimum of pH 7. Optimum growth temperature is 30–35 °C, with minimum of 25 °C and maximum of 60 °C. Catalase and β-galactosidase are produced, but gelatinase, arginine dihydrolase, lysine and ornithine decarboxylases, lipase, amylase and alginate are not. H₂S is not produced from thiosulfite. Denitrification does not occur. Acid is produced from glucose and a wide range of other carbohydrates.

Source: dust particles collected at a spacecraft-assembly facility.

DNA G + C content (mol%): not reported.

Type strain: FO-92, ATCC BAA-519, DSM 15077.

EMBL/GenBank accession number (16S rRNA gene): AF234863 (FO-92).

61. **Bacillus neidei** Nakamura, Shida, Takagi and Komagata 2002, 504^{VP}

nei'de.i. N.L. gen. n. *neidei* of the early microbiologist Neide.

Aerobic, Gram-positive, motile rods, forming spherical spores which lie terminally in swollen sporangia. Cells are about 1.0 by 3.0–5.0 µm. Colonies are translucent, thin, smooth, circular and entire, and reach 1 mm in diameter after 24 h of incubation at 28 °C. Optimum growth temperature 28–33 °C, with minimum 5–10 °C and maximum 40–45 °C. Catalase-positive. Biotin, thiamin and cystine are required for growth. Casein, starch, Tween 40 and 80, tyrosine and urea are not hydrolyzed. L-alanine, citrate β-hydroxybutyrate, propionate and pyruvate are not oxidized. Grows in presence of 5% NaCl, but sensitive to 0.001% lysozyme. Nitrate is not reduced to nitrite. No acid or gas produced from glucose and other common carbohydrates. Cell-wall peptidoglycan type is L-Lys-D-Glu. Phenotypically similar to *Bacillus fusiformis*, *Bacillus pycnus* and *Bacillus sphaericus*, and separable from these species by growth factor requirements, several substrate oxidation and decomposition tests, and differences in fatty acid compositions. See Table 9.

Source: soil.

DNA G + C content (mol%): 35 (T_m).

Type strain: NRRL Bd-87, JCM 11077, LMG 21635.

EMBL/GenBank accession number (16S rRNA gene): AF169520 (NRRL Bd-87).

Additional remark: this species has recently been classified as *Viridibacillus neidei* by Albert et al. (2007).

62. **Bacillus niacini** Nagel and Andreesen 1991, 137^{VP}

ni.a.ci'ni. N.L. n. *niacinum* niacin or nicotinic acid; N.L. gen. n. *niacini* of nicotinic acid.

Aerobic rods 0.9–1.4 by 3–5.6 µm, forming central, and sometimes subterminal, ellipsoidal spores which may swell the sporangia slightly. Cells may be pleomorphic and increase in width. Long chains may be formed when grown on complex media. Gram-variable when grown in nutrient broth, and Gram-positive when grown on nicotinate agar. Some strains motile. Colonies are smooth and have light beige centers surrounded by translucent areas of variable extension, and are about 3–5 mm in diameter. In the presence of molybdate, nicotinate can be used as sole source of carbon, nitrogen and energy. Grows at 10–40 °C. Catalase-positive or weakly positive; oxidase usually positive. Some strains are indole-positive. Gelatin is hydrolyzed, sometimes weakly; starch is hydrolyzed by some strains, urease is usually negative; casein, phenylalanine and tyrosine are not decomposed. Utilization of aspartate, citrate, formate and lactate as sole carbon sources varies between strains. Optimum pH for growth between 7 and 8. Nitrate is usually reduced to nitrite. Acid without gas is

produced from glucose and from a number of other carbohydrates, depending upon the strain.

Source: soil.

DNA G + C content (mol%): 37–39 (T_m).

Type strain: IFO 15566, DSM 2923, LMG 16677.

EMBL/GenBank accession number (16S rRNA gene): AB021194 (IFO 15566).

63. **Bacillus novalis** Heyrman, Vanparys, Logan, Balcaen, Rodríguez-Díaz, Felske and De Vos 2004, 52^{VP}

no.va'lis. L. gen. n. *novalis* of fallow land.

Facultatively anaerobic, Gram-positive, motile, slightly curved, round-ended rods, 0.6–1.2 µm in diameter, occurring singly and in pairs, and occasionally in short chains or filaments. Endospores are mainly ellipsoidal, and lie in subterminal and occasionally paracentral positions in slightly swollen sporangia. When grown on TSA, colonies are raised, butyrous, cream-colored, produce a soft brown pigment that diffuses in the agar, and have slightly irregular margins and smooth or eggshell-textured surfaces; they sometimes have iridescent centers when viewed by low-power microscopy. Optimal growth occurs at 30–40 °C, and the maximum growth temperature lies between 50 °C and 55 °C. Growth occurs from pH 4.0–5.0–9.5–10.0, and the optimum pH for growth is 7.0–9.0. Casein is hydrolyzed. In the API 20E strip, Voges–Proskauer reaction is negative, gelatin is hydrolyzed by most strains, and nitrate reduction is positive (sometimes weakly); reactions for o-nitrophenyl-β-D-galactopyranoside hydrolysis, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, citrate utilization, hydrogen sulfide production, urease, tryptophan deaminase, indole production, are negative. Hydrolysis of esculin positive. Acid without gas is produced (weakly by some strains) from the following carbohydrates in the API 50 CH gallery using the CHB suspension medium: N-acetyl-D-glucosamine, D-fructose, galactose (always weak), D-glucose, maltose, D-mannose, D-trehalose. The following reactions are variable between strains and, when positive, are usually weak: amygdalin, arbutin, D-cellobiose, β-gentiobiose, gluconate, glycerol, 5-keto-D-gluconate, D-lyxose, D-mannitol, ribose, sorbitol, D-xylose; the type strain is positive for sorbitol and D-xylose and weakly positive for: amygdalin, D-cellobiose, β-gentiobiose, D-mannitol. The major cellular fatty acids are C_{15:0 iso} and C_{15:0 anteiso}, present at a level of about 44 and 31% of the total fatty acid content, respectively.

Source: soil in the Drentse A agricultural research area, The Netherlands.

DNA G + C content (mol%): 40.0–40.5 (HPLC) and 40.5 for the type strain.

Type strain: LMG 21837, DSM 15603.

EMBL/GenBank accession number (16S rRNA gene): AJ542512 (LMG 21837).

64. **Bacillus odysseyi** La Duc, Satomi and Venkateswaran 2004, 200^{VP}

o.dys.se'yi. L. n. *Odyssea* the Odyssey; N.L. gen. n. *odysseyi* pertaining to the Mars Odyssey spacecraft, from which the organism was isolated.

Strictly aerobic, Gram-positive motile rods, 4–5 µm in length and 1 µm in diameter. Forms spherical endospores which are borne terminally and swell the sporangia. Spores show an additional exosporium layer. Description is based upon a single isolate. Colonies on TSA are round, smooth, flat with entire edges and beige in color. Sodium ions are not essential for growth; growth occurs in 0–5% NaCl. Grows at pH 6–10 (optimum at pH 7) and 25–42 °C (optimum 30–35 °C). With the exception of arabinose, breakdown of sugars to acids does not occur following prolonged incubation. Glucose is not utilized as sole carbon source. Pyruvate, amino acids, purine or pyrimidine bases and related compounds are preferred as carbon and energy sources. Catalase-positive, but does not produce gelatinase, arginine dihydrolase, lysine or ornithine decarboxylase, lipase, amylase or alginase. Does not produce H₂S from thiosulfite and is not involved in denitrification. Closely related to species that have been transferred to the novel genus *Lysinibacillus* (Ahmed et al., 2007c), but data on peptidoglycan composition and polar lipids are not available for *Bacillus odysseyi*, and so it has not been transferred to the new genus. See Table 9.

Source: the surface of the Mars Odyssey spacecraft.

DNA G + C content (mol%): not reported.

Type strain: 34hs-1, ATCC PTA-4993, NRRL B-30641, NBRC 100172.

EMBL/GenBank accession number (16S rRNA gene): AF526913 (34hs-1).

65. ***Bacillus okuhidensis*** Li, Kawamura, Shida, Yamagata, Deguchi and Ezaki 2002, 1208^{VP}

o.ku.hid.en'sis. N.L. masc. adj. *okuhidensis* referring to Okuhida in Gifu, Japan, where the strains were originally isolated.

Alkaliphilic, weakly Gram-positive rods, 0.5–1.0 by 5–7 µm, forming ellipsoidal, subterminal spores that may swell the sporangia slightly. Description is based upon two isolates. Motile by means of peritrichous flagella. Cells stain slightly Gram-positive in the exponential growth phase and Gram-negative in the stationary phase. Colonies are circular, convex, smooth, and yellowish. Growth temperature range 30–60 °C; optimum 45–50 °C. Optimal growth at pH 10.5; pH range 6.0–11.0. Grows in presence of 10% NaCl. Catalase- and oxidase-positive. Casein, starch and gelatin are hydrolyzed; hippurate, and Tween 20, 40 and 60 are not. Phenylalanine is not deaminated. Nitrate is reduced to nitrite. A range of carbohydrates can be utilized as sole sources of carbon. The major cellular fatty acids are C_{15:0 iso} (43.75% ± 0.7%) and C_{15:0 anteiso} (25.8% ± 0.6%). See Table 6.

Source: hot spa water.

DNA G + C content (mol%): 40.0–41.1 (HPLC).

Type strain: GTC 854, JCM 10945, DSM 13666.

EMBL/GenBank accession number (16S rRNA gene): AB047684 (GTC 854).

66. ***Bacillus oleronius*** Kuhnigk et al. 1996, 625^{VP} (Effective publication: Kuhnigk et al. 1995, 704.)

o.le.ro'ni.us. N.L. adj. *oleronius* of Île de Oléron, France, where the termite host thrives.

Cells are nonmotile, Gram-negative, medium-sized rods, that occur singly and in pairs, and sometimes form short

chains of 3–4 cells. They bear ellipsoidal endospores that lie in subterminal and paracentral positions within swollen sporangia. After 2 d on TSA colonies are approximately 1–2 mm diameter, circular, entire, shiny, beige or cream and butyrous with slightly translucent edges. Organisms are strictly aerobic and catalase-positive. Growth may occur between 30 °C and 50 °C, with an optimum of 37 °C. Casein is not hydrolyzed and starch is sometimes hydrolyzed weakly. Nitrate is reduced to nitrite, the Voges–Proskauer reaction is variable (type strain positive), citrate is not utilized, hydrogen sulfide and indole are not produced, and the ONPG reaction is negative. Esculin is hydrolyzed, gelatin is weakly hydrolyzed and urea is not hydrolyzed. Acid without gas is produced from *N*-acetylglucosamine, *D*-cellobiose, *D*-fructose, *D*-glucose, mannitol and *D*-tagatose. Acid production from the following carbohydrates is variable, and when positive it is weak: galactose, glycerol, maltose, *D*-mannose, ribose salicin, starch and *D*-trehalose; the type strain produces acid from: glycerol, maltose, ribose, starch and *D*-trehalose. The major cellular fatty acids (mean percentage + standard deviation of total fatty acids) after 24 h growth on brain heart infusion supplemented with vitamin B₁₂ at 37 °C are: C_{15:0 iso} (39.24 ± 1.38), C_{15:0 anteiso} (22.89 ± 2.22) and C_{17:0 anteiso} (20.78 ± 0.85).

Source: the hindgut of termite *Reticulitermes santonensis* (Feytaud), and from raw milk and cattle feed concentrate.

DNA G + C content (mol%): 35.2–34.7 (HPLC) and 35.2 for the type strain.

Type strain: Kuhnigk RT 10, DSM 9356, ATCC 700005, LMG 17952, CIP 104972.

EMBL/GenBank accession number (16S rRNA gene): X782492 (DSM 9356).

67. ***Bacillus pseudalcaliphilus*** Nielsen, Fritze and Priest 1995b, 879 (Effective publication: Nielsen, Fritze and Priest 1995a, 1760.)

pseu.dal.ca.li'phi.lus. Gr. adj. *pseudēs* false; N.L. adj. *alcalophilus* a specific epithet; N.L. adj. *pseudalcaliphilus* false *alcalophilus* because it is phenotypically closely related to *Bacillus alcalophilus* but phylogenetically distinct.

Alkaliphilic organisms forming ellipsoidal spores which lie paracentrally to subterminally in swollen sporangia. Cells 0.5–0.6 by 2.0–4.0 µm. Colonies are white and circular with undulate margins. Growth temperature range 10–40 °C. Optimal growth at about pH 10.0; no growth at pH 7.0. Maximum NaCl concentration tolerated is 10%. Nitrate is not reduced. Casein, gelatin, pullulan and starch are hydrolyzed. Hippurate and Tween 20 are not hydrolyzed; phenylalanine is not deaminated. Glucose and a range of other carbohydrates can be utilized as sole sources of carbon.

Phenotypically similar to *Bacillus alcalophilus*, but phylogenetically distinct. See Table 6.

Source: soil.

DNA G + C content (mol%): 38.2–39.0 (HPLC).

Type strain: Nielsen PN-137, DSM 8725, ATCC 700166, LMG 17951, CIP 105304.

EMBL/GenBank accession number (16S rRNA gene): X76449 (DSM 8725).

68. **Bacillus pseudofirmus** Nielsen, Fritze and Priest 1995b, 879^{VP} (Effective publication: Nielsen, Fritze and Priest 1995a, 1760.)
pseu.do.fir'mus. Gr. adj. *pseudēs* false; L. adj. *firmus* a specific epithet; N.L. adj. *pseudofirmus* false *firmus* referring to physiological similarities to *Bacillus firmus*.

Alkaliphilic and halotolerant organisms forming ellipsoidal spores which lie paracentrally to subterminally in unswollen sporangia. Cells 0.6–0.8 by 3.0–6.0 μm. Colonies are yellow and circular with irregular margins. Growth temperature range 10–45 °C. Optimal growth at about pH 9.0; no growth at pH 7.0 for most strains. Maximum NaCl concentration tolerated is 16–17%. Nitrate is not reduced. Casein, gelatin, starch and Tween 40 and 60 are hydrolyzed; some strains can hydrolyze pullulan. Hippurate and Tween 20 are not hydrolyzed. Phenylalanine is deaminated. Glucose and a range of other carbohydrates can be utilized as sole sources of carbon.

Phenotypically similar to *Bacillus firmus*, but alkalophilic and phylogenetically distinct. See Table 6.

Source: soil and animal manure.

DNA G + C content (mol%): 39.0–40.8 (HPLC).

Type strain: PN-3, DSM 8715, NCIMB 10283, LMG 17944, ATCC 700159.

EMBL/GenBank accession number (16S rRNA gene): X76439 (DSM 8715).

69. **Bacillus pseudomycooides** Nakamura 1998, 1035^{VP}
pseu.do.my.co.i'des. Gr. adj. *pseudēs* false; N.L. adj. *mycooides* fungus-like; N.L. adj. *pseudomycooides* false fungus-like.

Facultatively anaerobic, Gram-positive, nonmotile organisms forming ellipsoidal spores which lie paracentrally to subterminally in unswollen sporangia. Cells 1.0 by 3.0–5.0 μm, occurring singly and in short chains. Cells grown on glucose agar produce large amounts of storage material, giving a vacuolate or foamy appearance. Colonies are white to cream, opaque, and usually rhizoid. Growth temperature range 15–40 °C, optimum 28 °C. Grows at pH 5.7, in 7% NaCl, and in 0.001% lysozyme. Catalase-positive, oxidase-negative. Lecithinase and Voges–Proskauer reactions are positive. Citrate utilization variable; propionate not utilized. Nitrate is reduced to nitrite. Casein, starch and tyrosine are hydrolyzed. Acid without gas is produced from glucose and a limited range of other carbohydrates.

Phenotypically similar to *Bacillus cereus* and indistinguishable from *Bacillus mycooides* by conventional characters; distinguished from them by DNA relatedness and some differences in fatty acid composition. For distinguishing characters within the *Bacillus cereus* group, see the individual species descriptions and Table 7.

Source: mainly from soil.

DNA G + C content (mol%): 34.0–36.0 (T_m).

Type strain: NRRL B-617, DSM 12442, LMG 18993.

EMBL/GenBank accession number (16S rRNA gene): AF013121 (NRRL B-617).

70. **Bacillus psychrodurans** Abd El-Rahman, Fritze, Spröer and Claus 2002, 2132^{VP}

psy.chro.dur'ans. Gr. adj. *psychros* cold; L. pres. part. *durans* enduring; N.L. part. adj. *psychrodurans* cold-enduring.

Aerobic, Gram-positive, psychrotolerant rods 0.5–0.6 by 2.0–5.0 μm. Sporulation infrequently observed; spores

lie terminally in swollen sporangia and are predominantly spherical in casein-peptone soymeal-peptone agar cultures and predominantly ellipsoidal in marine agar cultures. No growth or very poor growth in/on nutrient agar/broth. Minimum growth temperature –2–0 °C and maximum 30–35 °C. Catalase-positive. Starch, Tween 20, 40, 60 and 80 (type strain negative for Tween 80) are hydrolyzed. Gelatin usually hydrolyzed. Esculin, casein and urea not hydrolyzed. Grows in presence of 3 and usually 5%, but not 7% NaCl. Sensitive to 0.001% lysozyme. Will grow anaerobically with KNO₃. Nitrate is reduced to nitrite. No acid or very weak acid production from glucose and other common carbohydrates; no gas produced. Cell-wall peptidoglycan type is L-Orn-D-Glu. Phenotypically similar to *Bacillus insolitus* and *Bacillus psychrotolerans*, and separable from these species by anaerobic growth with KNO₃, nitrate reduction, and NaCl tolerance. See Table 9.

Source: garden soil in Egypt.

DNA G + C content (mol%): 36–37 (Bd) and 36.3 for the type strain.

Type strain: 68E3, DSM 11713, NCIMB 13837, KCTC 3793.

EMBL/GenBank accession number (16S rRNA gene): AJ277984 (DSM 11713).

71. **Bacillus psychrosaccharolyticus** (ex Larkin and Stokes 1967) Priest, Goodfellow and Todd 1989, 93^{VP} (Effective publication: Priest, Goodfellow and Todd 1988, 1879.)

psy.chro.sacch'ar.o.lyt.ic.us. Gr. adj. *psychros* cold; Gr. n. *sakchâron* sugar; Gr. adj. *lutikos* able to dissolve; N.L. adj. *psychrosaccharolyticus* cold (adapted), sugar-fermenting.

Facultatively anaerobic, Gram-positive or variable, peritrichously motile, pleomorphic rods, which vary from coccoid to elongate, forming ellipsoidal spores which lie centrally or paracentrally in swollen sporangia; the spore may fill most of the sporangium and may lie laterally. Description is based on three strains. Cells range from 0.6–1.5 μm by 1.5–3.5 μm; normal size for cells grown on nutrient agar is 0.9–1.0 μm by 2.5–3.0 μm. Colonies are opaque and smooth. Growth occurs at 0–30 °C; sporulates and germinates at 0 °C. Grows between pH 6.0–7.2 and 9.5. Growth in presence of 2–5% NaCl varies. Nitrate is reduced. Casein, esculin, gelatin, pullulan, starch and urea are hydrolyzed. Acid without gas is produced from D-glucose and some other carbohydrates. Acetate, citrate, gluconate, malonate and succinate are not utilized.

Source: soil and lowland marshes.

DNA G + C content (mol%): 43–44 (T_m).

Type strain: NRRL-B3394, DSM 13778, LMG 9580, NCIMB 11729, ATCC 23296, KCTC 3399.

EMBL/GenBank accession number (16S rRNA gene): AB021195 (ATCC 23296).

72. **Bacillus psychrotolerans** Abd El-Rahman, Fritze, Spröer and Claus 2002, 2131^{VP}

psy.chro.tol'er.ans. Gr. adj. *psychros* cold; L. pres. part. *tolerans* tolerating; N.L. part. adj. *psychrotolerans* cold-tolerating.

Strictly aerobic, Gram-positive, psychrotolerant rods 0.4–1.0 by 2.0–7.0 μm. Sporulation infrequently observed; spores lie terminally in swollen sporangia and are predominantly spherical in cultures on casein-peptone soymeal-peptone agar

containing Mn⁺ and predominantly ellipsoidal in marine agar cultures. No growth or very poor growth in/on nutrient agar/broth. Minimum growth temperature -2–0°C and maximum 30–40°C. Catalase-positive. Starch, and Tween 20, 40 and 60 are hydrolyzed. Tween 80 usually hydrolyzed. Gelatin usually not hydrolyzed. Esculin, casein and urea not hydrolyzed. Grows in presence of 3, usually not at 5%, and not 7% NaCl. Sensitive to 0.001% lysozyme. Will not grow anaerobically with KNO₃. Nitrate is not reduced to nitrite. No acid or very weak acid production from glucose and other common carbohydrates; no gas produced. Cell-wall peptidoglycan type is L-Orn-D-Glu. Phenotypically similar to *Bacillus insolitus* and *Bacillus psychrotolerans*, and separable from these species by strict aerobic growth, inability to reduce nitrate, and NaCl tolerance. See Table 9.

Source: field soil in Germany.

DNA G + C content (mol%): 36–38 (Bd) and 36.5 for the type strain.

Type strain: 3H1, DSM 11706, NCIMB 13838, KCTC 3794.

EMBL/GenBank accession number (16S rRNA gene): AJ277983 (DSM 11706).

73. ***Bacillus pumilus*** Meyer and Gottheil in Gottheil 1901, 680^{AL}

pu'mi.lus. L. adj. *pumilus* little.

Aerobic, Gram-positive or Gram-variable, motile, small rods 0.6–0.7 by 2.0–3.0 µm, occurring singly and in pairs, and forming cylindrical to ellipsoidal spores which lie centrally, paracentrally and subterminally in unswollen sporangia (Figure 10a). Cells grown on glucose agar stain evenly. Colonial morphology is variable; colonies may be wrinkled and irregular (Figure 9e), and they are unpigmented and most are smooth and opaque. Minimum growth temperature >5–15°C, maximum 40–50°C. Growth occurs at pH 6.0 and 9.5; some strains will grow at pH 4.5. Grows in presence of 10% NaCl. Catalase-positive. Casein, esculin and gelatin are hydrolyzed; starch is not hydrolyzed. Phenylalanine is not deaminated. Citrate is utilized as sole carbon source; propionate is not. Nitrate is not reduced. Voges–Proskauer-positive. Acid without gas is produced from glucose and from a wide range of other carbohydrates.

Source: soil and many other environments, including foods, and clinical and veterinary specimens.

DNA G + C content (mol%): 39.0–45.1 (*T_m*) for 12 strains, 40.0–46.9 (Bd) for 25 strains, and to be 41.9 (*T_m*), 40.7 (Bd) for the type strain.

Type strain: NCDO 1766, ATCC 7061, DSM 27, JCM 2508, NCIMB 9369.

EMBL/GenBank accession number (16S rRNA gene): X60637 (NCDO 1766).

Isolates of *Bacillus pumilus* from Antarctic soils and penguin rookeries show some phenotypic distinction from other strains of the species, including the production of a diffusible yellow pigment by some strains on initial culture (Logan and Forsyth, unpublished observations).

74. ***Bacillus pycnus*** Nakamura, Shida, Takagi and Komagata 2002, 504^{VP}

pyc'nus. Gr adj. *pyknos* thick; N.L. adj. *pycnus* thick, referring to thick cells.

Aerobic, Gram-positive, motile rods, forming spherical spores which lie terminally in swollen sporangia. Cells are about 1.0–1.5 by 3.0–5.0 µm. Colonies are translucent, thin, smooth, circular and entire, and reach 1 mm in diameter after 24 h of incubation at 28°C. Optimum growth temperature 28–33°C, with minimum 5–10°C and maximum 40–45°C. Catalase-positive. Biotin, thiamin and cystine are not required for growth. Casein, starch, Tween 40 and 80, tyrosine and urea are not hydrolyzed. β-Hydroxybutyrate and pyruvate are oxidized; L-alanine, citrate and propionate are not oxidized. Does not grow in the presence of 5% NaCl or 0.001% lysozyme. Nitrate is not reduced to nitrite. No acid or gas produced from glucose and other common carbohydrates. Cell-wall peptidoglycan type is L-Lys-D-Glu. Phenotypically similar to *Bacillus fusiformis*, *Bacillus neidei* and *Bacillus sphaericus*, and separable from these species by growth factor requirements, several substrate oxidation and decomposition tests, and differences in fatty acid compositions. See Table 9.

Source: soil.

DNA G + C content (mol%): 35 (*T_m*).

Type strain: NRRL NRS-1691, JCM 11075, DSM 15030, LMG 21634.

EMBL/GenBank accession number (16S rRNA gene): AF169531 (NRS-1691).

75. ***Bacillus schlegelii*** Schenk and Aragno 1981, 215^{VP} (Effective publication: Schenk and Aragno 1979, 338.)

schle.gel'i.i. N.L. gen. n. *schlegelii* of Schlegel, named after H. G. Schlegel, a German bacteriologist.

Facultatively chemolithoautotrophic, thermophilic, strictly aerobic, motile, Gram-variable rods 0.6 by 2.5–5 µm, forming terminally located, spherical spores which swell the sporangia. Colonies are cream-colored, circular or spreading. No growth factors are required. Optimum growth temperature about 70°C; no growth at 37 or 80°C. Optimum pH for growth 6–7. Grows in presence of 3% but not 5% NaCl. Strictly respiratory, with oxygen as terminal electron acceptor. Nitrate is reduced to nitrite, but nitrate respiration does not occur. Catalase-positive and oxidase weakly positive. Grows chemolithoautotrophically, using H₂ as electron donor and CO₂ as carbon source, or CO which satisfies both requirements, or chemoorganoheterotrophically. Can also grow autotrophically on thiosulfate (Hudson et al., 1988). Hydrogenase is constitutive and has a temperature optimum between 70°C and 75°C. Carbohydrates are not metabolized. Utilizes acetate, butyrate, fumarate, propionate, succinate, phenol, 1-propanol and a small number of amino acids as sole carbon sources. Ammonium ions, asparagine and urea can be utilized as sole nitrogen sources. Casein is weakly hydrolyzed; gelatin, starch and urea are not hydrolyzed. It is unclear from phylogenetic studies as to whether this species still belongs in the genus *Bacillus*. See Tables 8 and 9.

Source: lake sediment, geothermal soils, and sugar factory sludge.

DNA G + C content (mol%): 62.3–65.4 (*T_m*) on the basis of two studies, and 67.1–67.7 (Bd) in one study; that of the type strain is 64.4 (*T_m*), 67.7 (Bd).

Type strain: Aragno MA-48, DSM 2000, LMG 7133, ATCC 43741, NCIMB 13107.

EMBL/GenBank accession numbers (16S rRNA gene): Z26934 (DSM 2000) and AB042060 (ATCC 43741);

these 16S rDNA sequences differ considerably from each other, showing only 98.2% similarity.

76. **Bacillus selenitireducens** Switzer Blum, Burns Bindi, Buzzelli, Stolz and Oremland 2001, 29^{VP}

se.le.ni.ti.re.du'cens. M.L. masc. gen. n. *selenitis* of selenite; L. part. adj. *reducens* reducing; M.L. part. adj. *selenitireducens* reducing selenite.

Facultatively anaerobic, nonmotile, non-spore-forming, Gram-positive rods 2–6 µm by 0.5 µm, which show weak microaerobic growth and anaerobic respiratory growth with Se(IV) (selenite), As(V) (arsenate), nitrate, nitrite, trimethylamine oxide and fumarate as electron acceptors. Description is based upon a single isolate. Quantitatively reduces Se(IV) to Se (0) (elemental selenium) during growth. Red colonies formed on lactate/selenite/yeast extract-supplemented lakewater medium incubated anaerobically at 20 °C. Grows fermentatively with fructose, glucose or starch. Uses lactate, glucose and pyruvate as electron donors. Moderately halophilic, with salinity optimum of 24–60 g/l NaCl. Moderately alkaliphilic, with optimum growth in the range pH 8.5–10. See Table 6.

Source: arsenic-rich sediment of Mono Lake, California.

DNA G + C content (mol%) of the type strain: 49.0 (T_m).

Type strain: MLS10, ATCC 700615, DSM 15326.

EMBL/GenBank accession number (16S rRNA gene): AF064704 (MLS10).

77. **Bacillus shackletonii** Logan, Lebbe, Verhelst, Goris, Forsyth, Rodríguez-Díaz, Heyndrickx and De Vos 2004b, 375^{VP}

sha.ckle.ton'i.i. N.L. adj. *shackletonii* of Shackleton, referring to *R.R.S. Shackleton*, the ship used by the first British scientific expedition to visit Candlemas Island, the vessel being named in honor of the celebrated Antarctic explorer Sir Ernest Shackleton.

Aerobic, Gram-variable, motile, round-ended rods 0.7–0.9 by 2.5–4.5 µm occurring singly. Gram-positive reactions are only seen in cultures of 18 h or less at 30 °C. Endospores are ellipsoidal, lie subterminally and occasionally paracentrally, and usually swell the sporangia. After 2 d on TSA colonies are 2–5 mm in diameter, have a granular appearance and butyrous texture, with opaque, cream-colored centers and translucent irregular margins. Minimum temperature for growth lies between 15 °C and 20 °C, the optimum temperature for growth is 35–40 °C, and the maximum growth temperature is 50–55 °C. Minimum pH for growth lies between 4.5 and 5.0, the optimum pH for growth is 7.0, and the maximum pH for growth lies between 8.5 and 9.0. Catalase-positive. Do not grow readily on casein agar, but when they do grow on it they may hydrolyze the casein. Starch is not hydrolyzed. At 30 °C in the API 20E strip, *o*-nitrophenyl-β-D-galactopyranoside is hydrolyzed slowly, reactions for arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, citrate utilization, hydrogen sulfide production, urease, tryptophan deaminase, indole production, Voges–Proskauer reaction, gelatin hydrolysis, and nitrate reduction are negative. (In the API 20E strip incubated at 40 °C, citrate may be utilized slowly, gelatin may be hydrolyzed slowly, and the Voges–Proskauer reaction may be positive). In the API 50 CH gallery hydrolysis

of esculin is positive. Acid without gas is produced from the following carbohydrates: amygdalin, cellobiose, D-glucose, N-acetylglucosamine and salicin; weak acid reactions were detected for arbutin, D-fructose, galactose, β-gentiobiose, lactose, maltose, D-mannitol, D-mannose, ribose, D-tagatose and D-trehalose. The major cellular fatty acids are C_{15:0} anteiso, C_{15:0} iso, C_{16:0} iso and C_{17:0} anteiso (respectively representing about 35, 31, 6 and 18% of total fatty acids).

Source: unheated volcanic soil taken from the eastern lava flow of Candlemas Island, South Sandwich archipelago.

DNA G + C content (mol%): 35.4 (type strain) to 36.8 (HPLC).

Type strain: Logan SSI024, LMG 18435, CIP 107762.

EMBL/GenBank accession number (16S rRNA gene): AJ250318 (LMG 18435).

78. **Bacillus silvestris** Rheims, Frühling, Schumann, Rohde and Stackebrandt 1999, 800^{VP}

sil.ves'tris. L. masc. adj. *Silvestris* of or belonging to a wood or forest, isolated from a forest.

Aerobic, Gram-positive, motile rods 0.5–0.7 by 0.9–2.0 µm, forming spherical spores which lie terminally in swollen sporangia. Description is based upon a single isolate. Colonies are whitish and shiny. Optimum growth temperature 20–30 °C, with minimum of 10 °C and maximum of 40 °C. Catalase-positive, oxidase-negative. Casein, esculin, gelatin, starch and Tween 80 and tyrosine are not hydrolyzed. Citrate and propionate are not utilized as sole carbon sources. Grows in the presence of up to 5% NaCl. Does not grow in the presence of lysozyme. Nitrate is not reduced to nitrite. No acid or gas produced from, and no utilization of, glucose and other common carbohydrates. Cell-wall peptidoglycan contains lysine, glutamic acid and alanine. This cell-wall composition differentiates this species from members of the novel genus *Lysinibacillus* that has been proposed to accommodate *Bacillus fusiformis*, *Bacillus sphaericus*, and the novel species *Lysinibacillus boronitolterans* (Ahmed et al., 2007c). See Table 8.

Source: forest soil.

DNA G + C content (mol%): 39.3 (HPLC).

Type strain: HR3-23, DSM 12223, LMG 18991.

EMBL/GenBank accession number (16S rRNA gene): AJ006086 (HR3-23).

79. **Bacillus simplex** (ex Priest, Goodfellow and Todd 1989) Heyrman, Logan, Rodríguez-Díaz, Scheldeman, Lebbe, Swings, Heyndrickx and De Vos 2005a, 129^{VP}

sim'plex. L. adj. *simplex* simple.

Rods are straight, 0.7–0.9 µm in diameter, round-ended or occasionally slightly tapered and occur in chains and sometimes singly or in pairs. Motile. Endospores are ellipsoidal, occasionally spherical, lie centrally, paracentrally or subterminally, and do not obviously swell the sporangia. Gram reaction is variable. Colonies on nutrient agar at 30 °C, are 3–6 mm in diameter after 2 d, cream-colored, glossy, with irregular margins, slightly raised and umbonate. Most strains are strictly aerobic, although some strains may grow weakly on nutrient agar in anaerobic conditions. They grow at 20° and 30 °C but are not able to grow at

45 °C. Strains grow well at pH 7 and pH 9; growth at pH 5 is variable. Casein hydrolysis is variable and the medium becomes tinted brown. Starch is hydrolyzed. Tolerance of 5% NaCl (w/v) is variable and no growth occurs with 7% NaCl (w/v). Oxidase-negative, catalase-positive. ONPG, arginine dihydrolase, lysine and ornithine decarboxylase, hydrogen sulfide production, urease, indole and Voges-Proskauer are negative; citrate utilization is negative, but type strain is positive in API Biotype 100 citrate assimilation test. Gelatin hydrolysis variable. Nitrate is reduced to nitrite. Hydrolysis of esculin is variable and weak. Acid without gas is produced weakly, from D-fructose, N-acetylglucosamine, D-glucose, inulin, D-trehalose and sucrose. Acid is produced weakly and variably from salicin. Two biovars may be recognized: strains belonging to *Bacillus simplex* Biovar 1 produce acid weakly and variably from L-arabinose, mannitol, D-raffinose, ribose and sorbitol, while acid production is always negative from D-cellobiose, glycerol, maltose, meso-inositol, and D-xylose; strains of *Bacillus simplex* Biovar 2, produce acid weakly from L-arabinose, mannitol, D-raffinose, ribose, sorbitol, and D-xylose, and are variable for weak acid production from D-cellobiose, glycerol, maltose and meso-inositol. For the variable characters the type strain shows: weak or moderate acid production for L-arabinose, mannitol, ribose and sorbitol, and no acid from D-raffinose. The major cellular fatty acids are C_{15:0 anteiso} and C_{15:0 iso}, present at on mean 59.03 (±5.88) and 15.55 (±2.95)% of the total fatty acids, respectively.

Heyrman et al. (2005a) considered that strains of "*Bacillus carotarum*" and its suggested synonyms "*Bacillus capri*," "*Bacillus cobayae*" and "*Bacillus musculi*," and strains of "*Bacillus maroccanus*" and "*Bacillus macroides*" NCIMB 8796 (=NCDO=LMG 18508), should be reclassified as *Bacillus simplex*.

Source: soil.

DNA G + C content (mol%): 39.5–41.8 (T_m).

Type strain: ATCC 49097, DSM 1321, LMG 11160, NRRL-NRS 960, IFO 15720.

EMBL/GenBank accession number (16S rRNA gene): AJ439078 (DSM 1321).

80. ***Bacillus siralis*** Pettersson, de Silva, Uhlén and Priest 2000, 2186^{VP}

si.ra'lis. L. masc. n. *sirus* grain pit, silo; N.L. adj. *siralis* belonging to the silo.

Aerobic, Gram-positive rods 0.5–0.8 by 2.0–3.0 µm, forming ellipsoidal spores which lie subterminally to terminally in swollen sporangia. Colonies on brain heart infusion agar after 24 h are 3–5 mm in diameter, and are circular and entire, light brown to brown in color, with shiny, glistening and granular surfaces; on nutrient agar the colonies are smaller, pale and opaque. Maximum growth temperature 50 °C. Catalase- and oxidase-positive. Grows in presence of 7% NaCl but not 10%. Nitrate is reduced to nitrite but not to dinitrogen; nitrate respiration positive. Casein, esculin and gelatin are hydrolyzed; starch is not. Citrate is not used as sole carbon source. Acid is not produced from glucose and other carbohydrates. Contains characteristic inserts of 49 bases in the distal region of the 16S rRNA genes.

Source: silage.

DNA G + C content (mol%): not reported.

Type strain: 171544, NCIMB 13601, CIP 106295, DSM 13140.

EMBL/GenBank accession number (16S rRNA gene): AF071856 (171544).

81. ***Bacillus smithii*** Nakamura, Blumenstock and Claus 1988, 70^{VP} smi'thi.i. N.L. gen. n. *smithii* named after Nathan R. Smith, American bacteriologist and *Bacillus* taxonomist.

Facultatively anaerobic, facultatively thermophilic, Gram-positive, motile rods 0.8–1.0 by 5.0–6.0 µm, forming ellipsoidal to cylindrical spores which lie terminally or subterminally in unswollen or slightly swollen sporangia. Colonies are unpigmented, translucent, thin, smooth, circular, entire, and about 2 mm in diameter. Growth temperature range 25–60 or 65 °C. Catalase- and oxidase-positive. No growth in presence of 3% NaCl or 0.001% lysozyme. Nitrate is not reduced to nitrite. DNA and hippurate are hydrolyzed; starch is weakly hydrolyzed; esculin and pullulan hydrolysis is variable; casein, chitin, gelatin, tyrosine and urea are not hydrolyzed. Utilization of citrate and propionate as sole carbon sources is variable. Acid without gas is produced from glucose and a variable range of other carbohydrates.

Source: evaporated milk, canned foods, cheese, and sugar beet juice.

DNA G + C content (mol%): 38.1–40.4 (Bd), 38.7–39.7 (T_m); that of the type strain is 40.2 (Bd).

Type strain: NRRL NRS-173, JCM 9076, LMG 12526, DSM 4216.

EMBL/GenBank accession number (16S rRNA gene): Z26935 (DSM 4216).

82. ***Bacillus soli*** Heyrman, Vanparys, Logan, Balcaen, Rodríguez-Díaz, Felske and De Vos 2004, 55^{VP}

so'li. L. gen. n. *soli* of soil.

Facultatively anaerobic, Gram-positive or Gram-variable, motile, round-ended rods 0.6–1.2 µm in diameter, sometimes curved, occurring singly and in pairs and chains. Ellipsoidal endospores are borne paracentrally, and may swell the sporangia. On TSA, colonies are butyrous, cream-colored, low, slightly umbonate, and have entire margins and glossy or eggshell textured surfaces. The optimum temperature for growth is 30 °C, and the maximum growth temperature lies between 40 °C and 45 °C. The optimum pH for growth is 7.0–8.0, and growth occurs from pH 5.0–4.0 to 9.0–9.5. Hydrolysis of casein is positive. In the API 20E strip, gelatin is hydrolyzed and nitrate reduction is positive; reactions for o-nitrophenyl-β-D-galactopyranoside hydrolysis, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, citrate utilization, hydrogen sulfide production, urease, tryptophan deaminase, indole production, and Voges-Proskauer are negative. Hydrolysis of esculin positive. Acid without gas is produced from the following carbohydrates in the API 50 CH gallery using the CHB suspension medium: N-acetyl-D-glucosamine, D-fructose, D-glucose, glycogen, maltose (weak), D-mannose, ribose (weak), starch and D-trehalose (weak). Acid production from galactose and sucrose is variable, and weak when positive; type strain is weakly positive for galactose and negative for sucrose. The major cellular fatty acids are C_{15:0 iso} and C_{15:0 anteiso}, present at a level of about 43 and 34%, respectively.

Source: soil of the Drentse A agricultural research area, The Netherlands.

DNA G + C content (mol%): 40.1–40.4 (type strain, 40.1) (HPLC).

Type strain: LMG 21838, DSM 15604.

EMBL/GenBank accession number (16S rRNA gene): AJ542513 (LMG 21838).

83. **Bacillus sonorensis** Palmisano, Nakamura, Duncan, Istock and Cohan 2001, 1678^{VP}

so.no.ren'sis. N.L. adj. *sonorensis* of the Sonoran, named after the Sonoran Desert, where the organism was found.

Facultatively anaerobic, Gram-positive, motile rods, forming ellipsoidal spores which lie subterminally in unswollen sporangia. Cells 1.0 by 2.0–5.0 µm, occurring singly and in pairs and short chains. Colonies are yellowish cream, with mounds and lobes of amorphous slime, and 2–4 mm in diameter after 2 d at 30 °C; colonies on tyrosine agar are brown. Minimum growth temperature about 15 °C and maximum about 55 °C. Growth is inhibited by 5% NaCl and by 0.001% lysozyme. Citrate and propionate are utilized. Catalase-positive. Casein and starch are hydrolyzed. Nitrate is reduced to nitrite. Acid without gas is produced from glucose and other carbohydrates.

Phenotypically similar to *Bacillus licheniformis* and distinguishable from that species mainly by pigment production on tyrosine agar, certain gene sequences, enzyme electrophoresis, and DNA relatedness.

Source: desert soil.

DNA G + C content (mol%): 46.0 (T_m).

Type strain: L87-10, NRRL B-23154, DSM 13779.

EMBL/GenBank accession number (16S rRNA gene): AF302118 (NRRL B-23154).

84. **Bacillus sphaericus** Meyer and Neide in Neide 1904, 337^{AL} sphae'ri.cus. L. adj. *sphaericus* spherical.

Aerobic, Gram-positive, motile rods, forming spherical spores which lie terminally in swollen sporangia (Figure 10f). Cells are about 1.0 by 1.5–5.0 µm. Colonies are opaque, unpigmented, smooth and often glossy, and usually entire. Minimum growth temperature 10–15 °C and maximum 30–45 °C. Grows at pH 7.0–9.5; some strains grow at pH 6.0. Catalase- and oxidase-positive. Biotin and thiamin are required for growth; cystine is not required. Tween 20 is hydrolyzed; casein, gelatin, Tween 80 and urea hydrolysis variable; starch, and tyrosine are not hydrolyzed. Phenylalanine is deaminated. Citrate is utilized as sole carbon source. Grows in the presence of 5% NaCl, but not in 7% NaCl. Nitrate is not reduced to nitrite. No acid or gas produced from glucose and other common carbohydrates. Cell-wall peptidoglycan type is L-Lys-D-Asp. See Table 9.

Ahmed et al. (2007c) proposed the transfer of this species to the new genus *Lysinibacillus*.

Source: soil and water, and a variety of other environments including foods, clinical specimens and mosquitoes.

DNA G + C content (mol%): 37.3 (T_m), 38.3 (Bd) for the type strain.

Type strain: IAM 13420, ATCC 14577, CCM 2120, DSM 28, NCIMB 9370, LMG 7134.

EMBL/GenBank accession number (16S rRNA gene): AJ310084 (DSM 28). Two other 16S rDNA sequences in

the EMBL/GenBank database, L14010 (ATCC 14577) and X60639 (NCDO 1767), are of poor quality.

Additional remarks: Nucleic acid studies have shown that *Bacillus sphaericus* is genetically heterogeneous, and have revealed six DNA relatedness groups (Krych et al., 1980; Rippere et al., 1997) and seven 16S rDNA sequence similarity groups (Nakamura et al., 2002); strains of three groups have been allocated to the species *Bacillus fusiformis* (Priest et al., 1988), *Bacillus neidei* and *Bacillus pycnus* (Nakamura et al., 2002). *Bacillus sphaericus* is phenotypically similar to *Bacillus fusiformis*, *Bacillus neidei* and *Bacillus pycnus*, and only separable from these species by growth factor requirements, several substrate oxidation and decomposition tests, and differences in fatty acid compositions. It is this lack of diagnostic characters that has hindered the recognition of the various molecularly defined groups as taxa of species rank.

Strains insecticidal for mosquitoes are found in DNA homology group IIA of Krych et al. (1980) (Rippere et al., 1997), and other taxonomic studies (see Priest, 2002) have confirmed the distinctness of the group. Serotyping (de Barjac et al., 1985) and phage typing (Yousten, 1984) schemes have been developed for group IIA. It must be emphasized that many members of the group are not mosquitocidal. Although strains in this group represent a distinct taxon, the lack of defining phenotypic characters has discouraged the proposal of a new species, and they remain allocated to *Bacillus sphaericus*; however, the name "*B. culicivorans*" has been suggested for the group (Priest, 2002). Recently, this species has been reclassified as *Lysinibacillus sphaericus* Ahmed et al. (2007c).

85. **Bacillus sporothermodurans** Pettersson, Lembke, Hammer, Stackebrandt and Priest 1996, 763^{VP}

spo.ro.ther.mo.du'rans. Gr. n. *sporos* seed, spore; Gr. adj. *thermos* warm, hot; L. adj. part. *durans* resisting. N.L. adj. part. *sporothermodurans* with heat-resisting spores.

Aerobic, Gram-positive cells that usually occur as motile, thin rods in chains. Strains require vitamin B₁₂ (cyanocobalamin) for satisfactory growth. After 2 d on brain heart infusion (BHI) agar supplemented with 5 mg/l MnSO₄ and with 1 mg/l vitamin B₁₂, colonies are 1–2 mm diameter, flat, circular, entire, beige or cream and smooth or glossy in appearance. They bear spherical to ellipsoidal endospores which lie in paracentral and subterminal, sometimes terminal, positions within slightly swollen and unswollen sporangia; the spores of the type strain, though scanty, are ellipsoidal, terminal, and do not swell the sporangia. Sporulation is infrequent but can be enhanced by using BHI-soil extract agar supplemented with vitamin B₁₂ and MnSO₄. Strains isolated from ultrahigh-temperature (UHT) treated (135–142 °C for several seconds) milk grow poorly and sporulate poorly, but their spores show very high heat resistance and have the ability to survive ultrahigh heat treatment. This very high heat resistance may decrease upon subculture. Isolates from farm environments may grow more readily than UHT milk isolates but be less heat resistant. Oxidase- and catalase-positive. Casein and starch are not hydrolyzed. Nitrate is reduced to nitrite, the Voges–Proskauer reaction is variable (type strain positive), citrate

utilization is variable (type strain negative), hydrogen sulfide and indole are not produced, and the ONPG reaction is negative. Gelatin and esculin are hydrolyzed, urea is not. Growth may occur between 20 °C and 55 °C, with an optimum of about 37 °C. Growth occurs between pH 5 and 9, and NaCl is tolerated up to 5%. Acid without gas is produced from *N*-acetylglucosamine, D-glucose, D-fructose, maltose, and from sucrose and D-trehalose by most strains, but reactions may be weak. Acid production from the following carbohydrates is variable: amygdalin, arbutin, D-cellobiose, gentiobiose, glycerol, mannitol, D-mannose, D-melezitose, methyl-D-glucoside, salicin, starch, D-tagatose, D-turanose and xylitol (weak). The type strain produces acid without gas from arbutin, D-cellobiose, glycerol, mannitol, D-melezitose, salicin, D-tagatose, D-turanose and xylitol, but not from amygdalin, gentiobiose, D-mannose, methyl-D-glucoside and starch.

Source: UHT-treated milk and dairy farm environments.

DNA G + C content (mol%): 36 (HPLC).

Type strain: M215, DSM 10559, LMG 17894, NCIMB 13600, KCTC 3777.

EMBL/GenBank accession number (16S rRNA gene): U49078 (M215).

86. **Bacillus subterraneus** Kanso, Greene and Patel 2002, 873^{VP} sub.ter.ra'ne.us. L. adj. *subterraneus* underground, subterranean, referring to the isolation source.

Facultatively anaerobic, Gram-negative, non-spore-forming, motile, curved rods, 0.5–0.8 by 2.0–25.0 µm, occurring singly and also in pairs and chains. Description is based upon a single isolate. After 2 d incubation at 40 °C, colonies on nutrient agar are 0.5–1.2 mm in diameter, translucent and convex, with undulating irregular edges, while on tryptic soy agar they are dark yellow to orange, mucoid and rhizoid. Optimum growth temperature 37–40 °C, temperature range for growth about 20–45 °C. pH range for growth 6.5–9.0. Utilizes amorphous iron (III), manganese (IV), nitrate, nitrite and fumarate as electron acceptors in the presence of yeast extract, or certain carbohydrates, ethanol or lactate. Electron acceptors are not required for growth, but growth is better in the presence of nitrate. Yeast extract can be used as sole carbon and energy source. Growth occurs in the presence of up to 9% NaCl. Catalase-positive, oxidase-negative. Esculin, gelatin and starch are hydrolyzed; casein and urea are not hydrolyzed.

Source: deep subterranean waters of the Great Artesian Basin of Australia.

DNA G + C content (mol%): 43 ± 1 (T_m).

Type strain: COOI3B, ATCC BAA-136, DSM 13966.

EMBL/GenBank accession number (16S rRNA gene): AY672638 (COOI3B).

87. **Bacillus thermoamylovorans** Combet-Blanc, Ollivier, Streicher, Patel, Dwivedi, Pot, Presnier and Garcia 1995, 15^{VP} ther.mo.a.my.lo.vo'rans. Gr. adj. *thermos* hot; Gr. n. *amyllum* starch; L. v. *vorare* to devour; N.L. adj. *thermoamylovorans* utilizing starch at high temperature.

Facultatively anaerobic, moderately thermophilic, Gram-positive, slightly motile rods, 0.45–0.5 µm by 3.0–4.0 µm. Description based upon a single isolate. Endospores have

not been detected; cells killed by heating at 80 °C for 5 min. Colonies are white and lenticular, and 2–3 mm in diameter after 2 d. Optimum growth temperature about 50 °C; maximum 58 °C. Grows between pH 5.4 and 8.5, with optimum pH 6.5–7.5. Catalase-positive, oxidase-negative. Amyolytic. Nitrate is not reduced to nitrite. Vitamins and nucleic acid derivatives will stimulate growth, but are not essential. Acid without gas is produced from glucose, starch and a range of other carbohydrates; heterolactic fermentation of hexoses yields acetate, formate, lactate and ethanol. See Table 8.

Source: Senegalese palm wine.

DNA G + C content (mol%): 38.8 ± 0.2 mol% (HPLC).

Type strain: CNCM I-1378, strain DKP, LMG 18084.

EMBL/GenBank accession number (16S rRNA gene): L27478 (CNCM I-1378).

88. **Bacillus thermocloacae** Demharter and Hensel 1989a, 495 (Effective publication: Demharter and Hensel 1989b, 274.) ther.mo.clo'a.cae. Gr. n. *therme* heat; L. n. *cloaca* sewer; N.L. gen. n. *thermocloacae* of a heated sewer.

Aerobic, moderately alkaliphilic and thermophilic, Gram-positive, nonmotile rods, 0.5–0.8 µm by 3.0–8.0 µm. Description is based upon three isolates. Spore formation only detected in one strain; ellipsoidal spores lie subterminally and terminally in swollen sporangia. Colonies are flat to convex, pale, transparent to opaque, and circular with entire or slightly lobed margins, and reach 2–5 mm in diameter after 1–2 d at 60 °C. Optimum growth temperature 55–60 °C; minimum 37 °C and maximum 70 °C. Optimum pH 8–9; no growth at pH 7. Grows in presence of up to 5% NaCl, but growth with 5% NaCl is weak. Catalase- and oxidase-positive. Casein, esculin, gelatin, starch and tributyrin not hydrolyzed. Voges–Proskauer-negative. Nitrate is not reduced to nitrite. No acid or gas are produced from glucose and other carbohydrates. See Tables 6 and 8.

Source: heat-treated sewage sludge.

DNA G + C content (mol%): 42.8–43.7 (T_m), 41.7–42.1 (HPLC).

Type strain: S 6025, DSM 5250.

EMBL/GenBank accession number (16S rRNA gene): Z26939 (DSM 5250).

89. **Bacillus thuringiensis** Berliner 1915, 29^{AL} thur.in.gi.en'sis. N.L. masc. adj. *thuringiensis* of Thuringia, the German province from where the organism was first isolated.

Facultatively anaerobic, Gram-positive, usually motile rods 1.0–1.2 by 3.0–5.0 µm, occurring singly and in pairs and chains, and forming ellipsoidal, sometimes cylindrical, subterminal, sometimes paracentral, spores which do not swell the sporangia; spores may lie obliquely in the sporangia. Sporangia carry parasporal bodies adjacent to the spores; these crystalline protein inclusions (Figure 10h) may be bipyramidal, cuboid, spherical to ovoid, flat-rectangular, or heteromorphous in shape. They are formed outside the exosporium and readily separate from the liberated spore. They are known as δ-endotoxins or insecticidal crystal proteins, and are protoxins which may be toxic for certain insects and other invertebrates including flatworms, mites, nematodes and protozoa. The ability to synthesize parasporal bodies is plasmid borne, has been transferred to strains

of *Bacillus cereus* and even to *Bacillus pumilus* (Selinger et al., 1998), and may be lost on subculture. Cells grown on glucose agar produce large amounts of storage material, giving a vacuolate or foamy appearance. Like those of *Bacillus cereus*, colonies are very variable in appearance, but nevertheless distinctive and readily recognized (Figure 9h): they are usually whitish to cream in color, large (2–7 mm in diameter), and vary in shape from circular to irregular, with entire to undulate, crenate or fimbriate edges; they usually have matt or granular textures, but smooth and moist colonies are not uncommon. Minimum temperature for growth is 10–15 °C, and the maximum 40–45 °C. Egg yolk reaction is positive. Catalase-positive, oxidase-negative. Casein, gelatin and starch are hydrolyzed. Voges–Proskauer-positive. Citrate is utilized as sole carbon source. Nitrate is reduced. Tyrosine is decomposed. Phenylalanine is not deaminated. Resistant to 0.001% lysozyme. Acid without gas is produced from glucose and a limited range of other carbohydrates. Some strains can produce diarrheal enterotoxin.

Phenotypically similar to other members of the *Bacillus cereus* group: *Bacillus anthracis*, *Bacillus cereus*, *Bacillus mycoides*, *Bacillus pseudomycoides* and *Bacillus weihenstephanensis*. *Bacillus thuringiensis* is distinguished by its characteristic parasporal crystals. Smith et al. (1952) and Gordon et al. (1973) considered *Bacillus thuringiensis* to be a variety of *Bacillus cereus*. For distinguishing characters within the *Bacillus cereus* group, see the individual species descriptions and Table 7.

Endospores are very widespread in soil and many other environments, and this organism has been isolated from all continents, including Antarctica. Although numerous strains are toxic to invertebrates, this property has not been demonstrated in many other strains. Natural epizootics do not seem to occur, and it has been suggested that the natural habitat of this organism is soil.

DNA G + C content (mol%): 33.5–40.1 (T_m) for two strains; 35.7–36.7 (Bd) for four strains, and 33.8 (T_m), 34.3 (Bd) for the type strain.

Type strain: IAM 12077, ATCC 10792, NRRL NRS-996, DSM 2046, LMG 7138, NCIMB 9134.

EMBL/GenBank accession number (16S rRNA gene): D16281 (IAM 12077).

Additional remarks: *Bacillus thuringiensis* has been divided on the basis of flagellar (H) antigens into 69 serotypes with 13 subantigenic groups, giving a total of 82 serovars (Lecadet et al., 1999); see also *Antigenic Structure*, above), but there is little correlation between serotype and insecticidal toxicity, the latter being mainly encoded by plasmids. Ribotyping data have shown good correlation with serotypes for 10 well known serovars (Priest et al., 1994); other approaches to subspecies analysis of *Bacillus thuringiensis* are discussed by Lecadet et al. (1999).

90. ***Bacillus tusciae*** Bonjour and Aragno 1985, 223^{VP} (Effective publication: Bonjour and Aragno 1984, 400.)

tus'cia.e. L. gen. n. *tusciae* from Tuscia, the Roman name for the region of central Italy where the organism was found.

Facultatively chemolithoautotrophic, moderately thermophilic, strictly aerobic, motile (by one lateral flagellum), Gram-positive rods 0.8 by 4–5 µm, forming subterminal,

ellipsoidal spores which swell the sporangia. Description is based upon two isolates. The spreading colonies are creamy-white and chalky. Heavy autotrophic cultures form a yellow, water-soluble pigment. No growth factors are required. Strictly respiratory, with oxygen as terminal electron acceptor. Nitrate is reduced to nitrite, but nitrate respiration does not occur. Grows chemolithoautotrophically, using H₂ as electron donor and CO₂ as carbon source, or chemoorganoheterotrophically. Optimum growth temperature about 55 °C; no growth at 35 or 65 °C. Optimum pH for growth 4.2–4.8; weak growth at pH 3.5 and 6.0. No growth in presence of 1% NaCl. Catalase weakly positive and oxidase-positive. Carbohydrates are not metabolized. Starch is not hydrolyzed. Utilizes a few alcohols, amino acids and organic acids as sole carbon sources, with ammonium as the nitrogen source. Ammonium ions, asparagine and urea can be utilized as sole nitrogen sources. See Table 8.

Source: an acidic pond in a solfatara in Italy.

DNA G + C content (mol%): 57–58 (T_m), and for the type strain 57.5 (T_m).

Type strain: Aragno T2, DSM 2912, LMG 17940, IFO 15312.

EMBL/GenBank accession number (16S rRNA gene): AB042062 (IFO 15312).

91. ***Bacillus vallismortis*** Roberts, Nakamura and Cohan 1996, 474^{VP} *val.lis.mor'tis*. L. n. *vallis* valley; L. fem. n. *mors* death; N.L. gen. fem. n. *vallismortis* of Death Valley.

Aerobic, Gram-positive, motile rods, forming ellipsoidal spores which lie centrally or paracentrally in unswollen sporangia. Cells 0.8–1.0 by 2.0–4.0 µm, occurring singly and in short chains. Colonies are opaque, smooth, circular and entire and 1.0–2.0 mm in diameter after 2 d at 28 °C. Optimum growth temperature 28–30 °C, with minimum of 5–10 °C and maximum of about 50 °C. Catalase-positive, oxidase-positive. Citrate is utilized as a sole carbon source; propionate is not. Casein and starch are hydrolyzed. Tween 80 is decomposed weakly, phenylalanine and tyrosine are not decomposed. Nitrate is reduced to nitrite. Acid without gas is produced from glucose and a range of other carbohydrates.

Indistinguishable from *Bacillus mojavensis*, *Bacillus subtilis* subsp. *subtilis* and *Bacillus subtilis* subsp. *spizizenii* by conventional phenotypic tests, and distinguished from those organisms principally by DNA relatedness, by data from restriction digestion analyses of certain genes, and by fatty acid analysis. Phenotypically distinguishable from *Bacillus atrophaeus* only by failure to produce dark brown pigmented colonies on media containing tyrosine or other organic nitrogen source. See Table 5.

Source: desert soil.

DNA G + C content (mol%): 43.0 (T_m).

Type strain: DV1-F-3, NRRL B-14890, DSM 11031, LMG 18725, KCTC 3707.

EMBL/GenBank accession number (16S rRNA gene): AB021198 (DSM 11031).

92. ***Bacillus vedderi*** Agnew, Koval and Jarrell 1996, 362 (Effective publication: Agnew, Koval and Jarrell 1995, 229.)

ved'deri. M.L. gen. n. *vedderi* of Vedder, named after A. Vedder, the Dutch microbiologist who described *Bacillus alcalophilus* in 1934.

Alkaliphilic, facultatively anaerobic, Gram-positive, motile, narrow rods forming ellipsoidal to spherical spores which lie terminally in swollen sporangia. Description is based upon a single isolate. Colonies are white, flat and circular, and 1.5 mm in diameter after 2 d growing on alkaline oxalate medium at 37 °C. Optimum growth temperature 40 °C; maximum 45–50 °C. Optimal growth at pH 10.0; pH range 8.9–10.5. Grows in presence of 7.5% NaCl, but not 10% NaCl. Growth stimulated by presence of vitamins (in yeast extract). Catalase- and oxidase-positive. Pectin and birchwood xylan are hydrolyzed; gelatin and carboxymethylcellulose are weakly hydrolyzed; casein, starch and oakwood xylan are not hydrolyzed. Glucose and a small range of other carbohydrates can be utilized as sole sources of carbon. See Table 6.

Source: red mud bauxite-processing waste, using alkaline oxalate enrichment.

DNA G + C content (mol%): 38.3 (T_m).

Type strain: JaH, DSM 9768, ATCC 7000130, LMG 17954, NCIM B 13458.

EMBL/GenBank accession number (16S rRNA gene): Z48306 (JaH).

93. **Bacillus vietnamensis** Noguchi, Uchino, Shida, Takano, Nakamura and Komagata 2004, 2119^{VP}

vi.et.nam.en'sis. N.L. adj. *vietnamensis* referring to Vietnam, the country where the type strain was isolated.

Cells are rod-shaped, measuring 0.5–1.0 by 2.0–3.0 µm, Gram-positive and aerobic. They are motile with peritrichous flagella. Ellipsoidal spores develop centrally in the cells and sporangia are not swollen. Catalase and oxidase are produced. Nitrate reduction, indole production, arginine dihydrolase and urease are negative. Growth occurs in the presence of lysozyme. Casein, starch, DNA, esculin, gelatin, *p*-nitrophenyl β-D-galactopyranoside and tyrosine are hydrolyzed. Production of hydrogen sulfide is not detected on trypticase soy agar. Acid is produced from glycerol, D-ribose, D-glucose, D-fructose, mannitol, *N*-acetyl D-glucosamine, maltose, sucrose, trehalose, inulin, starch and glycogen; no acid is produced from erythritol, D-arabinose, L-arabinose, D-xylose, L-xylose, adonitol, methyl β-D-xyloside, galactose, D-mannose (NRRL B-14850 produces acid from this sugar), L-sorbose, rhamnose, dulcitol, inositol, sorbitol, methyl α-D-mannoside, methyl β-D-glucoside, amygdalin, arbutin, salicin, cellobiose, lactose, melibiose, melezitose, D-raffinose, xylitol, β-gentiobiose, D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, D-gluconate, 2-ketogluconate and 5-ketogluconate. Assimilation is positive for glucose, D-mannitol, *N*-acetyl D-glucosamine, maltose, gluconate and DL-malic acid, and negative for L-arabinose, D-mannose, n-capric acid, citrate and adipic acid. Growth occurs at 0–15% (w/v) NaCl (optimum at 1%). The isolates are regarded as moderately halotolerant bacteria. Growth occurs at 10–40 °C (optimum at 30–40 °C) (16–3 and NRRL B-14850 grow at 50 °C). Growth occurs at pH 6.5–10.0 but not at pH 6.0. DNA G + C content is 43–44 mol% (HPLC). The major fatty acid is C_{15:0 anteiso} (48.3 ± 11.9%), with lesser C_{15:0 iso} (16.2 ± 4.4%). The major quinone is MK-7. *meso*-Diaminopimelic acid is found in the cell walls. Strains have been isolated from Vietnamese fish sauce and from the Gulf of Mexico. Major cellular fatty acids are C_{15:0 anteiso} (51.4%) and C_{15:0 iso} (19.8%).

Source: Vietnamese fish sauce.

DNA G + C content (mol%): 43 (HPLC).

Type strain 15-1, JCM 11124, NRIC 0531, NRRL 23890.

GenBank/EMBL accession number (16S rRNA gene): AB099708.

94. **Bacillus vireti** Heyrman, Vanparys, Logan, Balcaen, Rodríguez-Díaz, Felske and De Vos 2004, 54^{VP}

vi.re'ti. L. gen. n. *vireti* of a field.

Facultatively anaerobic, Gram-negative, motile, slightly curved, round-ended rods, 0.6–0.9 µm in diameter, occurring singly and in pairs. Do not produce endospores on TSA supplemented with 5 mg/l MnSO₄, but sporulate on *Bacillus fumarioli* agar at pH 7 after 48 h. Endospores are ellipsoidal, lie in central, paracentral, or sometimes subterminal positions, and may swell the sporangia slightly; the ends of the sporangia may be slightly tapered. After 3 d of growth on TSA, colonies are dark cream-colored, circular, raised and up to 4 mm in diameter, with entire edges. Colonies have loose biomass and egg-shell textured surfaces. The optimum temperature for growth is 30 °C, and the maximum growth temperature lies between 40 °C and 45 °C. Growth occurs from pH 4.0–5.0 to 7.0–7.5; the optimum lies at the upper end of this range. Casein is hydrolyzed. In the API 20E strip, gelatin is hydrolyzed and nitrate reduction is positive; *o*-nitrophenyl-β-D-galactopyranoside hydrolysis is variable, reactions for arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, citrate utilization, hydrogen sulfide production, urease, tryptophan deaminase, indole production, and Voges–Proskauer are negative. Hydrolysis of esculin positive. Acid without gas is produced from the following carbohydrates in the API 50 CH gallery using the CHB suspension medium: *N*-acetyl-D-glucosamine, D-fructose, L-fucose (weak), galactose (weak), D-glucose, glycogen, maltose, D-mannitol, D-mannose, methyl α-D-glucoside (weak), ribose (weak), starch, sucrose and D-trehalose. The following reactions are variable between strains and, when positive, are usually weak: gluconate, *meso*-inositol, methyl α-D-mannoside, rhamnose; type strain is weak for gluconate and methyl α-D-mannoside and negative for *meso*-inositol and rhamnose. The major cellular fatty acids are C_{15:0 iso} and C_{15:0 anteiso}, present at a level of about 47 and 34%, respectively.

Source: soil of Drentse A agricultural research area, The Netherlands.

DNA G + C content (mol%): 39.8–40.3 (type strain, 40.2) (HPLC).

Type strain: LMG 21834, DSM 15602.

EMBL/GenBank accession number (16S rRNA gene): AJ542509 (LMG 21834).

95. **Bacillus weihenstephanensis** Lechner, Mayr, Francis, Prüss, Kaplan, Wiessner-Gunkel, Stewart and Scherer 1998, 1380^{VP}

we'ihen.ste'phan.en'sis. N.L. masc. adj. *weihenstephanensis* referring to Freising-Weihenstephan in Southern Germany, where the type strain was isolated.

Phenotypically similar to *Bacillus cereus* and distinguished from it by ability to grow at 7 °C, inability to grow at 43 °C, and by certain 16S rDNA signature sequences. Distinguished from *Bacillus anthracis*, *Bacillus mycoides*, *B.*

pseudomycooides and *Bacillus thuringiensis* by the same characters that differentiate those species from *Bacillus cereus*. For distinguishing characters within the *Bacillus cereus* group, see the individual species descriptions and Table 7.

Source: pasteurized milk.

DNA G + C content (mol%): not reported, but can be expected to lie within the range reported for *Bacillus cereus*.

Type strain: DSM 11821, WSCB 10204, LMG 18989.

EMBL/GenBank accession number (16S rRNA gene): AB021199 (DSM 11821).

Additional remarks: Although psychrotolerance is an important distinguishing character of *Bacillus weihenstephanensis*, it must be appreciated that not all psychrotolerant organisms resembling *Bacillus cereus* are *Bacillus weihenstephanensis* (Stenfors and Granum, 2001), and the practical value of recognizing this close relative of *Bacillus mycooides* may be questioned.

Species *Incertae Sedis*

Claus and Berkeley (1986) listed 26 *species incertae sedis* in the First Edition of this *Manual*. 12 of these have been revived since then and, in some cases, transferred to other genera; either at the times of their revivals or later. Details are given in the species listings of the appropriate genera as follows: *Bacillus amyloliquefaciens* (Priest et al., 1987); *Bacillus flexus* (Priest et al., 1989); *Bacillus laevolacticus* (Andersch et al., 1994); *Bacillus psychrosaccharolyticus* (Priest et al., 1989); *Aneurinibacillus aneurinilyticus* (Heyndrickx et al., 1997; Shida et al., 1996); *Anoxybacillus flavithermus* (Pikuta et al., 2000a); *Geobacillus thermocatenulatus* (Golovacheva et al., 1975; Nazina et al., 2001); *Geobacillus thermodenitrificans* (Manachini et al., 2000; Nazina et al., 2001); *Paenibacillus agareredens* (Uetanabaro et al., 2003); *Paenibacillus apiarius* (Nakamura, 1996); *Paenibacillus larvae* subsp. *pulvificiens* (Heyndrickx et al., 1996c; Nakamura, 1984c); *Paenibacillus thiaminolyticus* (Nakamura, 1990; Shida et al., 1997). Many other names that have been proposed in the past for *Bacillus* species were discussed by Smith et al. (1952) and Gordon et al. (1973), and many were considered by these authors to be synonyms of established species. For comprehensive listings of such names the reader is referred to *Index Bergeyana* (Buchanan et al., 1966; Gibbons et al., 1981).

White et al. (1993) proposed the merger of the two species "*Bacillus caldotenax*" and "*Bacillus caldovelox*" (both Heinen and Heinen, 1972) within a revived *Bacillus caldotenax*, but found "*Bacillus caldolyticus*" (Heinen and Heinen, 1972) to show low homology with these two species. Sunna et al. (1997b) identified "*Bacillus caldolyticus*", "*Bacillus caldotenax*" and "*Bacillus caldovelox*," as members of *Bacillus thermoleovorans* on the basis of DNA homology studies, but this proposal has not been validated. In any case these species belong in the genus *Geobacillus* (see the chapter on *Geobacillus*). Polyphasic studies of "*Bacillus longisporus*," "*Bacillus nitritollens*" and "*Bacillus similibadius*" (all Delaporte, 1972) have not revealed homogeneous groupings among strains inherited from Delaporte (Logan and De Vos, unpublished). Heyrman et al. (2005a) found "*Bacillus carotarum*" and "*Bacillus maroccanus*" to be synonyms of *Bacillus simplex*.

Of the species remaining, the following may be considered for revival, and some may warrant transfer to other genera, after more detailed studies have been performed or after additional strains have been obtained and examined:

a. "*Bacillus agrestis*" Werner 1933, 468

The species was accepted as a synonym of *Bacillus megaterium* by Gordon et al. (1973) but differs from typical members of that species in that its cells are smaller (mean diameter <1.0 µm), poly-β-hydroxybutyrate is not formed, esculin is not hydrolyzed, and phenylalanine is not deaminated. This strain is not closely related to *Bacillus megaterium sensu stricto* (Hunger and Claus, 1981).

DNA G + C content (mol%): 37.4 (T_m).

Representative strain: NRS 602 (DSM 1316).

b. "*Bacillus aminovorans*" den Dooren de Jong 1926, 157

Strictly aerobic, motile rods, 0.8–1.5 × 1.5–5.0 µm, Gram-positive in young cultures. Spherical endospores are borne centrally and paracentrally, and do not swell the sporangia. Maximum growth temperature 37 °C. Feeble growth on nutrient agar, and better growth on trypticase peptone medium. Utilizes mono-, di- and trimethylamine and glucose. Fructose and maltose used by some strains. No growth with other carbohydrates, organic acids, or amino acids, except gluconate, glutamate, 3-hydroxybenzoate and citrate. Some strains utilize betaine. Farrow et al. (1994) did not find a specific relationship between this organism and the spherical spore-formers of Group 2 of Ash et al. (1991).

Source: Soil.

DNA G + C content (mol%): 40.4–41.8 (T_m) for about 20 strains.

Original strain: ATCC 7046 (DSM 1314).

c. "*Bacillus freudenreichii*" (Miquel) Chester 1898, 110

This species was described by Claus and Berkeley (1986) as very similar to *Bacillus* (now *Brevibacillus*) *brevis* in nutritional requirements (Bornside and Kallio, 1956), morphology and physiology, but differing in that it produces a considerable titratable alkalinity in urea broth and is less tolerant of acid. Additionally, growth occurs in 5% NaCl broth and phenylalanine is deaminated.

Source: Soil, river water and sewage.

Representative strain: ATCC 7053.

d. "*Bacillus macroides*" Bennett and Canale-Parola 1965, 204

Originally described as "*Lineola longa*" (Pringsheim, 1950). This organism is unreactive in routine phenotypic tests, and Claus and Berkeley (1986) considered that its characters conform to those of *Bacillus sphaericus* (with the one exception that its spore is frankly oval and scarcely distends the sporangium) and to *Bacillus badius*. Minimal nutritional requirements are a carbon energy source, NH₄-N, thiamine, biotin and, in one strain, guanine. Carbon sources include various amino acids and C2–C5 *n*-fatty acids, but not sugars. Proteolytic action is not detected within 3 weeks. By comparing the sequences of the 16S–23S internal transcribed spacer region of representatives of 27 *Bacillus* species and 19 strains representing five other endospore-forming genera, Xu and Cote (2003) found that "*Bacillus macroides*" strain ATCC 12905 (=LMG 18508=NCDO 1661) showed phylogenetic relationships with *Bacillus fusiformis* and *Bacillus sphaericus* (now both reclassified in *Lysinibacillus*; Ahmed et al., 2007c). Heyrman et al. (2005a) reclassified "*Bacillus macroides*" strain NCIMB 8796 (=DSM 54=LMG 18474) as

a strain of *Bacillus simplex*, and on the basis of subsequent work Heyrman et al. (unpublished) propose the revival of "*Bacillus macroides*" as *Lysinibacillus macroides*, for the single strain ATCC 12905.

Source: Cow dung, plant material decaying in water.

DNA G + C content (mol%): 37.6–38.9 (T_m).

Representative strain: ATCC 12905, LMG 18474, DSM 54.

e. "*Bacillus pacificus*" Delaporte 1967, 3071

Cells oval, exceptionally large, measuring 1.5–2.1 × 2.7–3.4 μm, with capsules and lipid inclusions. Motile, with one or two flagella inserted at or near one pole, or both poles. Spores are ellipsoidal and 1.3–1.5 × 2.7–3.4 μm in size. Best medium reported is 0.1% tryptone in sea water; no growth occurs on ordinary nutrient agar. Growth good at 28–40 °C but none at 4 °C. Glucose broth reaches pH 6 in 10 d; no acetoin is formed. Gelatin is slowly liquefied. Nitrate is reduced to nitrite. Catalase-positive. Grows in 10% NaCl.

Source: Shore sand, Pacific ocean, California.

Original strain: ATCC 25098 NCIMB 1862.

f. "*Bacillus xerothermodurans*" Bond and Favero 1977, 159

Strictly aerobic rods, 0.7–1.2 by 1.6–2.8 μm, which are pleomorphic, especially in older cultures. Spores are spherical to oval, and swell the sporangia. Scanning electron microscopy of spores revealed a surface honeycomb pattern of polygonal depressions surrounded by straight ridges. Unusual ultrastructure with an irregular, thick outer spore coat composed of globular subunits and laminated inner spore coat containing up to nine distinct layers. Catalase-positive. Growth occurs in 10% NaCl broth. Potato starch is hydrolyzed. Reactions in other properties studied are negative. Cleaned spore preparations show extreme resistance to dry heat, the strain was isolated after heating dry samples at 125 °C for 48 h.

Source: Sandy soil, Cape Kennedy, Florida.

Original strain: ATCC 27380, DSM 520.

Misclassified species

16S rRNA gene sequence comparison studies indicate that the following species are currently misclassified within *Bacillus*. They await formal proposals of transfer to other genera:

To transfer to *Geobacillus*

Bacillus thermantarcticus (nom. corrig. *Bacillus thermoantarcticus* [sic]) Nicolaus, Lama, Esposito, Manca, di Prisco and Gambacorta (1996). corrig. *Bacillus thermantarcticus* Nicolaus, Lama, Esposito, Manca, di Prisco and Gambacorta 2002, 3^{VP} therm'ant.arct'ic.us. Gr. n. *therme* heat, N.L. adj. *antarcticus* from Antarctica, from Antarctic geothermal soil.

Aerobic, Gram-positive, motile rods, 0.6–2.0 μm wide and 3.0–5.0 μm long, with oval endospores which are borne terminally. Description is based on a single isolate. Colonies are opaque, flat and circular with entire margins. In stationary phase of growth an exopolysaccharide is produced. Catalase-negative, oxidase-positive. Temperature range for growth is 37–65 °C, and optimal growth occurs at 63 °C. Growth occurs in the pH range 5.5–9.0, and optimum is pH 6.0. Growth is weak in the presence of 2% NaCl but inhibited by 5% NaCl. Growth occurs on yeast extract. Glucose, trehalose and xylose can be utilized as sole carbon sources. Citrate and propionate are not utilized. Nitrate is not reduced. Gelatin and starch are hydrolyzed,

but casein is not hydrolyzed. Hippurate and tyrosine are not degraded. Exo- and endocellular α-glucosidases, an intracellular alcohol dehydrogenase and an exocellular xylanase are produced. The major fatty acids at 60 °C are C_{17:0 anteiso} (36% of total), C_{17:0 iso} (27%), C_{15:0 iso} (15%) and C_{16:0 iso} (13%) (Nicolaus et al., 1995).

DNA G + C content (mol%): 53.7.

Type strain: DSM 9572, strain M1.

EMBL/GenBank accession number (16S rRNA gene): not available.

To transfer to *Paenibacillus*

Bacillus edaphicus Shelobolina et al. 1998, 631^{VP} (Effective publication: Shelobolina et al. 1997, 688.)

e.daph'ic.us Gr. n. *edaphos* ground; L. masc. suff. *-icus* adjectival suffix used with the sense of belonging to; N.L. adj. *edaphicus* living in soil.

Strictly aerobic, chemo-organotrophic, nonmotile regular rods 1–1.5 by 4–10 μm in size. Produce mucous, smooth, transparent, convex colonies with even edges, 0.8–2.0 cm in diameter, on synthetic media with carbohydrates but devoid of nitrogen sources. Cells grown on such media are surrounded by mucous capsules 7–12 μm thick. Colonies are smooth, moist, light and flat, but raised in the center, and 0.5 cm in diameter, and with even edges when grown on potato agar and on synthetic media with carbohydrates and ammonium nitrogen. No growth occurs on nutrient agar or in nutrient broth. On media containing ammonium nitrogen, ellipsoidal endospores (1–1.2 × 1.7–2.0 μm) with eight to ten longitudinal ridge-like protusions are formed. Cell-wall structure is of Gram-positive type. Catalase-positive. Glucose is not fermented, and nitrate is not reduced. Starch and tyrosine are hydrolyzed but gelatin is not liquefied. Sugars and polyols are used as carbon and energy sources, and acid is produced from a range of carbohydrates. Cells are resistant to lysozyme. Palmitic, anteisopentadecanoic and stearic acids are the most frequent in the cellular lipids. Temperature range for growth is 7–45 °C.

Source: soil.

DNA G + C content (mol%): 54.6–56.5 (type strain, 56.4) (T_m).

Type strain: DSM 12974, VKPM B-7517, strain T7.

EMBL/GenBank accession number (16S rRNA gene): AF006076.

Bacillus mucilaginosus Avakyan et al. 1998, 631^{VP} (Effective publication: Avakyan et al. 1986, 480; emend. Shelobolina et al. 1998, 631^{VP}; effective publication: Shelobolina et al. 1997, 688.) mu.ci.la.gi.no'sus. L. masc. adj. *mucilaginosus* slimy.

Strictly aerobic, chemo-organotrophic, nonmotile, regular, round-ended rods, borne singly and 1–1.2 by 4–7 μm in size; they are surrounded by capsules. On potato agar colonies are light gray, smooth, even-edged, wet and shiny; they do not exceed 0.5 cm in diameter. On Ashby sucrose agar and on synthetic media with carbohydrates and ammonium nitrogen, colonies are convex, semitransparent, mucous, even-edged, of viscous consistency, and 0.5–1 cm in diameter. No growth occurs on nutrient agar or nutrient gelatin, or in nutrient broth. On media containing ammonium nitrogen, and on potato agar, oval endospores (1–1.2 × 1.7–2.0 μm) with nine longitudinal ridge-like protusions are formed. Spores are borne centrally and subterminally to give a fusiform appearance to sporangia. Sporulation does not occur on media lacking a nitrogen source. Cell-wall structure is of Gram-positive type, but Gram

staining may yield varying results. Catalase-positive. Glucose is not fermented, and nitrate is not reduced. Starch is hydrolyzed, but tyrosine is not, and gelatin is not liquefied. Carbohydrates, polyols, and some organic acids are used as carbon and energy sources, and acid is produced from a range of carbohydrates. Cells are resistant to lysozyme. Anteioisopentadecanoic, palmitic and stearic acids are the most frequent in the cellular lipids. Temperature range for growth is 10–45 °C.

Source: soil.

DNA G + C content (mol%): 55.8 (T_m).

Type strain: VKM B-1480D, VKPM B-7519.

EMBL/GenBank accession number (16S rRNA gene): AF006077.

Note added in proof

Between the completion of the manuscript and tables (in late 2004) and the time of going to press (late 2007), the following new *Bacillus* species names were validly published, and with one exception (on account of a short sequence for *Bacillus tequilensis*) they have been included in Figure 8:

Bacillus acideceler Peak et al. 2007, 2035^{VP}

a.ci.de'ce.ler. N.L. neut. n. *acidum*, acid, L. masc. adj. *celer*, fast, N.L. masc. adj. *acidiceler*, fast-growing in acid.

Gram-positive, endospore-forming rod, isolated from a forensic specimen considered a credible threat of harboring anthrax.

DNA G + C content (mol%): 37.3.

Type strain: strain CBD 119, DSM 18954 and NRRL B-41736.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): DQ374637.

Bacillus acidicola Richard, Archambault, Rosselló-Mora and Tindall 2005, 2129^{VP}

a.ci.di'co.la. N.L. n. *acidum* an acid; L. suff. *-cola* an inhabitant of a place, a resident; N.L. masc. n. *acidicola* an inhabitant of acidic environments.

Cells occur singly or in chains, and in liquid culture can form filamentous rods that are 1.0–1.3 µm wide.

Source: acidic *Sphagnum* peat bog.

DNA G + C content (mol%): 42.3.2 (HPLC).

Type strain: 10, DSM 14745, ATCC BAA-366, NRRL B-23453.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AF547209 (10).

Bacillus aerius Shivaji, Chaturvedi, Suresh, Reddy, Dutt, Wainwright, Narlikar and Bhargava 2006, 1471^{VP}

ae'ri.us. L. masc. adj. *aerius* pertaining to the air, aerial.

Shows high 16S rRNA gene sequence similarity with *Bacillus aerophilus*, *Bacillus licheniformis*, *Bacillus sonorensis* and *Bacillus stratosphericus*.

Source: air sample collected at high altitude.

DNA G + C content (mol%): 45 T_m .

Type strain: 24K, MTCC 7303, JCM 13348.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AJ831843 (24K).

Bacillus aerophilus Shivaji, Chaturvedi, Suresh, Reddy, Dutt, Wainwright, Narlikar and Bhargava 2006, 1471^{VP}

ae.ro.phi'lus. Gr. n. *aêr* air; Gr. adj. *philos* loving; N.L. masc. adj. *aerophilus* air-loving.

Shows high 16S rRNA gene sequence similarity with *Bacillus aerius*, *Bacillus licheniformis*, *Bacillus sonorensis* and *Bacillus stratosphericus*.

Source: air sample collected at high altitude.

DNA G + C content (mol%): 44 T_m .

Type strain: 28K, MTCC 7304, JCM 13347.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AJ831844 (28K).

Bacillus akibai Nogi, Takami and Horikoshi 2005, 2314^{VP}
a.ki.ba'i. N.L. gen. n. *akibai* of Akiba, named after the Japanese microbiologist Teruhiko Akiba, who made fundamental contributions to the study of alkaliphilic bacteria.

Related to *Bacillus krulwichiae*.

Source: preparation of carboxymethyl cellulase.

DNA G + C content (mol%): 34.4 (HPLC).

Type strain: 1139, JCM 9157, ATCC 43226.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AB043858 (1139).

Bacillus altitudinis Shivaji, Chaturvedi, Suresh, Reddy, Dutt, Wainwright, Narlikar and Bhargava 2006, 1472^{VP}

al.ti'tu.di.nis. L. fem. n. *altitudo* altitude; L. fem. gen. n. *altitudinis* of altitude.

Shows high 16S rRNA gene sequence similarity with *Bacillus pumilus*.

Source: air sample collected at high altitude.

DNA G + C content (mol%): 43 (T_m).

Type strain: 41KF2b, MTCC 7306, JCM 13350.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AJ831842 (41KF2b).

Bacillus alveayuensis Bae, Lee and Kim 2005, 1214^{VP}

al.ve.a.yu.en'sis. L. n. *alveus* trough; N.L. masc. adj. *ayuensis* pertaining to Ayu (as a locality); N.L. masc. adj. *alveayuensis* pertaining to the Ayu Trough in the Pacific Ocean.

Thermophile, growing at up to 65 °C and growing optimally at 3% NaCl but inhibited by 5% NaCl.

Source: deep-sea sediment.

DNA G + C content (mol%): 38.7 (T_m).

The type strain is TM1, KCTC 10634, JCM 12523.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY605232 (TM1).

Bacillus arenosi Heyrman, Rodríguez-Díaz, Devos, Felske, Logan and De Vos 2005b, 115^{VP}

ar.en.o'si. L. gen. n. *arenosi* of a sandy place.

Closely related to *Bacillus arvi*. Spherical endospores are borne terminally and swell the sporangia slightly; largely unreactive in routine biochemical tests.

Source: soil.

DNA G + C content (mol%): 35 (HPLC).

Type strain: LMG 22166, DSM 16319.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AJ627212 (LMG 22166).

Comment: this species has recently been reclassified as *Viridibacillus arenosi* (Albert et al., 2007).

Bacillus arsenicus Shivaji, Suresh, Chaturvedi, Dube and Sen-gupta 2005, 1126^{VP}

ar.sen.i'cus. N.L. masc. adj. *arsenicus* pertaining to arsenic.

Grows in the presence of 20 mM arsenate and 0.5 mM arsenite.

Source: arsenic ore.

DNA G + C content (mol%): 35 (T_m).

Type strain Con a/3, MTCC 4380, DSM 15822, JCM 12167.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AJ606700 (Con a/3).

Bacillus arvi Heyrman, Rodríguez-Díaz, Devos, Felske, Logan and De Vos 2005b, 115^{VP}
ar'vi. L. gen. n. *arvi* of a field.

Closely related to *Bacillus arenosi*. Spherical endospores are borne terminally and swell the sporangia slightly; acid is produced from few carbohydrates.

Source: soil.

DNA G + C content (mol%): 35 (HPLC).

Type strain LMG 22165, DSM 16317.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AJ627211 (LMG 22165).

Comment: this species has recently been reclassified as *Viridibacillus arvi* (Albert et al., 2007).

Bacillus axarquiensis Ruiz-García, Quesada, Martínez-Checa, Llamas, Urdaci and Béjar 2005b, 1282^{VP}
a.xar.qui.en'sis. N.L. adj. masc. *axarquiensis* pertaining to Axarquía, the Arabic name for the region surrounding the city of Málaga in Southern Spain.

Halotolerant, biosurfactant producer.

Source: brackish river sediment.

According to Wang et al. (2007b), *Bacillus axarquiensis* and *Bacillus malacitensis* are later heterotypic synonyms of *Bacillus mojavensis*.

DNA G + C content (mol%): 42.5 (T_m).

Type strain CR-119, CECT 5688, LMG 22476.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY603657 (CR-119).

Bacillus bogoriensis Vargas, Delgado, Hatti-Kaul and Mattiasson 2005, 901^{VP}
bo.gori.en'sis. N.L. adj. *bogoriensis* pertaining to Lake Bogoria, a soda lake in Kenya.

Grows in pH range 1 and tolerates 2 M NaCl.

Source: soda lake.

DNA G + C content (mol%): 37.5 (HPLC).

Type strain: LBB3, ATCC BAA-922, LMG 22234.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY376312 (LBB3).

Bacillus boroniphilus Ahmed, Yokota and Fujiwara 2007a, 893^{VP} (Effective publication: Ahmed, Yokota and Fujiwara 2007c, 222.)
boron.i.phi'lus. N.L. n. *boron-onis* boron; Gr. adj. *philos* loving; N.L. masc. adj. *boroniphilus* boron-loving.

Boron is required for growth and more than 450 mM is tolerated. Also tolerates up to 7.0% (w/v) NaCl in the presence of 50 mM B in agar medium but grows optimally without NaCl.

From naturally boron-containing soil of Hisarcik area in the Kutahya Province, Turkey.

DNA G + C content (mol%): 41.1–42.2.

Type strain: T-15Z, ATCC BAA-1204, DAM 17376, IAM 15287, JCM 21738.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AB198719 (T-15Z).

Bacillus cellulosityticus Nogi, Takami and Horikoshi 2005, 2314^{VP}

cell.u.lo.si.ly'ti.cus. N.L. neut. n. *cellulosum* cellulose; Gr. adj. *lutikos* able to loosen, able to dissolve; N.L. masc. adj. *cellulosityticus* cellulose-dissolving.

Grows at pH 0 with optimum of pH 0, and tolerates up to 12% NaCl.

Source: a cellulase preparation.

DNA G + C content (mol%): 39.6 (HPLC).

Type strain: N4, DSM 2522, JCM 9156, ATCC 21833, CCRC 15439, CIP 109017.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AB043852 (N4).

Bacillus cibi Yoon, Lee and Oh 2005c, 735^{VP}
ci'bi. L. n. *cibus* -i food; L. gen. n. *cibi* of food.

Produces orange-yellow colonies, and ellipsoidal endospores are borne centrally or subterminally in swollen sporangia.

Source: a fermented seafood.

DNA G + C content (mol%): 45 (HPLC).

Type strain: JG-30, KCTC 3880, DSM 16189.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY550276 (JG-30).

Bacillus chagannorensis Carrasco, Marquez, Xue, Ma, Cowan, Jones, Grant and Ventosa 2007, 2087^{VP}
N.L. masc. adj. *chagannorensis* pertaining to Lake Chagannor.

A Gram-positive, moderately halophilic, spore-forming bacterium isolated from a soda lake, Lake Chagannor, in the Inner Mongolia Autonomous Region, China.

DNA G + C content (mol%): 53.8.

Type strain: CG-15, CCM 7371, CECT 7153, CGMCC 1.6292 and DSM 18086.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AM492159.

Bacillus decisifrondis Zhang, Xu and Patel 2007, 977^{VP}
de.ci.si.fron'dis. L. part. adj. *decisus* thrown off, dead, died; L. n. *frons frondis* of/from foliage; N.L. gen. n. *decisifrondis* from thrown off decayed foliage.

Produces cream, round, smooth colonies, and cells are motile rods, producing subterminal spherical spores in swollen sporangia.

Source: soil underlying the decaying leaf litter of a slash pine forest located in south east Queensland, Australia.

DNA G + C content (mol%): 41±1 (T_m).

Type strain: E5HC-32, DSM 17725, JCM 13601.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): DQ465405 (E5HC-32).

Bacillus foraminis Tiago, Pires, Mendes, Morais, da Costa and Veríssimo 2006, 2573^{VP}
fo.ra'mi.nis. L. n. *foramen* -inis a hole; L. gen. n. *foraminis* from a hole.

Spores not observed and cells do not exhibit resistance to 80 °C for 8 min.

Source: highly alkaline, non-saline groundwater.

DNA G C content (mol%): 43.1 (HPLC).

Type strain: CV53, LMG 23174, CIP 108889.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AJ717382 (CV53).

Bacillus hemicellulosilyticus Nogi, Takami and Horikoshi 2005, 2312^{VP}

hem.i.cell.u.lo.si.ly'ti.cus. N.L. neut. n. *hemicellulosum* hemicellulose; Gr. adj. *lutikos* able to loosen, able to dissolve; N.L. masc. adj. *hemicellulosilyticus* hemicellulose-dissolving.

Grows at pH 1 with optimum of pH 10, and tolerates up to 12% NaCl.

Source: a hemicellulase preparation.

DNA G + C content (mol%): 36.8 (HPLC).

Type strain: C-11, JCM 9152, DSM 16731.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AB043846 (C-11).

Bacillus herbersteinensis Wieser, Worliczek, Kämpfer and Busse 2005, 2122^{VP}

her.ber.stein'en.sis. N.L. masc. adj. *herbersteinensis* pertaining to Castle Herberstein in Styria, in which the chapel with the medieval wall painting is located from which the type strain was isolated.

Wide ranges of carbohydrates and organic acids are assimilated, but many amino acids are not assimilated and acid is not produced from most carbohydrates.

Source: medieval wall painting.

DNA G + C content (mol%): 36.2–36.9 (HPLC).

Type strain: D-1,5a, DSM 16534, CCM 7228.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AJ781029 (D-1,5a).

Bacillus humi Heyrman, Rodríguez-Díaz, Devos, Felske, Logan and De Vos 2005b, 116^{VP}

hu'mi. L. gen. n. *humi* of earth, soil.

Ellipsoidal and sometimes spherical endospores are borne terminally and swell the sporangia slightly; acid is produced from a few carbohydrates.

Source: soil.

DNA G + C content (mol%): 37.5 (HPLC).

Type strain: LMG 22167, DSM 16318.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AJ627210 (LMG 22167).

Bacillus idriensis Ko, Oh, Lee, Lee, Lee, Peck, Lee and Song 2006, 2543^{VP}

id.ri.en'sis. N.L. masc. adj. *idriensis* arbitrary specific epithet pertaining to IDRI, the Infectious Disease Research Institute, where this study was performed.

Related to *Bacillus cibi*.

Source: blood of a neonate with sepsis.

DNA G + C content (mol%): 41.2 (T_m).

Type strain: SMC 435, KCCM 90024, JCM 13437.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY904033 (SMC 435).

Bacillus infantis Ko, Oh, Lee, Lee, Lee, Peck, Lee and Song 2006, 2543^{VP}

in.fan'tis. L. gen. n. *infantis* of an infant, baby, the putative source of the type strain.

Related to *Bacillus firmus*.

Source: blood of a neonate with sepsis.

DNA G + C content (mol%): 40.8 (T_m).

Type strain: SMC 435, KCCM 90025, JCM 13438.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY904032 (SMC 435).

Bacillus koreensis Lim et al. 2006b, 62^{VP}

ko.re.en'sis. N.L. masc. adj. *koreensis* pertaining to Korea.

Closest relative is *Bacillus flexus*.

Source: rhizosphere of willow.

DNA G + C content (mol%): 36 (HPLC).

Type strain: BR030, KCTC 3914, DSM 16467.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY667496 (BR030).

Bacillus kribbensis Lim et al. 2007, 2914^{VP}

krib.ben'sis. N.L. masc. adj. *kribbensis* arbitrary name formed from the acronym of the Korea Research Institute of Bioscience and Biotechnology, KRIBB, where taxonomic studies on this species were performed.

Source: a field used for potato cultivation in Jeju, Korea.

DNA G + C content (mol%): 43.3 (HPLC).

Type strain: BT080, KCTC 13934, DSM 17871).

GenBank/EMBL/DDBJ accession number (16S rRNA gene): DQ280367 (BT080).

Bacillus lehensis Ghosh, Bhardwaj, Satyanarayana, Khurana, Mayilraj and Jain 2007, 241^{VP}

le.hen'sis. N.L. masc. adj. *lehensis* pertaining to Leh, in India, where the type strain was isolated.

Colonies are circular, convex, smooth and pigmented creamish-yellow, and cells are aerobic, Gram-positive, motile rods producing subterminal oval spores in unswollen sporangia.

Source: soil collected from Leh, India.

DNA G + C content (mol%): 41, 4 (T_m).

Type strain: MLB2, MTCC 7633, JCM 13820.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY793550 (MLB2).

Bacillus litoralis Yoon and Oh 2005, 1947^{VP}

li.to.ra'lis. L. masc. adj. *litoralis* of the shore.

Optimal growth in 2–3% NaCl; no growth without NaCl or with >11% NaCl.

Source: tidal sediment of Yellow Sea in Korea.

DNA G + C content (mol%): 35.2 (HPLC).

Type strain: SW-211, KCTC 3898, DSM 16303.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY608605 (SW-211).

Bacillus macauensis Zhang, Fan, Hanada, Kamagata and Fang 2006, 352^{VP}

ma.cau.en'sis. N.L. masc. adj. *macauensis* pertaining to Macau, the city where the type strain was isolated. Forms long, unbranched chains of cells; related to unnamed deep-sea isolates, *Bacillus barbaricus* and *Bacillus megaterium*.

Source: a drinking water treatment plant.

DNA G + C content (mol%): 40.8 (HPLC).

Type strain: ZFHKF-1, JCM 13285, DSM 17262.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY373018 (ZFHKF-1).

Bacillus malacitensis Ruiz-Garcia, Quesada, Martínez-Checa, Llamas, Urdaci and Béjar 2005b, 1282^{VP}

ma.la.ci.ten'sis. L. adj. masc. *malacitensis* pertaining to Flavia Malacita, the Roman name for Málaga in southern Spain.

Halotolerant; surfactant producing.

Source: brackish river sediment.

DNA G + C content (mol%): 41 (T_m).

Type strain: CR-95, CECT 5687, LMG 22477.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY603656 (CR-95).

Comment: this species is considered as a heterotypic synonym of *Bacillus mojavensis* (Wang et al., 2007b).

Bacillus mannanilyticus Nogi, Takami and Horikoshi 2005, 2314^{VP}

mann.an.i.ly'ti.cus. N.L. neut. n. *mannanum* mannan; Gr. adj. *lutikos* able to loosen, able to dissolve; N.L. masc. adj. *mannilyticus* mannan-dissolving.

Produces yellow colonies; pH range for growth is 0 with optimum of pH 9.

Source: a β -mannosidase and β -mannanase preparation.

DNA G + C content (mol%): 37.4 (HPLC).

Type strain: AM-001, JCM 10596, DSM 16130.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AB043864 (AM-001).

Bacillus massiliensis Glazunova, Raoult and Roux 2006, 1487^{VP}

mas.si.li.en'sis. L. masc. adj. *massiliensis* of Massilia, the ancient Greek and Roman name for Marseille, France, where the type strain was isolated.

Member of *Bacillus sphaericus* group, forming terminal spherical spores that swell the sporangia. Closely related to species that have been transferred to the novel genus *Lysinibacillus* (Ahmed et al., 2007c), but data on peptidoglycan composition and polar lipids are not available for *Bacillus massiliensis*, and so it has not been transferred to the new genus.

Source: cerebrospinal fluid.

DNA G + C content (mol%) not reported.

Type strain: 4400831, CIP 108446, CCUG 49529.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY677116 (4400831).

Bacillus muralis Heyrman, Logan, Rodríguez-Díaz, Scheldeman, Lebbe, Swings, Heyndrickx and De Vos 2005a, 129^{VP}

mu.ra'lis. L. masc. adj. *muralis* pertaining or belonging to walls.

Related to *Bacillus simplex*.

Source: mural painting in a church in Germany.

DNA G + C content (mol%): 41.2 (HPLC).

Type strain: LMG 20238, DSM 16288.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AJ628748 (LMG 20238).

Bacillus murimartini Borchert, Nielsen, Graber, Kaesler, Szewyck, Pape, Antrnikian and Schäfer 2007, 2892^{VP}

mu.ri.mar.ti'ni. L. n. *murus* wall; N.L. gen. n. *martini* of Martin (masc. name of a saint); N.L. gen. n. *murimartini* from the wall of the (St) Martin church in Greene-Kreienzen, Germany.

Source: a church wall mural painting in Germany.

DNA G + C content (mol%): 39.6.

Type strain: type strain LMG 21005 and NCIMB 14102.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AJ880003.

Bacillus niabensis Kwon, Lee, Kim, Weon, Kim, Go and Lee 2007, 1910^{VP}

niab.en'sis. N.L. masc. adj. *niabensis* arbitrary name formed from NIAB, the acronym for the National Institute of Agricultural Biotechnology, Korea, where taxonomic studies on this species were performed.

Colonies are yellowish-white, 2–3 mm in diameter, and circular with clear margins, and cells are motile, by means of single polar flagella. Forms ellipsoidal or oval spores that lie subterminally or terminally in swollen sporangia.

Source: cotton-waste composts in Suwon, Korea.

DNA G + C content (mol%): 37.7–40.9 (HPLC).

Type strain: 4T19, KACC 11279, DSM 17723.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY998119 (4T19).

Bacillus okhensis Nowlan, Dodia, Singh and Patel 2006, 1076^{VP}

ok.hen'sis. N.L. masc. adj. *okhensis* pertaining to Port Okha, a port of the Dwarka region in India, where the type strain was isolated.

Halotolerant and related to *Bacillus kruckwischiae*, bears a subterminal tuft of flagella, but spores have not been detected.

Source: soil of natural saltpan.

DNA G + C content (mol%): 41 (T_m).

Type strain: Kh101, JCM 13040, ATCC BAA-1137.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): DQ026060 (ATCC BAA-1137).

Bacillus oshimensis Yumoto, Hirota, Goto, Nodasaka and Nakajima 2005a, 910^{VP}

o'shi.men.sis. N.L. masc. adj. *oshimensis* from Oshima, the region where the micro-organism was isolated.

Grows in 0–20% NaCl, with 7% NaCl optimal; grows from pH 7, with pH 10 optimal.

Source: soil.

DNA G + C content (mol%): 40.8 (HPLC).

Type strain: K11, JCM 12663, NCIMB 14023.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AB188090 (K11).

Bacillus panaciterrae Ten, Baek, Im, Liu, Aslam and Lee 2006, 2864^{VP}

pa.na.ci.ter'rae. N.L. n. *Panax -acis* scientific name for ginseng; L. n. *terra* soil; N.L. gen. n. *panaciterrae* of soil of a ginseng field.

Utilizes a wide range of carbohydrates, amino acids and organic acids, and hydrolyzes chitin; forms ellipsoidal endospores centrally in swollen sporangia.

Source: soil.

DNA G + C content (mol%): 47.8 (HPLC).

Type strain: Gsoil 1517, KCTC 13929, CCUG 52470, LMG 23408.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AB245380 (Gsoil 1517).

Bacillus patagoniensis Olivera et al. 2005, 446^{VP}

pa.ta.go'ni.en.sis. N.L. masc. adj. *patagoniensis* pertaining to Patagonia, in Argentina, where the type strain was isolated.

Alkalitolerant and halotolerant.

Source: desert soil rhizosphere.

DNA G + C content (mol%): 39.7 (HPLC).

Type strain: PAT 05, DSM 16117, ATCC BAA-965.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY258614 (PAT 05).

Bacillus plakortidis Borchert, Nielsen, Graber, Kaesler, Szewyck, Pape, Antranikian and Schäfer 2007, 2892^{VP}

Source: material from the sponge *Plakortis simplex* that was obtained from the Sula-Ridge, Norwegian Sea.

DNA G + C content (mol%): 41.1.

Type strain: P203, DSM 19153 and NCIMB 14288.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AJ880003.

Bacillus pocheonensis Ten, Baek, Im, Larin, Lee, Oh and Lee 2007, 2535^{VP}

N.L. masc. adj. *pocheonensis* pertaining to Pocheon Province in South Korea.

A Gram-positive, nonmotile, endospore-forming rod.

Source: soil of a ginseng field in Pocheon Province, South Korea.

DNA G + C content (mol%): 44.9.

Type strain: Gsoil 420, KCTC 13943 and DSM 18135.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AB245377.

Bacillus qingdaonensis Wang, Li, Liu, Cao, Li and Guo 2007c, 1146^{VP}

qing.da.o.nen'sis. N.L. masc. adj. *qingdaonensis* pertaining to Qingdao, the name of the place from which the type strain was isolated.

A moderately haloalkaliphilic, aerobic, rod-shaped, nonmotile, Gram-positive organism capable of growth at salinities of 2.5–20% (w/v) NaCl. Spores were not observed.

Source: a crude sea-salt sample collected near Qingdao in eastern China.

DNA G + C content (mol%): 48 (HPLC).

Type strain: CM1, CGMCC 1.6134, JCM 14087.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): DQ115802 (CM1).

Bacillus ruris Heyndrickx, Scheldeman, Forsyth, Lebbe, Rodríguez-Díaz, Logan and De Vos 2005, 2553^{VP}

ru'ris. L. neut. n. *rur* the country, the farm; L. gen. n. *ruris* from the country, the farm.

Related to *Bacillus galactosidilyticus*.

Source: raw milk and dairy cattle feed concentrate.

DNA G + C content (mol%): 39.2 (HPLC).

Type strain: LMG 22866. DSM 17057.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AJ535639 (LMG 22866).

Bacillus safensis Satomi, La Duc and Venkateswaran 2006, 1739^{VP}

sa.fen'sis. N.L. masc. adj. *safensis* arbitrarily derived from SAF, the spacecraft-assembly facility at the Jet Propulsion Laboratory, Pasadena, CA, USA, from where the organism was first isolated.

Closely related to *Bacillus pumilus* on basis of 16S rRNA and *gyrB* gene sequences.

Source: a spacecraft-assembly plant.

DNA G + C content (mol%): 41.1.4 (HPLC).

Type strain: FO-36b, ATCC BAA-1126, NBRC 100820.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AF234854 (FO-36b).

Bacillus salarius Lim et al. 2006c, 376^{VP}

sa.la'ri.us. L. masc. adj. *salarius* of or belonging to salt.

Member of the alkaliphilic group (Group 6 of Nielsen et al., 1994) of *Bacillus*; grows at 0% NaCl, with optimum of 12% NaCl, and at pH 6.5 with optimum pH of 8.

Source: sediment of a salt lake.

DNA G + C content (mol%): 43 (HPLC).

Type strain: BH169, KCTC 3912, DSM 16461.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY667494 (BH169).

Bacillus saliphilus Romano, Lama, Nicolaus, Gambacorta and Giordano 2005a, 162^{VP}

sal.i.phi'lus. L. n. *sal* salt; Gr. adj. *philos* loving; N.L. masc. adj. *saliphilus* salt-loving.

A coccoid member of the alkaliphilic group (Group 6 of Nielsen et al., 1994) of *Bacillus*; grows at 5% NaCl, with optimum of 16% NaCl, and at pH 0 with optimum pH of 9. Spores not reported.

Source: green algal mat in a mineral pool.

DNA G + C content (mol%): 48.4 (HPLC).

Type strain: 6AG, DSM 15402, ATCC BAA-957.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AJ493660 (6AG).

Bacillus selenatarsenatis Yamamura, Yamashita, Fujimoto, Kuroda, Kashiwa, Sei, Fujita and Ike 2007, 1063^{VP}

se'le.nat.ar.se.na'tis. N.L. gen. n. *selenatis* of selenate; N.L. gen. n. *arsenatis* of arsenate; N.L. gen. n. *selenatarsenatis* of selenate and arsenate.

Gram-positive, spore-forming, motile rods. Colonies are round and white. Selenate is reduced to elemental selenium via the intermediate selenite, arsenate to arsenite and nitrate to ammonia via the intermediate nitrite.

Source: an effluent drain in a glass-manufacturing plant in Japan.

DNA G + C content (mol%): 42.8 (HPLC).

Type strain: SF-1, JCM 14380, DSM 18680.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AB262082 (SF-1).

Bacillus seohaeanensis Lee, Lim, Park, Jeon, Li and Kim 2006a, 1896^{VP}

seo.hae.an.en'sis. N.L. masc. adj. *seohaeanensis* of Seohaean, the Korean name for the west coast of Korea, where the type strain was isolated.

Related to *Bacillus aquimaris* and *Bacillus marisflavi*.

Source: a solar saltern.

DNA G + C content (mol%): 39 (HPLC).

Type strain: BH724, KCTC 3913, DSM 16464.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY667495 (BH724).

Bacillus stratosphericus Shivaji, Chaturvedi, Suresh, Reddy, Dutt, Wainwright, Narlikar and Bhargava 2006, 1471^{VP}

stra.to.sphe.ri'cus. N.L. fem. n. *stratosphera* stratosphere; L. suff. *-icus* adjectival suffix used with the sense of belonging

to; N.L. masc. adj. *stratosphericus* belonging to the stratosphere.

Shows high 16S rRNA gene sequence similarity with *Bacillus aerius*, *Bacillus aerophilus*, *Bacillus licheniformis* and *Bacillus sonensis*.

Source: air sample collected at high altitude.

DNA G + C content (mol%): 44 (T_m).

Type strain: 41KF2a, MTCC 7305, JCM 13349.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AJ831841 (41KF2a).

Bacillus taeanensis Lim, Jeon and Kim 2006a, 2905^{VP} *tae.an.en'sis*. N.L. masc. adj. *taeanensis* belonging to Taean, where the organism was isolated.

Neutrophilic and halotolerant, with optimum growth at 2–5% NaCl.

Source: solar saltern.

DNA G + C content (mol%): 36 (HPLC).

Type strain: BH030017, KCTC 3918, DSM 16466.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY603978 (BH030017).

Bacillus tequilensis Gatson, Benz, Chandrasekaran, Satomi, Venkateswaran and Hart 2006, 1481^{VP} *te.qui.len'sis*. N.L. masc. adj. *tequilensis* referring to Tequila, Mexico.

Member of the *Bacillus subtilis* group.

Source: Mexican shaft tomb sealed in approximately 74 AD.

DNA G + C content (mol%): not reported.

Type strain: 10b, ATCC BAA-819, NCTC 13306.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY197613; AY197613 (10b); the sequence contains only 549 bp and was therefore not included in the phylogenetic tree (Figure 8).

Bacillus thioparans Pérez-Ibarra, Flores and Garica-Varela 2007a, 1933^{VP} (Effective publication: Pérez-Ibarra, Flores and Garica-Varela 2007b, 295.)

thi.o'parus. Gr. n. *thios* sulfur; L. v. *paro* to produce; M.L. adj. *thioparus* sulfur-producing.

Source: a continuous wastewater treatment culture system operating with a bacterial consortium. Gram-variable, aerobic, moderately halotolerant, motile and endospore-forming rods.

DNA G + C content (mol%): 43.8 (T_m).

Type strain: BMP-1, BM-B-436 and CECT 7196.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): DQ371431.

Bacillus velezensis Ruiz-Garcia, Béjar, Martínez-Checa, Llamas and Quesada 2005a, 195^{VP}

vel.e.zen'sis. N.L. adj. masc. *velezensis* pertaining to Vélez, named thus for being first isolated from the river Vélez in Málaga, southern Spain.

Member of the *Bacillus subtilis* group.

Source: mouth of River Vélez, Spain.

DNA G + C content (mol%): 46.6.4 (T_m).

Type strain: CR-502, CECT 5686, LMG 22478.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY603658 (CR-502).

Bacillus wakoensis Nogi, Takami and Horikoshi 2005, 2312^{VP} *wa.ko.en'sis*. N.L. masc. adj. *wakoensis* of Wako, a city in Japan.

Related to *Bacillus krulwichiae*.

Source: preparation of cellulase.

DNA G + C content (mol%): 38.1 (HPLC).

Type strain: N-1, JCM 9140, DSM 2521.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AB043851 (N-1).

Genus II. *Alkalibacillus* Jeon, Lim, Lee, Xu, Jiang and Kim 2005b, 1894^{VP}

PAUL DE VOS

Al.ka.li.ba.cil'lus. N.L. n. *alkali* alkali; L. n. *bacillus* rod; N.L. masc. n. *Alkalibacillus* bacillus living under alkaline conditions.

Rod-shaped, Gram-positive (may be Gram-variable in older cultures) bacterium. Mostly long cells, 0.8–1.6 µm in diameter and 2.0–7.0 µm in length. Endospores are spherical and located terminally in swollen sporangia. Cell-wall peptidoglycan is of the A1γ type and *meso*-diaminopimelic acid is the diamino acid. Obligately aerobic. Cells are motile by peritrichous or polar flagella. MK-7 is always present as the major isoprenoid quinone; in one species, DeMK-6 is also found. The predominant fatty acids are C_{15:0 iso}, C_{15:0 ante} and C_{17:0 ante}. Phylogenetically, the genus belongs to the family *Bacillaceae*.

DNA G + C content (mol%): 37–41.

Type species: *Alkalibacillus haloalkaliphilus* (Fritze 1996a) Jeon, Lim, Lee, Xu, Jiang and Kim 2005b, 1894^{VP} (*Bacillus haloalkaliphilus* Fritze 1996a, 100).

Further descriptive information

Representatives of this genus were first described by Fritze (1996a). Colonies are creamy to white on salt-containing media. Except for strains of one species, no growth occurs on media without NaCl; optimal NaCl concentration for growth

is about 10%. The pH range for growth is 7.0–10.0 for most species, except for one which grows at pH 7.0–9.0; the optimal pH varies from 8.0 to 9.7 depending on the species. The temperature range for growth is from about 15 to 50 °C, with optimal growth between 30 °C and 37 °C. Enrichment media have been used in isolation campaigns. Media compositions can be found in the literature (Fritze, 1996a; Jeon et al., 2005b; Ren and Zhou, 2005b; Romano et al., 2005b; Usami et al., 2007), but always contain complex organic mixtures such as Casamino acids and yeast extract. Although nearly all strains need a relatively high concentration of salt, some were isolated from non-salty environments such as forest soil. In these particular cases, their role in the ecosystem is unclear. Members of the genus are widespread because they have been retrieved from various geographical regions.

Taxonomic comments

The genus *Alkalibacillus* now encompasses four species and was separated from the genus *Bacillus* by the reclassification of *Bacillus haloalkaliphilus*. Phylogenetically, members of the

genus *Alkalibacillus* are most closely related to those of the moderately halophilic genera *Tenuibacillus* and *Filobacillus*. A fifth species, "*Alkalibacillus halophilus*", which accommodates isolates from hypersaline soil in China has been isolated, but its name has not yet been validly published (Tian et al., 2007). 16S rRNA gene sequence analysis revealed that the closest phylogenetic relatives of the type species, *Alkalibacillus haloalkaliphilus*, are members of the recently described genera *Tenuibacillus* (Ren and Zhou, 2005b) and *Filobacillus* (Schlesner et al., 2001). The physiological characteristics of these

genera are very similar. Differences at the generic level are observed in cell-wall composition: in *Alkalibacillus*, the murein is of the A1 γ type, whereas it is of the A4 β type in *Filobacillus*. The microbiologist who wants to apply physiological tests for comparative analysis at the species/strain level should be aware that different incubation conditions may result in different characteristics. The question may be raised whether these genera, members of which differ by less than 4% in their 16S rRNA gene sequences, should not be reclassified into a single genus.

List of species of the genus *Alkalibacillus*

1. ***Alkalibacillus haloalkaliphilus*** (Fritze 1996a) Jeon, Lim, Lee, Xu, Jiang and Kim 2005b, 1894^{VP} (*Bacillus haloalkaliphilus* Fritze 1996a, 100).

ha.l.o.al.ka.li'phi.us. Gr. n. *hals* salt; N.L. n. *alkali* alkali; Gr. adj. *philos* loving; M.L. adj. *haloalkaliphilus* loving briny and alkaline media.

Strictly alkaliphilic, halophilic, and extremely halotolerant motile rods and filaments. Forms spherical spores that lie terminally and swell the sporangia. Cells are 0.3–0.5 \times 3.0–8.0 μ m. Colonies on alkaline nutrient agar supplemented with 5–10% NaCl are creamy-white, whereas with 20% NaCl they are yellowish. Grows at 15 and 40 °C. Optimal growth occurs at pH 9.7 or above; no growth is seen at pH 7.0. Grows in 20–25% NaCl; no growth or only very weak growth occurs without added NaCl and optimal sporulation occurs at 5% NaCl. Nitrate is not reduced to nitrite. Hippurate and 4-methyl-umbelliferone-glucuronide are hydrolyzed. Gelatin and starch are hydrolyzed weakly. Casein hydrolysis may be positive, weak or negative. Pullulan, Tween 20, and 80, and urea are not hydrolyzed. Strains have been isolated from brine, camel dung, loam, mud, and salt at Wadi Natrun, Egypt.

DNA G + C content (mol%): 37 (Bd) to 38 (HPLC).

Type strain: WN13, ATCC 700606, DSM 5271, LMG 17943, NCIMB 13457.

EMBL/GenBank accession number (16S rRNA gene): X72876 (DSM 5271).

2. ***Alkalibacillus filiformis*** Romano, Lama, Nicolaus, Gambacorta and Giordano 2005b, 2397^{VP}

fi.li.for'mis. L. neut. n. *filum* a thread; L. suff. *-formis*-like, of the shape of; N.L. masc. adj. *filiformis* thread-shaped.

Cells are Gram-positive, sporulating rods, 0.25–0.30 μ m in width and 9.0–11.0 μ m long. The terminally spherical endospores are located in swollen sporangia. Smooth, convex, and regular circular, white to transparent colonies are obtained on enrichment medium 1 (Romano et al., 2005b). Growth occurs between 15 °C and 45 °C, with optimal growth at 30 °C in media at pH 7–10 (optimal pH 9.0). Growth occurs in media without added NaCl, but is optimal in media with 10% salt added; one strain is known to tolerate up to 18% NaCl. In addition to the characteristics that allow species differentiation (Table 10), *Alkalibacillus filiformis* is able to grow on glucose as sole carbon source, does not hydrolyze phenylalanine, and does not reduce nitrate. Catalase reaction is weak. Shows α -glucosidase activity.

Menaquinones found are MK-7 (70%) and DeMK-6 (30%); phosphatidylglycerol and diphosphatidylglycerol are the predominant lipids. The major fatty acids are C_{15:0 iso}, C_{15:0 ante}, C_{16:0 iso}, C_{16:0}, C_{17:0 iso}, and C_{17:0 ante}. The cell wall is of type A1 γ (*meso*-diaminopimelic acid directly cross-linked). Accumulates glycine betaine (major component) and glutamate (minor component) for osmoprotection. The closest neighbor phylogenetically is *Alkalibacillus haloalkaliphilus* on the basis of 16S rRNA gene sequence analysis. Antibiotic sensitivity data are given in Romano et al. (2005b). The type strain was isolated from water of a small mineral pool with gas bubbles at the Malvizza site (Montecalvo Irpino, Campania Region, Italy).

DNA G + C content (mol%): 39.5 (HPLC).

Type strain: 4AG, DSM 15448, ATCC BAA-956.

EMBL/GenBank accession number (16S rRNA gene): AJ493661 (4AG).

3. ***Alkalibacillus salilacus*** Jeon, Lim, Lee, Xu, Jiang and Kim 2005b, 1895^{VP}

sa.li.lac'us. L. n. *sal* salt; L. n. *lacus* lake; N.L. gen. masc. n. *salilacus* of a salt lake.

Gram-positive motile rods of approximately 0.4–0.5 μ m wide and 1.6–3.0 μ m long. Spherical spores are formed terminally in swollen sporangia. Growth occurs at 15–40 °C, pH 7.0–9.0 and 5–20% (w/v) NaCl. Colonies on marine agar (MA) supplemented with 10% NaCl are cream, smooth, low convex, and circular/slightly irregular. Catalase-positive and oxidase-negative. Nitrate is reduced to nitrite. In addition to the characteristics given in Table 10, does not hydrolyze Tween 80, L-tyrosine, hypoxanthine, xanthine, or urea. Furthermore, in addition to the sugars and sugar alcohols mentioned in Table 10, acid is produced from L-arabinose, D-ribose, and α -D-lactose, but not from D-glucose, glycerol, D-xylose, L-rhamnose, adonitol, D-raffinose, arbutin, D-salicin, D-melibiose, or D-mannose. The predominant cellular fatty acids are C_{15:0 ante}, C_{15:0 iso}, C_{17:0 ante}, and C_{16:0 iso}. The type strain was isolated from a salt lake in the Xinjiang province of China.

DNA G + C content (mol%): 41.0 (HPLC).

Type strain: BH163, KCTC 3916, DSM 16460.

EMBL/GenBank accession number (16S rRNA gene): AY671976 (BH163).

4. ***Alkalibacillus silvisoli*** Usami, Echigo, Fukushima, Mizuki, Yoshida and Kamekura 2007, 773^{VP}

^aData are based on Table 1 in Usami et al. (2007). w, Weak.

Cells are Gram-positive (may become Gram-variable in old cultures) motile rods of 0.3–0.5 × 4.0–7.0 μm in size with a single polar flagella. Endospores are located terminally in swollen sporangia. The A1γ type of peptidoglycan is present with *meso*-diaminopimelic acid. Colonies in media with 10% NaCl are creamy and opaque. Growth occurs at NaCl concentrations between 5.0% and 25.0% (w/v) for the type strain, although a second strain can grow in media without added NaCl. Optimum concentration is again strain dependent and is 10.0–15.0% (w/v) for the type strain. The optimal pH range for growth may also be strain dependent and is between pH 8.5 and 9.5; growth is observed at pH 7.0–10.0. The temperature range observed varies from 20 °C to 50 °C (optimal 30–37 °C). Strictly aerobic. In addition to sugars given in Table 10, acid is produced from sucrose, but not from D-glucose or D-xylose. Catalase-positive

and oxidase-negative. Does not hydrolyze DNA, pullulan, or Tween 80. Does not reduce nitrate and gas production is not observed. Antibiotic sensitivity data are given in Usami et al. (2007). The predominant isoprenoid quinone is MK-7. The major cellular fatty acids are, in order of importance, C_{15:0 iso}, C_{17:0 ante}, C_{15:0 ante}, C_{16:0 iso}, C_{17:0 iso}, and C_{16:0 ante}. The type strain was isolated from non-saline surface soil from a forest in Kawagoe, Saitama Prefecture, Japan. A second strain, HN₂ (which has not yet been deposited in a culture collection), was isolated from non-saline surface soil from a forest in Yachiyo, Chiba Prefecture, Japan.

DNA G + C content (mol %): 37.0 (HPLC).

Type strain: BM2, JCM 14193, DSM 18495.

EMBL/GenBank accession number (16S rRNA gene): AB264528 (BM2).

Genus III. **Amphibacillus** Niimura, Koh, Yanagida, Suzuki, Komagata and Kozaki 1990, 299^{VP} emend. An, Ishikawa, Kasai, Goto and Yokota 2007b, 2492

YOUICHI NIIMURA AND KEN-ICHIRO SUZUKI

Am.phi.ba.cil'lus. Gr. pref. *amphi* both sides or double; L. dim. n. *bacillus* a small rod; N.L. masc. n. *Amphibacillus* rod capable of both aerobic and anaerobic growth.

Cells are rods, occurring singly, in pairs or, sometimes, in short chains. Gram-positive, or Gram-positive in the very early stages of growth and loosely Gram-positive in the stationary growth phase. Cells are motile by means of flagella or nonmotile. Heat-resistant. Oval endospores are formed in terminal or center position, but sometimes sporangia are rapidly lysed and the spores are liberated. Growth is good in both well-aerated and strictly anaerobic liquid media, and also on aerobic agar plates and anaerobic plates. Cell yields and growth rates

are almost the same under all these conditions. Growth does not occur in the absence of glucose under either aerobic or anaerobic conditions. Chemo-organotrophic. Main products from glucose are ethanol, acetic acid, and formic acid under anaerobic conditions and acetic acid under aerobic conditions. Lactic acid is sometimes produced under aerobic and anaerobic conditions. Alkaliphilic, sometimes halophilic or halotolerant. Respiratory quinones, cytochromes, and catalase are absent. Located within the phylogenetic group composed

of halophilic/halotolerant/alkaliphilic and/or alkalitolerant genera in *Bacillus* rRNA group 1.

DNA G + C content (mol%): 36–41.5 (T_m).

Type species: *Amphibacillus xylanus* Niimura, Koh, Yanagida, Suzuki, Komagata and Kozaki 1990, 300^{VP}.

Further descriptive information

The catalase test is an important and useful test for characterization and differentiation of facultatively anaerobic spore-forming bacilli. The presence of catalase is generally determined by the formation of bubbles from cells put in 3% H_2O_2 . When cells of *Amphibacillus fermentum* and *Amphibacillus tropicus* are cultured in high concentrations of Na_2CO_3 , small bubbles that are not caused by the catalase reaction are sometimes formed in the catalase test 2–3 min after mixing. The catalase reaction can be clearly distinguished from the reactions like that shown above by using a positive control, i.e., a catalase-positive strain such as *Bacillus subtilis*, because the true catalase reaction produces a lot of bubbles rapidly as soon as cells are put into H_2O_2 solution. Spectrophotometric analysis of catalase using cell-free extract also showed that *Amphibacillus fermentum* and *Amphibacillus tropicus* clearly lack catalase. Spectrophotometric analysis of catalase is useful for determination of the catalase reaction in cells cultured in high concentrations of Na_2CO_3 . Therefore, strains of the genus *Amphibacillus* are catalase-negative, as stated above in the genus description; however, the original descriptions of *Amphibacillus fermentum* and *Amphibacillus tropicus* indicate that they are catalase-positive (Zhilina et al., 2001a).

Amphibacillus xylanus, the type species of the genus, in spite of lacking a respiratory system and catalase, grows well on plates and in liquid cultures under both strictly anaerobic and aerobic conditions. *Amphibacillus xylanus* is distinctive in this trait from other facultative anaerobes. This characteristic is due to the presence of anaerobic and aerobic pathways producing similar amounts of ATP (Figure 11) (Nishiyama et al., 2001). Accordingly, it has been suggested that *Amphibacillus fermentum* and *Amphibacillus tropicus* have two major metabolic systems, as observed in *Amphibacillus xylanus*. However, it has also been suggested that these two species

differ from *Amphibacillus xylanus* in that they have a side enzymic pathway that produces lactic acid under both aerobic and anaerobic conditions (Y. Niimura and others, unpublished data).

During anaerobic metabolism in *Amphibacillus xylanus*, NADH formed from NAD^+ in the glycolytic pathway is reoxidized by NAD-linked aldehyde dehydrogenase and NAD-linked alcohol dehydrogenase. NADH produced by both the glycolytic pathway and pyruvate metabolism of the aerobic pathway should be oxidized to NAD during the reduction of oxygen to water by the NADH oxidase-Prx system, which provides metabolic balance in the aerobic pathway in *Amphibacillus xylanus*. The NADH oxidase-Prx system, which shows extremely high turnover numbers and low K_m values for peroxides, is induced markedly in the presence of hydrogen peroxide. Thus, the *Amphibacillus xylanus* NADH oxidase-Prx system plays an important role not only as an NAD-regenerating system, but also in removing peroxides in the bacterium, which lacks both a respiratory chain and catalase, conventional peroxide-removing enzymes. Enzyme assays and immunoblot analysis revealed that NADH oxidase participates in oxygen metabolism instead of the respiratory system in *Amphibacillus fermentum* and *Amphibacillus tropicus*, as in *Amphibacillus xylanus*, and the NADH oxidase-Prx system may also function as a peroxide-reduction system in *Amphibacillus tropicus* as well as in *Amphibacillus xylanus* (Y. Niimura and others, unpublished data).

Amphibacillus species are alkaliphilic, as they grow optimally at pH values above 8.5. In contrast to *Amphibacillus xylanus*, *Amphibacillus fermentum* and *Amphibacillus tropicus* are halophiles. The optimum NaCl concentrations for growth of *Amphibacillus fermentum* and *Amphibacillus tropicus* are 10.8% and between 5.4% and 10.8%, respectively. *Amphibacillus fermentum* and *Amphibacillus tropicus* do not require chloride ions, but need sodium ions and carbonate, having an obligate requirement for sodium carbonate: growth is observed after the replacement of NaCl with an equimolar amount of $Na_2CO_3 + NaHCO_3$.

Amphibacillus species require carbohydrates represented by glucose for growth in both aerobic and anaerobic conditions. A wide variety of mono-, oligo-, and polysaccharides is utilized under both conditions.

Enrichment and isolation procedures

The strains of the genus *Amphibacillus* isolated so far are alkaliphilic and show good growth on sugars under anaerobic conditions (Niimura et al., 1987, 1989). Therefore, alkaline media containing carbohydrates are used for isolation. Cultivation for enrichment and isolation is carried out anaerobically. Strains of *Amphibacillus xylanus* were isolated from alkaliphilic composts of manure with grass and rice straw in Japan. *Amphibacillus fermentum* and *Amphibacillus tropicus* were isolated during dry and rainy periods, respectively, from bottom sediment of a coastal lagoon of Lake Magadi, Kenya (Zhilina et al., 2001a). Successive enrichment cultures were applied under strictly anaerobic conditions with nitrogen and a reducing agent, titanium (III) citrate for *Amphibacillus xylanus* and Na_2S for *Amphibacillus fermentum* and *Amphibacillus tropicus*. Titanium (III) citrate is added just before use. The enrichment medium (I) for *Amphibacillus xylanus* is alkaliphilic (pH 10) and contains Na_2CO_3 solution and the enrichment medium (II) for *Amphibacillus fermentum* and *Amphibacillus tropicus* is also alkaliphilic (pH 10), containing 2.65 M Na^+ (0.9 M NaCl, 0.6 M Na_2CO_3 , and 0.55 M $NaHCO_3$). Alkaline solution ($Na_2CO_3/NaHCO_3$) is sterilized separately by filtration and mixed with the basal medium, which is sterilized just before use.

Numbers at branches indicate the confidence limits estimated by bootstrap analysis with 1,000 resampling trials (shown only for the major clusters). Tree courtesy of M. Miyashita.

Maintenance procedures

Strains of *Amphibacillus xylanus* are maintained on anaerobic culture medium containing xylan as a carbon source and stored at 5 °C at 1- to 2-month intervals. For long-term preservation, freezing and freeze-drying are used. Cells are harvested and resuspended in neutral media containing 10% glycerol or DMSO for freezing preservation and stored at -80 °C or lower. For drying, cells are suspended in 10% skim milk containing 1% monosodium L-glutamate for freeze-drying or in 0.1 M potassium phosphate buffer (pH 7.0) containing 3% monosodium L-glutamate, 1.5% adonitol, and 0.05% HCl-L-cysteine for

liquid drying. Handling of cell suspensions under anaerobic conditions is not necessary.

Differentiation of the genus *Amphibacillus* from other genera

The genus *Amphibacillus* is classified in the family *Bacillaceae*, a large family of aerobic Gram-positive low-G + C-containing bacteria. The three species of the genus *Amphibacillus* constitute an independent line of descent within the group composed of halophilic/halotolerant/alkaliphilic and/or alkalitolerant members in rRNA group 1 of the genus *Bacillus* based on 16S rRNA gene sequences and occupy a phylogenetic position closely related to the genera *Halolactibacillus*, *Paraliobacillus*, and *Gracilibacillus* (Figure 12).

The similarity values of the type strain of *Amphibacillus xylanus* to the type strains of *Gracilibacillus dipsosauri*, *Gracilibacillus halotolerans*, *Halolactibacillus halophilus*, *Halolactibacillus miurensis*, and *Paraliobacillus ryukyuensis* are ~92.9–93.9%. In contrast, the similarity values of the type strain of *Amphibacillus xylanus* to those of *Amphibacillus fermentum* and *Amphibacillus tropicus* are 93.4% and 94.0%, respectively.

The three species of the genus *Amphibacillus* share physiological, biochemical, and chemotaxonomic characteristics in common and can be distinguished clearly from members of the genera *Gracilibacillus* and *Paraliobacillus* in the HA group by their lack of catalase, cytochromes, and quinones (Table 11) (Ishikawa et al., 2002). The *Amphibacillus* species can be differentiated from *Halolactibacillus* by spore formation, main metabolic products, and good growth under both anaerobic and aerobic conditions (Ishikawa et al., 2005). The main metabolic product of *Halolactibacillus* species is lactic acid, in contrast to the main products of *Amphibacillus xylanus*, which are formic acid, acetic acid, and ethanol. In addition to production of formic acid, acetic acid, and ethanol, *Amphibacillus fermentum* and *Amphibacillus tropicus* also produce lactic acid like *Halolactibacillus* species (Y. Niimura and others, unpublished data). This phenotypic trait in metabolism and 16S rRNA gene sequence similarity indicate that the positions of *Amphibacillus fermentum* and *Amphibacillus tropicus* may be rather closer to members of the genus *Halolactibacillus* than those of the genus *Amphibacillus*.

List of species of the genus *Amphibacillus*

1. ***Amphibacillus xylanus*** Niimura, Koh, Yanagida, Suzuki, Komagata and Kozaki 1990, 300^{VP}
xy.la'nus. N.L. adj. *xylanus* pertaining to xylan.

The characteristics are as described for the genus and listed in Table 11. Cells are motile by means of flagella or nonmotile (type strain is nonmotile). In aerobic and anaerobic cultures, colonies on glucose agar are small, circular, smooth, convex, entire, and white after 1 d of incubation. Cells are rods, 0.3–0.5 μm in diameter and 0.9–1.9 μm long. Oval endospores are formed under both aerobic and anaerobic conditions.

Heat-resistant. Good growth occurs in both well-aerated and anaerobic cultures (E_h , -370 mV; pH 10) when titanium (III) citrate is used as a reducing agent. Cell yields and growth rates are the same under aerobic and anaerobic conditions. Growth

occurs: between pH 8.0 and 10.0, but not at pH 7.0; in the presence of 3% NaCl, but not in 6% NaCl; and between 25 °C and 45 °C, but not at 50 °C. Negative for nitrate reduction, H₂S production, and indole production.

Growth is not observed in nutrient broth. Citrate utilization and hydrolysis of gelatin are negative. D-Xylose, L-arabinose, D-ribose, D-glucose, D-fructose, esculin, salicin, maltose, sucrose, cellobiose, trehalose, soluble starch, pectin, and xylan (oat spelt) are utilized. Ethanol, acetic acid, and formic acid are produced from glucose under anaerobic conditions and acetic acid is produced under aerobic conditions. Lactic acid is not produced under either condition. The fermentation product from xylan is acetic acid in aerobic culture; formic acid, ethanol, and acetic acid are produced in anaerobic culture.

^dIshikawa et al. (2005).

^eIshikawa et al. (2002).

^fWainø et al. (1999).

^gPyruvate is produced under aerobic conditions.

The cell wall contains *meso*-diaminopimelic acid. The predominant cellular fatty acids are C_{15:0 anteiso}, C_{16:0}, C_{16:0 iso}, C_{14:0} and C_{15:0 iso}.

The type strain was isolated from an alkaline compost of manure with grass and rice straw.

DNA G + C content (mol%): 36–38 (*T_m*).

Type strain: Ep01, DSM 6626, JCM 7361, NBRC 15112.

GenBank accession number (16S rRNA gene): D82065, AJ496807.

2. ***Amphibacillus fermentum*** Zhilina, Garnova, Tourova, Kostrikin and Zavarzin 2002, 685^{VP} (Effective publication: Zhilina, Garnova, Tourova, Kostrikin and Zavarzin 2001a, 720) *fer.men.tum*. L. n. *fermentum* that which causes fermentation.

Cells are motile by means of one subterminal flagellum. Cells are rod-shaped, 0.5–0.75 μm in diameter and 1.5–4 μm long and occurring singly, in pairs, or sometimes in short chains. Spores are not observed, but cells are heat-resistant.

Good growth occurs in both well-aerated and anaerobic cultures. Strictly alkaliphilic. Growth occurs at pH 7.0–10.5, with optimum growth at pH 8.0–9.5. Growth is obligately dependent on the CO₃²⁻ ion. Growth occurs at a total mineralization of 0.17–3.3 M Na⁺ with an optimum of 1.87 M Na⁺ (in the form of sodium carbonates). The Cl⁻ ion is not required. Mesophilic. Growth is observed between 18 °C and 56 °C; optimal growth occurs at 36–38 °C. Chemo-organotrophic. Yeast extract is required for anabolic growth (the obligate requirement is methionine). Sulfur is used as an electron acceptor. Tolerant to sulfide. Sulfur reduction is not coupled to energy generation.

D-Glucose, maltose, mannose, xylose, fructose, sucrose, maltose, cellobiose, and trehalose are utilized anaerobically. In addition, ribose, arabinose, galactose, lactose, and N-acetylglucosamine are utilized aerobically. Ethanol, acetic acid, formic

acid, and lactic acid are produced anaerobically from glucose. Acetic acid and pyruvic acid, along with small amounts of lactic and formic acids, are produced aerobically from glucose.

The major cellular fatty acids are anteiso-, iso-branched, and straight-chain acids.

The type strain was isolated from the bottom sediment of a coastal lagoon of Lake Magadi, Kenya.

DNA G + C content (mol%): 41.5 (*T_m*).

Type strain: Z-7984, DSM 13869, UNIQEM 210.

GenBank accession number (16S rRNA gene): AF418603.

3. ***Amphibacillus tropicus*** Zhilina, Garnova, Tourova, Kostrikin and Zavarzin 2002, 685^{VP} (Effective publication: Zhilina, Garnova, Tourova, Kostrikin and Zavarzin 2001a, 720) *tro.pi.cus*. L. adj. *tropicus* tropical, an organism isolated from a tropical lake.

Cells are motile by means of peritrichous flagella. Cells are thin rods, 0.4–0.5 μm in diameter and 2–6 μm long and occurring singly or in pairs. Heat-resistant. Oval endospores are formed terminally.

Good growth occurs in both well-aerated and anaerobic cultures. Strictly alkaliphilic. Growth occurs at pH 8.0–11.5, with optimum growth between pH 9.5 and 9.7. Growth is obligately dependent on the CO₃²⁻ ion. Growth occurs at a total mineralization of 0.17–3.6 M Na⁺, with an optimum of 1–1.87 M Na⁺ (in the form of sodium carbonates). The Cl⁻ ion is not required. Mesophilic. Growth is observed between 18 °C and 56 °C; optimal growth is at 38 °C. Chemo-organotrophic. Yeast extract is required for anabolic growth (the obligate requirement is methionine). Sulfur is used as an electron acceptor. Sulfur reduction is not coupled to energy generation. High concentrations of sulfide are inhibitory.

D-Glucose, maltose, sucrose, cellobiose, trehalose, melibiose, peptone, yeast extract, and, at a low rate, Tween

80 are utilized anaerobically. Starch, glycogen, and xylan are hydrolyzed. In addition, xylose, fructose, and lactose are utilized aerobically. Yeast extract, peptone, and Tween 80 are not utilized aerobically. Ethanol, acetic acid, formic acid, and a small amount of lactic acid are produced anaerobically from glucose. Acetic acid, pyruvic acid, and lactic acid are produced aerobically from glucose. The major

cellular fatty acids are anteiso-, iso-branched, and straight-chain acids.

The type strain was isolated from the bottom sediment of a coastal lagoon of Lake Magadi, Kenya.

DNA G + C content (mol%): 39.2 (T_m).

Type strain: Z-7792, DSM 13870, UNIQEM 212.

GenBank accession number (16S rRNA gene): AF418602.

Genus IV. **Anoxybacillus** Pikuta, Lysenko, Chuvilskaya, Mendrock, Hippe, Suzina, Nikitin, Osipov and Laurinavichius 2000a, 2114^{VP} emend. Pikuta, Cleland and Tang 2003a, 1561

ELENA V. PIKUTA

An.o.xy.ba.cil'lus. Gr. pref. *an* without; Gr. adj. *oxys* acid or sour and in combined words indicating oxygen; L. masc. n. *bacillus* small rod; N.L. masc. n. *Anoxybacillus* small rod living without oxygen

Cells are rod-shaped and straight or slightly curved, sometimes with angular division and Y-shaped cells, 0.4–1.5 × 2.5–9.0 μm in size, often in pairs or short chains, with rounded ends. Gram-positive. Motile or nonmotile. Endospores are round, oval or cylindrical and resistant to heating and freezing. Spores are located at the end of the cells. There is not more than one spore per cell. Aerobes, facultative aerobes or facultative anaerobes; catalase-variable. Alkaliphilic, alkalitolerant or neutrophilic, moderately thermophilic. Chemorganotrophic, with a fermentative or oxygen respiration metabolism.

DNA G + C content (mol%): 42–57.

Type species: **Anoxybacillus pushchinoensis** corrig. Pikuta Lysenko, Chuvilskaya, Mendrock, Hippe, Suzina, Nikitin, Osipov and Laurinavichius 2000a, 2116^{VP} emend. Pikuta, Cleland and Tang 2003a, 1561.

Further descriptive information

Phylogenetic analysis indicated that the closest neighbor of *Anoxybacillus pushchinoensis* (with 98.8% similarity) was the bacterium designated "*Bacillus flavothermus*" (Pikuta et al., 2000a). Previous work had shown that the invalidly named species "*Bacillus flavothermus*" was phylogenetically distinct from other members of genus *Bacillus* (with 7–16% differences) and suggested that it be recognized as a separate genus (Rainey et al., 1994). Consequently, the new genus, *Anoxybacillus* was created to contain the species *Anoxybacillus pushchinoensis* and "*Bacillus flavothermus*," reclassified as *Anoxybacillus flavithermus* comb. nov., with the name correction. The name *Anoxybacillus* was chosen because of the ability of both species to live without oxygen.

Cell morphology of most species is the same; the cells are straight rods, except for *Anoxybacillus contaminans*, which are curved or curled. Cells of *Anoxybacillus pushchinoensis* and *Anoxybacillus kamchatkensis* may also have Y-shaped rods due to angular division, which begins in the exponential growth phase. One cell can have 2, 3, or 4 branched ends at the same time, but more often two branches of equal length arise from one cell at a pole. Some species are motile, but *Anoxybacillus pushchinoensis* and *Anoxybacillus voinovskiensis* are not. All species have terminal, spherical, oval, or cylindrical endospores. All species have a Gram-positive cell-wall structure with a thick layer of peptidoglycan, except for *Anoxybacillus contaminans*, which is Gram-variable. In the case of *Anoxybacillus pushchinoensis* K1, the outer and inner S-layers are clearly visible in ultrathin section. Old cells of some cultures have cytoplasm with dark granulations and light regions. Colonies

have different characteristics according to species. *Anoxybacillus pushchinoensis* has white colonies with a yellowish center, circular shape (lens-shaped in deep agar), granular surface, and uneven edges. Colonies of *Anoxybacillus flavithermus* are round in shape with a smooth surface and bright yellow in color (as a result of high concentration of flavins). Colonies of the species *Anoxybacillus gonensis* are cream-colored with irregular shape and rough edges. Colonies of *Anoxybacillus contaminans* are circular with regular margins and raised centers and edges, and are opaque, glossy, and cream-colored. *Anoxybacillus voinovskiensis* colonies are circular with faint cream color and colonies of *Anoxybacillus ayderensis* and *Anoxybacillus kestanbolensis* are regular circle-shaped with round edges and cream color. Colonies of *Anoxybacillus kamchatkensis* grown aerobically are pinpoint, yellowish translucent, round with even edges; anaerobically grown colonies of this species are white, opaque, round with even edges and flat surface. Strictly aerobic cells of *Anoxybacillus rupiensis* form whitish colonies, about 5 mm in diameter with irregular margin. Colonies of *Anoxybacillus amylolyticus* are circular, cream, and smooth.

Cells multiply by binary fusion with the formation of two daughter cells.

Many members of the genus *Anoxybacillus* are alkaliphilic, but not all of them are obligate alkaliphiles. Most of species can grow at neutral pH and are not dependent upon carbonate ions. The only slightly acidophilic species of this genus that grow optimally at pH 5.6 is *Anoxybacillus amylolyticus*. Some species require specific carbonate-containing media because of obligate dependence on carbonates, as in the case of *Anoxybacillus pushchinoensis*^{*}. The highest maximum pH for growth (pH 11.0) was observed for *Anoxybacillus ayderensis*. The common characteristic of all *Anoxybacillus* species is independence from NaCl and a comparatively low resistance to salt (5–6% NaCl inhibits growth). All species are moderately thermophilic bacteria with an optimal temperature for growth of 50–62 °C.

The genus contains saccharolytic and proteolytic species and, in natural communities, they perform the function of

* (per liter): NaCl, 5 g; Na₂CO₃, 2.76 g; NaHCO₃, 10.0 g; KCl, 0.2 g; K₂HPO₄, 0.2 g; MgCl₂·6H₂O, 0.1 g; NH₄Cl, 1.0 g; Na₂S·9H₂O, 0.5 g; resazurin, 0.001 g; yeast extract, 0.02 g; glucose, 5.0 g; vitamin solution (Wolin et al., 1963), 2 ml; trace mineral solution 1 ml (mg per 200 ml water: MnCl₂·4H₂O, 720; Fe(NH₄)(SO₄)₂·12H₂O, 400; FeSO₄·7H₂O, 200; CoCl₂·6H₂O, 200; ZnSO₄·7H₂O, 200; Na₂MoO₄·2H₂O, 20; NiCl₂, 100; CuSO₄·5H₂O, 20; AlK(SO₄)₂·12H₂O, 20; H₃BO₃, 20; and 5 ml HCl concentrated), and the final pH was adjusted to 9.5 with 6M NaOH. High purity nitrogen was used for the gas phase.

primary anaerobes or aerobes in the trophic chains of organic matter decomposition. They produce low energy products such as acetate, ethanol, and hydrogen that are used by secondary anaerobes or aerobes as electron donors. *Anoxybacillus flavithermus*, *Anoxybacillus kamchatkensis*, and *Anoxybacillus gonensis* have the capacity to hydrolyze both sugars and proteolytic products (amino acids in peptone and yeast extract), but *Anoxybacillus pushchinoensis* and *Anoxybacillus voinovskiensis* are saccharolytic and cannot grow on peptone, casein, gelatin, or yeast extract (yeast extract is used only as a source of carbon and vitamins).

Anoxybacillus species can use oxygen or nitrate as electron acceptors (except for *Anoxybacillus gonensis* and *Anoxybacillus rupiensis*, which do not reduce nitrate) and, without electron acceptors, they perform fermentation by the Embden–Meyerhof pathway. *Anoxybacillus pushchinoensis* is an aerotolerant anaerobe and prefers anaerobic conditions, but other species are facultative anaerobes. The only strictly aerobic species of this genus is *Anoxybacillus rupiensis*.

The percentage similarity as indicated by 16S rDNA sequence analysis is as follows: *Anoxybacillus pushchinoensis* and *Anoxybacillus flavithermus*, 98.9%; *Anoxybacillus flavithermus* and *Anoxybacillus gonensis*, 97%; and *Anoxybacillus pushchinoensis* and *Anoxybacillus gonensis*, 96%. *Anoxybacillus contaminans* has less than 97% similarity with *Anoxybacillus pushchinoensis*, *Anoxybacillus flavithermus*, and *Anoxybacillus gonensis*. *Anoxybacillus voinovskiensis* has 95.7% similarity with *Anoxybacillus flavithermus*, 94.8% with *Anoxybacillus gonensis*, and 94.5% with *Anoxybacillus pushchinoensis*. *Anoxybacillus ayderensis* has more than 98% similarity to the sequences of *Anoxybacillus gonensis* and *Anoxybacillus flavithermus*, and 97% similarity to *Anoxybacillus pushchinoensis*. *Anoxybacillus kestanbolensis* exhibits 97% similarity to *Anoxybacillus flavithermus* and higher than 96% similarity to *Anoxybacillus gonensis* and *Anoxybacillus pushchinoensis*. *Anoxybacillus amylolyticus* shows 98.2% similarity to *Anoxybacillus voinovskiensis* and 98.1% to *Anoxybacillus contaminans*; it is also shared a similarity of 96%, and 94% with *Anoxybacillus ayderensis* and *Anoxybacillus kestanbolensis*, respectively; it has 97.5% similarity with *Geobacillus tepidamans*. The level of 16S rRNA gene sequence similarity between *Anoxybacillus kamchatkensis* and the type strains of *Anoxybacillus* species (*Anoxybacillus pushchinoensis*, *Anoxybacillus flavithermus*, *Anoxybacillus gonensis*, *Anoxybacillus ayderensis*, and *Anoxybacillus kestanbolensis*) are correspondently following: 97.7%, 98.7%, 98.9%, 99.2%, and 97.6%. For *Anoxybacillus rupiensis* and *Geobacillus tepidamans* it shows 96.8%.

DNA–DNA hybridization between *Anoxybacillus pushchinoensis* and *Anoxybacillus flavithermus* showed 58.8% homology; *Anoxybacillus flavithermus* and *Anoxybacillus gonensis* showed 53.4% homology, and *Anoxybacillus pushchinoensis* and *Anoxybacillus gonensis* showed 45% homology. DNA–DNA hybridization between *Anoxybacillus ayderensis* and *Anoxybacillus gonensis* showed 68.6% homology, and between *Anoxybacillus kestanbolensis* and *Anoxybacillus flavithermus* showed 60.4% homology. DNA–DNA hybridization between *Anoxybacillus ayderensis* and *Anoxybacillus pushchinoensis* showed 45.1% homology, between *Anoxybacillus kestanbolensis* and *Anoxybacillus flavithermus* it was 42.9%, and between *Anoxybacillus ayderensis* and *Anoxybacillus kestanbolensis* it was 40.5%. Hybridization *Anoxybacillus amylolyticus* with *Anoxybacillus voinovskiensis* showed 32%, with *Anoxyba-*

cillus contaminans 30.7%, and with *Geobacillus tepidamans* 30.2%. Homology of *Anoxybacillus kamchatkensis* with *Anoxybacillus pushchinoensis*, *Anoxybacillus flavithermus*, *Anoxybacillus gonensis*, and *Anoxybacillus ayderensis* is 53%, 55%, 51%, and 51%, respectively. For *Anoxybacillus rupiensis* and *Geobacillus tepidamans* it shows 32%.

Anoxybacillus pushchinoensis is sensitive to the antibiotic bacitracin (100 µg/ml), but not to penicillin, vancomycin, ampicillin, streptomycin (all at 250 µg/ml), or chloramphenicol (100 µg/ml). The growth of *Anoxybacillus gonensis* is inhibited by chloramphenicol, ampicillin, streptomycin (25 µg/ml), and tetracycline (12.5 µg/ml). For *Anoxybacillus ayderensis* and *Anoxybacillus kestanbolensis*, the inhibition of growth by ampicillin (25 µg/ml), streptomycin (25 µg/ml), kanamycin (10 µg/ml), tetracycline (12.5 µg/ml), and gentamicin (10 µg/ml) was described. *Anoxybacillus amylolyticus* is sensitive to: kanamycin (5 µg/ml), penicillin G, ampicillin, gentamicin, chloramphenicol, tylosin, fusid acid (10 µg/ml), lincomycin (15 µg/ml), streptomycin (25 µg/ml), novobiocin, and tetracycline (30 µg/ml). Growth of *Anoxybacillus rupiensis* cells is inhibited by tetracycline, gentamicin, streptomycin, erythromycin, carbenicillin, and chloramphenicol, but the cells are resistant to ampicillin, oxacillin, penicillin, and nalidixic acid.

Most species of the genus have been isolated from hot springs. *Anoxybacillus flavithermus* was isolated from a hot spring in New Zealand; *Anoxybacillus gonensis*, *Anoxybacillus ayderensis*, and *Anoxybacillus kestanbolensis* were respectively isolated from the Gonen, Ayder, and Kestanbol hot springs in Turkey; *Anoxybacillus voinovskiensis* and *Anoxybacillus kamchatkensis* both were isolated from a hot spring on the Kamchatka peninsula in Russia. *Anoxybacillus amylolyticus* was isolated from geothermal soils of Mount Rittmann on Antarctica. *Anoxybacillus rupiensis* was isolated from hot springs in the region of Rupi basin in Bulgaria. *Anoxybacillus contaminans* was isolated as a contaminant of gelatin production plant in Belgium. The situation with *Anoxybacillus puschinensis* is not completely understood. The type strain K1 was isolated from manure (equine and porcine) that was collected 20 years previously from farms in the Moscow region of Russia and stored in a cold room at “Laboratory of Anaerobic Processes” of the Institute of Biochemistry and Physiology of Microorganisms in Pushchino, Russian Academy of Sciences. The original source of this bacterium may have been soils that survived passage through the digestive tract, or the manure itself may have been the natural ecosystem. It is known that the temperature of manure during long-term storage can increase spontaneously to the range appropriate for moderately thermophilic micro-organisms. Perhaps microniches were created with optimal pH and redox potential by microbial activity that could have provided suitable conditions for this organism. Microscopy of the manure sample before culture on laboratory media showed strain K1 cells were the dominant forms in the manure. Pathogenicity, antigenic structure, mutants, plasmids, phages, and phage typing have not been studied.

Enrichment and isolation procedures

Aerobic or anaerobic techniques can be used for cultivation of *Anoxybacillus* strains. Isolation of *Anoxybacillus flavithermus* and *Anoxybacillus gonensis* was performed in nutrient broth incubated

at 60–70 °C and individual colonies were obtained on agar by the streak plate method. Isolation and purification of *Anoxybacillus pushchinoensis* was performed by dilution methods in Hungate tubes under anaerobic conditions (medium described above). Colonies of *Anoxybacillus pushchinoensis* were obtained on 3% Difco agar (w/v), to which the carbonate solution was added separately after sterilization by the roll-tube method. Antibiotics can be used for isolating clean cultures from enrichments; the pure culture of *Anoxybacillus pushchinoensis* was isolated by adding 500 µg/ml penicillin and 500 µg/ml streptomycin to an enrichment culture.

Maintenance procedures

Most species of *Anoxybacillus* can be maintained on liquid or agar media (nutrient broth). For cultivation of *Anoxybacillus pushchinoensis*, the previously described medium is used, but culture of this species can be achieved by aerobic procedures. The best method for the long-term preservation of *Anoxybacillus* cultures is lyophilization.

Procedures for testing special characters

The determination of the moderately thermophilic nature, alkali-tolerance or alkaliphilic nature, dependence upon carbonate ions, relationship to oxygen, and spore formation does not require specific procedures. Isolation of DNA and amplification were performed by the usual methods, i.e., phenol/chloroform extraction and PCR (by *Thermus aquaticus* thermostable DNA polymerase).

Differentiation of the genus *Anoxybacillus* from other genera

Characters that distinguish *Anoxybacillus* from closely related taxa are listed in Table 12.

Taxonomic comments

The genus *Anoxybacillus* includes 10 species, *Anoxybacillus pushchinoensis*, *Anoxybacillus amylolyticus*, *Anoxybacillus ayderensis*, *Anoxybacillus contaminans*, *Anoxybacillus flavithermus*, *Anoxybacillus gonensis*, *Anoxybacillus kamchatkensis*, *Anoxybacillus kestanbolensis*, *Anoxybacillus rupiensis*, and *Anoxybacillus voinovskiensis*. On the basis of 16S rDNA sequencing studies, all ten species of the genus are closely related (94.5–99.2%), but the percentage homology by DNA–DNA hybridization (30.7–68.6%) and their different physiological properties indicate that they are ten distinct species. The species epithets were corrected during the reclassification of *Anoxybacillus flavithermus* (formerly “*Bacillus flavothermus*”) and emendation of the description of *Anoxybacillus pushchinoensis* (formerly *Anoxybacillus pushchinensis*). A tree showing the phylogenetic relationships of *Anoxybacillus* is shown in Figure 13.

The special attributes of the genus are as follows: moderate thermophilia, alkaliphilia, or alkali tolerance; spore formation; Gram-positive staining; and capability of growth in both aerobic and anaerobic conditions with sugars. Differentiation of species of the genus *Anoxybacillus* is shown in Table 13. Detailed characteristics of the species are presented in Table 14

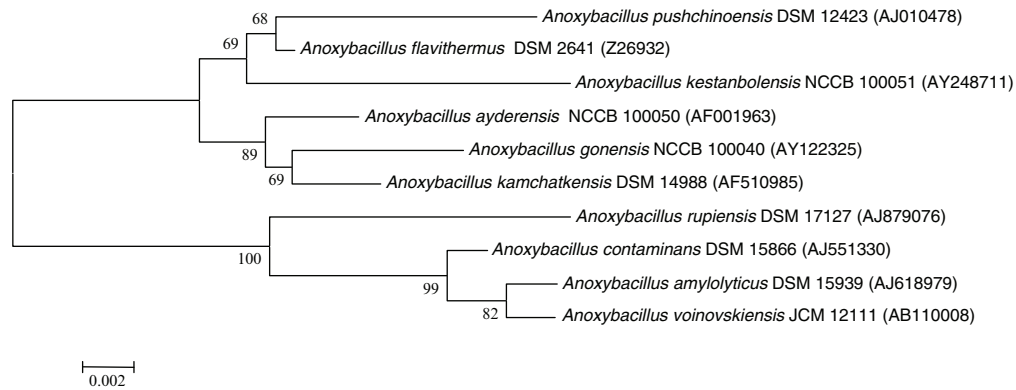

FIGURE 13. Evolutionary relationships within the genus *Anoxybacillus*. The evolutionary history was inferred using the neighbor-joining method. The bootstrap consensus tree inferred from 2,000 replicates is taken to represent the evolutionary history of the taxa. The percentage of replicate trees in which the associated taxa clustered together in the bootstrap test (2,000 replicates) are shown next to the branches. The tree is drawn to scale, with branch lengths in the same units as those of the evolutionary distances used to infer the phylogenetic tree. The evolutionary distances were computed using the Jukes–Cantor method and are in the units of the number of base substitutions per site. All positions containing gaps and missing data were eliminated from the dataset (Complete deletion option). There were a total of 1,298 positions in the final dataset. Phylogenetic analyses were conducted in MEGA software version 4.

List of species of the genus *Anoxybacillus*

1. ***Anoxybacillus pushchinoensis*** corrig. Pikuta, Lysenko, Chuvil'skaya, Mendrock, Hippe, Suzina, Nikitin, Osipov and Laurinavichius 2000a, 2116^{VP} emend. Pikuta, Cleland and Tang 2003a, 1561
 push.chi.noen'sis. N.L. masc. adj. *pushchinoensis* pertaining to Pushchino, a research center near Moscow, Russia, where the organism was isolated.
 Data are from Pikuta et al. (2000a) and Pikuta et al. (2003a). Straight rods, 0.4–0.5 × 2.5–3.0 μm in size, single, in pairs, sometimes in irregular curved chains. Gram-positive. Nonmotile. Y-shaped cells occur at angular division. Forms round endospores. Aerotolerant anaerobe, chemo-heterotrophic, alkaliphilic, moderately thermophilic. Grows at 37–65 °C, with an optimum at 62 °C. Obligate alkaliphile that cannot grow at pH 7.0; grows in a pH range of 8.0–10.5 with an optimum of 9.5–9.7. CO₃²⁻ is obligately required. Optimal growth at 1% NaCl; tolerant to 3% NaCl. Growth substrates are D-glucose, sucrose, D-fructose, D-trehalose, and starch. The major fermentation products are hydrogen and acetic acid. Nitrate is reduced to nitrite. Sulfate, sulfite, thiosulfate, and sulfur are not reduced. Yeast extract stimulates growth. Vitamins are required. Catalase-negative. Gelatin and casein are not hydrolyzed.
Source: cow and pig manure with neutral pH.
DNA G + C content (mol %): 42.2 ± 0.2 (HPLC).
Type strain: K1, ATCC 700785, DSM 12423, VKM B-2193.
GenBank accession number (16S rRNA gene): AJ010478.
2. ***Anoxybacillus amylolyticus*** Poli, Esposito, Lama, Orlando, Nicolaus, de Appolonia, Gambacorta and Nicolaus 2006, 1459^{VP} (Effective publication: Poli, Esposito, Lama, Orlando, Nicolaus, de Appolonia, Gambacorta and Nicolaus 2006, 305.)
 a.mi.lo.ly.ti.cus. Gr. n. *amulon* starch; connecting vowel -o-; Gr. adj. *luticos* able to dissolve; N.L. masc. adj. *amylolyticus* starch-dissolving.
 Data from Poli et al. (2006). Cells are Gram-positive, motile, straight rods, 0.5 × 2.0 – 2.5 μm in size. Spores are terminal, ellipsoidal to cylindrical endospores. Colonies are circular, smooth, and cream in color. Facultative anaerobe. Catalase-positive but oxidase-negative. Reduces nitrate to nitrite. Hydrolysis hippurate and starch. Utilizes D-galactose, D-trehalose, D-maltose, raffinose, and sucrose when the medium supplemented with 0.06% of yeast extract. It is positive for tyrosine decomposition. Sensitive to lysozyme. Negative with respect to casein and gelatin hydrolysis and phenylalanine deamination. Does not produce indole. On sugar media it is able to produce exopolysaccharide, possesses a constitutive extracellular amylase activity. Does not grow on media without yeast extract, but acetate (as source of carbon) with D-glucose, D-lactose, D-fructose, D-arabinose, D-cellobiose, D-mannose, D-ribose, D-xylose, D-sorbose, and glycerol. It is slightly acidophilic, growing at pH 5.6. It is thermophile, growth occurs between 45 °C and 65 °C with optimum temperature at 61 °C. Grow at NaCl 0.6% but not at concentrations higher than 3%. Antibiotics inhibited growth: kanamycin (5 μg), penicillin G, ampicillin, gentamicin, chloramphenicol, tylosin, fusid acid (10 μg), lincomycin (15 μg), streptomycin (25 μg), novobiocin, tetracycline (30 μg).
Source: geothermal soil of Mount Rittmann on Antarctica.
DNA G + C content (mol %): 43.5 (HPLC).
Type strain: MR3C, ATCC BAA-872, DSM 15939, CIP 108338.
GenBank accession number (16S rRNA gene): AJ618979.
3. ***Anoxybacillus ayderensis*** Dulger, Demirbag and Belduz 2004, 1503^{VP}
 ay.de.ren.sis. N.L. masc. adj. *ayderensis* pertaining to Ayder, a hot spring in the province of Rize, Turkey, from where organism was isolated.
 Data from Dulger et al. (2004). Cells are rod-shaped, Gram-positive, spore-forming, 0.55 × 4.60 μm in size. Location of spherical spores is terminal. Colonies are 1–2 mm in diameter, regular circle shaped with round edges, and cream color. Facultatively anaerobic, alkalitolerant, and moderately thermophilic chemo-organotroph. Catalase- and oxidase-positive. Nitrate reduced to nitrite. Starch and gelatin, but not casein hydrolyzed. Urease, indole, and hydrogen sulfide not produced. D-glucose, D-raffinose, D-sucrose, D-xylose, D-fructose, L-arabinose, maltose, D-mannose, and peptone utilized. Temperature range for growth 30–70 °C; optimum growth at 50 °C. Growth range at 0–2.5% NaCl and optimum growth occurs at 1.5%. Optimum pH is 7.5–8.5; pH range for growth is 6–11. Growth was inhibited in the presence of ampicillin, streptomycin, tetracycline, gentamicin, and kanamycin.
Source: Ayder hot spring, Turkey.
DNA G + C content (mol %): 54 (T_m).
Type strain: AB04, NCIMB 13972, NCCB 100050.
GenBank accession number (16S rRNA gene): AF001963.
4. ***Anoxybacillus contaminans*** De Clerck, Rodríguez-Díaz, Vanhoutte, Heyrman, Logan and De Vos 2004c, 944^{VP}
 con.ta'mi.nans. L. part. adj. *contaminans* contaminating.
 Data are from De Clerck et al. (2004c). Cells are curved or frankly curled, round ended, Gram-variable, feebly motile rods that occur singly, in pairs, or short chains. Sizes of cells are 0.7–1.0 × 4.0–10.0 μm. Endospores are oval and located subterminally or terminally within slightly swelled sporangia. Colonies are circular, 1–2 mm in diameter, with regular margins and raised centers and edges, and are opaque, glossy, and cream-colored. Facultatively anaerobic, catalase-positive, but oxidase-negative. Nitrate is reduced to nitrite. Moderately thermophilic. The temperature range for growth is 40–60 °C with the optimum at 50 °C. Alkalitolerant, grows with pH optimum at 7.0, minimum at pH 4–5, and maximum at pH 9–10. Doesn't require NaCl for growth; NaCl range for growth is 0–5%. Chemoheterotrophic. Gelatin, but not o-nitrophenyl-β-D-galactopyranoside or casein is hydrolyzed. All strains are negative for arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, citrate utilization, hydrogen sulfide production, urease, tryptophan deaminase, indole production, and the Voges-Proskauer reaction. Hydrolysis of esculin is weak. Small amounts of acid without gas are produced from L-arabinose, D-fructose, D-galactose, D-glucose, glycerol, glycogen, maltose, D-mannose, D-melezitose, methyl-D-glucoside, N-acetylglucosamine, D-raffinose, ribose, starch, sucrose, D-trehalose, D-turanose,

and D-xylose. Production of acid is negative for adonitol, amygdalin, D-arabinose, D- and L-arabitol, arbutin, D-cellobiose, dulcitol, D- and L-fucose, gentiobiose, gluconate, inulin, 2- and 5-keto-D-gluconate, lactose, D-lyxose, mannitol, D-melibiose, *meso*-inositol, methyl-D-mannoside, methyl-xyloside, rhamnose, salicin, sorbitol, L-sorbose, D-tagatose, L-xylose, and xylitol.

The major cellular fatty acids are C_{15:0 iso}, C_{16:0}, and C_{17:0 iso} (52, 11 and 12% of total fatty acid respectively). The following fatty acids are presented in smaller amounts: C_{14:0}, C_{15:0 anteiso}, C_{16:0 iso}, and C_{17:0 anteiso} (3, 7, 5 and 7% of total fatty acids, respectively).

Source: gelatin sample from gelatin production plant.

DNA G + C content (mol%): 44.4 (HPLC).

Type strain: DSM 15866, LMG 21881.

GenBank accession number (16S rRNA gene): AJ551330.

5. **Anoxybacillus flavithermus** (Heinen, Lauwers and Mulders 1982) Pikuta, Lysenko, Chuvilskaya, Mendrock, Hippe, Suzina, Nikitin, Osipov and Laurinavichius 2000a, 2116^{VP} (*Bacillus flavothermus* Heinen, Lauwers and Mulders 1982, 270.) *fla.vi.ther'mus*. L. adj. *flavus* yellow; Gr. adj. *thermos* warm; N.L. adj. *flavithermus* to indicate a yellow thermophilic organism

Data are from Heinen et al. (1982), Claus and Berkeley (1986), Sharp et al. (1992), Rainey et al. (1994), and Pikuta et al. (2000a). Rods, 0.85 × 2.3–7.1 μm. Motile. Gram-positive. Terminal spores. Colonies are round, smooth, yellow. Facultatively anaerobic. Catalase-positive. Oxidase-positive. Starch, but not gelatin, hydrolyzed. Grows in peptone-yeast extract media. Glucose, mannose, maltose, sucrose, arabinose, rhamnose, and sorbitol utilized. Positive for acetoin, arginine dihydrolase, lysine decarboxylase, tryptophan deaminase, and β-galactosidase. Nitrate reduced to nitrite. Urease, ornithine decarboxylase, indole, and H₂S not produced. Growth in 2.5% NaCl broth, but not in 3% NaCl. Optimal pH for growth of 6–9. No growth at pH 5.0. Temperature range for growth 30–72 °C; optimal growth at 60 °C (aerobic) and 65 °C (anaerobic). *Source*: hot spring, New Zealand.

DNA G + C content (mol%): 41.6 (HPLC).

Type strain: d.y., DSM 2641, NBRC 15317, LMG 18397.

GenBank accession number (16S rRNA gene): AF004589, Z26932.

6. **Anoxybacillus gonensis** Belduz, Dulger and Demirbag 2003, 1319^{VP}

go.nen.sis. N.L. masc. adj. *gonensis* pertaining to Gonen, a hot spring in the province of Balikesir, Turkey, where organism was isolated.

Data are from Belduz et al. (2003). Rod-shaped, Gram-positive, motile, spore-forming, measuring 0.75 × 5.0 μm. Terminal spherical endospores are formed. Colonies rough, cream-colored. Facultatively anaerobic. Catalase weak-positive. Oxidase-positive. Starch and gelatin hydrolyzed. Glucose, glycogen, raffinose, sucrose, xylose, mannitol, and peptone utilized. Nitrate not reduced to nitrite. Urease, indole, and H₂S not produced. Growth in 4% NaCl broth. Alkalitolerant: pH range for growth 6.0–10.0 and optimal pH for growth of 7.5–8.0. Moderate thermophile with temperature range from 40 °C to 70 °C and optimum at 55–60 °C.

Source: Gonen hot spring, Turkey.

DNA G + C content (mol%): 57 (*T_m*).

Type strain: G2, NCIMB 139330, NCCB 100040.

GenBank accession number (16S rRNA gene): AY122325.

7. **Anoxybacillus kamchatkensis** Kevbrin, Zengler, Lysenko and Wiegel 2005, 397^{VP}

kam.chat.ken'sis. L. adj. *kamchatkensis* pertaining to Kamchatka peninsula, Russia, where the organism was isolated.

Data are from Kevbrin et al. (2005). Cells are straight rods, 1.0 × 2.5–8.8 μm in size, single or in pairs. Gram-positive with Gram-positive-type cell wall. Motile by peritrichous flagella. Y-shaped (or branched) cells are infrequently observed. Forms terminal oval spores. Aerobically grown colonies are pinpoint, yellowish translucent, round with an even edge; anaerobically grown colonies are white, opaque, round with even edges and flat surface.

Facultative aerobe. Catalase- and oxidase-negative. Alkalitolerant moderate thermophile with an optimum growth temperature at 60 °C and range between 38 °C and 67 °C (no growth at or below 37 °C and at or above 68 °C). Grows in a pH^{25 °C} range of 5.7–9.9 with an optimum of 6.8–8.5. Yeast extract (0.1 g/l) and B₁₂ vitamin are required for growth on carbohydrates. Aerobic utilization of ribose, glucose, fructose, galactose, mannitol, maltose, trehalose, sucrose, pyruvate, yeast extract, peptone, tryptone, Casamino acids, and pectin. Anaerobic utilization of glucose, fructose, mannitol, maltose, trehalose, sucrose, and yeast extract. Starch, casein, and gelatin are not hydrolyzed. Fermentation products of glucose are lactate as main product and acetate, formate, and ethanol as minor products. End products of glucose oxidation are lactate, acetate, and traces of fumarate, succinate, and ethanol. Does not grow on: arabinose, xylose, xylitol, mannose, sorbitol, inositol, lactose, raffinose, and gluconate.

Source: volcanic thermal fields of the Geyser Valley in Kamchatka, Russia.

DNA G + C content (mol%): 42.3 (*T_m*).

Type strain: JW/VK-KG4, ATCC BAA-549, DSM 14988.

GenBank accession number (16S rRNA gene): AF510985.

8. **Anoxybacillus kestanbolensis** Dulger, Demirbag and Belduz 2004, 1503^{VP}

kes.tan.bo.len.sis. N.L. masc. adj. *kestanbolensis* pertaining to Kestanol, a hot spring in the province of Canakkale, Turkey, from where organism was isolated.

Data from Dulger et al. (2004). Cells are rod-shaped, Gram-positive, motile, spore-forming, with sizes 0.65 × 4.75 μm. Location of spherical endospores is terminal. Colonies are 1–1.5 mm in diameter, regular circle shaped with round edges, and cream color. Facultatively anaerobic, alkalitolerant, and moderately thermophilic chemo-organotroph. Catalase- and oxidase-positive. Nitrate is reduced to nitrite. Starch, but not gelatin and casein, is hydrolyzed. Urease, indole, and hydrogen sulfide are not produced. D-Glucose, D-raffinose, D-sucrose, D-fructose, maltose, D-mannitol, D-mannose, and peptone are utilized. Temperature range for growth is 40–70 °C and optimum at 50–55 °C. Grows in the absence of NaCl; growth range from 0 to 4% NaCl and optimum growth occurs at 2.5%. pH range for growth from 6.0

to 10.5 and optimum pH is 7.5–8.5. Growth was inhibited in presence of ampicillin, streptomycin, tetracycline, gentamicin, and kanamycin.

Source: Kestanbol hot spring, Turkey.

DNA G + C content (mol%): 50 (T_m).

Type strain: K4, NCIMB 13971, NCCB 100051.

GenBank accession number (16S rRNA gene): AY248711.

9. **Anoxybacillus rupiensis** Derekoa, Sjøholm, Mandeva, and Kambourova, 2007 581^{VP}

ru.pi.en'sis (N.L. masc. adj. *rupiensis* pertaining to Rupi Basin, the place of isolation of the type strain).

Data are from Derekoa et al. (2007). Straight, motile rods, 0.7–1.5 × 3.3–7.0 μm in size, single, in pairs, sometimes in chains. Gram-positive. Forms terminal ellipsoidal or cylindrical endospores. Colonies are whitish, 5 mm in diameter with irregular margin. Thermophile with range of growth between 35 °C and 67 °C (optimum 55 °C). pH range from 5.5 to 8.5 (optimum 6.0–6.5). Utilizes sugars, polysaccharides and polyols in the presence of proteinaceous substrates or inorganic nitrogen. Growing on ribose, xylose, fructose, glucose, and maltose. It does not grow on galactose, L-rhamnose, raffinose, sucrose, lactose, phenyl-alanine, tyrosine, and citrate. Hydrolyzing starch, casein, and xylan but not salicin, inulin, gelatin, olive oil, and pectin. Growth supported by mannitol but not by ribitol, galactitol and sorbitol. Indole is not produced, the Voges–Proskauer reaction and methyl red test are negative. Obligate aerobe, catalase-positive. Does not reduce nitrate to nitrite.

The major cellular fatty acids are C_{15:0 iso} and C_{17:0 iso}.

Source: terrestrial hot spring at Rupi Basin.

DNA G + C content (mol%): 41.7 (HPLC).

Type strain: R270, DSM 17127, NBIMCC 8387.

GenBank accession number (16S rRNA gene): AJ879076.

10. **Anoxybacillus voinovskiensis** Yumoto, Hirota, Kawahara, Nodasaka, Okuyama, Matsuyama, Yokota, Nakajima and

Hoshino 2004a, 1242^{VP}

vo.ino.vskien'sis. N.L. adj. *voinovskiensis* from Voinovskie, named after the Voinovskie Springs from where the microorganism was isolated.

Data from Yumoto et al. (2004a). Cells are Gram-positive, nonmotile, straight rods, 0.4–0.6 × 1.5–5.0 μm in size. Spores were never observed. Colonies are circular and faint cream in color. Facultatively anaerobic (prefers aerobic conditions). Catalase- and oxidase-positive. Nitrate is reduced to nitrite. Negative for hydrogen sulfide production and hydrolysis of casein, gelatin, starch, DNA, and Tween 20 and 80. Hydrolyzes Tween 40 and 60. Growth occurs at pH 7–8, but not at 9–10. Growth occurs at 30–64 °C with optimum temperature at 54 °C. Growth in the absence of NaCl but not at concentrations higher than 3%. Acid is produced from D-glucose, D-xylose, D-arabinose, D-fructose, maltose, D-mannose, sucrose, sorbitol, and cellobiose in aerobic conditions. Grows on peptone without sugars. No acid is produced from D-galactose, raffinose, melibiose, inositol, mannitol, trehalose, L-rhamnose, and lactose in aerobic conditions.

Source: hot spring in Kamchatka, Russia.

DNA G + C content (mol%): 43.9 (HPLC).

Type strain: TH13, JCM 12111, NCIMB 13956.

GenBank accession number (16S rRNA gene): AB110008.

Species Candidatus

The 16S rDNA sequence of “*Anoxybacillus hidirlerensis*” CT1Sari^T was deposited in GenBank with accession number EF433758 (Inan et al., unpublished) and “*Anoxybacillus bogroviensis*” with accession number AM409184 (Atanassova et al., unpublished).

Acknowledgements

The author is thankful to Dr Damien Marsic and Mr Richard Hoover for assistance.

Genus V. Cerasibacillus Nakamura, Haruta, Ueno, Ishii, Yokota and Igarashi 2004b, 1067^{VP}

PAUL DE VOS

Ce.ras.i.ba.cil'lus. L. neut. n. *cerasum* a cherry; L. masc. n. *bacillus* small rod; N.L. masc. n. *cerasibacillus* a cherry *Bacillus*, as the appearance of its sporangium is cherry-like.

Rod-shaped, **Gram-positive** bacterium, 0.8 μm in diameter and 2.5–5.0 μm in length, occurring as single rods, in pairs, or in short chains. Terminal **spherical endospores** are formed. Strictly aerobic. Growth occurs at 30–55 °C (optimal growth at 50 °C) and in the pH range 7.5–10 (optimum 8–9). Good growth occurs at low NaCl concentrations, but no growth is observed in TSB with 10% NaCl (assessed after 6 d incubation). **Catalase-positive**, does not reduce nitrate, and negative for the Voges–Proskauer test and indole production (API strip). **Casein is not hydrolyzed**. Acid production from xylose has been observed. Peptidoglycan of the *meso*-diaminopimelic acid type is present in the cell wall. The major cellular fatty acid is C_{15 iso} and **MK-7** is the main menaquinone type.

DNA G + C content (mol%): 33.9–41.8 (HPLC).

Type species: **Cerasibacillus quisquiliarum** Nakamura, Haruta, Ueno, Ishii, Yokota and Igarashi 2004b, 1067^{VP}.

Further information

Colonies on TSA plates at 37 °C are pigmented (light yellowish-brown), round, and opaque. Longer incubation at 37 °C and/or growth on TSA at 50 °C reveals amorphous, translucent colonies. The single strain (BLx) of the single species of the taxon was isolated from a decomposing system of kitchen refuse (Nakamura et al., 2004b) after its presence had been detected by a non-cultural based approach (denaturing-gradient gel electrophoresis, DGGE) (Haruta et al., 2002) and molecular characterization of the dominant bands. Nakamura et al. (2004a) showed that the abundance of strain BLx increased following a measured increase in gelatinase activity in the composting process, which may directly link the ecological/metabolic role of the strain in the composting process. This hypothesis was further supported by the observation that at least one of the

gelatinases of strain BLx has a very similar N-terminal amino acid sequence to the gelatinase found in the compost under study.

Enrichment procedures

Specific enrichment conditions for the vegetative cells are unknown, but spore formation seems to be stimulated by adding the following trace elements to a general medium: MgSO₄ (1 mM), Ca(NO₃)₂ (1 mM), MnCl₂ (10 μM), and FeSO₄ (1 μM).

Differentiation of the genus *Cerasibacillus* from other genera

Phylogenetically, the organism belongs to the *Virgibacillus-Lentibacillus* lineage as a clearly separated branch (16S rRNA gene

sequence analysis). Differentiation from these phylogenetically adjacent genera is possible based on morphological, physiological, and biochemical characteristics (Nakamura et al., 2004b).

Taxonomic comments

Due to its rather general habitat, it is likely that representatives are far more abundant in various thermophilic environments than is presently known. The reason for our lack of awareness of their metabolic role in various decay processes of organic compounds in nature and/or man-made processes is most probably linked to the particular growth conditions of the composting process of kitchen refuse, as well as the incubation conditions.

List of species of the genus *Cerasibacillus*

1. *Cerasibacillus quisquiliarum* Nakamura, Haruta, Ueno, Ishii, Yokota and Igarashi 2004b, 1067^{VP}

quis.qui.li.a.'rum. L. gen. pl. n. *quisquiliarum* of kitchen refuse.

This species is the only species described so far and its general characteristics conform to those of the genus. Further characteristics were determined using the API 50CHB system (bioMérieux), which measures: acid production from carbohydrates; hydrolysis of esculin, gelatin, starch, and urea; H₂S production; and nitrate reduction. This analysis demonstrated that gelatin is hydrolyzed, whereas starch, esculin, and urea are not. Acid is produced from D-ribose, L-sorbose, D-tagatose, and 5-ketogluconate, but not from

glycerol, erythritol, D-arabinose, L-arabinose, L-xylose, adonitol, methyl β-D-xylose, galactose, glucose, fructose, mannose, rhamnose, dulcitol, inositol, mannitol, sorbitol, methyl α-D-mannose, methyl α-D-glucose, N-acetylglucosamine, amygdalin, arbutin, salicin, cellobiose, maltose, lactose, melibiose, sucrose, trehalose, inulin, raffinose, glycogen, xylitol, gentiobiose, turanose, D-fucose, L-fucose, D-arabitol, L-arabitol, gluconate, or 2-ketogluconate.

DNA G + C content (mol%): 33.9–41.8 (HPLC).

Type strain: BLx, DSM 15825, IAM 15044, KCTC 3815.

EMBL/GenBank accession number (16S rRNA gene): AB107894 (BLx).

Genus VI. *Filobacillus* Schlesner, Lawson, Collins, Weiss, Wehmeyer, Völker and Thomm 2001, 430^{VP}

HEINZ SCHLESNER

Fi.lo.ba.cil'lus. L. neut. n. *filum* thread; L. n. bacillus rod; N.L. masc. n. *Filobacillus* a thread-like rod.

Rod-shaped cells, 0.3–0.4 × 3–7 μm. Spores are spherical and are located terminally. Sporangium is swollen. Motile by one laterally inserted flagellum. The cells stain Gram-negative, but the cell wall is of the Gram-positive type. KOH test negative. Colonies are white, smooth, and round with entire margins. Mesophilic. Optimum temperature for growth is between 30 °C and 38 °C. No growth at 42 °C.

Aerobic and chemo-organotrophic. Glucose is not fermented. No dissimilatory nitrate reduction. **Requires 2% NaCl for growth and tolerates up to 23%**; Optimum concentration 8–14%. pH range for growth 6.5–8.9; pH optimum 7.3–7.8. The cell wall contains an **L-Orn-D-Glu type murein** (variation A4β).

DNA G + C content (mol%): 35 (HPLC).

Type species: *Filobacillus milosensis* corrig. Schlesner, Lawson, Collins, Weiss, Wehmeyer, Völker, Thomm 2001, 430^{VP}.

Further descriptive information

Cells of *Filobacillus* are morphologically very similar to cells of a number of aerobic spore-forming bacteria, however, can easily be distinguished by several characteristics (Table 15).

16S rRNA analysis indicates that this organism is a member of the rRNA group I of *Bacillus*-like bacteria according to Ash et al. (1991).

Enrichment and isolation procedures

The only strain was isolated from the beach of Palaeochori Bay near a shallow water hydrothermal vent area, Milos, Greece. At a hot spot (surface temperature 62 °C) in front of the waterline, a hole of about 10 cm in depth was dug, and a sample was taken with a 20 ml syringe from the accumulating interstitial water. 100 μl of sample was transferred to 50 ml medium M36M: Casein after Hammarsten (Merck), 1.0 g; yeast extract, 0.25 g; gelatin, 1.0 g; Hutner's basal salts medium (HBM), 20 ml; vitamin solution no. 6 (Staley, 1968), 10 ml; artificial sea water (ASW, Lyman and Fleming, 1940), 3.5-fold concentrated, 970 ml. ASW was modified by addition of the following salts (per liter): MnCl₂, 0.4 g; Na₂SiO₃, 0.57 g; (NH₄)₂SO₄, 0.26 g. After an incubation of three weeks at 37 °C, upcoming colonies were streaked on medium M13(3x) + 10% NaCl: peptone, 0.75 g; yeast extract, 0.75 g; glucose, 0.75 g; NaCl, 100 g; HBM, 20 ml; vitamin solution no. 6, 10 ml; 0.1 M Tris/HCl buffer, pH 7.5 for liquid media, pH 8.5 for agar solid media, 50 ml; ASW, 250 ml; distilled water to 1 l.

Maintenance procedures

When grown on slants (M13(3x) + 10%NaCl), the strain can be kept at 4–5 °C for at least three months. It is easily revived from lyophilized cultures and can be stored at –70 °C in a solution of 50% glycerol in M13(3x) + 10% NaCl.

Differentiation of the genus *Filobacillus* from closely related taxa

Table 15 lists the major features which differentiate *Filobacillus* from other genera of spore-forming bacteria.

List of species of the genus *Filobacillus*

Genus VII. ***Geobacillus*** Nazina, Tourova, Poltarau, Novikova, Grigoryan, Ivanova, Lysenko, Petrunyaka, Osipov, Belyaev and Ivanov 2001, 442^{VP}

NIALL A. LOGAN, PAUL DE VOS AND ANNA DINSDALE

Ge.o.ba.cil'lus. Gr. n. *Ge* the Earth; L. dim. n. *bacillus* small rod; N.L. masc. n. *Geobacillus* earth or soil small rod.

Obligately thermophilic. Vegetative cells are rod-shaped and produce one endospore per cell. Cells occur either singly or in short chains and are motile by means of peritrichous flagella or they are nonmotile. The cell-wall structure is Gram-positive, but the Gram-stain reaction may vary between positive and negative. **Ellipsoidal or cylindrical endospores** are located terminally or subterminally in slightly swollen or non-swollen sporangia. Colony morphology and size are variable; pigments may be produced on certain media. Chemo-organotrophic. Aerobic or facultatively anaerobic. Oxygen is the terminal electron acceptor, replaceable in some species by nitrate. The temperature range for growth is 35–75 °C, with an optimum at 55–65 °C. Neutrophilic. Growth occurs at pH 6.0–8.5, with optimal growth at pH 6.2–7.5. Growth factors, vitamins, NaCl, and KCl are not required by most species. **Most species can utilize n-alkanes as carbon and energy sources.** Most species produce acid, but not gas from fructose, glucose, maltose, mannose, and sucrose. Most species produce catalase. Oxidase reaction varies. Phenylalanine is not deaminated, tyrosine is not degraded, and indole is not produced. The major cellular fatty acids are C_{15:0 iso},

C_{16:0 iso}, and C_{17:0 iso}, which make up more than 60% of the total. The main menaquinone type is MK-7. The lowest level of 16S rRNA gene sequence similarity between all *Geobacillus* species is around 93%, which indicates that at least some species need to be reclassified at the genus level. Species are widely distributed in nature, in heated and unheated environments.

DNA G + C content (mol%): 48.2–58 (T_m).

Type species: ***Geobacillus stearothermophilus*** (Donk 1920) Nazina, Tourova, Poltarau, Novikova, Grigoryan, Ivanova, Lysenko, Petrunyaka, Osipov, Belyaev and Ivanov 2001, 443^{VP} (*Bacillus stearothermophilus* Donk 1920, 373).

Further descriptive information

Phylogeny. A phylogenetic tree, based on 16S rRNA gene sequences, is shown in Figure 14. The tree includes all *Geobacillus* species with validly published names; *species incertae sedis* are omitted, but are listed below with some additional information. *Geobacillus debilis* holds a separate position and, on the basis of 16S rRNA gene sequence analysis, is most probably not

FIGURE 14. Unrooted neighbor-joining tree of *Geobacillus* type strains based on 16S rRNA gene sequences. Alignment of sequences was performed using CLUSTALX, BIOEDIT, and TREECON. Bootstrap values above 70% are shown (based on 1000 replications) at the branch points. Accession numbers for each strain are given in parentheses.

an authentic *Geobacillus* species. This is most likely also the case for *Geobacillus pallidus* and *Geobacillus tepidamans*. Phylogenetic analysis shows that on the basis of 16S rRNA gene sequences, *Geobacillus tepidamans* belongs to the genus *Anoxybacillus*, whereas *Geobacillus pallidus* does not seem to be closely related to any valid taxa.

It is well known that 16S rRNA gene sequences do not always allow species to be discriminated and that DNA–DNA hybridization data may be needed for this. However, sequences of other genes (the so-called core genes) may be more appropriate for discriminating these relatively recent branchings of the evolutionary tree that correspond to bacterial species (Stackebrandt et al., 2002).

Cell morphology. Vegetative cells are rod-shaped and produce one endospore per cell. Cells occur either singly or in short chains and are motile by means of peritrichous flagella or non-motile. The cell-wall structure is Gram-positive, but the Gram-stain reaction may vary between positive and negative.

Cell-wall composition and fine structure. Vegetative cells of the majority of *Bacillus* species that have been studied, and of the examined representatives of several genera whose species were previously accommodated in *Bacillus*, have the most common type of cross-linkage in which a peptide bond is formed between the diamino acid in position 3 of one subunit and the D-Ala in position 4 of the neighboring peptide subunit, so that

no interpeptide bridge is involved. The diamino acid in the two *Geobacillus* species for which it has been determined, *Geobacillus stearothermophilus* (Schleifer and Kandler, 1972) and *Geobacillus thermoleovorans* (Zarilla and Perry, 1987), is diaminopimelic acid and the configuration has been determined for the former as *meso*-diaminopimelic acid (*meso*-DAP); this cross-linkage is now usually known as DAP-direct (A1 (in the classification of Schleifer and Kandler, 1972).

Organisms growing at high temperatures need enzyme adaptations to give molecular stability as well as structural flexibility (Alvarez et al., 1999; Kawamura et al., 1998; Perl et al., 2000), heat-stable protein-synthesizing machinery, and adaptations of membrane phospholipid composition. They differ from their mesophilic counterparts in the fatty acid and polar headgroup compositions of their phospholipids. The effect of temperature on the membrane composition of *Geobacillus stearothermophilus* has been studied intensively. Phosphatidylglycerol (PG) and cardiolipin (CL) comprise about 90% of the phospholipids, but as the growth temperature rises the PG content increases at the expense of the CL content. The acyl-chain composition of all the membrane lipids also alters; the longer, saturated-linear and iso fatty acids with relatively high melting points increase in abundance, whereas anteiso fatty acids and unsaturated components with lower melting points decrease. As a result, the organism is able to maintain nearly constant membrane fluidity across its whole growth temperature range; this has been

termed homeoviscous adaption (Martins et al., 1990; Tolner et al., 1997). An alternative theory, homeophasic adaption, considers that maintenance of the liquid-crystalline phase is more important than an absolute value of membrane fluidity in *Bacteria* (Tolner et al., 1997).

Amino acid transport in *Geobacillus stearothermophilus* is Na⁺-dependent, which is unusual for neutrophilic organisms such as these, but common among marine bacteria and alkalophiles; however, the possession of primary and secondary Na⁺-transport systems may be advantageous to the organism by allowing energy conversion via Na⁺-cycling when the phospholipid adaptations needed to give optimal membrane fluidity at the organism's growth temperature also result in membrane leakiness (de Vrij et al., 1990; Tolner et al., 1997).

Colonial characteristics and life cycle. Colony morphologies and sizes are variable; pigments may be produced on certain media. Ellipsoidal or cylindrical endospores are located terminally or subterminally in slightly swollen or non-swollen sporangia. For details of sporulation, see the treatment of *Bacillus*.

Nutrition and growth conditions. All species of *Geobacillus* are obligately thermophilic chemo-organotrophs. They are aerobic or facultatively anaerobic and oxygen is the terminal electron acceptor, replaceable in some species by nitrate. Temperature ranges for growth generally lie between 37°C and 75°C, with optima between 55°C and 65°C. They are neutrophilic and grow within a relatively narrow pH range of 6.0–8.5 and their optima lie within the pH range 6.2–7.5. For the species tested, growth factors, vitamins, NaCl, and KCl are not required and most strains will grow on routine media such as nutrient agar. A wide range of substrates is utilized, including carbohydrates, organic acids, peptone, tryptone, and yeast extract; the ability to utilize hydrocarbons as carbon and energy sources is a widely distributed property in the genus (Nazina et al., 2001). A strain of *Geobacillus thermoleovorans* has been found to have extracellular lipase activity and high growth rates on lipid substrates such as olive oil, soybean oil, mineral oil, tributyrin, triolein, Tween 20, and Tween 40 (Lee et al., 1999a). A solvent-tolerant *Geobacillus pallidus* strain that degrades 2-propanol was reported by Bustard et al. (2002).

Pathogenicity. The body temperatures of humans and other animals lie at or near the minimum temperatures for growth for species of *Geobacillus* and there have been no reports of infections with these organisms.

Habitats. Although thermophilic aerobic endospore-formers and other thermophilic bacteria might be expected to be restricted to hot environments, they are also very widespread in cold environments and appear to be ubiquitously distributed in soils worldwide. Strains with growth temperature ranges of 40–80°C can be isolated from soils whose temperatures never exceed 25°C (Marchant et al., 2002); indeed, Weigel (1986) described how easy it is to isolate such organisms from cold soils and even from Arctic ice. That the spores of endospore-formers may survive in such cool environments without any metabolic activity is understandable, but their wide distribution and contribution of up to 10% of the cultivable flora suggests that they do not merely represent contamination from hot environments (Marchant et al., 2002). It has been suggested that the direct heating action of the sun on the upper layers of the soil and local heating from the fermentative and putrefactive

activities of mesophiles might be sufficient to allow multiplication of thermophiles (Norris et al., 1981). The first described strains of the species now called *Geobacillus stearothermophilus* were isolated from spoiled, canned corn and string beans. This organism and other *Bacillus* species have long been important in the canned food and dairy industries and are responsible for "flat sour" spoilage of canned foods and products such as evaporated milk (Kalogridou-Vassiliadou, 1992). The organisms may thrive in parts of the food-processing plant and their contaminating spores may survive the canning or dairy process and then outgrow in the product if it is held for any time at an incubating temperature. This is a particular problem for foods such as military rations that may need to be stored in tropical climates (Llaudes et al., 2001). *Geobacillus stearothermophilus* may represent up to a third of thermophilic isolates from foods (Deák and Temár, 1988) and approaching two-thirds of the thermophiles in milk (Chopra and Mathur, 1984). Other sources of *Geobacillus stearothermophilus* include geothermal soil, rice soils (García et al., 1982), desert sand, composts (Blanc et al., 1997), water, ocean sediments, and shallow marine hydrothermal vents (Caccamo et al., 2001). *Geobacillus vulcani* was isolated from a shallow (3 m below sea level) hydrothermal vent at Vulcano Island in the Eolian Islands, Italy (Caccamo et al., 2000). *Geobacillus caldoxylosilyticus* was found in Australian soils, and subsequently in uncultivated soils from China, Egypt, Italy, and Turkey, and in central heating system water (Obojska et al., 2002). *Geobacillus debilis* was found in cool soils in Northern Ireland. *Geobacillus thermodenitrificans* has been isolated from soils from Australia, Asia, and Europe, from shallow marine hydrothermal vents (Caccamo et al., 2001), from sugar beet juice, and, along with *Geobacillus thermoglucosidasius*, in other soils (Mora et al., 1998) and hot composts (Blanc et al., 1997). *Geobacillus tepidamans* was also isolated from sugar beet juice and geothermally heated soil in Yellowstone National Park. *Geobacillus toebii* was found in hot hay compost. *Geobacillus pallidus* has been found in compost, sewage, and wastewater treatment processes. *Geobacillus thermoleovorans* was first cultivated from soil, mud, and activated sludge collected in the USA and further isolations have been made from shallow marine hydrothermal vents (Maugeri et al., 2001), deep subterranean petroleum reservoirs (Kato et al., 2001), and Japanese, Indonesian, and Icelandic hot springs (Lee et al., 1999a; Markossian et al., 2000; Sunna et al., 1997a). *Geobacillus kaustophilus* was first isolated from pasteurized milk and other strains have been found in spoiled, canned food, and in geothermal and temperate soils from Iceland, New Zealand, Europe, and Asia (White et al., 1993). *Geobacillus jurasicus*, *Geobacillus subterraneus*, and *Geobacillus uzenensis* were all isolated from the formation waters of high-temperature oilfields in China, Kazakhstan, and Russia, whereas *Geobacillus lituanicus* was found in crude oil in Lithuania and *Geobacillus thermocatenu-latus* was isolated from a slimy bloom on the inside surface of a pipe in a steam and gas thermal bore-hole in thermal zone of Yangan-Tau mountain in the South Urals. *Geobacillus gargasensis* was isolated from a microbial mat that formed in the Garga hot spring in the Transbaikalian region of Russia (Nazina et al., 2004). Unidentified strains belonging to the genus *Geobacillus* have been reported from deep-sea hydrothermal vents lying at 2000 to 3500 m (Marteinsson et al., 1996) and from sea mud of the Mariana Trench at 10,897 m below the surface (Takami et al., 1997).

Enrichment and isolation procedures

Thermophiles may be obtained easily by incubating environmental or other samples in routine cultivation media at 65 °C and above. As for other aerobic endosporeformers, it is useful to heat-treat the specimens to select for endospores and encourage their germination (see *Enrichment and isolation procedures*, in *Bacillus*, above). Allen (1953) described enrichment methods for strains belonging to particular physiological groups. A selective procedure for the isolation of flat sour organisms from food was described by Shapton and Hindes (1963) using yeast-glucose-tryptone agar, which contains peptone (5 g), beef extract (3 g), tryptone (2.5 g), yeast extract (1 g), and glucose (1 g) in distilled water (1000 ml). The method is as follows: dissolve medium components by heating; adjust to pH 8.4; simmer for 10 min then pass through coarse filter paper if necessary; cool and make back up to 1000 ml; adjust to pH 7.4; add sufficient agar to solidify and 2.5 ml of 1% aqueous solution bromocresol purple; sterilize by autoclaving; prepare food sample in 1/4 strength Ringer's solution and pasteurize with molten medium at 108 °C (8 p.s.i. or 55 kPa) for 10 min; reduce temperature to 100 °C and maintain for 20 min; cool to 50 °C; pour plates and allow to set; incubate at 55 °C for 48 h and observe for yellow colonies.

The following procedures are those used in the isolation of strains of *Geobacillus* species, but do not necessarily represent methods especially designed to enrich or select for those species. *Geobacillus caldoxylosilyticus* was isolated from Australian soil by adding 0.1–0.2 g sample to minimal medium and incubating at 65 °C for up to 24 h (Ahmad et al., 2000b). Minimal medium contained: xylose, 10 g; K₂HPO₄, 4 g; KH₂PO₄, 1 g; NH₄NO₃, 1 g; NaCl, 1 g; MgSO₄, 0.25 g; trace mineral solution, 10 ml; water to 1000 ml; pH, 6.8; 1.5% agar was added when a solid medium was desired. Trace mineral solution contained: EDTA, 5.0 g; CaCl₂·2H₂O, 6.0 g; FeSO₄·7H₂O, 6.0 g; MnCl₂·4H₂O, 1.15 g; CoCl₂·6H₂O, 0.8 g; ZnSO₄·7H₂O, 0.7 g; CuCl₂·2H₂O, 0.3 g; H₃BO₃, 0.3 g; (NH₄)₆Mo₇O₂₄·4H₂O, 0.25 g; water, 1000 ml. After two transfers of 1 ml culture into fresh medium, enrichments were plated on solidified minimal medium and incubated at 65 °C for 24 h. Further isolations from soils taken from China, Egypt, Italy, and Turkey were made by heating samples at 90 °C for 10 min, plating on CESP agar and incubating at 65 °C for 24 h (Fortina et al., 2001a). CESP agar contained: casitone, 15 g; yeast extract, 5 g; soytone, 3 g; peptone, 2 g; MgSO₄, 0.015 g; FeCl₃, 0.007 g; MnCl₂·4H₂O, 0.002 g; water, 1000 ml; pH, 7.2. *Geobacillus gargensis* was isolated from the upper layer of a microbial mat from the Garga spring, Eastern Siberia, by serial dilutions and inoculation onto the agar medium described by Adkins et al. (1992) supplemented with 15 mM sucrose: TES [N-tris(hydroxymethyl)methyl-2-aminoethanesulfonic acid], 10 g; NH₄Cl, 1 g; NaCl, 0.8 g; MgSO₄·7H₂O, 0.2 g; CaCO₃ (precipitated chalk), 0.2 g; KCl, 0.1 g; K₂HPO₄, 0.1 g; CaCl₂·2H₂O, 0.02 g; yeast extract, 0.2 g; trace metal solution, 5 ml; vitamin solution, 10 ml; water to 1000 ml, pH, 7.0; agar was added to solidify. Trace metal solution (Tanner, 1989) contained: nitrilotriacetic acid (2 g, pH adjusted to 6 with KOH); MnSO₄·H₂O, 1 g; Fe(NH₄)₂(SO₄)₂·6H₂O, 0.8 g; CoCl₂·6H₂O, 0.2 g; ZnSO₄·7H₂O, 0.2 g; CuCl₂·2H₂O, 0.02 g; NiCl₂·6H₂O, 0.02 g; Na₂MoO₄·2H₂O, 0.02 g; Na₂SeO₄, 0.02 g; Na₂WO₄, 0.02 g; water, 1,000 ml. Vitamin solution (Tanner, 1989) contained: pyridoxine.HCl, 10 mg; thiamine.HCl, 5 mg; riboflavin, 5; calcium pantothenate, 5 mg; thioctic acid, 5 mg; *p*-aminobenzoic acid, 5 mg; nicotinic acid,

5 mg; vitamin B₁₂, 5 mg; biotin, 2 mg; folic acid, 2 mg; water, 1000 ml. Plates were incubated at 60 °C. Prickett (1928) isolated *Geobacillus kaustophilus* from uncooled pasteurized milk by plating on peptonized milk agar, followed by subculturing on the same medium or on nutrient agar supplemented with 1% yeast extract, 0.25% tryptophan broth, and 0.05% glucose. Donk (1920) reported finding *Bacillus* (now *Geobacillus*) *stearothermophilus* in spoiled cans of corn and string beans, but the method of isolation was not described; the reader is referred to the method described above for the isolation of flat sour organisms. Original strains of *Geobacillus pallidus* were isolated from heat-treated municipal and yeast factory wastes that had been held at 60 °C in an aerated laboratory fermenter. Dilutions of the homogenized effluents were cultivated for 3–5 d at 60 °C on the enriched nutrient agar medium of Ottow (1974): glucose, 1.0 g; peptone, 7.5 g; meat extract, 5.0 g; yeast extract, 2.5 g; Casamino acids, 2.5 g; NaCl, 5.0 g; agar, 13 g; tap water, 1000 ml; pH 7.2–7.4. *Geobacillus thermoleovorans* was isolated by adding soil, mud, and water samples to L-salts basal medium supplemented with 0.1% (v/v) n-heptadecane and incubated at 60 °C for 1–2 weeks, followed by transfer from turbid cultures to fresh medium of the same composition; after several such transfers, pure cultures were obtained by streaking on plates of L-salts basal medium supplemented with 0.2% (v/v) n-heptadecane and solidified with 2% agar (Merkel et al., 1978; Zarilla and Perry, 1987). L-salts (Leadbetter and Foster, 1958) contained: NaNO₃, 2.0 g; MgSO₄·7H₂O, 0.2 g; NaH₂PO₄, 0.09 g; KCl, 0.04 g; CaCl₂, 0.015 g; FeSO₄·7H₂O, 1.0 mg; ZnSO₄·7H₂O, 70.0 µg; H₃BO₃, 10.0 µg; MnSO₄·5H₂O, 10.0 µg; MoO₃, 10.0 µg; CuSO₄·5H₂O, 5.0 µg; deionized water, 1000 ml. *Geobacillus subterraneus* and *Geobacillus uzensis* were isolated from serial dilutions of thermophilic hydrocarbon-oxidizing enrichments taken from oilfields; the enrichments were inoculated onto the medium described by Zarilla and Perry (1987) supplemented with 0.1% n-hexadecane and incubated at 55–60 °C (Nazina et al., 2001). *Geobacillus jurassicus* was isolated from oilfield formation water by diluting enrichment cultures grown in a modification of the medium of Adkins et al. (1992) (NH₄Cl, 1 g; KCl, 0.1 g; KH₂PO₄, 0.75 g; K₂HPO₄, 1.4 g; MgSO₄·7H₂O, 0.2 g; CaCl₂·2H₂O, 0.02 g; NaCl, 1.0 g; water, 1000 ml; pH 7.0) supplemented with 4% (v/v) crude oil, incubated at 60 °C, and plated on the same medium solidified with 2% agar. *Geobacillus thermocatenulatus* was isolated from a slimy bloom at about 60 °C on the inside surface of a pipe in a steam and gas thermal bore-hole in the thermal zone of Mount Yangan-Tau in the South Urals using potato-peptone and meat-peptone media (Golovacheva et al., 1965; Golovacheva et al., 1975). Mora et al. (1998) isolated novel strains of *Geobacillus thermodenitrificans* from soil by suspending 1 g soil sample in 5 ml sterile distilled water and heat treating at 90 °C for 10 min, then plating 1 ml on nutrient agar and incubating at 65 °C for 24 h. *Geobacillus thermoglucoisidarius* was isolated from Japanese soil by adding 0.1 g sample to 5 ml medium I in large (1.8 × 19 cm) test tubes and incubating at 65 °C for 18 h with the tubes leaning at an angle of about 10°, followed by further enrichments in tubes of the same medium and then purification of plates of medium I solidified with 3% agar (Suzuki et al., 1976). Medium I contained: peptone, 5 g; meat extract, 3 g; yeast extract, 3 g; K₂HPO₄, 3 g; KH₂PO₄, 1 g; water, 1000 ml, pH 7.0. For *Geobacillus debilis*, 100 mg basalt till soil sample, taken at a depth of 50 mm below the surface, was suspended in 50 ml sterile Ringer's solution containing 0.1% Triton

X-100 and placed in a sonicating bath for 10 min. A sample (1 ml) was serially diluted in Ringer's solution and spread plates were prepared on nutrient broth at pH 6.8–7.2 solidified with 0.8% Gellan Gelrite gum and incubated at 70 °C for 24 h under aerobic conditions. Resulting colonies were isolated either onto specialized *Bacillus* medium (nutrient broth, 16 g; MgSO₄·7H₂O, 0.5 g; KCl, 2.0 g; 10⁻³ M Ca(NO₃)₂; 10⁻⁴ M MnCl₂; 10⁻⁶ M FeSO₄; glucose, 1 g; water, 1000 ml; Leighton and Doi, 1971), or trypticase soy broth solidified with agar or Gelrite Gellan gum, and further purified before being stored as stock cultures either at room temperature or at 4 °C. *Geobacillus lituanicus* was isolated using ten-fold serial dilutions of crude oil. The dilutions were inoculated onto Czapek agar and plates were incubated aerobically at 60 °C for 48 h. *Geobacillus tepidamans* was enriched from sugar beet extraction juice samples in SVIII/glc medium (peptone, 10 g; yeast extract, 5 g; meat extract, 5 g; glucose, 3 g; K₂HPO₄·3H₂O, 1.3 g; MgSO₄·7H₂O, 0.1 g; water, 1000 ml; pH 7.2 ± 0.2) at 55 °C and subcultured in SVIII/glc broth until pure cultures were obtained (Schäffer et al., 1999). Another strain of *Geobacillus tepidamans* was isolated from a high-temperature soil that was collected aseptically and transported back to the laboratory in sterile tubes suspended in heated water contained in a Thermos bottle. Soil samples were serially diluted in 0.1 M NH₄PO₄ buffer (pH 6.0; 65 °C), and aliquots from each dilution were spread onto 0.1% yeast extract agar. Single colonies were repeatedly subcultured until a pure culture was obtained. *Geobacillus toebii* was isolated from a suspension of hay compost plated onto solid modified basal medium and incubated at 60 °C for 3 d (Sung et al., 2002). The medium contained: polypeptone, 5 g; K₂HPO₄, 6 g; KH₂PO₄, 2 g; yeast extract, 1 g; MgSO₄·7H₂O, 0.5 g; L-tyrosine, 0.5 g; agar to solidify; and deionized water, 1000 ml. *Geobacillus vulcani* was isolated from a marine sediment sample by inoculation into Bacto Marine Broth (Difco) and Medium D (Castenholz, 1969; Degryse et al., 1978) and incubating aerobically for 3 d at 65 °C, followed by plating positive cultures onto Bacto Marine Agar (Difco).

Identification

There are rather few routine phenotypic characters that can be used reliably to distinguish between the members of *Geobacillus*. Characters testable by the API system (bioMérieux), especially acid production from a range of carbohydrates, that are valuable for differentiating between *Bacillus* species, show relatively little variation in pattern between several *Geobacillus* species. Most species show 16S rRNA gene sequence similarities higher than 96.5%, and so they cluster together quite closely in trees based on such data. They may also show high similarities in other phenotypic analyses. The distinction of six species by Nazina et al. (2001) was mainly supported by DNA–DNA relatedness data, and their differentiation table for eight species was compiled from the literature for all of the six previously established species, so that the characterization methods used were not strictly comparable; furthermore, data were incomplete for these species. The same is true of the differentiation table that accompanied the description of *Geobacillus toebii* (Sung et al., 2002). The species *Geobacillus kaustophilus*, *Geobacillus stearothermophilus*, *Geobacillus thermocatenu-latus*, *Geobacillus thermoglucosidasius*, and *Geobacillus thermoleovorans*, especially, need to be characterized alongside the recently described and other revived species in order to allow their descriptions to be emended where necessary.

16S rRNA gene sequencing is not reliable as a stand-alone tool for identification and a polyphasic taxonomic approach is advisable for the identification of *Geobacillus* species and the confident recognition of suspected new taxa. Species descriptions accompanying proposals of novel species will be based on differing test methods and reference strains of established taxa are often not included for comparison, so original descriptions should never be relied upon entirely. Nomenclatural types exist for a good reason and are usually easily available; there is no substitute for direct laboratory comparisons with authentic reference strains. Differentiation characteristics of *Geobacillus* species are given in Tables 17 and 18 provides additional information on biochemical characteristics.

Taxonomic comments

In the first edition of this *Manual*, Claus and Berkeley (1986) listed only three strict thermophiles (that is to say growing at 65 °C and above) in the genus *Bacillus*: *Bacillus acidocaldarius*, *Bacillus schlegelii*, and *Bacillus stearothermophilus*. The last-named of these species had been established for many years (Donk, 1920) and had become and remained something of a dumping-ground for any thermophilic, aerobic endospore-formers; the original strain of the species was thought to have been lost, but Gordon and Smith (1949) considered Donk's description to match most of the obligately thermophilic *Bacillus* strains that they studied. Walker and Wolf (1971), however, believed that two of their cultures [NRRL 1170 and NCA 26 (=ATCC 12980^T)] represented Donk's original strain. Mishustin (1950) renamed *Denitrobacterium thermophilum* of Ambroz (1913) as *Bacillus thermodenitrificans*, Heinen and Heinen (1972) proposed *Bacillus caldolyticus*, *Bacillus caldotenax*, and *Bacillus caldovelox*, and Golovacheva et al. (1975) described *Bacillus thermocatenu-latus*, but all of these species were listed as *species incertae sedis* by Claus and Berkeley (1986). However, the heterogeneity of *Bacillus stearothermophilus* was widely appreciated. Walker and Wolf (1971) found that their strains of *Bacillus stearothermophilus* formed three groups on the basis of biochemical tests (Walker and Wolf, 1961, 1971) and serology (Walker and Wolf, 1971; Wolf and Chowhury, 1971b), and their division of the species was further supported by studies of esterase patterns (Baillie and Walker, 1968), further studies with routine phenotypic characters (Logan and Berkeley, 1981), and polar lipids (Minnikin et al., 1977). Klaushofer and Hollaus (1970) also recognized these three major subdivisions within the thermophiles. Walker and Wolf (1971) regarded the recognition of only one thermophilic species of *Bacillus* in the 7th edition of *Bergey's Manual of Determinative Bacteriology* (Breed et al., 1957) as a "dramatic restriction," and in the 8th edition of *Bergey's Manual of Determinative Bacteriology* Gibson and Gordon (1974) commented that the species was "markedly heterogeneous" and that "the emphasis on ability to grow at 65 °C has the effect of excluding organisms that have temperature maxima between 55 °C and 65 °C, although they have not so far been distinguished from *Bacillus stearothermophilus* by any other property." They concluded, "As yet there has been no agreement on how classification in this part of the genus might be improved." Early studies on *Bacillus* thermophiles were comprehensively reviewed by Wolf and Sharp (1981), who also used the scheme of Walker and Wolf (1971) to allocate several thermophilic species to the three previously established groups.

^aSee Table 17 for explanation of footnotes.

Group 1 was the most heterogeneous assemblage. It comprised strains that produced gas from nitrate, hydrolyzed starch only weakly, and produced slightly to definitely swollen sporangia with cylindrical to oval spores; it was divided into five subgroups on the basis of growth temperature maxima and minima. This group accommodated the majority of strains received as *Bacillus stearothermophilus*, as well as *Bacillus caldotenax*, *Bacillus caldovelox*, *Bacillus kaustophilus* (Prickett, 1928), and *Bacillus thermodenitrificans*.

Group 2 contained strains of *Bacillus stearothermophilus* that were described as “relatively inert” and showed lower growth temperature ranges than members of the other groups, but which had greater salt tolerance. They produced definitely swollen sporangia with oval spores.

Group 3 strains hydrolyzed starch strongly and produced definitely swollen sporangia with cylindrical to oval spores. They were divided into four subgroups on the basis of certain biochemical characters and growth temperatures. Group 3 included the type strain of *Bacillus stearothermophilus*, *Bacillus calidolactis* (Galeslout and Labots, 1959; Grinsted and Clegg, 1955), and *Bacillus thermoliquefaciens* (Galeslout and Labots, 1959).

Having considered a wide range of evidence, Wolf and Sharp (1981) concluded that the earlier “restrictive attitude” (i.e., regarding *Bacillus stearothermophilus* as the only obligate thermophile in the genus) was “no longer tenable,” and regretted that differences in sporangial morphologies among thermophiles were disregarded by Gibson and Gordon (1974). Wolf and Sharp (1981) also showed the spread of DNA G + C content of 44–69 mol% among the *Bacillus* thermophiles, but they did not emphasize the taxonomic significance of this broad range. Claus and Berkeley (1986) were unable to take the taxonomy of the *Bacillus stearothermophilus* group any further, but noted that the heterogeneity of the species was indicated by the wide range of DNA base composition.

Following the pioneering work of the late 1960s and early 1970s, several novel thermophilic species were described, but the overall taxonomy of the group languished for some years, despite the continuing considerable interest in the biology of the thermophiles and the potential applications of their enzymes. Of the novel species described in the decade before 1980, when the Approved Lists of Bacterial Names were published (Skerman et al., 1980), only *Bacillus acidocaldarius* (Darland and Brock, 1971) was included; *Bacillus caldolyticus*, *Bacillus caldotenax*, *Bacillus caldovelox*, *Bacillus thermocatenu-latus*, and *Bacillus thermodenitrificans* were excluded. Subsequent proposals of thermophilic taxa included: *Bacillus flavothermus* (Heinen et al., 1982), *Bacillus thermoglucosidasius* (Suzuki et al., 1983), *Bacillus tusciae* (Bonjour and Aragno, 1984), *Bacillus acidoterrestris* (Deinhard et al., 1987a; Demharter and Hensel, 1989b), *Bacillus cycloheptanicus* (Deinhard et al., 1987b), *Bacillus pallidus* (Scholz et al., 1987), *Bacillus thermoleovorans* (Zarilla and Perry, 1987), *Bacillus thermocloacae* (Demharter and Hensel, 1989b), *Bacillus thermoaerophilus* (MeierStauffer et al., 1996), *Bacillus thermoamy-lovorans* (Combet-Blanc et al., 1995), *Bacillus thermosphaericus* (Andersson et al., 1995), *Bacillus thermantarcticus* (corrig. Nicolaus et al. (2002); *Bacillus thermoantarcticus* [sic], Nicolaus et al., 1996), and *Bacillus vulcani* (Caccamo et al., 2000). Also, some species that had been excluded from the Approved Lists were revived: *Bacillus thermoruber* (ex Guicciardi et al., 1968; Manachini

et al., 1985), *Bacillus kaustophilus* (ex Prickett, 1928; Priest et al., 1988), and *Bacillus thermodenitrificans* (ex Klaushofer and Hol-laus, 1970; Manachini et al., 2000). Several of these species were subsequently allocated to new genera as: *Alicyclobacillus acidocaldarius*, *Alicyclobacillus acidoterrestris*, *Alicyclobacillus cycloheptanicus* (Wisotzkey et al., 1992), *Brevibacillus thermoruber* (Shida et al., 1996), *Aneurinibacillus thermoaerophilus* (Heyndrickx et al., 1997), *Anoxybacillus flavithermus* (Pikuta et al., 2000a), and *Ureibacillus thermosphaericus* (Fortina et al., 2001b).

De Bartolemeo et al. (1991) subjected moderately and obli-gately thermophilic species of *Bacillus* to numerical taxonomic analysis and found four groups within *Bacillus stearothermophi-lus*; three groups corresponded with those previously recog-nized by Walker and Wolf (1971) and other authors, whereas the fourth group comprised biochemically inert strains of high G + C content that were incapable of growing above 65 °C. White et al. (1993) carried out a polyphasic, numerical taxo-nomic study on a large number of thermophilic *Bacillus* strains and recommended the revival of *Bacillus caldotenax* and *Bacil-lus thermodenitrificans* and proposed an emended description of *Bacillus kaustophilus*. However, the clusters they found in their numerical analysis revealed considerable heterogeneity within the species and species groups, and these clusters were often only separated from each other by small margins, indicating that separation of some of the species by routine tests would probably be difficult.

Ash et al. (1991) included strains of *Bacillus stearothermo-philus*, *Bacillus acidoterrestris*, *Bacillus kaustophilus*, and *Bacillus thermoglucosidasius* in their comparison of the 16S rRNA gene sequences of the type strains of 51 *Bacillus* species. Their strain of *Bacillus acidoterrestris* was later found to have been a con-taminant or misnamed culture (Wisotzkey et al., 1992), but their strains of *Bacillus stearothermophilus*, *B. kaustophilus*, and *Bacillus thermoglucosidasius* grouped together in an evolu-tionary line (called group 5) that was distinct from other *Bacillus* species, implying that these thermophiles might represent a separate genus. Rainey et al. (1994) compared the 16S rRNA gene sequences of 16 strains of 14 thermophilic *Bacillus* species and found that strains of *Bacillus caldolyticus*, *Bacillus caldotenax*, *Bacillus caldovelox*, *Bacillus kaustophilus*, *Bacillus thermocatenu-latus*, *Bacillus thermodenitrificans*, and *Bacillus thermoleovorans* grouped with *Bacillus stearothermophilus* at similarities of greater than 98%, whereas *Bacillus thermoglucosidasius* joined the group at 97% similarity. This group thus constituted group 5 *sensu* Ash et al. (1991), a coherent and phylogenetically distinct group of thermophilic *Bacillus* species that did not, however, include all the obligate thermophiles in the genus. Studholme et al. (1999) examined whether transformability is a trait associated with a particular phylogenetic group of thermophilic *Bacillus*. Two of their three transformable strains, all received as *Bacillus stearothermophilus*, were more closely related to *Bacillus thermod-enitrificans* and *Bacillus thermoglucosidasius* when their 16S rRNA gene sequences were compared; it was concluded therefore that although transformability might be strain-specific, it is not limited to a single thermophilic *Bacillus* species.

Sunna et al. (1997b) identified *Bacillus kaustophilus* and *Bacillus thermocatenu-latus* as well as “*Bacillus caldolyticus*,” “*Bacil-lus caldotenax*,” and “*Bacillus caldovelox*” as members of *Bacillus thermoleovorans* on the basis of DNA–DNA relatedness ranging from 73% to 88% between the type and reference strains of all

these species. They proposed the merger of these species and gave an emended description of *Bacillus thermoleovorans*, but this proposal has not been validated. However, Nazina et al. (2004) found DNA–DNA reassociation values of only 47–54% between *Bacillus kaustophilus*, *Bacillus thermocatenuatus*, and *Bacillus thermoleovorans*.

Following the discovery of two novel thermophilic, aerobic endospore-formers in petroleum reservoirs, Nazina et al. (2001) proposed that the valid species of Ash et al. Group 5 should be accommodated in a new genus, *Geobacillus*, along with the novel species *Geobacillus subterraneus* and *Geobacillus uzenensis*. The new genus thus contained eight species: *Geobacillus stearothermophilus* (type species), *Geobacillus kaustophilus*, *Geobacillus subterraneus*, *Geobacillus thermocatenuatus*, *Geobacillus thermodenitrificans*, *Geobacillus thermoglucosidasius*, *Geobacillus thermoleovorans*, and *Geobacillus uzenensis*, whereas *Bacillus pallidus*, *Bacillus schlegelii*, *Bacillus thermantarcticus*, *Bacillus thermoamylovorans*, *Bacillus thermocloacae*, *Bacillus tusciae*, and *Bacillus vulcani* remained in *Bacillus*. Zeigler (2005) analyzed the full-length *recN* and 16S rRNA gene sequences of the type strains of *Geobacillus subterraneus* and *Geobacillus uzenensis*, along with those of two other isolates described as belonging to *Geobacillus subterraneus* and found that they clustered within the same similarity group. It was not clear, however, whether the close relationship shown with these methods was due to sequencing errors in one or both GenBank entries or that the strain for *Geobacillus uzenensis* used in the study by Zeigler (2005) was not in fact the same as the type strain studied by Nazina et al. (2001).

It was clear from the phylogenetic analyses accompanying their proposals (Caccamo et al., 2000; Nicolaus et al., 1996) that *Bacillus thermantarcticus* and *Bacillus vulcani* belonged to *Geobacillus* and should be transferred to that genus; Nazina et al. (2004) formally proposed the transfer of the latter species. Zeigler (2005) recommended the transfer of *Bacillus thermantarcticus* to the genus *Geobacillus* on the basis of full-length *recN* and 16S rRNA gene sequences, but its transfer awaits formal proposal and this species is currently covered in *Bacillus*. Although *Bacillus schlegelii* and *Bacillus tusciae* remain in *Bacillus*, they lie at some distance from other members of the genus (see *Bacillus*). Following the proposal of *Geobacillus*, *Saccharococcus caldoxylosilyticus* (Ahmad et al., 2000b) has been transferred to the genus as *Geobacillus caldoxylosilyticus* (Fortina et al., 2001a), *Bacillus pallidus* has been transferred as *Geobacillus pallidus* (Banat et al., 2004), and six novel species, *Geobacillus toebii* (Sung et al., 2002), *Geobacillus gargensis* (Nazina et al., 2004), *Geobacillus debilis* (Banat et al., 2004), *Geobacillus lituanicus* (Kuisiene et al., 2004), *Geobacillus tepidamans* (Schaffer et al., 2004), and *Geobacillus jurassicus* (Nazina et al., 2005a; Nazina et al., 2005b) have been described.

This progress, however, leaves the long-established species and type species of the genus, *Geobacillus stearothermophilus*, without a modern description based upon a polyphasic taxonomic study. The description given by Nazina et al. (2001) for *Geobacillus stearothermophilus* is largely based upon the one given by Claus and Berkeley (1986) at a time when the species was essentially all-embracing for thermophilic *Bacillus* strains, albeit generally recognized as being heterogeneous. Also, strains of several revived species, such as *Geobacillus kaustophilus* and *Geobacillus thermodenitrificans*, might formerly have been classified within "*Bacillus stearothermophilus*" *sensu lato*, yet no emended description of

Geobacillus stearothermophilus has been published following these proposed revivals; it is clear, therefore, that *Geobacillus stearothermophilus* is without a practically useful definition at present.

Two new taxa were proposed during preparation of this article, but neither has been validated. A single strain of "*Geobacillus caldoproteolyticus*" (Chen et al., 2004) was isolated from sewage sludge in Singapore and deposited as DSM 15730 and ATCC BAA-818. Another proposal based upon a single isolate is "*Geobacillus thermoleovorans* subsp. *stromboliensis*" (Romano et al., 2005c), which was isolated from a geothermal environment in the Eolian Islands in Italy and deposited as DSM 15393 and ATCC BAA-979.

Miscellaneous comments

The major cellular fatty acid components of *Geobacillus* species following incubation at 55 °C are (percentages of total are given in parentheses) C_{15:0 iso} (20–40%; mean 29%), C_{16:0 iso} (6–39%; mean 25%), and C_{17:0 iso} (7–37%; mean 19.5%), which account for 60–80% of the total. As minor components, C_{15:0 ante} (0.6–6.4%; mean 2.3%), C_{16:0} (1.7–11.2%; mean 5.8%), and C_{17:0 ante} (3.1–18.7%; mean 7.3%) are detected (Nazina et al., 2001). The figures given by Fortina et al. (2001a) for *Geobacillus caldoxylosilyticus* and Sung et al. (2002) for *Geobacillus toebii* generally lie within these ranges, with the exception that strains of the former species showed 45–57% C_{15:0 iso}.

Direct comparison of profiles between the obligately thermophilic *Geobacillus* species and mesophilic aerobic endospore-formers is not normally possible as the assays of members of the two groups have not usually been done at the same temperature. For many species of *Bacillus sensu stricto*, fatty acid profiles obtained following incubation at 30 °C are C_{15:0 ante} (25–66%), C_{15:0 iso} (22–47%), and C_{17:0 ante} (2–12%). For the *Bacillus cereus* group, levels of C_{15:0 ante} were lower (3–7%) and amounts of unsaturated fatty acids were generally higher (>10%) (Kämpfer, 1994). The thermotolerant species *Bacillus coagulans* and *Bacillus smithii* showed higher amounts of C_{17:0 ante} (means of 28 and 42%, respectively), and generally lower amounts of C_{15:0 ante} (means of 55 and 12%, respectively) and C_{15:0 iso} (means of 9 and 19%, respectively), but for these data, the former was incubated at 30 °C and the latter at 57 °C.

Llarch et al. (1997) compared the fatty acid profiles of aerobic endospore-formers isolated from Antarctic geothermal environments; their six isolates had temperature ranges with minima between 17 °C and 45 °C and maxima between 62 °C and 73 °C, with optima of 60–70 °C. Two strains (growth temperature ranges of 37–70 °C and 45–73 °C) were found to lie nearest to *Bacillus stearothermophilus* in a phenotypic analysis, whereas two other isolates could be identified as strains of *Bacillus licheniformis* (temperature range 17–68 °C) and *Bacillus megaterium* (temperature range 17–63 °C), whose maximum growth temperatures were extended beyond those seen in strains from temperate environments. The fatty acid profiles for all of these strains were compared following incubation at 45 °C; the two *Bacillus stearothermophilus*-like strains showed profiles of C_{15:0 iso} (19 and 40%), C_{16:0 iso} (47 and 5%), and C_{17:0 iso} (7.5 and 23%), which accounted for 55–73% of the total, whereas for minor components the patterns were C_{15:0 ante} (2.6 and 9.6%), C_{16:0} (4 and 5.8%), and C_{17:0 ante} (4.6 and 8.7%); these profiles are consistent with those reported for *Geobacillus*. The profiles for the *Bacillus licheniformis* and *Bacillus megaterium* strains were C_{15:0 iso} [38.4 and 20.5%, respectively (values for mesophilic

strains of these species, from Kämpfer (1994), were 33–38 and 15–48%, respectively], $C_{16:0\text{ iso}}$ [5.2 and 1.9% (mesophiles 2 and 0.9–2.4%)], and $C_{17:0\text{ iso}}$ [24.4 and 2.3% (mesophiles 10 and 0.5–1.7%)], which accounted for 25–68% of the total, whereas for other components, the patterns were $C_{15:0\text{ ante}}$ [10.2 and 50% (mesophiles 30 and 32–67%)], $C_{16:0}$ [12.4 and 3.3% (mesophiles 2 and 1.5–2.8%)], and $C_{17:0\text{ ante}}$ [6 and 7.7% (mesophiles 10 and 1.7–3%)]. These profiles suggest that any potential distinctions between the rather variable fatty acid profiles of *Geobacillus* species and *Bacillus* species are largely lost when strains of each group are incubated at the same temperature.

List of species of the genus *Geobacillus*

1. ***Geobacillus stearotherophilus*** (Donk 1920) Nazina, Tourova, Poltarau, Novikova, Grigoryan, Ivanova, Lysenko, Petrunyaka, Osipov, Belyaev and Ivanov 2001, 443^{VP} (*Bacillus stearotherophilus* Donk 1920, 373)

ste.a.ro.ther.mo'phi.lus. Gr. n. *stear* fat; Gr. n. *therme* heat; Gr. adj. *philos* loving; N.L. adj. *stearotherophilus* (presumably intended to mean) heat- and fat-loving.

Aerobic, Gram-positive, Gram-variable, and Gram-negative motile rods, varying from 2 to 3.5 μm in length and 0.6 to 1.0 μm in diameter, normally present as single cells or in short chains. Ellipsoidal, occasionally cylindrical, spores are located subterminally and sometimes terminally within sporangia that are usually swollen (Figure 15). Colonies are circular and usually convex, and may be smooth and crenate. Minimum growth temperatures lie in the range 30–45 °C; maximum growth temperatures in the range 70–75 °C. Most strains grow in the range 40–70 °C. Grows in pH 6–8. Starch and gelatin are hydrolyzed; casein hydrolysis is usually positive, but often weak. Nitrate reduction is variable. Growth occurs in the presence of 2% NaCl and sometimes in 5%, but not 7% NaCl. Inhibited by 0.001% lysozyme. Acetate is utilized, but citrate is not usually utilized. Catalase variable and usually oxidase-negative. Acid without gas is produced

FIGURE 15. Photomicrograph of cells of the type strain of *Geobacillus stearotherophilus* viewed by phase-contrast microscopy, showing ellipsoidal, subterminal spores that slightly swell the sporangia. Bar = 2 μm . Photomicrograph prepared by N.A. Logan.

Maintenance procedures

Geobacillus strains may be preserved on slopes of a suitable growth medium that encourages sporulation, such as nutrient agar or trypticase soy agar containing 5 mg/l $\text{MnSO}_4 \cdot 7\text{H}_2\text{O}$. Slopes should be checked microscopically for spores, before sealing to prevent drying out, and stored in a refrigerator; on such sealed slopes, the spores should remain viable for many years. For longer-term preservation, lyophilization and liquid nitrogen may be used, as long as cryoprotectants are added.

from a range of carbohydrates. Hydrocarbons (C_{10} , C_{11}) may be used as carbon and energy sources. Major fatty acids are $C_{15:0\text{ iso}}$, $C_{16:0\text{ iso}}$, and $C_{17:0\text{ iso}}$, which comprise more than 60% of the total fatty acids.

Source: soil, hot springs, desert sand, Arctic waters, ocean sediments, food, and compost.

Bacillus stearotherophilus was for a long period regarded by many as the only obligate thermophile in the genus (see *Taxonomic comments*, above). In the First Edition of this *Manual*, Claus and Berkeley (1986) noted that the heterogeneity of the species was indicated by the wide range of DNA base composition, but they were unable to resolve the taxonomy of the group. Notwithstanding the proposal of the genus *Geobacillus*, several taxonomic studies of thermophilic aerobic endospore-formers, and the proposals of a number of new and revived species, the type species still awaits an emended, modern description based upon polyphasic study of a number of authentic strains following delineation of *Bacillus stearotherophilus sensu stricto*. The description given above is based upon data reported by Gordon et al. (1973), Logan and Berkeley (1984), Claus and Berkeley (1986), White et al. (1993), Kämpfer (1994), and Nazina et al. (2001).

DNA G + C content (mol%): 43.5–62.2 (T_m) and 46.0–52.0 (Bd); 51.5 and 51.9 (T_m) and 51.5 (Bd) for the type strain.

Type strain: ATCC 12980, DSM 22, NCIMB 8923, NCTC 10339.

EMBL/GenBank accession number (16S rRNA gene): AJ294817 (DSM 22).

2. ***Geobacillus caldoxylosilyticus*** (Ahmad et al., 2000b) Fortina, Mora, Schumann, Parini, Manachini and Stackebrandt 2001a, 2069^{VP} (*Saccharococcus caldoxylosilyticus* Ahmad, Scopes, Rees and Patel 2000b)

cal.do.xy.lo.si.ly'ti.cus. L. adj. *caldus* hot; N.L. neut. n. *xylosum* xylose; N.L. adj. *lyticus* dissolving, degrading; N.L. adj. *caldoxylosilyticus* hot and xylose-degrading.

Gram-positive, motile, catalase-positive rods, 4–6 μm in length and 0.5–1.0 μm in diameter, normally present as single cells or in short chains. Oval spores are located terminally within swollen sporangium. Colonies are small, flat, regular in shape, and off-white to beige in color. Type strain grows anaerobically, but other strains may grow only weakly in anaerobic conditions. The optimal growth temperature lies between 50 °C and 65 °C (range 42–70 °C). Optimum pH for growth is 6.5; no growth occurs at pH 5 or 11. Growth is inhibited by 3% NaCl. Nitrate reduction is positive, with weak

anaerobic production of gas from nitrate. Produces acid from glucose, fructose, sucrose, maltose, trehalose, lactose, galactose, cellobiose, arabinose, ribose, and xylose. Strains vary in their utilization of rhamnose and citrate. Starch and casein are hydrolyzed. All strains are negative for indole and urease production, and the Voges–Proskauer test. The main cellular fatty acids are C_{15:0 iso} and C_{17:0 iso}.

Source: soil from Australia, China, Egypt, Italy, and Turkey.

DNA G + C content (mol%): 44.0–50.2; 44.4 or 45.8 in two determinations (*T_m*) for the type strain.

Type strain: S1812, ATCC 700356, DSM 12041.

EMBL/GenBank accession number (16S rRNA gene): AF067651 (ATCC 700356).

3. **Geobacillus debilis** Banat, Marchant and Rahman 2004, 2199^{VP}

de'bil.is. L. masc. adj. *debilis* weak or feeble, referring to the restricted substrate range for this species.

Gram-negative rods, 0.5–1.0 μm wide by 1.0–14.0 μm long, and motile. Spores are produced sparsely and are terminal, sporangium not swollen. Colonies are flat and cream-colored with smooth margins. Description is based upon two isolates. Growth occurs at 50–70 °C, with an optimum above 60 °C. Obligate aerobe. Positive for catalase and oxidase. Produces acid from raffinose and trehalose; some strains also produce acid from ribose, sorbitol, and arabinose. Does not utilize starch, but casein and gelatin are used in some strains; very limited use of alkanes. The species is phylogenetically isolated and belongs most probably to a new genus.

Source: undisturbed subsurface soil in Northern Ireland.

DNA G + C content (mol%): 49.9 (HPLC).

Type strain: Tf, DSM 16016, NCIMB 13995.

EMBL/GenBank accession number (16S rRNA gene): AJ564616 (Tf).

4. **Geobacillus gargensis** Nazina, Lebedeva, Poltarau, Tourova, Grigoryan, Sokolova, Lysenko and Osipov 2004, 2023^{VP}

gar.gen'sis. N.L. masc. adj. *gargensis* of Garga, pertaining to the Garga hot spring located in Eastern Siberia (Russia), from which the type strain was isolated.

Aerobic, Gram-positive rods, motile by means of peritrichous flagella and produces terminally located ellipsoidal spores in slightly swollen sporangia. Description is based upon one isolate. Cells are 1.0–1.5 μm wide and 6–12 μm long. Chemo-organotrophic metabolism. Acid but no gas is produced from a wide range of carbohydrates. Utilizes hydrocarbons (C12–C16), acetate, butyrate, lactate, pyruvate, fumarate, succinate, peptone, tryptone, nutrient broth, potato agar, and yeast extract as carbon and energy sources. No growth occurs on methanol, ethanol, propanol, butanol, isobutanol, formate, or citrate (Simmons'). Nitrate is reduced to nitrite. Unable to grow autotrophically on H₂ + CO₂. Unable to produce NH₃ from peptone. Catalase-positive. Starch, esculin, and casein are hydrolyzed, but gelatin is not. Urea is not decomposed and H₂S and indole are not produced. The egg-yolk lecithinase, Voges–Proskauer, and methyl red tests are negative. Growth factors, vitamins, NaCl, and KCl are not required for growth. The temperature range for growth is 45–70 °C, with optimum growth at 60–65 °C. Growth occurs at pH 5.5–8.5, with optimum

growth at pH 6.5–7.0. Able to grow in both the absence of NaCl and the presence of 1% (w/v) NaCl. Major fatty acids are the iso-branched saturated fatty acids C_{15:0 iso}, C_{16:0 iso}, and C_{17:0 iso}.

Source: the Garga hot spring, Transbaikal region, Russia.

DNA G + C content (mol%): 52.9 (*T_m*).

Type strain: Ga, DSM 15378, VKM B-2300.

EMBL/GenBank accession number (16S rRNA gene): AY193888 (Ga).

5. **Geobacillus jurassicus** Nazina, Sokolova, Grigoryan, Shestakova, Mikhailova, Poltarau, Tourova, Lysenko, Osipov and Belyaev 2005b, 983^{VP} (Effective publication: Nazina, Sokolova, Grigoryan, Shestakova, Mikhailova, Poltarau, Tourova, Lysenko, Osipov and Belyaev 2005b, 50)

ju.ras.si'cus. N.L. masc. adj. *jurassicus* of Jurassic, referring to the geological period of oil-bearing formation, from where the strains were isolated.

Cells are rod-shaped, motile due to peritrichous flagella, and produce terminally located ellipsoidal spores in slightly swollen sporangia. Description is based upon two isolates. Cell wall is Gram-positive. Colonies grown on nutrient agar are round, mucous, colorless, and have a diameter of about 2 mm. Aerobic and chemo-organotrophic. Acid, but not gas, is produced from a wide range of carbohydrates. The utilized carbon and energy sources are hydrocarbons (C₆, C₁₀, C₁₁, C₁₄, and C₁₆), methane-naphthenic oil, acetate, butyrate, pyruvate, lactate, benzoate, fumarate, succinate, malate, ethanol, peptone, tryptone, and yeast extract. Can grow in nutrient broth and on potato agar. Cannot grow on methanol, propanol, butanol, isobutanol, phenol, phenylacetate, alanine, glutamate, serine, formate, propionate, or Simmons' citrate agar. Poor growth is observed on asparagine and glutamine. Catalase-positive and produces NH₃ from peptone. Urea and tyrosine are not degraded. Phenylalanine is not deaminated. H₂S, indole, and dihydroxyacetone are not produced. Esculin, gelatin, and starch are hydrolyzed. Casein is not hydrolyzed. Does not grow autotrophically on H₂ + CO₂ and does not ferment glucose with gas production. The egg-yolk lecithinase, Voges–Proskauer, and methyl red tests are negative. Fe²⁺ is not used as an electron acceptor. Nitrate is not reduced to nitrite or dinitrogen. Grows at temperatures between 45 °C and 65 °C, with optimum growth at 58–60 °C. Grows at pH 6.4–7.8, with optimum growth at pH 7.0–7.2. Can grow in the absence of NaCl and in the presence of 5–5.5% (w/v) NaCl. Major cellular fatty acids are C_{15:0 iso}, C_{16:0 iso}, and C_{17:0 iso}.

Source: the formation water of a high-temperature oilfield.

DNA G + C content (mol%): 53.8–54.5 and 54.5 for the type strain (*T_m*).

Type strain: DS1, VKM B-2301, DSM 15726.

EMBL/GenBank accession number (16S rRNA gene): AY312404 (DS1).

6. **Geobacillus kaustophilus** (Priest, Goodfellow and Todd 1988) Nazina, Tourova, Poltarau, Novikova, Grigoryan, Ivanova, Lysenko, Petrunyaka, Osipov, Belyaev and Ivanov 2001, 444^{VP} (“*Bacillus kaustophilus*” Prickett 1928, 38; *Bacillus kaustophilus* nom. rev. Priest, Goodfellow and Todd 1988, 1879; emend. White, Sharp and Priest 1993, PAGE)

kau.sto'phil.us. Gr. adj. n. *kaustos* burnt, red hot; Gr. adj. *philos* loving; N.L. masc. adj. *kaustophilus* loving intense heat.

Priest et al. (1988) proposed the revival of this species on the basis of five strains, and White et al. (1993) emended the description after study of 14 strains. As there are several discrepancies between the two descriptions, the later (White et al., 1993) description is followed where such discrepancies occur; however, there are also some discrepancies between the description given by White et al. (1993) and the characters presented in the table accompanying the description.

Facultatively aerobic, motile, Gram-positive rods, 0.7–1.5 µm in diameter by 2.0–4.5 µm in length. Ellipsoidal spores are located terminally and subterminally within sporangia that are usually swollen. Colonies are 2–3 mm in diameter, circular to irregular, smooth, convex and entire. Translucent, but with faint brown color when incubated at 37–45 °C, becoming more intensely reddish-brown with prolonged incubation. Pigment is produced on tyrosine. Minimum growth temperature is 37 °C, optimum 60–65 °C, maximum 68–72 °C. Catalase- and oxidase-positive. Nitrate is reduced to nitrite by some strains. Casein and starch are hydrolyzed; most strains hydrolyze tributyrin, gelatin, and esculin. Voges–Proskauer-negative. Acid without gas is produced from a range of carbohydrates. Growth in the presence of 2% NaCl varies; usually no growth occurs in 5% NaCl. Note Sunna et al. (1997b) considered that this species should be merged with *Bacillus thermoleovorans*, but this proposal has not been validated.

Source: pasteurized milk and soil.

DNA G + C content (mol%): 52–58, and 53.9 for the type strain (T_m).

Type strain: ATCC 8005, LMG 9819, NCIMB 8547.

EMBL/GenBank accession number (16S rRNA gene): X60618 (NCIMB 8547).

7. ***Geobacillus lituanicus*** Kuisiene, Raugalas and Chitavichius 2004, 1993^{VP}

li.tu.a'ni.cus. M.L. adj. *lituanicus* of Lithuania, referring to the Lithuanian oilfield from where the type strain was isolated.

Cells are rod-shaped, occurring in chains, motile by means of peritrichous flagella, varying in length from 4.4 to 5.8 µm and in diameter from 1.1 to 1.4 µm. Description is based upon one isolate. Oval subterminal endospores are produced within the slightly distended sporangia. Gram staining is positive. Colonies are small, round, tawny, convex, opaque, and shiny. Obligately thermophilic, the optimal growth temperature ranges between 55 °C and 60 °C, with a minimum of 55 °C and a maximum of 70 °C. Aerobic/facultatively anaerobic chemo-organotroph; nitrate is the terminal electron acceptor under anaerobic conditions. Inhibited by lysozyme. Proteolytic. *Geobacillus thermoleovorans* is the closest phylogenetic neighbor.

Source: the crude oil of a high-temperature oilfield.

DNA G + C content (mol%): 52.5 (according to DNAS-TAR software; Kuisiene et al., 2004).

Type strain: N-3, DSM 15325, VKM B-2294.

EMBL/GenBank accession number (16S rRNA gene): AY044055 (N-3).

8. ***Geobacillus pallidus*** Scholz, Demharter, Hensel and Kandler (1987) Banat, Marchant and Rahman 2004, 2200^{VP} (*Bacillus pallidus* Scholz, Demharter, Hensel and Kandler 1987, PAGE) pa'l.li.dus. L. masc. adj. *pallidus* pale, referring to the pale colony color.

Thermophilic, aerobic, Gram-positive, motile rods 0.8–0.9 × 2–5 µm, occurring singly and in pairs and chains. Forms central to terminal ellipsoidal to cylindrical spores that swell the sporangia slightly. Colonies are flat to convex, circular or lobed, smooth and opaque, and reach diameters of 2–4 mm after 4 d incubation at 55 °C. Optimum growth occurs at 60–65 °C with a minimum of 37 °C and a maximum of 65–70 °C. Grows at pH 8.0–8.5. Catalase- and oxidase-positive. Casein, gelatin, and urea are not hydrolyzed; starch is weakly hydrolyzed; tributyrin is hydrolyzed. Grows in the presence of up to 10% NaCl. Citrate is not utilized as sole carbon source. Nitrate is not reduced. Acid without gas is produced from glucose and from a small number of other carbohydrates. Phylogenetically, *Geobacillus pallidus* most probably does not belong to this genus. However, further research is needed before reclassification can be established.

Source: heat-treated sewage sludge.

DNA G + C content (mol%): 39–41 (T_m).

Type strain: H12, DSM 3670, LMG 11159, KCTC 3564.

EMBL/GenBank accession number (16S rRNA gene): Z26930 (DSM 3670).

9. ***Geobacillus subterraneus*** Nazina, Tourova, Poltarau, Novikova, Grigoryan, Ivanova, Lysenko, Petrunyaka, Osipov, Belyaev and Ivanov 2001, 443^{VP}

sub.ter.ra'ne.us. L. adj. *subterraneus* subterranean, below the Earth's surface.

Gram-positive, rod-shaped cells, 0.8–1.5 µm by 4.6–8.0 µm, motile by means of peritrichous flagella and producing subterminally or terminally located ellipsoidal spores in unswollen sporangia. Description is based upon three isolates. Colonies are round, mucous, and colorless. Growth temperature range is between 45–48 °C and 65–70 °C. pH range for growth is 6.0–7.8. Growth occurs without NaCl and in the presence of 3–5% NaCl. Acid, but no gas, is produced from cellobiose, galactose, glycerol, mannose, and ribose. No acid is produced from adonitol, arabinose, inositol, raffinose, rhamnose, sorbitol, or xylose. Utilizes the following carbon and energy sources: hydrocarbons (C₁₀–C₁₆), methane-naphthenic and naphthenic-aromatic oil, acetate, benzoate, butanol, butyrate, ethanol, formate, fumarate, lactate, phenol, phenylacetate, pyruvate, succinate, peptone, tryptone, nutrient broth, potato agar, and yeast extract. Nitrate is reduced to dinitrogen. Does not grow autotrophically on H₂ + CO₂. Casein, gelatin, and urea are not hydrolyzed. Esculin and starch are degraded. Phenylalanine is not deaminated, Fe³⁺ is not reduced, and tyrosine is not decomposed. Dihydroxyacetone, H₂S, and indole are not produced. The egg-yolk lecithinase and Voges–Proskauer reactions are negative. Major fatty acids are C_{15:0 iso}⁷, C_{16:0 iso}⁷, and C_{17:0 iso}⁷, which comprise more than 80% of the total fatty acids.

Source: formation waters of high-temperature oilfields.

DNA G + C content (mol%): 49.7–52.3 (T_m).

Type strain: 34, DSM 13552, VKM B-2226, AS 12763.

EMBL/GenBank accession number (16S rRNA gene): AF276306 (34).

10. **Geobacillus tepidamans** Schaffer, Franck, Scheberl, Kosma, McDermott and Messner 2004, 2366^{VP}

te.pid.a'mans. L. adj. *tepidus* (luke) warm; L. part. adj. *amans* loving; N.L. part. adj. *tepidamans* loving warm (conditions).

Straight rods, 3.9–4.7 × 0.9–1.2 μm in size, single cells, sometimes in short chains. Description is based upon two isolates. Gram-positive, motile. Moderately thermophilic. Forms oval terminal endospores that swell the sporangia. Positive or weakly positive for catalase. Requires oxygen as an electron acceptor. Covered with an oblique S-layer lattice, composed of identical S-layer glycoprotein protomers. Grows at 39–67 °C, with an optimum of 55 °C; the pH range for optimal growth is 6–9. Type strain is inhibited by 3% NaCl. Inhibited by 0.001% lysozyme. DNA and Tween 80 are hydrolyzed. Negative for the Voges–Proskauer reaction (pH 6.5–7) and acid production from basal medium. The major cellular fatty acids are C_{15:0 iso} and C_{17:0 iso}. The type strain of this species is phylogenetically very close to *Anoxybacillus* and most probably belongs to this genus.

Source: a sugar-beet factory in Austria and from geothermally heated soil, Yellowstone National Park, USA.

DNA G + C content (mol%): 42.4–43.2, and 43.2 for the type strain (HPLC).

Type strain: GS5-97, ATCC BAA-942, DSM 16325.

EMBL/GenBank accession number (16S rRNA gene): AY563003 (GS5-97).

11. **Geobacillus thermocatenulatus** (Golovacheva, Loginova, Salikhov, Kolesnikov and Zaitseva 1975) Nazina, Tourova, Poltarau, Novikova, Grigoryan, Ivanova, Lysenko, Petrunyaka, Osipov, Belyaev and Ivanov 2001, 444^{VP} (*Bacillus thermocatenulatus* Golovacheva, Loginova, Salikhov, Kolesnikov and Zaitseva 1975, 230)

ther.mo.ca.ten'ul.at.us. Gr. n. *therme* heat; N.L. adj. *catenulatus* chain-like; N.L. adj. *thermocatenulatus* thermophilic, chain-like, referring to two of the organism's features.

Facultatively anaerobic, Gram-positive, peritrichously motile rods, 0.9 × 6–8 μm, forming long chains. Description is based on a single isolate. The cylindrical spores are 1.0 × 1.7–2.0 μm in size, are borne terminally and swell the sporangia slightly. Colonies on malt-peptone and potato-peptone agars are round and raised, with entire margins, and a yellowish bloom; they show slight concentric striation and have paste-like consistency. Minimum growth temperature is about 35 °C, optimum is 65–75 °C on agar and 55–60 °C in broth, and maximum growth temperature is about 78 °C. Casein is hydrolyzed weakly, but gelatin, starch, and urea are not hydrolyzed. Grows in presence of 4% NaCl. Nitrate is reduced to gaseous nitrogen. Citrate is utilized. Acetoin, H₂S, and indole are not produced. Acid without gas is produced from cellobiose, fructose, galactose, glucose, glycerol, mannitol, sucrose, and trehalose. Maltose, mannose, and a number of hydrocarbons (C₁₀–C₁₆) are utilized as carbon and energy sources. The major cellular fatty acids are C_{15:0 iso}, C_{16:0 iso}, and C_{17:0 iso}, making up more than 75% of the total. Note Sunna et al. (1997b) considered that this species should be merged with *Bacillus thermoleovorans*, but this proposal has not been validated.

Source: a slime layer inside a hot-gas bore-hole pipe.

DNA G + C content (mol%): 69 (TLC and paper chromatography; as reported by Golovacheva et al. (1975) or 55.2 (T_m, as reported by Nazina et al., 2001).

Type strain: DSM 730, VKM B-1259, strain 178.

EMBL/GenBank accession number (16S rRNA gene): Z26926 (DSM 730).

12. **Geobacillus thermodenitrificans** (Manachini, Mora, Nicastro, Parini, Stackebrandt, Pukrall and Fortina 2000) Nazina, Tourova, Poltarau, Novikova, Grigoryan, Ivanova, Lysenko, Petrunyaka, Osipov, Belyaev and Ivanov 2001, 444^{VP} (*Denitrobacterium thermophilum* Ambroz 1913; *Bacillus thermodenitrificans* Mishustin 1950; *Bacillus thermodenitrificans* Klaushofer and Hollaus, 1970; *Bacillus thermodenitrificans* nom. rev. Manachini, Mora, Nicastro, Parini, Stackebrandt, Pukall and Fortina 2000, 1336)

ther.mo.de.ni.tri'fi.cans. Gr. n. *therme* heat; N.L. part. adj. *denitrificans* denitrifying; *thermodenitrificans* thermophilic denitrifying, referring to two of the organism's features.

Gram-positive, straight rods, 0.5–1 × 1.5–2.5 μm; endospores are oval, subterminal or terminal, and do not distend the sporangium. Colonies are flat with lobate margins and off-white to beige in color. Growth occurs at 50–65 °C and some strains, including the type strain, are capable of growth at 45 and 70 °C. The optimum pH values for growth lie between 6 and 8. Catalase-positive. Grows in the presence of 3% NaCl. Resistant to phenol concentrations of 10–20 mM. Nitrate and nitrite are reduced to gas and gas is produced anaerobically from nitrate. Most strains are able to hydrolyze starch and a few strains degrade casein weakly. Anaerobic growth in glucose broth, growth at pH 9, and citrate utilization are variable between strains. Negative for indole and urease production, and the Voges–Proskauer reaction. Arabinose, cellobiose, fructose, galactose, glucose, lactose, maltose, mannose, ribose, trehalose, and xylose are utilized as sole carbon sources. The main fatty acids are C_{15:0 iso} and C_{17:0 iso}, which account for over 66–69% of the total; minor fatty acids are C_{16:0}, C_{16:0 iso}, and C_{17:0 ante}.

Source: soil.

DNA G + C content (mol%): 48.4–52.3, and 50.3 for the type strain (T_m).

Type strain: DSM 465, LMG 17532, ATCC 29492.

EMBL/GenBank accession number (16S rRNA gene): Z26928 (DSM 465).

13. **Geobacillus thermoglucosidasius** (Suzuki, Kishigami, Inoue, Mizoguchi, Eto, Takagi and Abe 1983) Nazina, Tourova, Poltarau, Novikova, Grigoryan, Ivanova, Lysenko, Petrunyaka, Osipov, Belyaev and Ivanov 2001, 444^{VP} (*Bacillus thermoglucosidasius* Suzuki, Kishigami, Inoue, Mizoguchi, Eto, Takagi and Abe 1983, 493)

ther'mo.glu.co.si.da'si.us. Gr. n. *therme* heat; N.L. adj. *glucosidasius* of glucosidase; N.L. adj. *thermoglucosidasius* indicating the production of heat-stable glucosidase.

Strictly aerobic, Gram-positive, motile rods, 0.5–1.2 × 3.0–7.0 μm; the ellipsoidal endospores are borne terminally and swell the sporangium. Colonies are 0.8–1.2 mm in diameter, flat, smooth, translucent, glistening, circular, entire, and faintly brown in color. Smooth, viscid pellicles are formed in broth. Growth occurs between 42 °C and

67–69 °C; optimal growth temperature is 61–63 °C. Growth occurs at initial pH values of 6.5–8.5. Positive for catalase and oxidase. Grows in the presence of 0.5%, but not 2% NaCl. Nitrate is reduced to nitrite, but denitrification does not occur. H₂S is produced. Citrate utilization is positive in Christensen's medium, but negative in Simmons' medium. Casein and starch are hydrolyzed, but gelatin is not. Urease-positive. Indole production and Voges–Proskauer reaction are negative. Acid without gas is produced from cellobiose, fructose, glucose, glycerol, maltose, mannose, mannitol, rhamnose, salicin, sorbitol, starch, sucrose, trehalose, and xylose. Exo-oligo-1,6-glucosidase is synthesized in large amounts. The main cellular fatty acids are C_{15:0 iso}, C_{16:0 iso}, C_{16:0}, C_{17:0 iso}, and C_{17:0 ante}, making up 90% of the total.

Source: Japanese soil.

DNA G + C content (mol%): 45–46 (T_m).

EMBL/GenBank accession number (16S rRNA gene): AB021197 (ATCC 43742).

14. **Geobacillus thermoleovorans** (Zarilla and Perry 1987) Nazina, Tourova, Poltarau, Novikova, Grigoryan, Ivanova, Lysenko, Petrunyaka, Osipov, Belyaev and Ivanov 2001, 444^{VP} (*Bacillus thermoleovorans* Zarilla and Perry 1987, 263)

therm'ole.o.vo'rans. Gr. n. *therme* heat; L. n. *oleum* oil; L. v. *vorare* to devour; N.L. pres. part. *thermoleovorans* indicating heat-requiring bacteria capable of utilizing oil (hydrocarbons).

Obligately thermophilic, strictly aerobic, generally Gram-negative, nonmotile, rod-shaped cells, 1.5–3.5 µm in length. The oval endospores are borne terminally and swell the sporangia slightly. Colonies are not pigmented. Growth factors are not required. Growth occurs at temperatures between 45 °C and 70 °C, with optimum growth occurring between 55 °C and 65 °C. Grows within the pH range 6.2–7.5. Catalase-positive. Starch is usually hydrolyzed. Voges–Proskauer reaction is negative. A variety of compounds serve as carbon and energy sources, including casein, yeast extract, nutrient broth, peptone, tryptone, acetate, butyrate, pyruvate, cellobiose, galactose, glucose, glycerol, maltose, mannitol, mannose, ribose, sucrose, trehalose, xylose, and n-alkanes (C₁₃–C₂₀). Ammonium salts can be used as nitrogen sources and most strains can utilize NaNO₃. The major dibasic amino acid in the peptidoglycan is diaminopimelic acid. The major cellular fatty acids are C_{15:0 iso}, C_{16:0 iso}, and C_{17:0 iso}, making up more than 60% of the total fatty acids.

Source: soil near hot water effluent, non-thermal muds and activated sludge.

DNA G + C content (mol%): 52–58 (T_m).

Type strain: ATCC 43513, DSM 5366, strain LEH-1.

EMBL/GenBank accession number (16S rRNA gene): M77488 (ATCC 43513).

Note: “*Geobacillus thermoleovorans* subsp. *stromboliensis*” has been proposed by Romano et al. (2005c).

15. **Geobacillus toebii** Sung, Kim, Bae, Rhee, Jeon, Kim, Kim, Hong, Lee, Yoon, Park and Baek 2002, 2254VP

to.e'bi.i. N.L. neut. gen. n. *toebii* derived from toebi, a special farmland compost in Korea, from which the organism was isolated.

Aerobic, Gram-positive, motile rods, 2.0–3.5 µm long and 0.5–0.9 µm wide. Ellipsoidal spores are located subterminally to terminally in swollen sporangia. Description is based on a single isolate. Growth occurs at 45–70 °C with optimal growth at 60 °C. No growth is observed at 80 °C. Growth at 60 °C occurs between pH 6.0 and 9.0, with an optimum pH of about 7.5. No growth is observed in the presence of 0.02% azide or 5% NaCl. Catalase-positive. Acid is produced from D-glucose and inositol, but not from xylose or mannitol. Casein is hydrolyzed, but esculin, gelatin, and starch are not. n-Alkanes are utilized, but acetate, formate, and lactate are not. Denitrifier. The Voges–Proskauer test is positive. Cell-wall peptidoglycan contains *meso*-diaminopimelic acid. The major cellular fatty acids are C_{15:0 iso}, C_{16:0 iso}, and C_{17:0 iso}, which comprise over 85% of the total. Produces factors that stimulate the growth of *Symbiobacterium toebii*.

Source: farmland hay compost in Kongju, Korea.

DNA G + C content (mol%): 43.9 (HPLC).

Type strain: SK-1, DSM 14590, KCTC 0306BP.

EMBL/GenBank accession number (16S rRNA gene): AF326278 (SK-1).

16. **Geobacillus uzenensis** Nazina, Tourova, Poltarau, Novikova, Grigoryan, Ivanova, Lysenko, Petrunyaka, Osipov, Belyaev and Ivanov 2001, 443^{VP}

u.ze.nen'sis. N.L. adj. *uzenensis* of Uzen, referring to the Uzen oilfield, Kazakhstan, from where the type strain was isolated.

Gram-positive or negative, rod-shaped cells, 0.9–1.7 × 4.7–8.5 µm, motile by means of peritrichous flagella and producing terminally located ellipsoidal spores in swollen or non-swollen sporangia. Description is based on two isolates. Colonies are round, mucous and colorless. Growth temperature range is 45–65 °C. pH range for growth is 6.2–7.8. Growth occurs without NaCl and in the presence of up to 4% NaCl. Acid, but no gas, is produced from arabinose, cellobiose, galactose, glycerol, maltose, mannitol, mannose, ribose, and trehalose. No acid is produced from adonitol, inositol, raffinose, rhamnose, sorbitol, or xylose. Utilizes the following carbon and energy sources: hydrocarbons (C₁₀–C₁₆), methane-naphthenic and naphthenic-aromatic oil, acetate, benzoate, butanol, butyrate, ethanol, fumarate, lactate, malate, phenol, phenylacetate, propionate, pyruvate, succinate, peptone, tryptone, nutrient broth, potato agar, and yeast extract. Nitrate is reduced to nitrite. Does not grow autotrophically on H₂ + CO₂. Esculin, gelatin, and starch are hydrolyzed, but not casein. Phenylalanine is not deaminated. Fe³⁺ is not reduced. Tyrosine and urea are not decomposed. Dihydroxyacetone, H₂S, and indole are not produced. The egg-yolk lecithinase, Voges–Proskauer, and methyl red tests are negative. Major fatty acids are C_{15:0 iso}, C_{16:0 iso}, C_{16:0}, C_{17:0 iso}, and C_{17:0 ante}, which comprise more than 80% of the total fatty acids.

Source: formation waters of high-temperature oilfields.

DNA G + C content (mol%): 50.4–51.5 (T_m).

Type strain: U, DSM 13551, VKM B-2229, AS 12764.

EMBL/GenBank accession number (16S rRNA gene): AF276304 (U).

17. *Geobacillus vulcani* (Caccamo et al., 2000) Nazina, Lebedeva, Poltarau, Tourova, Grigoryan, Sokolova, Lysenko and Osipov 2004, 2023^{VP} (*Bacillus vulcani* Caccamo, Gugliandolo, Stackebrandt and Maugeri 2000, 2011)

vul.ca'ni. N.L. gen. masc. n. *vulcani* of the volcano, pertaining to the Eolian Island volcano with a shallow marine hydrothermal vent, from where the organism was isolated.

Aerobic, Gram-positive, motile rods, 4–7 µm long and 0.6–0.8 µm wide, with oval endospores that are borne terminally. Description is based on a single isolate. Negative for catalase and oxidase. Temperature range for growth is 37–72 °C, and optimal growth occurs at 60 °C. Growth occurs in the pH range 5.5–9.0, and optimum is pH 6.0. Growth occurs in the presence of 0–3% NaCl, with optimal growth at 2% NaCl. The following carbon sources support growth: adipate, cellobiose, citrate, fructose, galactose, gluconate, glucose, lactose, malate, maltose, mannitol, mannose, phenylacetate, sucrose, and trehalose. Acid is produced from a wide range of carbohydrates. Positive for Voges–Proskauer test. Indole and H₂S are not produced. Nitrate is not reduced. Esculin, gelatin, starch, and Tween 20 are hydrolyzed, but casein, Tween 80, and urea are not. The major fatty acids are C_{17:0 iso} (21% of total), C_{15:0 iso}

(16.6%), C_{16:0 iso} (14.6%), and C_{17:0 ante} (11.4%); unsaturated acids are absent but nC_{18:0} are present (13%).

DNA G + C content (mol%): 53.0 (HPLC).

Type strain: 3s-1, CIP 106305, DSM 13174.

EMBL/GenBank accession number (16S rRNA gene): AJ293805 (3s-1).

Species Incertae Sedis

Of the thermophilic, aerobic endospore-forming bacteria that were listed as *species incertae sedis* by Claus and Berkeley (1986), “*Bacillus thermocatenuatus*” and “*Bacillus thermodontrificans*” have been validly published and transferred to the genus *Geobacillus*. The remaining invalid, thermophilic species listed by Claus and Berkeley (1986) were “*Bacillus caldolyticus*,” “*Bacillus caldotenax*,” “*Bacillus caldovelox*,” and “*Bacillus flavothermus*.”

“*Bacillus flavothermus*” (Heinen et al., 1982) has been revived and accommodated within *Anoxybacillus* (Pikuta et al., 2000a) as *Anoxybacillus flavithermus*; members of this genus will grow aerobically, but prefer anaerobic conditions (Pikuta et al., 2003a).

Sharp et al. (1980) found high DNA–DNA relatedness between “*Bacillus caldotenax*” and “*Bacillus caldovelox*,” but low relatedness between these two species and “*Bacillus caldolyticus*.” White et al. (1993) therefore merged “*Bacillus caldotenax*” and “*Bacillus caldovelox*” (Heinen and Heinen, 1972) into one species as “*Bacillus caldotenax*” but this proposal has not been validated; they left “*Bacillus caldolyticus*” as a *species incertae sedis*, although DNA–DNA relatedness of 93% between this organism and “*Bacillus caldotenax*” was found. Sharp et al. (1992) also investigated the relatedness of “*Bacillus caldolyticus*,” “*Bacillus caldotenax*,” “*Bacillus caldovelox*,” and *Bacillus kaustophilus* using metabolic studies and phage typing. Rainey et al. (1994) found that “*Bacillus caldovelox*,” “*Bacillus caldolyticus*,” and “*Bacillus caldotenax*” shared almost identical 16S rRNA gene sequences with *Bacillus kaustophilus* and *Bacillus thermoleovorans* and concluded that DNA pairing studies would be required in order to determine whether all five species should be combined into one species. As mentioned above (see *Taxonomic comments*),

Sunna et al. (1997b) identified *Bacillus kaustophilus* and *Bacillus thermocatenuatus*, as well as “*Bacillus caldolyticus*,” “*Bacillus caldotenax*,” and “*Bacillus caldovelox*,” as members of *Bacillus thermoleovorans*, and they proposed the merger of all these species as *Bacillus thermoleovorans*, but this proposal has not been validated. The taxonomic position of “*Bacillus caldovelox*,” “*Bacillus caldolyticus*,” and “*Bacillus caldotenax*,” along with *Bacillus caldolyticus* and *Bacillus thermantarcticus*, was also questioned by Nazina et al. (2001) following biochemical and physiological characterization, fatty acid analysis, DNA–DNA hybridization, and 16S rRNA gene sequence comparisons. Zeigler (2005) also supported the findings of Sunna et al. (1997b), with *Bacillus kaustophilus*, *Bacillus thermocatenuatus*, and *Bacillus thermoleovorans* clustering together, alongside the type strains of *Bacillus vulcani* and *Bacillus lituanicus*. The status of each of the three species “*Bacillus caldolyticus*,” “*Bacillus caldotenax*,” and “*Bacillus caldovelox*” therefore still remains unclear, as the findings and conclusions of Sharp et al. (1980) and White et al. (1993) are not in complete accord with those of Rainey et al. (1994), Sunna et al. (1997b), and Zeigler (2005). Outline descriptions of these species, taken from Heinen and Heinen (1972), Logan and Berkeley (1984), Sharp et al. (1989), and White et al. (1993), therefore follow.

a. “*Bacillus caldolyticus*” Heinen and Heinen, 1972, 17.

Cell diameter is 0.7 µm. Motile. Spores are ellipsoidal to cylindrical, subterminal and terminal, swelling the sporangium. Aerobic, with weak growth in glucose broth under anaerobic conditions. Catalase-negative; oxidase-positive. Casein, gelatin, and starch are hydrolyzed. Acid is produced without gas from cellobiose, fructose, galactose, glucose, glycerol, glycogen, maltose, mannitol, mannose, melezitose, raffinose, ribose, salicin, starch, sucrose, and trehalose. Grows in 2% NaCl broth. No growth at pH 5.7 or in the presence of sodium azide. Optimum pH range 6.0–8.0. Grows at 55 °C, optimum growth temperature is 72 °C, maximum temperature for growth is 82 °C. According to Sharp et al. (1980), nitrate is reduced to nitrite, but Logan and Berkeley (1984) reported a negative reaction in this character. Sharp et al. (1980) found only 38% DNA–DNA relatedness with “*Bacillus caldotenax*,” but White et al. (1993) found 93% relatedness with “*Bacillus caldotenax*.”

Source: a hot natural pool in the USA.

DNA G + C content (mol%): 52.3 (T_m).

Type strain: DSM 405, IFO 15313, LMG 17975.

EMBL/GenBank accession number (16S rRNA gene): Z26924 (DSM 405).

b. “*Bacillus caldotenax*” Heinen and Heinen 1972, 17.

Cell diameter is 0.5 µm. Motile. Spores are ellipsoidal, subterminal and terminal, swelling the sporangium. Aerobic, with weak growth in glucose broth under anaerobic conditions. Catalase-negative; oxidase-positive. Casein, gelatin, and starch are hydrolyzed. Acid is produced without gas from cellobiose, fructose, galactose, glucose, glycerol, glycogen, maltose, mannitol, mannose, melezitose, raffinose, ribose, salicin, starch, and sucrose. Claus and Berkeley (1986) indicated that this organism does not produce acid from trehalose, but Logan and Berkeley (1984) and White et al. (1993) reported that the reference strain was positive

for this character. Grows in 2% NaCl broth. No growth at pH 5.7 or in the presence of sodium azide. Optimum pH range 7.5–8.5. Grows at 55 °C, optimal growth temperature is 80 °C, and maximum growth temperature is 85 °C. According to Sharp et al. (1980), nitrate is reduced to nitrite, but Logan and Berkeley (1984) reported a negative reaction in this character. Sharp et al. (1980) found only 38% DNA–DNA relatedness with “*Bacillus caldolyticus*,” but high relatedness with “*Bacillus caldovelox*,” whereas White et al. (1993) found 93% relatedness between “*Bacillus caldotenax*” and “*Bacillus caldolyticus*.”

DNA G + C content (mol %): 54.6 (T_m).

Type strain: DSM 406, IFO 15314, LMG 17974.

EMBL/GenBank accession number (16S rRNA gene): Z26922 (DSM406).

c. “*Bacillus caldovelox*” Heinen and Heinen 1972, 17.

Cell diameter is 0.6 µm. Motile. Spores are ellipsoidal, subterminal and terminal, swelling the sporangium. Aerobic, with weak growth in glucose broth under anaerobic conditions. Catalase-negative; oxidase-positive. Casein, gelatin, and starch are hydrolyzed. Acid is produced without gas

from cellobiose, fructose, galactose, glucose, glycerol, glycogen, maltose, mannitol, mannose, melezitose, raffinose, ribose, salicin, starch, sucrose, and trehalose. Grows in 2% NaCl broth. No growth at pH 5.7 or in the presence of sodium azide. Optimum pH range 6.3–8.5. Grows at 55 °C, optimum growth temperature is 60–70 °C, maximum growth temperature is 76 °C (Sharp et al., 1980). According to Sharp et al. (1980), nitrate is reduced to nitrite, but Logan and Berkeley (1984) reported a negative reaction in this character. Sharp et al. (1980) found high DNA relatedness between “*Bacillus caldovelox*” and “*Bacillus caldotenax*.”

Source: superheated pool water in the USA.

DNA G + C content (mol %): 65.1 (T_m ; Sharp et al., 1980), but this value may be an error (Sharp et al., 1992).

Type strain: DSM 411, IFO 15315, LMG 14463.

EMBL/GenBank accession number (16S rRNA gene): Z26925 (DSM 411).

Note: The proposals for “*Geobacillus caldoproteolyticus*” (Chen et al., 2004) and “*Geobacillus thermoleovorans* subsp. *stromboliensis*” (Romano et al., 2005c) await validation; see *Taxonomic comments*, above.

Genus VIII. *Gracilibacillus* Wainø, Tindall, Shumann and Ingvorsen 1999, 829^{VP}

THE EDITORIAL BOARD

Gra.ci.li.ba.cil'lus. L. adj. *gracilis* slender; L. masc. n. *bacillus* a rod; N.L. masc. n. *Gracilibacillus* the slender bacillus/rod.

Gram-positive, spore-forming rods (mostly thin) or filaments. Terminal ellipsoidal and/or spherical endospores. Motile. Halotolerant with growth occurring in 0–20% (w/v) NaCl. Strains produce acid from D-glucose. Catalase-positive. Starch and esculin are hydrolyzed. Tests for arginine dihydrolase, lysine, and ornithine decarboxylases and indole production are negative. The predominant cellular fatty acids are C_{15:0 anteiso}⁷, C_{15:0 iso}⁷, C_{17:0 anteiso}⁷, and C_{16:0}. The major polar lipids are phosphatidylglycerol and diphosphatidylglycerol. The predominant menaquinone type is MK-7. The main cell-wall peptidoglycan contains meso-diaminopimelic acid and is directly cross-linked (peptidoglycan type A1γ). *Gracilibacillus* can be distinguished from other closely related genera by 16S rRNA gene sequences.

DNA G + C content (mol %): 35.8–39.4.

Type species: *Gracilibacillus halotolerans* Wainø, Tindall, Shumann and Ingvorsen 1999, 829^{VP}.

Further descriptive information

Gracilibacillus currently contains four species. Three species, *Gracilibacillus halotolerans*, *Gracilibacillus boracitolerans*, and *Gracilibacillus orientalis* were originally placed in the genus *Gracilibacillus* (Wainø et al., 1999; Ahmed et al., 2007b; and Carrasco et al., 2006, respectively). *Gracilibacillus dipsosauri* (originally described as *Bacillus dipsosauri* by Lawson et al., 1996) was transferred from *Bacillus* to *Gracilibacillus* by Wainø et al. (1999). Table 19 gives characteristics helpful for differentiating the species of *Gracilibacillus*.

Sources. Strains of *Gracilibacillus* were isolated from diverse sources. The type strain, *Gracilibacillus halotolerans*, was isolated

from surface mud of Great Salt Lake, Utah, USA. *Gracilibacillus boracitolerans* was isolated from soil naturally high in boron minerals in the Hisarcik area of the Kutahya Province of Turkey. *Gracilibacillus dipsosauri* was isolated from the salt glands of a desert iguana found near Las Vegas, Nevada, USA. *Gracilibacillus orientalis* was isolated from two salt lakes located in Inner Mongolia, China. There are three reported strains of *Gracilibacillus orientalis*, but only one of the other three species.

Cell and colony morphology and growth requirements. Strains are spore-forming, rod-shaped organisms occurring as single cells, usually thin cells, and filaments. Cells are 0.3–0.9 × 1.8–10 µm. Colonies of the four species are entire and 0.3–3.0 mm in diameter. *Gracilibacillus boracitolerans* colonies are viscous and contain a light pink to red pigment. Colonies of the other three species are white to cream and smooth. The optimal temperature of incubation ranges from 25 °C to 47 °C. The range of growth for the four species in NaCl is 0–20%; *Gracilibacillus orientalis* is the only species that requires NaCl for growth; however, *Gracilibacillus dipsosauri* grows more poorly without it. *Gracilibacillus dipsosauri* can grow under anaerobic conditions, whereas *Gracilibacillus halotolerans* and *Gracilibacillus orientalis* are obligate aerobes (data not available for *Gracilibacillus boracitolerans*). The optimal pH for growth is 7.5–8.5 for *Gracilibacillus boracitolerans* and 7.5 for the other three species.

Phenotypic analysis. Phenotypic characteristics are given in the genus description, in Table 19, and in the individual species descriptions. Casein is not hydrolyzed by the three species tested (no data available for *Gracilibacillus boracitolerans*). *Gracilibacillus halotolerans* is the only H₂S-, urease-, and Voges–Proskauer-positive species. *Gracilibacillus halotolerans*, *Gracilibacillus boracitolerans*,

and *Gracilibacillus orientalis* produce β -galactosidase (data not available for *Gracilibacillus dipsosauri*).

Whole-cell fatty acid profiles for the four species are similar. The ranges of the predominant cellular fatty acids found in the four species (Ahmed et al., 2007b) grown in marine broth (Difco) or, for *Gracilibacillus orientalis*, marine broth plus 1.5% (w/v) NaCl are C_{15:0 anteiso} (30–46%), C_{15:0 iso} (6.4–28%), C_{17:0 anteiso} (9.9–19%), C_{16:0} (5.3–16%), C_{16:0 iso} (1.9–7.1%), and C_{15:0} (1.9–6.6%). C_{17:0 iso} is present in *Gracilibacillus boracitolerans*, *Gracilibacillus dipsosauri*, and *Gracilibacillus orientalis* (3.2–6.8%), but not in *Gracilibacillus halotolerans*.

Genotypic analysis. The G + C content of the type strains of each species ranges from 35.8 to 39.4 mol%. DNA–DNA hybridization among three strains of the species of *Gracilibacillus orientalis* is 94–98% (Carrasco et al., 2006). Hybridization of the DNA of the *Gracilibacillus boracitolerans* type strain to the type strains of the other three *Gracilibacillus* species and to the type strain of *Paraliobacillus ryukuensis* (Ishikawa et al., 2002), a close relative, was 13–26% (Ahmed et al., 2007b).

Phylogenetic analysis. The 16S rRNA gene sequence of the type strain of *Gracilibacillus boracitolerans* clustered with *Gracilibacillus orientalis* at 96.7%, *Gracilibacillus halotolerans* at 95.5%, and *Gracilibacillus dipsosauri* at 95.4%. In addition, there was a 95.7% similarity with *Paraliobacillus ryukuensis* (Ahmed et al., 2007b).

Enrichment and isolation procedures

Enrichment and isolation procedures for each species are described in the following publications: *Gracilibacillus halotolerans* (Wainø et al., 1999), *Gracilibacillus boracitolerans* (Ahmed et al., 2007a), *Gracilibacillus dipsosauri* (Deutch, 1994), and *Gracilibacillus orientalis* (Ventosa et al., 1983).

Maintenance procedures

Strains grow on marine agar and broth (Difco) with or without 1.5% (w/v) NaCl and on 10% MH (moderate halophile) medium (Garabito et al., 1997). Isolates can be maintained by lyophilization and as a glycerol (35% w/v) stock at –80 °C.

Differentiation of the genus *Gracilibacillus* from other genera

The closest relatives to *Gracilibacillus* are given in the phylogenetic tree (Figure 2) generated by Ludwig et al., this volume. It differs from *Paraliobacillus ryukuensis*, *Amphibacillus xylanus* (Niimura et al., 1990), and *Halolactibacillus halophilus* (Ishikawa et al., 2005), its closest relatives, because they are fermenters and require glucose for growth under aerobic conditions. In addition, *Halolactibacillus halophilus* does not form spores and does not contain respiratory quinones. Table 20 gives major characteristics for differentiating the type strains of these genera.

List of species of the genus *Gracilibacillus*

1. *Gracilibacillus halotolerans* Wainø, Tindall, Schumann and Ingvorsen 1999, 829^{VP}

ha.lo'to.le.rans. Gr.n. *hals* salt; L. adj. *tolerans* tolerating; N.L. adj. *halotolerans* salt-tolerating.

Characteristics of *Gracilibacillus halotolerans* are given in the genus description and in Table 19. Cells are thin rods, 0.4–0.6 × 2–5 µm (filamentous forms also occur) and are motile with peritrichous flagella. Cells grow at 6–50 °C with optimum growth at 47 °C. Growth occurs in 0–20% (w/v) NaCl with optimal growth at 0% NaCl. The pH range for growth is 5–10 with optimal growth at approximately pH 7.5.

Gracilibacillus halotolerans is differentiated from the other species by its production of urease and H₂S (Table 19). Tween

80 is hydrolyzed and alkaline phosphatase is produced. Phenylalanine deaminase, chitinase, and lecithinase are not produced. Acid is produced from D-glucose and D-xylose, but they are not fermented (Wainø et al., 1999).

Using Tris-medium (10% NaCl) and 0.2% (w/v) substrates (Wainø et al., 1999), the following compounds are used for growth: amylose, DL-arabinose, D-cellobiose, D-fructose, D-galactose, glycogen, inulin, lactose, maltose, D-mannose, D-melibiose, D-melezitose, raffinose, L-rhamnose, starch, D-trehalose, D-xylose, glycerol, L-ascorbic acid, D-galacturonic acid, D-gluconic acid, D-glucuronic acid, L-malate, oxoglutaric acid, N-acetylglucosamine, trimethylamine, and Tween 80. Growth does not occur on fucose, butanol, ethanol,

^c*Gracilibacillus dipsosauri* exhibits anaerobic respiration (see species description).

methanol, pentanol, propanol, D-sorbitol, acetate, adipic acid, anisic acid, benzoate, butyrate, caproic acid, caprylate, citrate, formate, fumarate, glutaric acid, glycolate, glyoxylate, lactate, nicotinate, picolinic acid, propionate, pyruvate, succinate, valerate, L-alanine, L-arginine, L-aspartate, betaine, L-cysteine, L-glutamate, L-lysine, L-methionine, L-ornithine, L-phenylalanine, L-proline, L-serine, L-threonine, tryptophan, acetamide, benzamide, sulfanilamide, ethanolamine, and methylamine.

Cells are susceptible to bacitracin, carbenicillin, erythromycin, novobiocin, penicillin, and rifampin, but resistant to gentamicin, kanamycin, nalidixic acid, neomycin, and tetracycline.

In addition to the major polar lipids, phosphatidylglycerol and diphosphatidylglycerol, two phospholipids of unknown structure were detected. The primary cellular fatty acid composition (discussed in the genus description) is similar to the other species except that C_{17:0 iso} is not detected (Ahmed et al., 2007b).

Genotypic and phylogenetic data are given in the genus description. In addition, using 16S rRNA gene sequencing, Wainø et al. (1999) reported that the type strain showed a 96% similarity to *Gracilibacillus dipsosauri*.

DNA G + C content (mol%): 38 (HPLC).

Type strain: DSM 11805, ATCC 700849.

GenBank accession number (16S rRNA gene): AF036922.

2. *Gracilibacillus boracitolerans* Ahmed, Yokota and Fujiwara 2007b, 800^{VP}

bo.ra'ci.i.to'le.rans. N.L. n. *boracium* boron; L. part. adj. *tolerans* tolerating; N.L. part. adj. *boracitolerans* boron-tolerating.

Characteristics of *Gracilibacillus boracitolerans* are given in the genus description and Table 19. Individual cells are 0.3–0.9 × 2.0–4.5 μm, occurring singly and occasionally in pairs; filaments also occur. Spherical endospores are produced in non-swollen or slightly swollen sporangia and are in a terminal or subterminal position. Cells are motile by a long, filamentous, monotrichous flagellum. Ahmed et al. (2007b) studied colonies on BUG agar medium (pH 7.5) at 30 °C for 4 d. Young colonies are dirty white, but become pink and then red in several days. The pink or red pigments may diffuse into the agar after several days. They are 2–3 mm in diameter, circular with entire margins, slightly convex, translucent, and viscous. Growth occurs at 16–37 °C with an optimum temperature of 25–28 °C. There is no growth at 45 °C. The NaCl tolerance range is 0–11% (w/v) with an optimal range of 0.5–3.0%. The pH range for growth was 6.0–10.0 with optimal pH of 7.5–8.5. The type strain tolerates 0–450 mM boron, but grows optimally without boron.

Gracilibacillus boracitolerans can be differentiated from the other species because it is gelatinase-negative and Voges–Proskauer-positive (Table 19). Further phenotypic tests indicate that *Gracilibacillus boracitolerans* gives a positive *O*-nitrophenyl β-D-galactopyranoside (ONPG) test, but is negative for tryptophan deaminase and citrate utilization (API 20E; BioMérieux). Cells can produce acid from L-arabinose, D-ribose, glucose, D-mannose, esculin, D-cellobiose, D-maltose, D-lactose, D-melibiose, and D-trehalose; weak acid is produced from D-xylose, methyl β-D-xylopyranoside, D-fructose, D-mannitol, and D-sorbitol (API 50CHB). Strong enzyme activity (API ZYM) occurs for alkaline phosphatase, β-galactosidase, and α- and β-glucosidase, whereas weak enzyme activity occurs with α-galactosidase, esterase (C8), esterase lipase (C8), and leucine arylamidase.

Using the Biolog system, cells can oxidize 3-methyl glucose, amygdalin, arbutin, D-cellobiose, dextrin, D-fructose, D-galactose, D-mannitol, D-mannose, D-melizitolose, D-melibiose, D-ψicose, D-raffinose, D-ribose, D-sorbitol, D-trehalose, D-xylose, gentiobiose, glycerol, lactulose, L-arabinose, maltose, maltotriose, palatinose, salicin, sucrose, turanose, α-D-glucose, α-D-lactose, methyl α-D-galactoside, methyl β-D-galactoside, methyl α-D-glucoside, methyl β-D-glucoside, DL-lactic acid, D-glucuronic acid, gluconic acid, pyruvic acid, and α-ketobutyric acid.

Cells are resistant to penicillin, amoxycillin, and metronidazole (ATB-VET Strip; BioMérieux).

In addition to the major polar lipids phosphatidylglycerol and diphosphatidylglycerol, moderate to minor amounts of an unknown aminolipid and three polar lipids were detected. The primary cellular fatty acids (discussed in the genus description) are similar to those of the other species, especially *Gracilibacillus orientalis* (GC-based Microbial Identification System; MIDI).

Genetic and phylogenetic data are given in the genus description.

DNA G + C content (mol%): 35.8 (HPLC).

Type strain: T-16X, DSM 17256, IAM 15263, ATCC BAA-1190.

GenBank accession number (16S rRNA gene): AB197126.

3. *Gracilibacillus dipsosauri* Wainø, Tindall, Schumann and Ingvorsen 1999, 829^{VP} (*Bacillus dipsosauri* Lawson, Deutch and Collins 1996, 112)

dip.so.sau'ri. N.L. zool. name *Dipsosaurus* the desert iguana. N.L. gen. n. *dipsosauri* of the desert iguana because it was first isolated from the nasal salt glands of the desert iguana.

Dipsosaurus dorsalis, a desert iguana, has salt glands in its nasal cavities that allow it to excrete a concentrated brine of KCl during osmotic stress (Deutch, 1994). *Gracilibacillus dipsosauri* (formerly *Bacillus dipsosauri*) is the first reported Gram-positive, spore-forming halophile isolated from an animal with salt glands. Its characteristics suggested that it belonged in the genus *Bacillus* (which contains bacilli that form round, terminal spores). However, phylogenetic studies (Lawson et al., 1996) showed that it displayed relatively low sequence similarities with all members of the genus *Bacillus* tested (approximate range 84–93%). It was placed in the genus *Bacillus* as a matter of convenience. In 1999 Wainø et al. transferred it to the new genus, *Gracilibacillus*, because it clustered with the new species, *Gracilibacillus halotolerans* (96% similarity).

Characteristics of *Gracilibacillus dipsosauri* are given in the genus description and Table 19. Deutch (1994) observed that in trypticase soy broth (TSB) cultures containing 0.5–1.5 M (2.9–8.8% w/v) NaCl, cells were thin motile rods $0.3 \times 2\text{--}3\ \mu\text{m}$. With 2 M (11.7 w/v) NaCl, cells were more filamentous and nonmotile. Spherical endospores within swollen terminal sporangia were formed after 2–3 d on TSB agar containing 1 M (7.5% w/v) KCl. Longer filaments containing several spherical endospores were sometimes observed. Sporulation occurred less frequently in liquid cultures. Growth temperature ranges from 28 °C to 50 °C with an optimal temperature of 45 °C. No growth was observed at 2.5 M (14.6%) NaCl (Deutch, 1994), but it did grow well at 2.5 M (18.75%) KCl. Carrasco et al. (2006) reported that *Gracilibacillus dipsosauri* grows in 0–15% (w/v) NaCl with an optimum of 3%. Deutch (1994) reported that although growth was observed without added salt, there was a longer lag time and growth rate was slower than normal. The pH range for growth is 6.5–10 with an optimum of 7.5. Cells grow aerobically and anaerobically in media containing nitrate or nitrite as terminal electron acceptors; however, they behave as strict aerobes in thioglycollate broth. Colonies are smooth, white, circular, and 2.0 mm in diameter when grown at 37 °C on TSB agar.

Gracilibacillus dipsosauri can be distinguished from the other species because it can grow anaerobically, it hydrolyzes gelatin and reduces nitrate (Table 19). In addition, using phenol red fermentation broth, weak acid is produced in glucose, sucrose, mannitol, and dulcitol. No acid or gas was seen during fermentation in API test strips or in Bromocresol purple fermentation broths. Triacylglycerides, ONPG, and *p*-nitrophenylgalactoside are hydrolyzed. Phospholipids and red blood cells are not hydrolyzed. Methyl red test is negative.

Cells are sensitive to chloramphenicol, kanamycin, and triple sulfa, but resistant to ampicillin, bacitracin, and streptomycin.

In addition to the major polar lipids, phosphatidylglycerol and diphosphatidylglycerol, two phospholipids of unknown structure were detected. The primary cellular fatty acids are similar to those of the other species (discussed above).

Genotypic and phylogenetic data are given in the genus description.

DNA G + C content (mol%): 39.4.

Type strain: ATCC 700347, DD1, NCFB 3027, DSM 11125.

GenBank accession number (16S rRNA gene): X82436.

4. **Gracilibacillus orientalis** Carrasco, Márquez, Yanfen, Ma, Cowan, Jones, Grant and Ventosa 2006, 56^{VP} o.ri.en.ta'lis. L. adj. *orientalis* eastern, bacterium inhabiting the East.

Characteristics of *Gracilibacillus orientalis* are given in the genus description and Table 19. Individual cells are $0.7\text{--}0.9 \times 2.0\text{--}10.0\ \mu\text{m}$. Spherical endospores are formed in swollen sporangia at a terminal position. Colonies are 0.3–0.6 mm in diameter and cream-colored and opaque with entire margins when cultivated for 2 d on agar containing 10% MH medium. Growth occurs at 4–45 °C with an optimum temperature of 37 °C. *Gracilibacillus orientalis* is moderately halotolerant; the NaCl tolerance range is wide, 1–20% (w/v), with an optimal growth at 10.0%. The pH range for growth is 5.0–9.0 with an optimum of 7.5.

Gracilibacillus orientalis can be differentiated from other species because it requires NaCl for growth and is oxidase-negative (Table 19). Further phenotypic characteristics include acid production from arabinose, galactose, glycerol, D-fructose, D-lactose, D-mannitol, D-xylose, maltose, D-trehalose, and sucrose. Phosphatase test is positive. Tween 80 is not hydrolyzed and methyl red, phenylalanine deaminase, and Simmons citrate tests are negative. Compounds used as sole carbon and energy sources are acetate, citrate, formate, fumarate, D-fucose, lactose, propanol, D-sorbitol, and valerate. Compounds not utilized as sole carbon and energy sources are D-arabinose, D-cellobiose, D-galactose, maltose, D-mannose, D-melibiose, D-melezitose, L-raffinose, D-trehalose, D-xylose, butanol, ethanol, methanol, benzoate, propionate, and succinate. Compounds not used as sole carbon, nitrogen and energy sources are L-alanine, L-arginine, aspartic acid, L-cysteine, phenylalanine, glutamic acid, DL-lysine, L-methionine, L-ornithine, L-threonine, tryptophan, and L-serine.

Cells are susceptible to bacitracin, chloramphenicol, erythromycin, and rifampin. They are resistant to ampicillin, gentamicin, kanamycin, nalidixic acid, neomycin, novobiocin, and penicillin.

In addition to the major polar lipids, phosphatidylglycerol and diphosphatidylglycerol, *Gracilibacillus orientalis* contains phosphatidylethanolamine and a phospholipid and two amino phospholipids of unknown structure. The cellular fatty acid profile of the type strain is similar to those reported for the other three species (discussed in the genus description). It is especially similar to *Gracilibacillus boraciotolerans* in that it contains the same components in slightly differing amounts (Ahmed et al., 2007b).

Genotypic and phylogenetic data are given in the genus description. In addition, using 16S rRNA gene sequencing, Carrasco et al. (2006) reported that the type strain clustered with the type strain of *Gracilibacillus halotolerans* (95.4% similarity) and the type strain of *Gracilibacillus dipsosauri* (95.4%). The other closely related relative was *Paraliobacillus ryukyensis* (94.8%).

DNA G + C content (mol%): 37.1 (T_m).

Type strain: XH-63, CCM 7326, AS 1.4250 CECT 7097.

GenBank accession number (16S rRNA gene): AM040716.

Genus IX. **Halobacillus** Spring, Ludwig, Marquez, Ventosa and Schleifer 1996, 495^{VP}

STEFAN SPRING

Ha.lo.ba.cil'lus. Gr. n. *hals* salt; L. n. *bacillus* rod; N.L. masc. n. *Halobacillus* salt (-loving) rod.

Spherical to oval cells, 1.0–2.5 µm in diameter, occurring singly, in pairs, or aggregates (packets of four or more cells) or straight rod-shaped cells with pointed ends having a width of 0.5–1.4 µm and a length of 2.0–4.5 µm, occurring singly, in pairs, or short chains. The length of rod-shaped cells can be up to 20 µm under some culture conditions. Gram-positive. Endospores are formed. Motility, if present, is tumbling and conferred by one or more flagella. Colonies are circular, smooth, slightly raised, and opaque. Pigmentation by a nondiffusible pigment is variable ranging from cream-white or pale yellow to bright orange.

Chemo-organotrophic. Strictly aerobic, respiratory metabolism. Moderately halophilic. Growth is optimal at salt concentrations between 5% and 10%, temperatures of 30–38 °C, and pH values between 7.0 and 8.0. Catalase and oxidase are produced. The cell wall contains peptidoglycan of the Orn-D-Asp type (A4β type according to the murein key of Schleifer and Kandler, 1972). The cellular fatty acid pattern is characterized by major amounts of branched fatty acids, especially C_{15:0 anteiso} and a significant amount of C_{16:1 ω7c} alcohol.

Widely distributed in a variety of hypersaline environments ranging from salt marsh soils and sediments to fermented food and mural paintings.

DNA G + C content (mol %): 40–43.

Type species: Halobacillus halophilus (Claus, Fahmy, Rolf and Tosunoglu 1983) Spring, Ludwig, Marquez, Ventosa and Schleifer 1996, 495^{VP} (*Sporosarcina halophila* Claus, Fahmy, Rolf and Tosunoglu 1983, 503.)

Further descriptive information

The type species of the genus, *Halobacillus halophilus*, is characterized by coccoid cell morphology (Figure 16a), whereas all other known species (e.g., *Halobacillus trueperi*) are rod-shaped (Figure 16b). It is unlikely that the absence of a uniform morphotype within the genus indicates a fundamental difference between the species. It probably reflects an ongoing development of cell morphologies from spherical to rod-shaped, or vice versa, with common transition forms like oval or wedge-shaped cells.

Upon division, cells of *Halobacillus halophilus* are hemispherical but have a tendency to elongate giving rise to oval cells. Abnormally large cells occur often. Division into two or three perpendicular planes in *Halobacillus halophilus* can lead to the formation of threes, tetrads, or packets of eight or more cells. In contrast, strains of the other known *Halobacillus* species are characterized by rod-shaped cells that form short chains. The morphology of the rod-shaped cells is usually not very regular. The cells have pointed ends that often taper towards one end, resulting in shapes resembling an elongated egg or wedge.

Spores are either spherical and located centrally or laterally (*Halobacillus halophilus*, Figure 16a) or, more frequently, ellipsoidal with a subterminal or central position (all other described species, Figure 16b). They are highly refractile, survive heating at 75 °C for at least 10 min, and have a size in the range 0.5 to 1.5 µm. The walls of endospores of *Halobacillus halophilus*

FIGURE 16. Phase-contrast photomicrographs of sporulating cultures of (a) *Halobacillus halophilus* DSM 2266^T and (b) *Halobacillus trueperi* DSM 10404^T. Bars = 10 µm.

contain diaminopimelic acid which is not found in walls of vegetative cells (Claus et al., 1983). The spores of this species also contain dipicolinic acid (Fahmy et al., 1985).

With the exception of *Halobacillus karajensis* all *Halobacillus* species are motile. Motility is difficult to detect in some strains and depends on culture conditions and growth phase. Flagella can be exceedingly long and are inserted predominantly as tufts at both poles and sometimes laterally.

Colonies may be bright orange, pale yellow, or cream-white. Pigmentation varies among strains and depends on salt concentration and incubation time. The pigment is water insoluble and nondiffusible.

Halobacillus halophilus is an obligate, moderate halophilic bacterium that requires sodium, magnesium, and chloride ions for growth. Poor or no growth occurs at NaCl concentrations below 3% and MgCl₂ concentrations below 0.5%. The chloride dependence

of growth in *Halobacillus halophilus* has been studied extensively; flagella synthesis, endospore germination, and glycine betaine transport have been found to be dependent on the chloride concentration (Dohrmann and Muller, 1999; Rossler and Muller, 1998, 2001; Rossler et al., 2000). In contrast, the salt requirement of *Halobacillus trueperi* and *Halobacillus litoralis* is less pronounced; both of these species show good growth in medium supplemented with only 0.5% NaCl (Table 21).

All known members of the genus *Halobacillus* are positive for the hydrolysis of gelatin and DNA; they are negative for nitrate reduction, Voges–Proskauer reaction, and hydrolysis of urea and Tween 80.

Whole-cell fatty acid compositions of the validly published *Halobacillus* species are shown in Table 22 (R. M. Kroppenstedt, personal communication). In general, the fatty acid patterns are very similar among the species of the genus and

^aValues are percentages of total fatty acids.

^bThe position of the double bond in unsaturated fatty acids is located by counting from the methyl (ω) end of the carbon chain; *cis* and *trans* isomers are indicated by the suffixes c and t, respectively.

^cSummed feature 4 contained one or more of the following fatty acids: C_{17:1 iso1} and/or C_{17:1 anteiso}.

differences are mainly due to varying quantities of some fatty acids. Branched fatty acids of the iso- and anteiso-type with a chain length of 15:0, 16:0 and 17:0 are clearly dominant as in many other species of Gram-positive, spore-forming halophilic or halotolerant bacilli (e.g., Niimura et al., 1990; Heyndrickx et al., 1998; Wainø et al., 1999). In contrast, the occurrence of the unsaturated fatty acids C_{16:1 ω7c} alcohol and C_{16:1 ω11c} seems to be a typical characteristic of the genus *Halobacillus*. The polar lipid pattern of members of the genus *Halobacillus* resembles that of *Marinococcus albus* and is comprised of phosphatidyl glycerol, diphosphatidyl glycerol, and an unknown glycolipid similar to that found in *Salinicoccus roseus* (Wainø et al., 1999).

The menaquinone system has been determined only in *Halobacillus halophilus* and *Halobacillus karajensis*. In these species MK-7 is the predominant menaquinone (Amoozegar et al., 2003; Claus et al., 1983).

Based on comparative analyses of 16S rRNA gene sequences, the genus *Halobacillus* is located phylogenetically at the periphery of the *Bacillus* rRNA group I as defined by Ash et al. (1991). The rRNA group I is also known as the core cluster of the genus *Bacillus* comprising the true *Bacillus* species. Members of the genus *Halobacillus* form a distinct branch within this phylogenetic group along with other phenotypically diverse species that display various traits that are not in accord with the characteristics of *Bacillus subtilis*, the type species of the genus *Bacillus*.

Consequently, several of these newly isolated species that were only loosely associated with the rRNA group I were placed in novel genera (e.g., *Amphibacillus* gen. nov., Niimura et al., 1990; *Halobacillus* gen. nov., Spring et al., 1996; and *Filobacillus* gen. nov., Schlesner et al., 2001). Several species which were closely related to the newly described taxa but originally affiliated to the genus *Bacillus* or *Sporosarcina*, in the case of *Halobacillus*, were relocated into newly proposed genera as new combinations (e.g., *Gracilibacillus dipsosauri* comb. nov.; Wainø et al., 1999) and *Virgibacillus pantothenicus* comb. nov.; Heyndrickx et al., 1998). In the phylogenetic tree in Figure 17, the location of *Halobacillus* species among other related taxa of Gram-positive, moderately halophilic bacteria is shown. The species most closely related to members of the genus *Halobacillus* are *Marinococcus albus* and *Bacillus halophilus* which together form a stable cluster in most trees independent of the calculation method used (Figure 17). The similarity values of almost complete 16S rRNA gene sequences among members of this group range from 94.2% to 99.3%.

Enrichment and isolation procedures

Most members of the genus *Halobacillus* have been isolated by plating serial diluted suspensions of particulate matter from hypersaline sites on solid media. Selective enrichment methods in liquid media are not available. Suitable media for isolating *Halobacillus* species are Bacto Marine Agar 2216 (Difco)

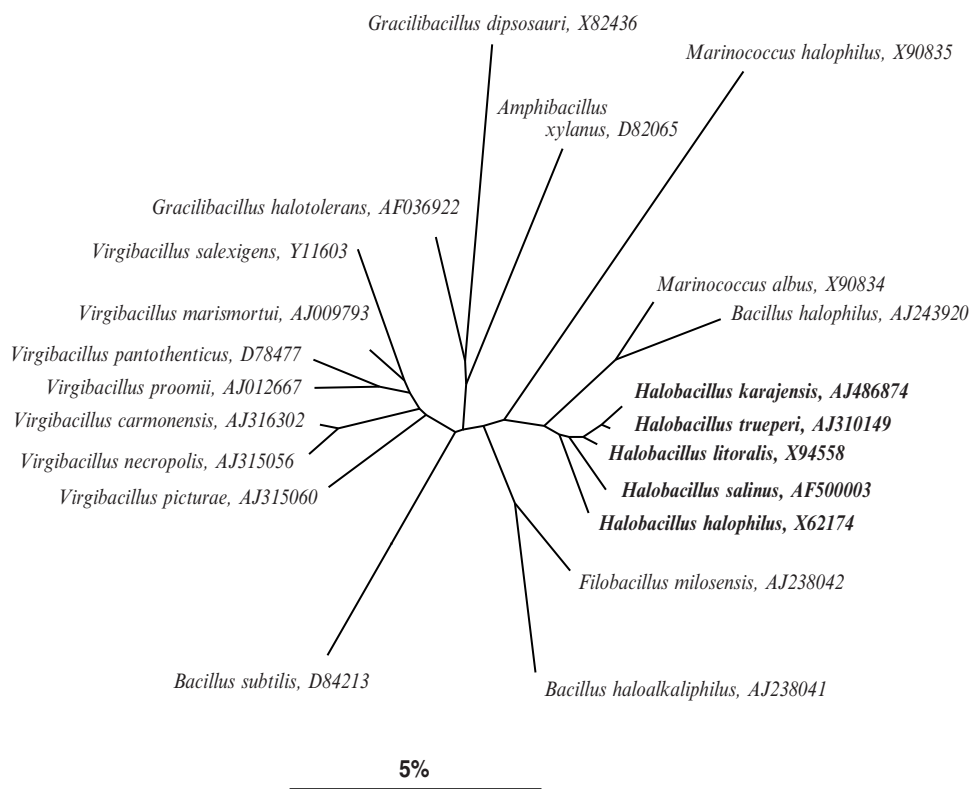

FIGURE 17. Phylogenetic tree based on almost complete 16S rRNA gene sequences showing the position of members of the genus *Halobacillus* among their closest relatives. The GenBank/EMBL accession number for each sequence is shown in parentheses. The tree was reconstructed using the ARB program package (Ludwig and Strunk, 1997). It is derived from a distance matrix on a selection of 16S rRNA sequences using the neighbor-joining method of Saitou and Nei (1987). Phylogenetic distances were calculated as described by Jukes and Cantor (1969). The sequence of *Bacillus subtilis* was used as an outgroup. The bar indicates 5% estimated sequence divergence.

or nutrient agar supplemented with double concentrated sea water (Claus et al., 1992). Several methods have been reported to reduce background growth of undesired microbial species thriving under similar conditions. Claus and Fahmy (1986) heated suspensions of soil samples at 70 °C for 10 min in order to kill vegetative cells and enrich for spore-formers. They noted that it is important to plate heat treated samples on nutrient agar medium supplemented with double concentrated sea water to ensure efficient germination of spores. The number of undesired colonies may be further reduced by increasing the NaCl concentration of the isolation agar to 20% or more, which is tolerated by most strains of *Halobacillus* but inhibitory to several related genera (Spring et al., 1996). Pinar et al. (2001) supplemented enrichment media with 50 µg cycloheximide per ml to avoid fungal growth.

Colonies on agar plates normally appear after 3 d of incubation at 30 °C in the dark. In most cases, colonies of *Halobacillus* strains will develop a pale-yellow to orange pigmentation, which is only seen in older colonies reaching a diameter of 1–2 mm. In addition, one species has been reported to show only a cream-white pigmentation (Amoozegar et al., 2003). Hence, a clear affiliation of novel isolates to the genus *Halobacillus* is not possible solely on the basis of morphological characteristics. For purification, cell material taken from appropriate colonies should be resuspended in a drop of nutrient broth and restreaked onto agar plates of suitable composition.

Maintenance procedures

Vegetative cultures of *Halobacillus*, grown on nutrient agar slants supplemented with 3–10% NaCl and 0.5% MgCl₂, are viable usually for about 6 months if tightly sealed to avoid drying and stored between 4 °C and 10 °C in the dark. Viability is increased to several years if sporulated cultures are kept at 4 to 20 °C in screw-capped tubes. Fahmy et al. (1985) recommended the following medium to obtain good sporulation in *Halobacillus halophilus* at an incubation temperature below 25 °C: peptone, 5.0 g; yeast extract, 1.0 g; NaCl, 24.32 g; MgCl₂·6H₂O, 10.99 g; Na₂SO₄, 4.06 g; CaCl₂·2H₂O, 1.51 g; KCl, 0.69 g; NaHCO₃, 0.20 g; KBr, 0.10 g; SrCl₂·6H₂O, 0.042 g; H₃BO₃, 0.027 g; Na₂SiO₃·9H₂O, 0.005 g; NaF, 0.003 g; NH₄NO₃, 0.002 g; FePO₄·4H₂O, 0.10 g; MnCl₂, 0.01 g; agar, 15 g; distilled water, 1,000 ml.

For the long-term preservation of *Halobacillus* strains, freeze-drying of vegetative cells or of spores is recommended. As a protective menstrum, skim-milk (20% w/v) or serum containing 5% meso-inositol is suitable. Both vegetative cells and spores can be successfully preserved for long periods in liquid nitrogen without severe loss in survival using glycerol (10%) or dimethyl-sulfoxide (5%) as cryoprotective agents.

List of species of the genus *Halobacillus*

In addition to the description given for the genus, several traits of *Halobacillus* species that are useful for their differentiation are summarized in the species descriptions. In Table 21, distinguishing characteristics of *Halobacillus* species are listed.

1. ***Halobacillus halophilus*** (Claus, Fahmy, Rolf and Tosunoglu 1983) Spring, Ludwig, Marquez, Ventosa and Schleifer

Differentiation of the genus *Halobacillus* from other genera

The genus *Halobacillus*, despite its intrageneric variability, can be distinguished easily from most members of the other related taxa shown in the phylogenetic tree in Figure 10. Within this group, only the species *Virgibacillus salexigens*, *Virgibacillus marismortui*, and *Bacillus halophilus* are phenotypically quite similar. They are also Gram-positive, spore-forming, obligately aerobic, grow at neutral pH values, and show a requirement for salt in the medium. The differentiation from the genus *Halobacillus* is, however, possible by analyzing the murein type of the cell wall, which is *m*-Dpm in these species in contrast to Orn-D-Asp in members of the genus *Halobacillus*. *Filobacillus milosensis* is the only representative of this phylogenetic group with a similar murein structure to that of *Halobacillus* (A4β), but cells stain Gram-negative and the cell-wall murein contains Orn-D-Glu instead of Orn-D-Asp. Several species related to *Halobacillus* are facultatively anaerobic; they include *Amphibacillus* species, *Gracilibacillus* species, *Virgibacillus pantothenicus*, and *Virgibacillus proomii*. Other taxa can be discriminated by their obligate alkaliphilic growth (*Amphibacillus*, *Bacillus haloalkaliphilus*) or the absence of spores (*Marinococcus*). *Gracilibacillus halotolerans* is the only member of this phylogenetic group which is halotolerant rather than moderately halophilic, growing optimally in media without salt.

Taxonomic comments

A novel representative of the genus *Halobacillus* was isolated from fish fermentation tanks in Thailand. Strain fs-1 was selected for the secretion of proteinases that are thought to accelerate the liquefaction of fish necessary for the production of fish sauce. A formal description of this strain as *Halobacillus thailandensis* was published by Chaiyanan et al. (1999). According to the given description, this species is phylogenetically and phenotypically quite similar to *Halobacillus litoralis* and *Halobacillus trueperi*, however neither the type strain fs-1 nor its 16S rRNA gene sequence has been deposited in a public culture collection or database. Therefore, the name of this species has never been validated.

A novel *Halobacillus* species, *Halobacillus salinus*, has been isolated from a salt lake of the East Sea in Korea (Yoon et al., 2003b). At the time of chapter preparation, only the 16S rRNA gene sequence of this newly described species was available. The phylogenetic position is shown in Figure 10.

Acknowledgements

I am grateful to R. M. Kroppenstedt for providing data on whole-cell fatty acid patterns of *Halobacillus* strains.

Spherical or oval cells, occurring singly, in pairs, triads, tetrads, or packages. Spherical cells 1.0–2.5 µm in diam-

eter, oval cells 1.0–2.0 by 2.0–3.0 µm. Motile by one or more randomly spaced flagella on each cell. Endospores round, 0.5–1.5 µm, located centrally or laterally. Colonies round, smooth, opaque, and forming an orange, nondiffusible pigment. Casein, gelatin, pullulan, and starch are hydrolyzed, but esculin, Tween 80, and tyrosine are not hydrolyzed. Generally no acid produced from glucose or other sugars. Salinity range for growth between 2% and 15% NaCl; temperature range between 15 °C and 37 °C; pH range between 7.0 and 9.0.

Source: salt marsh soils.

DNA G + C content (mol%): 40.1–40.9 (T_m).

Type strain: 3, ATCC 35676, DSM 2266.

GenBank accession number (16S rRNA gene): X62174.

2. **Halobacillus karajensis** Amoozegar, Malekzadeh, Malik, Schumann and Spröer 2003, 1062^{VP}

ka.ra.jen'sis. N.L. adj. *karajensis* from the region of Karaj, Iran, where the organism was isolated.

Cells are rod-shaped, 0.8–0.9 by 2.5–4.0 µm, occurring singly, in pairs, or in short chains. Filamentous cells can be observed under suboptimal conditions for growth. Non-motile. Endospores are ellipsoidal or spherical and located at a central or subterminal position. Colonies round, smooth, opaque, and with a white or cream color. Gelatin, casein, esculin, and starch are hydrolyzed, but Tween 80 and tyrosine are not hydrolyzed. Acid is produced from D-fructose, D-glucose, maltose, mannitol, mannose, and raffinose, but not from D-arabinose, D-galactose, sucrose, and D-xylose. Salinity range for growth between 1.0% and 24% NaCl; temperature range between 10 °C and 49 °C; pH range 6.0–9.6.

Type strain: MA-2, DSM 14948, LMG 21515.

GenBank accession number (16S rRNA gene): AJ486874.

3. **Halobacillus litoralis** Spring, Ludwig, Marquez, Ventosa and Schleifer 1996, 495^{VP}

li.to.ra'lis. L. masc. adj. *litoralis* pertaining to the shore.

Cells are rod-shaped, 0.7–1.1 by 2.0–4.5 µm, occurring singly, in pairs, or in short chains. Sometimes filamentous cells up to 20 µm long can be observed. Motile by means of several flagella inserted at both poles or laterally. Endospores are ellipsoidal or sometimes spherical and located at a central or subterminal position. Colonies round, smooth, opaque, and forming an orange, nondiffusible pigment. Gelatin is

hydrolyzed, but casein, esculin, pullulan, starch, Tween 80, and tyrosine are not hydrolyzed. Acid is produced from D-fructose, D-glucose, maltose, D-mannitol, sucrose, D-trehalose, and D-xylose, but not from D-galactose. Salinity range for growth between 0.5% and 25% NaCl; temperature range between 10 °C and 43 °C; pH range between 6.0 and 9.5.

Source: sediment obtained from the Great Salt Lake (Utah).

DNA G + C content (mol%): 42 (T_m).

Type strain: SL-4, ATCC 700076, CIP 104798, DSM 10405, LMG 17438.

GenBank accession number (16S rRNA gene): X94558.

4. **Halobacillus trueperi** Spring, Ludwig, Marquez, Ventosa and Schleifer 1996, 495^{VP}

true'peri. N.L. gen. n. *trueperi* of Trueper, in honor of Hans G. Trüper, a German microbiologist.

Cells are rod-shaped, 0.7–1.4 by 2.0–4.5 µm, occurring singly, in pairs, or in short chains. Sometimes cells up to 20 µm long are present. Motile by means of several flagella, which are inserted at both poles or laterally. Endospores are ellipsoidal or sometimes spherical and located at a central or subterminal position. Colonies round, smooth, opaque and forming an orange, nondiffusible pigment. Gelatin and pullulan are hydrolyzed, but casein, esculin, starch, Tween 80, and tyrosine are not hydrolyzed. Acid is produced from D-fructose, D-galactose, D-glucose, maltose, D-trehalose, and sucrose, but not from D-mannitol and D-xylose. Salinity range for growth between 0.5% and 30% NaCl; temperature range between 10 °C and 44 °C; pH range between 6.0 and 9.5.

Source: sediment obtained from the Great Salt Lake (Utah).

DNA G + C content (mol%): 43 (T_m).

Type strain: SL-5, ATCC 700077, CIP 104797, DSM 10404, LMG 17437.

GenBank accession number (16S rRNA gene): AJ310149.

Note added in proof: Since this chapter was prepared, the following new species have been validly published: *Halobacillus aindingensis* (Liu et al., 2005), *Halobacillus campisalis* (Yoon et al., 2007a), *Halobacillus dabanensis* (Liu et al., 2005), *Halobacillus faecis* (An et al., 2007a), *Halobacillus kuroshimensis* (Hua et al., 2007), *Halobacillus locisalis* (Yoon et al., 2004a), *Halobacillus mangrovi* (Soto-Ramirez et al., 2008), *Halobacillus profundi* (Hua et al., 2007), and *Halobacillus yeomjeoni* (Yoon et al., 2005a).

Genus X. **Halolactibacillus** Ishikawa, Nakajima, Itamiya, Furukawa, Yamamoto and Yamasato 2005, 2435^{VP}

Ha.lo.lac'ti.ba.cil'lus. Gr. n. *hals* salt; L. n. *lac* lactic milk; L. masc. n. *bacillus* stick, a small rod; N.L. masc. n. *Halolactibacillus* salt (-loving) lactic acid rodlet.

Cells are **Gram-positive, nonspore-forming, straight rods**, occurring singly, in pairs, or in short chains, and elongated. **Motile with peritrichous flagella. Catalase- and oxidase-negative.** Nitrate is not reduced. Starch and casein are hydrolyzed.

Growth does not occur in the absence of sugars. Slightly halophilic and highly halotolerant. Alkaliphilic. Mesophilic. In anaerobic cultivation, L-lactic acid is the major end product from glucose. In addition to lactate, considerable amounts of

formate, acetate, and ethanol are produced in a molar ratio of approximately 2:1:1 without gas production. Carbohydrates and related compounds are aerobically metabolized to acetate and pyruvate without production of lactate, formate, and ethanol. The cell-wall peptidoglycan is *meso*-diaminopimelic acid. Cellular fatty acids are of the straight-chain, anteiso-branched saturated, iso-branched saturated, and monounsaturated acids. Major cellular fatty acids are C_{13:0 ante} and C_{16:0}. Respiratory quinones and cytochromes are absent. Located within the phylogenetic group composed of halophilic/halotolerant/alkaliphilic and/or alkalitolerant genera in *Bacillus* rRNA group 1.

DNA G + C content (mol %): 38.5–40.7.

Type species: Halolactibacillus halophilus Ishikawa, Nakajima, Itamiya, Furukawa, Yamamoto and Yamasato 2003b, 2437^{VP}.

Further descriptive information

Descriptive information is based on the descriptions of *Halolactibacillus halophilus* (six strains) and *Halolactibacillus miurensis* (five strains).

The genus *Halolactobacillus* is a lactic acid bacterium belonging to family *Bacillaceae*, order *Bacillales*, class “*Bacilli*” in phylum “*Firmicutes*.”

Phylogenetic position of the genus *Halolactibacillus* based on 16S rRNA gene sequence analysis is given in Figure 18. The characteristics of *Halolactibacillus halophilus* and *Halolactibacillus miurensis* are listed in Table 23, Table 24, and Table 25.

Lactate is produced in yields of 50–60% of the amount of glucose consumed at an optimum pH under anaerobic cultivation. The other end products are formate, acetate, and ethanol in a molar ratio of μ 2:1:1. No gas is produced (Table 24). The L-isomer of lactate is 80–95% of the total lactate produced. The amount of lactate relative to that of the other three products is markedly affected by the initial pH of the fermentation medium. The lactate yield increases at acidic pH values and decreases at the more alkaline pH values. At all pH values, carbon recovery from glucose consumed is about 100%, and the 2:1:1 molar ratio of formate, acetate, and ethanol produced is retained (Table 24).

The similar alkaliphilic lactic acid bacteria, *Marinilactibacillus psychrotolerans* and *Alkalibacterium olivapovlenticus*, likewise produce formate, acetate, and ethanol at a molar ratio of 2:1:1 (in

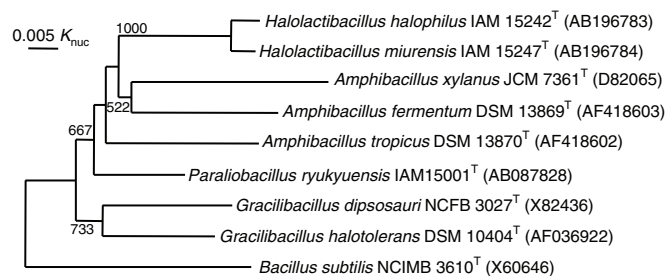

FIGURE 18. Phylogenetic relationships between *Halolactibacillus* and some other related bacteria belonging to the phylogenetic group composed of halophilic/halotolerant/alkaliphilic and/or alkalitolerant genera in *Bacillus* rRNA group 1. The tree, reconstructed using the neighbor-joining method, is based on a comparison of μ 1,400 nucleotides. *Bacillus subtilis* NCIMB 3610^T is used as an outgroup. Bootstrap values, expressed as a percentage of 1,000 replications, are given at branching points.

addition to lactate) under anaerobic conditions. Their product ratios relative to lactate are similarly affected by the initial pH of the fermentation medium (Ishikawa et al., 2003b). Pyruvate is converted to lactate by lactate dehydrogenase and to formate, acetate, and ethanol by pyruvate-formate lyase. It is considered that the product balance depends on the relative activities of the two enzymes involved (Ishikawa et al., 2003b; Janssen et al., 1995; Rhee and Pack, 1980). *Halolactibacillus*, as well as *Marinilactibacillus psychrotolerans* and *Alkalibacterium olivapovlenticus*, are lactic acid bacteria in which pyruvate-formate lyase would be active (especially in *Halolactibacillus*) in the pH range that results in normal growth.

Halolactibacillus metabolizes glucose oxidatively, though it lacks respiratory quinones and cytochromes. Products from glucose under aerobic cultivation conditions are acetate, pyruvate, and lactate, but formate and ethanol are not produced (Table 25). The imbalance in carbon recovery can be ascribed to CO₂ generation, if *Amphibacillus xylanus*, a facultative anaerobe lacking in catalase, respiratory quinones, and cytochromes (Niimura et al., 1989; Niimura et al., 1990) and some homofermentative lactic acid bacteria (*Lactobacillus*, *Pediococcus*, and *Streptococcus*; Sakamoto and Komagata, 1996) are similar to *Halolactibacillus* in the aerobic metabolism of glucose. The oxidative pathway of glucose in these bacteria is mediated by the NADH oxidase/peroxidase system to produce acetate and CO₂ from pyruvate using O₂ as an electron acceptor. Assuming that equimolar amounts of acetate and CO₂ are produced in *Halolactibacillus* and *Marinilactibacillus psychrotolerans*, carbon recovery under aerobic conditions can be calculated as 93–97% (nearly 100%).

Halolactibacillus requires glucose for growth even under aerobic conditions. Under aerobic conditions, growth in 2.5% NaCl GYPF broth (GYPF (GYPB) broth: (per liter) 10 g glucose, 5 g yeast extract, 5 g peptone, 5 g fish extract (beef extract), 1 g K₂HPO₄, 1 g sodium thioglycolate, and 5 ml salt solution (per liter, 40 mg MgSO₄·7H₂O, 2 mg MnSO₄·4H₂O, 2 mg FeSO₄·7H₂O, pH 8.5) is weak when the initial glucose concentration is decreased to 0.1%, and does not occur when glucose is omitted. In GCY broth (composed of 1.0% glucose, 0.5% Vitamin assay Casamino acids (Difco), 0.05% yeast extract, and inorganic components of GYPF broth, pH 8.5), the final OD₆₆₀ of the culture is about 0.20 and in the absence of glucose is less than 0.02.

Halolactibacillus is slightly halophilic (Kushner, 1978; Kushner and Kamekura, 1988) and highly halotolerant. The optimum NaCl concentrations for growth are 2.0% (0.34 M) to 3.0% (0.51 M) for *Halolactibacillus halophilus* and 2.5% (0.43 M) to 3.0% for *Halolactibacillus miurensis*. The maximum specific growth rates, μ_{max} (h⁻¹), of *Halolactibacillus halophilus* IAM 15242^T are 0.18 in 0%, 0.22 in 0.5%, 0.30 in 1.0%, 0.46 in 1.5%, 0.48 in 2.0%, 0.54 in 2.5%, 0.40 in 3.0%, 0.40 in 3.75%, and 0.40 in 5.0% NaCl. Those of *Halolactibacillus miurensis* IAM 15247^T are 0.40 in 0%, 0.44 in 0.5%, 0.56 in 1.0%, 0.56 in 1.5%, 0.56 in 2.0%, 0.70 in 2.5%, 0.60 in 3.0%, 0.48 in 3.75%, and 0.48 in 5.0% NaCl.

Halolactibacillus halophilus is able to grow between 0 and 23.5–24.0% (4.02–4.11 M) NaCl and *Halolactibacillus miurensis* in 0–25.5% (4.36 M) NaCl.

Halolactibacillus is alkaliphilic, as it grows optimally at pH values above 8.0 (Jones et al., 1994) (8.0–9.0 for *Halolactibacillus halophilus* and 9.5 for *Halolactibacillus miurensis*). For *Halolactibacillus halophilus*

^bData from Ishikawa et al. (2005).

^cFatty acid compositions are of strain IAM 15242^T (*Halolactibacillus halophilus*) and of strain IAM 15247^T (*Halolactibacillus miurensis*).

IAM 15242^T, the μ_{\max} values (h⁻¹) are 0.38 at pH 7.0, 0.40 at pH 7.5, 0.42 at pH 8.0, 0.52 at pH 8.5, 0.50 at pH 9.0, and 0.14 at pH 9.5. For *Halolactibacillus miurensis* IAM 15247^T, they are 0.46 at pH 7.0, 0.46 at pH 7.5, 0.46 at pH 8.0, 0.46 at pH 8.5, 0.48 at pH 9.0, 0.68 at pH 9.5, and 0.40 at pH 10.0. The final pH of cultures in 2.5% NaCl GYPF broth reaches 5.2–6.0, which is 0.5–1.3 pH units lower than the minimum pH required to initiate growth.

Halolactibacillus is mesophilic. The optimum growth temperatures of *Halolactibacillus halophilus* and *Halolactibacillus miurensis* are 30–37 °C and 37–40 °C, respectively. The μ_{\max} values (h⁻¹) of *Halolactibacillus halophilus* IAM 15242^T are 0.48 at 25 °C, 0.58 at 30 °C, 0.60 at 37 °C, 0.42 at 40 °C, and 0.06 at 42.5 °C. Those of *Halolactibacillus miurensis* IAM 15247^T are 0.62 at 25 °C,

0.64 at 30 °C, 0.74 at 37 °C, 0.74 at 40 °C, and 0.18 at 42.5 °C. Growth occurs at 5–10 °C to 40 °C and at 5–45 °C for *Halolactibacillus halophilus* and *Halolactibacillus miurensis*, respectively. One exceptional strain, *Halolactibacillus miurensis* IAM 15249, is able to grow at –1.8 °C.

A fairly wide range of hexoses, disaccharides, trisaccharides, and related compounds are fermented. Among 6 sugar alcohols, mannitol and glycerol are fermented. D-Ribose is fermented by both species. Three other pentoses are fermented by *Halolactibacillus miurensis* but not by *Halolactibacillus halophilus*. Gluconate is fermented without production of gas by both species.

The G + C contents of the DNA of *Halolactibacillus* fall into narrow ranges: 39.6–40.7 mol% for *Halolactibacillus halophilus*

and 38.5–40.0 mol% for *Halolactibacillus miurensis*. DNA–DNA relatedness values among the strains of *Halolactibacillus halophilus* are 82–92% and those among the strains of *Halolactibacillus miurensis* are 79–96%. DNA–DNA relatedness values between the two species is 20–40%. Levels of DNA–DNA relatedness between the type strains of *Halolactibacillus* species and the strains of the phylogenetically related genera, *Amphibacillus*, *Gracilibacillus*, and *Paraliobacillus*, are 2–24%. The sequence similarities of 16S rRNA genes (1491 bases in length and covering positions 41–1508) between the type strains of the two species of *Halolactibacillus* is 99.1%. The similarity values of *Halolactibacillus* to *Paraliobacillus*, *Amphibacillus*, *Gracilibacillus*, and *Virgibacillus marismortui* are 94.8–95.1%, 92.9–94.3%, 93.7–94.1%, and 93.8–94.2%, respectively. *Halolactibacillus* constitutes an independent line of descent within the group composed of halophilic/halotolerant/alkaliphilic and/or alkalitolerant genera (henceforth referred to as the HA group in this chapter) in rRNA group 1 of the phyletic group classically defined as the genus *Bacillus* (Ash et al., 1991), and occupies a phylogenetic position that is closely related to the genera *Paraliobacillus*, *Gracilibacillus*, and *Amphibacillus* (Figure 18).

Halolactibacillus strains were isolated from decaying algae and living sponge collected from Oura beach on the Miura Peninsula in the middle of the Japanese mainland. *Halolactibacillus* is a marine inhabitant. It was isolated from marine organisms and is slightly halophilic, halotolerant, and alkaliphilic which are physiological properties consistent with the physico-chemical conditions found in sea water [total salt concentration 3.2–3.8% (w/v), pH 8.2–8.3 (surface)]. *Marinilactibacillus psychrotolerans*, isolated from marine organisms, is also a marine-inhabiting lactic acid bacterium and slightly halophilic, halotolerant, and alkaliphilic (Ishikawa et al., 2003b). For such organisms, Ishikawa et al. (2003b) proposed the term “marine lactic acid

bacteria.” *Halolactibacillus*, as well as *Marinilactibacillus psychrotolerans*, is a marine lactic acid bacterium on the basis of habitat, physiological properties, and lactic acid fermentation.

Enrichment and isolation procedures

Halolactibacillus can be isolated from marine materials by successive enrichment cultures in 7% NaCl GYPF or GYPB (glucose-yeast extract-peptone-fish or beef extract) isolation broth, pH 9.5 or 10.0 at 30 °C under anaerobic cultivation conditions. The first enrichment culture in which the pH has decreased below 7.0 is selected and subcultured. The second enrichment culture incubated at 30 °C is pour-plated with an agar medium supplemented with CaCO₃, overlaid with an agar medium containing 0.1% sodium thioglycolate, and incubated anaerobically. Prolonged incubation in enrichment culture should be avoided as cells in culture tend to autolyse. The compositions of the media and the procedures were described by Ishikawa et al. (2003b).

Maintenance procedures

Halolactibacillus species are maintained by serial transfer in a stab culture stored at 5–10 °C at 1–2-month intervals. The medium is 7% NaCl GYPF or GYPB agar supplemented with 12 g Na₂CO₃, 3 g NaHCO₃, and 5 g CaCO₃ per liter. Solutions of main components, buffer compounds, and CaCO₃ are autoclaved separately and mixed aseptically. *Halolactibacillus* species can be maintained in 2.5% NaCl GYPF or GYPB agar, pH 9.0, supplemented with 5 g CaCO₃ per liter. To prepare this medium, a double-strength solution of the main components is adjusted to pH 9.0, sterilized by filtration, and aseptically mixed with an equal volume of autoclaved 2.6% agar solution. Then, autoclaved CaCO₃ (as a slurry with a small amount of water) is added. Strains are maintained by freezing at –80 °C or below in 2.5% GYPFK or GYPBK broth (GYPF (GYPB)

broth in which the concentration of K₂HPO₄ is increased to 1%) supplemented with 10% (w/v) glycerol. Strains are kept by L-drying in an adjuvant solution composed of (per liter) 3 g sodium glutamate, 1.5 g adonitol, and 0.05 g cysteine hydrochloride in 0.1 M phosphate buffer (KH₂PO₄-K₂HPO₄), pH 7.0 (Sakane and Imai, 1986). Strains can be kept by freeze-drying with a standard suspending fluid containing an appropriate concentration of NaCl.

Differentiation of *Halolactibacillus* species from other related genera and species

Halolactibacillus is distinguished from facultatively anaerobic and/or phylogenetically close members of the HA group by the combination of physiological, biochemical, and chemot-

axonomic characteristics (Table 26). Among these characteristics, catalase, respiratory quinones, cytochromes, and major fatty acids are of high differentiating value. *Halolactibacillus* conforms to two genera in the group of typical lactic acid bacteria, *Marinilactibacillus* and *Alkalibacterium*, with respect to the phenotypic properties of cellular morphology, motility, halophilic and halotolerant properties, and lactic acid fermentation pattern. In addition to lactate, *Halolactibacillus halophilus*, *Halolactibacillus miurensis*, *Marinilactibacillus psychrotolerans*, and *Alkalibacterium olivapovlyticus* anaerobically produce formate, acetate, and ethanol with a molar ratio of 2:1:1 and the ratio of the three products to lactate is affected by the pH of cultivation medium. They share the ability to metabolize glucose aerobically to produce pyruvate and acetate. However,

Halolactibacillus can be distinguished from these lactic acid bacteria by the chemotaxonomic characteristics of peptidoglycan type and cellular fatty acid composition. *Halolactibacillus* is phenotypically similar to *Paraliobacillus ryukyensis* which has a lactic acid fermentation pattern similar to that described above, but is differentiated from this bacterium by the lack of spore formation, catalase, respiratory quinones, and cytochromes.

Halolactibacillus halophilus and *Halolactibacillus miurensis* can be distinguished on the basis of fermentation pattern of carbon compounds: *Halolactibacillus halophilus* does not ferment L-arabinose, D-xylose, D-melezitose, or inulin but ferment glycerol, whereas *Halolactibacillus miurensis* ferments these carbohydrates and weakly ferments glycerol (Table 23).

Taxonomic comments

Halolactibacillus possesses all the essential characteristics of lactic acid bacteria that have been attributed to the most typical lactic acid bacteria including production of lactic acid through the Embden–Meyerhof pathway and lack of catalase, quinones, cytochromes, and respiratory metabolism, but is discrete in the phylogenetic group in which it belongs. Typical lactic acid bacteria can be considered to have evolved retrogressively from facultative anaerobes as close ancestors (Whittenbury, 1964). *Halolactibacillus* also may have evolved as a lactic acid bacterium by following independent but similar evolutionary processes within the HA group while retaining physiological characteristics consistent with the physico-chemical factors of salt concentration and pH that prevail in marine environments.

List of species of the genus *Halolactibacillus*

1. ***Halolactibacillus halophilus*** Ishikawa, Nakajima, Itamiya, Furukawa, Yamamoto and Yamasato 2005, 2437^{VP}

ha.lo.phi'lus. Gr. n. *hals* salt; Gr. adj. *philos* loving; N.L. masc. adj. *halophilus* salt-loving.

The characteristics are as described for the genus and as listed in Table 23, Table 24, and Table 25. The morphology is as shown in Figure 19. Deep colonies in 2.5% NaCl GYPF agar medium are pale yellow, and lenticular, with diameters of 2–4 mm after 3 d at 30 °C. Surface colonies are round, convex, entire, pale yellow, and transparent, with diameters of 0.8–1.0 mm after 3 d at 30 °C. Cells are 0.6–0.9 × 3.6–4.5 μm, occurring singly, in pairs, or in short chains, and elongated. The density and size of colonies that develop on semisolid medium that is evenly inoculated are uniform from the surface to the bottom.

Source: decaying marine algae and a living sponge. The G + C content of the type strain is 40.2 mol%.

DNA G + C content (mol%): 39.6–40.7 (HPLC).

Type strain: M2-2, DSM 17073, IAM 15242, JCM 21694, NBRC 100868, NRIC 0628.

GenBank accession number (16S rRNA gene): AB196783.

2. ***Halolactibacillus miurensis*** Ishikawa, Nakajima, Itamiya, Furukawa, Yamamoto and Yamasato 2005, 2437^{VP}

mi.u.ren'sis. N.L. masc. adj. *miurensis* from the Miura Peninsula, Japan, where the strains were isolated.

The characteristics are as described for the genus and as listed in Table 23, Table 24, and Table 25. The morphology is as shown in Figure 19. Deep colonies in 2.5% NaCl GYPF agar medium are pale yellow and lenticular, with diameters of 2–4 mm after 3 d at 30 °C. Surface colonies are round, convex, entire, pale yellow, and transparent, with diameters of 1.0–1.5 mm after 3 d at 30 °C. Cells are 0.6–0.9 × 3.6–4.5 μm, occurring singly, in pairs, or in short chains, and elongated. The density and size of colonies that develop on semisolid medium that is evenly inoculated are uniform from the surface to the bottom. The G + C content of the type strain is 38.5 mol%.

Source: decaying marine alga.

DNA G + C content (mol%): 38.5–40.0 (HPLC).

Type strain: M23-1, DSM 17074, IAM 15247, JCM 21699, NBRC 100873, NRIC 0633.

GenBank accession number (16S rRNA gene): AB196784.

FIGURE 19. Photomicrographs of cells and peritrichous flagella of (a) *Halolactibacillus halophilus* IAM 15242^T and (b) *Halolactibacillus miurensis* IAM 15247^T grown anaerobically at 30 °C for 2 d on NaCl GYPFK agar. Bars = 2 μm.

Genus XI. *Lentibacillus* Yoon, Kang and Park 2002, 2047^{VP} emend. Jeon, Lim, Lee, Lee, Lee, Xu, Jiang and Kim 2005a, 1342

JEROEN HEYRMAN AND PAUL DE VOS

Len.ti.ba.cil'lus. L. adj. *lentus* slow; L. dim. n. *bacillus* small rod; N.L. masc. n. *Lentibacillus* slowly growing bacillus/rod.

Rod-shaped cells, forming terminal endospores that swell the sporangia. Gram-variable, motile or nonmotile. Colonies are white to cream-colored, smooth and circular to slightly irregular. Catalase-positive, oxidase variable, and urease-negative. Unable to hydrolyze starch, tyrosine, or xanthine. No acid production from D-melibiose, raffinose, or L-rhamnose. **Moderately to extremely halophilic. The major fatty acid is C_{15:0 anteiso} and branched saturated fatty acids account for 95% total fatty acids.** The cell-wall peptidoglycan contains *meso*-diaminopimelic acid at position 3 of the peptide subunit. The predominant menaquinone is MK-7. The major polar lipids are diphosphatidylglycerol and phosphatidylglycerol.

DNA G + C content (mol%): 42.0–44.0.

Type species: *Lentibacillus salicampi* Yoon, Kang and Park 2002, 2047^{VP}.

Further descriptive information

As also discussed for the genus *Oceanobacillus*, *Lentibacillus* is part of a quite recently described lineage of halotolerant or halophilic genera in the *Bacillus sensu lato*-group, which may undergo further taxonomic changes in the future. *Lentibacillus*, which was first proposed for a single strain described as *Lentibacillus salicampi* (Yoon et al., 2002), has been extended with the addition of four further species, namely *Lentibacillus juripiscarius* (Namwong et al., 2005), *Lentibacillus salarius* (Jeon et al., 2005a), *Lentibacillus lacisalsi* (Lim et al., 2005c), and *Lentibacillus halophilus* (Tanasupawat et al., 2006). Additional strains of the type species *Lentibacillus salicampi* have also been isolated (Namwong et al., 2005).

Cells are rods of 0.2–0.7 × 1.0–6.0 µm that form spherical or oval endospores. Of all the species in the genus, only cells of *Lentibacillus juripiscarius* are nonmotile. The genus name is based on the slow growth observed for *Lentibacillus salicampi* (Yoon et al., 2002). Strains belonging to the other *Lentibacillus* species generally show slow growth on media with low NaCl content [e.g., Marine Agar (MA)]; however, they grow well on media with higher NaCl content. For *Lentibacillus salicampi* (Yoon et al., 2002), optimal growth occurs at NaCl concentrations of 4–8% (w/v), no growth occurs without NaCl, and the upper NaCl (w/v) limit is 23%, according to Yoon et al. (2002), or 25%, according to Namwong et al. (2005). *Lentibacillus juripiscarius* (Namwong et al., 2005) requires 3–30% (w/v) NaCl, with an optimum of 10%. *Lentibacillus lacisalsi* (Lim et al., 2005c) requires 5–25% (w/v) NaCl for growth and grows optimally in the range 12–15%. *Lentibacillus salarius* (Jeon et al., 2005a) grows in 1–20% (w/v) NaCl and shows optimal growth at 12–14%. *Lentibacillus halophilus* is an extreme halophile, showing an NaCl range for growth of 12–30% (w/v), with an optimum of 20–26%. Unlike other members of the genus, *Lentibacillus lacisalsi* is not able to grow at a pH below 7. *Lentibacillus salicampi* has been described as strictly aerobic (Yoon et al., 2002). However, with the isolation of additional strains, Namwong et al. (2005) demonstrated that *Lentibacillus salicampi* and *Lentibacillus juripiscarius* are able to grow anaerobically in medium containing

nitrate (1%, w/v). *Lentibacillus halophilus* was unable to grow under anaerobic conditions on media with or without added nitrate (1%, w/v). For *Lentibacillus lacisalsi* and *Lentibacillus salarius*, anaerobic growth was only tested on media without added nitrate. Additional discriminative characteristics are summed up in Table 27. For the type strain of *Lentibacillus salicampi*, conflicting results have been reported for acid production from carbohydrates. Namwong et al. (2005) isolated additional strains of *Lentibacillus salicampi* and analyzed them together with the type strain. In their analysis, the type strain of *Lentibacillus salicampi* (JCM 11462^T) produced acid from cellobiose (weak), D-fructose, D-galactose (weak), D-glucose, D-mannose (weak), D-ribose, and xylose (sometimes weak). These results were reproducible. According to Yoon et al. (2002), strain SF-20^T (=JCM 11462^T) did not produce acid from any of these sugars. Whether these conflicting results are due to examination of a different subculture of the type strain is not clear. Fatty acids that can occur in amounts above 20% are C_{15:0 anteiso}, C_{16:0 iso}, and C_{17:0 anteiso}. Additional fatty acids that may occur in moderate amounts (±5–20%) are C_{14:0 iso} and C_{15:0 iso}. However, it is not possible to compare the profiles for the different species, as both the growth media (MA, MA + 10% NaCl, JCM medium no. 377) and the incubation time (2, 3, 7d) were different. It is known that culture conditions can have a major influence on the fatty acid profile (Drucker, 1981). Furthermore, Jeon et al. (2005a) determined the fatty acid profile of *Lentibacillus salarius* from cells grown on MA for 5d and MA + 10% NaCl for 2d. The obtained fatty acid profiles differed markedly. In order to use fatty acid profiles as a distinguishing character within *Lentibacillus*, strains need to be grown and analyzed under strictly standardized conditions. Also, for comparison with closely related genera (e.g., *Oceanobacillus* and *Virgibacillus*) standard conditions are necessary.

Enrichment and isolation procedures

Lentibacillus salicampi strain SF-20^T (Yoon et al., 2002), *Lentibacillus salarius* (Jeon et al., 2005a), and *Lentibacillus lacisalsi* (Lim et al., 2005c) were all isolated from sediment from a salt field (Korea) or lake (China) by plating on MA (Difco) supplemented with salt (8.1, 15, and 20%, w/v, respectively). Additional strains of *Lentibacillus salicampi* and *Lentibacillus juripiscarius* were isolated from fish sauce by plating on JCM medium no. 377, designated *Lentibacillus* medium (composition per liter: 100 g NaCl, 5 g Casamino acids, 5 g yeast extract, 1 g glutamic acid, 2 g KCl, 3 g trisodium citrate, 20 g MgSO₄, 36 mg FeCl₂·4H₂O, 0.36 mg MnCl₂·4H₂O, 20 g agar; pH 7.2). *Lentibacillus halophilus* was isolated from JCM medium no. 168, which is identical to medium no. 377, except for the addition of 200 g NaCl instead of 100 g.

No specific selective isolation procedures have been described for *Lentibacillus*, but representatives of the genus might be selected for, together with other halotolerant/halophilic bacteria, by using media containing 15% (w/v) NaCl. Inoculation of such media could be preceded by a heating step (5–10 min at 80 °C) in order to select for spore-formers.

Maintenance procedures

Lentibacillus strains can be preserved in the refrigerator in tubes containing broth medium or agar slopes, after checking the culture microscopically for sporulation. For long-term preservation, lyophilization or liquid nitrogen may be used under cryoprotection.

Procedures for testing of special characters

Lentibacillus strains were described using standard methodology, except for the addition of NaCl to the culture media.

Differentiation from closely related taxa

Phylogenetically, the genera most closely related to *Lentibacillus* are *Virgibacillus* and *Oceanobacillus*. *Lentibacillus* is not readily distinguishable from *Virgibacillus* and *Oceanobacillus* can only be differentiated from *Lentibacillus* by its slightly lower G + C content (35.8–40.1 and 42.0–44.0 mol% for *Oceanobacillus* and *Lentibacillus*, respectively) (see also section on *Oceanobacillus*).

The distinction between *Lentibacillus* and other halophilic endospore-forming genera of the *Bacillaceae* is also not straightforward, as discussed in more detail for the genus *Oceanobacillus*. *Lentibacillus* has peptidoglycan that contains meso-diaminopimelic acid and the predominant menaquinone is MK-7, which differentiates it from the genera *Halobacillus*, *Filobacillus*, *Jeotgalibacillus*, *Amphibacillus*, and *Halolactibacillus*. Differentiation from other halophilic endospore-forming genera is, when possible, based on only minor phenotypic differences. Furthermore, as many of the remaining halophilic endospore-forming genera are represented by a single species, it is likely that the discovery

of additional species or strains within these genera/species will result in an even less pronounced differentiation.

Taxonomic comments

The main reason for the creation of a separate genus status for *Lentibacillus salicampi* was its phylogenetic position as determined by 16S rRNA gene sequence analysis. In a neighbor-joining tree (Saitou and Nei, 1987) constructed by Yoon et al. (2002), *Lentibacillus salicampi* diverged at the bottom of a cluster including *Virgibacillus pantothenicus*, *Virgibacillus proomii*, *Virgibacillus salexigens* (formerly *Salibacillus salexigens*) and *Virgibacillus marismortui* (formerly *Salibacillus marismortui*). Since at the time of the description *Virgibacillus* and *Salibacillus* were still separate genera, Yoon et al. (2002) concluded that their isolate could not be attributed to one or the other and described it as a novel genus. Phenotypically, this description was supported by the slow growth and fatty acid profile of the strain. Since the time of the description, *Salibacillus* has been transferred to *Virgibacillus* (Heyrman et al., 2003<qu ref=58>), five novel *Virgibacillus* species have been described (Heyrman et al., 2003b; Lee et al., 2006b; Yoon et al., 2005b), and *Bacillus halodenitrificans* has been transferred to *Virgibacillus* as *Virgibacillus halodenitrificans* (Yoon et al., 2004c). Furthermore, *Lentibacillus* has been expanded with the description of *Lentibacillus juripiscarius* (Namwong et al., 2005), *Lentibacillus salarius* (Jeon et al., 2005a), *Lentibacillus lacisalsi* (Lim et al., 2005c), and *Lentibacillus halophilus* (Tanasupawat et al., 2006). Additionally, the closely related genus *Oceanobacillus* has been described to accommodate the species *Oceanobacillus iheyensis*

(Lu et al., 2002; Lu et al., 2001) and later expanded by the description of *Oceanobacillus oncorhynchi* (Yumoto et al., 2005b) and the transfer of *Virgibacillus picturae* (Heyrman et al., 2003b) to *Oceanobacillus* as *Oceanobacillus picturae* (Lee et al., 2006b). With every addition of a novel species in the genera *Lentibacillus*, *Virgibacillus*, and *Oceanobacillus*, the phylogenetic relationships between these genera changed and the phenotypic differences originally differentiating them disappeared. As the majority of species belonging to *Lentibacillus*, *Virgibacillus*, and

Oceanobacillus have been described in the last five years, future species descriptions in the neighborhood of these genera can be expected. The description of two novel species within the genus *Lentibacillus*, namely *Lentibacillus kapialis* and *Lentibacillus halodurans*, and two novel *Oceanobacillus* species, namely *Oceanobacillus chironomi* and *Oceanobacillus profundus*, are in press. These data will probably allow better assessment of whether the current situation is satisfactory or whether further rearrangements are necessary.

List of species of the genus *Lentibacillus*

1. *Lentibacillus salicampi* Yoon, Kang and Park 2002, 2047^{VP}

sa.li.cam'pi. L. n. *sal* salt; L. n. *campus* field; N.L. gen. n. *salicampi* of a salt field.

Morphology and general characters are as for the generic description and further descriptive information.

Cells are Gram-variable rods, 0.4–0.7 × 2.0–4.0 μm, motile by a single flagellum. Optimal growth temperature is 30 °C. Growth occurs at 15 and 40 °C, but not at 10 or above 41 °C. Optimal pH for growth is 6.0–8.0 and no growth is observed at pH 5.0. Esculin and hypoxanthine are not hydrolyzed. Acid is produced from stachyose, but not from adonitol, lactose, D-melezitose, myo-inositol, D-sorbitol, or sucrose. Conflicting results are reported in literature for the acid production from, e.g., cellobiose and D-galactose.

Source: a salt field of the Yellow Sea in Korea and fish sauce (Thailand).

DNA G + C content (mol%): 44.0 (reverse-phase HPLC).

Type strain: SF-20, ATCC BAA-719, CIP 107807, JCM 11462, KCCM 41560, KCTC 3792.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY057394.

2. *Lentibacillus halophilus* Tanasupawat, Pakdeeto, Namwong, Thawai, Kudo and Itoh 2006, 1862^{VP}

ha.lo'phi.us. Gr. n. *hals*, *halos* salt; Gr. adj. *philos* loving; N.L. masc. adj. *halophilus* salt-loving.

Morphology and general characters are as for the generic description and further descriptive information.

Cells are Gram-positive rods, mostly 0.4–0.6 × 1.0–3.0 μm, though longer cells (up to 6 μm) or short filaments are also observed. Growth occurs between 15 °C (weakly) and 42 °C, but not at 10, 45, or 50 °C. Optimum temperature range is 30–37 °C. Growth is observed between pH 6 and 8, but not at pH 5 or 9; optimum pH is 7.0–7.5. Does not hydrolyze esculin, arginine, gelatin, phenylalanine, or hypoxanthine. Acid is not produced from cellobiose, D-galactose, D-melezitose, myo-inositol, salicin, sorbitol, or sucrose.

Source: fish-sauce fermentation in Thailand.

DNA G + C content (mol%): 42.1–43.1 (reverse-phase HPLC).

Type strain: PS11-2, JCM 12149, TISTR 1549, PCU 240.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AB191345.

3. *Lentibacillus juripiscarius* Namwong, Tanasupawat, Smitintont, Visessanguan, Kudo and Itoh 2005, 319^{VP}

ju.ris.pis'ca.ri.us. L.n. *jus*, *juris* sauce; L. adj. *piscarius* -a -um of, or belonging to, fish; N.L. masc. adj. *juripiscarius* of a fish sauce.

Morphology and general characters are as for the generic description and further descriptive information.

Cells are Gram-positive, nonmotile rods, 0.4–0.5 × 1.5–6.0 μm. Growth range is 10–45 °C, with an optimum at 37 °C. Grows at pH 5.0–9.0, with an optimum at pH 7.0. Hydrolyzes gelatin, but not arginine, hypoxanthine, phenylalanine, or tributyrin. Negative results for Voges–Prouskauer reaction, methyl red test, and indole and H₂S formation. Produces acid from sucrose, but not from amygdalin, cellobiose, D-galactose, inulin, melezitose, methyl α-D-glucoside, myo-inositol, salicin, or sorbitol.

Source: fish sauce (Thailand).

DNA G + C content (mol%): 43.0 (reverse-phase HPLC).

Type strain: IS40–3, CIP 108664, DSM 16577, JCM 12147, PCU 229, TISTR 1535.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AB127980.

4. *Lentibacillus lacisalsi* Lim, Jeon, Song, Lee, Ju, Xu, Jiang and Kim 2005c, 1807^{VP}

la.ci.sal'si. L. masc. n. *lacus* lake; L. adj. *salsus* -a -um salted, salt; N.L. gen. n. *lacisalsi* of a salt lake.

Morphology and general characters are as for the generic description and further descriptive information. Description is based on a single strain.

Cells are 0.4–0.6 × 1.2–3.0 μm, motile with peritrichous flagella. Growth occurs at 15–40 °C and pH 7.0–9.5, with optimum growth at 30–32 °C and pH 8.0. Does not hydrolyze esculin or hypoxanthine. Does not produce acid from adonitol, arbutin, or D-salicin.

Source: a salt lake in China.

DNA G + C content (mol%): 44.0 (reverse-phase HPLC).

Type strain: BH260, KCTC 3915, DSM 16462.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY667497.

5. *Lentibacillus salarius* Jeon, Lim, Lee, Lee, Lee, Xu, Jiang and Kim 2005a, 1342^{VP}

sa.la'ri.us. L. masc. adj. *salarius* of, or belonging to, salt, because of the isolation of this micro-organism from saline sediment.

Morphology and general characters are as for the generic description and further descriptive information. Description is based on a single strain.

Cells are Gram-positive rods, $0.2\text{--}0.3 \times 1.5\text{--}3.0\ \mu\text{m}$, motile by flagella. Growth occurs at $15\text{--}50\ ^\circ\text{C}$ and pH 6.0–8.5, with optimum growth at $30\text{--}35\ ^\circ\text{C}$ and pH 7.0–7.5. Able to hydrolyze esculin, but not hypoxanthine. Does not produce acid from adonitol, arbutin, or D-salicin.

Source: saline soil in China.

DNA G + C content (mol%): 43.0 (reverse-phase HPLC).

Type strain: BH139, KCTC 3911, DSM 16459.

GenBank/EMBL/DDBJ accession number (16S rRNA gene): AY667493.

Genus XII. **Marinococcus** Hao, Kocur and Komagata 1985, 535^{VP} (Effective publication: Hao, Kocur and Komagata 1984, 456.)

ANTONIO VENTOSA

Ma.ri.no.coc'cus. Gr. adj. *marino* marine; Gr. n. *kokkos* a grain or berry; N. L. masc. n. *Marinococcus* marine coccus.

Gram-positive, spherical cells, $1.0\text{--}1.2\ \mu\text{m}$ in diameter, occurring singly, in pairs, tetrads, or clumps. Motile. The motile cells usually have one or two flagella. Non-spore-forming. Colonies are circular and smooth and may be either orange, yellowish orange or creamy white. Moderately halophilic. Growth occurs in media with 5 to 20% NaCl. Optimum temperature for growth is $28\text{--}37\ ^\circ\text{C}$. Chemo-organotrophic. Metabolism respiratory. Strictly aerobic. Catalase-positive. Acid may or may not be produced from sugars. The cell wall contains peptidoglycan of *meso*-diaminopimelic acid type. The major menaquinone is MK-7. Found in sea water, solar salterns, and saline soils.

DNA G + C content (mol%): 43.9–48.5.

Type species: **Marinococcus halophilus** Hao, Kocur and Komagata 1985, 535^{VP} (Effective publication: Hao, Kocur and Komagata 1984, 456.) (*Planococcus halophilus* Novitsky and Kushner 1976.).

Further descriptive information

The major cellular fatty acids of *Marinococcus halophilus* and *Marinococcus albus* are C_{15:0 anteiso} acid and C_{17:0 anteiso} acid (Hao et al., 1984). Similar results were obtained by Monteoliva-Sanchez et al. (1989) for a group of isolates belonging to *Marinococcus halophilus*. For *Marinococcus halotolerans* the major fatty acids are C_{15:0 anteiso}, C_{17:0 anteiso} and C_{16:0 iso} (Li et al., 2005). The quinone system of *Marinococcus* is menaquinone, with MK-7 as the major component (Hao et al., 1984; Li et al., 2005; Marquez et al., 1992). The phospholipids of *Marinococcus halotolerans* are phosphatidylinositol and diphosphatidylglycerol (Li et al., 2005). Species of the genus *Marinococcus* have low extracellular hydrolytic activity, except *Marinococcus halophilus*, which has proteolytic activity. In a screening focused on the isolation of moderately halophilic bacteria with hydrolytic activities from several hypersaline environments, a *Marinococcus* strain able to produce a lipase has been reported (Sanchez-Porro et al., 2003).

The ability of *Marinococcus halophilus* and *Marinococcus albus* to precipitate carbonates has been studied in several strains isolated from the Salar de Atacama (Chile). The bioliths precipitated were spherical and varied with the salinity; they were of magnesium calcite, with Mg content increasing with increasing salinity (Rivadeneira et al., 1999). Several plasmids have been detected in *Marinococcus halophilus*; the complete nucleotide sequence (3874 bp) of one of these plasmids, designated pPL1, has been determined. Plasmids have not been detected in *Marinococcus albus* (Louis and Galinski, 1997a).

The species of the genus *Marinococcus* are moderately halophilic, which are defined as those micro-organisms that grow

optimally in media with 3–15% NaCl. To grow over a wide range of salt concentrations, moderately halophilic bacteria accumulate organic osmotic solutes (Ventosa et al., 1998). In the species of the genus *Marinococcus* the main osmotic solutes are ectoine and hydroxyectoine (Ventosa et al., 1998). The genes responsible for the synthesis of the compatible solute ectoine have been identified and sequenced. The three genes (*ectA*, *ectB*, and *ectC*) of the biosynthetic pathway of ectoine were cloned by functional expression in *Escherichia coli*; these genes were not only expressed, but also osmoregulated in *Escherichia coli* (Louis and Galinski, 1997b). A stress-inducible promoter region from *Marinococcus halophilus* has been investigated upstream of the *ectA* gene, using the green fluorescent protein as a reporter molecule (Bestwater and Galinski, 2002). *Marinococcus halophilus* does not entirely rely on ectoine synthesis for osmoadaptation, and similarly to other halophilic bacteria, it can also take up compatible solutes from the external medium. To allow for the uptake of external solutes, *Marinococcus halophilus* is equipped with osmoregulated transport systems, similarly to nonhalophilic bacteria; two transporters for compatible solutes belonging to the betaine-carnitine-choline transporter family have been reported for *Marinococcus halophilus* (Vermeulen and Kunte, 2004). Two structural genes encoding a betaine transporter named BetM, which also accepts ectoine as an additional substrate, and a transport system specific for the uptake of ectoines named EctM have been identified and characterized (Vermeulen and Kunte, 2004). The protein stabilization by several naturally occurring osmolytes has been investigated. Knapp et al. (1999) showed that the osmolyte hydroxyectoine purified from *Marinococcus* is a very efficient stabilizer and they suggest that this compatible solute could be an interesting stabilizer in biotechnological processes in which enzymes are applied in the presence of denaturants or at high temperature.

Enrichment and isolation procedures

Organisms of the genus *Marinococcus* have been isolated from different hypersaline or saline environments, such as water of ponds of salterns, saline soils, or sea water. Specific enrichment or selective isolation media have not been described. They grow well in complex culture media supplemented with a mixture of salts. The strains can be isolated either by direct inoculation on plates or by diluting the samples in sterile salt solution and then plating them on the isolation medium. The medium described

by Ventosa et al. (1983) can be used. The composition of this medium is as follows (in g/l): NaCl, 178.0; MgSO₄·7H₂O, 1.0; CaCl₂·2H₂O, 0.36; KCl, 2.0; NaHCO₃, 0.06; NaBr, 0.23; FeCl₃·6H₂O, trace; proteose-peptone no. 3 (Difco), 5.0; yeast extract (Difco), 10.0; glucose, 1.0; Bacto-agar (Difco), 20.0. The pH is adjusted to 7.2. Plates are incubated aerobically at 30–37°C for 7–15 d. Colonies of *Marinococcus halophilus* and *Marinococcus halotolerant* are yellow-orange or orange, water-insoluble pigmented, while the colonies of *Marinococcus albus* are creamy white. Recently, *Marinococcus* has been isolated from marine sponges growing at a depth of about 300 m on the Sula Ridge close to the Norwegian coast; a rapid identification of *Marinococcus* and other bacterial isolates has been described, based on a rapid proteometric clustering using Intact-Cell MALDI-TOF (ICM) mass spectrometry (Dieckmann et al., 2005).

Maintenance procedures

Strains belonging to *Marinococcus* can be maintained by the standard procedures such as freeze-drying or storage at –80°C or under liquid nitrogen. Slant cultures can be conserved several months at room temperature by using a medium with 10% salts. Nutrient agar plus a mixture of salts or MH medium can be used. The composition of MH medium is (in g/l): NaCl, 81.0; MgCl₂, 7.0; MgSO₄, 9.6; CaCl₂, 0.36; KCl, 2.0; NaHCO₃, 0.06; NaBr, 0.026; proteose-peptone no. 3 (Difco), 5.0; yeast extract (Difco), 10.0; glucose, 1.0; Bacto-agar (Difco), 20.0 (Ventosa et al., 1982; Ventosa et al., 1983).

Differentiation of the genus *Marinococcus* from other genera

The genus *Marinococcus* can be differentiated from other Gram-positive cocci by comparative analysis of the 16S rRNA sequence as well as by several phenotypic and chemotaxonomic features. The species of *Marinococcus* are moderately halophilic, growing in media with 5–20% NaCl; besides, they are motile Gram-positive cocci, in contrast to other related halophilic cocci of the genera *Salinicoccus* (Ventosa et al., 1990b), *Nesterenkonia* (Stackebrandt et al., 1995), or *Jeotgalicoccus* (Yoon et al., 2003c) that are nonmotile. *Marinococcus* has MK-7 as the characteristic predominant menaquinone system, similarly to *Jeotgalicoccus* (Yoon et al., 2003c), in contrast to *Salinicoccus*, which has MK-6 (Ventosa et al., 1990b), and *Nesterenkonia*, which has MK-8, MK-7, and MK-6 (Stackebrandt et al., 1995). Another differential feature of *Marinococcus* is that its cell wall contains murein of the meso-diaminopimelic acid type, while *Salinicoccus* contains murein of the L-Lys-Gly₅ type (Ventosa et al., 1990b), *Nesterenkonia* has murein of the L-Lys-Gly L-Glu type (Stackebrandt et al., 1995), and *Jeotgalicoccus* has murein of the L-Lys-Gly₃₋₄-L-Ala(Gly) type (Yoon et al., 2003c).

Taxonomic comments

Novitsky and Kushner (1976) studied a motile, halophilic coccus obtained from the culture collection of the National Research Council of Canada (NRCC), designated NRCC 14033. This organism was probably a contaminant in the original culture of *Micrococcus* sp. H₅, originally isolated from salted mackerel by Venkataraman and Sreenivasan (1954) and they proposed to place it as a new species of the genus *Planococcus*, as *Planococcus halophilus*, on the basis of its salt

requirements (it cannot grow on nutrient medium at 30°C without added salt) and the different cell-wall peptidoglycan, possessing meso-diaminopimelic acid (Novitsky and Kushner, 1976). This species was included in the Approved Lists of Bacterial Names (Skerman et al., 1980). Ventosa et al. (1983) studied 38 moderately halophilic Gram-positive cocci isolated from several saline soils and the ponds of a saltern in Spain; the 25 strains of group I were assigned to the species *Planococcus halophilus*, the 10 strains of group II were similar to the species *Sporosarcina halophila* (currently named as *Halobacillus halophilus*), and group III comprised three strains that differed from other previously described species and were tentatively designated *Planococcus* sp. On the basis of the phenotypic features as well as the chemotaxonomic data of the type strain of *Planococcus halophilus* as well as several representative strains of the study of Ventosa et al. (1983), Hao et al. (1984) proposed to place *Planococcus halophilus* in a new genus, *Marinococcus*, as *Marinococcus halophilus*, and the three strains of group III of the study of Ventosa et al. (1983) in the new species *Marinococcus albus*. An extensive study of the type strain of *Marinococcus halophilus* and another 55 additional strains isolated from hypersaline soils and salterns located in different areas of Spain was carried out by Marquez et al. (1992); besides the phenotypic data reported by Hao et al. (1984), they reported the results for many phenotypic features, including the growth on different compounds as the sole source of carbon and energy or carbon, nitrogen, and energy, as well as their antibiotic susceptibility. The G + C content of the studied strains ranged from 46.6 to 48.8 mol% (Marquez et al., 1992).

A numerical taxonomic study based on the phenotypic features of 22 strains of moderately halophilic motile cocci isolated from the Salar de Atacama (Chile) showed that they were closely related to *Marinococcus* (Valderrama et al., 1991). The chemotaxonomic data as well as the results of the DNA–DNA hybridization studies showed that strains included in phenons A and B of the previous study constitute additional strains of the species *Marinococcus albus* and *Marinococcus halophilus*, respectively (Márquez et al., 1993). The species *Marinococcus hispanicus*, proposed by Marquez et al. (1990) to accommodate five moderately halophilic Gram-positive nonmotile cocci, was recently transferred to the genus *Salinicoccus*, as *Salinicoccus hispanicus* (Ventosa et al., 1992), on the basis of the chemotaxonomic results and nucleic acids hybridization studies. Recently, a third species of the genus *Marinococcus*, *Marinococcus halotolerant* has been isolated from a saline soil located in Qinghai, north-west China (Li et al., 2005). Phylogenetic analysis of *Marinococcus halophilus* and *Marinococcus halotolerans* based on the 16S rRNA showed that they belong to the low G + C Gram-positive branch but are not closely related to any other species (Farrow et al., 1992; Li et al., 2005). Currently, it is accepted that the species *Marinococcus albus* is not phylogenetically related to the other two *Marinococcus* species, constituting an incoherent phylogenetic cluster, and these data clearly support the placement of *Marinococcus albus* in a different genus.

Differentiation of the species of the genus *Marinococcus*

Some differential features of the species of the genus *Marinococcus* are given in Table 28.

TABLE 28. Differential characteristics of the species of the genus *Marinococcus*^a

Characteristic	1. <i>M. halophilus</i>	2. <i>M. albus</i>	3. <i>M. halotolerans</i>

List of species of the genus *Marinococcus*

1. ***Marinococcus halophilus*** Hao, Kocur and Komagata 1985, 535^{VP} (Effective publication: Hao, Kocur and Komagata 1984, 456) (*Planococcus halophilus* Novitsky and Kushner (1976)

Hal.o.phi'lus. Gr. n. *hals* the sea, salt; Gr. adj. *philos* loving; N.L. masc. adj. *halophilus* salt-loving.

See the generic description for many features.

Colonies on nutrient agar plate with 5–20% NaCl are circular, entire, glistening, convex, smooth, and yellow orange. In salt broth or nutrient broth containing NaCl, slight turbidity is formed with sediment.

Halophilic. Optimum growth in media with 5–15% NaCl. Catalase-positive. Benzidine test for porphyrine positive. Acid but not gas is produced from D-glucose, glycerol, D-xylose, D-trehalose, maltose, sucrose, and D-mannitol in MOF medium of Leifson. Acid is not produced from lactose, D-arabinose, D-galactose, and D-fructose. Gelatin, casein, and esculin are hydrolyzed.

The following tests are negative: oxidase, urease, extracellular DNase, production of acetoin, production of H₂S, production of indole, hydrolysis of starch, tyrosine, and Tween 80, nitrate reduction, arginine dihydrolase, lysine and ornithine decarboxylases, phenylalanine deaminase, phosphatase, egg yolk reaction, hemolysis, growth on nutrient agar without salt, and growth on Simmons citrate agar.

Source: sea water, solar salterns, and saline soils.

DNA G + C content (mol%) 46.4 (*T_m*).

Type strain: strain HK 718, CCM 2706, IAM 12844, JCM 2479, ATCC 27964, DSM 20408, LMG 17439.

GenBank accession number (16S rRNA gene): X90835.

2. ***Marinococcus albus*** Hao, Kocur and Komagata 1985, 535^{VP} (Effective publication: Hao, Kocur and Komagata 1984, 456.) al'bus. L. adj. *albus* white.

See the generic description for many features.

Colonies on nutrient agar plate with 5–20% NaCl are round, smooth, opaque, and nonpigmented. Halophilic. Optimum growth in media with 5–15% NaCl.

The following tests are positive: Benzidine test for porphyrine, oxidase, nitrate reduction, urease, and DNase. The following tests are negative: production of acid from glucose and other sugars, hydrolysis of gelatin, casein, starch, esculin, and Tween 80, production of acetoin, production of H₂S, production of indole, arginine dihydrolase, lysine and ornithine decarboxylases, phenylalanine deaminase, phosphatase, egg yolk reaction, hemolysis, growth on nutrient agar without salt, and growth on Simmons citrate agar.

Source: solar salterns.

DNA G + C content (mol%) 44.9 (*T_m*).

Type strain: strain HK 733, CCM 3517, IAM 12845, JCM 2574, ATCC 49811, DSM 20748, LMG 17430.

GenBank accession number (16S rRNA gene): X90834.

3. ***Marinococcus halotolerans*** Li, Schumann, Zhang, Chen, Tian, Xu, Stackebrandt and Jiang 2005, 1803^{VP}

Ha.lo.to'le.rans. Gr. n. *hals* salt; L. pres. part. *tolerans* tolerating; N.L. part. adj. *Halotolerans* referring to the ability of the organism to tolerate high salt concentrations.

See the generic description for many features.

Colonies are circular, opaque and orange pigmented. Halophilic. The optimum concentration of MgCl₂·6H₂O for growth is 10% (this salt can be substituted by NaCl or KCl). The optimum growth pH and temperature are 7.0–7.5 and 28 °C, respectively. Catalase-positive and oxidase-negative. Acid is produced from esculin, glucose and mannitol. Nitrate is reduced.

The following tests are negative: hydrolysis of gelatin, casein, Tween 80 and starch, methyl red, Voges–Proskauer, production of melanin, indole, and H₂S, arginine dihydrolase and ornithine decarboxylase. The following substrates are utilized: maltose, mannitol, glucose, mannose, fructose, cellobiose, salicin, acetamide, galactose, xylose and dextrin; adonitol, arabinose, arabitol, rhamnose, inositol and sorbitol are not utilized.

Source: a saline soil from Qinghai, north-west China.

DNA G + C content (mol%): 48.5 (HPLC).

Type strain: YIM 70157, DSM 16375, KCTC 19045.

GenBank accession number (16S rRNA gene): AY817493.

Genus XIII. **Oceanobacillus** Lu, Nogi and Takami 2002, 687^{VP} (Effective publication: Lu, Nogi and Takami 2001, 296) emend. Yumoto, Hirota, Nodasaka and Nakajima 2005b, 1523 emend. Lee, Lim, Lee, Lee, Park, Kim 2006b, 256

JEROEN HEYRMAN AND PAUL DE VOS

O.ce.a.no.ba.cil'lus. Gr. n. *okeanos* the ocean; L. dim. n. *bacillus* a small rod; N.L. masc. n. *Oceanobacillus* the ocean bacillus (rod).

Rod-shaped cells, forming ellipsoidal subterminal or terminal endospores that swell the sporangia. Gram-positive and motile by peritrichous flagella. Colonies are circular and white to beige. Obligatory aerobic or facultative anaerobic. **Facultative or obligatory alkaliphilic** and mesophilic. **Halotolerant or halophytic, optimal growth at NaCl concentrations 3–10% (w/v) and able to grow in concentrations up to 20% (w/v)**. Catalase-positive; oxidase-variable. Negative for urease and indole production. **The major cellular fatty acid is C_{15:0 anteiso}**. The main menaquinone type is MK-7.

DNA G + C content (mol %): 35.8–40.1.

Type species: Oceanobacillus iheyensis Lu, Nogi and Takami 2002, 687^{VP} (Effective publication: Lu, Nogi and Takami 2001, 296.).

Further descriptive information

Oceanobacillus is part of a phylogenetic cluster of halotolerant or halophilic genera in the *Bacillus sensu lato* group, also including the genera *Alkalibacillus*, *Amphibacillus*, *Cerasibacillus*, *Filobacillus*, *Gracilibacillus*, *Halobacillus*, *Halolactibacillus*, *Jeotgalibacillus*, *Lentibacillus*, *Marinibacillus*, *Paraliobacillus*, *Pontibacillus*, *Salinibacillus*, *Tenuibacillus*, *Thalassobacillus*, and *Virgibacillus*. Thirteen out of 17 of these genera were described since the year 2000, indicating that this is a quite recent lineage that is expected to undergo further taxonomic changes based on a better understanding of the phylogeny. *Oceanobacillus*, first described with the single species *Oceanobacillus iheyensis* by Lu et al. (2001), has been extended recently with two species, *Oceanobacillus oncorhynchi* (Yumoto et al., 2005b) and *Oceanobacillus picturae* comb. nov. (Lee et al., 2006b; basonym *Virgibacillus picturae*, Heyrman et al., 2003b).

Romano et al. (2006) subdivided *Oceanobacillus oncorhynchi* into two subspecies, each containing a single strain: *Oceanobacillus oncorhynchi* subsp. *oncorhynchi* and *Oceanobacillus oncorhynchi* subsp. *incaldanensis*. Whether or not *Oceanobacillus oncorhynchi* subsp. *incaldanensis* should be transferred to a separate species is debatable (see *Taxonomic comments*).

Cells are rods of 0.4–0.8 × 1.1–6 µm that mainly occur singly. Spore formation was not observed in *Oceanobacillus oncorhynchi* subsp. *incaldanensis* strain 20AG (DSM 16557, ATCC BAA-954) (Romano et al., 2006). However, the authors did not check whether or not the strain grew after a heating step (10 min at 80 °C) or whether spores were observed after growth on medium supplemented with manganese to enhance spore formation (Charney et al., 1951). *Oceanobacillus* stains are extremely halotolerant, being able to grow in medium containing up to 21% (w/v) NaCl. Most *Oceanobacillus* strains can grow in the absence of NaCl. Strain 20AG (DSM 16557, ATCC BAA-954), the only representative of *Oceanobacillus oncorhynchi* subsp. *incaldanensis*, is the only member of *Oceanobacillus* that is not able to grow without added salt (the minimal requirement is 5% NaCl). The optimal NaCl concentration for cell growth lies between 3% and 10% (w/v) for the different members of *Oceanobacillus*. For *Oceanobacillus iheyensis*, it was determined that salt tolerance was pH dependent (lower salt tolerance at higher pH) and that the lag

phase and generation is extended with increasing NaCl concentration (Lu et al., 2001). All *Oceanobacillus* stains are alkalitolerant, *Oceanobacillus iheyensis* has a pH range of 6.5–10.0 (Lu et al., 2001), *Oceanobacillus picturae* of 7.0–10.0 (Lee et al., 2006b), and *Oceanobacillus oncorhynchi* subsp. *incaldanensis* of 6.5–9.5 (Romano et al., 2006). *Oceanobacillus oncorhynchi* subsp. *oncorhynchi* is the only alkaliphilic member of *Oceanobacillus*, not able to grow below pH 9.0 (Yumoto et al., 2005b). The subspecies of *Oceanobacillus oncorhynchi* show differences in spore formation, pH, and NaCl range and further differ in their ability to grow under anaerobic conditions. *Oceanobacillus oncorhynchi* subsp. *oncorhynchi* is the only member of *Oceanobacillus* showing growth under anaerobic conditions. All strains are mesophilic, cell growth occurs at temperatures of 5–42 °C with an optimum between 25 °C and 37 °C. In addition, *Oceanobacillus iheyensis* can grow at pressures of up to 30 MPa, which corresponds to the pressure at a depth of 3,000 m. This is not unexpected, since *Oceanobacillus iheyensis* was isolated at a depth of 1,050 m from the Iheya Ridge of the Nansei Islands (27°47.18' N, 126°54.15' E). A strain with 100% 16S rDNA sequence similarity to *Oceanobacillus picturae* has been isolated from coastal sediment (Francis et al., 2001); the dormant spores of this strain enzymically oxidized soluble Mn(II) to insoluble Mn(IV) oxides and, therefore, Francis et al. (2001) cautiously speculated that the production of Mn(II)-oxidizing spores by *Virgibacillus picturae* may have contributed to the biodeterioration of the mural paintings.

Acid production (not tested for *Oceanobacillus oncorhynchi* subsp. *incaldanensis*) is (weakly) positive for D-glucose, D-fructose, and D-mannose, and negative for amygdalin, D-arabinose, myo-inositol, and 5-keto-D-gluconate. In the Biolog (Biolog Inc.) test, *Oceanobacillus iheyensis* assimilates only four substrates, namely α-D-glucose, maltose, D-mannose, and turanose (Lu et al., 2001). Hydrolysis of starch (not tested for *Oceanobacillus picturae*) is negative. Differential characters are listed in Table 29.

Oceanobacillus iheyensis strain HTE831^T (Lu et al., 2001) and *Oceanobacillus oncorhynchi* subsp. *incaldanensis* strain 20AG (Romano et al., 2006) were both susceptible to ampicillin, bacitracin, chloramphenicol, and penicillin G. *Oceanobacillus iheyensis* is further resistant to erythromycin, nalidixic acid, and spectinomycin, and is susceptible to carbenicillin, gentamicin, kanamycin, novobiocin, rifampin, and tetracycline. *Oceanobacillus oncorhynchi* subsp. *incaldanensis* is resistant to kanamycin and tetracycline, and susceptible to erythromycin, lincomycin, streptomycin, tetracycline, and vancomycin.

Major cellular fatty acids for *Oceanobacillus iheyensis* and *Oceanobacillus oncorhynchi* subsp. *oncorhynchi* (Lee et al., 2006b; Yumoto et al., 2005b) are C_{15:0 iso} (31.6–34.3% and 22.7%, respectively) and C_{15:0 anteiso} (25.3–38.7% and 49.3%, respectively). *Oceanobacillus picturae* shows dominant amounts of C_{15:0 anteiso} (53.1–59.2%) and moderate amounts of C_{14:0 iso} (8.8–10.7%), C_{16:0 iso} (7.0–10.4%), and C_{17:0 anteiso} (11.9–14.3%) (Heyrman et al., 2003b; Lee et al., 2006b). For *Oceanobacillus oncorhynchi* subsp. *incaldanensis* (Romano et al., 2006), it is only stated that the fatty acids C_{14:0 anteiso}, C_{15:0 iso}, and C_{15:0 anteiso} account for about

TABLE 29. Differential characteristics of *Oceanobacillus* species^{a,b}

Characteristic	1. <i>O. iheyensis</i>	2. <i>O. oncorhynchi</i> subsp. <i>oncorhynchi</i>	3. <i>O. oncorhynchi</i> subsp. <i>incaldanensis</i>	4. <i>O. picturae</i>

^aSymbols: +, positive; –, negative; +/w, weak to moderately positive reaction; –/w, negative or weakly positive reaction; w, weak reaction; NG, not given. Spore shape abbreviations: E, ellipsoidal; S, spherical. Spore position abbreviations: T, terminal; ST, subterminal.

^bData compiled from Lu et al. (2001); Yumoto et al. (2005b); Lee et al. (2006b); Romano et al. (2006).

90% of the total fatty acid content. Lu et al. (2001) estimated the genome size of *Oceanobacillus iheyensis* around 3.6 Mb by pulsed field gel electrophoresis after digestion with *ApaI* or *Sse8387I*. The whole genome sequence of *Oceanobacillus iheyensis* was determined (Takami et al., 2002). It is a single circular chromosome consisting of 3,630,528 bp with a mean G + C content of 35.7% (36.1% and 31.8% in the coding and noncoding region, respectively). From the total genome, 3,496 protein coding sequences were found, covering 85% of the chromosome. The mean size of the predicted proteins in *Oceanobacillus iheyensis* is 32,804 kDa, ranging from 2.714 to 268,876 kDa. Comparative analysis of the genome sequence of *Oceanobacillus iheyensis* with those of *Bacillus subtilis*, *Bacillus halodurans*, *Staphylococcus aureus*, and *Clostridium acetobutylicum* (Takami et al., 2002) revealed that 838 out of 3,496 (24.0%) putative proteins identified in the *Oceanobacillus iheyensis* genome have no orthologous relationship to proteins encoded in the four other genomes. Further, 354 proteins (10.1%) were identified as common proteins only among *Bacillus*-related species and 243 putative proteins (7.0%) were shared only between the two alkaliphiles, *Oceanobacillus iheyensis* and *Bacillus halodurans* (Brown et al., 2003) studied the presence of genes resembling *Staphylococcus aureus* isoleucyl-transfer-RNA synthetase 2 (IleRS2) and *Streptococcus pneumoniae* methionyl-tRNA synthetase 2 (MetRS2) in genomes of Gram-positive bacteria. These genes render an organism resistant to antibiotics inhibiting IleRS1 and MetRS1. The genome of *Oceanobacillus iheyensis* contains an IleRS2 homolog similar to that of *Staphylococcus aureus*, no IleRS1, and a typical MetRS1.

Enrichment and isolation procedures

HTE831^T, the only representative of *Oceanobacillus iheyensis*, was isolated from a deep-sea mud sample on a medium consisting of 1% polypeptone, 0.5% yeast extract, 0.1% K₂HPO₄, and 0.02% MgSO₄·7H₂O supplemented with 3% NaCl (Lu et al., 2001). The strain grows well in Marine Broth (Difco). R-2^T, the only representative of *Oceanobacillus oncorhynchi* subsp. *oncorhynchi*, was obtained by enriching 1 ml of a viscous liquid of rainbow trout skin in 250 ml PYA broth (pH 10) for 30 h at 27 °C, shaken at 140

r.p.m. (Yumoto et al., 2005b). PYA medium contains 8 g peptone, 3 g yeast extract, 1 g K₂HPO₄, 3.5 mg EDTA, 3 mg ZnSO₄·7H₂O, 10 mg FeSO₄·7H₂O, 2 mg MnSO₄·5H₂O, 1 mg CuSO₄·5H₂O, 2 mg Co(NO₃)₂·6H₂O, and 1 mg H₃BO₃ in 11 NaHCO₃/Na₂CO₃ buffer (100 mM in deionized water, pH 10). Strain 20AG, the only representative of *Oceanobacillus oncorhynchi* subsp. *incaldanensis*, was enriched from an algal mat in the following medium (per liter, pH 9.0): 3.0 g Na₂CO₃, 2.0 g KCl, 1.0 g MgSO₄·7H₂O, 100.0 g NaCl, 3.0 g Na₃-citrate, 10.0 g yeast extract, 0.36 mg MnCl₂·4H₂O, and 50 mg FeSO₄ (Romano et al., 2006). Na₂CO₃ and NaCl were autoclaved separately. Strains of *Oceanobacillus picturae* were isolated from standard media (TSA and R2A) with 10% salt added and were further subcultured on Marine Agar.

Oceanobacillus strains might be selected for, together with other halotolerant and alkaliphilic bacteria, on media supplemented with 15% NaCl and adjusted to pH 9.5. Further, inoculation of such media could be preceded by a heating step (5–10 min at 80 °C) in order to kill vegetative cells and so select for endospore-formers. Whether *Oceanobacillus oncorhynchi* subsp. *incaldanensis* (Romano et al., 2006) survives such a heating step should be checked.

Maintenance procedures

Oceanobacillus strains can easily be preserved in the refrigerator in tubes containing broth medium or agar slopes after checking the culture microscopically for sporulation. For long term preservation, lyophilization or liquid nitrogen may be used with the addition of a proper cryoprotectant.

Procedures for testing special characters

All *Oceanobacillus* species were described by using standard methodology, without genus-specific alterations of the protocols.

Differentiation from closely related taxa

Phylogenetically, the genera most closely related to *Oceanobacillus* are *Virgibacillus* and *Lentibacillus*. *Oceanobacillus* cannot be distinguished from *Virgibacillus* on the genus level. *Oceanobacillus* can only be differentiated from *Lentibacillus* by its slightly lower G + C content (35.8–40.1 and 42.0–44.0 mol%, respectively).

The distinction between *Oceanobacillus* and other halophilic endospore-forming genera of the *Bacillaceae* is also not straightforward. *Halobacillus* (Amoozegar et al., 2003; Liu et al., 2005; Spring et al., 1996; Yoon et al., 2004a; Yoon et al., 2005a; Yoon et al., 2003b) is the only genus that has been shown to contain peptidoglycan of the Orn-D-Asp type (A4 β), however, this feature was not tested for *Oceanobacillus*. *Gracilibacillus* (Carrasco et al., 2006; Wainø et al., 1999) tests positive for starch hydrolysis (not tested for *Oceanobacillus picturae*). Members of *Amphibacillus* (Niimura et al., 1990; Zhilina et al., 2001b) lack isoprenoid quinones and are catalase-negative. *Amphibacillus* shares these features with *Halolactibacillus* (Ishikawa et al., 2005).

Halolactibacillus strains further grow at NaCl concentrations of 25% and show C_{13:0 anteiso} and C_{16:0} as the major fatty acids. Strain YKJ-13^T, the only representative of *Jeotgalibacillus alimentarius* (Yoon et al., 2001c) contains MK-7 and MK-8 as the predominant menaquinones and the peptidoglycan type is L-Lys-direct (A1 α). *Oceanobacillus* differs from *Marinibacillus* (Rüger, 1983; Rüger et al., 2000; Yoon et al., 2004a; Yoon et al., 2001c) in that members of the latter genus require sea water for growth. *Filobacillus* (Schlesner et al., 2001), represented by a single strain, contains peptidoglycan of the Orn-D-Glu type (variation A4 β) and does not produce acid from D-glucose (not tested for *Oceanobacillus oncorhynchi* subsp. *incaldanensis*). O15-7^T, the only representative of *Paraliobacillus* (Ishikawa et al., 2002), has a glucose requirement during aerobic cultivation. However, *Oceanobacillus oncorhynchi* subsp. *oncorhynchi*, the only representative of *Oceanobacillus* able to grow under anaerobic conditions, was not tested for this feature. *Cerasibacillus* (Nakamura et al., 2004b) and *Tenuibacillus* (Ren and Zhou, 2005a), represented by one and two strains respectively, do not produce acid from D-fructose, D-glucose, or D-mannose (not tested for *Oceanobacillus oncorhynchi* subsp. *incaldanensis*). *Thalassobacillus* (Garcia et al., 2005), yet another one-strain genus, has endospores in central position and a slightly higher G + C content (42.8 in comparison with 35.8–40.1 for *Oceanobacillus*). *Alkalibacillus* (Jeon et al., 2005b; Romano et al., 2005b), *Pontibacillus* (Lim et al., 2005a; Lim et al., 2005b), and *Salinibacillus* (Ren and Zhou, 2005a) are not readily distinguishable from *Oceanobacillus*. As many of the above-mentioned genera are represented by a single species which is often only represented by one or two strains, it is possible that the discovery of additional species or strains within these genera will result in even fewer discriminatory characteristics.

Taxonomic comments

Since the description of *Oceanobacillus*, several taxonomic rearrangements have occurred. Lu et al. (2001) created a separate genus status for *Oceanobacillus iheyensis* as the species diverged at the bottom of a cluster including *Bacillus halodenitrificans* (currently *Virgibacillus halodenitrificans*), *Virgibacillus pantothenticus*, *Virgibacillus proomii*, *Salibacillus marismortui*, and *Salibacillus salexigens* (currently *Virgibacillus marismortui* and *Virgibacillus salexigens*; Heyrman et al., 2003b).

Since at the time of description, *Virgibacillus* and *Salibacillus* were still separate genera, Lu et al. (2001) concluded that their isolate could not be attributed to one or the other and proposed a novel genus. Further, a DNA–DNA relatedness study was performed between *Oceanobacillus iheyensis* and *Virgibacillus pantothenticus*, *Virgibacillus salexigens*, *Virgibacillus marismortui*,

and *Bacillus halodenitrificans*. All homology values were below 30%. Lu et al. (2001) concluded from these low values that strain HTE831^T (*Oceanobacillus iheyensis*) should not be categorized as a member of a new species within a known genus. Such a conclusion is false since no comments on genus affiliation can be deduced from DNA–DNA relatedness values. Since the description of *Oceanobacillus iheyensis*, the species of *Salibacillus* were transferred to *Virgibacillus* (Heyrman et al., 2003b), *Bacillus halodenitrificans* was transferred to *Virgibacillus* (Yoon et al., 2004c), and five novel *Virgibacillus* species have been described including *Virgibacillus carmonensis*, *Virgibacillus necropolis*, *Virgibacillus picturae* (basonym of *Oceanobacillus picturae*; Heyrman et al., 2003b), *Virgibacillus dokdonensis* (Yoon et al., 2005b) and *Virgibacillus koreensis* (Lee et al., 2006b). Yumoto et al. (2005b) described *Oceanobacillus oncorhynchi* as a novel species. Further, the closely related genus *Lentibacillus* was described by Yoon et al. (2002) and expanded with four novel species (Jeon et al., 2005a; Lim et al., 2005c; Namwong et al., 2005; Tanasupawat et al., 2006). With every addition of a novel species in the genera *Oceanobacillus*, *Virgibacillus*, and *Lentibacillus*, the phylogenetic relationships between these genera have changed and the phenotypic differences originally differentiating them have disappeared. This led for example to the transfer of *Virgibacillus picturae* to *Oceanobacillus* on the basis of a 16S rDNA tree (Lee et al., 2006b). The majority of species belonging to *Virgibacillus*, *Oceanobacillus*, and *Lentibacillus* were described in the last five years. Therefore, future species descriptions in the neighborhood of these genera can be expected. The following new species descriptions were “in press” at the time of writing but have since been published (albeit too late for discussion in this section): *Lentibacillus kapiialis* (Pakdeeto et al., 2007), *Lentibacillus halodurans* (Yuan et al., 2007), *Oceanobacillus chironomi* (Raats and Halpern, 2007), and *Oceanobacillus profundus* (Kim et al., 2007a). These descriptions will probably allow better assessment of whether the three genera should remain as currently described or whether further rearrangements are necessary.

Romano et al. (2006) isolated a bacterial strain from an algal mat that showed 99.5% 16S rDNA sequence similarity to *Oceanobacillus oncorhynchi*. This strain differed from *Oceanobacillus oncorhynchi* in that no spore formation was observed and the cells were larger, while growth occurred at acidic pH and no anaerobic growth occurred without added NaCl. Furthermore, hydrolysis of PNPg and differences in fatty acid composition were reported. DNA–DNA relatedness of this strain to the type strain of *Oceanobacillus oncorhynchi* was 59.0%. Referring to the new guidelines on the species concept for prokaryotes (Rosselló-Mora and Amann, 2001; Stackebrandt et al., 2002), Romano et al. (2006) concluded that the nearly identical 16S rRNA gene sequence (99.5% similarity), DNA–DNA relatedness above 50%, and few phenotypic differences did not justify a classification of this single strain into a separate species. Therefore, they described this strain as a subspecies of *Oceanobacillus oncorhynchi*, namely *Oceanobacillus oncorhynchi* subsp. *incaldanensis*. Looking at the data given by Romano et al. (2006), the taxonomic status of *Oceanobacillus oncorhynchi* subsp. *incaldanensis* is debatable. Though it is true that the current bacterial species concept (Rosselló-Mora and Amann, 2001; Stackebrandt et al., 2002) states that the value for species delineation on the basis of DNA–DNA relatedness (set at 70%) should be interpreted in a more relaxed manner.

However, in this particular case, the DNA relatedness value is clearly below 70% and there are several phenotypic differences. Of course, as both subspecies of *Oceanobacillus oncorhynchi* are only represented by a single strain, it is difficult

to assess whether the phenotypic variation found is intra- or interspecies variation. This clearly demonstrates that the analysis of several strains per (sub)species is necessary to allow clear distinction.

List of species of the genus *Oceanobacillus*

1. ***Oceanobacillus iheyensis*** Lu, Nogi and Takami 2002, 687^{VP} (Effective publication: Lu, Nogi and Takami 2001, 296.)
i.he.yen'sis. N.L. masc. adj. *iheyensis* pertaining to the Iheya Ridge, Okinawa Trough, Japan.
Morphology and general characters as for generic description.
Cells are 0.6–0.8 × 2.5–3.5 μm. Obligatory aerobe. Growth occurs at 0–21% (w/v) NaCl, with optimum growth at 3% NaCl. Growth occurs at temperatures of 15–42 °C (optimum 30 °C). The pH range for growth is 6.5–10 (optimum 7.0–9.5). Nitrate reduction to nitrite is negative. Hydrolyzes gelatin, casein, Tween 40, and Tween 60. Does not hydrolyze starch. Acid is produced from glycerol, but not from galactose, glucitol, D-melibiose, rhamnose, and D-trehalose. The following four substrates are oxidized in the Biolog test: α-D-glucose, maltose, D-mannose, and turanose. The major cellular fatty acids are C_{15:0} anteiso, C_{15:0 iso} and C_{14:0 iso}.
Source: mud at a depth of 1050 m on the Iheya Ridge.
DNA G + C content (mol %): 35.8 (reverse-phase HPLC).
Type strain: HTE831, CIP 107618, DSM 14371, JCM 11309.
GenBank accession number (16S rRNA gene): AB010863.
2. ***Oceanobacillus oncorhynchi*** Yumoto, Hirota, Nodasaka and Nakajima 2005b, 1523^{VP} emend. Romano, Lama, Nicolaus, Poli, Gambacorta and Giordano 2006, 809.
on.co.rhyn'chi. N.L. gen. n. *oncorhynchi* of *Oncorhynchus*, named after the rainbow trout *Oncorhynchus mykiss*.
Morphology and general characters as for generic description.
Growth occurs at 10–40 °C, with the optimum at 30–37 °C. Does not hydrolyze casein, gelatin, and starch. Oxidase-positive. Reduces nitrate to nitrite.
DNA G + C content (mol %): 38.5 (reverse-phase HPLC).
Type strain: R-2, JCM 12661, NCIMB 14022.
GenBank accession number (16S rRNA gene): AB188089.
- 2a. ***Oceanobacillus oncorhynchi* subsp. *oncorhynchi*** Yumoto, Hirota, Nodasaka and Nakajima 2005b, 152^{VP} emend. Romano, Lama, Nicolaus, Poli, Gambacorta and Giordano 2006, 809.
Cells are 0.4–0.6 × 1.1–1.4 μm. Facultative anaerobe. Growth occurs at 0–22% (w/v) NaCl with the optimum at 7% (w/v). The pH range for growth is 9.0–10.0; no growth at 7.0–8.0. Hydrolyzes Tween 40. Does not hydrolyze lipid (tributyrin) or Tweens 20, 60, and 80. Reactions for ONPG hydrolysis and deamination of phenylalanine are negative. Acid is produced from D-melibiose, sucrose, raffinose, D-galactose, and trehalose. No acid is produced from D-arabinose, *myo*-inositol, and sorbitol. The major fatty acids are C_{15:0 anteiso} (49.3%), C_{15:0 iso} (22.7%), and C_{17:0 anteiso} (18.0%).
Source: the skin of the rainbow trout (*Oncorhynchus mykiss*).
DNA G + C content (mol %): 38.5 (reverse-phase HPLC).
Type strain: R-2, JCM 12661, NCIMB 14022.
GenBank accession number (16S rRNA gene): AB188089.
- 2b. ***Oceanobacillus oncorhynchi* subsp. *incaldanensis*** Romano, Lama, Nicolaus, Poli, Gambacorta and Giordano 2006, 808^{VP}
in. cald. en'sis. N.L. masc. adj. *incaldensis* pertaining to the Incaldana site, southern Italy, where the type strain was isolated
Cells are 0.5–0.8 × 1.2–2.0 μm. Nonspore-forming. Strictly aerobic. Growth occurs at 5–20% (w/v) NaCl, with the optimum at 10% (w/v). The pH range for growth is 6.5–9.5 with an optimum at pH 9.0. Grows on D-arabinose, D-cellobiose, D-fructose, D-galactose, D-glucose, D-lactose, D-maltose, D-mannose, D-ribose, D-sorbose, D-sucrose, D-trehalose, D-xylose, glycerol, Na-acetate, and Na-citrate as sole carbon sources. KOH positive. Negative for aminopeptidase. The main fatty acids are C_{14:0 anteiso}, C_{15:0 iso} and C_{15:0 anteiso}, accounting for about 90% of the total fatty acid composition. The predominant polar lipids are phosphatidyl glycerol and diphosphatidyl choline.
Source: an algal mat collected from a sulfurous spring in the Santa Maria Incaldana site (Mondragone, Italy).
DNA G + C content (mol %): 40.1 (reverse-phase HPLC).
Type strain: 20AG, ATCC BAA-954, DSM 16557.
GenBank accession number (16S rRNA gene): AJ640134.
3. ***Oceanobacillus picturae*** (Heyrman et al., 2003b) Lee, Lim, Lee, Lee, Park and Kim 2006b, 256^{VP} (*Virgibacillus picturae* Heyrman, Logan, Busse, Balcaen, Lebbe, Rodriguez-Diaz, Swings and De Vos 2003b, 509.)
pictur.ae. L. gen. n. *picturae* of a painting.
Morphology and general characters as for generic description.
Cells are 0.5–0.7 × 2.0–6.0 μm. Obligatory aerobe. Weak growth without added NaCl and optimal growth at NaCl (w/v) concentrations of 5 and 10%. Temperature range for growth is 5–40 °C with optimal growth at 25–35 °C. Positive results for ONPG and nitrate reduction. Negative for arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, citrate utilization, hydrogen sulfide production, urease, tryptophan deaminase, and Voges–Proskauer. Growth on different sugars as sole carbon source is weakly positive for raffinose and negative for D-arabinose, cellobiose, D-fructose, and D-xylose. The major fatty acids are C_{15:0 anteiso} (59.2%), C_{15:0 anteiso} (11.9%), and C_{14:0 iso} (10.7%). The polar lipid pattern contains predominant amounts of diphosphatidyl glycerol and moderate amounts of phosphatidyl glycerol.
Source: mural paintings in Austria and Spain.
DNA G + C content (mol %): 39.5 (reverse-phase HPLC).
Type strain: DSM 14867, LMG 19492, KCTC 3821.
GenBank accession number (16S rRNA gene): AJ315060.

Genus XIV. **Paraliobacillus** Ishikawa, Ishizaki, Yamamoto and Yamasato 2003a, 627^{VP} (Effective publication: Ishikawa, Ishizaki, Yamamoto and Yamasato 2002, 275.)

KAZUHIDE YAMASATO AND MORIO ISHIKAWA

Pa.ra.li.o.ba.cil'lus. Gr. adj. *paralios* littoral; L. n. *bacillus* rod; N.L. masc. n. *Paraliobacillus* rod inhabiting littoral (marine) environment.

Cells are Gram-positive, **endospore-forming rods** that are **motile by peritrichous flagella** (Figure 20). **Facultatively anaerobic. Catalase-positive when cultivated aerobically.** Pseudocatalase-negative. **Requires carbohydrate, sugar alcohol, or related compounds for growth in both aerobic and anaerobic conditions. Glucose is aerobically metabolized to produce acetate and pyruvate as main organic acids. In anaerobic cultivation, lactate, formate, acetate, and ethanol are the end products from glucose, with a molar ratio of approximately 2:1:1 for the latter three products, without gas production. Slightly halophilic and extremely halotolerant. Slightly alkaliphilic.** Contains *meso*-diaminopimelic acid in cell-wall peptidoglycan. **The menaquinone type is menaquinone-7. Cytochromes are present.** Occupies an independent lineage within the halophilic/halotolerant/alkaliphilic and/or alkalitolerant group* in rRNA group 1 of the phyletic group classically defined as the genus *Bacillus* (Ash et al., 1991).

DNA G + C content (mol%): 35.6 (HPLC).

Type species: Paraliobacillus ryukyensis Ishikawa, Ishizaki, Yamamoto and Yamasato 2003a, 627^{VP} (Effective publication: Ishikawa, Ishizaki, Yamamoto and Yamasato 2002, 275.).

FIGURE 20. Photomicrograph of cells and peritrichous flagella of *Paraliobacillus ryukyensis* IAM 15001^T grown anaerobically on 2.5% NaCl GYPF agar^{††} at 20 °C for 2 d. Bar = 2 μm.

*A monophyletic subgroup within rRNA group 1 *Bacillus*, which is composed of halophilic, halotolerant, alkaliphilic and/or alkalitolerant organisms (Ishikawa et al., 2003b). The present composing genera or species are *Bacillus halophilus* (Ventosa et al., 1989), *Amphibacillus* (Niimura et al., 1990), *Halobacillus* (Claus et al., 1983; Spring et al., 1996), *Virgibacillus* (Heyndrickx et al., 1998; Heyndrickx et al., 1999; Heyrman et al., 2003b), *Gracilibacillus* (Deutch, 1994; Lawson et al., 1996; Waino et al., 1999), *Filobacillus* (Schlensker et al., 2001), *Oceanobacillus* (Lu

Further descriptive information

Descriptive information is based on one strain of *Paraliobacillus ryukyensis* (Ishikawa et al., 2002). The phylogenetic position of *Paraliobacillus* based on 16S rRNA gene sequence analysis is given in Figure 18.

The characteristics of *Paraliobacillus ryukyensis* are listed in Table 30, Table 31, and Table 32. *Paraliobacillus ryukyensis* utilizes a wide range of carbohydrates and related compounds: pentoses, hexoses, disaccharides, trisaccharides, polysaccharides, sugar alcohols, and related carbon compounds. Ethanol, formate, lactate, pyruvate, and components of the TCA cycle are not utilized.

Paraliobacillus ryukyensis is slightly halophilic, as it grows optimally in NaCl concentrations between 0.75% (w/v) and 3.0% (Kushner, 1978; Kushner and Kamekura, 1988). The specific growth rates, μ_{\max} (h⁻¹), are 0.22 in 0–0.5% (w/v), 0.36–0.38 in 0.75–3.0%, 0.31 in 4.0%, 0.28 in 5.0%, and 0.20 in 7.0% NaCl. This bacterium is highly tolerant to an elevated NaCl concentration, growing at 22% which is comparable to the extremely halotolerant members in the halophilic/halotolerant/alkaliphilic and/or alkalitolerant group¹ in rRNA group 1 (HA group).

With respect to growth responses to pH of cultivation medium, the μ_{\max} (h⁻¹) values are 0.18 at pH 5.5, 0.36 at pH 6.0, 0.38 at pH 6.5, 0.40 at pH 7.0–8.5, and 0.20 at pH 9.0. *Paraliobacillus ryukyensis* can be characterized as slightly alkaliphilic according to Jones et al. (1994) who defined alkaliphiles as organisms that grow optimally at a pH greater than 8. The final pH is 4.5 in both aerobic and anaerobic cultivations, which is 1.0 pH unit lower than the minimum pH for growth initiation (pH 5.5).

Generation of catalase is induced by oxygen; *Paraliobacillus ryukyensis* produces catalase on an agar plate or in aerated broth medium, but no catalase activity is detected for anaerobically grown cells.

Paraliobacillus ryukyensis requires carbohydrate (and related carbon compounds) for growth. Under anaerobic conditions, growth does not occur in 2.5% NaCl GYPF broth[†] without glucose. Under aerobic conditions, absorbances at 660 nm of stationary cultures in broth media of 2.5% NaCl GP[‡] and 2.5% NaCl GCY[§] are 0.29 and 0.38, respectively, while those in the absence of glucose are below 0.03.

et al., 2001), *Paraliobacillus* (Ishikawa et al., 2002), *Lentibacillus* (Yoon et al., 2002), *Cerasibacillus* (Nakamura et al., 2004b), *Alkalibacillus* (Fritze, 1996a; Jeon et al., 2005b), *Halobacillus* (Ishikawa et al., 2005), *Tenuibacillus* (Ren and Zhou, 2005b), *Pontibacillus* (Lim et al., 2005a), *Salinibacillus* (Ren and Zhou, 2005a), *Thalassobacillus* (Garcia et al., 2005), *Ornithinibacillus* (Mayer et al., 2006), *Pau-cisalibacillus* (Nunes et al., 2006), and *Pelagibacillus* (Kin et al., 2007b).

[†] GYPF (GYPB) broth is composed of (per liter) 10 g glucose, 5 g yeast extract, 5 g peptone, 5 g fish extract (beef extract), 1 g K₂HPO₄, 1 g sodium thioglycolate, and 5 ml salt solution (per ml, 40 mg MgSO₄·7H₂O, 2 mg MnSO₄·4H₂O, 2 mg FeSO₄·7H₂O), pH 8.5. Sterilized by filtration. Sodium thioglycolate is omitted for aerobic cultivation.

[‡] 2.5% GP broth is composed of (per liter) 10 g glucose, 10 g peptone, and inorganic components of GYPF broth, pH 8.5. Sterilized by filtration.

[§] 2.5% NaCl GCY broth is composed of (per liter) 10 g glucose, 5 g Vitamin assay Casamino acids (Difco), 0.5 g yeast extract, and inorganic components of GYPF broth[†], pH 8.5. Sterilized by filtration.

^c*Paraliobacillus ryukyensis* IAM 15001^T was cultivated in GYPF broth, pH 8.0, under aerobic cultivation by shaking and under anaerobic cultivation.

TABLE 32. Effect of the initial pH of the medium on the composition of products of glucose fermentation by *Paraliobacillus ryukyensis* IAM 15001^{Ta,b}

Initial pH	End products (mol/mol glucose)				Lactate yield from consumed glucose (%)	Carbon recovery (%)
	Lactate	Formate	Acetate	Ethanol		
6.5	1.03	0.94	0.41	0.37	51	93
7.0	1.00	0.84	0.43	0.48	50	94
8.0	0.41	1.60	0.67	0.65	21	91
9.0	0.16	1.85	0.88	0.93	8	100

^a*Paraliobacillus ryukyensis* IAM 15001^T was cultivated in heavily buffered 2.5% NaCl GYPF broths with different initial pH values. Decrease in pH during cultivation was 0.5 units or less.

^bData from Ishikawa et al. (2005).

Under aerobic conditions, acetate, pyruvate, and a small amount of lactate are produced without production of formate and ethanol. The carbon recovery varies from 36% to 64% depending on growth phase; at the exponential phase it is about twofold that at the stationary phase, accompanying much increased production of pyruvate and acetate (Table 31). In anaerobic cultivation, lactate, formate, acetate, and ethanol are produced from glucose without gas production, with a well-balanced carbon recovery (96–103%). The molar ratio for formate, acetate, and ethanol is approximately 2:1:1 (Table 31). The amount of lactate produced relative to the total amount of the other three products is markedly affected by the pH during cultivation (Table 32). As the initial pH of the medium is

lowered, the relative amount of lactate increases, while the relative total amount of the other three products decreases. The opposite occurs when the initial pH is increased. For each of the initial pH, the molar ratio for the three products relative to the lactate produced is substantially retained. *Exiguobacterium aurantiacum* (Collins et al., 1983; Gee et al., 1980), a facultative anaerobe in *Bacillaceae*, *Trichococcus (Lactosphaera)*; Janssen et al., 1995), *Marinilactibacillus* (Ishikawa et al., 2003b), *Halolactibacillus* (Ishikawa et al., 2005), and *Alkalibacterium* (Ishikawa et al., 2003b) exhibit the same behavior in glucose fermentation with respect to the effect of pH of the cultivation medium. The product balance is considered to depend on the relative activities of the two enzymes involved in pyruvate metabolism,

pyruvate-formate lyase and lactate dehydrogenase (Gunsalus and Niven, 1942; Janssen et al., 1995; Rhee and Pack, 1980). The ratio of the L(+) isomer to the total amount of lactate produced was 52%.

Both aerobically and anaerobically grown cells possess menaquinone-7, the concentration of which is much greater in aerobic cultivation.

The sequence similarities of 16S rRNA genes of *Paraliobacillus*, approximately 1500 bases in length covering the positions 32–1510 (*Escherichia coli* numbering system), to *Gracilibacillus*, *Amphibacillus*, and *Halolactibacillus*, the phylogenetically closest genera, are 94.7–95.8%, 92.6–94.3%, and 93.7–94.1%, respectively. The similarity values between *Paraliobacillus* and other members of the HA group are below 95.1%.

Paraliobacillus ryukyensis was isolated from a decomposing marine alga taken at a foreshore site near the Oujima islet adjacent to the main island of Okinawa, Japan. Because this bacterium was isolated from a marine substrate and possesses slightly halophilic, highly halotolerant, and slightly alkaliphilic properties, the organism is considered to be well-adapted to marine environments as have been other members of the HA group inhabiting saline environments. Since only one strain has been isolated to date, the habitat and ecology of *Paraliobacillus* cannot be generalized.

Enrichment and isolation procedures

Since only one strain has been isolated, generalized method for isolation cannot be given. Strain IAM 15001^T was isolated by successive enrichment culture in 7% and 18% NaCl GYPFSK isolation broths** (each was cultured for 21 d and 15 d, respectively) and was pour-plated with 12% NaCl GYPFSK isolation agar (2.0% agar) supplemented with 5 g (per liter) CaCO₃.

Maintenance procedures

Paraliobacillus ryukyensis is maintained by serial transfer in a stab culture stored at 5–10 °C at 1-month intervals. The medium is 7% NaCl GYPF or GYPB agar, pH 7.5, supplemented with 5 g/l CaCO₃, autoclaved at 110 °C for 10 min. Marine agar 2216 (Difco) supplemented with glucose and CaCO₃ can be used. The strain has been maintained by freezing at –80 °C or below in 2.5% NaCl GYPFK or GYPBK broth^{††}, pH 7.5, supplemented with 10% (w/v) glycerol. Marine broth 2216 (Difco) supplemented with glucose and 10% (w/v) glycerol can also be used. The strain can be preserved by L-drying in an adjuvant solution composed of (per liter) 3 g sodium glutamate, 1.5 g adonitol, and 0.05 g cysteine hydrochloride in 0.1 M phosphate buffer (KH₂PO₄–K₂HPO₄), pH 7.0 (Sakane and Imai, 1986) or by lyophilization with a standard cryoprotectant containing an appropriate concentration of NaCl.

Procedures for testing special characters

Spores are abundantly formed on yeast extract salts agar which is composed of (per liter) 5 g yeast extract, 20 g NaCl, 5 g MgCl₂·7H₂O, 0.2 g CaCl₂, 0.1 g KH₂PO₄, 10 ml salt solution[†], and

15 g agar, pH 7.5, autoclaved at 110 °C for 10 min and Marine agar 2216 (Difco). Spore formation is scarce on an agar medium which contains glucose and low concentrations of Mg²⁺ and Ca²⁺, such as 2% NaCl GYPF or GYPB agar[†], pH 7.5.

For anaerobic cultivation in pH experiments, AnaeroPack-Keep (Mitsubishi Gas Chemical Company, Tokyo) which absorbs O₂ but does not generate CO₂ is adequate.

Differentiation of *Paraliobacillus* from other related genera and species

Paraliobacillus is differentiated from other members of the HA group by the combination of morphological, physiological, biochemical, and chemotaxonomic features. Comparison of characteristics of closely related/phenotypically similar bacteria is summarized in Table 33. *Paraliobacillus* is differentiated from aerobes in the HA group by acid-producing fermentation. This bacterium is distinguished from facultative anaerobes in the HA group, from *Virgibacillus* (*Virgibacillus pantothenicus* and *Virgibacillus proomii*) by glucose requirement under aerobic conditions, and from *Amphibacillus* by the formation of catalase and the possession of respiratory quinone and cytochromes. *Paraliobacillus* is phenotypically similar to *Halolactibacillus* in the HA group, and *Marinilactibacillus* and *Alkalibacterium* in typical lactic acid bacteria group in lactic acid fermentation pattern (see *Further descriptive information*) and similar to *Marinilactibacillus* and *Halolactibacillus* in glucose requirement under aerobic conditions. *Paraliobacillus* is differentiated from *Halolactibacillus*, *Marinilactibacillus*, and *Alkalibacterium* by the formation of spores and catalase and the possession of respiratory quinones, from *Halolactibacillus* and *Marinilactibacillus* further by the possession of cytochromes (no data for *Alkalibacterium*), and from *Marinilactibacillus* and *Alkalibacterium* further by peptidoglycan type and major cellular fatty acid composition.

Paraliobacillus ryukyensis shares a requirement for glucose under aerobic conditions with *Amphibacillus xylanus* (Niimura et al., 1990), *Amphibacillus tropicus* (Zhilina et al., 2001a), and *Amphibacillus fermentum* (Zhilina et al., 2001a). From these bacteria, *Paraliobacillus ryukyensis* is differentiated by the characteristics described above and the optimum and range of pH for growth.

Taxonomic comments

Induction of catalase by oxygen is considered to be characteristic of *Paraliobacillus ryukyensis*, as it has not yet been observed for facultative anaerobes. Oxygen or hydrogen peroxide induction of catalase reported for facultative anaerobes (Whittenbury, 1964; Finn and Condon, 1975; Hassan and Fridovich, 1978; Loewen et al., 1985) is involved in stimulated or increased production of catalase which is produced at low level when not subjected to oxidizing agent.

Echigo et al. (2005) isolated five strains of spore-formers which are highly halotolerant from non-saline Japanese soils, which can grow at 20–25% NaCl and have 95.5–96% similarities of partial 16S rRNA gene sequences to *Paraliobacillus ryukyensis*. These authors discussed the possibility that the isolates are vagrants that have accumulated in soils and were transported by Asian dust storms over open seas, having survived for long periods in a dormant state as spores. Though their habitats are unclear and detailed taxonomic characterization was not done, these spore-formers may be related to *Paraliobacillus*.

** GYPFSK isolation broth is GYPF broth[†], pH 7.5, to which 50 ml soy sauce and 10 mg (per liter) cycloheximide are added and in which concentration of K₂HPO₄ is increased to 1%. Autoclaving is at 110 °C for 10 min.

†† GYPFK (GYPBK) broth is GYPF (GYPB) broth in which concentration of K₂HPO₄ is increased to 1%.

TABLE 33. Characteristics differentiating *Paraliobacillus* from related members of the halophilic/halotolerant/alkaliphilic and/or alkalitolerant group in *Bacillus* rRNA group 1, *Alkalibacterium* species and *Marinilactibacillus psychrotolerans*^a

FIGURE 21. Photomicrograph of spores and sporangia of *Paraliobacillus ryukyuensis* IAM 15001^T grown on yeast extract salts agar (composition, see *Procedures for testing special characters*) at 37 °C for 3 d. Bar = 5 μm.

List of species of the genus *Paraliobacillus*

1. ***Paraliobacillus ryukyuensis*** Ishikawa, Ishizaki, Yamamoto and Yamasato 2003a, 627^{VP} (Effective publication: Ishikawa, Ishizaki, Yamamoto and Yamasato 2002, 276.)

ryu.kyu.en'sis. N.L. adj. *ryukyuensis* from the Ryukyu Islands, Japan, where the type strain was isolated.

The characteristics are as described for the genus and as listed in Table 30, Table 31, and Table 32. Colonies on 2.5% NaCl GYPF agar are round, convex, entire, yellow, and transparent, with diameters of 1.2–1.5 mm after 3 d growth at 30 °C. Deep colonies are creamy white, opaque,

and lenticular, with diameters of 0.5–1.5 mm. Cells are 0.4–0.5 × 2.3–4.5 μm occurring singly, in pairs, or in chains. Endospores are spherical to ellipsoidal (predominant form) and terminal, measuring 0.9–1.0 × 0.9–1.4 μm (Figure 21). Sporangia are definitely swollen (Figure 21).

Source: a decomposing marine alga.

DNA G + C content (mol %): 35.6 (HPLC).

The type strain: O15-7, DSM 15140, IAM 15001, JCM 21472, NBRC 10,0001, NRIC 0520.

GenBank accession number (*16S rRNA gene*): AB087828.

Genus XV. ***Pontibacillus*** Lim, Jeon, Song and Kim 2005a, 168^{VP} emend. Lim, Jeon, Park, Kim, Yoon and Kim 2005b, 1030

PAUL DE VOS

Pon.ti.ba.cil'lus. L. n. *pontus* the sea; L. masc. n. *bacillus* a small staff, a wand; N.L. masc. n. *Pontibacillus bacillus* pertaining to the sea.

Gram-positive, spore-forming rods, 0.4–0.9 μm × 2.3–4 μm. Motile by means of peritrichous flagella. Terminal, spherical endospores in swollen sporangia. Catalase-positive. Urease-negative. Oxidase is reported to be different in the different species. Strictly aerobic. No growth occurs in media without NaCl or with more than 15% NaCl. Cell-wall peptidoglycan contains A1γ type *meso*-DAP. Major isoprenoid quinone is MK-7. Predominant cellular fatty acids are C_{15:0 ante}, C_{15:0 iso}, and C_{16:0 iso} on Marine Agar (MA). Phylogenetically, the genus belongs to the family *Bacillaceae*.

DNA G + C content (mol %): 40.8–42.

Type species: ***Pontibacillus chungwhensis*** Lim, Jeon, Song and Kim 2005b, 169^{VP}.

Further descriptive information

After 2 d of incubation on MA colonies are creamy-yellow, slightly irregular in shape. Optimal growth occurs in media containing

2.0–9.0% NaCl. Both species grow in the pH range of 6.5–9.0 with slight differences per species. All tests were performed at 35 °C. Phylogenetically, *Pontibacillus* belongs to the *Bacillaceae* with, as close neighbors, other salt-tolerant taxa of the *Bacillaceae* such as *Gracilibacillus*, *Virgibacillus*, *Halobacillus*, *Filobacillus*, and *Lentibacillus* at the level of 93.3–95.9% 16S rDNA similarity.

Strains of *Pontibacillus* have been isolated from a solar saltern in Korea on media that must contain mineral salts and trace elements.

Differentiation of the genus *Pontibacillus* from other genera

Apart from the sequence analysis of the 16S rDNA (see above), *Pontibacillus* can be discriminated at the generic level by a number of biochemical characteristics as given in Table 1 in Lim et al. (2005b). The interested researcher must be aware that often the data given are limited to the type strains of the phy-

TABLE 34. Characteristics differentiating *Pontibacillus* species (type strains)^{a,b}

logenetically closest taxa and that the methodology applied to obtain these phenotypic data may be different, resulting in less reliable comparisons.

Taxonomic comments

The genus *Pontibacillus* now encompasses two species, *Pontibacillus chungwhensis* and *Pontibacillus marinus*, that were both iso-

lated from the same niche (solar saltern) and are most probably not reflecting the real ecological, biochemical, and physiological variation of the genus.

List of species of the genus *Pontibacillus*

1. *Pontibacillus chungwhensis* Lim, Jeon, Song and Kim 2005b, 169^{VP}

chung.when'sis. N.L. masc. adj. *chungwhensis* belonging to Chungwha, where the organism was isolated.

Cells are μ 0.6–0.9 μ m \times 2.3–3.0 μ m. The colonies on MA are yellow, low convex, smooth, and circular (slightly irregular). Temperature for growth ranges from 15 °C to 45 °C with an optimum from 35 °C to 40 °C in the pH range of 6.5–9.5 (with optimum pH 7.5–8.5). Optimal growth occurs in media containing 2–5% w/v NaCl and no growth occurs without NaCl or in the presence of more than 15% (w/v) NaCl. Nitrate is not reduced to nitrite. Oxidase-negative. Casein, starch, and Tween 80 are hydrolyzed while esculin, L-tyrosine, hypoxanthine, xanthine, and gelatin are not. Acids are produced from D-glucose, D-ribose, maltose, glycerol, and D-trehalose, but not from D-xylose, L-arabinose, L-rhamnose, α -D-lactose, adonitol, D-raffinose, D-mannitol, D-fructose, arbutin, D-salicin, D-melibiose, or D-mannose. Cellular fatty acid profiles on MA and MA plus 3% (w/v) NaCl can be found from the species differentiation table (Table 34).

DNA G + C content (mol%): 41 (HPLC).

Type strain: BH030062, DSM 16287, KCTC 3890.

GenBank accession number (16S rRNA gene): AY553296.

2. *Pontibacillus marinus* Lim, Jeon, Park, Kim, Yoon and Kim 2005a, 1030^{VP}

ma'rin.us. L. masc. adj. *marinus* of the sea.

Rods of 0.4–0.9 μ m \times 3.3–4.0 μ m. Strictly aerobic. Catalase- and oxidase-positive. Nitrate is reduced to nitrite. Creamy colonies on MA, flat, smooth, and circular to slightly irregular. Growth occurs at 15–40 °C with an optimum at 30 °C, pH 6.0–9.0 with an optimum pH of 7.0–7.5 and 1–9% (w/v) NaCl with an optimum of 2–5%. Tween 80 and esculin are hydrolyzed. Hydrolysis of casein, starch, gelatin, L-tyrosine, hypoxanthine, xanthine, and urea is not observed. Production of acid is observed from sucrose, D-melibiose, D-trehalose, D-raffinose, D-fructose, D-ribose, and maltose, but not from D-glucose, glycerol, D-xylose, L-arabinose, L-rhamnose, α -D-lactose, adonitol, D-mannitol, inositol, or D-mannose. Major cellular fatty acids on MA are C_{15:0 iso}, C_{15:0 ante}, and C_{16:1 ω7c} alcohol. Further information is given in the species differentiation table (Table 34).

DNA G + C content (mol%): 42.0 (HPLC).

Type strain: BH030004, DSM 16465, KCTC 3917.

GenBank accession number (16S rRNA gene): AY603977.

Genus XVI. *Saccharococcus* Nystrand 1984a, 503^{VP} (Effective publication: Nystrand 1984b, 217.)

EDITORIAL BOARD

Sac.cha.ro.coc'cus. Gr. n. *sakchâr* sugar; L. n. *coccus* a grain, berry; N.L. masc. n. *Saccharococcus* the sugar coccus, a coccus isolated from beet sugar extraction.

Spherical cells of 1–2 μ m in diameter occurring in irregular clusters. Nonmotile, nonspore-forming. Gram-positive; the cell wall contains peptidoglycan with mesodiaminopimelic acid as diamino acid. Theichoic acids are not present. The cells are lysed by 100 μ g/ml of egg white lysozyme. Aerobic and heterotrophic. **Catalase and oxidase are produced. Thermophilic** with an optimal range

of 68–70 °C and a maximum range of 75–78 °C. Acid, but no gas is produced from most mono- and disaccharides. L(+)Lactic acid is the main metabolite from the carbohydrate degradation.

DNA G+C content (mol%): 48.

Type species: ***Saccharococcus thermophilus*** Nystrand, 1984a, 503^{VP} (Effective publication: Nystrand, 1984b, 217.).

Further descriptive information

Various strains of cocci have been isolated from five different sugar beet extraction plants in Sweden (Nystrand, 1984b). At that time, bacterial contamination pointed to members of the genus *Bacillus*, mainly *Bacillus stearothermophilus* (now *Geobacillus thermophilus*, see *Geobacillus*, above). The cell morphology and the lack of endospore formation favored the new generic description. Biochemically, the isolates were characterized on the basis of the API panels that were available at that time. Complete details are given in Nystrand (1984b). Strains were resistant to polymyxin B and sensitive to chloramphenicol, tetracycline, erythromycin, neomycin, penicillin-G, streptomycin, and bacitracin. The strains are also sensitive to a number of disinfectants but relatively tolerant to formaldehyde. This observation has practical implications concerning disinfection of the sugar production plants where the bacteria were at the basis of important loss of sucrose. The contamination source can be found in the contaminating soil. At least some strains contain plasmids that are quite similar in length to the plasmids of *Geobacillus stearothermophilus*.

Enrichment and isolation procedures

The members of *Saccharococcus thermophilus* could only be isolated from fresh samples immediately after their removal from the sugar beet extraction process. Preservation occurs by freeze-drying in a medium of 10% skim milk and 2% sucrose. Strains were isolated on Tryptone Glucose Extract Agar with an addition of 5 g/l sucrose after incubation at 70 °C for 16–24 h.

The strains require regular (daily) transfer to fresh medium to ensure their viability.

Differentiation of the genus *Saccharococcus* from closely related genera

Sequence analysis of the 16S rRNA gene revealed that *Saccharococcus thermophilus* falls in the immediate vicinity of members of the *Geobacillus* species with sequence similarity values of around 97% (Fortina et al., 2001a). These authors did not reclassify *Saccharococcus thermophilus* as a member of *Geobacillus* most probably because of its morphological and biochemical differences from the geobacilli. Phylogenetically, *Saccharococcus* is a member of *Geobacillus* which was already discovered by Rainey and Stackebrandt (1993) and is supported by the presence of the unusual tertiary polyamine, N4 (aminopropyl) spermidine (Hamana et al., 1993). Polyamines are regarded as evolutionary taxonomic markers and most often support phylogenetic relationships demonstrated via 16S rRNA gene sequence analysis.

Taxonomic comments

The genus *Saccharococcus* belongs in the same phylogenetic group as the genus *Geobacillus*. Reclassification at the generic level would have important nomenclatural implications because of the priority rule. Indeed, the genus *Geobacillus* should be renamed "*Saccharococcus*" which would mean that "coccus" as trivial characteristic would be linked to "bacillus"-like morphology as is the case for the present members of *Geobacillus*.

List of species of the genus *Saccharococcus*

1. ***Saccharococcus thermophilus*** Nystrand, 1984a, 503^{VP} (Effective publication: Nystrand, 1984b, 217.)

ther.mo'phi.lus. Gr. n. *therme* heat; Gr. adj. *philos* loving; N.L. adj. *thermophilus* heat-loving.

Characteristics are the same as that for the genus. Biochemical characteristics are mentioned in detail by Nystrand (1984b). API systems reveal that a large variety of sugars (mono-, di-, and trisaccharides) can be used. Further positive reactions are reported for the sugar alcohols mannitol and sorbitol, *N*-acetylglucosamine, and glycerol. The presence of chymotrypsin, esterase, esterase lipase, α -galactosidase, α -glucosidase, various phosphatases, and leucine arylamidase are reported

via the API ZYM; tetrathionate reductase and lipase are reported via API 50E and gelatinase via the API 20E methodologies. Methyl red-positive and Voges–Proskauer-negative. Phenotypic differentiation between *Saccharococcus thermophilus* and most closely related *Geobacillus* members is given in Table 35.

Genus XVII. *Tenuibacillus* Ren and Zhou 2005b, 98^{VP}

PAUL DE VOS

Te.nu.i.ba.cil'lus. L. adj. *tenuis* slender, thin, slim; L. n. *bacillus* small rod; N.L. masc. n. *Tenuibacillus* a slender rod.

Gram-positive, aerobic, organotrophic rods of about 0.3–0.5 μ m wide and 2.0–6.0 μ m long. Motile by a single polar flagellum. Terminal spherical spores in a swollen sporangium are formed. NaCl is needed for growth. Nitrate is not reduced to nitrite. Positive for catalase and oxidase; negative for phosphoesterase and cellulase. Produces H₂S, but not NH₃. Methyl red and Voges–Proskauer tests are negative. *meso*-Diamin-

opimelic acid is the peptidoglycan component. Phylogenetically, *Tenuibacillus* belongs to the *Bacillaceae* and closest 16S rRNA gene sequence similarities are found with members of the genera *Filobacillus* and *Alkalibacillus*. Other moderate halophiles/halotolerants such as *Lentibacillus*, *Gracilibacillus*, and *Virgibacillus* are more distantly related phylogenetically. The major fatty acids are C_{15:0 iso}, C_{15:0 ante}, C_{17:0 iso}, and C_{16:0 iso}.

Type species: ***Tenuibacillus multivorans*** Ren and Zhou 2005b, 98^{VP}.

Further descriptive information and differentiation from other genera

The optimal growth temperature reported is between 36 °C and 41 °C in media that contain optimally 5–8% (w/v) NaCl at pH 7. *Tenuibacillus* representatives were isolated on Halophiles Moderate (HM) agar plates (Ventosa et al., 1982) from a neutral hypersaline lake in China (Ren and Zhou, 2005b). The phenotypic and phylogenetic diversity of the genus is unknown as only two strains of the species, which show 99.8% 16S rRNA gene sequence similarity to each other in the most variable region

of the cistron, have been reported and also because the most closely related genus phylogenetically (*Filobacillus*) also comprises only one species. The classic phenotypic characteristics of moderate halophilic sporeformers are generally very similar and, hence, their discrimination is based merely on genetic diversity. Although the isolation source of *Tenuibacillus* (hypersaline lake in China) may at first sight seem to be a relatively isolated ecosystem, it is to be expected that more representatives are present in similar environments. Further differences between *Filobacillus* and *Tenuibacillus* can be found in murein type (L-ornithine for cross-linking in *Filobacillus*), fatty acid composition (the ratio of C_{15:0 iso} to C_{15:0 ante} differs in both taxa), oxidase reaction, position of the flagella, and the Gram-staining reaction (for further details, see Ren and Zhou, 2005b).

List of species of the genus *Tenuibacillus*

1. ***Tenuibacillus multivorans*** Ren and Zhou 2005b, 98^{VP}

mul.ti.vor'ans. L. part. adj. *multus* many, numerous; L. v. *vorō* to devour, swallow; N.L. part. adj. *multivorans* devouring numerous kinds of substrates.

Gram-positive in fresh cultures and Gram-variable in aged cultures. The description complies with the genus description and is based on two strains. On HM medium, the circular, translucent, convex colonies (about 1–2 mm in diameter after 2 d) become brown from the center outwards upon ageing. NaCl range for growth is 1–20%; no growth is observed at either 37 °C or 20 °C in rich media without NaCl. Temperature range for growth is 21–42 °C (optimum 36–41 °C). pH range for growth is 6.5–9.0 (optimum pH 7.0–8.0). General physiological and biochemical testing according to methods described

by Smibert and Krieg (1981) reveals that the saccharides, polysaccharides, and sugar alcohols tested, including arabinose, xylose, D-fructose, glucose, D-mannose, rhamnose, DL-sorbose, cellobiose, D-galactose, lactose, maltose, melibiose, sucrose, trehalose, melezitose, D-raffinose, inulin, dulcitol, erythritol, glycerol, inositol, mannitol, and salicin, are metabolized, but acid is not produced from them. Gelatin, casein, esculin, and Tween 40 and 60 are hydrolyzed, but starch, and Tween 20 and 80 are not.

Source: a hypersaline lake, Ai-Ding Lake, in the Xinjiang Uigur autonomous area of North-West China.

DNA G + C content (mol%): 36.5–37 (HPLC).

Type strain: 28-1, AS 1.344, NBRC 100370.

EMBL/GenBank accession number (16S rRNA gene): AY319933 (28-1).

Genus XVIII. *Thalassobacillus* Garcia, Gallego, Ventosa and Mellado 2005, 1793^{VP}

ANTONIO VENTOSA, ENCARNACIÓN MELLADO AND PAUL DE VOS

Tha.las'so.ba.cil'lus. Gr. fem. n. *thalassa* sea; L. masc. n. *bacillus* rod; N.L. masc. n. *Thalassobacillus* rod from the sea.

Gram-positive rods forming ellipsoidal endospores exhibiting a central position. Motile. The catalase reaction is positive, whereas oxidase and urease are negative. Nitrate reduction to nitrite is positive. Members are moderately halophilic and do not grow in media without NaCl. Peptidoglycan type A1 γ with meso-diaminopimelic acid is found as major component of the cell wall. Major fatty acids are C_{15:0 ante}, C_{16:0 iso}, and C_{15:0 iso}. MK-7 is the predominant menaquinone. Based on comparative 16S rRNA gene sequence analysis, belongs phylogenetically to the family Bacillaceae in a separate lineage close to the genus *Halobacillus*; other genera that include moderately halophilic species, for example, *Virgibacillus*, *Lentibacillus*, *Gracilibacillus*, and *Pontibacillus*, etc., are more distantly related.

DNA G + C content (mol%): 42.4 (T_m , type strain of the type species).

Type species: *Thalassobacillus devorans* Garcia, Gallego, Ventosa and Mellado 2005, 1793^{VP}.

Further descriptive information

This genus currently contains only *Thalassobacillus devorans*, represented only by the type strain, indicating that the genomic

and phenotypic variability of this taxon is unknown. The strain was obtained after an isolation campaign to search for aromatic-hydrocarbon-degrading halophiles in Southern Spain. It is well known that these components, either natural or anthropogenic, are recalcitrant compounds that lead to health and environmental problems. In the bioremediation processes, salt is often a limiting factor (Oren et al., 1992). Other described moderately halophilic degraders of aromatic compounds include members of the genera *Halomonas*, *Marinobacter*, and *Arhodomonas* (Adkins et al., 1993; Alva and Peyton, 2003; Garcia et al., 2004; Hedlund et al., 2001; Huu et al., 1999; Muñoz et al., 2001; Nicholson and Fathepure, 2004). Isolated after enrichment in a medium containing KOH (0.075 M), KH₂PO₄ (0.1 M), (NH₄)₂SO₄ (0.015 M), and 1% (v/v) MgSO₄/FeSO₄ solution (MgSO₄, 1.6 mM; FeSO₄, 39 μ M), to which 10% NaCl, 0.005% yeast extract, and 0.05% (w/v) phenol were added (Garcia et al., 2005). Differentiation from other genera is merely on differences in 16S rRNA gene sequences. Furthermore, members of the genus *Halobacillus*, the closest relative phylogenetically, contain Orn-D-Asp in the cell wall, whereas the only *Thalassobacillus* species contains meso-diaminopimelic acid.

List of species of the genus *Thalassobacillus*1. *Thalassobacillus devorans* Garcia, Gallego, Ventosa and Mellado 2005, 1793^{VP}

de.vo'rans. L. v. *devorare* to devour; L. part. adj. *devorans* devouring (organic compounds).

Cells are rods, 1.0–1.2 μ m wide and 2.0–4.0 μ m long. Motile by means of flagella. On complex medium with 10% salts, the cream-colored colonies are uniformly round, circular, regular, and convex. Moderately halophilic: grows in media with salt concentrations between 0.5% and 20% (w/v) NaCl, with optimal growth in 7.5–10% (w/v) NaCl. No growth occurs in media without NaCl. No other salt requirements determined. Growth occurs between 15 °C and 45 °C and at pH 6.0–10.0, with optimal growth at 37 °C and pH 7.0. Strictly aerobic. Indole, methyl red, and Voges–Proskauer tests are negative. Gelatin and Tween

80 are hydrolyzed, but starch, casein, and esculin are not. Acid production is observed from D-glucose, trehalose, D-mannose, and D-fructose. The metabolic fingerprint has been determined using the Biolog GP panel. Only a limited number of substrates were respired, including sugars, sugar alcohols, and a limited number of acids. Most compounds of the Biolog GP microplates were not metabolized (for details, see Garcia et al., 2005). Other characteristics are as for the genus. The type strain was isolated from a saline soil in southern Spain.

DNA G + C content (mol%): 42.4 (T_m).

Type strain: G-19.1, DSM 16966, CECT 7046, CCM 7282.

EMBL/GenBank accession number (16S rRNA gene): AJ717299 (G-19.1).

Genus XIX. *Virgibacillus* Heyndrickx, Lebbe, Kersters, De Vos, Forsyth and Logan 1998, 104^{VP} emend. Wainø, Tindall, Schumann and Ingvorsen 1999, 830 emend. Heyrman, Logan, Busse, Balcaen, Lebbe, Rodríguez-Díaz, Swings and De Vos 2003b, 510

JEROEN HEYRMAN, PAUL DE VOS AND NIALL LOGAN

Vir.gi.ba.cil'lus. L. n. *virga* a green twig, transf., a branch in a family tree; L. dim. n. *bacillus* a small rod and also a genus of aerobic endospore-forming bacteria; N.L. masc. n. *Virgibacillus* a branch of the genus *Bacillus*.

Motile, Gram-positive rods, 0.3–0.8 μ m \times 2–8 μ m in size. Occur singly, in pairs, chains or, especially in older cultures, filaments. Bear spherical to ellipsoidal endospores that lie in terminal (sometimes subterminal or paracentral) positions in

swollen sporangia. Aerobic or weakly facultatively anaerobic. Catalase-positive. Colonies are of small to moderate diameter (0.5–5 mm after 2 d on marine agar or trypticase soy agar), circular and slightly irregular, smooth, glossy or sometimes matt,

low convex, and slightly transparent to opaque; usually unpigmented or creamy to yellowish white, but one species produces a pink pigment on marine agar. In the API 20E strip and in conventional tests, the Voges–Proskauer reaction is negative, indole is not produced, nitrate reduction to nitrite is variable. Casein is hydrolyzed by all species, and esculin and gelatin are hydrolyzed, sometimes weakly, by most species. In the API 20E strip, urease and hydrogen sulfide are usually not produced, but a few strains give weak positive reactions for the latter; a few strains also give positive reactions for arginine dihydrolase, citrate utilization, and *o*-nitrophenyl- β -D-galactoside. **Growth is stimulated by 4–10% NaCl.** Growth may occur between 10 °C and 50 °C, with an optimum of about 28 °C or 37 °C. **For the species examined, raffinose can be used as sole carbon source;** no growth on D-arabinose, D-fructose, or D-xylose. The major fatty acid is C_{15:0 ante}. The major polar lipids are diphosphatidyl glycerol and phosphatidyl glycerol. Five phospholipids and one polar lipid of unknown structure are present in all species. The presence of phosphatidyl ethanolamine and other lipids varies. The main menaquinone type is MK-7, with minor to trace amounts of MK-6 and MK-8. In the species examined, the cell wall contains peptidoglycan of the *meso*-diaminopimelic acid type (Arahal et al., 1999; Claus and Berkeley, 1986). Inhabitants of soil and other, especially salty, environments; also isolated from food, water, and clinical specimens.

DNA G + C content (mol%): 36–43.

Type species: Virgibacillus pantothenicus (Proom and Knight 1950) Heyndrickx, Lebbe, Kersters, De Vos, Forsyth and Logan 1998, 105^{VP} emend. Heyndrickx, Lebbe, Kersters, Hoste, De Wachter, De Vos, Forsyth and Logan 1999, 1089 (*Bacillus pantothenicus* Proom and Knight, 1950, 539.).

Further descriptive information

Virgibacillus cells are motile, salt-tolerant, Gram-positive rods, 0.3–0.8 μ m \times 2–8 μ m. They occur singly, in pairs, or short chains or filaments. They bear oval to ellipsoidal endospores that lie in swollen sporangia. On marine agar, colonies are small, circular, low-convex, and slightly transparent to opaque. Although some species, notably *Virgibacillus pantothenicus*, *Virgibacillus proomii* and *Virgibacillus dokdonensis*, will grow on routine cultivation media such as nutrient agar and trypticase soy agar, all species grow on media supplemented with 4–10% NaCl, and all grow well on marine agar. Marine agar and broth may be prepared by making up a solution of an ocean salts mixture (as sold for keeping tropical fish or available from some chemical suppliers) according to the supplier's instructions, and adding nutrients such as peptone and/or yeast extract as required; marine agar and broth are also available commercially from bacteriological media suppliers. Several species will tolerate salt concentrations of 20–25%. Two species, *Virgibacillus marismortui* and *Virgibacillus salexigens*, will not grow in the absence of salt, and *Virgibacillus carmonensis* and *Virgibacillus necropolis* grow poorly, if at all, without salt. *Virgibacillus dokdonensis*, *Virgibacillus koreensis*, *Virgibacillus halodenitrificans*, *Virgibacillus pantothenicus*, and *Virgibacillus proomii* show some growth in anaerobic conditions, but the other species of the genus are strictly aerobic.

The different members of the genus show a wide range of activities in routine phenotypic tests, and perhaps this reflects undiscovered requirements for growth factors and/or special

environmental conditions. *Virgibacillus carmonensis* and *Virgibacillus necropolis* give very weak reactions in routine phenotypic tests even when the test media have been supplemented with 7% salt (Heyrman et al., 2003b). Although one strain of *Virgibacillus proomii* was isolated from a clinical specimen and another from processed food, there have been no reports of *Virgibacillus* strains being associated with disease or food spoilage.

The fatty acid profile of *Virgibacillus* strains shows a dominance of branched fatty acids. The major fatty acid is C_{15:0 ante}, accounting for 58, 52, 43, 34, 68, 55, 38, and 31% of the total fatty acids in *Virgibacillus carmonensis*, *Virgibacillus halodenitrificans*, *Virgibacillus koreensis*, *Virgibacillus marismortui*, *Virgibacillus necropolis*, *Virgibacillus pantothenicus*, *Virgibacillus proomii*, and *Virgibacillus salexigens*, respectively (Lee et al., 2006b). For *Virgibacillus dokdonensis* (Yoon et al., 2005b), the amount of C_{15:0 ante} (tested under different culture conditions) was 34%. The importance of using standardized growth conditions for chemotaxonomic characterization has been shown for *Virgibacillus* by Wainø et al. (1999). The major polar lipids are diphosphatidyl glycerol and, in smaller amounts, phosphatidyl glycerol. Five phospholipids and one polar lipid of unknown structure are present in all species. The presence of phosphatidyl ethanolamine varies; it is present in *Virgibacillus dokdonensis*, *Virgibacillus pantothenicus*, and *Virgibacillus marismortui*, and to a lesser extent in *Virgibacillus proomii*, but it is present only at trace levels or is undetectable in the other species (Heyrman et al., 2003b; Yoon et al., 2005b). The presence of other polar lipids also varies between species and, overall, the polar lipid profiles of the genus appear to be species- or strain-specific. The main menaquinone type is MK-7, occurring at levels of 94–99%, with minor amounts of MK-6 and trace to minor amounts of MK-8 (Heyrman et al., 2003b; Lee et al., 2006b; Yoon et al., 2005b; Yoon et al., 2004c); this is similar to the profile seen in most other aerobic, endospore-forming bacteria. The peptidoglycans of *Virgibacillus dokdonensis*, *Virgibacillus halodenitrificans*, *Virgibacillus koreensis*, *Virgibacillus pantothenicus*, and *Virgibacillus marismortui* contain *meso*-diaminopimelic acid (Arahal et al., 1999; Claus and Berkeley, 1986; Lee et al., 2006b; Yoon et al., 2005b; Yoon et al., 2004c).

Virgibacillus strains generally have an aerobic respiratory type of metabolism, though *Virgibacillus dokdonensis*, *Virgibacillus koreensis*, *Virgibacillus pantothenicus*, and *Virgibacillus proomii* can also grow in an anaerobic chamber (Heyndrickx et al., 1999; Lee et al., 2006b; Yoon et al., 2005b). *Virgibacillus halodenitrificans* can grow in the presence of nitrate as alternative e-acceptor, indicating the capacity of anaerobic respiration. Members of the genus are catalase-positive and are usually able to hydrolyze gelatin, esculin, and casein (Heyrman et al., 2003b; Lee et al., 2006b; Yoon et al., 2005b). *Virgibacillus pantothenicus* has a nutritional requirement for pantothenic acid, thiamine, and biotin (Proom and Knight, 1950). The type strain of *Virgibacillus halodenitrificans* requires organic (reduced) sulfur (Denariáz et al., 1989). Other than the features given in species descriptions accompanying the proposals of new taxa, *Virgibacillus* strains have rarely been tested for their physiological properties. Kuhlmann and Bremer (2002) studied various aerobic endospore-formers for the synthesis of compatible solutes (organic osmolytes that organisms may produce and accumulate in very high concentrations in order to adjust to high-osmolality environments). Endogenous synthesis of ectoine and glutamate was observed in the type strains of both *Virgibacillus pantothenicus* and

Virgibacillus salexigens; the former also produced proline and the latter hydroxyectoine. Of the thirteen members of *Bacillaceae* tested, these strains were the only ones producing three compatible solutes, and *Virgibacillus salexigens* was the only one that produced hydroxyectoine.

Virgibacillus occurs in various salty and non-salty habitats. *Virgibacillus pantothenicus* was originally isolated from soils in southern England (Proom and Knight, 1950) and has also been found in hypersaline soil and salterns (Garabito et al., 1998), antacids (Claus and Berkeley, 1986), canned chicken (Heyndrickx et al., 1999), and the alimentary tracts of worker honey bees (Gilliam and Valentine, 1976); *Virgibacillus proomii* has been isolated from soil, infant bile, and a water supply (Heyndrickx et al., 1999); *Virgibacillus salexigens* was isolated from Spanish salterns and hyper saline soils (Garabito et al., 1997); *Virgibacillus halodenitrificans* was isolated from a French solar evaporation pond (Denariáz et al., 1989); *Virgibacillus marismortui* was found in water samples that had been taken from the Dead Sea by B.E. Volcani in 1936 and held as sealed enrichment cultures for 57 years (Arahal et al., 1999); *Virgibacillus necropolis* and *Virgibacillus carmonensis* were isolated from samples of biofilms taken from damaged mural paintings in the Roman Servilia tomb in the necropolis of Carmona, Spain (Heyrman et al., 2003b). *Virgibacillus koreensis* was isolated from a salt field near Taean-Gun on the Yellow Sea in Korea (Lee et al., 2006b), while *Virgibacillus dokdonensis* has been isolated from sea water collected at Dokdo, a Korean island in the East Sea (Yoon et al., 2005b).

The international databases EMBL and GenBank contain 16S rDNA sequences of all members of *Virgibacillus* as it is currently described. In addition, partial sequences of the *recA* and *spkB* (spore photoproduct lyase) genes are available for *Virgibacillus salexigens* and *Virgibacillus marismortui*. These genes were sequenced by Maughan et al. (2002), to comment on the ancestry between "*Bacillus permians*" and *Virgibacillus marismortui* (see *Taxonomic comments*). For *Virgibacillus pantothenicus*, a sequence of the betaine/carnitine/choline transporter (*ectT*) gene involved in osmoregulation is available. In addition, *ectA*, *ectB* (diaminobutyric acid aminotransferase), and *ectC* (ectoine synthase) are also available for *Virgibacillus pantothenicus* and *Virgibacillus salexigens*.

Enrichment and isolation procedures

No specific selective isolation procedures for *Virgibacillus* species have been described, but representatives of the genus might be selected for, together with other halotolerant/halophilic bacteria, by using media with 5–10% NaCl added. Inoculation of such media could be preceded by a heating step (e.g., 5–10 min at 80 °C) in order to kill vegetative cells and so select for endospore-formers.

Virgibacillus pantothenicus and *Virgibacillus proomii* strains were originally isolated on routine media, such as nutrient agar (Heyndrickx et al., 1999; Proom and Knight, 1950), but in the case of the former, isolation followed enrichment in 4% NaCl broth. All other species were originally isolated on media containing 7–10% NaCl (Arahal et al., 1999; Garabito et al., 1997; Heyrman et al., 2003b; Lee et al., 2006b) or on Marine Agar (Yoon et al., 2005b). *Virgibacillus* strains all grow well on marine agar. Optimal growth temperatures are between 25 °C and 30 °C for *Virgibacillus carmonensis*, *Virgibacillus koreensis*, and *Virgibacillus necropolis*, and 37 °C for the other species.

Virgibacillus pantothenicus was originally isolated from samples of soil collected in southern England by adding the soil to 10 ml broth (presumably nutrient broth) that had been supplemented with 4% NaCl to give a volume of 15 ml, followed by shaking to mix and incubation at 28 °C or 37 °C for 2 d. A loopful of enrichment was then plated on nutrient agar and incubated at 37 °C (Knight and Proom, 1950; Proom and Knight, 1950).

The description of *Bacillus halodenitrificans* is based upon study of one of four strains isolated from a solar evaporation pond (Denariáz et al., 1989) by injecting samples into Hungate tubes containing a yeast extract medium (Na₂HPO₄, 3.8 g, or NaH₂PO₄, 1.43 g, or KH₂PO₄, 1.3 g; (NH₄)₂SO₄, 1 g; yeast extract, 1 g; Mg(NO₃)₂·6H₂O, 1 g) supplemented with 1.06 M NaNO₃ and either 1% sodium acetate, 1% tryptone, or 10 ml sodium lactate per 1000 ml, and incubating for 1–2 weeks at 37 °C. The cultures produced N₂O and were inoculated into fresh tubes of medium, incubated for 1 d, and streaked onto the acetate-supplemented medium containing 1.7 M NaCl and 1.5% agar for aerobic incubation at 37 °C.

Arahal et al. (1999) isolated *Bacillus marismortui* from water samples that had been taken from the surface level of the Northern basin of the Dead Sea near the mouth of the River Jordan by B.E. Volcani in 1936; 1% peptone had been added and the closed 500 ml bottles had been stored in the dark at 18–20 °C and left unopened for 57 years. The three isolation media used were formulated as follows: SW-10 (Nieto et al., 1989) medium contained yeast extract, 5 g; NaCl, 81 g; MgSO₄, 9.6 g; MgCl₂, 7 g; KCl, 2 g; CaCl₂, 0.36 g; NaHCO₃, 0.06 g; NaBr, 0.026 g; water 1000 ml; pH 7.2. HM medium (Ventosa et al., 1982) contained: yeast extract, 10 g; proteose peptone, 5 g; glucose, 1 g; NaCl, 178.0 g; MgSO₄·7H₂O, 1.0 g; CaCl₂·2H₂O, 0.36 g; KCl, 2.0 g; NaHCO₃, 0.06 g; NaBr, 0.23 g; FeCl₃·6H₂O, trace; water 1000 ml; pH 7.2 adjusted with KOH. M4 medium (Arahal et al., 1999) contained NaCl, 103 g; MgSO₄·7H₂O, 18 g; CaCl₂·2H₂O, 0.25 g; KCl, 0.19 g; peptone, 0.5 g; water 1000 ml; pH 7.2. Cultures were incubated at 37 °C in an orbital shaker.

Virgibacillus salexigens was isolated from ponds of solar salterns and from hyper saline soils by direct inoculation, or following dilution of samples in sterile salt solution, onto plates of HM medium (described above for *Virgibacillus marismortui*) solidified with 20 g/l agar; plates were incubated at 37 °C (Garabito et al., 1997; Ventosa et al., 1983).

Virgibacillus carmonensis and *Virgibacillus necropolis* were isolated from scrapings of biofilms on ancient mural paintings by homogenizing the samples in physiological water, preparing a dilution series, and then plating on five different media: (i) trypticase soy broth (BBL) solidified with Bacto agar (Difco); (ii) the aforementioned trypticase soy agar supplemented with 10% NaCl; (iii) R2A agar (Difco); (iv) R2A agar supplemented with 10% NaCl; (v) starch-casein medium, which contained starch, 10 g; casein, 0.3 g; KNO₃, 2 g; K₂HPO₄, 2 g; NaCl, 2 g; MgSO₄·7H₂O, 0.05 g; CaCO₃, 0.02 g; FeSO₄·7H₂O, 0.01 g; agar, 20 g; water 1,000 ml. All media were supplemented with 0.03% cycloheximide to inhibit fungal growth. Plates were incubated aerobically at 28 °C for three weeks (Heyrman et al., 1999).

Virgibacillus koreensis (Lee et al., 2006b) was isolated on nutrient agar containing artificial sea water including 7% NaCl and was further subcultured on marine agar (Difco). *Virgibacillus dokdonensis* was isolated from sea water on marine agar.

Maintenance procedures

Virgibacillus strains can easily be preserved on slopes of a suitable growth medium that encourages sporulation; slopes should be checked microscopically for spores before sealing and storage in a refrigerator. For long term preservation, lyophilization and liquid nitrogen may be used as long as a cryoprotectant is added.

Procedures for testing special characters

Reliable and relatively rapid identification at the genus level is possible by comparative 16S rDNA sequencing since sequences from reference strains are available for comparison in international databases. For more rapid identification, the sequencing can be restricted to the first ± 500 bp since this part contains four hypervariable regions (of 20–30 bp). The remaining $\pm 1,000$ bp sequence only contains two hypervariable regions. Determination of the nearly complete 16S rDNA sequence may give an idea about the species rank of a novel isolate, however, DNA–DNA hybridization experiments should be performed to verify this assumption, as demanded by the current bacterial species concept (Stackebrandt et al., 2002).

Identification is also possible using polyacrylamide gel electrophoresis of cellular proteins, amplified rDNA restriction analysis (Heyndrickx et al., 1999), and fatty acid analysis (Heyndrickx et al., 1999; Heyrman et al., 2003b; Lee et al., 2006b). However, these methods depend on the availability of reference profiles and have not been tested for all species of the genus under the same culture conditions.

Identification solely on the basis of phenotypic data are not straightforward because other taxa of aerobic endospore-forming bacteria share many phenotypic properties with *Virgibacillus*. Also, as already noted, *Virgibacillus carmonensis* and *Virgibacillus necropolis* give very weak reactions in routine phenotypic tests, even when the test media have been supplemented with 7% salt. It is useful to supplement all test media in this way (excepting, of course, salt tolerance test media), and to follow the test protocols recommended for *Bacillus* species; suspension media for miniaturized tests in the API system (bioMérieux, France) may also be supplemented with NaCl. However, it must be appreciated that mere growth in these media does not signify the presence of *Virgibacillus* as many other taxa will grow in these conditions, and that data obtained with such media are not strictly comparable with data from test media not supplemented with NaCl. Phenotypic characteristics differentiating between the currently described *Virgibacillus* species are given in Table 36. Additional data are given in Table 37.

Taxonomic comments

Knight and Proom (1950) attempted to identify 296 *Bacillus* isolates from soil and investigated the nutritional requirements of 220 strains. They found that 11 of their isolates had nutritional requirements different from those of other *Bacillus* species. Their initial growth was stimulated by the addition of 4% NaCl, and (for most strains) pantothenic acid “satisfied a nutritional requirement”. They accordingly proposed the new species *Bacillus pantothenicus* (Proom and Knight, 1950).

Garabito et al. (1997) isolated six moderately halophilic strains from salterns and hypersaline soils and proposed them as the novel species *Bacillus salexigens*. In a dendrogram based on 16S rDNA sequences, *Bacillus salexigens* formed a phylogenetic branch with *Halobacillus halophilus*, *Halobacillus litoralis*, *Bacillus*

dipsosauri (now *Gracilibacillus dipsosauri*; Wainø et al., 1999), and *Bacillus pantothenicus*. Within this branch, *Bacillus salexigens* showed highest sequence similarities to *Halobacillus litoralis* and *Bacillus pantothenicus* (95.8 and 95.5%, respectively). However, the mol% G + C of *Bacillus salexigens* (39.5 mol%) and *Halobacillus halophilus* (51.1 mol%) differed. *Bacillus salexigens* was also found to differ from all the members of *Halobacillus* in the composition of its cell-wall peptidoglycan which is the meso-diaminopimelic acid type in *Bacillus salexigens* and the Orn-D-Asp type in *Halobacillus* (Spring et al., 1996). Garabito et al. (1997) therefore allocated their novel species to *Bacillus* rather than to *Halobacillus*. They further observed that *Bacillus salexigens* was most closely related to *Bacillus pantothenicus*, a species that was allocated to phylogenetic group 1 (*Bacillus sensu stricto*) by Ash et al. (1991) and they suggested that both species might represent a phylogenetic group in the genus *Bacillus sensu lato* that is distinct from the six phylogenetic groups recognized at that time. Heyndrickx et al. (1998) performed a polyphasic study on 12 strains received as *Bacillus pantothenicus* using amplified 16S rDNA restriction analysis, fatty acid methyl ester analysis, SDS-PAGE of whole-cell proteins, and routine diagnostic characters based on the API system and morphological observations. Since *Bacillus pantothenicus* was known to lie at the border of rRNA group 1 of Ash et al. (1991), Heyndrickx et al. (1998) compared their data with those obtained for representative *Bacillus* species belonging to both rRNA groups 1 and 2, other related genera, and *Bacillus dipsosauri*. Unfortunately, a species only very recently published at that time, *Bacillus salexigens* (Garabito et al., 1997) was not studied by Heyndrickx et al. From the phylogenetic point of view, *Amphibacillus*, *Halobacillus*, and *Marinococcus* were found to be the most closely related genera. However, the *Bacillus pantothenicus* strains differed from these genera in various respects including their ability to grow on media without salt, their pH-ranges (*Amphibacillus* contains obligate alkalophiles that lack isoprenoid quinones; Niimura et al., 1990), cell-wall type (*Halobacillus* has a different murein type, as mentioned above), and cell morphology (*Marinococcus* has a coccoid cell morphology and does not form endospores; Hao et al., 1984). Based on these findings it was proposed to accommodate the *Bacillus pantothenicus* strains in a new genus, *Virgibacillus* (Heyndrickx et al., 1998), and nine of the strains investigated were renamed *Virgibacillus pantothenicus*; additional strains were subsequently proposed as the new species *Virgibacillus proomii* (Heyndrickx et al., 1999).

Earlier, Arahall et al. (1999) investigated a group of 91 isolates from the Dead Sea. On the basis of 16S rDNA sequence data, this group of isolates appeared to be most closely related to *Virgibacillus pantothenicus* and *Bacillus salexigens* (with 16S rDNA sequence similarities of 97.8 and 96.6%, respectively). The authors argued that there were sufficient differentiating characteristics between their isolates and *Virgibacillus pantothenicus* to warrant the proposal of a separate species, namely their isolates' inability to grow without NaCl or to grow under anaerobic conditions and their higher G + C content of 39.0–42.8 mol% compared with 36.9–38.3 for *Virgibacillus pantothenicus*. The Dead Sea isolates were therefore proposed as the new *Bacillus* species, *Bacillus marismortui*. In the same volume of the *International Journal of Systematic Bacteriology*, Wainø et al. (1999) had proposed the transfer of *Bacillus salexigens* to the novel genus *Salibacillus* and differentiated this genus from *Virgibacillus* by the characteristics described above (Garabito et al., 1997) and by differences in polar lipid and fatty acid patterns.

^bData from Arahal et al. (1999); Garabito et al. (1997); Heyndrickx et al. (1998, 1999); Heyrman et al. (2003b); Proom and Knight (1950), Yoon et al. (2005b, 2004c), and Lee et al. (2006b).

^cAbbreviations: E, ellipsoidal; S, spherical; CR, conflicting results between the table and the species description in Arahal et al. (1999).

^dFor the type strain the opposite reaction was reported by Heyrman et al. (2003b).

Vreeland et al. (2000) claimed to have isolated a spore-former from within a 250 million-year-old primary salt crystal, a strain that is closely related to *Bacillus marismortui* and *Virgibacillus pantothenicus* according to 16S rDNA sequence analysis, and the authors submitted their sequence data to the GenBank database under the name “*Bacillus permians*” (accession no. AF166093). However, this isolate showed 99% 16S rDNA

sequence similarity to *Bacillus marismortui*, representing a divergence smaller than that seen between two strains of *Bacillus marismortui*. On this account, because of its very low rate of nucleotide substitution (perhaps four orders of magnitude lower than the typical rate for prokaryotes), and because it does not occupy an ancestral position in a tree based upon 16S rRNA sequence comparisons, its antiquity has been questioned

^bData from Arahal et al. (1999); Garabito et al. (1997); Heyndrickx et al. (1998, 1999); Heyrman et al. (2003b); Proom and Knight (1950), Yoon et al. (2005b, 2004c), Lee et al. (2006b).

(Graur and Pupko, 2001; Nickle et al., 2002). Maughan et al. (2002) sequenced a part of the *recA* and *splB* genes of "*Bacillus permians*" and its closest relatives to further investigate their ancestry. Although these authors were cautious in making conclusions, the results further question the authenticity of the finding of Vreeland et al. (2000).

After the creation of the genus *Salibacillus*, Arahall et al. (2000) transferred *Bacillus marismortui* to *Salibacillus* and differentiated this genus from *Virgibacillus* (*Virgibacillus pantothenicus* and *Virgibacillus proomii*) on the basis of spore shape, the inability of *Salibacillus* species to grow under anaerobic conditions or to grow without NaCl, their production of H₂S, their failure to produce acid from D-galactose and D-trehalose, and their failure to hydrolyze starch and Tween 80 (although no data for these last two characters were available for *Virgibacillus proomii*). They further claimed distinction on the basis of the optimal growth of *Salibacillus* strains in 10% NaCl (although this was never tested for *Virgibacillus pantothenicus* and *Virgibacillus proomii*), and the differing G + C contents of the type strains (although there was overlap in these when the G + C data for other strains were also taken into account).

Yoon et al. (2002) described the novel genus *Lentibacillus* on the basis of a single isolate which was proposed as the novel species *Lentibacillus salicampi*. This organism clustered close to *Salibacillus* and *Virgibacillus* in a phylogenetic tree based on 16S rDNA sequence comparisons, but it showed slower growth and a higher proportion of the fatty acid C_{16:0 iso} in comparison with *Virgibacillus* and *Salibacillus*, and therefore the authors considered that it warranted separate genus status. Lu et al. (2002, 2001) described another halophilic endospore-forming genus, *Oceanobacillus*, based on a single strain isolated from the deep-sea. Since at the time of description *Virgibacillus* and *Salibacillus* were still separate genera, Lu et al. (2001) concluded that their isolate could not be attributed to one or the other and proposed a novel genus, despite the limited distinguishing characteristics between their isolate and the members of both existing genera.

The properties distinguishing *Virgibacillus* and *Salibacillus* were reinvestigated by Heyrman et al. (2003b) when they characterized three potential new species isolated from walls and mural paintings. In a phylogenetic tree based on 16S rDNA sequences, the novel isolates formed a monophyletic branch with the members of *Virgibacillus* and *Salibacillus* and were positioned approximately equidistantly from these two genera. The mural isolates and the type strains of *Virgibacillus* and *Salibacillus* species were compared in their growths at different salt concentrations, and it was found that all strains grew optimally at salt concentrations of 5–10%. They also investigated the polar lipid patterns of all type strains, since Wainø et al. (1999) distinguished *Virgibacillus pantothenicus* and *Salibacillus salexigens* on the basis that only the pattern of the former species contains phosphatidylethanolamine, an aminophospholipid, and a glycolipid. The polar lipid pattern

of *Salibacillus marismortui* also showed a moderate amount phosphatidylethanolamine, and the other polar lipid patterns did not allow a satisfactory distinction between members of *Virgibacillus* and *Salibacillus*. Heyrman et al. (2003b) concluded that the remaining characteristics for differentiating the genera were not convincing enough to maintain their separation, and they proposed the transfer of the two species of *Salibacillus* to *Virgibacillus*. They also discovered three novel *Virgibacillus* species among their isolates from walls and mural paintings: *Virgibacillus carmonensis*, *Virgibacillus necropolis*, and *Virgibacillus picturae*. Unfortunately, the authors did not include the single strain genera *Lentibacillus* and *Oceanobacillus*, which had been described only recently. *Virgibacillus* thus contained seven species but, on the basis of 16S rDNA sequence comparisons, as already noted, *Bacillus halodenitrificans* also fell within the genus, and Yoon et al. (2004c) have proposed its transfer to this genus. Lee et al. (2006b) isolated a novel *Virgibacillus* strain from a Korean salt field and described it as *Virgibacillus koreensis*. The genus *Oceanobacillus* had since then expanded by one species, *Oceanobacillus oncorhynchi* (Yumoto et al., 2005b), and *Lentibacillus* by three species *Lentibacillus juripiscarius* (Namwong et al., 2005), *Lentibacillus salarius* (Jeon et al., 2005a), and *Lentibacillus lacisalsi* (Lim et al., 2005c). In a phylogenetic tree including members of *Virgibacillus*, *Oceanobacillus*, and *Lentibacillus* (lacking *Lentibacillus lacisalsi*), Lee et al. (2006b) observed that *Virgibacillus picturae* clustered closer to *Oceanobacillus* and transferred the species as *Oceanobacillus picturae*. In the same year, Yoon et al. (2005b) described *Virgibacillus dokdonensis*.

As discussed above, the majority of species belonging to *Virgibacillus*, *Oceanobacillus*, and *Lentibacillus* were described in the last 5 years. In addition, major changes such as the transfer of *Salibacillus* to *Virgibacillus* and the descriptions of *Oceanobacillus* and *Lentibacillus* were all made in a short time interval; as a result, the different studies were not able to compare results. With every addition of a novel species in the genera *Oceanobacillus*, *Virgibacillus*, and *Lentibacillus*, the phylogenetic relationships between these genera changed and the phenotypic differences originally differentiating them disappeared. Therefore, future species descriptions in the neighborhood of these genera can be expected. This will probably allow better assessment of whether the three genera should remain as currently described or whether further rearrangements are necessary. Two novel additions to the genus *Virgibacillus* are already listed as in press, *Virgibacillus halophilus* and *Virgibacillus olivae*.

List of species of the genus *Virgibacillus*

1. ***Virgibacillus pantothenicus*** (Proom and Knight 1950) Heyndrickx, Lebbe, Kersters, De Vos, Forsyth and Logan 1998, 105^{VP} emend. Heyndrickx, Lebbe, Kersters, Hoste, De Wachter, De Vos, Forsyth and Logan 1999, 1089 (*Bacillus pantothenicus* Proom and Knight, 1950, 539.) pan.to.then'tic.us. N.L. *acidum pantothenicum* pantothenic acid; N.L. adj. *pantothenicus* relating to pantothenic acid.

Cells are motile, Gram-positive, usually long, rods ($0.5\text{--}0.7 \times 2\text{--}8 \mu\text{m}$) that sometimes (especially in older cultures) form chains and/or filaments. They bear spherical to ellipsoidal endospores which lie in terminal, sometimes subterminal, positions in swollen sporangia. After 2 d on trypticase soy agar, colonies are 1–4 mm in diameter, low convex, circular and slightly irregular, butyrous (sometimes slightly tenacious when cells form filaments), creamy-gray, and almost opaque with an eggshell or glossy appearance; the appearance under $10\times$ magnification is reminiscent of white soap flakes in a grayish matrix. After 4 d, colonies smell of ammonia and are 5–10 mm in diameter with lobed and/or fimbriate margins. Organisms are facultatively anaerobic. They have a nutritional requirement for pantothenic acid, thiamine, biotin, and amino acids. Hydrogen sulfide is usually not produced, but a few strains give weak positive reactions in the API 20E strip; a few strains also give positive reactions for arginine dihydrolase, citrate utilization, and *o*-nitrophenyl- β -D-galactoside in the API 20E strip. Nitrate reduction to nitrite is variable. Esculin and casein are hydrolyzed; gelatin is usually hydrolyzed. Growth is stimulated by 4% NaCl and not inhibited by 10% NaCl. Growth may occur between 15 °C and 50 °C with an optimum of about 37 °C. Acid without gas is produced from the following carbohydrates: *N*-acetylglucosamine, D-arabinose, arbutin, D-fructose, galactose, D-glucose, glycerol, maltose, D-mannose, α -methyl-D-glucoside, rhamnose, ribose, salicin, starch, sucrose, D-tagatose, trehalose, and D-turanose; acid production from the following carbohydrates is variable: amygdalin, cellobiose, L-fucose, β -gentiobiose, gluconate, lactose, α -methyl-D-mannoside, and sorbitol. The major cellular fatty acids (>10%) are C_{15:0 ante} and C_{17:0 ante}.

DNA G + C content (mol%): 36.9 (T_m).

Type strain: B0018, ATCC 14576, CCUG 7424, CFBP 4270, CIP 51.24, DSM 26, HAMBI 476, JCM 20334, LMG 7129, NCIMB 8775, NCDO 1765, NCTC 8162, NRRL NRS-1321, VKM B-507.

GenBank accession number (16S rRNA gene): X60627.

2. ***Virgibacillus carmonensis*** Heyrman, Logan, Busse, Balcaen, Lebbe, Rodríguez-Díaz, Swings and De Vos 2003b, 507^{VP}

car.mo.nen'sis. N.L. adj. *carmonensis* of Carmona referring to the mural paintings of the necropolis at Carmona, Spain, from where the strains were isolated.

Cells are motile, Gram-positive rods ($0.5\text{--}0.7 \times 2\text{--}7 \mu\text{m}$) that mostly occur singly, sometimes in pairs and short chains. They bear ellipsoidal, sometimes nearly spherical, endospores that lie in subterminal positions in swollen sporangia. After 24 h on marine agar, colonies are 0.5–1.0 mm in diameter, low convex, circular with slightly irregular margins, smooth, and transparent with the larger colonies having a pink tint. After 2 d the colonies turn bright pink and opaque. Organisms do not grow in an anaerobic chamber at 37 °C. The temperature range for growth is 10–40 °C with optimal growth 25–30 °C. No growth without added salt and optimal growth at NaCl concentrations of 5 and 10%. In the API 20E kit, strains

give positive results for nitrate reduction, and negative results for *o*-nitrophenyl- β -D-galactosidase, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, citrate utilization, hydrogen sulfide production, urease, tryptophan deaminase, and gelatinase. Casein hydrolysis positive. No hemolysis on 5% horse blood agar and no growth on this medium when supplemented with 7% NaCl. With the exception of very weak reactions in esculin hydrolysis and acid production from 5-keto-D-gluconate, strains are unreactive in the API 50CHB gallery even when the CHB suspension medium is supplemented with 7% NaCl. In marine broth, in which the peptone component is replaced by the tested sugar 1% (w/v), growth is observed for the following sugars: cellobiose (weak growth), D-melibiose, raffinose, sucrose, and D-trehalose. No growth on D-arabinose, D-fructose, D-glucose, DL-lactose, and D-xylose. The major cellular fatty acids (>10%) are C_{15:0 ante} and C_{17:0 ante}.

Source: samples of biofilms taken from damaged ancient mural paintings.

DNA G + C content (mol%): 38.9 (HPLC).

Type strain: DSM 14868, LMG 20964.

GenBank accession number (16S rRNA gene): AJ316302.

3. ***Virgibacillus dokdonensis*** Yoon, Kang, Lee, Lee and Oh 2005b, 1836^{VP}

dok.do.nen'sis. N.L. masc. adj. *dokdonensis* of Dokdo, a Korean island.

Description is based on a single strain. Cells are Gram-variable rods, $0.6\text{--}0.8 \times 2.5\text{--}5.0 \mu\text{m}$, motile by peritrichous flagella. They bear ellipsoidal or spherical endospores that lie in terminal or subterminal positions in swollen sporangia. After 2 d on marine agar (MA) supplemented with 3% (w/v) NaCl, colonies are 3–5 mm in diameter, flat, irregular, translucent and milky white in color. Growth occurs under anaerobic conditions on MA and MA supplemented with nitrate. Growth may occur between 15 °C and 50 °C with an optimum around 37 °C. Optimal growth in the presence of 4–5% (w/v) NaCl. Growth occurs without NaCl and in the presence of 23% (w/v) NaCl, but not in the presence of >24%. In the API 20E kit, the strain gives negative results for nitrate reduction, hydrogen sulfide production, urease, arginine dihydrolase, lysine decarboxylase, and ornithine decarboxylase. Oxidase-positive. Hydrolysis of esculin, casein, gelatin, starch, Tween 20, 40, 60, and 80. Hypoxanthine, xanthenes and tyrosine are not hydrolyzed. When assayed with the API ZYM system, alkaline phosphatase, esterase (C4), esterase lipase (C8), α -chymotrypsin, naphthol-AS-BI-phosphohydrolase, and α -glucosidase are present. Acid is produced from D-cellobiose, D-galactose, D-fructose, *myo*-inositol, lactose, maltose, D-mannose, D-ribose, sucrose, and D-sorbitol. The following substrates are utilized: acetate, D-cellobiose, citrate, D-glucose, D-fructose, D-mannose, maltose, pyruvate, salicin, and sucrose. The major fatty acids (>10%) are C_{15:0 ante}, C_{15:0 iso}, C_{17:0 ante}, and C_{16:0 iso}.

Source: sea water collected at the island Dokdo (Korea).

DNA G + C content (mol%): 36.9 (HPLC).

Type strain: DSW-10, DSM 16826, CIP 109001, KCTC 3933.

GenBank accession number (16S rRNA gene): AY822043.

4. **Virgibacillus halodenitrificans** (Denariáz, Payne and Le Gall 1989) Yoon, Oh and Park 2004c, 2166^{VP} (*Bacillus halodenitrificans* Denariáz, Payne and Le Gall 1989, 150.)

ha.lo.de.ni.tri'fi.cans. Gr n. *hals* salt, the sea; N.L. v. *denitrifico* to denitrify; N.L. part. adj. *halodenitrificans* salt-requiring denitrifier.

Description is based upon two strains. Moderately halophilic, denitrifying, Gram-variable, rods 0.6–0.8 × 2.5–4.0 µm, occurring singly or in short chains and forming flexuous elongated (15 µm) cells in anaerobic culture. Motile by means of single or peritrichous flagella; motility in young cultures shows frequent spinning and twisting; only a few flagella are observed, in lateral and polar positions. Forms terminal or subterminal ellipsoidal spores that swell the sporangia. Anaerobic growth on marine agar only occurs when nitrate is present; nitrate is reduced to nitrite (Yoon et al., 2004c); Denariáz et al. (1989) reported a reduction to N₂O, but not to N₂. Colonies on marine agar are circular to slightly irregular, raised, translucent, and cream-colored, with diameters of µ 2–3 mm, after 3 d incubation at 37 °C. Grows at temperatures ranging from 10 °C to 45 °C, with an optimum of 35–40 °C. The pH range for growth is 5.8–9.6 with an optimum of around 7.4. Grows between 2% and 23% NaCl (2–25% for the type strain), optimum 3–7% NaCl; the strain described by Yoon et al. (2004c) grew in the presence of 0.5% NaCl. Ammonia and glutamine are utilized as nitrogen sources; arginine, nitrate, and urea are not. Uses a range of amino acids, carbohydrates, and organic acids as carbon and energy sources. Oxidase-positive. Hydrolyzes casein and gelatin, but not esculin, starch, Tween 80, or urea. Arginine dihydrolase, lysine and ornithine decarboxylase-negative. The type strain contains large amounts of type *b* and *c* cytochromes which confer a pink-orange color to concentrated cell suspensions. The major fatty acids (>10%) are C_{15:0 ante}, C_{17:0 ante} and C_{16:0 iso}. For further information on the type strain, the reader should consult also Denariáz et al. (1989).

Source: a saltern in France.

DNA G + C content (mol%): 38 (chemical determination and HPLC).

Type strain: ATCC 49067, DSM 10037, JCM 12304, KCTC 3790, LMG 9818.

GenBank accession number (16S rRNA gene): AB021186, AY543169.

5. **Virgibacillus koreensis** Lee, Lim, Lee, Lee, Park and Kim 2006b, 254^{VP}

ko.re.en'sis. N.L. masc. adj. *koreensis* for Korea, where the type strain was isolated.

Description based on a single strain. Facultatively anaerobic, Gram-positive rods, 0.5–0.7 × 2.0–7.0 µm, motile by peritrichous flagella. Ellipsoidal spores are produced in terminal positions. On marine agar, colonies are circular,

low-convex, smooth, semi-translucent and cream-colored. Growth occurs optimally at a NaCl concentration of 5–10% (w/v) and no growth occurs at concentrations of more than 20%. Growth occurs in the temperature range of 10–45 °C, with an optimum at 25 °C. The strain tests positive for β-galactosidase and negative for nitrate reduction, indole production, arginine hydrolysis, hydrogen sulfide production, and urease. Hydrolyzes esculin but not gelatin. Oxidase-positive. Acid is produced from esculin, amygdalin, L-arabinose, cellobiose, D-fructose, D-glucose (weak), maltose, D-trehalose (weak) and D-xylose. The major fatty acids (>10%) are C_{15:0 ante} and C_{16:0 iso}.

Source: salt field near Taean-Gun on the Yellow Sea in Korea.

DNA G + C content (mol%): 41 (HPLC).

Type strain: BH30097, CIP 109159, JCM 12387, KCTC 3823.

GenBank accession number (16S rRNA gene): AY616012.

6. **Virgibacillus marismortui** (Arahal, Márquez, Volcani, Schleifer and Ventosa 1999) Heyrman, Logan, Busse, Balcaen, Lebbe, Rodríguez-Díaz, Swings and De Vos 2003b, 510^{VP} (*Bacillus marismortui* Arahal, Márquez, Volcani, Schleifer and Ventosa 1999, 529; *Salibacillus marismortui* Arahal, Márquez, Volcani, Schleifer and Ventosa 2000, 1503.)

ma.ris.mor'tu.i. L. gen. n. *maris* of the sea; L. adj. *mortuus* dead; N.L. gen. n. *marismortui* of the Dead Sea.

Strictly aerobic, motile, Gram-positive rods, 0.5–0.7 × 2.0–3.6 µm, occurring singly, in pairs or in short chains. Oval endospores are produced in terminal or subterminal positions in the swollen sporangia. Colonies are cream-colored, circular, entire, and opaque. Growth occurs in 5–25% (w/v) total salts with optimal growth at 10% (w/v) salts. No growth occurs in the absence of salts. Growth occurs in the temperature range 15–50 °C, with an optimum temperature of 37 °C, and in the pH range 6.0–9.0 with an optimum of pH 7.5. Oxidase-positive. Acid is produced from D-fructose, D-glucose, glycerol, and maltose, but not from D-arabinose, D-galactose, lactose, D-mannitol, sucrose, D-trehalose, or D-xylose. Casein, DNA, and gelatin are hydrolyzed. Starch and Tween 80 are not hydrolyzed. Urease-positive. Methyl red test is positive. Nitrate is reduced to nitrite, but nitrite is not reduced. Arginine dihydrolase, Simmons citrate, H₂S production and phenylalanine deaminase tests are negative. D-Fructose, inulin, maltose, D-mannitol, D-mannose, pyruvate, D-raffinose, D-rhamnose, and succinate are utilized as sole carbon and energy sources. Susceptible to chloramphenicol, erythromycin, penicillin G, streptomycin, and tetracycline; resistant to nalidixic acid, neomycin, novobiocin, and rifampin. The major fatty acids (>10%) are C_{15:0 ante} and C_{15:0 iso}.

Source: stored enrichment cultures of water taken from the Dead Sea.

DNA G + C content (mol%): 40.7 (T_m).

Type strain: 123, ATCC 700626, CECT 5066, CIP 105609, DSM 12325, LMG 18992.

GenBank accession number (16S rRNA gene): AJ009793.

7. **Virgibacillus necropolis** Heyrman, Logan, Busse, Balcaen, Lebbe, Rodríguez-Díaz, Swings and De Vos 2003b, 507^{VP}

ne.cro.po'lis. N.L. adj. *necropolis* of the necropolis, referring to the mural paintings of the necropolis of Carmona, Spain, where the strain was isolated.

Description based on a single strain. Strictly aerobic, motile, Gram-positive rods 0.5–0.7 × 2–5 µm, and coccoid rods, which occur singly, and in pairs or short chains; the cells in the chains tend to lie at angles to each other. Ellipsoidal endospores lie in terminal or subterminal positions in the rods, or centrally in coccoid cells, and they swell the sporangia. After 24 h on marine agar, the colonies are 0.2–0.5 mm in diameter, low convex, circular with entire margins, and smooth, cream-colored, and slightly transparent (but becoming opaque after 2 d growth). The temperature range for growth is 10–40 °C with optimal growth at 25–35 °C. Growth without added salt is weak, and optimal growth occurs at NaCl-concentrations of 5 and 10%. In the API 20E kit, it gives a positive result for nitrate reduction, a very weak reaction for gelatinase, and negative results for *o*-nitrophenyl-β-D-galactosidase, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, citrate utilization, hydrogen sulfide production, urease, and tryptophan deaminase. Casein hydrolysis is positive. Partial hemolysis on 5% horse blood agar, but no growth on this medium when supplemented with 7% NaCl. Generally unreactive in the API 50CHB gallery, using CHB suspension medium supplemented with 7% NaCl, but very weak reactions which did not qualify as positive results are seen in the following tests: glycerol, ribose, D-glucose, D-fructose, D-mannose, N-acetylglucosamine, D-trehalose, D-tagatose, and 5-keto-D-gluconate. In marine broth, in which the peptone component is replaced by the tested sugar at 1% (w/v), growth is observed for the following sugars: cellobiose, D-glucose, DL-lactose (weak growth), D-melibiose, raffinose, sucrose, and D-trehalose. No growth on D-arabinose, D-fructose, and D-xylose. The major fatty acids (>10%) are C_{15:0 ante} and C_{17:0 ante}.

Source: samples of biofilms taken from damaged ancient mural paintings.

DNA G + C content (mol%): 37.3 (HPLC).

Type strain: DSM 14866, LMG 19488.

GenBank accession number (16S rRNA gene): AJ315056.

8. **Virgibacillus proomii** Heyndrickx, Lebbe, Kersters, Hoste, De Wachter, De Vos, Forsyth and Logan 1999, 1087^{VP}

proom.i.i. N.L. gen. n. *proomii* of Proom, referring to Harold Proom, the person who, with B.C.J.G. Knight, first isolated a member of this species and who described *Bacillus pantothenticus*.

Motile, Gram-positive, usually long, rods 0.5–0.7 × 2–8 µm which sometimes, especially in older cultures, form chains and/or filaments. They bear spherical to ellipsoidal endospores which lie in terminal, sometimes subterminal, positions in swollen sporangia. After 2 d on trypticase soy agar, colonies are 1–4 mm in diameter, low convex, circular, and slightly irregular, butyrous (sometimes slightly tenacious when cells form filaments), creamy-gray and almost opaque with an eggshell or matt appearance; the appearance under 10× magnification

is reminiscent of white soap flakes in a grayish matrix. After 4 d, colonies smell of ammonia and are 5–10 mm in diameter with lobed and/or fimbriate margins. Organisms are weakly facultatively anaerobic. A few strains may give positive reactions for arginine dihydrolase and citrate utilization in the API 20E strip. Hydrogen sulfide is not produced. Nitrate is not reduced to nitrite. Hydrolysis of esculin and casein are positive; hydrolysis of gelatin usually positive. Growth may occur between 15 °C and 50 °C with an optimum of about 37 °C. Acid without gas is produced from the following carbohydrates: N-acetylglucosamine, arbutin, D-fructose, galactose, D-glucose, inositol, maltose, D-mannose, ribose, salicin, D-tagatose, and trehalose; acid production from the following carbohydrates is variable: amygdalin, cellobiose, and gluconate (these three usually negative), glycogen, α-methyl-D-glucoside, rhamnose, starch, and sucrose. The major fatty acids (>10%) are C_{15:0 ante}, C_{17:0 ante}, and C_{15:0 iso}.

Source: soil, water, and a clinical specimen of infant bile.

DNA G + C content (mol%): 37 (HPLC).

Type strain: BO413, F 2737/77, CIP 106304, DSM 13055, LMG 12370.

GenBank accession number (16S rRNA gene): AJ012667.

9. **Virgibacillus salexigens** (Garabito, Arahal, Mellado, Márquez and Ventosa 1997) Heyrman, Logan, Busse, Balcaen, Lebbe, Rodríguez-Díaz, Swings and De Vos 2003b, 509^{VP} (*Bacillus salexigens* Garabito, Arahal, Mellado, Márquez and Ventosa 1997, 739; *Salibacillus salexigens* Wainø, Tindall, Schumann and Ingvorsen 1999, 830).

sal.ex'i.gens. L. n. *sal* salt; L. v. *exigo* to demand; N.L. part. adj. *salessigens* salt-demanding.

Strictly aerobic, motile, Gram-positive rods, 0.3–0.6 × 1.5–3.5 µm, occurring singly, in pairs, or in short chains. Oval endospores are produced in central or subterminal positions in swollen sporangia. Colonies are unpigmented, smooth, circular, convex, and entire. Growth occurs in the presence of 7–20% (w/v) total salts with optimal growth at 10% (w/v) salts. According to the original description, no growth occurred with 25% NaCl, but Heyrman et al. (2003b) reported weak growth with this salt concentration. No growth occurs in the absence of salts. Growth occurs in the temperature range 15–45 °C, with an optimum temperature of 37 °C, and in the pH range 6.0–11.0 with an optimum of pH 7.5. Oxidase-positive. Acid is produced from D-fructose, D-glucose, glycerol, maltose, D-mannitol, and mannose, but not from dulcitol, D-galactose, lactose, D-melibiose, L-rhamnose, D-trehalose, or D-xylose. Esculin, casein, DNA, and gelatin are hydrolyzed. Starch, Tween 80, and tyrosine are not hydrolyzed. H₂S is produced. Arginine dihydrolase, lysine and ornithine decarboxylase, phenylalanine deaminase, and Simmons citrate test negative. N-acetyl-D-glucosamine, N-acetyl-glutamate, adenosine, L-alanyl-glycine, cellobiose, 2'-deoxyadenosine, dextrin, D-fructose, D-glucose, glycerol, glycyl-L-glutamate, inosine, L-lactate, maltose, maltotriose, D-mannose, D-melibiose, pyruvate, D-psicose, D-raffinose, D-ribose, salicin, sucrose, thymidine,

uridine, and D-xylose are utilized as sole carbon and energy sources. *p*-Hydroxyphenylacetic acid and succinic acid are not utilized as sole carbon and energy sources. Susceptible to ampicillin, carbenicillin, cephalotin, chloramphenicol, erythromycin, novobiocin, and penicillin G; resistant to nalidixic acid and polymyxin. The

major fatty acids (>10%) are C_{15:0 iso} and C_{15:0 ante}. Habitats are solar salterns and saline soils.

DNA G + C content (mol %): 39.5 (T_m).

Type strain: C-20Mo, ATCC 700290, CCM 4646, CCUG 52350, CIP 105608, DSM 11483, LMG 21520.

GenBank accession number (16S rRNA gene): Y11603.

Family II. *Alicyclobacillaceae* fam. nov.

MILTON S. DA COSTA AND FRED A. RAINEY

A.li.cy.clo.ba.cil.la'ce.ae. N.L. masc. n. *Alicyclobacillus* type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Alicyclobacillaceae* the *Alicyclobacillus* family.

Cells are straight rods of variable length, generally nonmotile. Terminal or subterminal ovoid endospores are formed. The majority of the species stain Gram-positive. Strains are nonpigmented. **Aerobic** with a strictly respiratory type of metabolism, but a few strains reduce nitrate to nitrite and some reduce Fe³⁺. Mesophilic, slightly thermophilic, and thermophilic, and acidophilic. Menaquinone-7 is the predominant respiratory quinone. Many species possess ω -cyclohexane or ω -cycloheptane, but some do not. Branched chain iso- and anteiso- fatty acids and straight chain fatty acids are present in all species. Most species are chemoorganotrophic; some species are mixotrophic. Organic compounds are used as sole carbon and energy sources; acid is produced from several

carbohydrates. Mixotrophic species utilize Fe²⁺, S⁰, and sulfide minerals in the presence of yeast extract or sole organic compounds. The species of the genus *Alicyclobacillus*, the sole genus of the family *Alicyclobacillaceae*, form a distinct phylogenetic lineage based on 16S rRNA gene sequence comparisons (Figure 22). Found in soils and water of geothermal areas, soils, fruit juices, and ores.

DNA G+C content (mol%): 49–62.

Type genus: *Alicyclobacillus* Wisotzkey, Jurtshuk, Fox, Deinhard and Poralla 1992, 267^{VP} emend. Goto, Mochida, Asahara, Suzuki, Kasai and Yokota 2003, 1542 emend. Karavaiko, Bogdanova, Tourova, Kondrat'eva, Tsaplina, Egorova, Krasil'nikova and Zakharchuk 2005, 946.

Genus I. *Alicyclobacillus* Wisotzkey, Jurtshuk, Fox, Deinhard and Poralla 1992, 267^{VP} emend. Goto, Mochida, Asahara, Suzuki, Kasai and Yokota 2003, 1542 emend. Karavaiko, Bogdanova, Tourova, Kondrat'eva, Tsaplina, Egorova, Krasil'nikova and Zakharchuk 2005, 946

MILTON S. DA COSTA, FRED A. RAINEY AND LUCIANA ALBUQUERQUE

A.li.cy.clo.ba.cil'lus. Gr. adj. *aliphos* fat; Gr. n. *kyklos* circle; L. n. *bacillus* small rod; N.L. masc. n. *Alicyclobacillus* small rod with ω -alicyclic fatty acids.

Straight rods, 0.3–1.1 μm \times 1.5–6.3 μm . Terminal or subterminal ovoid endospores are formed. In some strains the sporangium is swollen. The majority of the species stain Gram-positive; one species stains Gram-negative. Many of the strains are **nonmotile, but others have motility**. **Colonies are not pigmented**. **Aerobic** with a strictly respiratory type of metabolism, but a few strains reduce nitrate to nitrite, and some reduce Fe³⁺. The strains of these organisms have variable oxidase and catalase reactions. **Mesophilic, slightly thermophilic, and thermophilic**, with an optimum growth temperature 35–65°C; the temperature range for growth 4–70°C. **Acidophilic**; the pH range for growth is from about 0.5–6.5; the optimum is from pH 1.5–5.5. **Menaquinone-7** is the predominant respiratory quinone. Two phospholipids, one aminoglycolipid, one glycolipid, and a sulfonolipid are generally present. Fatty acids are predominantly ω -cyclohexane or ω -cycloheptane; three species do not possess these fatty acids. Branched chain iso- and anteiso-fatty acids and straight-chain fatty acids are also present. Some strains are known to possess hopanoids. Most species are **chemoorganotrophic**; two species are **mixotrophic**. Monosaccharides, disaccharides, amino acids, and organic acids are used as sole carbon and energy sources; acid is produced from several carbohydrates. Mixotrophic species utilize Fe²⁺, S⁰, and sulfide minerals in the presence of yeast extract or sole organic compounds. Some strains require yeast extract or cofactors for growth. Found in **soil and water of geothermal areas, nongeothermal soils, fruit juices, and ores**.

DNA G+C content (mol%): 48.7–62.5.

Type species: *Alicyclobacillus acidocaldarius* (Darland and Brock, 1971) Wisotzkey, Jurtshuk, Fox, Deinhard and Poralla 1992, 267 (*Bacillus acidocaldarius* Darland and Brock 1971, 9.)

Further descriptive information

The first strains of *Alicyclobacillus acidocaldarius* were classified in the genus *Bacillus* by Darland and Brock (1971) because these aerobic acidothermophiles were Gram-positive and produced endospores. Moreover, another slightly thermophilic and acidophilic endospore former, *Bacillus coagulans*, had been described, and it was logical to include the new species in a ubiquitous genus that also included thermophilic species (Becker and Pederson, 1950). More than a decade later, two other acidophilic and slightly thermophilic species named *Bacillus acidoterrestis* and *Bacillus cycloheptanicus* were described (Deinhard et al., 1987a, 1987b). By this time it had been recognized that *Bacillus acidocaldarius*, *Bacillus acidoterrestis*, and *Bacillus cycloheptanicus* possessed unique ω -alicyclic fatty acids and that the three species were closely related (De Rosa et al., 1971b; Poralla and König, 1983). With the application of 16S rRNA gene sequence analysis, it became evident that the genus *Bacillus* was heterogeneous (Ash et al., 1991a). However, an early phylogenetic study of Gram-positive bacilli showed that *Bacillus acidoterrestis* did not cluster with the other two species that possessed ω -alicyclic fatty acids (Ash et al., 1991b). The reason for this anomaly was resolved when it was discovered that the strain supplied by the Deutsche Sammlung von Mikroorganismen und Zellkulturen (DSMZ), Braunschweig, Germany, was not the type strain of *Bacillus acidoterrestis* (Wisotzkey et al., 1992). These authors, using the correct strain, compared the 16S rRNA gene sequences of the three acidothermophilic organisms leading to the proposal that these organisms did not belong to the genus *Bacillus*, as defined at the time, and proposed the genus *Alicyclobacillus* to accommodate the three

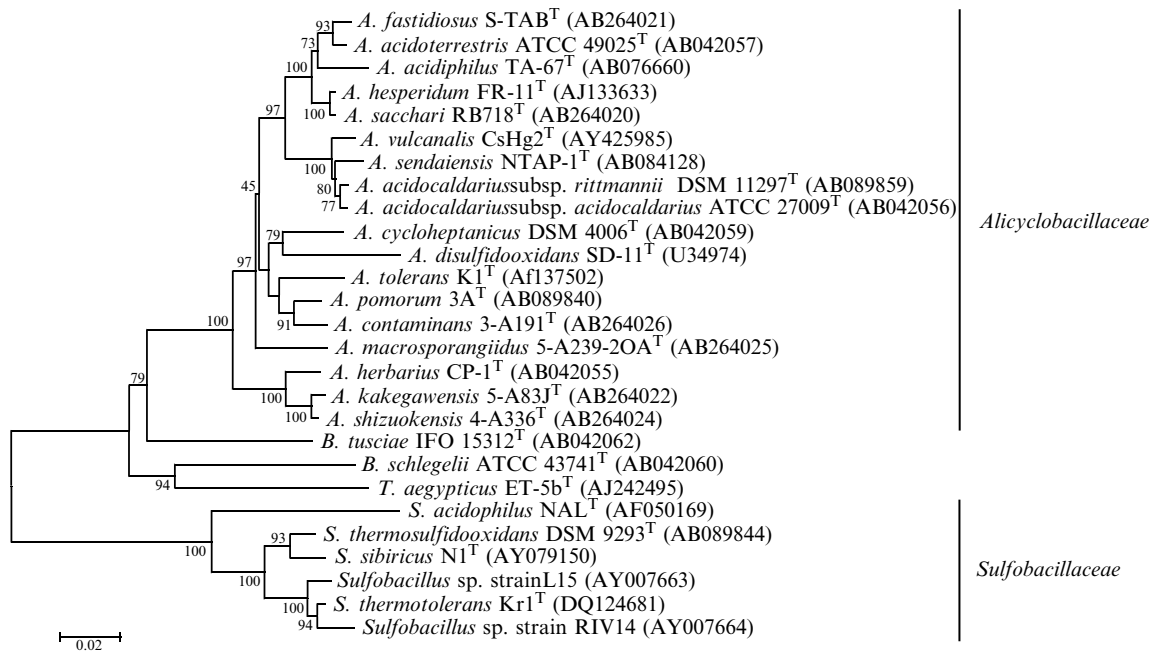

FIGURE 22. 16S rRNA gene sequence-based phylogeny of members of the genera *Alicyclobacillus* and *Sulfobacillus* and related taxa. Bar = 2 inferred nucleotide substitutions per 100 nucleotides.

species already described (Wisotzkey et al., 1992). After more than a decade, 14 new species have been described or reclassified as members of this genus.

All strains examined produce endospores which tend to be terminal or subterminal and have an ovoid morphology; some species have swollen sporangia, but others do not. The strains of the genus *Alicyclobacillus* generally stain Gram-positive, but *Alicyclobacillus sendaiensis* stains Gram-negative (Tsuruoka et al., 2003), reflecting a thin cell wall found in many strains of the genus. Many of the species of this genus are not motile, but motility has been reported in others. The type strains of *Alicyclobacillus herbarius* (Goto et al., 2002a), *Alicyclobacillus acidophilus* (Matsubara et al., 2002), *Alicyclobacillus pomorum* (Goto et al., 2003), *Alicyclobacillus contaminans*, *Alicyclobacillus kakegawensis*, *Alicyclobacillus macrosporangiidus*, *Alicyclobacillus sacchari*, and *Alicyclobacillus shizuokensis* (Goto et al., 2007) possess motility, however, the position of the flagella on the cells has not been reported (Table 38).

The species of the genus *Alicyclobacillus* can be grouped into three categories in terms of their growth temperature ranges. The strains of the species *Alicyclobacillus acidocaldarius* and of two unnamed genomic species have a growth temperature range of about 45–70°C, with an optimum growth temperature of about 65°C (Albuquerque et al., 2000; Goto et al., 2002b; Karavaiko et al., 2005; Nicolaus et al., 1998). Another group of species, *Alicyclobacillus acidophilus*, *Alicyclobacillus acidoterrestris*, *Alicyclobacillus cycloheptanicus*, *Alicyclobacillus herbarius*, *Alicyclobacillus hesperidum*, *Alicyclobacillus sendaiensis*, *Alicyclobacillus vulcanalis*, *Alicyclobacillus tolerans*, *Alicyclobacillus pomorum*, *Alicyclobacillus contaminans*, *Alicyclobacillus fastidio-*

sus, *Alicyclobacillus kakegawensis*, *Alicyclobacillus macrosporangiidus*, and *Alicyclobacillus shizuokensis* have a lower temperature range, 20–65°C, with an optimum for growth of 40–55°C. The species *Alicyclobacillus disulfidooxidans* and *Alicyclobacillus tolerans*, formerly classified in the genus *Sulfobacillus*, have lower growth temperature ranges of about 4–55°C and optimum growth temperatures of about 35–42°C (Table 38). All strains of the species of the genus *Alicyclobacillus* are acidophilic with pH optima for growth in the range 1.5–5.5 and pH optima of 0.5–6.5, the most acidophilic strains being those of the mesophilic species *Alicyclobacillus tolerans* and *Alicyclobacillus disulfidooxidans* which have pH optima for growth of about 1.5–2.5 (Karavaiko et al., 2005).

Most strains of the genus *Alicyclobacillus* appear to be strictly chemoorganotrophic, although the vast majority of these have not been examined for mixotrophic metabolism found in the species *Alicyclobacillus tolerans* or *Alicyclobacillus disulfidooxidans*. Some species of the genus *Alicyclobacillus* assimilate a large variety of carbohydrates, polyols, organic acids, and amino acids for growth, although most descriptions of the species of this genus report only the formation of acid from sugars, and little is known about the assimilation of noncarbohydrate carbon sources (Albuquerque et al., 2000). The strains of *Alicyclobacillus tolerans* and *Alicyclobacillus disulfidooxidans* are facultatively chemoorganotrophic and mixotrophic. For example, *Alicyclobacillus tolerans* strain K1^T prefers mixotrophic growth conditions rather than growth on organic substrates alone (Karavaiko et al., 2005). Higher growth rates and higher biomass yields are obtained when this organism is grown on Fe²⁺, glucose, and yeast extract than when they are grown on glucose and yeast

extract alone. Autotrophic growth on Fe^{2+} is poor and ceases after two transfers of the culture; strain KI^T fixes CO_2 very weakly. Mixotrophic growth also takes place with elemental sulfur, sulfide minerals, and yeast extract (Karavaiko et al., 2005). The species *Alicyclobacillus disulfidooxidans* has been reported to grow autotrophically (Dufresne et al., 1996).

The pathways involved in carbon and energy metabolism have not been reported in most strains of the genus *Alicyclobacillus*. In fact, only one strain, formerly classified as a species of the genus *Sulfobacillus*, has been examined in this respect. The type strain of *Alicyclobacillus tolerans* has enzymes of the Embden–Meyerhof pathway, but not those of the Entner–Doudoroff or pentose-phosphate pathways under mixotrophic growth (Karavaiko et al., 2001). This same strain is known to have a complete tricarboxylic acid cycle (Karavaiko et al., 2002).

The most notable characteristic of the alicyclobacilli is, without doubt, the high levels of ω -cyclohexane and ω -cycloheptane fatty acids (De Rosa et al., 1971b) which gave the organisms their generic epithet. These terminal cyclic fatty acids are found in 14 of the 17 validly named species. ω -Cyclohexane fatty acids, predominantly ω -cyclohexylundecanoic acid ($\text{C}_{17:0}^{\omega\text{-cyclohexane}}$) and ω -cyclohexyltridecanoic acid ($\text{C}_{19:0}^{\omega\text{-cyclohexane}}$), constitute the major acyl chains of most species, and $\text{C}_{17:0}^{\omega\text{-cyclohexane}}$ can reach levels as high as 80% of the total fatty acids in *Alicyclobacillus acidophilus* (Table 39). The major fatty acids of *Alicyclobacillus cycloheptanicus*, *Alicyclobacillus kakegawensis*, *Alicyclobacillus shizuokensis*, and *Alicyclobacillus herbarius* have been identified as the very rare ω -cycloheptane fatty acids, namely ω -cycloheptylundecanoic acid ($\text{C}_{18:0}^{\omega\text{-cycloheptane}}$) and ω -cycloheptyltridecanoic acid ($\text{C}_{20:0}^{\omega\text{-cycloheptane}}$), where the former may reach about 86% of the total fatty acids in *Alicyclobacillus cycloheptanicus* (Deinhard et al., 1987b). The type strain of *Alicyclobacillus tolerans* also possesses $\text{C}_{17:0}^{\omega\text{-cyclohexane } 2\text{OH}}$ that reaches about 11.3% of the total fatty acids (Karavaiko et al., 2005). The ω -cycloheptane fatty acid-containing alicyclobacilli also possess lower amounts (2.3–3.5% of the total fatty acids) of $\text{C}_{18:0}^{\omega\text{-cycloheptane } 2\text{OH}}$ (Deinhard et al., 1987b; Goto et al., 2002a). All strains also possess low amounts of straight-chain and branched-chain iso- and anteiso-fatty acids. However, the type strains of *Alicyclobacillus pomorum*, *Alicyclobacillus contaminans*, and *Alicyclobacillus macrosporangiidus*, unlike other strains of the genus *Alicyclobacillus*, do not possess ω -cyclohexane or ω -cycloheptane fatty acids. These organisms possess only straight-chain and branched-chain iso- and anteiso-fatty acids. The lack of ω -alicyclic fatty acids in these organisms indicate that they are not necessary for growth of the alicyclobacilli at high temperature and low pH, as was sometimes hypothesized. These fatty acids remain, however, a hallmark characteristic of the bacteria of the genus *Alicyclobacillus*, although ω -alicyclic fatty acids are also found in species of the genus *Sulfobacillus* (M. S. da Costa, F. A. Rainey, and L. Albuquerque, unpublished results) and in the unrelated bacteria *Curtobacterium pusillum* (Suzuki et al., 1981) and *Propionibacterium cyclohexanicum* (Kusano et al., 1997), where they are also the major fatty acids.

Hopanoids are pentacyclic triterpenoids that are found in the membranes of many bacteria (Ourisson et al., 1987). The hopanoids are structurally similar to sterols and cause condensation of phospholipids in model membranes (Poralla et al., 1980). These lipids were identified in *Alicyclobacillus acidocal-*

darius as 1,2,3,4-tetrahydroxypentane-29-hopane and 1-(*O*- β -*N*-acylglucosaminyl)-2,3,4-tetrahydroxypentane-29-hopane (Langworthy et al., 1976; Langworthy and Mayberry, 1976; Poralla et al., 1980). Hopanoids have also been found in *Alicyclobacillus acidoterrestris*, but not in *Alicyclobacillus cycloheptanicus*. Other strains have not been examined (Deinhard et al., 1987a, 1987b).

The first definite isolation of strains of *Alicyclobacillus* was by Brock and Darland (1970) and Darland and Brock (1971) from acidic and thermal environments in Yellowstone National Park. Brock and Darland described the type species of the genus, although strains of these organisms were probably isolated earlier by Uchino and Doi (1967) who reported acidophilic sporeformers from Japanese hot springs. Many strains of alicyclobacilli have been isolated from such environments all over the world, namely from the solfatara at Pisciarelli in Italy (De Rosa et al., 1971a), acidic soils associated with geothermal activity in Japan (Goto et al., 2002b; Hiraishi et al., 1997; Tsuruoka et al., 2003), the Furnas area on the Island of São Miguel in the Azores (Albuquerque et al., 2000), Coso Hot Springs in California (Simbahan et al., 2004), and the Antarctic (Nicolaus et al., 1991, 1998). Alicyclobacilli appear to be ubiquitous colonists of acidic geothermal environments. However, many strains have now been isolated from other environments, some of them quite unexpected. Strains of *Alicyclobacillus acidoterrestris* and *Alicyclobacillus cycloheptanicus* were isolated from soils that were not closely associated with geothermal activity such as garden soil, soil from woods, and apple juice (Cerny et al., 1984; Deinhard et al., 1987a, 1987b; Hippchen et al., 1981). Recently, strains of six new species have been isolated from farm soils and beverages in Japan (Goto et al., 2007). The type strains of the mesophilic species *Alicyclobacillus tolerans* and *Alicyclobacillus disulfidooxidans* were isolated from lead-zinc ores in Uzbekistan and wastewater sludge in Canada, respectively (Dufresne et al., 1996; Kovalenko and Malakhova, 1983).

Strains of seven species of alicyclobacilli have been isolated from unusual environments, namely beverages. As noted previously, one strain classified as *Alicyclobacillus acidoterrestris* was isolated from apple juice (Cerny et al., 1984; Hippchen et al., 1981). Later isolates of this same species were recovered from spoiled acidic beverages where they cause off-flavor, particularly in fruit juices (Jensen, 1999; Pettipher et al., 1997; Splittstoesser et al., 1994; Yamazaki et al., 1996). These organisms are believed to colonize soil and then contaminate the juices via the fruits used to make them (Eguchi et al., 1999) where they can grow and produce guaiacol and halophenols (Matsubara et al., 2002). The spores survive the pasteurization processes, germinate, and grow in fruit juices, giving rise to off-flavors. These organisms have been recognized as important spoilage organisms of fruit juices (Chang and Kang, 2004). Recently, several strains classified as new species of this genus have been isolated from herbal tea and fruit juices in Japan (Goto et al., 2002a, 2003, 2007; Matsubara et al., 2002).

Enrichment, isolation and growth conditions

The original strains of Darland and Brock (1971) were isolated with a liquid medium composed of 1.0 or 10.0 g glycerol, or glucose, or ribose, 1.0 g yeast extract, 0.2 g $(\text{NH}_4)_2\text{SO}_4$, 0.5 g $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.25 g $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$, 3.0 g KH_2PO_4 in 1 l of water

with the pH adjusted to 2–5 with H₂SO₄. Turbid cultures were streaked on the same medium solidified with 2.0% agar and adjusted to pH 3.5–4.0. Later formulations of this medium containing 5.0 g/l of glucose also included, in a few cases, the addition of 1 ml of the trace element solution of Farrand et al. (1983). The medium with or without the trace element solution is commonly called *Bacillus acidocaldarius* Medium (BAM) and is used extensively for the isolation and growth of chemoorganotrophic strains of alicyclobacilli. The incuba-

tion temperature of the enrichments and the cultures depends on the organisms sought. Other modifications of the original medium include the addition of 0.02 g/l of FeCl₃·6H₂O and 0.35 g/l of tryptone (Simbahan et al., 2004). Several investigators have used completely different media; one medium used by Tsuruoka et al. (2003) contains 1.5% gelatin, 0.01% yeast extract, 0.85% NaCl, 0.3% KH₂PO₄, and 0.001% MgSO₄·7H₂O at pH 4.8. Another medium used by Goto et al. (2003) for the isolation of alicyclobacilli from juices contained 2.0 g yeast

extract, 1.0 g glucose, 2.0 g soluble starch, and 15 g agar in 1 l of water adjusted to pH 3.7. Yeast extract is generally added to the media, although many strains do not require it for growth. The species *Alicyclobacillus cycloheptanicus* is known to require isoleucine, methionine or vitamin B₁₂, and pantothenate (Deinhard et al., 1987b).

The strains of mixotrophic species, such as *Alicyclobacillus tolerans*, are sensitive to high concentrations of organic compounds and have, therefore, been isolated and grown on different media with low amounts of organic carbon. The strains of this species have been grown in Manning medium (Manning, 1975;

DSMZ medium 1023) containing 0.2 g of yeast extract, 33.4 g FeSO₄·7H₂O, 6.0 g (NH₄)₂SO₄, 0.2 g KCl, 1.0 g MgSO₄·7H₂O, 0.02 g Ca(NO₃)₂, and 0.2 g K₂HPO₄ in 1 l of water adjusted to pH 2.5–2.7 with 0.05 M H₂SO₄ and incubated at 40°C. The species *Alicyclobacillus disulfidooxidans* has been routinely grown on a medium composed of Solution A, which contains 0.1 g of yeast extract, 3.0 g (NH₄)₂SO₄, 0.1 g KCl, 0.5 g MgSO₄·7H₂O, 0.5 g KH₂PO₄, and 0.1 g Ca(NO₃)₂·4H₂O, in 1 l of water adjusted to pH 2.5 with H₂SO₄. Solution A is autoclaved, and filter-sterilized solution B containing 2.5 g glutathione in 10.0 ml of water is added to 1.0 liter of solution A (ATCC medium 2091).

Most isolates of the genus *Alicyclobacillus* have been obtained by enrichment in BAM or Manning medium. Water or biofilm samples are inoculated into liquid medium and incubated at 40–65°C for 2–3 d. Turbid cultures are spread on the same medium solidified with agar (2–3%) and incubated at the same temperature until the organisms can be isolated. Alternatively, samples are directly spread on solid media. Membrane filtration methods have also been used for the isolation of strains of *Alicyclobacillus* and offer the advantage of recovering a larger number of different colonial types and minor populations than liquid enrichments which tend to select clones that grow better in the media used or that constitute the major populations of the samples. The membrane filtration method can be used with water or soil. Adequate volumes of the samples or dilutions are filtered through 47-mm-diameter cellulose nitrate or acetate membrane filters with pore sizes of 0.22 or 0.45 µm. The filters are placed on the surface of plates of BAM medium or a similar low-nutrient medium solidified with 2–3% agar; the plates are inverted and incubated for 2–7 d wrapped in plastic film at the appropriate temperature. Soil is resuspended in water, large particles are allowed to sediment, and the suspensions or dilutions are filtered through membrane filters (Albuquerque et al., 2000). Nonpigmented colonies can easily be observed and picked for further purification.

The selective isolation of alicyclobacilli has also been achieved by heating spores to inactivate vegetative cells of other acidophilic organisms. Heating at 80°C for 10 minutes resulted in a very high recovery of viable spores of *Alicyclobacillus acidoterrestis* and the selection of high proportions of alicyclobacilli from fruit juices (Walls and Chuyate, 2000).

Maintenance procedures

All strains grow well on one of the media described above. During incubations, Petri plates should be wrapped in plastic film to prevent evaporation. Cultures on solid medium can be maintained for a few weeks in the dark at room temperature. For long term storage, cultures can be frozen at –70°C in cryotubes containing broth supplemented with a final concentration of 15% (v/v) glycerol. Freeze-dried and liquid nitrogen storage cultures have been maintained for several years without loss of viability.

Taxonomic comments

The genus *Alicyclobacillus* presently comprises 17 species and 2 genomic species. The majority of the species are easily distinguished from each other by phenotypic and chemotaxonomic characteristics (Table 38 and Table 39). In the past, the presence of high levels of ω-alicyclic fatty acids, spore formation, and the thermoacidophilic nature of the organisms was considered sufficient for the presumptive identification of the chemoorganotrophic bacteria of this genus. The descriptions of *Alicyclobacillus pomorum*, *Alicyclobacillus contaminans*, and *Alicyclobacillus macrosporangiidus*, which do not possess ω-alicyclic, made it more difficult to recognize strains of alicyclobacilli without resorting to 16S rRNA gene sequence analysis. The absence of ω-alicyclic fatty acid also inevitably led to the emendation of the genus *Alicyclobacillus* (Goto et al., 2003). The mesophilic nature of *Alicyclobacillus tolerans* and *Alicyclobacillus disulfidooxidans*, which grow at lower temperatures than the other members of the genus, also make it

more difficult to recognize and distinguish some members of this genus from those of the unrelated genus *Sulfobacillus*. The description of two genomic species that could not be distinguished from the type strain of *Alicyclobacillus acidocaldarius*, the description of a subspecies of *Alicyclobacillus acidocaldarius*, and the reclassification of two new species formerly classified in the genus *Sulfobacillus* indicate that further discussion of the taxonomy of these organisms is merited.

Two unnamed genomic species, whose phenotypes were difficult to distinguish from that of the type strain of *Alicyclobacillus acidocaldarius*, were designated genomic species 1 and genomic species 2 by Albuquerque et al. (2000) and Goto et al. (2002b). Genomic species 1 was initially represented by strains FR-3 (DSM 11983) and FR-6 (DSM 11984^T) from the Furnas area of the Island of São Miguel in the Azores. Later Goto et al. (2002b), who described the second genomic species from soils in Japan, also isolated several strains designated KHA 31, MIH 2, UZ 1, and KHC 3 with 16S rRNA gene sequences that were identical to the Azorean genomic species 1 strains. The phenotypic characteristics of the Azorean and Japanese strains were extremely variable, while the fatty acid composition was too similar to that of the type strain of *Alicyclobacillus acidocaldarius* to allow differentiation. On the other hand, DNA–DNA reassociation studies showed that strains FR-6 and the Japanese strains shared over 89% homology with each other, but only 56–66% homology with *Alicyclobacillus acidocaldarius*. Another strain, designated MIH 332 (DSM 14672) and examined by Goto et al. (2002b), also had phenotypic and chemotaxonomic characteristics that were similar to those of the type strain of *Alicyclobacillus acidocaldarius* but a DNA–DNA reassociation value of only 39% with the type strain of the species and 44% with the DNA of strains of genomic species 1. In view of the similar phenotypes of the strains of genomic species 1, genomic species 2, and the type strain of *Alicyclobacillus acidocaldarius*, new species could not be formally described (Albuquerque et al., 2000; Goto et al., 2002b). The studies of Albuquerque et al. (2000) and Goto et al. (2002b) clearly showed large variations in the production of acid from individual carbohydrates that made it very difficult to define a common phenotype within the *Alicyclobacillus acidocaldarius* group of strains. Moreover, the isolates and the type strain had very similar fatty acid compositions that did not distinguish the organisms from each other.

The description of the subspecies *Alicyclobacillus acidocaldarius* subsp. *rittmannii* by Nicolaus et al. (1998), led to the automatic classification of the type strain of Darland and Brock (1971) as *Alicyclobacillus acidocaldarius* subsp. *acidocaldarius*. The description of this subspecies was based on the close phylogenetic relationship of strain MR-1^T (DSM 11297^T) isolated from the Antarctic, with the type strain of *Alicyclobacillus acidocaldarius* with which it shared 99.1% 16S rRNA gene sequence similarity, a DNA–DNA reassociation value of 69.7%, and a distinctive fatty acid composition. However, the fatty acid composition of strain MR-1 was not compared with the type strain of *Alicyclobacillus acidocaldarius* but with a strain designated Pisciarelli (De Rosa et al., 1971a), which may or may not belong to this species. To our knowledge, 16S rRNA gene sequence analysis has not been performed with strain Pisciarelli nor has this organism been characterized in detail.

Strain MR-1 has a fatty acid composition that is different from strain Pisciarelli and which is also different from that of the type strain of *Alicyclobacillus acidocaldarius* (ATCC 27009^T, DSM 446^T), although the latter fatty acid composition was obtained in a different study (Albuquerque et al., 2000). The simple fact that the subspecies is based on one strain alone and that other investigators have found a bewildering diversity of acid production patterns from carbohydrates argues against the classification of strain MR-1 into a new subspecies. Moreover, the fatty acid composition was compared with a strain that is not the type strain of the species. It is therefore difficult to accept the validity of *Alicyclobacillus acidocaldarius* subsp. *rittmanni*. We are, therefore, of the opinion that *Alicyclobacillus acidocaldarius* subsp. *rittmanni* is not a valid subspecies of the species *Alicyclobacillus acidocaldarius*.

Two strains, now assigned as species of *Alicyclobacillus*, were formally classified as *Sulfobacillus*. Strain SD-11^T was classified as *Sulfobacillus disulfidooxidans* on the basis of its ability to utilize elemental sulfur and pyrite as sole source of energy (Dufresne et al., 1996). Phylogenetic analysis showed that strain SD-11^T fell within the radiation of the species of the genus *Alicyclobacillus* (Goto et al., 2002a, 2003; Matsubara et al., 2002) and was later classified as *Alicyclobacillus disulfidooxidans* (Karavaiko et al., 2005). Another strain, designated K1^T was isolated from lead-zinc ores and named “*Sulfobacillus thermosulfidooxidans* subsp. *thermotolerans*” because it also had the ability to oxidize iron, elemental sulfur, and sulfides, but the name of this taxon was never validly published (Kovalenko and Malakhova, 1983). Strain K1^T was recently reclassified as *Alicyclobacillus tolerans* because of its close phylogenetic relationship to other species of *Alicyclobacillus* (Karavaiko et al., 2005). Strain K1^T is closely related, based on 16S rRNA gene sequence analysis, to other unclassified organisms, some of which share several characteristics with this strain, namely strains SC, AGC-2,

GSM, and CLG, and may or may not belong to the species *Alicyclobacillus tolerans*. It was necessary, therefore, to emend the description of the genus *Alicyclobacillus* to include species with mixotrophic metabolism that had not been previously recognized in this genus (Karavaiko et al., 2005).

The phylogenetic relationships of the species of the genus *Alicyclobacillus* based on 16S rRNA gene sequence comparisons are shown in Figure 23. The 16S rRNA gene sequence similarity within the genus ranges from 90.7–99.6 based on the comparison of 1352 nucleotide positions. Although the species of the genus fall into four subclusters, only three of these subclusters are supported by significant bootstrap values (Figure 23). One cluster comprises the species *Alicyclobacillus acidocaldarius*, *Alicyclobacillus sendaiensis*, and *Alicyclobacillus vulcanalis*, of which the 16S rRNA gene sequences share 98.4% similarity. The second cluster comprises the species *Alicyclobacillus hesperidum*, *Alicyclobacillus sacchari*, *Alicyclobacillus fastidiosus*, *Alicyclobacillus acidoterrestis*, and *Alicyclobacillus acidiphilus*, sharing 16S rRNA gene sequence similarities in the range 96.7–99.7%. The most closely related *Alicyclobacillus* species based on 16S rRNA gene sequence comparisons are *Alicyclobacillus hesperidum* and *Alicyclobacillus sacchari* at 99.7% similarity. The branching of these two subclusters is also supported by a bootstrap value of 97%. The third phylogenetic cluster (*Alicyclobacillus cycloheptanicus*, *Alicyclobacillus disulfidooxidans*, *Alicyclobacillus tolerans*, *Alicyclobacillus pomorum*, and *Alicyclobacillus contaminans*) as shown in Figure 23 is not supported on the basis of bootstrap analyses. In all analyses, cluster IV (*Alicyclobacillus herbarius*, *Alicyclobacillus kakegawensis*, and *Alicyclobacillus shizuokensis*) falls outside the main *Alicyclobacillus* species group and shares 91.6–93.4% 16S rRNA gene sequence similarity to the other species of the genus. The species *Alicyclobacillus macrosporangiidus* does not cluster with any of the other species of the genus but is the outgroup of clusters I, II, and III.

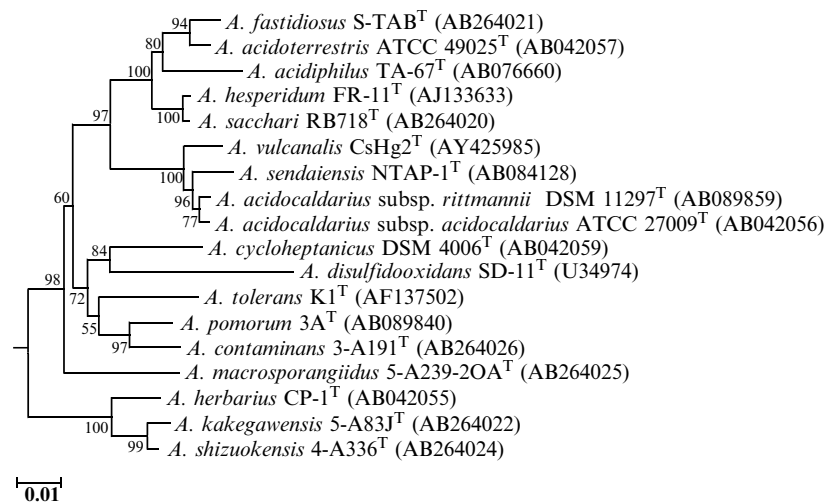

FIGURE 23. Phylogenetic tree indicating the relationships of the *Alicyclobacillus* species based on 16S rRNA gene sequence comparisons. The scale bar represents one inferred nucleotide change per 100 nucleotides. The numbers on the branching points are bootstrap values from 1000 replicate analyses. *Bacillus subtilis* was used as an outgroup organism.

List of species of the genus *Alicyclobacillus*

1. ***Alicyclobacillus acidocaldarius*** (Darland and Brock 1971) Wisotzkey, Jurtshuk, Fox, Deinhard and Poralla 1992, 267^{VP} (*Bacillus acidocaldarius* Darland and Brock 1971, 9.)
a.ci.do.ca.da'ri.us. L. adj. *acidus* acid; L. adj. *caldarius* hot; N.L. adj. *acidocaldarius* pertaining to acid thermal environments.
The strains of this species are Gram-positive and form rod-shaped cells 2–3 µm × 0.7–0.8 µm. Short chains are present. The sporangia are not swollen; ellipsoidal endospores located subterminally or terminally. Colonies are nonpigmented. The predominant membrane acyl chains are C_{17:0 ωcyclohexane} and C_{19:0 ωcyclohexane}; straight-chain and branched-chain fatty acids are also present. Hopanoids and a sulfonolipid are present. The major respiratory quinone is menaquinone-7 (MK-7). Aerobic and chemo-organotrophic. Anaerobic growth does not occur in medium containing nitrate. Nitrate is not reduced to nitrite. The pH range for growth is 2.0–6.0; optimum pH around 3.0–4.0. The temperature range for growth is 45–70°C; optimum temperature is around 60–65°C. Oxidase-negative and weakly catalase-positive. Strains utilize hexoses, disaccharides, organic acids, and amino acids for growth. Acid is produced from sugars. Growth factors are not required. Strains of this species have been isolated from acidic thermal soils and water. The type strain was isolated from Yellowstone National Park.
DNA G+C content (mol%): 60.3 (T_m) or 62.3 (Bd).
Type strain: 104-1A, ATCC 27009, BCRC 14685, CCUG 28521, CIP 106131, DSM 446, HAMB1 2073, HAMB1 2071, NBRC 15652, JCM 5260, KCTC 1825, LMG 7119, NCCB 89167, NCIMB 11725, NRRL B-14509.
GenBank accession number (16S rRNA gene): AB042056, AJ496806, X60742.
2. ***Alicyclobacillus acidophilus*** Matsubara, Goto, Matsumura, Mochida, Iwaki, Niwa and Yamasoto 2002, 1684^{VP}
a.ci.di'phi.us. L. n. *acidum* acid; Gr. adj. *philos* loving; N.L. adj. *acidophilus* acid-loving.
Rod-shaped cells that are 4.8–6.3 µm × 0.9–1.1 µm. Gram stain is positive. The cells are motile. Subterminal or terminal oval spores are formed; sporangia are swollen. Colonies are nonpigmented. Growth occurs at 20–55°C; the optimum growth temperature is about 50°C. The optimum pH is about 3.0; growth occurs at pH 2.5–5.5. Strains are cytochrome-oxidase-negative and catalase is positive. Aerobic and chemoorganotrophic. Yeast extract or growth factors are not required for growth. Nitrate is not reduced to nitrite. Gelatin, starch, phenylalanine, and tyrosine are not hydrolyzed. Voges–Proskauer test is weakly positive and indole production is negative. The predominant membrane fatty acids are C_{17:0 ωcyclohexane} and C_{19:0 ωcyclohexane}; straight-chain and branched-chain fatty acids are also present. Major respiratory quinone is menaquinone-7 (MK-7). Acid is produced from several sugars. The type strain of this species was isolated from spoiled fruit juice.
DNA G+C content (mol%): 54.1 (HPLC).
Type strain: TA-67, DSM 14558, IAM 14935, JCM 21417, NBRC 100859, NRIC 6496.
GenBank accession number (16S rRNA gene): AB059677, AB076660.
3. ***Alicyclobacillus acidoterrestris*** (Deinhard, Blanz, Poralla and Altan 1987a) Wisotzkey, Jurtshuk, Fox, Deinhard and Poralla 1992, 268^{VP} (*Bacillus acidoterrestris* Deinhard, Blanz, Poralla and Altan 1987a, 52.)
a.ci.do ter.res'tris. L. n. *acidum* acid; L. adj. *terrestris* soil; N.L. adj. *acidoterrestris* acid-loving and isolated from soil.
The strains of this species stain Gram-positive and form rod-shaped cells 2.9–4.3 µm × 0.6–0.8 µm. The sporangia are not generally swollen; oval endospores located subterminally or terminally. Colonies are nonpigmented. The predominant membrane fatty acids are C_{17:0 ωcyclohexane} and C_{19:0 ωcyclohexane}; straight-chain and branched-chain fatty acids are also present. Hopanoids and sulfonolipids are present. The major respiratory quinone is menaquinone-7 (MK-7). Aerobic and chemoorganotrophic. Nitrate is not reduced to nitrite. The pH range for growth is 2.2–5.8; optimum pH around 4.0. The temperature range for growth is about 35–55°C; optimum temperature is 42–53°C. Oxidase-negative and weakly catalase-positive. Strains utilize hexoses, disaccharides, organic acids, and amino acids for growth. Acid is produced from sugars. Growth factors are not required. Strains of this species have been isolated from soils and apple juice. The type strain was isolated from garden soil in Germany.
DNA G + C content (mol%): 51.6 (T_m).
Type strain: GD3B, ATCC 49025, CIP 106132, DSM 3922, LMG 16906.
GenBank accession number (16S rRNA gene): AB042057, AJ133631, AY573797.
4. ***Alicyclobacillus contaminans*** Goto, Mochida, Kato, Asahara, Fujita, An, Kasai and Yokoto 2007, 1281^{VP}
con.ta'mi.nans. L. part. adj. *contaminans* contaminating, referring to contamination of fruit juice.
Strains of this species stain Gram-positive or Gram-variable for old cultures. Cells are straight rods 4.0–5.0 µm × 0.8–0.9 µm with rounded ends. Motile. Endospores are ellipsoidal and subterminal with swollen sporangia. Colonies on BAM agar after 48 h are nonpigmented circular, opaque, entire, umbonate, and 3–5 mm in diameter. The predominant fatty acids are C_{16:0 iso}, C_{17:0 iso}, and C_{17:0 ante}. The major respiratory quinone is menaquinone-7 (MK-7). Strictly aerobic and chemoorganotrophic. The pH optimum for growth is 4.0–4.5 with no growth at pH 3.0 or 6.0; the temperature range for growth is 35–60°C; optimum growth temperature is 50–55°C. Growth occurs in the presence of 0–2% (w/v) NaCl but not 5% (w/v) NaCl. Oxidase- and catalase-negative. Nitrate is not reduced to nitrite. Voges–Proskauer test and indole production are negative. Gelatin and esculin are hydrolyzed, but phenylalanine, starch, and tyrosine are not; arbutin hydrolysis is variable. Acid is produced from a number of sugars and sugar alcohols. The type strain of this species was isolated from soil of a crop field in Fuji city. An additional strain, E-8 (=IAM 15228), was isolated from orange juice.
DNA G + C content (mol%): 60.6 (HPLC).
Type strain: 3-A191, DSM 17975, IAM 15224, JCM 21678, NBRC 103102.
GenBank accession number (16S rRNA gene): AB264026.
5. ***Alicyclobacillus cycloheptanicus*** (Deinhard, Saar, Krischke and Poralla 1987b) Wisotzkey, Jurtshuk, Fox, Deinhard and Poralla 1992, 268^{VP} (*Bacillus cycloheptanicus* Deinhard, Saar, Krischke and Poralla 1987b, 72.)

cy.clo.hep.ta'ni.cus. Gr. n. *kyclos* circle; Gr. n. *hepta* seven; N.L. adj. *cycloheptanicus* referring to the ω -cycloheptyl fatty acids.

The strains of this species stain Gram-positive and form non-motile rod-shaped cells $2.5\text{--}4.5\ \mu\text{m} \times 0.4\text{--}0.6\ \mu\text{m}$. Short chains during exponential phase. The sporangia are slightly swollen; endospores are oval and subterminal. Colonies are creamy white and opaque. About 90% of the fatty acids are $C_{18:0\ \omega\text{cycloheptane}}$, $C_{20:0\ \omega\text{cycloheptane}}$, and $C_{18:0\ \omega\text{cycloheptane}\ 2OH}$. The major respiratory quinone is menaquinone-7 (MK-7). A sulfolipid is present. Aerobic and chemoorganotrophic. Nitrate is not reduced to nitrite. The pH range for growth is 3.0–5.5; optimum pH 3.5–4.5; the temperature range for growth is 40–53°C; optimum temperature is about 48°C. Acid is produced from sugars. Methionine or vitamin B₁₂, pantothenate, and isoleucine are required for growth. Strains of this species have been isolated from soil. The type strain was isolated from soil in Germany.

DNA G + C content (mol %): 55.6 (T_m).

Type strain: SCH, ATCC 49028, ATCC BAA-2, CIP 106133, DSM 4006, HAMBI 2074, LMG 17941, NBRC 15310.

GenBank accession number (16S rRNA gene): AB042059, X52489.

6. **Alicyclobacillus disulfidooxidans** (Dufresne, Bousquent, Bassinot and Guay 1996) Karavaiko, Bogdanova, Tourova, Kondrat'eva, Tsaplina, Egorova, Krasil'nikova Zakharchuk 2005, 946^{VP} (*Sulfobacillus disulfidooxidans* Dufresne, Bousquent, Bassinot and Guay 1996, 1063.)

di.sul.fi.do.ox'i.dans. N.L. n. *disulfidum* disulfide; N.L. v. *oxido* oxidize; N.L. adj. *disulfidooxidans* disulfide-oxidizing.

Aerobic Gram-variable rods, $0.3\text{--}0.5\ \mu\text{m} \times 0.9\text{--}3.6\ \mu\text{m}$. Endospores are oval and produced subterminally; sporangium swollen. Optimum growth temperature is about 35°C; the growth temperature range is 4–40°C. Optimum pH for growth is 1.5–2.5; pH range for growth is 0.5–6.0. The predominant membrane fatty acids are $C_{17:0\ \omega\text{cyclohexane}}$ and $C_{19:0\ \omega\text{cyclohexane}}$. Menaquinone-7 (MK-7) is the major respiratory quinone. Mixotrophic. Glucose, glycerol, glutamate, glutathione, cysteine, cystine, cystamine, dithio(bis)benzothiazole, S⁰, Fe²⁺, and Fe₂S are used for growth. Acid is not produced from sugars. Yeast extract is required. The type strain of this species was isolated from wastewater sludge in Canada.

DNA G + C content (mol %): 53.0 (T_m).

Type strain: SD-11, ATCC 51911, DSM 12064.

GenBank accession number (16S rRNA gene): AB089843, U34974.

7. **Alicyclobacillus fastidiosus** Goto, Mochida, Kato, Asahara, Fujita, An, Kasai and Yokoto 2007, 1281^{VP}

fas.ti.di.o'sus. L. masc. adj. *fastidiosus* fastidious, referring to its fastidious character.

Strains of this species stain Gram-positive or Gram-variable for old cultures. Cells are straight rods, $4.0\text{--}5.0\ \mu\text{m} \times 0.9\text{--}1.0\ \mu\text{m}$ with rounded ends. Nonmotile. Endospores are ellipsoidal and subterminal with swollen sporangia. Colonies on BAM agar after 48 h are nonpigmented circular, opaque, entire, flat, and 3–4 mm in diameter. The predominant fatty acids are $C_{17:0\ \omega\text{cyclohexane}}$ and $C_{19:0\ \omega\text{cyclohexane}}$. The major respiratory quinone is menaquinone-7 (MK-7). Strictly aerobic and chemoorganotrophic. The pH optimum for growth is 4.0–4.5 with no growth at pH 2.0 or 5.5. The temperature

range for growth is 20–55°C; optimum growth temperature is 40–45°C. Growth occurs in the presence of 0–2% (w/v) NaCl but not 5% (w/v) NaCl. Oxidase-negative and catalase-positive. Nitrate is not reduced to nitrite. Voges–Proskauer test and indole production are negative. Gelatin is hydrolyzed, but esculin, arbutin, phenylalanine, starch, and tyrosine are not. Acid is produced from a number of sugars and sugar alcohols. The type strain of this species was isolated from apple juice.

DNA G + C content (mol %): 53.9 (HPLC).

Type strain: S-TAB, DSM 17978, IAM 15229, JCM 21683, NBRC 103109.

GenBank accession number (16S rRNA gene): AB264021.

8. **Alicyclobacillus herbarius** Goto, Matsubara, Mochida, Matsumura, Hara, Niwa and Yamasoto 2002a, 112^{VP}

her.ba'ri.us. N.L. adj. *herbarius* pertaining to herb, from which the organism was isolated.

Rod-shaped cells that stain Gram-positive. The cells are motile. Oval endospores located subterminally are formed; sporangia are swollen. Colonies are nonpigmented. Growth occurs at 35–65°C; the optimum growth temperature is 55–60°C. The optimum pH is 4.5–5.0; growth does not occur at pH 3.0 or pH 6.5. Aerobic and chemoorganotrophic. Oxidase-negative and catalase-positive. Yeast extract or growth factors are not required for growth. The major fatty acid is $C_{18:0\ \omega\text{cycloheptane}}$, $C_{18:0\ \omega\text{cycloheptane}\ 2OH}$, $C_{20:0\ \omega\text{cycloheptane}}$, and branched-chain fatty acids are also present. Major respiratory quinone is menaquinone-7 (MK-7). Reduce nitrate to nitrite. Voges–Proskauer test and indole production are negative. Gelatin and starch are not hydrolyzed. Acid is produced from several sugars. The type strain of this species was isolated from herbal tea made from dried hibiscus flowers.

DNA G + C content (mol %): 56.2 (HPLC).

Type strain: CP-1, DSM 13609, IAM 14883, JCM 21376, NBRC 100860, NRIC 0477.

GenBank accession number (16S rRNA gene): AB042055.

9. **Alicyclobacillus hesperidum** Albuquerque, Rainey, Chung, Sunna, Nobre, Grote, Antranikian and da Costa 2000, 454^{VP}

hes.pe'ri.dum. L. fem. pl. n. *hesperidum* of the Hesperides, mythological figures whom the Greeks believed to have lived at the western edge of the Earth, interpreted by the authors as being located in the Azores.

Rod-shaped cells that are $2.1\text{--}3.9\ \mu\text{m} \times 0.5\text{--}0.7\ \mu\text{m}$. Gram stain is positive. The cells are nonmotile. Terminal spores are formed; sporangia are not swollen. Colonies are nonpigmented. Growth occurs at 40–55°C; the optimum growth temperature is 50–53°C. The optimum pH is 3.5–4.0; growth does not occur at pH 2.0 or pH 6.0. Cytochrome oxidase-negative and catalase weakly positive or negative. Yeast extract or growth factors are not required for growth. The major fatty acids are $C_{17:0\ \omega\text{cyclohexane}}$ and $C_{19:0\ \omega\text{cyclohexane}}$; branched-chain fatty acids are also present in large proportions. Major respiratory quinone is menaquinone-7 (MK-7). Aerobic and chemoorganotrophic. Nitrate is not reduced to nitrite. Gelatin, hide powder, and starch are hydrolyzed, but elastin and fibrin are not. Utilize many hexoses and disaccharides, but pentoses and polyols, with the exception of mannitol and glycerol, are not utilized as single carbon sources. Acid is produced from virtually the same sugars that are utilized as single carbon

sources. Strains of this species have been isolated from solfataric soils at Furnas, Island of São Miguel, the Azores.

DNA G + C content (mol%): 53.3 (HPLC).

Type strain: FR-11, DSM 12489.

GenBank accession number (16S rRNA gene): AB059678, AJ133633.

10. **Alicyclobacillus kakegawensis** Goto, Mochida, Kato, Asahara, Fujita, An, Kasai and Yokoto 2007, 1283^{VP}

ka.ke.ga.wa.en.sis. N.L. masc. adj. *kakegawensis* pertaining to Kakegawa, a city in Shizuoka Prefecture, Japan, where the type strain was isolated.

Strains of this species stain Gram-positive or Gram-variable for old cultures. Cells are straight rods 4.0–5.0 µm × 0.6–0.7 µm with rounded ends. Motile. Endospores are oval and subterminal with swollen sporangia. Colonies on BAM agar after 48 h are nonpigmented circular, opaque, entire, flat, and 2–3 mm in diameter. The predominant fatty acids are C_{18:0 ωcyclohexane}, C_{18:0 ωcyclohexane 2OH} and C_{20:0 ωcyclohexane}. The major respiratory quinone is menaquinone-7 (MK-7). Strictly aerobic and chemoorganotrophic. The pH optimum for growth is 4.0–4.5 with no growth at pH 3.0 or 6.5. The temperature range for growth is 40–60°C; optimum growth temperature is 50–55°C. Growth occurs in the presence of 0–2% (w/v) NaCl but not 5% (w/v) NaCl. Oxidase-negative. Catalase weakly positive. Nitrate is not reduced to nitrite. Voges–Proskauer test and indole production are negative. Esculin and arbutin are hydrolyzed, but gelatin, phenylalanine, starch, and tyrosine are not. Acid is produced from a number of sugars and sugar alcohols. The type strain of this species was isolated from soil of a crop field in Kakegawa city.

DNA G + C content (mol%): 61.3 (HPLC).

Type strain: 5-A83J, DSM 17979, IAM 15227, JCM 21681, NBRC 103104.

GenBank accession number (16S rRNA gene): AB264022.

11. **Alicyclobacillus macrosporangioides** Goto, Mochida, Kato, Asahara, Fujita, An, Kasai and Yokoto 2007, 1283^{VP}

ma.cro.spo.ran'gi.i.dus. Gr. adj. *macro*s big; N.L. n. *sporangium* sporangia; L. suff. *-idus* suffix expressing a quality or tendency; N.L. masc. adj. *macrosporangioides* having large sporangia.

Strains of this species stain Gram-positive or Gram-variable for old cultures. Cells are straight rods 5.0–6.0 µm × 0.7–0.8 µm with rounded ends. Motile. Endospores are oval and terminal with swollen sporangia. Colonies on BAM agar after 48 h are nonpigmented circular, opaque, entire, convex, and 2–4 mm in diameter. The predominant fatty acids are C_{16:0 iso}, C_{17:0 iso} and C_{17:0 ante}. The major respiratory quinone is menaquinone-7 (MK-7). Strictly aerobic and chemoorganotrophic. The pH optimum for growth is 4.0–4.5 with no growth at pH 3.0 or 6.5; the temperature range for growth is 35–60°C; optimum growth temperature is 50–55°C. Growth occurs in the presence of 0–5% (w/v) NaCl but not 7% (w/v) NaCl. Oxidase-negative. Catalase weakly positive. Nitrate is not reduced to nitrite. Voges–Proskauer test and indole production are negative. Esculin is hydrolyzed, but arbutin, gelatin, phenylalanine, starch, and tyrosine are not. Acid is produced from a number of sugars and sugar alcohols. The type strain of this species was isolated from soil of a crop field in Fujieda city.

DNA G + C content (mol%): 62.5 (HPLC).

Type strain: 5-A239–2O-A, DSM 17980, IAM 15370, JCM 21814.

GenBank accession number (16S rRNA gene): AB264025.

12. **Alicyclobacillus pomorum** Goto, Mochida, Asahara, Suzuki, Kasai and Yokota 2003, 1542^{VP}

po.mo'rum. L. neut. n. *pomum* fruit; L. gen. pl. neut. n. *pomorum* of fruits.

The strains of this species stain Gram-positive, but are Gram-variable in older cultures, and form motile rod-shaped cells 2.0–4.0 µm × 0.8–1.0 µm. The sporangia are swollen; oval endospores located subterminally. Colonies are nonpigmented. Growth does not occur at pH 2.5 or 6.5, the optimum pH for growth is 4.5–5.0. The temperature range for growth is 30–60°C; the optimum temperature for growth is about 45–50°C. Chemoorganotrophic and strictly aerobic. Does not reduce nitrate to nitrite. The predominant membrane acyl chains are iso- and anteiso-branched; ω-cyclohexane fatty acids are not detected. The major respiratory quinone is menaquinone-7 (MK-7). Oxidase-positive and catalase-positive. Esculin, gelatin, and starch are hydrolyzed, but arbutin, phenylalanine, and tyrosine are not. Acid is produced from several sugars. Growth factors are not required. The type strain of this species was isolated from spoiled mixed fruit juice.

DNA G + C content (mol%): 53.1 (HPLC).

Type strain: 3A, DSM 14955, IAM 14988, JCM 21459, NBRC 100861.

GenBank accession number (16S rRNA gene): AB089840.

13. **Alicyclobacillus sacchari** Goto, Mochida, Kato, Asahara, Fujita, An, Kasai and Yokoto 2007, 1283^{VP}

sac'cha.ri. L. gen. n. *sacchari* of sugar, referring to the source of isolation.

Strains of this species stain Gram-positive or Gram-variable for old cultures. Cells are straight rods 4.0–5.0 µm × 0.6–0.7 µm with rounded ends. Motile. Endospores are ellipsoidal and subterminal with swollen sporangia. Colonies on BAM agar after 48 h are nonpigmented circular, opaque, entire, umbonate, and 3–5 mm in diameter. The predominant fatty acids are C_{17:0 ωcyclohexane} and C_{19:0 ωcyclohexane}. The major respiratory quinone is menaquinone-7 (MK-7). Strictly aerobic and chemoorganotrophic. The pH optimum for growth is 4.0–4.5 with no growth at pH 2.0 or 6.0. The temperature range for growth is 30–55°C; optimum growth temperature is 45–50°C. Growth occurs in the presence of 0–2% (w/v) NaCl but not 5% (w/v) NaCl. Oxidase- and catalase-negative. Nitrate is not reduced to nitrite. Voges–Proskauer test and indole production are negative. Arbutin, gelatin, and starch are hydrolyzed, but esculin, phenylalanine, and tyrosine are not. Acid is produced from a number of sugars and sugar alcohols. The type strain of this species was isolated from liquid sugar.

DNA G + C content (mol%): 56.6 (HPLC).

Type strain: RB718, DSM 17974, IAM 15230, JCM 21684, NBRC 103105.

GenBank accession number (16S rRNA gene): AB264020.

14. **Alicyclobacillus sendaiensis** Tsuruoka, Isono, Shida, Hemmi, Nakayama and Nishino 2003, 1084^{VP}

sen.dai.en'sis. N.L. adj. *sendaiensis* of Sendai, a city in Myagi Prefecture, Japan, where the type strain was isolated.

Nonmotile rod-shaped cells that are 2.0–3.0 µm × 0.8 µm. Gram stain is negative. Terminal round spores. Colonies are nonpigmented. Growth occurs at 40–65 °C; the optimum growth temperature is about 55 °C. The optimum pH is about 5.5; growth occurs at pH 2.5–6.5. Oxidase- and catalase-negative. Yeast extract or growth factors are not required for growth. The predominant membrane fatty acids are C_{17:0}^ωcyclohexane and C_{19:0}^ωcyclohexane⁷; straight-chain and branched-chain fatty acids are also present. Major respiratory quinone is menaquinone-7 (MK-7). Aerobic and chemoorganotrophic. Nitrate is reduced to nitrite. Voges–Proskauer test positive. Gelatin is hydrolyzed. Acid is produced from several sugars. The type strain of this species was isolated from soil in Japan.

DNA G + C content (mol %): 62.3 (HPLC).

Type strain: NTAP-1, ATCC-BAA 609, JCM 11817, NBRC 100866.

GenBank accession number (16S rRNA gene): AB084128, AB222247.

15. ***Alicyclobacillus shizuokensis*** Goto, Mochida, Kato, Asahara, Fujita, An, Kasai and Yokoto 2007, 1283^{VP}

shi.zu.o.ken'sis. N.L. masc. adj. *shizuokensis* pertaining to Shizuoka, a city in Shizuoka Prefecture, Japan, where the type strain was isolated.

Strains of this species stain Gram-positive or Gram-variable for old cultures. Cells are straight rods 4.0–5.0 µm × 0.7–0.8 µm with rounded ends. Motile. Endospores are oval and subterminal with swollen sporangia. Colonies on BAM agar after 48 h are nonpigmented circular, opaque, entire, convex, and 1–2 mm in diameter. The predominant fatty acids are C_{18:0}^ωcyclohexane⁷, C_{18:0}^ωcyclohexane 2OH⁷ and C_{20:0}^ωcyclohexane. The major respiratory quinone is menaquinone-7 (MK-7). Strictly aerobic and chemoorganotrophic. The pH optimum for growth is 4.0–4.5 with no growth at pH 3.0 or 6.5. The temperature range for growth is 35–60 °C; optimum growth temperature is 45–50 °C. Growth occurs in the presence of 0–5% (w/v) NaCl but not 7% (w/v) NaCl. Oxidase-negative and catalase-positive. Nitrate is not reduced to nitrite. Voges–Proskauer test and indole production are negative. Esculin and arbutin are hydrolyzed, but gelatin, phenylalanine, starch, and tyrosine are not. Acid is produced from a number of sugars and sugar alcohols. The type strain of this species was isolated from soil of a crop field in Shizuoka city.

DNA G + C content (mol %): 60.5 (HPLC).

Type strain: 4-A336, DSM 17981, IAM 15226, JCM 21680, NBRC 103103.

GenBank accession number (16S rRNA gene): AB264024.

16. ***Alicyclobacillus tolerans*** (Kovalenko and Malakhova, 1983) Karavaiko, Bogdanova, Tourova, Kondrat'eva, Tsaplina, Egorova, Krasil'nikova and Zakharchuk 2005, 946^{VP} (“*Sulfobacillus thermosulfidooxidans* subsp. *thermotolerans*” Kovalenko and Malakhova 1983, 763.)

to.le'rans. L. adj. *tolerans* tolerant to changes in growth temperature and pH.

Cells are nonmotile rod-shaped cells 3–6 µm × 0.9–1.0 µm. Gram stain is positive. Terminal or subterminal oval spores are formed; sporangia are swollen. Growth occurs at about 20–55 °C; the optimum growth temperature is about 37–42 °C. The optimum pH is around 2.5–2.7; growth occurs at pH 1.5–5.0. Mixotrophic; Fe²⁺, S⁰, and sulfide minerals are oxidized in the presence of organic substrates. Fe³⁺ is also reduced. Facultative chemoorganotrophic. Oxidase weakly positive. Catalase weakly positive. Nitrate is not reduced to nitrite. Yeast extract enhances growth but is not required. The predominant membrane acids are C_{17:0}^ωcyclohexane⁷, C_{19:0}^ωcyclohexane⁷ and C_{17:0}^ωcyclohexane 2OH⁷; branched-chain fatty acids were also detected. Acid is produced from several sugars. The type strain of this species was isolated from oxidizable lead-zinc ores in Uzbekistan.

DNA G + C content (mol %): 48.7 (HPLC).

Type strain: K1, DSM 16297, VKM B-2304.

GenBank accession number (16S rRNA gene): AB222265, AF137502.

17. ***Alicyclobacillus vulcanalis*** Simbahan, Drijber and Blum 2004, 1706^{VP}

vul.ca.na'lis. N.L. masc. adj. *vulcanalis* of Vulcan, belonging to Vulcan, Roman god of fire and metal making.

Rod-shaped cells that are 1.5–2.5 µm × 0.4–0.7 µm. Gram stain is positive. Terminal spores are formed. Colonies are nonpigmented. Growth occurs at 35–65 °C; the optimum growth temperature is about 55 °C. The optimum pH is about 4.0; growth occurs at pH 2.0–6.0. Cytochrome oxidase-negative and catalase-negative. Aerobic and chemoorganotrophic. Yeast extract or growth factors are not required for growth. Starch is hydrolyzed. The predominant membrane fatty acids are C_{17:0}^ωcyclohexane and C_{19:0}^ωcyclohexane⁷; straight-chain and branched-chain fatty acids are also present. The major respiratory quinone is menaquinone-7 (MK-7). Acid is produced from several sugars. The type strain of this species was isolated from a geothermal pool in California.

DNA G + C content (mol %): 62.0 (HPLC).

Type strain: CsHg2, ATCC-BAA 915, DSM 16176.

GenBank accession number (16S rRNA gene): AB222267, AY425985.

Family III. *Listeriaceae* fam. nov.

WOLFGANG LUDWIG, KARL-HEINZ SCHLEIFER AND WILLIAM B. WHITMAN

Lis.te.ri.a'ce.ae. N.L. fem. n. *Listeria* type genus of the family; suff. *-aceae* ending denoting family;
N.L. fem. pl. n. *Listeriaceae* the *Listeria* family.

The family *Listeriaceae* is circumscribed for this volume on the basis of phylogenetic analyses of the 16S rRNA sequences and includes the genus *Listeria* and its close relative *Brochothrix*. Cells are short rods that may form filaments. Cells stain Gram-positive, and the cell walls contain *meso*-diaminopimelate. The major lipid components

include saturated straight-chain and methyl-branched fatty acids. Endospores are not formed. Menaquinones are the sole respiratory quinone. Growth is aerobic and facultative anaerobic, and glucose is fermented to lactate and other products.

Type genus: Listeria Pirie 1940a, 383.

Genus I. *Listeria* Pirie 1940a, 383^{Al}

JAMES McLAUCHLIN AND CATHERINE E. D. REES

Lis.te'ri.a. N.L. fem. n. *Listeria* named after Lord Lister, English surgeon and pioneer of antiseptics.

Regular, short rods, 0.4–0.5 × 1–2 µm with parallel sides and blunt ends. Usually occur singly or in short chains. In older or rough cultures, filaments of ≥6 µm in length may develop. **Gram-positive** with even staining, but some cells, especially in older cultures, lose their ability to retain the Gram stain. **Not acid-fast. Capsules not formed.** Do not form spores. All species **motile with peritrichous flagella when cultured <30°C. Aerobic and facultative anaerobic.** Colonies (24–48 h) are 0.5–1.5 mm in diameter, round, translucent, low convex with a smooth surface and entire margin, non-pigmented with a crystalline central appearance. May be sticky when removed from agar surfaces, usually emulsify easily, and may leave a slight impression on the agar surface after removal. Older cultures (3–7 d) are larger, 3–5 mm in diameter, have a more opaque appearance, sometimes with a sunken center: rough colonial forms may develop. In 0.25% (w/v) agar, 8% (w/v) gelatin and 1.0% (w/v) glucose semi-solid medium, growth along the stab after 24 h at 37°C is followed by irregular, cloudy extensions into the medium. Growth spreads slowly through the entire medium. An umbrella-like zone of maximal growth occurs 3–5 mm below the surface. **Temperature limits of growth <0 to 45°C; optimal growth at 30–37°C. Do not survive heating at 60°C for 30 min.** Growth occurs between pH 6 and pH 9. Growth occurs in nutrient broth supplemented with up to 10% (w/v) NaCl. Catalase-positive, oxidase-negative. **Cytochromes produced. Homofermentative anaerobic catabolism of glucose results in production of L(+)-lactic acid, acetic acid plus other end products. Acid but no gas produced from other sugars. Methyl-red-positive, Voges–Proskauer-positive.** Exogenous citrate not utilized. **Organic growth factors are required.** Indole is not produced. Esculin and sodium hippurate are hydrolyzed. Urea is not hydrolyzed. Gelatin, casein, and milk are not hydrolyzed.

The cell wall contains a directly cross-linked peptidoglycan based on *meso*-diaminopimelic acid (*meso*-DAP) (variation A1γ of Schleifer and Kandler, 1972): the cell wall does not contain arabinose. Mycolic acids are not present. The long-chain fatty acids consist of predominantly straight-chain saturated, anteiso-methyl-branched-chain types. When grown at 37°C, the major fatty acids are 14-methylhexadecanoic (anteiso-C_{17:0}) and

12-methyltetradecanoic (anteiso-C_{15:0}). Menaquinones are the sole respiratory quinones; the major quinone contains seven isoprene units (MK-7).

All members of the genus *Listeria* are widely distributed in nature and have been isolated from soil, vegetation, sewage, water, animal feed, fresh and frozen poultry, slaughterhouse wastes, and the feces of healthy animals including humans. *Listeria monocytogenes* is pathogenic to man. *Listeria monocytogenes* and, to a lesser extent, *Listeria ivanovii* are pathogenic to a wide range of animals, especially sheep and goats. The disease in humans and livestock is predominantly transmitted by the consumption of food or feed contaminated by *Listeria monocytogenes*. The colonization by *Listeria monocytogenes* of specific sites within food manufacturing environments for long periods, together with its ability to grow in a wide range of foods (including those containing sodium chloride or sodium nitrate as preservative) at low temperatures makes this bacterium of particular concern as a contaminant of ready-to-eat refrigerated foods (Farber and Peterkin, 1991).

DNA G+C content (mol%): 36–42.5 (*T_m*).

Type species: Listeria monocytogenes Pirie 1940a.

Further descriptive information

Numerical taxonomic studies (Wilkinson and Jones, 1977) together with biochemical (Collins et al., 1979b; Fiedler, 1988), DNA base composition (Hartford and Sneath, 1993; Rocourt et al., 1982a) and 16S rRNA gene sequence studies (Collins et al., 1991) show that all the species of the genus *Listeria* form a homogeneous group. On the basis of the sequencing of the 16S rRNA gene (as well as other genes), members of the genus *Brochothrix* (*Brochothrix thermosphacta* and *Brochothrix campestris*) are the closest relatives to *Listeria*, which is consistent with chemical and numerical taxonomic approaches (Collins et al., 1979b; Wilkinson and Jones, 1977); these two genera justify family status as *Listeriaceae*. The family *Listeriaceae* shows relatedness to other low-G+C Gram-positive bacteria, especially to species of *Bacillus* (Collins et al., 1991; Glaser et al., 2001). Indeed, the completed genome sequences of *Listeria monocytogenes* and *Listeria innocua* showed a close relationship to that from *Bacillus subtilis* and suggest a common origin (Glaser et al., 2001). *Listeria monocytogenes sensu lato* was reclassified into *Listeria monocytogenes sensu stricto*,

Listeria innocua, *Listeria ivanovii*, *Listeria seeligeri*, and *Listeria welshimeri* (Rocourt et al., 1982a); it is not always possible to be certain of the species designations cited in the older literature.

Six species (*Listeria monocytogenes*, *Listeria innocua*, *Listeria ivanovii*, *Listeria seeligeri*, *Listeria welshimeri*, and *Listeria grayi*) were recognized on the basis of DNA–DNA hybridization studies (Rocourt et al., 1982a). This classification was supported by the results of a second DNA–DNA homology study (Hartford and Sneath, 1993) and an analysis of multilocus enzyme electrophoresis (Boerlin et al., 1991). The study by Hartford and Sneath (1993) suggested a very close relationship between *Listeria monocytogenes* and *Listeria innocua* and there may be some overlap between these two species. 16S rRNA gene sequencing also supports this classification (Collins et al., 1991) together with sequencing of 23S rRNA genes (Sallen et al., 1996; Thompson et al., 1992), and 16S–23S intergeneric spacer regions (Drebot et al., 1996; Graham et al., 1997). Signature sequences in the V2 region of the 16S rRNA genes for the different *Listeria* species are: RAGUGUGGCGCAUGCCACGCU (*Listeria monocytogenes* and *Listeria innocua*); AGUAGUGACGCAUGUCAUCAC (*Listeria ivanovii*); AGGAGUGACGCAUGUCACUAC (*Listeria seeligeri*); AGUGGUGGCGCAUGCCACGGC (*Listeria welshimeri*); and AAUCACUCCGCAUGGAGCAGG (*Listeria grayi*) (Collins et al., 1991).

Complete genome sequences are available for *Listeria monocytogenes* (serotype 1/2a), *Listeria innocua* and *Listeria welshimeri* (Glaser et al., 2001; Hain et al., 2006; Nelson et al., 2004). However genome sequences other *Listeria monocytogenes* serotypes and for *Listeria seeligeri* and *Listeria ivanovii* have also been completed, and the genomes of further *Listeria monocytogenes* strains and *Listeria grayi* are currently being sequenced (<http://www.genomesonline.org>). The *Listeria* genome encode approximately 2800 potential proteins, of which two thirds have an assigned gene function, leaving some 900 genes with unknown function. Although differences between the species are seen due to gene acquisition or gene deletion, very little rearrangement or inversion of genome segments is detected resulting in a highly conserved synteny in gene organization. This may be due to the generally low occurrence of transposons and insertion sequences in *Listeria* genomes.

Comparative genomic analysis has confirmed that *Listeria monocytogenes* and *Listeria innocua* are closely related and form a distinct group from *Listeria welshimeri*, *Listeria ivanovii* and *Listeria seeligeri*, while *Listeria grayi* forms the deepest branch within the genus (Schmid et al., 2005). Looking at the evolution and pathogenicity of members of the genus, it appears that the non-pathogenic species have evolved by genome reduction from a progenitor strain that carried the virulence genes (Buchrieser et al., 2003; Doumith et al., 2004; Hain et al., 2006).

All *Listeria* species produce regular, short rods, 0.4–0.5 × 1–2 µm with parallel sides and blunt ends. Coccoid forms 0.4–0.5 µm in diameter and 0.4–0.6 µm in length are sometimes seen in smears from infected tissue (*Listeria monocytogenes* only) or from liquid cultures but rarely from colonies from solid media. These coccoid forms can be mistaken for streptococci when growing on microbiological media, but can be differentiated using a catalase test. Filaments up to 96 µm are developed by some *Listeria monocytogenes* strains (Rowan et al., 2000) and are also seen when strains are grown in media containing high levels of NaCl; formation of these filaments is reversible

(Jorgensen et al., 1995). A murein hydrolase (p60) has been shown to have an essential role in cell division (Pilgrim et al., 2003) and is down-regulated in strains which form exceptionally long filaments (Kuhn and Goebel, 1989).

Colonies of all *Listeria* species show limited variation and usually appear as non-pigmented, round, translucent, low-convex with a smooth surface, entire margin and crystalline central appearance on fresh isolation. After several days, colonies become less translucent and creamier in color, margins become less entire, and a central depression may form. Rough forms in which individual bacteria do not septate and are unusually long occur where colonies have an undulating rough surface and an uneven edge: bacteria from these colonies usually autoagglutinate. Some of these long forms in *Listeria monocytogenes* are due to a defective p60 protein which has murein hydrolase activity and is required for normal septum formation and is essential for cell viability (Wuenschel et al., 1993). The growth of all *Listeria* species generates a characteristic sweet caramel or buttery smell due to the generation of butyric acid.

Two to six peritrichous flagella are produced by all *Listeria* species (Peel et al., 1988a, b) grown below 30°C. Tumbling motility is observed for cultures grown between 20–30°C, and expression of the structural gene for the flagellin protein (*flaA*) has been shown to be temperature regulated and repressed at 37°C (Dons et al., 1992). Repression of flagellae at 37°C is necessary for full virulence (Grundling et al., 2004; Kathariou et al., 1995). High-level expression is seen at 25°C, corresponding to the temperature at which tumbling motility is observed. Even in the absence of active motility, strong induction of flagella biosynthesis occurs below 20°C and flagellae have a role in attachment to solid surfaces (Vatanyoopaisarn et al., 2000). Synthesis of flagellae is reported to be sensitive to catabolite repression (Galsworthy et al., 1990) and to the osmolarity of the medium (Sanchez-Campillo et al., 1995). Motility tests should be performed in media that do not contain high concentrations of free carbohydrate since the pH drops rapidly to <5.5 and the organism can appear to be nonmotile. In hanging-drop preparations, characteristic tumbling and rotatory movements alternate with periods of rest. Brain heart infusion broths are recommended since motility can be detected using hanging drops after 4h: nutrient broths can also be used, but motility may not be detected until after overnight incubation. Motility can also be demonstrated in semi-solid agar in “U” tubes. Maximal turbidity in liquid and semi-solid agar is present 2–3 mm below the surface in an umbrella-like pattern. After some d the organisms settle to the bottom in floccules. Some cultures within *Listeria* species other than *Listeria monocytogenes* may also elaborate flagella when grown at 37°C.

All species multiply rapidly in milk (Pine et al., 1989).

All *Listeria* species grow well on most non-selective bacteriological media including blood agar base, nutrient, tryptose, and tryptose soy or brain heart infusion agars. Growth is enhanced by the addition of a suitable fermentable carbohydrate (0.2–1% (w/v) glucose is suitable for all species) blood or serum.

All species grow best at neutral to slightly alkaline pH. Some cultures grow at pH 9.6 but usually die at pH lower than 5.5, consequently viable transfers may not be successful from cultures used in fermentation reactions where acid is produced. Two different mechanisms for adapting to acid stress have been described. Two glutamate decarboxylases (GadA and GadB), and a cognate H⁺ antiporter homolog (GadC), contribute to

the regulation of cytoplasmic pH by the consumption of H⁺ ions (Cotter et al., 2001) are essential for survival in both gastric juices and acidic foods (Hill et al., 2002). GadB is induced under acid stress condition via the SigB stress regulon (Cotter et al., 2001). In addition an H⁺ ATPase has been shown to have a role in acid survival and in the induction of an acid-tolerance response (Cotter et al., 2000). The genes encoding the ATPase (*atpC* and *atpD*) appear to be regulated by PrfA (Glaser et al., 2001). To date no mechanism for surviving alkaline stress conditions has been elucidated.

Listeria ivanovii, *Listeria monocytogenes*, and *Listeria seeligeri* are hemolytic on agars containing sheep, cow, horse, rabbit or human blood: the remaining three species are non-hemolytic. Variation may occur between the species' blood because of the presence of antibodies: it is therefore preferable to use saline-washed erythrocytes. Media containing plant-extracts, such as tryptose soy agar, should not be used due to an observed repression of the hemolysin gene by the plant sugar cellobiose (Park and Kroll, 1993). Treatment of media with activated charcoal can increase the levels of both hemolysis (Ripio et al., 1996) and lecithinase activity in plate assays (Ermolaeva et al., 2003). Prolonged heat treatment of the media will also diminish the hemolytic activity (Sheikh-Zeinoddin et al., 2000).

The zones of hemolysis produced by *Listeria monocytogenes* and *Listeria seeligeri* are narrow, have an indistinct margin, and, especially for *Listeria seeligeri*, may be detected only by removal of the colony from the agar surface. *Listeria ivanovii* produces wider zones of hemolysis (especially after 36 h incubation) with sharper edges and may also have double or multiple zones. Because of the relatively weak hemolytic reactions produced by *Listeria*, the use of layered blood agar plates is recommended. The *Listeria monocytogenes* type strain is nonhemolytic, CAMP-test-negative, and nonmotile and may be misidentified as *Listeria innocua*. This strain however, unlike *Listeria innocua* cultures, does exhibit amino acid peptidase activity. Wild-type *Listeria monocytogenes* occur with similar properties, these can be identified on the basis of the detection of hemolysin gene fragments by PCR and 16S rRNA gene sequencing (J. McLauchlin, unpublished data).

Agglutination of human, rabbit, guinea pig or sheep erythrocytes does not occur (Seeliger, 1961).

Listeria monocytogenes, *Listeria seeligeri*, and *Listeria ivanovii* all show positive CAMP test or enhancement of hemolysis reactions (Christie et al., 1944): *Listeria monocytogenes* and *Listeria seeligeri* are CAMP-test-positive with *Staphylococcus aureus* and negative with *Rhodococcus equi*; *Listeria ivanovii* is CAMP-test-positive with *Rhodococcus equi* and negative with *Staphylococcus aureus*. *Listeria grayi*, *Listeria seeligeri*, and *Listeria welshimeri* are all CAMP-test-negative (Rocourt et al., 1982a). Because the enhancement of hemolysis can be weak (especially between *Listeria seeligeri* and *Staphylococcus aureus*), a thin layer (2 mm) of 5% (v/v) washed sheep erythrocytes in nutrient agar poured over a nutrient agar base is recommended. In addition, not all *Staphylococcus aureus* strains are suitable since some produce too much lysis alone: *Staphylococcus aureus* NCTC 1803 and *Rhodococcus equi* NCTC 1621 are recommended for this test.

All *Listeria* species grow in complex media supplemented with 10% (w/v) NaCl. Some *Listeria monocytogenes* strains can tolerate 20% (w/v) NaCl: retention of viability for >1 year in 16% (w/v) NaCl at pH 6.0 has been reported (Seeliger, 1961). *Listeria* species can utilize a range of compounds as osmopro-

tectants: the rank order of a variety of different compounds tested was glycine > betaine > proline betaine > acetyl carnitine/carnitine/ γ -butrobetaine > 3-dimethylsulfoniopropionate (Bayles and Wilkinson, 2000): the temperature of cultivation can influence the effectiveness of individual compounds. Ko et al. (1994) identified a chill-activated glycine betaine transporter which was 15 times more active at 7°C than at 30°C, and thus glycine betaine may also serve as a cryoprotectant for *Listeria*. Accumulation of glycine betaine and carnitine occurs via at least two glycine betaine transporters, BetL (Ko and Smith, 1999) and Gbu (Sleator et al., 1999), and one carnitine transporter encoded by the *opuC* operon (Fraser et al., 2000). Full resistance to osmotic stress also requires induction of a set of stress-response genes controlled by the alternate sigma factor SigB (Becker et al., 1998), including the ABC transporter OpuC (Sleator et al., 2001) and the general stress protein Ctc (Gardan et al., 2003).

All strains grow on 10% (w/v) and 40% (w/v) bile agar. Wetzler et al. (1968) reported that generally growth on 40% (w/v) bile (Bacto ox gall) was better than that obtained on 10% (w/v) bile. Slight growth occurs on MacConkey agar. A gene encoding a bile salt hydrolase (*bsh*) has been identified in *Listeria monocytogenes* and deletion of this gene resulted in decreased resistance to bile *in vitro*. The gene is up-regulated by virulence regulator PrfA, and contributes to the survival of the bacterium in the intestinal and hepatic phases of listeric infection (Dussurget et al., 2002). This gene is not present in the non-pathogenic species *Listeria innocua*.

All strains grow in the presence of 0.025% (w/v) thallos acetate; 3.75% (w/v) potassium thiocyanate; 0.04% (w/v) potassium tellurite; 0.01% (w/v) 2,3,5-triphenyltetrazolium chloride, tellurite and tetrazolium are reduced. Strains do not grow in the presence of 0.02% (w/v) sodium azide. Wetzler et al. (1968) reported no growth in the presence of potassium cyanide. No growth occurs on the medium of Gardner (1966). All species are catalase-positive when grown on the usual laboratory media but may give a negative reaction if cultures on media containing low concentrations of meat and yeast extract. Catalase-negative *Listeria monocytogenes* strains have been observed (Bubert et al., 1997). Friedman and Alm (1962) reported that catalase activity is depressed in media containing higher (10% (w/v)) concentrations of glucose. Catalase and superoxide dismutase production was increased in three *Listeria monocytogenes* strains by addition of iron to tryptose soy broth (Fisher and Martin, 1999): addition of iron to the medium will repress the production of listeriolysin (Bockmann et al., 1996). The addition of selenium resulted in increasing production of catalase and listeriolysin (Fisher and Martin, 1999).

Carbohydrate is essential for growth of *Listeria* strains and glucose is the usual choice. Fully chemically defined media that successfully support the growth of *Listeria monocytogenes* in both batch (Friedman and Roessler, 1961; Jones et al., 1995; Phan-Thanh and Gormon, 1997; Premaratne et al., 1991; Romick et al., 1996; Siddiqi and Khan, 1982, 1989; Trivett and Meyer, 1971) and continuous culture (Jones et al., 1995) have been described. The medium of Trivett and Meyer (1971) comprised: sodium and potassium phosphate, ammonium chloride, magnesium sulfate, ferric chloride, sodium hydroxide, nitriloacetic acid, L-cysteine, L-leucine, DL-isoleucine, DL-valine, DL-methionine, L-arginine, L-histidine, riboflavin, thiamine, D-biotin,

α -lipoic acid, and glucose. The medium of Phan-Thanh and Gormon (1997) was similar to that of Trivett and Meyer (1971), but also included L-glutamine, L-tryptophan, L-phenylalanine, adenine, pyridoxal, para-aminobenzoic acid, and nicotinamide. In a defined medium, pyruvate, acetate, citrate, isocitrate, 2-oxoglutarate, succinate, fumarate, and malate do not support growth of *Listeria monocytogenes* in the absence of glucose, nor do they increase growth in the presence of glucose (Trivett and Meyer, 1971). The medium described by Phan-Thanh and Gormon (1997) supported all *Listeria* species in batch culture. Pyruvate, malate, succinate and 2-oxoglutarate have been reported to be oxidized at low rates by *Listeria monocytogenes* (Friedman and Alm, 1962; Kolb and Seidel, 1960). In a complex medium, pyruvate is utilized as a carbon source by some strains. *Listeria monocytogenes* appears to utilize a split noncyclic citrate pathway which has an oxidative and a reductive portion. The pathway is probably important in biosynthesis but not for a net gain in energy (Trivett and Meyer, 1971). It has been shown that *Listeria monocytogenes* can induce the enzymes required for the utilization of glucose 1-phosphate when grown under conditions which induce the virulence regulator PrfA (Ripio et al., 1997) and therefore growth conditions (especially temperature) should be considered when determining sugar-utilization profiles. Catabolism of glucose proceeds by the Embden–Meyerhof pathway both aerobically and anaerobically. Under anaerobic conditions the catabolism of glucose by all *Listeria* species is homofermentative, i.e., lactate is produced exclusively (Pine et al., 1989). Under aerobic conditions cell yields are considerably increased, and all species produce lactic, acetic, isobutyric, and isovaleric acids: there are differences between strains in the relative amounts of lactic and acetic acids produced (Pine et al., 1989). Friedman and Alm (1962) and Daneshvar et al. (1989) also reported the production of acetoin and pyruvate by *Listeria monocytogenes* under aerobic conditions. There is no evidence for the Entner–Doudoroff pathway, but glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase have been reported to be present (Miller and Silverman, 1959). Under anaerobic conditions, only hexoses and pentoses support growth, but under aerobic conditions maltose and lactose support growth of some species, but sucrose does not (Pine et al., 1989). No growth occurred with lactose under anaerobic conditions, but all species grew under aerobic conditions and *Listeria grayi* utilized both the galactose and glucose moieties but *Listeria monocytogenes* and *Listeria innocua* only the glucose (Pine et al., 1989). Analysis of cultures grown at 5°C in sterile milk suggested that glucose was the major and limiting substrate (Pine et al., 1989).

All species are Methyl red-positive and Voges–Proskauer-positive when tested at 48 h by the method of O’Meara or that of Barritt (see Barrow and Feltham, (1993), for methods).

When testing for the production of acid from carbohydrates, the composition of the basal medium and the pH indicator used are important. *Listeria* species are actively saccharolytic and a basal media which contains traces of fermentable carbohydrate and a pH indicator which changes color rather near neutrality can result in false-positive reactions. A variety of basal media and pH indicators have been used. Purple Broth Base (Difco) peptone water medium with phenol red as indicator (Rocourt et al., 1983) supplemented with 0.5 or 1% (w/v) of the carbohydrate are suitable for testing for acid production.

All carbohydrates should be sterilized by filtration and not by autoclaving.

Members of the genus *Listeria* are remarkably similar in their phenotypic characteristics (Feresu and Jones, 1988; Kämpfer, 1992; Kämpfer et al., 1991; Rocourt et al., 1985b; Rocourt et al., 1983; Wilkinson and Jones, 1977). Lists of results of phenotypic tests are shown in Table 40 and Table 41. All species produce acid from esculin, glucose, trehalose and salicin.

Exogenous citrate is not utilized. Iron is stimulatory for the growth of *Listeria monocytogenes* in stationary or aerated cultures (Sword, 1966; Trivett and Meyer, 1971), but aeration improves growth only in the presence of adequate iron (Trivett and Meyer, 1971). H₂S is not produced. Ornithine, lysine, glutamic acid, and arginine decarboxylases are not produced, nor is an arginine dihydrolase present. Phosphatase is produced and methylene blue is decolorized. Tributyrinase activity is absent, and the hydrolysis of Tweens 20, 40, 60, and 80 takes place slowly.

Rocourt et al. (1983) showed that the species of *Listeria* could be differentiated using a small number of tests, which was later confirmed by others (Kämpfer et al., 1991; McLauchlin, 1997). Kämpfer et al. (1992, 1991) showed that *Listeria monocytogenes* could be distinguished from other members of the genus by the absence of an arylesterase on alanine-substituted substrates. A patent has been granted for the use of arylesterase activity on glycine substituted substrates for the identification of *Listeria* (Monget, 1992), and this reaction is used in a commercially available identification kit (Bille et al., 1992; McLauchlin, 1997). A method based on detection of amino acid peptidase activity using alanine-derived substrates for the rapid differentiation of *Listeria monocytogenes* from the rest of the genus has been described (Clark and McLauchlin, 1997; McLauchlin, 1997).

The cell wall of *Listeria monocytogenes* has the appearance of a thick multilayered structure typical of Gram-positive bacteria (Ghosh and Murray, 1967). The cell-wall peptidoglycan contains *meso*-DAP as the diamino acid (variation A1 γ of Schleifer and Kandler, 1972). Alanine and glutamic acid are also present (Fiedler et al., 1984; Fiedler and Ruhland, 1987; Fiedler and Seger, 1983; Kamisango et al., 1982; Robinson, 1968; Schleifer and Kandler, 1972; Srivastava and Siddique, 1973). In addition to *N*-acetylmuramic acid and *N*-acetylglucosamine, glucosamine also occurs as a component of the cell-wall polysaccharide (Fiedler and Seger, 1983; Hether et al., 1983; Ullmann and Cameron, 1969). Ribitol and lipo-teichoic acids are present in *Listeria monocytogenes* (Fiedler, 1988; Fiedler et al., 1984; Fujii et al., 1985; Hether and Jackson, 1983; Kamisango et al., 1983; Ruhland and Fiedler, 1987; Uchikawa et al., 1986b, a); these, together with flagella antigens, are responsible for the serological types (Fiedler et al., 1984; Wendlinger et al., 1996). Cell surface and secreted proteins occur, some of which are involved with the virulence of *Listeria monocytogenes* and *Listeria ivanovi*. The production of many of the surface-associated virulence genes is temperature-dependent and these are expressed above 30°C. Many, but not all, of the surface-associated virulence genes characterized to date are under the control of the central virulence regulator PrfA (Vazquez-Boland et al., 2001). L forms have been reported in *Listeria monocytogenes* (Gray and Killinger, 1966; Markova et al., 1997) and may have a role in infection.

Mycolic acids are not present (Jones et al., 1979) and MK-7 is the major menaquinone with MK-6 and MK-5 present as minor components for all species examined (Collins and Jones, 1981).

^cNo acid produced by *Listeria grayi* subsp. *murrayi*.

^dNo acid produced by *Listeria ivanovii* subsp. *londoniensis*.

^eNitrates reduced to nitrites by *Listeria grayi* subsp. *murrayi*.

^fTween 80 esterase not produced by *Listeria grayi* subsp. *murrayi*.

The polar lipid composition is similar in *Listeria monocytogenes*, *Listeria innocua*, *Listeria welshimeri*, and *Listeria seeligeri*, and comprises phosphatidylglycerol, diphosphatidylglycerol, galactosylglucosyldiacylglycerol and L-lysylcardiolipin (Fischer and Leopold, 1999; Kosaric and Carroll, 1971; Shaw, 1974). Other more polar phospholipids were suggested to be polyprenol phosphate and glycerol-1-phospholipid plus a D-ananyl derivative (Fischer and Leopold, 1999). The fatty acid compositions of *Listeria monocytogenes*, *Listeria innocua*, and *Listeria ivanovii* are very similar. All contain predominantly straight-chain saturated anteiso- and iso-methyl-branched-chain types. The major fatty acids are 14-methylhexadecanoic (anteiso-C_{17,0}) and 12-methyltetradecanoic (anteiso-C_{15,0}) (Carroll et al., 1968; Feresu and Jones, 1988; Julak et al., 1989; Kosaric and Carroll, 1971; Nichols et al., 2002; Ninet et al., 1992; Raines et al., 1968; Tadayon and Carroll, 1971). The composition of the fatty acids changes under different growth conditions (Nichols et al., 2002; Puttmann et al., 1993), with a reduction of the fatty acid chain-length and alteration of branching from iso to anteiso forms with decreasing temperature in order to maintain membrane fluidity and function and to permit continued growth at lower temperatures (Annous et al., 1997).

Jones et al. (1979) reported cytochromes *abb*₁ in *Listeria monocytogenes* NCTC 7973, but in a later study cytochromes *a*₁*bdo* were demonstrated to be present in *Listeria monocytogenes*, *List-*

eria innocua and *Listeria ivanovii* (S. B. Feresu, D. Jones and M. D. Collins, personal communication).

Plasmid DNA has been detected in all species of *Listeria*, most of which are larger than 20 MDa (Dykes et al., 1994; Fistrovici and Collins-Thompson, 1990; Flamm et al., 1984; Kolstad et al., 1990; Perez-Diaz et al., 1982; Peterkin et al., 1992; Slade and Collins-Thompson, 1990). Most of the larger plasmids in *Listeria monocytogenes* encode resistance to cadmium (Lebrun et al., 1994a; Lebrun et al., 1994b): the proportion of cultures with these large plasmids varies markedly depending upon the serovar of *Listeria monocytogenes* (McLauchlin et al., 1997). Plasmid DNA was detected in the complete sequence of the *Listeria innocua* genome, and was shown to be 54 MDa in size with 79 genes (Glaser et al., 2001). Smaller plasmids encoding resistance to tetracycline alone (3 MDa; Poyart-Salmeron et al., 1992) and multiresistance to chloramphenicol, erythromycin, streptomycin and tetracycline (25 MDa; Hadorn et al., 1993; Poyart-Salmeron et al., 1990; Quentin et al., 1990; Tsakris et al., 1997) have been detected, although these are rare. Trimethoprim resistance due to the *dfiD* gene has been found to be encoded on a 2.5 MDa plasmid of *Listeria innocua* (Charpentier and Courvalin, 1997). Two bacteriocins have been found to be encoded on a 1.9 kDa plasmid of *Listeria innocua* (Kalmokoff et al., 2001). Transfer of native listerial plasmids has been demonstrated *in vitro* between strains of *Listeria monocytogenes*, to

^bData from Seeliger and Jones (1986), Kämpfer et al. (1991) and Rocourt and Catimel (1985).

other *Listeria* species, and to other species of bacteria including *Bacillus subtilis*, *Enterococcus faecalis*, *Streptococcus agalactiae*, and *Staphylococcus aureus* (Charpentier and Courvalin, 1999; Flamm et al., 1984; Perez-Diaz et al., 1982; Vicente et al., 1988). Cloning vectors based on the plasmid replicons pC194 (from *Staphylococcus aureus*; Sullivan et al., 1984) and pE194 (from *Enterococcus*; Chakraborty et al., 1992) have been successfully used for gene cloning experiments in *Listeria*.

Transposons *Tn1545*, *Tn916*, and *Tn917* (and their derivatives) introduced and expressed in *Listeria monocytogenes* have proved to be extremely useful tools in understanding the basis of virulence in the bacterium (Vazquez-Boland et al., 2001). Transfer of *Tn1545* has been demonstrated between *Enterococcus faecalis* and *Listeria monocytogenes* in the digestive tract of

gnotobiotic mice (Doucet-Populaire et al., 1991). A transposon, similar to *Tn917* (designated *Tn5422*) has been detected in plasmid DNA of *Listeria monocytogenes* (Lebrun et al., 1994a; Lebrun et al., 1994b).

Lysogenic phage are commonly carried by *Listeria* (Audurier et al., 1977; Bannerman et al., 1996; Loessner, 1991; Loessner et al., 1994; Rocourt et al., 1985b; Rocourt et al., 1986; Rocourt et al., 1982b). They are generally morphologically similar with isometric heads, long non-contractile tails and correspond to the Myoviridae or Syphoviridae families (Loessner et al., 1994; Rocourt, 1986; Rocourt et al., 1986). The complete genome sequence of one lysogenic phage, A118, has been reported (Loessner et al., 2000) and phage integration was shown to occur in a homolog of the *Bacillus comK* gene, although no known function has yet

been determined for this gene in *Listeria*. To date, no phage conversion has been reported due to toxin genes associated with prophage sequences. A lytic phage (A511) of the Myoviridae family with a double stranded DNA genome of approximately 116kbp has also been described (Loessner et al., 1994). The phage genomes characterized to date have been linear double-stranded DNA of 35–116kbp (Loessner et al., 1994; Rocourt et al., 1986) with G+C base compositions of 37–39mol% (Loessner et al., 1994) (Loessner et al., 1994). Lytic properties of sets of phages have been used for subtyping *Listeria monocytogenes*. Bacteriocin (monocin) production is common within the genus (Bannerman et al., 1996; Curtis and Mitchell, 1992; Kalmokoff et al., 2001; Rocourt et al., 1986).

The cell surface of *Listeria* species contains a number of different antigens. Somatic (O factor) antigens based, at least in part, on ribitol teichoic acid substitution, together with flagella (H factor) antigens, have been characterized using highly absorbed rabbit antisera for serotyping members of the genus (Seeliger and Hohne, 1979; Table 42). Antigenic cross-reactions with other genera have been reported (Seeliger, 1961), in particular with some *Bacillus* species that share a common cell-wall structure.

Listeria species are usually sensitive to amikacin, amoxycillin, ampicillin, azlocillin, ciprofloxacin, chloramphenicol, clin-

damycin, coumermycin, doxycycline, enoxacin, erythromycin, gentamicin, imipen, netilmicin, penicillin, rifampin, trimethoprim, and vancomycin. This genus is less sensitive to norfloxacin and ofloxacin, and is resistant to the cephalosporins, phosphomycin, and polymyxin (Charpentier et al., 1995; MacGowan, 1990; Riviera et al., 1993). Tetracycline is less active against *Listeria monocytogenes*, and 2–5% of strains are highly resistant (Poyart-Salmeron et al., 1992): this rate of resistance has not changed over the past 30 years in the UK (Threlfall et al., 1998). Most of these highly resistant cultures contain a chromosomally encoded *tetM* gene (together with a transposon, int-Tn), which also confers resistance to minocycline (Poyart-Salmeron et al., 1992). The *tetM* gene has also been detected in *Listeria innocua* and *Listeria welshimeri* (Charpentier and Courvalin, 1999; Facinelli et al., 1993). Plasmid-encoded tetracycline resistance in *Listeria monocytogenes* is rarer than that chromosomally encoded. The latter is encoded by a *tetL* (minocycline-sensitive; Poyart Salmeron et al., 1992) or a *tetS* determinant (minocycline-resistant; Charpentier et al., 1993; Hadorn et al., 1993). The *tetS* gene was first described in *Listeria monocytogenes*, but has since been detected in *Listeria innocua*, *Listeria welshimeri*, and *Enterococcus faecalis* (Charpentier and Courvalin, 1999; Charpentier et al., 1994). Plasmid-encoded resistance to chloramphenicol (*cat22I*), erythromycin (*ermAM*), streptomycin (*aad6*) and tetracycline (*tetS*) has been detected in *Listeria monocytogenes* (Charpentier and Courvalin, 1999; Hadorn et al., 1993; MacGowan, 1990; Poyart-Salmeron et al., 1990; Quentin et al., 1990; Threlfall et al., 1998). Other genes encoding resistance to tetracycline (*tetK*) and streptomycin (*aad6*) have been detected in *Listeria innocua* (Charpentier and Courvalin, 1999). A gene that encodes resistance to erythromycin (*ermC*) has been detected in *Listeria monocytogenes* and *Listeria innocua* (Roberts et al., 1996).

Listeria monocytogenes has long been used as a low-grade intracellular pathogen to study cellular immunity (Kaufmann, 1993), and more recent advances in molecular biology have further assisted the understanding of listeriosis at the cellular level (Vazquez-Boland et al., 2001). Of the six species of *Listeria*, only cultures of *Listeria monocytogenes* and *Listeria ivanovii* are virulent in all the models as measured by LD₅₀, the kinetics of bacterial growth in host tissue, survival in the liver and spleen or the death of the experimental animal. All the non-hemolytic species of *Listeria* (*Listeria innocua*, *Listeria welshimeri*, and *Listeria grayi*) and the weakly hemolytic *Listeria seeligeri* are avirulent in mouse-pathogenicity tests (Mainou-Fowler et al., 1988). *Listeria monocytogenes*, *Listeria ivanovii* and, to a lesser extent *Listeria seeligeri*, show properties of invasion and spreading in a range of mammalian cells growing *in vitro*, but other *Listeria* species do not (Farber et al., 1991; Pine et al., 1991; Van Langendonck et al., 1998).

Listeria monocytogenes enters both phagocytic and non-phagocytic cells. A listerial surface protein, internalin A (which is reminiscent of the M protein of the group A streptococci), has been shown to be involved with the initial stages of invasion of all cell types. A second cell surface protein (internalin B) is required for entry into hepatocyte-like but not into enterocyte-like cells. The receptor for internalin A is E-cadherin which is a mammalian surface protein involved in cell-to-cell adhesion. The cell-wall teichoic acid is also required for adhesion of *Listeria* to mammalian cells (Abachin et al., 2002). The listerial cell-surface protein, p60 (with murein hydrolase activity) may

^cFactor II is heat labile.

^dUndesignated combinations of O factors also occur.

also be involved in the invasion of fibroblasts and a second surface-exposed autolysin (Ami) has been shown to be involved in adhesion to eukaryotic cells (Milohanic et al., 2000).

Within mammalian phagocytic cells, the majority of cells in phagocytic vacuoles are rapidly killed. However, some bacteria survive in the vacuole, and those in the membrane-bound compartment of the non-professional phagocyte (which probably confers on the bacterium some protection from host defences in the extracellular environment), mediate the dissolution of the vacuole membrane by means of a thiol-activated hemolysin (listeriolysin O), in combination with the action of a phospholipase C (phosphatidyl inositol-specific). *Listeria monocytogenes* then enters the host-cell cytoplasm where growth occurs. In the cytoplasm, the organism becomes surrounded by polymerized host-cell actin, which becomes preferentially polymerized at the older pole of the bacterium following cell division. The ability to polymerize actin confers intracellular mobility on the bacterium is dependent on the Act A protein and may be mediated by binding with host-cell profilactin and vasodilator-stimulated phosphoprotein (VASP), although the exact mode of action is not understood. The resulting comet tail-like structure can push the bacterial cell into an adjacent mammalian cell, where it again becomes encapsulated in a vacuole. At this stage the vacuole is double-membrane-bound from the two host cells. The primary role of the second phospholipase enzyme (a broad-spectrum lecithinase enzyme which hydrolyzes phosphatidylcholine or lecithin) is believed to be in the fusion and subsequent dissolution of these membranes (although again the hemolysin and phospholipase C may also contribute in this process; a distinct role may not exist for each of the Hly, PlcBC and PlcC proteins; rather, these enzymes work synergistically to achieve optimal levels of activity at different stages of the infection process). After release into the cytosol, intracellular growth and movement within the newly invaded cell is then repeated and the focus of infection continues to enlarge by this process of cell-to-cell spread (Vazquez-Boland et al., 2001).

The genes involved in the invasion and intracellular movement in mammalian cells are organized into a main virulence cluster containing adjacent operons which are all directly regulated by the central virulence regulator PrfA. The internalin genes are located in a separate gene cluster and are only partially regulated by PrfA, there being a basal level of expression even in the absence PrfA induction. Similar sets of virulence genes are also present in *Listeria ivanovii* and *Listeria seeligeri*. Virulence for *Listeria monocytogenes* is therefore a multifactorial property and at least nine genes and their products are required for infection, invasion, survival, mobility and cell-to-cell spread (Vazquez-Boland et al., 2001), although additional genes (especially those for cell-surface components) are also likely to be involved with the infectious process (Autret et al., 2001; Engelbrecht et al., 1998; Raffelsbauer et al., 1998). It is possible that the genes for intracellular parasitism have evolved for *Listeria monocytogenes*, as well as for *Listeria ivanovii* and *Listeria seeligeri*, to invade lower multicellular eukaryotic organisms resident in the environment. Internalin genes also occur in the non-pathogenic species *Listeria innocua* (Vazquez-Boland et al., 2001).

A wide range of animals are susceptible to experimental infection, but rabbits, mice and, to a lesser extent, rats are most frequently used since these animals die following inoculation of live bacteria by the intravenous or intraperitoneal route. The

guinea pig is a better model of human infection than the mouse due to a single amino-acid difference between the murine and human E-cadherin molecules: this change reduces the affinity of the internalin A protein for the receptor and compromises invasion by *Listeria* in the mouse model (Lecuit et al., 1999). In guinea pigs and transgenic mice carrying the humanized E-cadherin gene, internalin was found to mediate invasion of enterocytes and crossing of the intestinal barrier (Lecuit et al., 2001). Virulence assays are usually performed using either intraperitoneal or tail-vein injection. Delivery directly into the animal overcomes the limitations of E-cadherin specificity when strains are administered by the oral route.

Enrichment and isolation procedures

Culture from blood or cerebrospinal fluid does not require special media. Tissues should be homogenized, suspended in broth and subcultured onto blood agar. The incubation of medulla homogenates at refrigeration temperatures for some weeks has been reported as necessary to obtain cultures which grow on artificial media (Gray and Killinger, 1966). For specimens such as feces, vaginal secretions, food and environmental samples, special selective media are necessary.

Before the mid-1980s, "cold enrichment", utilizing the ability of *Listeria* to outgrow competing organisms at refrigeration temperatures in non-selective broths, was the main method used for selective isolation (Gray and Killinger, 1966). When growing on transparent media illuminated by oblique transmitted light and viewed at low magnification ("Henry" illumination technique), all *Listeria* colonies have a characteristic blue color with a central "ground glass" appearance (Gray, 1957). However, because of the degree of skill required in recognizing characteristic colonies, the lack of specificity, and the slowness of these methods (some workers subcultured broths for up to 6 months), procedures have been much improved.

Media have been developed that rely on a number of selective agents; these include acriflavin, lithium chloride, colistin, ceftazidime, cefotetan, fosfomicin, moxolactam, nalidixic acid, cycloheximide, and polymyxin. Such media have resulted in the widespread ability of microbiology laboratories (especially those involved with the examination of foods) to selectively isolate *Listeria*. Numerous enrichment and selective isolation media have now been developed. Those mentioned here (or modifications of these) are used most frequently for the examination of foods. For selective broths, the US Food and Drugs Administration (FDA) method (Lovett et al., 1987), the US Department of Agriculture (USDA) method (McClain and Lee, 1988), or the Netherlands Government Food Inspection Service (NGFIS) method described by van Netten et al. (1989) are most often used. Selective agars most frequently used are those of Curtis et al. ((1989a); "Oxford" formulation) or the PALCAM agar of van Netten et al. (1989). These media are listed in internationally agreed standard methods (International Organization for Standardization, 1996, 1998).

The FDA method uses a single enrichment broth containing acriflavin, nalidixic acid, and cycloheximide. The USDA method consists of a double enrichment using first a University of Vermont primary enrichment broth 1 (UVMI; containing esculin nalidixic acid and acriflavin) which is subcultured into a Fraser Broth (containing esculin, nalidixic acid, lithium chloride and acriflavin). The NGFIS Method uses a single L-PALCAM (or Liquid-PALCAM) broth, the name of which is

an acronym of the ingredients, polymyxin B, acriflavin, lithium chloride, ceftazidime, [a]esculin and mannitol.

After incubation the selective broths are subcultured onto selective agars, most usually PALCAM agar (containing the same agents as L-PALCAM broth) or Oxford Agar. The latter agar contains esculin, lithium chloride, cycloheximide, colistin, acrifalvin, cefotetan, and fosfomycin. On Oxford agar all *Listeria* species show a typical colonial appearance and hydrolyze esculin, to produce black zones around the colonies. On PALCAM agar the colonies have a cherry red background. It is beyond the scope of this contribution to describe the preparation of these media; for further details see Baird et al. (1987). For comparisons of the efficiency of the different selective techniques for the isolation of *Listeria* from foods, see Warburton et al. (1991) and Hayes et al. (1992).

All *Listeria* species are isolated by these methods and are morphologically indistinguishable from each other. However, Curtis et al. (1989b) reported differences in the minimal inhibitory concentrations of selective agents used in microbiological media and found that *Listeria ivanovii* and *Listeria seeligeri* were more sensitive to fosfomycin than *Listeria innocua*, *Listeria monocytogenes*, and *Listeria welshimeri*. Consequently, colonies of *Listeria ivanovii* and *Listeria seeligeri* grow more slowly and are smaller on Oxford agar, which uses fosfomycin as a selective agent.

To differentiate *Listeria monocytogenes* from other *Listeria* species on selective agars, substrates have been added to selective media to detect phospholipase (Notermans et al., 1991) or β -D-glucosidase and enhanced hemolysis (Beumer et al., 1997). Selective media, based on lipase and β -D-glucosidase activity which successfully differentiates *Listeria monocytogenes* from populations of other *Listeria* species are commercially available (Vlaemynck et al., 2000).

Maintenance procedures

Listeria species can be preserved for decades at room temperature in the dark on stab or sloped non-selective agars such as nutrient or tryptose soy agars provided the preservation vessels are well sealed and do not allow the agar to dehydrate. *Listeria* can also be preserved in glycerol on glass beads at less than -20°C (Feltham et al., 1978) or by lyophilization.

Differentiation of the genus *Listeria* from other genera

Table 43 lists the features most useful in differentiating the genus *Listeria* from other Gram-positive, non-spore-forming, rod-shaped bacteria. Identification of new *Listeria* isolates may be achieved by the following: examination of cellular and colonial morphology; growth at 37°C ; oxygen requirements: catalase production; hydrolysis of esculin and sodium hippurate; alkaline phosphatase production; and production of acid from carbohydrates in a suitable medium. Determination of the cell-wall and lipid composition and 16S rRNA gene sequence analysis are not necessary for routine identification.

Bacteria with which members of the genus *Listeria* are most likely to be confused are those of the genera *Brochothrix*, *Erysipelothrix*, *Lactobacillus*, and *Kurthia*. As mentioned earlier, coccobacillary forms of the genus *Listeria* may be confused with streptococci, which are catalase-negative.

Listeria may be distinguished easily from the genus *Kurthia* by their different oxygen requirements. *Kurthia* species are strictly aerobic and produce little or no acid in sugar-fermentation

tests. In contrast to *Listeria*, the cell walls of *Kurthia* species contain lysine (Keddie, 1981a).

Listeria species may be distinguished from *Erysipelothrix* species by the negative catalase test, good growth on the usual nutrient media, and colonial morphology; motility; possession of more vigorous saccharolytic activity; hydrolysis of esculin and sodium hippurate, and non-production of H_2S . *Listeria* species and *Erysipelothrix rhusiopathiae* are antigenically distinct. *Listeria* species contain cytochromes and menaquinones, which are absent in *Erysipelothrix rhusiopathiae*. The two genera also differ in the chemical composition of the cell-wall peptidoglycan: that of *Listeria* is based on meso-DAP while the cell wall of *Erysipelothrix rhusiopathiae* contains lysine.

Listeria species may be distinguished from most lactobacilli by the catalase test. There are, however, some catalase-positive lactobacilli and rare strains of *Listeria* that are catalase-negative. Members of the genus *Listeria* grow very poorly or not at all on MRS medium (De Man et al., 1960), on which lactobacilli grow very well. When investigated at the correct incubation temperature (20 – 25°C), *Listeria* are motile while most lactobacilli are not. Lactobacilli have a different colonial morphology to *Listeria* species, there are differences in the fermentation patterns of the two genera, and all strains of *Listeria* examined possess meso-DAP in the cell wall. Some lactobacilli also possess this amino acid in the cell wall but in other lactobacilli it is replaced by lysine or ornithine (Schleifer and Kandler, 1972). Serologically, the genera *Listeria* and *Lactobacillus* are distinct.

Members of the genus *Listeria* may be confused with *Brochothrix* species. Members of both genera are frequently isolated from prepackaged meats and poultry held at refrigeration temperatures. Both contain meso-DAP in the cell wall, MK-7 as the major isoprenoid quinone, and have an identical fatty acid composition (Feresu and Jones, 1988; Schleifer and Kandler, 1972). The inability of *Brochothrix thermosphacta* to grow at 37°C and the inability of *Listeria* species to grow on the medium of Gardner (1966) serve to distinguish the two genera. *Brochothrix thermosphacta* does not hydrolyze sodium hippurate but produces acid from a greater number of sugars. Serologically, the two taxa are distinct (Wilkinson and Jones, 1977).

Taxonomic comments

As described above, analysis of sequence data from the 16S rRNA confirms the close relationship within the genus *Listeria*, and indicates a close phylogenetic relationship (93% sequence similarity) with the genus *Brochothrix* (Collins et al., 1991). This latter genus comprises two species (*Brochothrix thermosphacta* and *Brochothrix campestris*) which have many phenotypic properties in common with *Listeria* (Collins et al., 1991; Seeliger and Jones, 1986; Sneath and Jones, 1986). These two genera justify status as the family *Listeriaceae* (Collins et al., 1991). 16S rRNA gene sequence analyses show relationships with other Gram-positive genera of low G+C content, including members of the genus *Bacillus* (Collins et al., 1991). Indeed, the completed genome sequences of *Listeria monocytogenes* and *Listeria innocua* show a close relationship to that from *Bacillus subtilis* and suggest a common origin (Glaser et al., 2001).

Although originally described as a monospecific genus containing only *Listeria monocytogenes* (Pirie, 1940a), six species of *Listeria* are now recognized (Moore et al., 1985; Skerman et al., 1980). The group of bacteria originally named *Listeria*

monocytogenes (*Listeria monocytogenes sensu lato*) was redefined on the basis of DNA–DNA hybridization studies (Rocourt et al., 1982a) to comprise the species *Listeria monocytogenes sensu stricto*, *Listeria innocua* (Seeliger, 1981), *Listeria welshimeri* (Rocourt and Grimont, 1983), *Listeria seeligeri* (Rocourt and Grimont, 1983), and *Listeria ivanovii* (Seeliger et al., 1984). The genus includes one other species, *Listeria grayi* (Errebo Larsen and Seeliger, 1966). This classification is supported by the results of a second DNA–DNA homology study (Hartford and Sneath, 1993) and an analysis of multilocus enzyme electrophoresis (Boerlin et al., 1991). The study by Hartford and Sneath (1993) suggested a very close relationship between *Listeria monocytogenes* and *Listeria innocua* and there may be some overlap between these two species. DNA–DNA hybridization values obtained between different *Listeria* species are given in Table 44. Numbers of nucleotide differences and homology values of a continuous stretch of 1458 nucleotides of the 16S rRNA of *Listeria* species are given in Table 45. Signature sequences for different *Listeria* species within the V2 region of the 16S rRNA genes have been described (Collins et al., 1991).

On the basis of both phenotypic and genotypic characters, *Listeria grayi* shows a more distant relationship to the rest of the genus (Boerlin et al., 1991; Collins et al., 1991; Feresu and Jones, 1988; Hartford and Sneath, 1993; Kämpfer et al., 1991; Rocourt et al., 1982a; Wilkinson and Jones, 1977), but there is clear justification for the retention of *Listeria grayi* within the genus (Collins et al., 1991; Rocourt et al., 1987). There is insufficient justification for the renaming of this species as a new genus "*Murraya*" as suggested by Stuart and Welshimer (1974).

It is not anticipated that there will be major changes in the classification of this family in the future.

The species previously known as "*Listeria denitrificans*" (Prévot, 1961) is not a member of the genus *Listeria* and has been reclassified in a new genus *Jonesia denitrificans* (Rocourt et al., 1987).

Historical note. The original isolation of *Listeria monocytogenes* by Murray and colleagues (Murray et al., 1926) named this bacterium "*Bacterium monocytogenes*". The name was changed to "*Listerella monocytogenes*" following the recognition of the same bacterium by Pirie, which had been originally named as "*Listerella hepatolytica*" (Pirie, 1927). The genus was renamed *Listeria* (Pirie, 1940b) since "*Listerella*" had already been used for another genus of organisms (Pirie, 1940a). The conservation of the name *Listeria* was approved by the Judicial Commission on Bacteriological Nomenclature and Taxonomy (Judicial-Commission, 1954).

Comments on strains of *Listeria monocytogenes*

Although numerous *Listeria monocytogenes* cultures are available for study, most characterization has been performed on a small selection of strains (Table 46).

The type strain (originally designated 53 XXIII and was isolated from an animal in Cambridge, UK, in 1924; Murray et al., 1926) now shows atypical characteristics: most variants of this strain are non-hemolytic, CAMP-test-negative and some nonmotile (Kathariou and Pine, 1991), although hemolytic reactions on rabbit (Kathariou and Pine, 1991) and sheep (J. McLauchlin, unpublished data) blood have been detected. The type strain is non-virulent in laboratory models. A second culture from the 1924 outbreak (Murray et al., 1926) designated 58 XXIII was isolated from a different animal 2 d after the type strain. This second isolate is virulent in laboratory models, but generates non-hemolytic and avirulent mutants amongst the

TABLE 46. *L. monocytogenes* strains commonly used for laboratory characterization

Strain designation	Original source	Serovar	Available from: ^a	Comments
53 XXIII	Rabbit peritoneal exudates, Cambridge, UK, 1924 ^b	2-Jan	ATCC 15313, NCTC 10357, CIP 82.110, SLCC 53 SLCC 5850	Type strain, used for taxonomic and other studies ^c
58 XXIII	Guinea pig mesenteric lymph node, Cambridge UK, 1924 ^b	1/2a	NCTC 7973, ATCC 35152, CIP 54.149, SLCC 2371, ATCC 43248–51 ^d	Used for taxonomic, immunological, physiological, molecular biological, and virulence studies
Mackness/EGD	Origin uncertain, obtained by G.B. Mackness from E.G.D. Murray, Canada, in the 1960s ^e	1/2a	NCTC 12427, SLCC 5764	Extensively used for immunological, physiological, molecular biological, and virulence studies. Complete genome sequence available ^f
DPL10403S	Streptomycin-resistant variant of 10403 obtained from the laboratory of M.L. Gray, USA ^g	1/2a	Extensively used for molecular biological and virulence studies	
LO28	Human clinical isolate, Spain ^h	1/2c	Extensively used for molecular biological and virulence studies	
Scott A	Human clinical isolate, USA ⁱ	4b	ATCC 49594 ^j , ATCC 700302 ^j , ATCC 700301 ^j	Used as control strain, especially by food microbiologists in the USA
646/86	Soft cheese associated with case of human listerial meningitis, UK ^k	4b	NCTC 11994	Used as control strain, especially by food microbiologists in the UK

^aNCTC, National Collection of Type Cultures, London, UK; ATCC, American Type Culture Collection, Manassas, VA, USA; CIP, Institut Pasteur Collection, Paris, France; SLCC, Special Listeria Culture Collection, established by H.P.R. Seeliger in Wurzburg, now held by H. Hof, University of Heidelberg, Germany.

^bData from Murray et al. (1926).

^cCulture shows atypical reactions, usually nonhemolytic, nonmotile, and CAMP-test-negative; deletions in the *prfA* gene.

^dSpontaneously produced nonhemolytic variants with deletions in the *prfA* gene.

^eH. Hof, University of Heidelberg, personal communication.

^fData from Glaser et al. (2001).

^gData from Bishop and Hinrichs (1987).

^hData from Vicente et al. (1985).

ⁱData from Fleming et al. (1985).

^jAtypical forms, either forming petite colonies (Siragusa et al., 1990) or showing increased resistance to nisin (Mazzotta and Montville, 1997).

^kData from Bannister (1987).

hemolytic phenotype (Pine et al., 1987). Deletions of part of the *prfA* gene have been detected in the type strain and the non-hemolytic 58 XXIII (Gormley et al., 1989; Leimeister-Wachter and Chakraborty, 1989; Leimeister-Wachter et al., 1990). A request to substitute 58 XXIII for the type strain (53 XXIII; Jones and Seeliger, 1983) was rejected (Wayne, 1986). The type strain (53 XXIII) is serogroup 1/2 (flagella can not be detected in cultures from the NCTC or ATCC) and strain 58 XXIII serovar 1/2a. Representatives of these two cultures (53 XXIII and 58 XXIII) from various sources are indistinguishable by phage or pulsed-field gel electrophoresis and are therefore likely to be the same strain (J. McLauchlin, unpublished data).

The cultures designated EGD or Mackaness are used synonymously by some workers (Sokolovic and Goebel, 1989) and were originally obtained from E.G.D. Murray by G.B. Mackaness at the Trudeau Institute (USA) in the 1960s, although the initial origin(s) of these cultures are obscure. Mackaness certainly used 58XXIII (see above) as represented by NCTC 7973 (Miki and Mackaness, 1964), but also describes the use of "a recent human isolate supplied by Dr EGD Murray" (Blanden et al., 1966). Later publications from this laboratory refer to "EGD" without reference to the exact origin of the culture (Mackaness, 1969). Although some workers use the designations EGD and Mackaness synonymously (Sokolovic and Goebel, 1989), physiological and genetic differences between EGD and Mackaness have been reported (Bubert et al., 1992; Sokolovic and Goebel, 1989). DNA from an EGD strain was shown to have the same restriction pattern around the region of the hemolysin gene as 58 XXIII (Gormley et al., 1989). EGD and Mackaness are both serovar 1/2a, and on the basis of phage typing and pulsed-field

gel electrophoresis, two different types occur, either of which are designated EGD or Mackaness and these probably represent two distinct strains (J. McLauchlin, unpublished data). One of these strains is indistinguishable from those isolated from the 1924 outbreak in Cambridge which is the origin of the type strain (J. McLauchlin, unpublished data). EGD has been used extensively for immunological, and pathogenesis studies, and was the subject of much molecular biological analysis, including the production of a whole genome sequence (Glaser et al., 2001).

Two other *Listeria monocytogenes* strains have been studied using molecular biological techniques for the analysis of pathogenesis: i.e., DLP 10403S (serovar 1/2a) and LO28 (serovar 1/2c).

Two distinct strains have been used extensively by food microbiologists (Scott A and NCTC 11994), both of which are serovar 4b, which is the serotype most often involved with human infection. Scott A is principally used in the USA and NCTC 11994 in the UK. Both these strains were associated with human disease (Bannister, 1987; Fleming et al., 1985).

Differentiation of species of the genus *Listeria*

The differential characters of the species of *Listeria* are listed in Table 40. The antigenic structure used for serotyping *Listeria monocytogenes* together with a descriptive table of characters of *Listeria* species are shown in Table 42 and Table 41, respectively.

List of species of the genus *Listeria*

1. *Listeria monocytogenes* (Murray, Webb and Swann 1926) Pirie 1940a, 383^{AL} (*Bacterium monocytogenes* Murray, Webb and Swann 1926, 408)

mo.no.cy.to'ge.nes. N.L. n *monocytum* a blood cell, monocyte; Gr. v. *gennaio* to produce; N.L. adj. *monocytogenes* monocyte-producing.

Characteristics and differentiation from other *Listeria* species are given in Table 40. Antigenic composition for serotyping is shown in Table 42.

Habitat: Widely distributed in nature, found in soil, mud, sewage, vegetation and in the feces of animals and man. Pathogenic for animals and man; most cases are food- or feed-borne. In humans causes systemic illness (most often septicemia and/or meningitis) in immunocompromised adults or juveniles, as well as infecting the unborn infant.

DNA G+C content (mol%): 37–39 (T_m); 38 (Bd).

Type strain: ATCC 15313, CIP 82.110, DSM 20600, NCTC 10357, SLCC 53, 53XXII.

GenBank accession number (16S rRNA gene): U84148.

Complete genome sequences: *Listeria monocytogenes* EGD (2,944,528 bp; 39 mol% G+C, 2853 protein-coding genes) CLIP 11262 (Glaser et al., 2001). Unfortunately, the *Listeria monocytogenes* type strain was not included in the above studies.

Additional remarks: On the basis of both multilocus enzyme electrophoresis (Bibb et al., 1990; Piffaretti et al., 1989) and restriction fragment and sequence analysis of specific genes

(Comi et al., 1997; Gutkunst et al., 1992; Rasmussen et al., 1991; Vines et al., 1992; Vines and Swaminathan, 1998; Wiedmann et al., 1997), three lineages of *Listeria monocytogenes* have been identified that represent distinct evolutionary branches. These lineages correspond to serovars 1/2a, 1/2c and 3c (Lineage I), serovars 4b, 1/2b and 3b (Lineage II) and serovars 4a and 4c (Lineage III). Outbreaks of disease are most commonly associated with organisms from Lineages I and II and Lineage III have almost solely been isolated from animal hosts. However particular phenotypic characters that account for these differences have not been identified.

2. *Listeria grayi* Errebo Larsen and Seeliger 1966, 19^{AL} emend. Rocourt, Boerlin, Grimont, Jacquet and Piffaretti 1992, 173.

gray'i. N.L. gen. n. *grayi* of Gray, named in honor of M. L. Gray, an American bacteriologist.

Characteristics and differentiation from other *Listeria* species are given in Table 40. Antigenic composition for serotyping is shown in Table 42.

Habitat: Widely distributed in nature, found in soil, mud, sewage, vegetation and in the feces of animals and man. Not pathogenic for animals or man.

DNA G+C content (mol%): 41–42 (T_m).

Type strain: ATCC 19120, CCUG 4983, CCUG 5118, CIP 6818, CIP 105447, DSM 20601, LMG 16490, NCAIM B.01871, NCTC 10815, V-1.

GenBank accession number (16S rRNA gene): X56150, X98526.

Additional remarks: There are two subspecies of *Listeria grayi* (Rocourt et al., 1992): *Listeria grayi* subsp. *grayi* and *Listeria grayi* subsp. *murrayi* (previously named "*Listeria murrayi*"; Welshimer and Meredith, 1971). Differences between these two biotypes are shown in Table 47.

3. **Listeria innocua** (ex Seeliger and Schoofs 1979) Seeliger 1983, 439^{VP} (Effective publication: Seeliger 1981, 492).

in.noc'u.a. L. adj. *innocuus* harmless.

Characteristics and differentiation from other *Listeria* species are given in Table 40. Antigenic composition for serotyping is shown in Table 42.

Habitat: Widely distributed in nature, found in soil, mud, sewage, vegetation and in the feces of animals and man. Not pathogenic to animals or man.

DNA G+C content (mol%): 36–38 (T_m), 38 (Bd).

Type strain: ATCC 33090, CCUG 15531, CIP 80.11, DSM 20649, LMG 11387, NCTC 11288, SLCC 3379, 58/1971.

GenBank accession number (16S rRNA gene): X56152, X98527.

Complete genome sequences is available: *Listeria innocua* CLIP 11262 (3,011,209 bp; 37 mol% G+C, 2973 protein-coding genes) (Glaser et al., 2001).

4. **Listeria ivanovii** Seeliger, Rocourt, Schrettenbrunner, Grimont and Jones 1984, 336^{VP}

i.van.ov'i.i. N.L. gen. n. *ivanovii* of Ivanov, named in honor of Ivan Ivanov, a Bulgarian bacteriologist.

Characteristics and differentiation from other *Listeria* species are given in Table 40. Antigenic composition for serotyping is shown in Table 42.

Habitat: Widely distributed in nature, found in soil, mud, sewage, vegetation and in the feces of animals and man. Pathogenic for animals.

DNA G+C content (mol%): 37–38 (T_m).

Type strain: ATCC 19119, CCUG 15528, CIP 78.42, CLIP 12510, DSM 20750, LMG 11388, NCTC 11846, SLCC 2379, SV5.

GenBank accession number (16S rRNA gene): X56151, X98528.

Additional remarks: There are two subspecies of *Listeria ivanovii*, *Listeria ivanovii* subsp. *ivanovii* and *Listeria ivanovii* subsp. *londoniensis* (Boerlin et al., 1992). Differences between these taxa are shown in Table 47.

5. **Listeria seeligeri** Rocourt and Grimont 1983, 869^{VP}

see'li.ger.i. N.L. gen. n. *seeligeri* of Seeliger, named in honor of Heinz P.R. Seeliger, a German bacteriologist.

Characteristics and differentiation from other *Listeria* species are given in Table 40. Antigenic composition for serotyping is shown in Table 42.

Habitat: Widely distributed in nature, found in soil, mud, sewage, vegetation and in the feces of animals and man. Not pathogenic for animals or man.

DNA G+C content (mol%): 36 (T_m).

Type strain: Weis 1120, ATCC 35967, CCUG 15530, CIP 100100, DSM 20751, LMG 11386, NCAIM B.01873, NCTC 11856, SLCC 3594.

GenBank accession number (16S rRNA gene): X56148.

6. **Listeria welshimeri** Rocourt and Grimont 1983, 867^{VP}

wel.shi'mer.i. N.L. gen. n. *welshimeri* of Welshimer, named in honor of Herbert J. Welshimer, an American bacteriologist.

Characteristics and differentiation from other *Listeria* species are given in Table 40. Antigenic composition for serotyping is shown in Table 42.

Habitat: Widely distributed in nature, found in soil, mud, sewage, vegetation and in the feces of animals and man. Not pathogenic for animals or man.

TABLE 47. Phenotypic characteristics distinguishing subspecies of *Listeria ivanovii* and *Listeria grayi*^{a,b}

Characteristic	Species/subspecies	
	<i>L. ivanovii</i> subsp. <i>ivanovii</i>	<i>L. ivanovii</i> subsp. <i>londoniensis</i>
<i>Production of acid from:</i>		
N-Acetyl β-d-mannosamine ^c	–	+
Ribose	+	–
DNA–DNA hybridization	Group I	Group II
Multilocus enzyme electrophoresis cluster	Group I	Group II
Ribotype patterns using chromosomal DNA digested with <i>EcoRI</i>	EIV1 and EIV2	EIV3 and EIV4
Strains available ^d	NCTC 11846, ATCC, 19119, CIP 78.42	NCTC 12701, ATCC 49954, CIP 103466
	<i>L. grayi</i> subsp. <i>grayi</i>	<i>L. grayi</i> subsp. <i>murrayi</i>
Reduction of NO ₂ [–] to NO ₃ [–]	+	–
<i>Acid production from:</i>		
D-Lyxose	–	+
Methyl α-D-glucoside	+	–
L-Rhamnose	d	–
D-Turanose	–	+
Tween 80 esterase	+	–
Nonmurein composition of cell wall	Glucose, glucosamine	Rhamnose, glucose, glucosamine
Strains available	NCTC 10815, ATCC, 19120, CIP 105447	NCTC 10812, ATCC 25401, CIP 76.124

^aSymbols: +, >85% positive; d, different strains give different reactions (16–84% positive); –, 0–15% positive; w, weak reaction; ND, not determined.

^bData from Boerlin et al. (1992), Fiedler et al. (1984), Kämpfer et al. (1991), Rocourt and Catimel (1985), and Rocourt et al. (1992).

^cFermentation after 18–24 h.

^dNCTC = National Collection of Type Cultures, London, UK; ATCC = American Type Culture Collection, Manassas, VA, USA; CIP = Institut Pasteur Collection, Paris, France.

DNA G+C content (mol%): 36 (T_m).

Type strain: Welshimer V8, ATCC 35897, CCUG 15529, CIP 81.49, DSM 20650, LMG 11389, NCAIM B.01872, NCTC 11857, SLCC 5334.

GenBank accession number (16S rRNA gene): X56149, X98532.

Infrasubspecies divisions

The considerable recent interest in *Listeria monocytogenes* and in the epidemiology of listeriosis has resulted in the development of phenotypic and genotypic typing systems. Most of these methods were compared on a common set of cultures in a large multicentered study (Bille and Rocourt, 1996).

On the basis of agglutination reactions with absorbed rabbit antisera, *Listeria monocytogenes* can be subdivided into 13 serovars (Seeliger and Hone, 1979; Table 42). However, this system offers limited practical discrimination for epidemiological and ecological studies since the majority of strains causing disease (usually >90%) in both humans and other animals belong to serovars 1/2a, 1/2b, and 4b (Low and Donachie, 1997; McLauchlin, 1990; Seeliger and Hohne, 1979). Other phenotypic tests used for typing *Listeria monocytogenes* include: reactions with panels of lysogenic phage (lysotyping; Rocourt et al., 1985a; Loessner, 1991; McLauchlin et al., 1996); susceptibility to bacteriocins (monocins; Curtis and Mitchell, 1992); multilocus enzyme electrophoresis (Bibb et al., 1990; Piffaretti et al., 1989); and resistance to cadmium and arsenite (McLauchlin et al., 1997). Phage typing has had widespread use for epidemiological

typing, although interlaboratory comparability of results generated in different laboratories is problematic (McLauchlin et al., 1996).

The advent and widespread availability of molecular biological techniques has led to numerous molecular approaches to molecular typing, including: plasmid profiling (McLauchlin et al., 1997); restriction endonuclease digest of total chromosomal DNA (Nocera et al., 1993; Wesley and Ashton, 1991); probing Southern blots of chromosomal restriction endonuclease digests with probes for rRNA genes (ribotyping; Graves et al., 1991; Jacquet et al., 1992; Jaradt et al., 2002) or randomly cloned chromosomal DNA fragments (Ridley, 1995); separation of large DNA fragments by pulsed-field gel electrophoresis obtained by using low-frequency-cleavage restriction endonucleases (pulsed-field gel electrophoresis typing; Brosch et al., 1991); random amplification of polymorphic DNA (RAPD) analysis (Mazurier and Wernars, 1992); and amplified fragment length polymorphism (AFLP) analysis (Ripabelli et al., 2000). Some of these molecular methods allow a greater degree of interlaboratory comparability, and successful networks of laboratories have been established using standardized methods for pulsed-field gel electrophoresis with automatic pattern comparison of strain databases over the internet (Swaminathan et al., 2001). Results from methods based on random amplification of chromosomal sequences are still subject to laboratory variability. DNA sequenced based approaches are likely to become widely used in the future (Cai et al., 2002).

Genus II. *Brochothrix* Sneath and Jones 1976, 102^{AL}

PETER H. A. SNEATH

Bro.chothr'ix. Gr. n. *brochos* a loop; Gr. n. *thrix* a thread; N.L. fem. n. *Brochothrix* loop(ed) thread.

Regular unbranched rods, usually 0.6–0.75 μm in diameter and 1–2 μm in length. **Occur singly, in short chains, or in long filament-like chains that fold into knotted masses.** In older cultures the rods may give rise to coccoid forms, which develop into rod forms when subcultured onto a suitable medium. **Capsules are not formed.** **Gram-positive**, but some cells (both rod and coccoid forms) lose the ability to retain the Gram stain. **No endospores are produced.** **Nonmotile.** **Aerobic and facultatively anaerobic.** After 24–48 h, colonies on nutrient agar are opaque, 0.75–1.00 mm in diameter, and convex with entire margin. In older cultures (>2 d) the edge of the colony often breaks up and the center may become raised to give a “fried-egg” appearance. **Nonpigmented.** Nonhemolytic. **Optimum temperature 20–25°C; growth occurs within the range 0–30°C; over 30°C growth rarely occurs.** **Catalase is produced.** **Fermentative metabolism of glucose results in the production of L(+)-lactic acid and some other products.** **Methyl-red-positive.** Nitrate is not reduced. Indole-negative. H_2S -negative. No growth at pH 3.9 or on acetate medium. Arginine not hydrolyzed. Acid but no gas is produced from a number of carbohydrates. Acetoin and acetate are the major end products of aerobic metabolism of glucose. **Usually Voges–Proskauer-positive.** **Exogenous citrate and urea not utilized.** **Enzymes of the tricarboxylic acid cycle are almost totally absent.** Organic growth factors are required. The cell wall contains a directly cross-linked peptidoglycan based upon *meso*-diaminopimelic acid (*meso*-DAP). Mycolic acids are not present. The long chain fatty acid compo-

sition is predominately of the straight chain saturated, iso- and anteiso- methyl-branched chain types. Menaquinones are the sole respiratory quinones.

DNA G+C content (mol%): 36–38 (T_m).

Type species: ***Brochothrix thermosphacta*** (McLean and Sulzbacher 1953) Sneath and Jones 1976, 103^{AL} (*Microbacterium thermosphactum* McLean and Sulzbacher 1953, 432.).

Further descriptive information

Strains of *Brochothrix* grow at 4°C, but not at 37°C. Strains are positive for the following arylamidases (Talon et al., 1988): phenylalanine, histidine, glycyl-phenylalanine, seryl-tyrosine, glutamate, tryptophan, and histidyl-L-phenylalanine.

The following carbohydrates are fermented: glucose, ribose, fructose, mannose, *N*-acetylglucosamine, salicin, maltose, trehalose, and usually (>85%) glycerol, amygdalin, and cellobiose. Esculin is hydrolyzed.

Strains are sensitive to novobiocin, amikacin, tobramycin, gentamicin, ampicillin, and usually to tetracycline. Strains are resistant to oxacillin, nalidixic acid, and usually to colistin.

Enrichment and isolation procedures

Brochothrix thermosphacta is an important spoilage organism of meat and meat products stored aerobically or vacuum-packed at chill temperatures (Dainty and Hibbard, 1980; Gardner, 1981; Jones, 1992). Consequently, almost all isolation methods described for *Brochothrix thermosphacta* are concerned with its recovery from such sources.

After its first reputed isolation from pork trimmings and finished pork sausage (Sulzbacher and McLean, 1951), *Brochothrix thermosphacta* has been isolated on numerous occasions from the same sources and from a variety of animal and poultry meats or products based on them (see Gardner, 1981; Jones, 1992). Until fairly recently, there were few reports of the isolation of *Brochothrix thermosphacta* from other sources. McLean and Sulzbacher (1953) occasionally isolated it from equipment and tables used to prepare sausages, but assumed that its presence there was the result of contamination by pork trimmings since it could be isolated repeatedly from unopened barrels of such trimmings. Using a selective medium, Gardner (1966) isolated bacteria which he thought resembled *Brochothrix thermosphacta* from soil and feces. Collins-Thompson et al. (1971) suggested that some lipolytic Gram-positive bacteria isolated from dairy sources by Jayne-Williams and Skerman (1966) could be *Brochothrix thermosphacta*, but the published description of these organisms does not support this suggestion.

Brochothrix thermosphacta has been isolated from a wide variety of food products (especially meats) including fish (Gardner, 1981; Jones, 1992; Lannelongue et al., 1982; Nickelson et al., 1980). Both *Brochothrix thermosphacta* and *Brochothrix campestris* have been isolated from soil and grass, and the former has also been isolated from sheep wool and sheep feces (Talon et al., 1988). They are probably wide spread in the environment.

Enrichment is not usually performed for the isolation of *Brochothrix thermosphacta*. Wolin et al. (1957) placed irradiated sliced beef in sterile Petri dishes containing 3–5 ml sterile distilled water and incubated at 2°C in a slanting position until spoilage was evident. Samples plated out on a suitable nutrient agar yielded good growth of *Brochothrix thermosphacta*. There do not appear to be any other reports of enrichment.

Brochothrix thermosphacta is often the dominant organism in prepackaged meats and meat products stored at refrigerator temperature. The conditions prevailing during such storage selectively favor its growth. *Brochothrix thermosphacta* grows at 1–4°C and under conditions of low O₂ concentration (Gardner et al., 1967). The organism is mainly limited to the meat surface and grows at the meat/cling film interface (Ingram and Dainty, 1971). More recently, *Brochothrix* species have been shown to be dominant in salmon stored under Modified Atmosphere Packed (MAP) conditions (Rudi et al., 2004).

Swabs of various meat surfaces are directly plated onto suitable media, e.g., glycerol nutrient agar^{*} (Gardner, 1966) or glucose nutrient agar[†] (Sulzbacher and McLean, 1951; Wolin et al., 1957). Alternatively, samples of macerated meat or other materials suspended in saline (0.85%, w/v) or peptone water (0.1%, w/v) are shaken vigorously and appropriate dilutions spread on to the same media (see above) to give well separated colonies. In addition to *Brochothrix thermosphacta*, such procedures can result in the recovery of a wide variety of other bacteria, e.g., micrococci, staphylococci, lactobacilli, *Kurthia* species, and pseudomonads.

^{*} Glycerol nutrient agar: peptone (Oxoid), 20g; yeast extract (Oxoid), 2g; glycerol, 15g; K₂HPO₄, 1g; MgSO₄·7H₂O, 1g; agar (Oxoid No.3), 13g; distilled water, 1000ml; pH7.0. Autoclave 121°C for 15 min.

[†] Glucose nutrient agar: tryptone (Difco), 10g; yeast extract (Difco), 5g; K₂HPO₄, 5g; NaCl, 5g; agar (Difco), 15g; distilled water, 1000ml; pH7.0. Autoclave 121°C for 15 min.

Selective isolation of *Brochothrix thermosphacta* is achieved by the use of the selective medium (STAA)[‡] of Gardner (1966). After incubation of appropriate material on the medium at 20–22°C for 2d, almost all the colonies are those of *Brochothrix thermosphacta*. A few pseudomonads may also grow; these may be detected by their positive oxidase reaction. Members of the genera *Lactobacillus*, *Listeria*, *Erysipelothrix*, *Streptococcus*, and *Bacillus* and those coryneform bacteria tested do not grow on this medium. *Brochothrix campestris* can also be isolated on STAA (Talon et al., 1988).

Maintenance procedures

Cultures may be preserved for short periods (months rather than years) in nutrient agar (plus 0.1% (w/v) glucose) stabs in screw-capped bottles. After overnight incubation at 25–30°C, the caps should be screwed tightly and the bottles stored at room or refrigerator temperature in the dark.

Longer-term preservation (over 7 years) may be achieved by freezing on glass beads at –70°C (Feltham et al., 1978). The organisms can also be preserved by lyophilization.

Differentiation of the genus *Brochothrix* from other genera

Identification of new isolates may be achieved by examination of cellular morphology, maximum growth temperature, oxygen requirements, catalase production, and tests such as production of acid from various carbohydrates. The chemical composition of the cell wall and the lipid composition also aid the identification of *Brochothrix* but it is not usually necessary to perform these analyses for routine identification.

Morphologically, *Brochothrix* may be confused with *Kurthia*, but the two genera can be distinguished by their different O₂ requirements. *Brochothrix* is facultatively anaerobic while *Kurthia* is strictly aerobic. In addition, *Brochothrix* strains produce acid from a wide variety of carbohydrates, whereas *Kurthia* is asaccharolytic. The presence of *meso*-diaminopimelic acid (*meso*-DAP) as the cell-wall diamino acid also distinguishes *Brochothrix* from *Kurthia* (Schleifer and Kandler, 1972). The latter contains lysine in the cell wall.

The cell-wall peptidoglycan composition of *Brochothrix* also serves to distinguish it from *Erysipelothrix* which, like *Kurthia*, contains lysine as the major cell-wall diamino acid. Other features which distinguish *Brochothrix* from *Erysipelothrix* are the inability of *Brochothrix* to grow at 35°C and the catalase reaction. If the test is carried out under the correct conditions, *Brochothrix* is always catalase-positive while *Erysipelothrix* is catalase-negative.

Strains of *Brochothrix* are most likely to be confused with some members of the genus *Lactobacillus* and with the genus *Listeria*. The distinctive morphology and inability to grow at 35°C, presence of catalase, cytochromes and menaquinones (Collins and Jones, 1981; Collins et al., 1979a; Davidson and Hartree, 1968), and inability to grow on acetate medium, together with low mol% G+C differentiate *Brochothrix* from those lactobacilli which possess a cell-wall peptidoglycan containing *meso*-DAP. The fatty acid composition of *Brochothrix* is also different from that of lactobacilli. (Shaw, 1974; Shaw and Stead, 1970)

Brochothrix shares many characters in common with *Listeria*. Both genera are facultative anaerobes, produce acid from carbo-

[‡] STAA agar: to the molten glycerol nutrient agar (see above) add the following solutions in sterile distilled water: streptomycin sulfate (Glaxo) to a final concentration of 500 µg/ml, actidione (Upjohn) to 50 µg/ml, thallos acetate to 50 µg/ml. Mix well and dispense.

hydrates, contain catalase, possess *meso*-DAP as the cell-wall peptidoglycan, and have similar mol% G+C. They both fail to grow on acetate medium.

Colonies of *Brochothrix thermosphacta* do not show the blue-green coloration exhibited by *Listeria* when viewed by obliquely transmitted white light. *Brochothrix* is unable to grow at 35°C and is nonmotile unlike *Listeria*, and has a different morphology. No serological cross-reactions between *Brochothrix thermosphacta* and *Listeria* have been reported (Wilkinson and Jones, 1975).

Taxonomic comments

The genus *Brochothrix* is comprised of the bacteria isolated by Sulzbacher and McLean (1951) and named *Microbacterium thermosphactum* by McLean and Sulzbacher (1953) and *Brochothrix campestris* which was isolated by Talon et al. (1988). The genus

was tentatively placed in the family *Lactobacillaceae* by Sneath and Jones (1976). Strains of *Brochothrix thermosphacta* show over 85% DNA relatedness to one another, and strains of *Brochothrix campestris* show over 87% relatedness to one another; the two species show 15–40% relatedness (Talon et al., 1988).

Brochothrix and *Listeria* are closely related and form part of the super-cluster containing *Lactobacillus*, *Streptococcus*, and *Bacillus* (Collins et al., 1991; Morse et al., 1996; Stackebrandt and Woese, 1981; Talon et al., 1990). The closeness of *Brochothrix* to *Listeria* is supported by study of RNA polymerase (Morse et al., 1996).

Differentiation of species of the genus *Brochothrix*
There are two species of the genus *Brochothrix*. For the general characterization of the species, see the generic description. Additional characteristics are given under the species descriptions and the main differential characteristics of the two species are listed in Table 48.

List of species of the genus *Brochothrix*

1. ***Brochothrix thermosphacta*** (McLean and Sulzbacher 1953) Sneath and Jones 1976, 103^{AL} (*Microbacterium thermosphactum* McLean and Sulzbacher 1953, 432.).

ther'mos.phac.ta. Gr. n. *therme* heat; Gr. adj. *sphactos* slain; N.L. fem. adj. *thermosphacta* killed by heat.

Gram-positive rods with long chains, loops, and knots; no capsules; nonhemolytic. Does not survive heating at 63°C for 5 min. Cytochromes are produced. Acetate is a major end product of aerobic metabolism of glucose. Enzymes of the tricarboxylic acid cycle are almost totally absent.

In addition to the features given in the generic description, acid is produced fermentatively from cellobiose, dextrin, dulcitol, galactose, gentiobiose, lactose, mannitol, raffinose, sucrose, tagatose, and xylose. Weak or delayed acid production from adonitol, inositol, and melibiose. Acid seldom produced from erythritol, methyl D-glucoside, rhamnose, sorbose, or starch. Variable for arabinose, arbutin, inulin, melezitose, and sorbitol. Milk is made slightly acid, otherwise unchanged. Oxidase-negative. Sodium hippurate and cellulose are not hydrolyzed. Gelatin is not liquefied; casein may be hydrolyzed. Gluconate is not oxidized. Phosphatase is produced but not sulfatase or lecithinase. Deoxyribonuclease and ribonuclease activities are absent or very weak. Tweens 20, 40, and 80 are not hydrolyzed; Tween 60 hydrolysis is variable. Cellulose, tyrosine, and xanthine are not hydrolyzed. Grows on and reduces 0.05% potassium tellurite. Slime often formed from sucrose. Often reduces 0.01% tetrazolium. Grows in the presence of 6.5% NaCl and usually in the presence of 8% NaCl. Grows in the presence of 0.1% sodium nitrite and 0.03% thallos acetate. Often resistant to furadoine. Sensitive to gentamicin, polymyxin B, erythromycin, novobiocin, and ampicillin; resistant to nalidixic acid and streptomycin.

The cellwalls contain *meso*-DAP, glutamic acid, and alanine, but not arabinose or galactose. Mycolic acids are not present. Long chain fatty acids are predominantly of the straight chains saturated iso- and anteiso-methyl-branched chain types; the major ones are 12-methyltetradecanoic and 14-methylhexadecanoic acids. The major phospholipids are phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylethanolamine. The glycolipid fraction contains acetylated glucose and small amounts of glycosyl diglyceride. Menaquinones are the sole respiratory quinones. The major menaquinone contains seven isoprene units (MK-7).

Two colony types are frequently present even in young (24h) plate cultures (see Barlow and Kitchell, 1966). The colony types can appear so different that the culture may be thought to be contaminated. One type is convex, with entire edge and smooth surface; the other is flatter, with irregular edge and rough surface. On restreaking, individual colonies of both types give rise to colonies which exhibit both kinds of morphology.

Colony size is increased markedly if glucose is included in the medium; on such a medium *Brochothrix thermosphacta* has a sour odor due to the production of lactic acid, acetoin, acetic acid, and other fatty acids. Although it is facultatively anaerobic, better growth occurs in air.

There is general agreement that the temperature limits of growth are between 0°C and 30°C. However, limited growth has been noted at 35°C and one strain has been reported to grow at 37°C and at 45°C (see Gardner, 1981).

Brochothrix thermosphacta was originally classified in the genus *Microbacterium*, members of which are relatively heat-resistant; consequently, much attention has been paid to the heat resistance of this species (Gardner, 1981) because of its importance in food spoilage. All workers agree that the organism does not survive heating at 63°C for 5 min. However, Gardner (1981) has suggested that it is more useful to characterize the heat resistance by its D value (decimal reduction time), defined as the time (min) for a 10-fold reduction in the population under specified conditions.

The optimum pH for growth of *Brochothrix thermosphacta* is 7.0 but growth occurs from pH 5.0 to 9.0 (Brownlie, 1966). The ability of *Brochothrix thermosphacta* to grow in the presence of NaCl has been examined by many workers (Gardner, 1981).

TABLE 48. Differential characteristics of species of the genus *Brochothrix*

	<i>B. campestris</i>	<i>B. thermosphacta</i>
Growth with 8% NaCl after 2 d	–	+
Growth with and reduction of 0.05% potassium tellurite	–	+
Hippurate hydrolysis	+	–
Acid from rhamnose	+	–

All strains grow in the presence of 6.5% NaCl, but reports differ on growth at higher concentrations. Many strains tolerate 10% NaCl. Whether the differences are due to different strains or to different methodologies is not clear (Gardner, 1981).

Growth is inhibited by nitrite, but this is related to pH and temperature (Brownlie, 1966). Low pH and low temperatures increase the inhibition.

Collins-Thompson and Rodriguez-Lopez (1980) state that, unlike many lactic acid bacteria, *Brochothrix thermosphacta* does not appear to have a nitrite reductase system. It tolerates 500 ppm of SO_2 under both aerobic and anaerobic conditions (Dowdell and Board, 1971). Palmitic acid is inhibitory in liquid culture (Macaskie, 1982). Addition of nisin to meat products significantly inhibits its growth (Cutter and Siragusa, 1998). *Brochothrix thermosphacta* does not grow on the acetate medium of Rogosa et al. (1951) and only poorly on the MRS medium of De Man et al. (1960). These media were devised, respectively, for the selective isolation and for the cultivation of lactobacilli.

Sutherland et al. (1975) reported that *Brochothrix thermosphacta* attacked tributyrin but not beef fat. However, Patterson and Gibbs (1978) found that not one of their 95 isolates attacked tributyrin, an observation in agreement with the results of Davis et al. (1969). Collins-Thompson et al. (1971) demonstrated the presence of a glycerol ester hydrolase in *Brochothrix thermosphacta*. This lipase was active on tripropionin, tributyrin, tricaproin, tricapyrin and trilaurin but not tripalmitin. The temperature optimum of the lipase was 35–37°C with little or no activity below 20°C.

Brochothrix thermosphacta possesses a high level of enzymes associated with the catabolism of glucose (Collins-Thompson et al., 1972; Grau, 1983). Fermentative metabolism of glucose always results in the production of L(+)-lactic acid. Other end products appear to depend on the conditions of growth. McLean and Sulzbacher (1953) found only L(+)-lactic acid present in detectable quantities. Davidson et al. (1968) also reported L(+)-lactic acid to be the main end product of glucose fermentation, but small amounts of acetic and propionic acids were also detected. In glucose-limited continuous culture under anaerobic conditions, the end products of glucose metabolism have been identified as L(+)-lactic acid and ethanol (Hitchener et al., 1979). Grau (1983) reported that the organism ferments glucose anaerobically to L(+)-lactate, acetate, formate, and ethanol, and that the ratio of these products varies with the conditions of growth. Although McLean and Sulzbacher (1953) reported CO_2 production from fermentation of carbohydrates, this has not been confirmed in subsequent studies.

Aerobically the major end products of glucose metabolism are acetoin, and acetic, isobutyric, and isovaleric acids (Dainty and Hibbard, 1980). The relative proportions are also affected by growth conditions. Low glucose concentrations and neutral pH favor fatty acid production; high glucose and low pH favor acetoin production. Similar results were obtained with ribose and glycerol. Acetoin and probably acetic acid are derived from the carbohydrates, and isobutyric and isovaleric acids are derived from valine and leucine respectively (Dainty and Hibbard, 1980).

When *Brochothrix thermosphacta* is grown in a complex medium, enzymes of the tricarboxylic acid (TCA) cycle are almost totally absent (Collins-Thompson et al., 1972) However,

it has been suggested that in a defined, less complex medium, the TCA cycle enzymes may be sufficiently active to provide substrates for synthesis but not to provide energy (Grau, 1979).

Brochothrix thermosphacta requires cysteine, lipoate, nicotinate, pantothenate, *p*-aminobenzoate, biotin, and thiamine for aerobic growth in a glucose-mineral salts medium (Grau, 1979). The organism can also grow anaerobically in this medium. Macaskie et al. (1981) showed that most, but not all, of the yeast extract requirement of *Brochothrix thermosphacta* can be fulfilled by thiamine.

Brochothrix thermosphacta contains cytochromes and is unequivocally catalase-positive when cultured on a suitable medium and incubated at 20°C. Care must be taken when examining cultures for the presence of catalase. Production of the enzyme is dependent on both the growth medium and the temperature of incubation. Davidson et al. (1968) noted that *Brochothrix thermosphacta* strains grown on APT Medium (Difco) incubated at 20°C were always catalase-positive but that weak or negative reactions were obtained on HIA Medium (Difco) incubated at the same temperature. The same authors reported that negative results were obtained frequently if the bacteria were grown on either medium incubated at 30°C. This has been our experience, but we have found that BAB No. 2 (Difco) is a satisfactory alternative medium for APT (Difco). Davidson and Hartree (1968) showed that *Brochothrix thermosphacta* contained cytochromes *aa₃b* and noted the same effects of growth medium and temperature on the quantitative cytochrome content of the organism. No satisfactory explanation can be offered for the differences in cytochrome and catalase content. It does not appear to be due to a difference in the concentration of heme compounds in the different media. In APT Medium (Difco) – a medium which favors the formation of catalase and cytochromes – the concentration of heme compounds has been reported to be too low to be detected by the sensitive hemochromogen technique (Davidson and Hartree, 1968) but they noted that the APT Medium (Difco) does contain added iron (8.0 µg/ml). Gill et al. (1992) found that *Brochothrix thermosphacta* produced cytochromes of the *a*-, *b*- and *d*-types at 10–15°C. In high oxygen concentrations they were mostly of the *a*-type but at low oxygen tension these disappeared and were replaced by *d*-type cytochromes.

Little serological work has been carried out with *Brochothrix thermosphacta*. Wilkinson and Jones (1975) could demonstrate no serological relationships between *Brochothrix thermosphacta* and species of the genera *Listeria*, *Erysipelothrix*, and *Kurthia*.

Bacteriophages active on *Brochothrix thermosphacta* have been isolated from aqueous extracts of spoiled beef (Greer, 1983). Phage plaque size and plating efficiency were reported to be increased significantly when the incubation temperature was reduced from 25 to 1°C. Fourteen distinct phage lysotypes were detected. Greer (1983) suggested that phage typing may provide a rapid method of differentiating *Brochothrix thermosphacta* strains. None of the high titer lysates of any of the *Brochothrix thermosphacta* phages was capable of lysing *Corynebacterium flavescens*, *Microbacterium lacticum*, *Lactobacillus mali*, *Lactobacillus plantarum*, *Jonesia denitrificans*, or *Listeria grayi*.

All the *Brochothrix thermosphacta* strains typed by Greer (1983) appeared to form a homogeneous group on the basis of their

other phenotypic characters. However, as indicated by phage typing, the species may not be as homogeneous as currently thought. An investigation of the esterases of a number of *Brochothrix thermosphacta* strains by gel electrophoresis indicated the presence of seven groups among the strains examined. There was no association between groups based on esterase patterns and source of isolation (Gardner, personal communication). It is possible that strains of *Brochothrix campestris* have been misidentified as *Brochothrix thermosphacta* (McCormick et al., 1998).

There is no evidence that *Brochothrix thermosphacta* is pathogenic. It is an economically important meat-spoilage organism because it grows in a wide variety of meats and meat products at low temperatures, and produces malodorous metabolic end products which make affected meat unpalatable. The main products that affect flavor are acetoin, diacetyl, and 3-methylbutanol (Dainty and Mackey, 1992). *Brochothrix thermosphacta* constitutes the major proportion of the microflora in packaged meats under vacuum-pack or aerobic high CO₂ concentration packing if the packaging film is of low permeability to oxygen. If the film is of high permeability, pseudomonads predominate, and *Listeria monocytogenes* may increase (Tsigarida et al., 2000). *Brochothrix thermosphacta* grows better at 5°C than 1°C; it is tolerant of carbon dioxide and can compete with lactic acid bacteria at low pH (Dainty and Mackey, 1992).

DNA G+C content (mol%): 34.6–36.2 (T_m).

Type strain: ATCC 11509, CCUG 35132, CIP 103251, DSM 20171, HAMBI 1439, NBRC 12167, LMG 17208, NCTC 10822.

GenBank accession number (16S rRNA gene): AY543023, M58798.

- cam.pes’tris. L. fem. adj. *campestris* from the fields.
- Gram-positive rods, usually a mixture of long and short rods, found singly or in pairs. Colonies are circular, not pigmented, 0.7–1.0 mm in diameter after 48 h at 25°C.
- In addition to the features given in the genus description, *Brochothrix campestris* shows the following characteristics: no growth with 8% or 10% NaCl or with 0.05% potassium tellurite; slime is not produced from sucrose; 0.01% tetrazolium is reduced; sodium hippurate is hydrolyzed; gelatin is not liquefied.
- Acid but no gas is formed from arbutin and rhamnose and usually from gentobiose. Results are variable for inositol, mannitol, starch, sucrose, and tagatose. Sensitive to furadoine.
- Brochothrix campestris* produces a bacteriocin, brochocin-C (McCormick et al., 1998; Siragusa and Cutter, 1993). This is active on a wide range of Gram-positive bacteria, including strains of *Brochothrix thermosphacta* and species of *Carnobacterium*, *Kurthia*, *Enterococcus*, *Lactobacillus*, *Pediococcus*, and *Listeria*, but not on intact Gram-negative bacteria (although it is active on EDTA-treated cells of *Escherichia coli*). It is a class II bacteriocin which is cleaved to two peptides, BrcA and BrcB. The gene for a brochocin-C immunity protein, BrcI, is adjacent to the gene for brochocin-C. Brochocin-C may have promise as a food preservative.

Family IV. *Paenibacillaceae* fam. nov.

PAUL DE VOS, WOLFGANG LUDWIG, KARL-HEINZ SCHLEIFER AND WILLIAM B. WHITMAN

Pae.ni.ba.cil.la'ce.ae. N.L. masc. n. *Paenibacillus* type genus of the family; suff. *-aceae* ending denoting family; N.L. fem. pl. n. *Paenibacillaceae* the *Paenibacillus* family.

The family *Paenibacillaceae* is circumscribed for this volume on the basis of phylogenetic analyses of the 16S rRNA sequences and includes the genus *Paenibacillus* and its close relatives. This family is distributed between two phylogenetic clusters. *Paenibacillus*, *Brevibacillus*, *Cohnella*, and *Thermobacillus* are monophyletic and represent the first group. The second clearly monophyletic group comprises the genera *Aneurinibacillus*, *Ammoniphilus*, and *Oxalophagus*. Although these two clusters are often associated together in several types of analyses, the evidence to unite them is not strong. However, in the absence of clear evidence for a separation, the second cluster is retained within the family. In contrast, *Thermicanus*, which was also classified within this family by Garrity et al. (2005), appears to represent a novel lineage of the *Bacilli*. In recognition of its ambiguous status, it was reclassified within Family X *Incertae Sedis*.

Cells are straight to curved rods, generally 0.5–1.0 × 2–6 μm. While the cell-wall type is Gram-positive and contains *meso-*

diaminopimilic acid, cells may stain Gram-negative, variable or positive. Oval or ellipsoidal endospores are formed, frequently swelling the sporangium. Motility with peritrichous flagellation is common, although some species are nonmotile. May be strictly aerobic, microaerophilic, facultative aerobic, or obligate anaerobic. May be catalase-positive or -negative. Organoheterotrophs, utilizing complex media, carbohydrates and amino acids. Some species utilize only oxalic acid as sole carbon and energy source. Both mesophilic and thermophilic, neutrophilic and alkaliphilic. Isolated from soil, roots, feces, blood, and other sources. Abundant fatty acids include C_{15:0 anteiso}, C_{15:0 iso}, C_{16:0 iso}, and C_{16:0}. The major isoprenoid quinones are MK-7 or MK-6 (*Thermobacillus*).

DNA G+C content (mol%): 36–59.

Type genus: ***Paenibacillus*** Ash, Priest and Collins 1994, 852^{VP} (Effective publication: Ash, Priest and Collins 1993, 259) emend. Shida, Takagi, Kadowaki, Nakamura and Komagata 1997a, 297.

Genus I. ***Paenibacillus*** Ash, Priest and Collins 1994, 852^{VP} (Effective publication: Ash, Priest and Collins 1993, 259) emend. Shida, Takagi, Kadowaki, Nakamura and Komagata 1997a, 297

FERGUS G. PRIEST

Pae.ni.ba.cil'lus. L. adj. *paene* almost; bacterial name *Bacillus*; N.L. masc. n. *Paenibacillus* almost a bacillus.

Rod-shaped cells of Gram-positive structure, but usually stain variable or negative in the laboratory. Oval endospores are formed that distend the sporangium. Motile by means of peritrichous flagella. Facultatively anaerobic or strictly aerobic. Most species are catalase-positive. Colonies are generally smooth and translucent, light brown, white, or sometimes light pink in color. Optimum growth generally occurs at 28–40°C and pH 7.0, although strains of some species are alkaliphilic. Growth is inhibited by 10% NaCl. **Major fatty acid is C_{15:0 anteiso}.** Additional important fatty acid fractions often contain C_{16:0}, C_{15:0 iso}, and C_{17:0 anteiso}. **Two forward PCR primers, PAEN515F (5'-GCTCG-GAGAGTGACGGGTACCTGAGA) and 843F (5'-TCGATAC-CCTTGGTGCCGAAGT) have been described, either of which can be used with an appropriate reverse primer, for example 1484R (TACCTTGTTACGACTTCACCCCA), for diagnostic amplification from the 16S rRNA gene.**

DNA G+C content (mol%): 40–59.

Type species: ***Paenibacillus polymyxa*** (Prazmowski 1880) Ash, Priest and Collins 1994, 852^{VP} (Effective publication: Ash, Priest and Collins 1993, 259) (*Clostridium polymyxa* Prazmowski 1880, 37; *Bacillus polymyxa* Macé 1889, 588).

Further descriptive information

Phylogenetic treatment. *Paenibacillus* emerged from the early phylogenetic dissection of *Bacillus sensu lato* based on 16S rRNA gene sequences (Ash et al., 1993). Originally referred to as RNA group 3, it soon became evident that this monophyletic

group was distinct from other endospore-forming bacteria. Two conserved areas of the 16S rRNA gene have been exploited for identification of *paenibacilli*. A sequence from 843–862 (*Escherichia coli* numbering) was used to provide the original diagnostic oligonucleotide probe (5'-TCGATACCCTGGT-GCCGAAGT) (Ash et al., 1993) and, although the genus has expanded to more than 80 species, this sequence remains highly specific. *Paenibacillus alginolyticus* and *Paenibacillus chondroitinus* show one base variation from the consensus (the A at position 5 is missing) and *Paenibacillus apiarius* contains a C at position 19; all other *Paenibacillus* species included in this chapter contain this sequence intact. A second oligonucleotide primer has been found useful for diagnostic purposes (Shida et al., 1997a). The variation in 16S rRNA gene sequences is greater in the target region of primer PAEN515F (5'-GCTCG-GAGAGTGACGGGTACCTGAGA) and it has not been tested with representatives of all *Paenibacillus* species. In particular, bases 6–10 (i.e., GAGAGTGA) are very unstable in the various species sequences. Nevertheless, in my experience, it has provided accurate and reproducible assignment of strains to the genus. Either of these primers can be used as a forward primer with a universal reverse primer for diagnostic PCR (Pettersson et al., 1999). An overall phylogenetic tree is given in Figure 24 based on 16S rRNA gene sequences. According to Goto et al. (2002), the HV region of the 16S rRNA gene is the best region for species discrimination, although only a limited number of species have been tested.

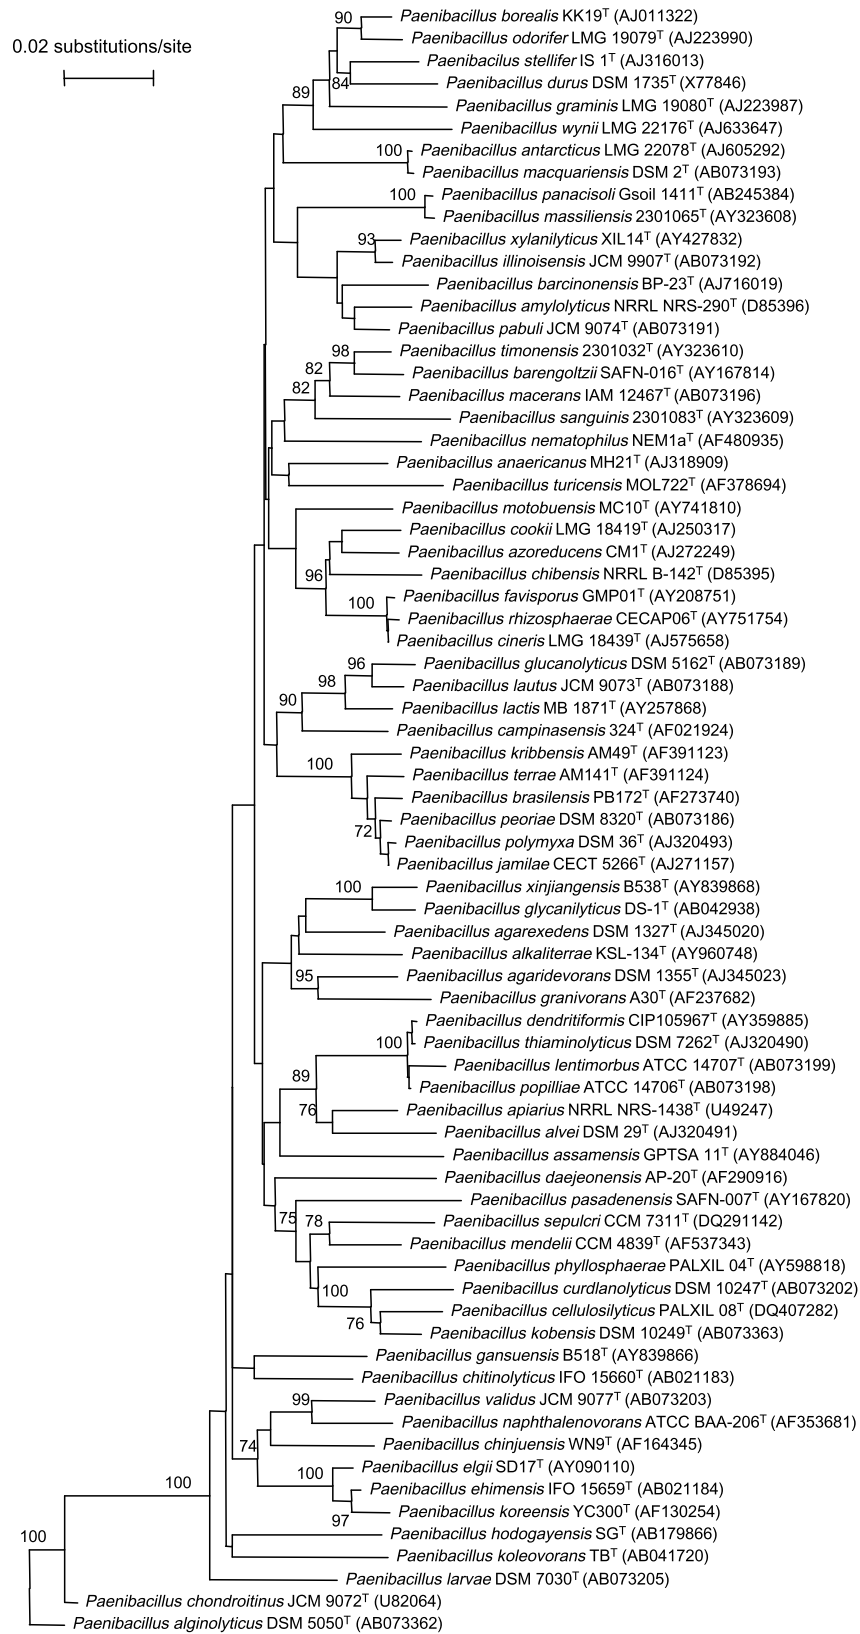

FIGURE 24. Phylogenetic neighbor-joining tree of all type strains within the genus *Paenibacillus* based on 16S rRNA gene sequences. Tree was constructed using CLUSTAL_X, BioEdit (1367 bp) and TREECON software. Bootstrap values are based on 1000 replications; values above 70% are shown at the branch nodes.

Cell structure and morphology. Paenibacilli are rod-shaped organisms generally measuring 2–5 μm in length and 0.5–0.8 μm in width. Although they have a Gram-positive wall structure, they almost invariably appear Gram-negative under the microscope, especially in older cultures. All species produce endospores that are usually of a greater diameter than the mother cell or sporangium and thus produce swelling of the sporangium (Figure 25). The spores of *Paenibacillus macerans* and *Paenibacillus polymyxa* have a heavily ridged surface and those of *Paenibacillus borealis* have a similar striped morphology (Elo et al., 2001). In transverse section, this can be confused with a spiked morphology. Most species are motile by peritrichous flagella, although in a few cases motility may be restricted to a minority of cells (e.g., *Paenibacillus popilliae*) or be absent (*Paenibacillus lentimorbus*). The cell wall peptidoglycan of those species that have been studied is invariably of the meso-diaminopimelic acid (DAP) type. Capsules are produced by some species under suitable growth conditions. *Paenibacillus polymyxa*, for example, synthesizes a levan capsule when grown with sucrose as carbon source. Some species produce extracellular polysaccharide (Aguilera et al., 2001; Yoon et al., 2002). S-layers are probably present in most species, although they have been reported in relatively few (e.g., *Paenibacillus alvei* and *Paenibacillus polymyxa*). The complete structure of the S-layer glycoprotein and its linkage to the peptidoglycan layer of the cell wall have been reported for *Paenibacillus alvei* (Schaffer et al., 2000).

The fatty acid composition of the paenibacilli is characteristic, containing predominantly $\text{C}_{15:0 \text{ anteiso}}$, which generally comprises around 55% total fatty acids, but ranges from 34% (*Paenibacillus naphthalenovorans*) to 80% (*Paenibacillus macquariensis*). $\text{C}_{17:0 \text{ anteiso}}$, $\text{C}_{16:0 \text{ iso}}$, and $\text{C}_{16:0}$ generally comprise the remainder of the fatty acids.

Colony characteristics. Paenibacilli usually produce small, translucent or light brown/white, sometimes pink or yellowish, colonies on agar plates. Colonies of pure cultures often show variations in opacity. This may be due to the degree of sporulation, the colonies becoming less translucent as they sporulate. Most paenibacilli are non-pigmented, the only exceptions are *Paenibacillus larvae* subsp. *pulvifaciens*, which may produce yellow-orange colonies, and the light pink colonies of *Paenibacillus chinjuensis*.

FIGURE 25. Phase-contrast micrograph of sporulating cells of *Paenibacillus polymyxa* DSM 36^T. Bar = 5 μm .

Paenibacillus alvei is notable for its motile microcolonies that rapidly migrate over agar media, even on well-dried plates. Other species with motile colonies include some taxa previously included in *Bacillus circulans*, such as *Paenibacillus glucanolyticus*, and some recently described species including *Paenibacillus campinasensis* and *Paenibacillus curdlanolyticus*. Colony motility can readily be observed at a magnification of about $\times 50$ under transmitted light.

Paenibacillus strains have also been noted for the formation of complex colonial patterns when grown under suboptimal conditions such as on low nutrient media (Cohen et al., 2000) or in the presence of antibiotics (Ben-Jacob et al., 2000). The term morphotype is used to describe the pattern-forming capacity of micro-organisms (Fujikawa and Matsushita, 1989). Different morphotypes of *Paenibacillus dendritiformis* produce both “tip-splitting” and “chiral” patterns (Figure 26) when grown under starvation conditions such as 0.2% peptone agar (Tcherpakov et al., 1999).

Nutrition and metabolism. Most paenibacilli grow on nutrient agar at neutral pH although inclusion of a fermentable carbon source (e.g., 0.5% glucose) will generally enhance growth. Tryptone soy agar (TSA) is a good alternative to nutrient agar. Exceptions include *Paenibacillus campinasensis* and *Paenibacillus daejeonensis*, which are alkaliphiles and do not grow below pH 7.5, and the fastidious insect pathogens *Paenibacillus lentimorbus* and *Paenibacillus popilliae*, which are best grown in J-broth: tryptone, 5.0 g; yeast extract, 15.0 g; K_2HPO_4 , 3.0 g; glucose (sterilized separately), 2.0 g; and distilled water to 1000 ml. The pH should be adjusted to 7.3–7.5 before autoclaving. MYGGP broth (Dingman and Stahly, 1983) is an alternative and comprises: Mueller–Hinton broth, 10 g; yeast extract, 10.0 g; K_2HPO_4 , 3.0 g; glucose (sterilized separately), 0.5 g; sodium pyruvate, 1.0 g; and distilled water to 1000 ml. The pH is adjusted to 7.1 before autoclaving. Some recently described species (e.g., *Paenibacillus cookii* and *Paenibacillus cineris*) need a lower pH for optimal growth. Media can be solidified by the addition of agar. *Paenibacillus larvae* will grow on nutrient agar, but is best grown on one of these more complex media. Most species grow optimally at around 30°C. However, *Paenibacillus macquariensis* is an exception to this being a psychrophile with a maximum growth temperature of 25°C and *Paenibacillus cineris* has a very wide temperature range for growth (0–50°C), probably due to dramatic changes in its natural environment (fumaroles).

Paenibacillus species do not form spores under all cultural conditions. Supplementation of nutrient media with a mixture of salts, for example MnCl_2 (50 μM), CaCl_2 (700 μM) and MgCl_2 (1 mM), is usually effective in enhancing sporulation.

Paenibacillus species are noted for their ability to hydrolyze a variety of carbohydrates. Carboxymethyl cellulose, chitin, chondroitin, curdlan (β -1,3-glucan), pustulan (β -1,6-glucan), β -1,4-glucan, pullulan (maltotriose units linked by α -1,6-glycosidic bonds), starch and xylan are variously hydrolyzed by different species. Indeed, *Paenibacillus glycanilyticus* was selectively isolated on the basis of its ability to hydrolyze the β -linked extracellular heteropolysaccharide from *Nostoc commune* (Dasman et al., 2002). *Paenibacillus naphthalenovorans* and *Paenibacillus validus* are atypical in their ability to degrade hydrocarbons (Daane et al., 2002), although few species have been tested in this respect so it may be more common than appreciated.

FIGURE 26. Pattern-forming colonial growth in *Paenibacillus* showing T (tip-splitting), C (chiral), and V (vortex) morphotypes. The fourth panel shows a close-up of the chiral tips. T and C are two variants of *Paenibacillus dendritiformis* that form in response to changes in the agar concentration. Vortex is an isolate of *Paenibacillus* that is closely related to *Paenibacillus lautus* (photographs courtesy of D. L. Gutnick, University of Tel Aviv).

These bacteria are predominantly facultative anaerobes but, as the genus has expanded, more strictly aerobic species have been introduced (Table 49). During growth of *Paenibacillus macerans* with glucose as carbon source, the Embden–Meyerhof pathway is used to generate pyruvate, which is converted initially to ethanol, acetic acid, and small amounts of formate. As the culture ages, the formate and acetate are catabolized to H₂, CO₂, and acetone (Weimer, 1984); hence the production of acid and gas from carbohydrates noted in the diagnostic tests (Table 49). *Paenibacillus polymyxa* is noted for its production of 2,3-butanediol during sugar catabolism, particularly at low pH (Marwoto et al., 2002; Raspoet et al., 1991). Like *Paenibacillus macerans*, it also produces hydrogen during sugar fermentation. The ability to use nitrate as an exogenous electron acceptor during anaerobic growth is a variable feature of these bacteria (Table 49).

The genus *Paenibacillus* currently includes 10 nitrogen-fixing species, although it needs to be mentioned that this character has not been tested systematically (Table 49). The *nifH* (dinitrogen reductase) gene has been detected in several of these species and is more closely related to the *nifH* of other aerobic prokaryotes than to the genes present in the anaerobic nitrogen-fixing genera such as *Clostridium* (Achouak et al., 1999). Nitrogen fixation does not seem to occur among other aerobic, endospore-forming genera.

Insect pathogenicity Members of the genus *Paenibacillus* have not been associated with human or mammalian pathogenicity, but some strains are important pathogens of insects. *Paenibacillus larvae* subsp. *larvae* causes foulbrood of honeybee (*Apis mellifera*) larvae (Chantawannakul and Dancer, 2001). The bacterium produces a fatal septicemia following ingestion of endospores. The spores germinate and grow in the larval midgut. Vegetative cells then traverse the epithelium and enter the hemocoel where they grow and sporulate in massive numbers. Infected individuals turn brown, then black, and the resultant mass becomes a hard scale of material deposited on the side of the honeycomb cell. The disease is so important that infected hives must be destroyed, generally by burning (Matheson and Reid, 1992). Methods for the recognition of *Paenibacillus larvae* subsp. *larvae* by PCR have been published (Alippi et al., 2002).

Paenibacillus larvae subsp. *pulvifaciens* has been associated with powdery scale of beehives. This material comprises the remnants of dead larvae, but it is still not clear whether the bacterium causes larval death. Indeed, it seems likely that the bacterium is non-pathogenic since reintroduction of the bacterium into healthy larvae does not induce the disease (Gilliam and Dunham, 1978). Recently both subspecies have been united again into the same species, *Paenibacillus larvae*, without subspecies discrimination based on a polyphasic study of additional strains (Genersch et al., 2006).

Paenibacillus lentimorbus and *Paenibacillus popilliae* cause milky disease in certain scarabaeid beetle larvae, notably the Japanese beetle, a common pest of lawn grass. The disease is named after the characteristic appearance of the normally translucent larvae, which become turbid due to the massive growth and sporulation of the bacteria in the hemolymph (Klein and Kaya, 1995). In brief, the larva eats the spore that germinates in the hindgut. Vegetative cells invade the hemolymph where they grow and sporulate, often reaching 10¹⁰ cells per ml. Death follows about 2 weeks after initial ingestion. Crystal proteins have been

observed in sporulating cells of *Paenibacillus popilliae*, although their contribution to virulence has not been established. They have also been noted in a subgroup of *Paenibacillus lentimorbus* strains from South America that could be distinguished by DNA hybridization and molecular typing using random amplified polymorphic DNA (Harrison et al., 2000; Rippere et al., 1998). It is also noteworthy that crystal-forming strains have been isolated from insects other than Japanese beetle (*Popillia japonica*). Interestingly, the crystal protein of *Paenibacillus popilliae* shares some 40% sequence identity with the Cry2 polypeptides of *Bacillus thuringiensis* (Zhang et al., 1997). The two species are responsible for slightly different forms of milky disease. *Paenibacillus popilliae* causes type A milky disease and *Paenibacillus lentimorbus* has been associated with type B. The latter is characterized by the appearance of brown clots that block the circulation of hemolymph and lead to gangrenous conditions in the affected parts. The two species can be distinguished using molecular taxonomic techniques (Rippere et al., 1998).

Paenibacillus lentimorbus and *Paenibacillus popilliae* are often referred to as obligate pathogens of insects because it has proved impossible to determine *in vitro* conditions for sporulation and consequently growth in the host is necessary for the life cycle of the bacterium to be completed. This inability to culture spores *in vitro* has hampered the introduction of these bacteria for the biocontrol of Japanese beetle.

Ecology The normal habitat of the paenibacilli is the soil, particularly soils rich in humus and plant materials in which they presumably aid composting through the secretion of extracellular carbohydrases and other enzymes. Strains of several species, in particular the nitrogen-fixing species such as *Paenibacillus polymyxa*, have been associated with the rhizosphere of plants and important crop species. These bacteria enhance the growth of various plants by the production of phytohormones (Lebuhn et al., 1997; Timmusk et al., 1999) or by providing nutrients including nitrogen. They also produce antifungal compounds (Beatty and Jensen, 2002; Walker et al., 1998) and enzymes (Mavingui and Heulin, 1994) that help suppress fungal disease. *Paenibacillus polymyxa* is ubiquitous as a rhizosphere bacterium, particularly associated with grasses including crop plants such as wheat (Guemouri-Athmani et al., 2000). *Paenibacillus durus* (previously *Paenibacillus azotofixans*), on the other hand, has only been found in Brazilian and Hawaiian soils (Rosado et al., 1998). *Paenibacillus borealis* was isolated from humus in Scandinavian spruce forests, suggesting geographic localization of various species (Elo et al., 2001).

Enrichment and isolation procedures

There are no general methods for the isolation of members of the genus *Paenibacillus*. Standard procedures for selective isolation of endospores are helpful. Samples are generally heated above 70°C for 10 mins or longer to destroy vegetative cells and plated onto appropriate media for germination and outgrowth of endospores. Variations on this theme may enable the isolation of a more diverse range of bacteria. For example, exposure to 50% ethanol for 60 min will allow the survival of endospores while killing vegetative cells and may enable the recovery of spores that may be sensitive to heat. A method based on selective germination can be useful for *Paenibacillus* strains. A soil sample is heat-treated as described above, inoculated in broth for

TABLE 49. (continued)

a short period (e.g., 4 h) to allow spores to germinate and then heat-treated a second time before plating onto suitable media. Many common *Bacillus* species such as *Bacillus cereus*, *Bacillus licheniformis*, and *Bacillus subtilis* that germinate and grow vigorously can be eliminated in this way, whereas the *Paenibacillus* spores that germinate slowly survive the second pasteurization and form colonies on the plates.

In general, broths based on carbohydrate catabolism and incubated anaerobically for spore germination and outgrowth, followed by aerobic growth on plates of the same composition to eliminate anaerobic endospore-forming bacteria prove reasonably selective for *Paenibacillus* strains. For example, *Paenibacillus polymyxa* has been selectively isolated by incubating pasteurized soil samples in tubes of broth comprising peptone (10.0 g), lactose or starch (10.0 g), and distilled water to 1000 ml (pH 6.8–7) and containing a Durham tube. Culture from tubes showing gas formation is subcultured on to neutral red-peptone-starch-agar plates (prepared by adding agar and 0.005% neutral red to the broth described above). Colonies of *Paenibacillus polymyxa* accumulate the neutral red and are red-pigmented. Other carbohydrates for enrichment of specific species include alginate for *Paenibacillus alginolyticus* and *Paenibacillus chondroitinus* (Nakamura, 1987), colloidal chitin for *Paenibacillus koreensis* (Chung et al., 2000), curdlan for *Paenibacillus curdlanolyticus* and *Paenibacillus kobensis* (Kanzawa et al., 1995), and a polysaccharide derived from *Nostoc commune* for *Paenibacillus glycanilyticus* (Dasman et al., 2002). Ingenuity in the selection of carbohydrates will lead to the isolation of a great diversity of species. Enrichments with hydrocarbons have been used to isolate *Paenibacillus naphthalenovorans* (Daane et al., 2002). Nitrogen-free media are used for isolation of the nitrogen-fixing taxa (Elo et al., 2001).

Maintenance procedures

Paenibacillus species are best stored as spore preparations. Most strains produce spores readily when grown on nutrient medium supplemented with trace elements. A typical supply of trace elements includes the salts described above. If this fails, soil extract can be added to nutrient media. This involves crushing and sieving 400 g air-dried soil, which is then autoclaved in 1000 ml water for 60 min at 121°C. After the particles have settled out, the liquid is decanted and sterilized again for 30 min. This soil extract is added at 10% (by vol.) to nutrient agar or other media. Assuming that good crops of endospores can be obtained, the mixture of spores and cells can be scraped from the plate, resuspended as a turbid suspension in 20% (by vol.) sterile glycerol and frozen at –20°C. This suspension can be thawed and refrozen several times for use as a working culture. Stock cultures can be simply prepared by drying spores on a small piece of sterile filter paper and keeping it wrapped in sterile foil at room temperature. Pieces can be cut from the filter paper aseptically and immersed in broth to produce working cultures. It is sometimes preferable to store more refined spore preparations. These can be prepared by treating crude spore and cell suspensions with sterile lysozyme (100 µg/ml) for 30–60 min followed by repeated washes by centrifugation in sterile distilled water. Such spore preparations can be stored at 4°C in sterile water for many years with no appreciable loss of viability. For bacteria that do not readily differentiate into endospores, freeze-drying or storage at –80°C in 20% glycerol are alternatives.

Differentiation of the genus *Paenibacillus* from other genera

There are no diagnostic phenotypic features for the genus *Paenibacillus* although the presence of an endospore that distinctly swells the sporangium (Figure 25) is indicative. The only definitive identification to genus level is by means of PCR using the primers PAEN515F or 843F (see above) that, with a suitable reverse primer, amplify fragments from *Paenibacillus* strains exclusively, although this has not been tested thoroughly for all new species. Procedures for PCR amplification have been reported (Pettersson et al., 1999).

Taxonomic comments

The genus *Paenibacillus* was created in 1993 to accommodate a monophyletic lineage of endospore-forming bacteria previously classified in the genus *Bacillus* (Ash et al., 1993). The choice of *Paenibacillus polymyxa* as type species was challenged on the basis of priority of publication (Tindall, 2000), but *Paenibacillus polymyxa* has been retained as type species. Since 2005, the number of *Paenibacillus* species has nearly doubled from about 50 to more than 80 at this moment. The G+C content span of the overall genomic DNA at the generic level is about 20%, which is a very good indicator for the important genotypic, and hence also the phenotypic, heterogeneity of a taxon. It is generally accepted that generic variation at the genus level should not be more than 10–15%, which means that the taxonomy of *Paenibacillus* at the generic level certainly deserves to be reconsidered. As indicated above, there are no clear-cut phenotypic traits that discriminate *Paenibacillus* from other genera. Moreover, at the species level, phenotypic data are often very difficult to interpret taxonomically for obvious reasons. Firstly, the methodology that has been applied throughout the various species descriptions is often different. In our hands, the best data are obtained by a combination of API 20E, API 20NE, and API 50CH test panels combined with Biolog data because these methods are standardized, thus allowing the most comparative analysis. The Vitec approach is most probably another, although more limited, method that seems to be reliable for phenotypic analysis but has not yet been applied in a general context for *Paenibacillus* species. Secondly, the interpretation of the data, given by various authors is not always straightforward. A typical example concerns data on “utilization of carbon sources”, which is often confused with “oxidation” of substrates as measured in the Biolog panel. Thirdly, and perhaps most importantly, novel species with validly described names are increasingly “one-strain species”, with complete ignorance of phenotypic variability as a consequence. However, all identification procedures based on the above-mentioned commercialized phenotypic test panels are based on statistic interpretation of data! Most recent developments in bacterial taxonomy are comparative sequence analysis of house-keeping genes such as *rpoB*, *gyrA* or *gyrB*, *recA*, etc., to discriminate between species and even within species. Studies in *Paenibacillus* are very recent and mainly concentrate on typing aspects of these genes (Durak et al., 2006; Vollu et al., 2006). Although very promising taxonomic insights can be obtained with this kind of approach, more sequence data are needed before taxonomic rearrangements of *Paenibacillus* will be possible.

A final taxonomic issue concerns *Paenibacillus azotofixans*, which is regarded as a later synonym of *Paenibacillus durus* (Logan et al., 1998). The Judicial Commission recently concluded that *Paenibacillus durus* has priority over *Paenibacillus azotofixans*.

List of species of the genus *Paenibacillus*

- 1. *Paenibacillus polymyxa*** (Prazmowski 1880) Ash, Priest and Collins 1994, 852^{VP} (Effective publication: Ash, Priest and Collins 1993, 259) (*Clostridium polymyxa* Prazmowski 1880, 37; *Bacillus polymyxa* Macé 1889, 588)

po.ly.my'xa. Gr. pref. *poly* much, many; Gr. n. *myxa* slime or mucous; N.L. n. *polymyxa* much slime.

Colonies on nutrient agar are thin, often with amoeboid spreading. On glucose agar, colonies are usually heaped and mucoid with a matt surface. Levan is synthesized from sucrose, forming large capsules. Facultative anaerobe. Ferments glucose to 2,3-butanediol, ethanol, CO₂, and H₂. Reduces nitrate to nitrite. Many sugars and carbohydrates are fermented, including pectin, pullulan, starch, and xylan, but action on cellulose is weak. Most strains fix atmospheric nitrogen under anaerobic conditions. Biotin (or a trace of yeast extract) is required for growth in minimal medium. Major fatty acids are C_{15:0 anteiso} and C_{17:0 anteiso}.

Isolated from decomposing plants and soil. Associated with the rhizosphere where many strains provide protection to the plant and enhance plant growth.

DNA G+C content (mol%): 43–46 (Bd).

Type strain: NRRL NRS-1105, ATCC 842, DSM 36, NCIMB 8158, KCTC 3858, LMG 13294.

EMBL/GenBank accession number (16S rDNA) of the type strain: AJ320493 (DSM 36).
- 2. *Paenibacillus agarexedens*** (Wieringa 1941) Uetanabaro, Wahrenburg, Hunger, Pukall, Spröer, Stackebrandt, de Canhos, Claus and Fritze 2003, 1055^{VP} (*Bacillus agar-exedens* Wieringa 1941, 125)

a.gar.ex.e'dens. N.L. n. *agarum* agar; L. v. *exedere* to eat up, utilize; N.L. part. adj. *agarexedens* agar-utilizing.

Cells are Gram-negative (in young cells the Gram stain is uneven), motile, strictly aerobic rods (0.5–1.4 by 2–8 µm). Spores are ellipsoidal and most of the sporangia are not swollen. Colonies on peptone-urea agar are whitish and round with entire margins. Colonies sink into the agar within a few days, but do not liquefy it. Growth is inhibited by peptones, but this is reversed by urea. Mesophilic; maximum temperature for growth is 40°C (type strain: 35°C). No growth at pH 5.7 or in 5% NaCl. Oxidase-positive, nitrate is not reduced to nitrite, and no denitrification (i.e., gas production from nitrate) occurs. Positive for hydrolysis of agar, starch, hippurate, and esculin, but negative for dextran and pectin. Negative for: Voges–Proskauer test; urease, dextranase, DNase, and lysine decarboxylase; hydrolysis of poly-β-hydroxybutyric acid, casein, pectin, Tween 80, and chitin; and production of indole, dihydroxyacetone, and dextrin crystals.

Isolated from soil.

DNA G+C content (mol%): 47–49 (T_m).

Type strain: CIP 107437, DSM 1327.

EMBL/GenBank accession number (16S rDNA) of the type strain: AJ345020.
- 3. *Paenibacillus agaridevorans*** Uetanabaro, Wahrenburg, Hunger, Pukall, Spröer, Stackebrandt, de Canhos, Claus and Fritze 2003, 1056^{VP}

a.gar.i.de.vo'rans. N.L. n. *agarum* agar; L. part. adj. *devorans* consuming, devouring; N.L. part. adj. *agaridevorans* agar-devouring.

Cells are Gram-negative (Gram staining is uneven in young cells), strictly aerobic, motile rods (0.6–0.8 by 2–5 µm). Spores are ellipsoidal and most of the sporangia are not swollen. Colonies on agar media sink into the agar within a few days; no liquefaction of agar occurs. Colonies on peptone-urea agar are whitish and round with entire margins. Growth is inhibited by peptones, but this may be neutralized by urea. Mesophilic, maximum growth temperature of 35°C. No growth at pH 5.7 and in media with 5% NaCl. Oxidase-positive. Nitrate is not reduced and no gas is formed from nitrate anaerobically. Hydrolyzes agar, dextran, esculin, and hippurate, but not pectin. Produces acid, but no gas, from agar and glucose. Negative for: Voges–Proskauer test; urease, DNase, and lysine decarboxylase; hydrolysis of starch, poly-β-hydroxybutyric acid, casein, pectin, Tween 80, and chitin; tyrosine degradation; deamination of phenylalanine; and production of indole, dihydroxyacetone, and dextrin crystals.

Isolated from volcanic soil, Paricutin volcano, Mexico.

DNA G+C content (mol%): 50–52 (T_m).

Type strain: CIP 107436, DSM 1355.

EMBL/GenBank accession number (16S rDNA) of the type strain: AJ345023 (DSM 1355).
- 4. *Paenibacillus alginolyticus*** (Nakamura 1987) Shida, Takagi, Kadowaki, Nakamura and Komagata 1997a, 295^{VP} (*Bacillus alginolyticus* Nakamura 1987, 285)

al.gi.no.ly'ti.cus. N.L. adj. *alginicus* pertaining to alginic acid; Gr. adj. *lyticus* dissolving; N.L. adj. *alginolyticus* alginic acid-dissolving.

Cells are Gram-positive, aerobic rods (0.5–1.0 by 4–6 µm). Motile, occurring singly and in short chains. Colonies are non-pigmented, translucent, smooth, and circular. Ellipsoidal spores are formed in swollen sporangia. Optimum growth temperature is 28–30°C with minima of 5–10°C and maxima of 35–40°C. Growth in the presence of 0.001% lysozyme occurs at pH 5.6–5.7. Growth is inhibited by 3% NaCl in the media. Oxidase is not produced and the Voges–Proskauer test is negative. Nitrate is not reduced to nitrite. Produces acid, but no gas, from a variety of sugars and hydrolyzes numerous polysaccharides including alginate, carboxymethyl cellulose and β-1,2-glucan. Can be selectively isolated by growth in minimal medium with sodium alginate as sole carbon source and a trace of yeast extract (0.1 g/l). Major fatty acids are C_{15:0 anteiso} and C_{16:0 iso}.

Isolated from soil.

DNA G+C content (mol%): 47–49 (Bd).

Type strain: DSM 5050, NRRL NRS-1347.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB073362 (DSM 5050).

Additional remarks: This species represents DNA homology group 3 of *Bacillus circulans sensu lato* (Nakamura and J. Swezey, 1983).

5. **Paenibacillus alkaliterrae** Yoon, Kang, Yeo and Oh 2005, 2342^{VP} al.ka.li.ter'rae. Arabic n. *alkali* (*al-qaliy*) the ashes of saltwort; L. gen. n. *terrae* of the soil or earth; N.L. gen. n. *alkaliterrae* of high-pH soil.

Gram-positive, aerobic, motile, sporulating rods (1.5–3.0 by 0.4–0.5 µm). Ellipsoidal spores are positioned centrally or subterminally in swollen sporangia. Colonies on 2-fold diluted nutrient agar (pH 7.5) are circular to slightly irregular, smooth, sticky, glistening, raised, ivory-colored, and 2.0–4.0 mm in diameter after 5 d at 30°C. Growth occurs between 10 and 37°C with optimal growth at 30°C. Grows at pH 7.0–9.5 with optimal growth at 7.5. Denitrification is not growth supportive on 2-fold diluted nutrient agar supplemented with nitrate. Esculin is hydrolyzed, but Tweens 20, 40 and 60, hypoxanthine, and xanthine are not. D-Glucose, D-fructose, D-galactose, D-cellobiose, D-mannose, trehalose, D-xylose, L-arabinose, sucrose, maltose, and salicin are utilized, but benzoate, pyruvate, formate, and L-glutamate are not. Arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, and tryptophan deaminase are absent. An API ZYM profile has been recorded. Antibiotic profiles are reported. The cell wall peptidoglycan contains *meso*-DAP and the predominant menaquinone is MK-7. The major fatty acid is C_{15:0 anteiso}.

The type strain was isolated from an alkaline soil in Kwangchun, Korea.

DNA G+C content (mol%): 49.4 (HPLC).

Type strain: KSL-134, KCTC 3956, DSM 17040.

EMBL/GenBank accession number (16S rDNA) of the type strain: AY960748 (KSL-134).

6. **Paenibacillus alvei** (Cheshire and Cheyne 1885) Ash, Priest and Collins 1995, 197^{VP} (Effective publication: Ash, Priest and Collins 1993, 259) (*Bacillus alvei* Cheshire and Cheyne 1885, 581) al've.i. L. n. *alveus* a beehive; L. gen. n. *alvei* of a beehive.

Grows as actively motile colonies that spread across agar media. Free spores may lay side-by-side in long rows on the agar. Facultative anaerobe, but does not use nitrate as electron acceptor under anaerobic conditions. Production of indole from tryptophan and dihydroxyacetone on glycerol agar is distinctive. Minimal nutritional requirements are several amino acids plus thiamine or thiamine and biotin. Major fatty acids are C_{15:0 anteiso}, C_{15:0 iso}, and C_{16:0}.

Originally isolated from honeybee larvae suffering from European foulbrood, but not the etiological agent and not an insect pathogen. Can be isolated from beehives and soil surrounding beehives.

DNA G+C content (mol%): 45–47 (*T_m*).

Type strain: ATCC 6344, DSM 29, NCIMB 9371.

EMBL/GenBank accession number (16S rDNA) of the type strain: AJ320491 (DSM 29).

7. **Paenibacillus amylolyticus** (ex Kellerman and McBeth 1912) Ash, Priest and Collins 1995, 197^{VP} (Effective publication: Ash, Priest and Collins 1993, 259) (*Bacillus amylolyticus* ex Kellerman and McBeth (1912); Nakamura 1984b, 224

emend. Shida, Takagi, Kadowaki, Nakamura and Komagata 1997b, 303

am.yo.ly'ti.cus. L. n. *amylyum* starch; Gr. adj. *lyticus* dissolving; N.L. adj. *amylolyticus* dissolving starch.

Cells are facultative anaerobes. Rod-shaped (0.5–1.0 by 3.0–5.0 µm). Colonies on agar are grayish-white, translucent, smooth, and circular. Optimum growth temperature is 28–30°C with respective minima and maxima being 10–15 and 40–45°C. Nitrate is reduced to nitrite. Produces acid from a range of sugars and hydrolyzes starch. Major fatty acids are C_{15:0 anteiso} and C_{16:0}.

Habitat: soil.

DNA G+C content (mol%): 46.3–46.6 (Bd).

Type strain: ATCC 9995, DSM 3034, NRRL NRS-290.

EMBL/GenBank accession number (16S rDNA) of the type strain: D85396 (NRRL NRS-290).

Additional remarks: This species represents DNA hybridization group 11 of *Bacillus circulans sensu lato* (Nakamura and J. Swezey, 1983).

8. **Paenibacillus anaericanus** Horn, Ihssen, Matthies, Schramm, Acker and Drake 2005, 1263^{VP}

an.ae.ri.ca'nus. Gr. pref. *an* no, not; Gr. n. *aer* air; Gr. adj. *ikanos* capable; N.L. masc. adj. *anaericanus* capable of anaerobic growth.

Cells are Gram-negative, facultatively anaerobic, motile rods (2.0–5.0 by 0.5–1.0 µm) that grow in chains; cells are linked by connecting filaments. Cells have a three-layered cell wall without outer membrane. Contains *b*-type cytochromes. Terminal to subterminal ellipsoidal spores are formed. Colonies are flat, smooth, circular, and entire. Grows at 5–40°C and pH 5.8–8.6, with optimum growth at 30–35°C and pH 7.7. Doubling time under optimal conditions is 5 h. Catalase- and oxidase-positive. Grows in media containing 2% NaCl, but not in 5% NaCl. Formate, acetate, and ethanol are formed when glucose is fermented. Nitrate and sulfate are not dissimilated. Low amounts (1 mM) of nitrite are reduced to N₂O.

The type strain was isolated from the gut of the earthworm *Aporrectodea caliginosa* (collected from garden soil in Bayreuth, Germany).

DNA G+C content (mol%): 42.6 (HPLC).

Type strain: MH21, DSM 15890, ATCC BAA-844.

EMBL/GenBank accession number (16S rDNA) of the type strain: AJ318909 (MH21).

9. **Paenibacillus antarcticus** Montes, Mercadé, Bozal and Guinea 2004, 1523^{VP}

ant.arc'ti.cus. L. masc. adj. *antarcticus* of the Antarctic environment, where the organism was isolated.

Cells are Gram-variable, facultatively anaerobic rods (0.7 by 2.5 µm), motile by means of peritrichous flagella. Subterminal or terminal ellipsoidal spores are formed in swollen sporangia. Colonies grown on TSA are non-pigmented, circular, slightly convex, bright, and cream-colored. Growth is not inhibited by the presence of 4% NaCl or 0.001% lysozyme. Growth occurs at 4 and 31°C, but not at 0 or 32°C; optimal growth occurs at 10–15°C. Oxidase, catalase, urease, and methyl red reactions are positive. Nitrate reduction and H₂S production are negative. The predominant fatty acid is C_{15:0 anteiso}.

DNA G+C content (mol%): 40.7 (HPLC).

Type strain: 20CM, LMG 22078, CECT 5836.

EMBL/GenBank accession number (16S rDNA) of the type strain: AJ605292 (LMG 22078).

10. **Paenibacillus apiarius** (Katznelson 1955) Nakamura 1996, 692^{VP} (*Bacillus apiarius* Katznelson 1955, 635)
a.pi.a'ri.us. N.L. adj. *apiarius* relating to bees.
 Cells are facultatively anaerobic, Gram-variable, motile rods (0.7–0.8 by 3.0–5.0 µm). Spores have thick walls; they appear to be rectangular in swollen sporangia. Agar colonies are non-pigmented, translucent, thin, smooth, and entire with a mean diameter of about 1.0 mm after 24 h incubation on TGY agar (Haynes et al., 1955) at 28°C. Optimum growth temperature is 28°C with 40°C and 15°C as minima and maxima. Growth occurs at pH 5.7, in the presence of 0.001% lysozyme, and in the presence of 5% NaCl, but is inhibited by 7% NaCl. Oxidase-negative. Nitrate is reduced to nitrite. Acid, but not gas, is produced from sugars. Hydrolyzes casein and starch. Major fatty acids are C_{15:0 anteiso}, C_{15:0 iso}, and C_{17:0 anteiso}.
 Isolated from honeybees, their larvae and their hives, but not an insect pathogen.
DNA G+C content (mol%): 52–54 (Bd).
Type strain: ATCC 29575, DSM 5581, NRRL NRS-1438.
EMBL/GenBank accession numbers (16S rDNA) of the type strain: U49427 (NRRL NRS-1438) and AJ320492 (DSM 5581).
Comment: The sequence with accession number AJ320492 is a usable sequence linked to DSM 5581, but sequence AB073201, also linked to DSM 5581, differs considerably and is likely the incorrect sequence for phylogenetic studies.
11. **Paenibacillus assamensis** Saha, Mondal, Makyilraj, Krishnamurthi, Bhattacharya and Chakrabarti 2005, 2579^{VP}
as.sam.en'sis. N.L. masc. adj. *assamensis* pertaining to Assam, a north-eastern state in India, where the type strain was isolated.
 Gram-variable, motile, strictly aerobic, spore-forming cells; occurs singly or in pairs. Endospores are ellipsoidal and subterminal, occurring in bulging sporangia. Cells are 1.0–2.5 µm long and 0.5–0.6 µm wide. On TSA, colonies are round, convex with undulated margins, and light yellowish-white in color, spreading as single colonies over the entire plate. Growth occurs between 20 and 37°C and at pH 6.8–12.0. Up to 2.5% NaCl is tolerated. Oxidase, catalase, gelatinase, and arginine dihydrolase reactions are positive, but urease, DNase, phenylalanine deaminase, lysine, and ornithine decarboxylase are negative. Indole and H₂S are not formed. Nitrate is not reduced and the Voges–Proskauer test is negative. Gas is not produced from glucose. Positive for the methyl red test. Cannot utilize acetate, citrate, or propionate. Hydrolyzes starch, esculin, and casein, but not tyrosine, ONPG, or Tweens 20, 40 and 80. Acid is produced from various carbohydrates. Can grow in the presence of 0.01% lysozyme, but not in 0.001% lysozyme. The major fatty acid is C_{15:0 anteiso}. *meso*-DAP is reported as a cell-wall amino acid and MK-7 as the diagnostic menaquinone. PAEN 515F and PAEN 862F signature sequences in the 16S rRNA gene support the phylogenetic position of the species in the genus *Paenibacillus*.
 The type strain was isolated from a warm-spring water sample from Assam, India.
DNA G+C content (mol%): 41.2 (HPLC).
Type strain: GPTSA 11, MTCC 6934, JCM 13186.
EMBL/GenBank accession number (16S rDNA) of the type strain: AY884046 (GPTSA 11).
12. **Paenibacillus azoreducens** Meehan, Bjourson and McMullan 2001, 1684^{VP}
azo.re.duc'ens. Gr. n. *azo* a combining form meaning nitrogen; N.L. pres. part. *reducens* reducing; N.L. adj. *azoreducens* nitrogen-reducing, referring to the ability to decolorize azo dyes.
 Cells are Gram-variable, facultatively anaerobic rods (0.5–0.8 by 3.0–6.0 µm), motile by peritrichous flagella. Ellipsoidal spores are formed in swollen sporangia. Colonies on nutrient agar containing glucose are creamish-yellow, flat, smooth, and circular. Growth occurs between 10 and 50°C with optimal growth at 37°C and pH 7. Growth is inhibited by 5% NaCl. Does not use nitrate as an electron acceptor under anaerobic conditions. Acid is produced from a range of sugars. Oxidase-negative. Positive for hydrogen sulfide production. Completely decolorizes the azo dye Remazol Black B (25–400 mg/l) within 24 h. Major fatty acids are C_{15:0 anteiso}, C_{16:0}, and C_{17:0 anteiso}.
 Habitat unknown, but isolated from textile industrial waste water.
DNA G+C content (mol%): 47 (HPLC).
Type strain: CM1, DSM 13822, NCIMB 13761.
EMBL/GenBank accession number (16S rDNA) of the type strain: AJ272249 (CM1).
13. **Paenibacillus barcinonensis** Sánchez, Fritze, Blanco, Spröer, Tindall, Schumann, Kroppenstedt, Diaz and Pastor 2005, 937^{VP}
bar.ci.no.nen'sis. L. masc. adj. *barcinonensis* from *Barcino*, the Roman name for Barcelona, the city in Spain where the strain was isolated.
 Gram-positive, facultatively anaerobic rods (0.5–1 by 1.5–4.5 µm). Ellipsoidal endospores form in swollen sporangia at a subterminal position. Colonies are circular to slightly irregular, pale yellow in color, and 0.5 mm in diameter after 2 d growth at 30°C in nutrient broth. Growth occurs at 10–40°C and pH 5.0–10.4. Growth occurs in the presence of 5% (w/v) NaCl and 0.001% (w/v) lysozyme. Catalase-positive. Oxidase- and urease-negative. Nitrate is not reduced to nitrite or nitrogen. Casein and starch are not hydrolyzed. Citrate and propionate are not utilized. Acid is produced from various carbohydrates. The major fatty acids are C_{15:0 anteiso}, C_{16:1ω11c}, C_{15:0 iso}, and C_{16:0}. The predominant menaquinone is MK-7. The major polar lipids present are diphosphatidylglycerol, phosphatidylethanolamine, and two unidentified amino-phospholipids.
 The type strain was isolated from soil from a rice field in the Ebro River delta, Spain.
DNA G+C content (mol%): 45.0 (type strain, HPLC).
Type strain: BP-23, CECT 7022, DSM 15478.
EMBL/GenBank accession number (16S rDNA) of the type strain: AJ716019 (BP-23).
14. **Paenibacillus barengoltzii** Osman, Satomi and Venkateswaran 2006, 1514^{VP}
ba.ren.gol'tzi.i. N.L. gen. n. *barengoltzii* of Barengoltz, referring to Jack Barengoltz, a well-known American physicist and NASA planetary protection scientist.

Cells are Gram-positive, strictly aerobic, spore-forming rods (0.5–0.8 by 3.0–5.0 µm), motile by peritrichous flagella. Ellipsoidal spores are formed in swollen sporangia. Colonies are flat, smooth, circular, entire, and brownish-yellow on nutrient agar without production of soluble pigments. Growth occurs between 10 and 50°C and pH 4.5–9.0 with optimum growth at 37°C and pH 7.0. Growth occurs in the presence of 2% NaCl and 0.001% lysozyme, but is inhibited by 5% NaCl. Positive for catalase, oxidase, and the Voges–Proskauer reaction. Hydrogen sulfide and indole are not produced. Denitrification is not reported, but nitrate is reduced to nitrite. Gelatin is not liquefied, esculin is hydrolyzed, and β-galactosidase is produced. Of the carbon substrates tested, only gluconate is utilized. Acid is not produced from D-glucose. Furthermore, the vast majority of API 20E, API 20NE, and Biolog carbohydrate tests were negative.

The type strain was isolated from clean room floors of the Jet Propulsion Laboratory Spacecraft Assembly Facility, Pasadena, CA, USA; strain SAFN-125 (=ATCC BAA-1210) is a reference strain.

DNA G+C content (mol%): not reported.

Type strain: SAFN-016, ATCC BAA-1209, NBRC 101215.

EMBL/GenBank accession number (16S rDNA) of the type strain: AY167814 (SAFN-016).

15. **Paenibacillus borealis** Elo, Suominen, Kämpfer, Juhanoja, Salkinoja-Salonen and Haahtela 2001, 542^{VP}

bo.re.a'lis. N.L. adj. *borealis* pertaining to the north (wind) boreal.

Cells are Gram-negative, facultatively anaerobic, motile rods (0.75–1.0 by 3–5 µm). Ellipsoidal spores formed in swollen sporangia are subterminal or terminal. Mature spores have an unusual striped morphology when visualized by electron microscopy. Flat, smooth, opaque colonies are formed on nutrient agar. The temperature range for growth is 5–37°C with an optimum at 28°C. Grows at pH 5.6–8.0 with an optimum of pH 7. Does not tolerate 5% NaCl, 0.001% lysozyme, or 0.02% sodium azide. Nitrate is not reduced under anaerobic conditions. Acid and gas are produced from various sugars. Atmospheric nitrogen is fixed. Selective isolation can be achieved in N-free media, with or without yeast extract, and with glucose as carbon source. Major cellular fatty acids are C_{15:0 anteiso}, C_{15:0 iso}, and C_{16:0}.

Isolated from acid humus in Norway spruce forest in Finland and from the rhizoplane of birch trees.

DNA G+C content (mol%): 54 (HPLC).

Type strain: KK19, CCUG 43137, DSM 13188.

EMBL/GenBank accession number (16S rDNA) of the type strain: AJ011322 (KK19).

16. **Paenibacillus brasiliensis** von der Weid, Frois Duarte, van Elsas and Seldin 2002, 2152^{VP}

bra.sil.en'sis. N.L. adj. *brasiliensis* referring to Brazil, the country where the strains were isolated.

Cells are Gram-positive to Gram-variable facultatively anaerobic rods. Endospores are ellipsoidal, predominantly central to subterminal, and distend the sporangium. Colonies are about 10 mm in diameter, bright yellow on TBN agar (glucose, yeast extract, biotin, thiamine medium; Seldin

et al., 1983), circular with entire margins, and adhere to the agar. Grows well on GB medium (glucose, 10 g; peptone, 10 g; NaCl, 5 g; yeast extract, 1 g; meat extract, 2 g; distilled water to 1 l and adjusted to pH 7.2 with NaOH; Seldin et al., 1983). The maximum temperature for growth is 42°C with an optimum of 30–32°C. Grows at pH 5–7 and in the presence of 2% NaCl, but not in 5% NaCl or in the presence of lysozyme. Acid and gas are produced from glucose. Acid is produced from a restricted number of carbohydrates. Reduces nitrate to nitrite. Voges–Proskauer reaction is positive. All strains fix atmospheric nitrogen.

Isolated from the rhizosphere of maize sown in the Minas Gerais area of Brazil.

DNA G+C content (mol%): not reported.

Type strain: PB172, ATCC BAA-413, DSM 14914.

EMBL/GenBank accession number (16S rDNA) of the type strain: AF273740 (PB172).

17. **Paenibacillus campinasensis** Yoon, Yim, Lee, Shin, Sato, Lee, Park and Park 1998, 836^{VP}

cam.pi.na.sen'sis. N.L. adj. *campinasensis* referring to Campinas, the city in Brazil where the College of Food Engineering, State University of Brazil is located.

Cells are Gram-variable, facultatively anaerobic rods (0.6–0.9 by 3.0–6.0 µm) that are motile by means of peritrichous flagella. Ellipsoidal spores are formed in swollen sporangia. Colonies are flat, smooth, opaque, and motile, particularly on wet agar plates. Alkaliphilic, optimal growth at pH 10.0 and no growth at neutral pH. Growth in 7% NaCl is distinctive. Biochemical reactions reported are based on Biolog GN test panel results and do not provide information on acid production from carbohydrates. Gelatin, casein, esculin, and starch are hydrolyzed. Oxidase- and urease-negative. Produces crystalline cyclodextrins from starch. The major fatty acid is C_{15:0 anteiso}.

DNA G+C content (mol%): 51 (HPLC).

Type strain: 324, KCTC 0364BP, BCRC 17341, JCM 11200.

EMBL/GenBank accession number (16S rDNA) of the type strain: AF021924 (324).

18. **Paenibacillus cellulosilyticus** Rivas, García-Fraile, Mateos, Martínez-Molina and Velázquez 2006, 2779^{VP}

cel.lu.lo.si.ly'ti.cus. N.L. n. *cellulosum* cellulose; Gr. adj. *lutikos* able to loose, able to dissolve; N.L. adj. *lyticus -a -um* dissolving; N.L. masc. adj. *cellulosilyticus* cellulose-dissolving.

Gram-variable, aerobic or facultatively anaerobic, spore-forming rods (0.8–0.9 by 4.0–4.2 µm), motile by peritrichous flagella. Subterminal, ellipsoidal spores are formed in swollen sporangia. Chemo-organotrophic and xylanolytic. Colonies on yeast extract-glucose medium are circular, flat, white/creamy, opaque, and usually 1–3 mm in diameter after 48 h at 28°C. Growth occurs at 10–37°C with optimal growth at 28°C. Optimum pH is 7. Grows in the presence of 2% NaCl, but not in 5% NaCl. Nitrate is not reduced to nitrite. Growth in anaerobic agar is reported as negative. Cellulases, xylanases, amylases, and β-galactosidase are actively produced, but gelatinase, caseinase, arginine dihydrolase, indole, lysine decarboxylase, ornithine decarboxylase, urease, tryptophan deaminase, phenylalanine deaminase, and hydrogen sulfide are not. Esculin is hydrolyzed. Gas is not

produced from D-glucose. A number of sugars and gluconate are assimilated. Acid is produced from a limited number of carbohydrates. The major quinone is MK-7. Main fatty acids are C_{15:0 anteiso} and C_{16:0 iso}.

The type strain was isolated from the bract phyllosphere of *Phoenix dactylifera* in Palma de Mallorca (Spain) on XED medium (xylan, 0.7%; yeast extract, 0.3%; agar, 2.5%, w/v).

DNA G+C content (mol%): 51 (T_m).

Type strain: PALXIL08, LMG 22232, CECT 5696.

EMBL/GenBank accession number (16S rDNA) of the type strain: DQ407282 (PALXIL08).

19. **Paenibacillus chibensis** Shida, Takagi, Kadowaki, Nakamura and Komagata 1997b, 306^{VP}

chi.ben'sis. N.L. adj. *chibensis* referring to Chiba, a Japanese prefecture where the research laboratory of Higeta Shoyu Co., Ltd. is located.

Cells are Gram-positive, strictly aerobic rods (0.5–0.8 by 3.0–5.0 µm), motile by means of peritrichous flagella. Ellipsoidal spores are formed in swollen sporangia. Colonies are brownish-yellow, flat, smooth, circular, and entire. Growth occurs at 10–50°C and pH 4.5–9.0 with optimal growth at 37°C and pH 7.0. Growth occurs in the presence of 2% NaCl and 0.001% lysozyme, but is inhibited by 5% NaCl and 0.02% sodium azide. Catalase-positive and oxidase-negative; Voges–Proskauer reaction is negative. Hydrogen sulfide, indole, dihydroxyacetone, and lecithinase are not produced. Nitrate is reduced to nitrite; ammonium and nitrate are utilized. Acid, but no gas, is produced from glucose and a number of other sugars. Starch is hydrolyzed, but casein, gelatin, DNA, Tweens 20, 60 and 80, urea, and hippurate are not. Major fatty acids are C_{15:0 anteiso}, C_{16:0 iso} and C_{17:0 anteiso}.

Habitat: unknown.

DNA G+C content (mol%): 52.5–53.2 (HPLC).

Type strain: NRRL B-142, DSM 11731, JCM 9905.

EMBL/GenBank accession number (16S rDNA) of the type strain: D85395 (NRRL B-142).

20. **Paenibacillus chinjuensis** Yoon, Seo, Shin, Kho, Kang and Park 2002, 419^{VP}

chin.ju.en'sis. N.L. adj. *chinjuensis* of Chinju, the city in Korea where the type strain was isolated.

Cells are Gram-positive to Gram-variable, facultatively anaerobic rods (0.8–1.1 by 3.0–5.0 µm), motile by peritrichous flagella. Ellipsoidal spores are formed in swollen sporangia. Colonies are light pink, smooth, glossy, circular, and convex with entire margins after 3–4 d on TSA. No growth occurs in media containing 2% (w/v) or more NaCl. Growth occurs at 20–45°C, but not at 15 or 50°C with optimum growth at 30–37°C. The optimal pH for growth is 6.5–7.3. Growth is very slow or inhibited below pH 4.5 and above pH 9. Does not use nitrate as a terminal electron acceptor. Ferments sugars producing acid but no gas. Hydrolyzes arbutin, casein, gelatin, and starch. Major fatty acids are C_{15:0 anteiso} and C_{15:0 iso}. Cell-wall peptidoglycan contains meso-DAP. The predominant menaquinone is MK-7.

Isolated from soil in Chinju, Korea.

DNA G+C content (mol%): 53 (HPLC).

Type strain: WN9, JCM 10939, KCTC 8951P.

EMBL/GenBank accession number (16S rDNA) of the type strain: AF164345 (WN9).

21. **Paenibacillus chitinolyticus** (Kuroshima, Sakane, Takata and Yokota 1996) Lee, Pyun and Bae 2004, 932^{VP} (*Bacillus chitinolyticus* Kuroshima, Sakane, Takata and Yokota 1996, 79)

chi.ti.no.ly'ti.cus. N.L. n. *chitinum* chitin; Gr. adj. *lutikos* able to loose, able to dissolve; N.L. adj. *lyticus* -a -um dissolving; N.L. masc. adj. *chitinolyticus* decomposing chitin.

Cells are Gram-variable, aerobic rods (0.4–0.6 by 1.7–3 µm), motile by peritrichous flagella. Ellipsoidal spores are formed in swollen sporangia. Colonies are pale brown, irregular, and raised with undulate margins. The optimal growth temperature is 25–37°C, with maxima of 42–45°C and minima of 18–20°C. Oxidase is produced, Voges–Proskauer test is positive. Nitrate is reduced to nitrite. Acid, but no gas, is produced from a few carbohydrates. Variable for casein and gelatin hydrolysis. Starch is not hydrolyzed. Major fatty acid is C_{15:0 anteiso} and MK-7 is the major quinone. Decomposes chitin.

Isolated from forest soil samples obtained in Kaya, Kagoshima Prefecture, Japan.

DNA G+C content (mol%): 51.3–52.8 (HPLC).

Type strain is: EAG-3, KCTC 3791, NBRC 15660.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB021183 (IFO 15660).

22. **Paenibacillus chondroitinus** (Nakamura 1987) Shida, Takagi, Kadowaki, Nakamura and Komagata 1997a, 297^{VP} (*Bacillus chondroitinus* Nakamura 1987, 285)

chon.droi'ti.nus. N.L. adj. *chondroitinus* of chondroitin, pertaining to chondroitin.

Cells are Gram-positive, aerobic, motile rods (0.5–1.0 by 4.0–6 µm), occurring singly and in short chains. Ellipsoidal spores are formed in swollen sporangia. Agar colonies are non-pigmented, translucent, smooth, circular, entire, and 1–2 mm in diameter after 3 d at 28°C. Optimum growth temperature is 28–30°C with minima of 5–10°C and maxima of 35–40°C. Growth occurs at pH 5.6–5.7 and is usually inhibited by 0.001% lysozyme or 3% NaCl in the medium. Oxidase is not detected; nitrate is not reduced to nitrite. Hydrolyzes alginate and chondroitin sulfate, but not β-glucans. Acid, but no gas, is produced from sugars. Isolated following enrichment growth with alginate as major carbon source. Major fatty acids are C_{15:0 anteiso} and C_{16:0 iso}.

Isolated from soil.

DNA G+C content (mol%): 47–48 (Bd).

Type strain: DSM 5051, NRRL NRS-1351, JCM 9072.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB073206 (JCM 9072).

Additional remarks: This species represents DNA homology group 4 of *Bacillus circulans sensu lato* (Nakamura and Swezey, 1983).

23. **Paenibacillus cineris** Logan, De Clerck, Lebbe, Verhelst, Goris, Forsyth, Rodríguez-Díaz, Heyndrickx and De Vos 2004, 1075^{VP}

c'ne.ris. L. gen. masc. n. *cineris* of/from ash, referring to the volcanic, ash-based soil from which the type strain was isolated.

Cells are motile, Gram-negative or Gram-variable, facultatively anaerobic, round-ended rods (0.7–0.9 by

2.5–4.0 µm), occurring singly and in pairs. Endospores are formed within 2–3 d incubation on *Bacillus fumaroli* agar (BFA) at 30°C; they are ellipsoidal, paracentral and subterminal and swell the sporangia. After 2 d at 30°C, colonies are 1–5 mm in diameter, low convex, circular with slightly irregular edges, opaque, glossy, and light beige to grayish in color with paler margins. Grows on nutrient agar. Catalase- and oxidase-positive. Minimum growth temperature is 8–15°C; maximum is 50°C. Optimal pH for growth is 7.0 with minima varying from pH 5.0 to 6.5 and maxima from pH 7.5 to 11.0. Growth occurs in the presence of 3% NaCl, but is inhibited by 5% NaCl. Hydrolysis of casein is weakly positive. Nitrate is reduced. Gelatin is not hydrolyzed. Hydrolysis of esculin is positive. Acid is produced without gas from various carbohydrates. An antibiotic reaction profile has been determined. The major cellular fatty acids are C_{15:0 anteiso}, C_{16:0}, C_{17:0 anteiso}, and C_{16:0 iso} (representing about 46, 18, 10, and 9% of total fatty acids, respectively).

Isolated from the ashy soil of a cold, dead fumarole at the foot of Lucifer Hill, a volcano on Candlemas Island, South Sandwich Archipelago, Antarctica. Strain LMG 21976 is reference strain.

DNA G+C content (mol%): 51.5 (HPLC).

Type strain: Logan B1768, LMG 18439, CIP 108109.

EMBL/GenBank accession number (16S rDNA) of the type strain: AJ575658 (LMG 18439).

24. **Paenibacillus cookii** Logan, De Clerck, Lebbe, Verhelst, Goris, Forsyth, Rodríguez-Díaz, Heyndrickx and De Vos 2004, 1075^{VP}

cook'i.i. N.L. gen. n. *cookii* of Cook, referring to Captain James Cook, of HMS *Resolution*, who discovered Candlemas Island on Candlemas Day (2 February), 1775.

Cells are Gram-negative or Gram-variable, rounded, facultatively anaerobic, motile rods (0.6–0.8 by 3.0–3.5 µm). Endospores, formed within 2–3 d incubation on BFA incubated at 30°C are ellipsoidal, lie subterminally, and swell the sporangia slightly. After 2 d at 30°C, colonies are 1–4 mm in diameter, convex, yellowish, and transparent with opaque centers; motile microcolonies are formed and spread across the surface of the agar, rotating clockwise and anticlockwise. Grows on nutrient agar. Catalase-positive or weakly positive and oxidase-positive. Minimum growth temperature varies between 15 and 20°C and the maximum growth temperature is 50°C. The optimal pH for growth is 7, with respective minima and maxima of pH 5.0–5.5 and pH 7.5–10. Growth occurs in the presence of 5% NaCl, but is inhibited by 7% NaCl. Casein hydrolysis is positive, but weak. Nitrate is reduced. Hydrolysis of gelatin is variable; that of esculin is positive. Urease-negative. Acid is produced without gas from various carbohydrates. An antibiotic profile has been recorded with the disk method. The major cellular fatty acids are C_{15:0 anteiso}, C_{17:0 anteiso}, C_{16:0 iso}, C_{16:0}, and C_{15:0 iso} (representing about 36, 20, 13, 11, and 6.5% of total fatty acids, respectively).

Isolated from geothermal soil taken from an active fumarole on Lucifer Hill, a volcano on Candlemas Island, South Sandwich Archipelago, Antarctica, and from a gelatin extract of bovine bones.

DNA G+C content (mol%): 51.6 (HPLC).

Type strain: LMG 18419, CIP 108110, Logan B1718.

EMBL/GenBank accession number (16S rDNA) of the type strain: AJ250317 (LMG 18419).

25. **Paenibacillus curdlanolyticus** (Kanzawa, Harada, Takeuchi, Yokota and Harada 1995) Shida, Takagi, Kadowaki, Nakamura and Komagata 1997a, 297^{VP} (*Bacillus curdlanolyticus* Kanzawa, Harada, Takeuchi, Yokota and Harada 1995, 517) curd.lan.o.ly'ti.cus. N.L. n. *curdlanum* curdlan, a polysaccharide produced by bacteria; Gr. adj. *lutikos* dissolving; N.L. adj. *curdlanolyticus* hydrolyzing curdlan.

Agar colonies are flat, smooth, opaque, and motile on minimal medium with curdlan as carbon source. Strictly aerobic, reduces nitrate to nitrite under anaerobic conditions. Acid, but no gas, is produced from sugars. Carboxymethyl cellulose, curdlan (a β-1,3-glucan), pustulan (a β-1,6-glucan), pullulan, and starch are hydrolyzed. Major fatty acids are C_{15:0 anteiso} and C_{16:0 iso}.

Isolated from soil.

DNA G+C content (mol%): 50–52 (HPLC).

Type strain: IFO 15724, DSM 10247, LMG 18050, ATCC 51898.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB073202 (DSM 10247).

26. **Paenibacillus daejeonensis** Lee, Lee, Chang, Hong, Oh, Pyun and Bae 2002, 2110^{VP}

dae.je.on.en'sis. N.L. masc. adj. *daejeonensis* referring to Daejeon, Korea, the geographical origin of the novel species.

Cells are Gram-variable, spore-forming rods that are motile by means of peritrichous flagella. Ellipsoidal spores form in swollen sporangia. Colonies are circular, flat, smooth, opaque, and white on TSA adjusted to pH 10 with Na₂CO₃. Cells do not grow at pH 6.0, but grow at pH 7.0–13.0 with an optimum pH of 8.0. Alkaliphilic. Positive for esculin hydrolysis, β-galactosidase, oxidase, and catalase. Gelatin is not liquefied. Negative for nitrate reduction, urease, and H₂S production. Acid is produced from a restricted number of carbohydrates. The major isoprenoid quinone is menaquinone MK-7. Major fatty acids are C_{15:0 anteiso} and C_{16:0 iso}, with significant amounts of C_{15:0} and C_{16:0}. Cell-wall peptidoglycan contains *meso*-DAP.

Isolated from soil of Daejeon City, Korea. KCTC 3750 and JCM 11237 are reference strains.

DNA G+C content (mol%): 53 (HPLC).

Type strain: AP-20, JCM 11236, KCTC 3745, CIP 107805.

EMBL/GenBank accession number (16S rDNA) of the type strain: AF290916 (AP-20).

27. **Paenibacillus dendritiformis** Tcherpakov, Ben-Jacob and Gutnick 1999, 244^{VP}

den.dri.ti.for'mis. Gr. n. *dendron* tree; N.L. adj. *formis* shaped; N.L. adj. *dendritiformis* tree-shaped, referring to the tree like-shapes of the colonies on agar.

Gram-negative. Cells are either small (2–3 µm long by 0.5–1.0 µm wide; T morphotype) or large (4–6 µm long by 1.0–1.5 µm wide; C morphotype), and motile. The former produces branched colony morphology on thin, peptone agar plates and the latter produces a chiral morphology on this medium. Colonies on nutrient agar are non-pigmented,

translucent, thin, smooth, entire, and 1.0–2.0 mm in diameter. The transformation of C–T morphotypes and vice versa depends on the agar concentration of the medium. Spores are round, cylindrical, or ellipsoidal in swollen sporangia. Oxidase is present. Voges–Proskauer is negative. Nitrate is not reduced to nitrite. Facultatively anaerobic, producing acid from glucose. Major fatty acids are C_{15:0 anteiso} and C_{17:0 anteiso}.

Habitat: soil.

DNA G+C content (mol%): 55 (method not reported).

Type strain: Gutnick strain T168, 30A1, CIP 105967, DSM 18844, LMG 21716, T168.

EMBL/GenBank accession number (16S rDNA) of the type strain: AY359885 (CIP 105967).

28. **Paenibacillus durus** (Smith and Cato 1974) Collins, Lawson, Willems, Cordoba, Fernandez-Garayzabel, Garcia, Cai, Hippe and Farrow 1994, 824^{VP} (*Clostridium durum* Smith and Cato 1974, 1396)

du'rus. L. masc. adj. *durus* hard, tough.

Colonies on GB agar are 1–2 mm in diameter, whitish, circular to slightly irregular, and convex with entire margins. Little or no growth occurs in nutrient broth under aerobic conditions, but abundant growth is observed in GB broth. Cells are capsulated and weakly motile. Facultatively anaerobic, but does not reduce nitrate to nitrite. Acid and gas are produced from sugars. Fixes nitrogen under anaerobic conditions. Selectively isolated by anaerobic incubation on nitrogen-free minimal medium containing thiamine and biotin. Major cellular fatty acids are C_{15:0 anteiso} and C_{16:0}.

Isolated from the rhizoplane and rhizosphere soil of various grasses and marine sediments.

DNA G+C content (mol%): 50 (T_m ; a mean value of measurements ranging from 48–53).

Type strain: ATCC 27763, CIP 105291, DSM 1735, LMG 15707, VPI 6563-1.

EMBL/GenBank accession number (16S rDNA) of the type strain: X77846 (DSM 1735). More reliable 16S rRNA gene sequences are AB033195, which is linked to *Paenibacillus azotofixans* DSM 5976^T, or AJ251192, which is linked to *Paenibacillus azotofixans* ATCC 35681^T.

Additional remarks: *Paenibacillus azotofixans* and *Paenibacillus durus* (formerly *Clostridium durum*) were combined into one taxon by Rosado et al. (1997) as *Paenibacillus azotofixans* but, following a request to the Judicial Commission by Logan et al. (1998), *Paenibacillus durus* was ruled to have priority over *Paenibacillus azotofixans*.

29. **Paenibacillus ehimensis** (Kuroshima, Sakane, Takata and Yokota 1996) Lee, Pyun and Bae 2004, 931^{VP} (*Bacillus ehimensis* Kuroshima, Sakane, Takata and Yokota 1996, 79) e.hi.men'sis. N.L. masc. adj. *ehimensis* of or belonging to Ehime, referring to Ehime Prefecture, Japan, the source of the soil samples from which the organisms were isolated.

Cells are aerobic rods (0.4–0.6 by 1.7–5 µm), motile by peritrichous flagella. Gram reaction is usually positive, although some strains stain Gram-negative. Ellipsoidal spores are formed in swollen sporangia. Colonies are creamy to pale brown, circular, and convex with entire margins. The optimum growth temperature ranges from 28 to 40°C with maxima of 50–53°C and minima of 18–20°C.

Catalase and oxidase are produced. Voges–Proskauer test is negative. Nitrate is reduced to nitrite. Acid, but no gas, is produced from few carbohydrates. Gelatin and starch are hydrolyzed; variable for hydrolysis of casein. Decomposes chitin.

Isolated from garden soil in Matsuyama, Ehime Prefecture, Japan.

DNA G+C content (mol%): 52.9–54.9 (HPLC).

Type strain: EAG-5, IFO 15659, KCTC 3748.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB021184 (IFO 15659).

30. **Paenibacillus elgii** Kim, Bae, Jeon, Chun, Oh, Hong, Baek, Moon and Bae 2004, 2034^{VP}

el'gi.i. N.L. gen. n. *elgii* arbitrary name formed from the company name LG, where taxonomic studies on this species were performed.

Cells are facultatively anaerobic, Gram-variable rods (0.8–1.0 by 3.0–5.0 µm) that are motile with peritrichous flagella. Ellipsoidal spores are formed in swollen sporangia and mature spores have stripes on the surface. Colonies on nutrient agar are circular, flat, smooth, opaque, and white. Temperature range for growth is 20–45°C; growth occurs at pH 6.0–8.5 (optimum 7.0). Can grow in the presence of 2% NaCl. Catalase-positive, oxidase-negative. Nitrate is reduced to nitrite. Indole is produced, but H₂S is not. Casein, esculin, and starch are hydrolyzed. Acid is produced from a restricted number of sugars. Glucose, ribose, *N*-acetylglutamate, and Tween 40 are assimilated. The major isoprenoid quinone is menaquinone MK-7. The major cellular fatty acid is C_{15:0 anteiso}. Cell-wall peptidoglycan contains *meso*-DAP.

Isolated from roots of *Perilla frutescens* in Seocheon County, Korea. Strain SD18 (=KCTC 3756) is a reference strain.

DNA G+C content (mol%): 51.7 (T_m).

Type strain: SD17, KCTC 10016BP, NBRC 100335.

EMBL/GenBank accession number (16S rDNA) of the type strain: AY090110 (SD17).

31. **Paenibacillus favisporus** Velázquez, de Miguel, Poza, Rivas, Rosselló-Mora and Villa 2004, 61^{VP}

fa.vi.spo'rus. L. masc. n. *favus* a honeycomb; Gr. n. *spora* a seed, spore; N.L. masc. adj. *favisporus* referring to the honeycomb form of spores.

Cells are Gram-variable, motile, aerobic or facultatively anaerobic, spore-forming rods (0.5–0.7 by 2–3 µm). Spores slightly swell the sporangia and are subterminal. Spores have an ornamentation similar to that of honeycomb. Colonies on yeast extract-glucose medium are circular, convex, white with a central brown spot, translucent, and usually 1–3 mm in diameter within 48 h at 37°C. Optimal growth temperature is 37°C; optimal growth pH is 7. Chemo-organotrophic and xylanolytic. Oxidase- and catalase-positive. Phylogenetically, most closely related to *Paenibacillus azoreducens*. The main fatty acid is C_{15:0 anteiso}. Gas is not produced from D-glucose. Acid is produced from various carbohydrates. Cellulose and starch are utilized as carbon sources. In contrast, no growth occurs using L-arabinose, citrate, inositol, sorbitol, glucitol, or xylitol as carbon sources. Gelatinase, urease, and amylase are produced actively, but casein is not

hydrolyzed and hydrogen sulfide is not formed. Nitrate is reduced to nitrite. An antibiotic profile has been obtained.

Isolated from old cow dung in Salamanca, Spain.

DNA G+C content (mol%): 53% (HPLC).

Type strain: GMP01, LMG 20987, CECT 5760.

EMBL/GenBank accession number (16S rDNA) of the type strain: AY208751 (GMP01).

32. **Paenibacillus gansuensis** Lim, Jeon, Lee, Xu, Jiang and Kim 2006a, 2133^{VP}

gan.su.en'sis. N.L. masc. adj. *gansuensis* belonging to Gansu, from where the type strain was isolated.

Cells are Gram-positive motile rods (0.7–0.9 by 1.7–2.4 µm). Colonies are glistening, translucent, semi-sticky, irregular, slightly raised, and pale yellow on R2A agar. Growth occurs at 10–45°C (optimum 35–40°C). Nitrate is not reduced to nitrite. Catalase- and oxidase-negative. Esculin, casein, and Tween 80 are hydrolyzed. Hypoxanthine, tyrosine, starch, and xanthine are not hydrolyzed. Acids are produced from various carbohydrates. Phylogenetically, most closely related to *Paenibacillus chitinolyticus* and *Paenibacillus daejeonensis*. The 16S rRNA signatures PAEN 862F and PAEN 515F are reported to be present in the rRNA gene of this species. The major isoprenoid quinone is MK-7 and the major fatty acid is C_{15:0 anteiso}; smaller, but still significant, amounts (around 10%) of C_{16:0}, C_{17:0 anteiso}, C_{16:0 iso}, and C_{15:0 iso} are also present.

Isolated from a desert soil sample from Gansu Province in China.

DNA G+C content (mol%): 50 (HPLC).

Type strain: B518, KCTC 3950, DSM 16968.

EMBL/GenBank accession number (16S rDNA) of the type strain: AY839866 (B518).

33. **Paenibacillus glucanolyticus** (Alexander and Priest 1989) Shida, Takagi, Kadowaki, Nakamura and Komagata 1997a, 297^{VP} (*Bacillus glucanolyticus* Alexander and Priest 1989, 113).

glu.can.o.ly'ti.cus. N.L. n. *glucanum* glucan (a polysaccharide of D-glucose monomers) Gr. adj. *lutikos* dissolvable; N.L. adj. *glucanolyticus* hydrolyzing glucose polymers.

Cells are facultatively anaerobic, long (>3.0 µm), thin (0.9 µm) rods that produce ellipsoidal terminal spores that swell the sporangia. Colonies are flat, smooth, opaque, and motile on nutrient agar plates. Grows at pH 5.7 and 17–37°C, but not at 5 or 50°C with variable growth at 45°C. Reduces nitrate to nitrite. Voges–Proskauer reaction is negative. Produces acid, but no gas, from sugars. Hydrolyzes a range of carbohydrates including carboxymethyl cellulose, curdlan (a β-1,3-glucan), pustulan (a β-1,6-glucan), β-1,2-glucan, pullulan, and starch. Major fatty acids are C_{15:0 anteiso}, C_{16:0 iso}, and C_{16:0}.

Habitat: soil.

DNA G+C content (mol%): 48.1 (T_m).

Type strain: DSM 5162, NCIMB 12809.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB073189 (DSM 5162).

34. **Paenibacillus glycanilyticus** Dasman, Kajiyama, Kawasaki, Yagi, Seki, Fukusaki and Kobayashi 2002, 1671^{VP}

gly.can.i.ly'ti.cus. N.L. *glucanum* glycan, a heteropolysaccharide; Gr. adj. *lutikos* dissolving; N.L. adj. *glycanilyticus* degrading heteropolysaccharide.

Cells are Gram-positive, facultatively aerobic rods (0.5–0.8 by 3.0–5.0 µm), motile by means of peritrichous flagella. Endospores are ellipsoidal in swollen sporangia. Colonies are flat, smooth, circular, entire, and pinkish-yellow when grown on peptone-yeast extract agar. Optimal growth temperature is 28–37°C; no growth is observed at 50°C. Oxidase is not produced. Distinctive property is the ability to hydrolyze the β-1,4-linked xylogalactoglucan backbone of the heteropolysaccharide extracted from *Nostoc commune*. Major fatty acids are C_{15:0 anteiso} and C_{16:0 iso}.

Habitat: soil.

DNA G+C content (mol%): 50.5 (HPLC).

Type strain: DS-1, JCM 11221, NRRL B-23455.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB042938 (DS-1).

35. **Paenibacillus graminis** Berge, Guinebretière, Achouak, Normand and Heulin 2002, 613^{VP}

gra'mi.nis. L. gen. neut. n. *graminis* of grass.

Cells are motile, Gram-positive, facultatively anaerobic rods (0.5–1.0 by 3.0–4.0 µm), occurring singly or in short chains. Ellipsoidal spores are formed in swollen sporangia. Nutrient agar colonies are cream-colored, smooth with regular, entire margins, and measure 1.0 to 2.0 mm in diameter after 3 d growth at 30°C on TSA. Growth temperature varies from 5–10°C (minimum) to 35–40°C (maximum). Oxidase is not produced. Acid and gas are produced from various carbohydrates. Nitrate is reduced to nitrite. Fixes nitrogen under anaerobic conditions and, at least for the type strain, the *nifH* gene has been demonstrated.

Habitat: soil, maize rhizosphere and wheat roots.

DNA G+C content (mol%): 52.1 (T_m).

Type strain: RSA19, ATCC BAA-95, LMG 19080.

EMBL/GenBank accession number (16S rDNA) of the type strain: AJ223987 (LMG 19080).

36. **Paenibacillus granivorans** van der Maarel, Veen and Wijnbenga 2001, 264^{VP} (Effective publication: van der Maarel, Veen and Wijnbenga 2000, 347)

gra.ni.vo'rans. L. pl. n. *grani* granules; L. part. adj. *vorans* eating, devouring; N.L. part. adj. *granivorans* granules-eating, referring to its ability to hydrolyze granular starch.

Cells are Gram-positive, strictly aerobic rods (0.5–0.8 by 1.5–4.0 µm), motile by peritrichous flagella. Ellipsoidal spores are produced that do not swell the sporangia. Growth occurs optimally at 37°C (maximum of 45°C) and between pH 6–8.5 (with optimum at pH 7.0). Inhibition of growth is observed in media containing 5% NaCl. Reduces nitrate to nitrite, oxidase-negative, and produces acid from glucose and other sugars. Hydrolyzes starch, but not casein or gelatin. Has the distinctive ability to degrade native potato starch granules. Major fatty acid is C_{15:0 anteiso} (>70% of total).

Isolated from wastewater from potato starch production plant.

DNA G+C content (mol%): 47.8 (HPLC).

Type strain: A30, CBS 229.89.

EMBL/GenBank accession number (16S rDNA) of the type strain: AF237682.

37. **Paenibacillus hodogayensis** Takeda, Suzuki and Koizumi 2005, 740^{VP}
 ho.do.ga.yen'sis. N.L. masc. adj. *hodogayensis* pertaining to Hodogaya, the name of a district in Yokohama, Japan, the geographical origin of isolation of the type strain.
 Cells are Gram-variable or Gram-negative, aerobic, motile, spore-forming rods (1.3–1.7 by 2.3–2.8 µm). Ellipsoidal spores are formed in non-swollen or slightly swollen sporangia. Colonies on TYN agar (containing 5 g tryptone, 2.5 g yeast extract, 2.5 g NaCl, and 15 g agar in 1 l distilled water) are white, convex, and opaque. Optimum growth is at 30°C and pH 8. No growth occurs at 50°C or in the presence of 5% (w/v) NaCl. Catalase- and oxidase-positive. Nitrate is not reduced. Indole is not produced. Voges–Proskauer reaction is negative. Citrate is not utilized. Acids are produced from various carbohydrates. The predominant cellular fatty acid is C_{15:0 anteiso}. The major quinone is MK-7(H₂). The PAEN515F binding site has been demonstrated in the 16S rRNA gene.
DNA G+C content (mol%): 55 (HPLC).
Type strain: SG, JCM 12520, KCTC 3919.
EMBL/GenBank accession number (16S rDNA) of the type strain: AB179866 (SG).
38. **Paenibacillus illinoisensis** Shida, Takagi, Kadowaki, Nakamura and Komagata 1997b, 304^{VP}
 il.li.nois.en'sis. N.L. adj. *illinoisensis* referring to Illinois, the state where Microbial Properties Research, National Center for Agricultural Utilization Research, U.S. Department of Agriculture is located.
 Cells are Gram-positive, facultatively anaerobic rods (0.5–0.8 by 3.0–5.0 µm), motile by means of peritrichous flagella. Endospores are ellipsoidal in swollen sporangia. Colonies are flat, smooth, circular, entire, and yellowish-gray. Optimal growth occurs at 37°C with 10 and 50°C as minimum and maximum, respectively. Grows at pH 4.5–9.0 with optimum at pH 7.0. Growth occurs in media with 2% NaCl, but is inhibited by 5% NaCl or 0.02% azide. Does not reduce nitrate to nitrite. Acid is produced from various sugars. Major fatty acids are C_{15:0 anteiso}, C_{16:0}, and C_{17:0 anteiso}.
 Isolated from soil.
DNA G+C content (mol%): 47.6–48.3 (Bd).
Type strain: DSM 11733, IFO 15959, JCM 9907.
EMBL/GenBank accession number (16S rDNA) of the type strain: AB073192 (JCM 9907).
Additional remarks: This species represents DNA homology group 6 of *Bacillus circulans sensu lato* (Nakamura and J. Swezey, 1983).
39. **Paenibacillus jamilae** Aguilera, Monteoliva-Sánchez, Suárez, Guerra, Lizama, Bannasar and Ramos-Cormenzana 2001, 1691^{VP}
 ja.mi'lae. N.L. fem. n. *jamilae* residual water of olive oil production, from *jamilá* a specific term of Arabic origin commonly used in Andalusia, Spain.
 Cells are Gram-variable, facultatively anaerobic rods (0.5–1.2 by 4.5–6.5 µm), motile by means of peritrichous flagella. Endospores are ellipsoidal in swollen sporangia. Colonies are convex, mucoid, opaque, and motile (microcolonies) on wet agar plates. Optimal growth occurs at 30–40°C and pH 5–12. Grows in media with 2% NaCl, but is inhibited by 5% NaCl. Reduces nitrate to nitrite. Oxidase-
- negative. Acid, but no gas, is produced from various sugars. Major fatty acid is C_{15:0 anteiso}.
 Isolated from corn-compost treated with olive mill waste water.
DNA G+C content (mol%): 40.6–40.8 (T_m).
Type strain: CECT 5266, DSM 13815.
EMBL/GenBank accession number (16S rDNA) of the type strain: AJ271157 (CECT 5266).
40. **Paenibacillus kobensis** (Kanzawa, Harada, Takeuchi, Yokota and Harada 1995) Shida, Takagi, Kadowaki, Nakamura and Komagata 1997a, 297^{VP} (*Bacillus kobensis* Kanzawa, Harada, Takeuchi, Yokota and Harada 1995, 517)
 ko.ben'sis. N.L. adj. *kobensis* referring to Kobe City, Hyogo Prefecture, Japan, the source of the soil from which the organisms were isolated.
 Cells are Gram-positive, facultatively aerobic rods (0.5–1.0 by 2.0–6.0 µm), motile by peritrichous flagella. Ellipsoidal spores are formed in swollen sporangia. Colonies are flat, smooth, and opaque on nutrient agar plates and are motile during growth on minimal medium with glucose or curdlan (a β-1,3-glucan) as carbon source. Grows in the presence of 0.001% lysozyme, but not in media containing 5% NaCl. No growth at 50°C. Negative for oxidase and the Voges–Proskauer reaction. Nitrate is reduced to nitrite. Curdlan, pullulan, pustulan (a β-1,6-glucan), and starch are hydrolyzed, but carboxymethyl cellulose and β-1,2-glucans are not. Acid, but no gas, is produced from sugars. Major fatty acids are C_{15:0 anteiso} and C_{16:0 iso}.
 Isolated from soil.
DNA G+C content (mol%): 50–52 (HPLC).
Type strain: DSM 10249, IFO 15729.
EMBL/GenBank accession number (16S rDNA) of the type strain: AB073363 (DSM 10249).
41. **Paenibacillus koleovorans** Takeda, Kamagata, Shinmaru, Nishiyama and Koizumi 2002, 1600^{VP}
 ko.le.o.vo'rans. Gr. n. *koleon* sheath; L. v. *vorare* to devour; N.L. part. adj. *koleovorans* sheath-devouring.
 Cells are Gram-negative, facultatively anaerobic rods (0.4–0.7 by 1–3.2 µm). Ellipsoidal spores are formed in swollen sporangia. Spores have an unusual spiked surface morphology. The creamy-gray colonies that are formed on 1% tryptone agar are of two types: flat and translucent or convex and opaque (this is not connected with degree of sporulation). Does not grow in nutrient broth. Optimal growth temperature is 30°C and optimal pH is 7. In media containing 5% (w/v) NaCl, growth is inhibited. Does not reduce nitrate to nitrite. Voges–Proskauer reaction is negative. Characteristically hydrolyzes the sheath material of *Sphaerotilus natans* and produces acid from a very restricted range of sugars. Major fatty acids are C_{15:0 anteiso}, C_{15:0 iso}, and C_{16:0}.
 Isolated from soil and river water.
DNA G+C content (mol%): 54.0–55.8 (HPLC).
Type strain: TB, JCM 11186, KCTC 13912.
EMBL/GenBank accession number (16S rDNA) of the type strain: AB041720 (TB).
42. **Paenibacillus koreensis** Chung, Kim, Hwang and Chun 2000, 1499^{VP}
 ko.re.en'sis. N.L. masc. adj. *koreensis* indicating Korea, the geographical origin of isolation.

Cells are Gram-variable, facultatively anaerobic rods (0.5–0.9 by 2.3–4.5 µm), motile by means of peritrichous flagella. Endospores are ellipsoidal in swollen sporangia. Colony morphology is variable on 0.1× TSA, but is typically circular, flat smooth, and opaque. Grows at 10–50°C, with an optimum at 38–48°C. Growth is inhibited by 7% NaCl in the medium. Reduces nitrate to nitrite. Positive for oxidase and negative for Voges–Proskauer reaction. Hydrolyzes casein, chitin, chitosan, esculin, and starch. Selective isolation has been achieved using colloidal chitin as carbon source. Ferments various sugars with the formation of acid, but no gas. Produces an iturin-like antifungal antibiotic. Major fatty acid is C_{15:0 anteiso}.

Isolated from soil.

DNA G+C content (mol%): 54 (T_m).

Type strain: YC300, KCTC 2393, KCCM 40903.

EMBL/GenBank accession number (16S rDNA) of the type strain: AF130254 (YC300).

43. **Paenibacillus kribbensis** Yoon, Oh, Yoon, Kang and Park 2003, 299^{VP}

krib.ben'sis. N.L. masc. adj. *kribbensis* arbitrary name formed from the acronym of the Korea Research Institute of Bioscience and Biotechnology, KRIBB, where taxonomic studies on this species were performed.

Cells are Gram-variable, facultatively anaerobic rods (1.3–1.8 by 4.0–4.7 µm), motile by means of peritrichous flagella. Endospores are ellipsoidal in swollen sporangia. Colonies are cream-colored, circular to slightly irregular, flat to low convex, and translucent on TSA. Growth occurs at 10–44°C, but not at 4 or 45°C, with optimum growth at 30–37°C. Growth is optimal with 0–2% NaCl in the medium, but is inhibited by 5% NaCl. Reduces nitrate to nitrite. Oxidase- and urease-negative. Hydrolyzes casein, esculin, gelatin, and starch. Produces acid, but no gas, from a variety of sugars. Major fatty acids are C_{15:0 anteiso}, C_{15:0 iso}, C_{16:0}, and C_{17:0 anteiso}.

Isolated from soil.

DNA G+C content (mol%): 48 (HPLC).

Type strain: AM49, JCM 11465, KCTC 0766BP.

EMBL/GenBank accession number (16S rDNA) of the type strain: AF391123 (AM49).

44. **Paenibacillus lactis** Scheldeman, Goossens, Rodriguèz-Diàz, Pil, Goris, Herman, De Vos, Logan and Heyndrickx 2004, 889^{VP}

lac'tis. L. masc. n. *lac* milk; L. gen. n. *lactis* from milk, referring to milk (and its environment on the dairy farm) as the principal isolation source.

Cells are Gram-negative or Gram-variable, straight and round-ended, aerobic, motile rods (0.6–0.9 by 3–6 µm) that may occasionally be slightly tapered and curved. Endospores are ellipsoidal or cylindrical, are located subterminally and occasionally paracentrally, and usually swell the sporangia. Colonies grown for 4 d on TSA at 30°C are opaque, cream-colored, slightly convex, and round, with rough or spreading transparent edges and with an eggshell surface texture. Motile microcolonies may spread across the surface of the agar and rotate in a clockwise direction. Colony diameter is 1–2 mm. Optimal growth temperature falls between 30 and 40°C, with maxima between 50 and 55°C. Optimum pH for

growth is 7.0 with pH 5.0–6.0 and pH 10.5–11.0 as minima and maxima, respectively. Casein is not hydrolyzed. Nitrate reduction is variable. Hydrogen sulfide production, urease reaction, and hydrolysis of gelatin are negative. Hydrolysis of esculin is positive. Acid is produced without gas from various carbohydrates. The major cellular fatty acids based on measurements of 10 strains are C_{15:0 anteiso}, C_{16:0}, C_{15:0 iso}, C_{17:0 anteiso}, C_{16:0 iso}, and C_{17:0 iso}.

Isolated from raw and heat-treated milk in Belgium.

DNA G+C content (mol%): 51.6 (HPLC; mean value).

Type strain: MB 1871, LMG 21940, DSM 15596.

EMBL/GenBank accession number (16S rDNA) of the type strain: AY257868 (MB 1871).

45. **Paenibacillus larvae** (White 1906) Heyndrickx, Vandemeulebroecke, Hoste, Janssen, Kersters, De Vos, Logan, Ali and Berkeley 1996a, 278^{VP} (*Bacillus larvae* White 1906, 42; *Paenibacillus larvae* Ash, Priest and Collins 1995, 197)

lar'vae. L. n. *larva* a larva; N.L. gen. n. *larvae* of a larva.

Cells are facultatively anaerobic rods. Spores are formed sparsely *in vitro*. Fastidious, does not survive serial transfer in nutrient broth. Grows well on Columbia blood agar containing 5% horse blood. Reduction of nitrate to nitrite is variable. Catalase is not produced or produced very weakly. Acid, but no gas, is produced from various sugars.

The species was divided into the subspecies *Paenibacillus larvae* subsp. *larvae* and *Paenibacillus larvae* subsp. *pulvificiens* by Heyndrickx et al. (1996a), but recently the existence of two subspecies has been reconsidered by Genersch et al. (2006), who proposed reclassification into a single species based on a polyphasic study encompassing more strains than the former studies and by which the former subspecies discrepancies based on PAGE profiling of cell proteins became uncertain. Forms small (<1 mm diameter), regular, glossy, grayish colonies on Columbia blood agar after incubation for 2 to 4 d at 37°C, sometimes with a bright orange pigment. The only known host for the bacterium is the larva of the honeybee (*Apis mellifera*) in which it causes the disease American foulbrood. This disease occurs throughout the world and is a serious threat to apiary. The name is derived from the odor of the decaying larvae. Major fatty acids are C_{15:0 anteiso}, C_{15:0 iso}, and C_{17:0 anteiso}.

Isolated from diseased honeybee larvae and the honey, wax, and pollen of affected hives and from powdery scales of honeybee larvae.

DNA G+C content (mol%): 42–43 (T_m).

Type strain: ATCC 9545, DSM 7030, LMG 15969; additional reference strains are the former type strains of *Paenibacillus pulvificiens*, i.e., ATCC 13537, DSM 3615, LMG 15974.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB073205 (DSM 7030).

46. **Paenibacillus lautus** (Batchelor 1919) Heyndrickx, Vandemeulebroecke, Scheldeman, Kersters, De Vos, Logan, Aziz, Ali and Berkeley 1996b, 995^{VP} (*Bacillus lautus* Batchelor 1919, 30; *Bacillus lautus* Nakamura 1984b, 225)

lau'tus. L. part. adj. *lautus* washed, splendid.

Grows on routine media such as nutrient agar producing circular to irregularly shaped, low, convex, grayish colonies

that are 1 to 2 mm in diameter. There is a tendency for motile colonies to spread across the agar surface. Grows in 5% NaCl. Facultatively anaerobic, reduces nitrate to nitrite. Hydrolyzes a range of carbohydrates including carboxymethyl cellulose, curdlan (a β -1,3-glucan), pustulan (a β -1,6-glucan), β -1,2-glucan, and starch. Acid, but no gas, is produced from sugars. Major fatty acid is C_{15:0 anteiso}.

Isolated from soil and human intestinal tracts.

DNA G+C content (mol%): 50–52 (Bd).

Type strain: DSM 3035, LMG 11157, JCM 9073.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB073188 (JCM 9073).

Additional remarks: This species represents DNA hybridization group 9 of *Bacillus circulans sensu lato* (Nakamura and Swezey, 1983).

47. **Paenibacillus lentimorbus** (Dutky 1940) Pettersson, Ripper, Yousten and Priest 1999, 538^{VP} (*Bacillus lentimorbus* Dutky 1940, 68)

len.ti.mor'bus. L. adj. *lentus* slow; L. n. *morbus* disease; N.L. n. *lentimorbus* the slow disease.

Cells are Gram-variable or Gram-negative, facultatively anaerobic rods (0.5–0.7 by 1.8–7 μ m). Endospores are ellipsoidal in swollen sporangia. Growth occurs at 20–35°C. Nutritionally fastidious, requires J-broth (Gordon et al., 1973) or MYGPG (Costilow and Coulter, 1971) medium (see *Nutrition and metabolism*). On these media, forms cream-colored colonies less than 1 mm in diameter. Sporulation in laboratory media has not been reported. Spores are produced *in vivo* during growth in susceptible insect larvae. Spores may be accompanied by a parasporal crystal (type strain does not produce a crystal). Catalase-negative and does not reduce nitrate. Fails to grow in 2% NaCl or 1 μ g/ml vancomycin, which distinguishes it from *Paenibacillus popilliae*. Causative agent of type B milky disease in Japanese beetle (*Popillia japonica* Newman) and related scarab larvae, which is characterized by brown clots that block the circulation of hemolymph. Major fatty acids are C_{15:0 anteiso} and C_{16:0}.

Isolated from diseased larvae of a Japanese beetle.

DNA G+C content (mol%): 38 (T_m).

Type strain: ATCC 14707.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB073199 (ATCC 14707).

Additional remarks: Some strains, named *Paenibacillus lentimorbus*, have been erroneously identified at the species level.

48. **Paenibacillus macerans** (Schardinger 1905) Ash, Priest and Collins 1995, 197^{VP} (Effective publication: Ash, Priest and Collins 1993, 259) (*Bacillus macerans* Schardinger 1905, 772)

ma'ce.rans. L. part. adj. *macerans* softening by steeping, retting.

Colonies on nutrient agar are thin, round to spreading. Facultatively anaerobic, reduces nitrate to nitrite. Nitrogen is generally fixed under anaerobic conditions. Hydrolyzes chitin; some strains hydrolyze pectin. Crystalline (Schardinger) dextrans are produced typically from starch. Ethanol and acetic acid are produced in the early stages of glucose fermentation followed by the disappearance of

formate and acetate with gas (H₂ and CO₂) and acetone production (Weimer, 1984). Major fatty acids are C_{15:0 anteiso}, C_{16:0}, and C_{16:0 iso}.

Major habitat is composting plant materials, less common in nutrient-poor soils.

DNA G+C content (mol%): 52–53 (T_m).

Type strain: IAM 12467, ATCC 8244, DSM 24, NCIMB 9368.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB073196 (IAM 12467).

Additional remarks: The four different sequences available for the type strain differ considerably; the IAM sequence is recommended for phylogenetic studies.

49. **Paenibacillus macquariensis** (Marshall and Ohye 1966) Ash, Priest and Collins 1995, 197^{VP} (Effective publication: Ash, Priest and Collins 1993, 259.) (*Bacillus macquariensis* Marshall and Ohye 1966, 41)

mac.qua.ri.en'sis. N.L. adj. *macquariensis* pertaining to Macquarie Island.

Colonies on nutrient agar are opaque and smooth with translucent fimbriate edges. Colonies are 0.5 to 1 mm in diameter after incubation for 4 d at 20°C. Facultative anaerobe. Does not reduce nitrate to nitrite. Psychrophilic, maximum growth temperature is 25°C and optimum is 15–20°C. Will grow at 0°C within 3 weeks. Major fatty acid is C_{15:0 anteiso} (80% of total).

Isolated from soil from Macquarie Island (sub Antarctic).

DNA G+C content (mol%): 39 (T_m).

Type strain: ATCC 23464, DSM 2, NCIMB 9934.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB073193 (DSM 2).

50. **Paenibacillus massiliensis** Roux and Raoult 2004, 1051^{VP} mas.si.li.en'sis. L. masc. adj. *massiliensis* of Massilia, the old Greek and Roman name for Marseille, where the type strain was isolated.

Cells are Gram-positive, facultatively anaerobic rods (0.5 by 2.0–4.0 μ m), motile by peritrichous flagella. Ellipsoidal endospores are formed in swollen sporangia. Grows on routine media and forms translucent, beige-colored, flat colonies after incubation for 24 h at 30°C. Catalase-positive, oxidase-negative. Optimal growth occurs at 30–37°C, but can grow at 50°C. Growth occurs in the presence of 5% (w/v) NaCl. Nitrate is reduced, but gelatin is not liquefied. Acid is produced from various carbohydrates.

Type strain was isolated from blood culture.

DNA G+C content (mol%): not reported.

Type strain: 2301065, CIP 107939, CCUG 48215.

The EMBL/GenBank accession number (16S rDNA) of the type strain: AY323608 (2301065).

51. **Paenibacillus mendelii** Šmerda, Sedláček, Páova, Durnová, Smíšková and Havel 2005, 2353^{VP}

men.de'li.i. N.L. gen. n. *mendelii* of Mendel, to honor J. G. Mendel, the founder of genetics.

Cells are Gram-variable, aerobic or facultatively anaerobic, spore-forming rods. Spores are oval with a subterminal position in a swollen sporangium. Optimal growth occurs between 25 and 30°C; no growth is observed at 50°C or in media with 5% NaCl. Colonies on nutrient agar are

circular, smooth, flat, bright, translucent with entire edges, and about 1–2 mm in diameter. Positive for catalase, oxidase, lecithinase, β -galactosidase, and hydrolysis of esculin. Acid is produced from various carbohydrates. Acetoin and indole are not produced. Negative for hydrolysis of casein, starch, hippurate urea, gelatin, Tween 80, and tyrosine. Citrate is not utilized. Arginine dihydrolase and DNase are not produced. Nitrate is not reduced. Hydrolysis of agar is not observed. An antibiotic profile has been reported. The major fatty acid is $C_{15:0}^{anteiso}$. The closest phylogenetic neighbors are *Paenibacillus phyllosphaerae*, *Paenibacillus curd-lanolyticus*, and *Paenibacillus kobensis*.

Habitat is not known, but the type strain was isolated from surface-sterilized pea seeds.

DNA G+C content (mol%): 50.8 (HPLC).

Type strain: C/2, CCM 4839, LMG 23002.

EMBL/GenBank accession number (16S rDNA) of the type strain: AF537343 (C/2).

52. **Paenibacillus motobuensis** Iida, Ueda, Kawamura, Ezaki, Takade, Yoshida and Amako 2005, 1814^{VP}

mo.to.bu.en'sis. N.L. masc. adj. *motobuensis* pertaining to Motobu in Okinawa, Japan, where the type strain was isolated.

Cells are Gram-negative, facultatively anaerobic rods (0.6–1.0 by 1.0–3 μ m), motile by peritrichous flagella. Ellipsoidal spores are located terminally. Colonies are circular, flat, smooth, and opaque white. Growth occurs at 20–55°C, with an optimum of 37°C. The pH range for growth is 6.0–8.0 (optimum is pH 8.0). Growth occurs in the presence of 5% NaCl, but is inhibited by 10%. Positive catalase and oxidase reactions. Negative Voges–Proskauer reaction. Nitrate is reduced to nitrite. The major fatty acid is $C_{15:0}^{anteiso}$ (39.8%). Various compounds of the Biolog GP pallet are oxidized.

The type strain was isolated from a composting machine containing soil from Motobu, Okinawa, Japan.

DNA G+C content (mol%): 47 (HPLC).

Type strain: MC10, GTC 1835, JCM 12774, CCG 50090.

EMBL/GenBank accession number (16S rDNA) of the type strain: AY741810 (MC10).

53. **Paenibacillus naphthalenovorans** Daane, Harjono, Barns, Launen, Palleroni and Håggblom 2002, 137^{VP}

naph.tha.le.no.vo'rans. L. neut. n. *naphthalene* from Persian *neft* naphtha; L. v. *vorare* to devour; N.L. part. adj. *naphthalenovorans* naphthalene-devouring.

Cells are Gram-positive, strictly aerobic rods (0.8 by 2.8–4.0 μ m), motile by means of peritrichous flagella. Ellipsoidal spores are formed in swollen sporangia. Forms white, translucent, mucoid colonies on solid media. Optimal growth occurs at 30–37°C, but does not grow at 10 or 55°C. Growth is inhibited in media with 5% NaCl and variable if 3% NaCl is present. Some strains reduce nitrate to nitrite. Acid is produced from a limited range of sugars. Able to use naphthalene as sole carbon source. Major fatty acids are $C_{15:0}^{anteiso}$, $C_{16:0}$ and $C_{16:1}$.

Isolated from soil from estuarine sediments and rhizosphere of salt marsh plants.

DNA G+C content (mol%): 49 (HPLC).

Type strain: ATCC BAA-206, DSM 14203.

EMBL/GenBank accession number (16S rDNA) of the type strain: AF353681 (ATCC BAA-206).

54. **Paenibacillus nematophilus** Enright, McInerney and Griffin 2003, 439^{VP}

ne.ma.to'phi.lus. N.L. n. *nematoda* nematode; Gr. adj. *philos* loving or having affinity for; N.L. adj. *nematophilus* nematode-loving.

Cells are Gram-negative to Gram-variable (older cultures), motile rods (0.5–1.0 by 3.5–7.0 μ m). Oval-shaped endospores are produced in swollen, spindle-shaped sporangia and lie in a central/paracentral position. Endospore is retained within the sporangium. Forms small (0.5–4.0 mm in diameter) colonies on nutrient agar that are thin, non-pigmented, regular, smooth, and slightly umbonate with an undulate edge. Grows in 2% but not 3% (w/v) NaCl. Grows optimally at 30°C. Growth occurs at 10–37°C, but not at 5 or 40°C. Grows at pH 6–11, but not at pH 5.6. Oxidase-negative. Positive for Voges–Proskauer test. Grows weakly anaerobically, does not reduce nitrate. Hydrolyzes esculin and starch, but not casein or gelatin. Produces acid, but no gas, from various sugars. Major fatty acids are $C_{15:0}^{anteiso}$ and $C_{16:0}$.

Isolated from *Heterorhabditis* species, which are insect-pathogenic nematodes. The sporangia of the bacterium adhere to the free-living, infective stage of the nematode, which carries it to new hosts in which the bacterium reproduces.

DNA G+C content (mol%): 44 (HPLC).

Type strain: NEM1a, DSM 13559.

EMBL/GenBank accession number (16S rDNA) of the type strain: AF480935 (NEM1a).

55. **Paenibacillus odorifer** Berge, Guinebretière, Achouak, Normand and Heulin 2002, 614^{VP}

o.do'ri.fer. L. n. *odor* smell; L. suff. n. *-fer* carrier; L. n. *odorifer* carrier of smell.

Cells are Gram-positive, motile, facultatively anaerobic rods (0.5–1.0 by 2.0–4.0 μ m), occurring singly or in short chains. Oval terminal spores are formed in swollen sporangia. Nutrient agar colonies are cream-colored, smooth with regular margins, and measure 1.5–3 mm in diameter after incubation for 3 d at 30°C on TSA. Oxidase-negative. Nitrate is reduced to nitrite. Acid is produced from various carbohydrates. Fixes nitrogen under anaerobic conditions and, at least for the type strain, the presence of the *nifH* gene has been shown. Produces a characteristic, fruity, volatile aroma on nutrient media.

Isolated from wheat roots and vegetable purées.

DNA G+C content (mol%): 44 (T_m).

Type strain: ATCC BAA-93, LMG 19079.

EMBL/GenBank accession number (16S rDNA) of the type strain: AJ223990 (LMG 19079).

56. **Paenibacillus pabuli** (ex Schieblich 1923) Ash, Priest and Collins 1995, 197^{VP} (Effective publication: Ash, Priest and Collins 1993, 259.) (*Bacillus pabuli* ex Schieblich 1923; Nakamura 1984b, 225)

pa'bu.li. L. gen. n. *pabuli* of fodder.

Cells are 2.0–4.0 μ m long by 0.5–1.0 μ m wide. Facultatively anaerobic. Does not reduce nitrate to nitrite. Hydrolyzes

carboxymethyl cellulose, curdlan, pectin, and starch, but not chitin, or β -1,2- and β -1,6-glucans. Acid, but no gas, is produced from various sugars. Major fatty acid is $C_{15:0}$ anteiso (about 70% of total).

Isolated from soil and fodder.

DNA G+C content (mol%): 48–50 (Bd).

Type strain: DSM 3036, NRRL NRS-924, JCM 9074.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB073191 (JCM 9074).

Additional remarks: This species represents DNA hybridization group 5 of *Bacillus circulans sensu lato* (Nakamura and Swezey, 1983).

57. **Paenibacillus panacisoli** Ten, Baek, Im, Lee, Oh and Lee 2006, 2680^{VP}

pa.na.ci.so'li. N.L. n. *Panax-acis* scientific name of ginseng; L. n. *solum* soil; N.L. gen. n. *panacisoli* of soil of a ginseng field.

Cells are Gram-positive, facultatively anaerobic, motile, spore-forming rods (0.4–0.6 by 2.0–5.0 μ m). Spores are oval and occur subterminally in swollen sporangia. On R2A, colonies are 0.5–1.0 mm in diameter, convex, irregular, undulate, non-glossy, and slightly yellowish after 1 d. Optimal growth occurs at 37°C, with 42–45°C and 15–20°C as respective maxima and minima. Optimal pH for growth is 6.5, with pH 4.5–5 and pH 8.5–9 as respective minima and maxima. Oxidase and catalase reactions are positive. Nitrate is reduced to nitrite. Tolerates 5% (w/v) NaCl, but not 7%. No growth occurs on TSA, MacConkey agar, or nutrient agar. Hydrolyzes xylan and casein (weakly), but not chitin, starch, cellulose, DNA, or esculin. Utilization of compounds for growth is limited to a few carbohydrates. Positive in API 20E for gelatin hydrolysis and tryptophan deaminase; negative for arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, β -galactosidase, urease, indole and hydrogen sulfide production, citrate utilization, and the Voges–Proskauer reaction. Acid production from carbohydrates is usually weak, if present at all. MK-7 is the predominant menaquinone. The major fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{16:0}$. Phylogenetically, the most closely related species are *Paenibacillus xylanilyticus*, *Paenibacillus illinoisensis*, *Paenibacillus pabuli*, and *Paenibacillus amylolyticus*.

The type strain was isolated from soil of a ginseng field of Pocheon Province, South Korea.

DNA G+C content (mol%): 53.9 (HPLC).

Type strain: Gsoil 1411, KCTC 13020, LMG 23405.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB245384 (Gsoil 1411).

58. **Paenibacillus pasadenensis** Osman, Satomi and Venkateswaran 2006, 1512^{VP}

pa.sa.den.en'sis. N.L. masc. adj. *pasadenensis* referring to Pasadena, the city in which the JPL-SAF is located.

Cells are Gram-positive, spore-forming rods (0.5–0.8 by 3.0–5.0 μ m), motile by peritrichous flagella. Ellipsoidal spores are formed in swollen sporangia. On nutrient agar, colonies are flat, smooth, circular, entire, and brownish-yellow, with no soluble pigment formation. Catalase and oxidase tests and the Voges–Proskauer reaction are positive. Hydrogen sulfide and indole are not produced. Nitrate is

not reduced to nitrite. Gelatin is liquefied, esculin is hydrolyzed, and β -galactosidase is produced. Growth occurs in the presence of 2% NaCl and 0.001% lysozyme. Growth is inhibited by 3% NaCl. Utilizes α -cyclodextrin, D-cellobiose, D-fructose, maltose, D-melibiose, methyl β -D-glucoside, D-ribose, pyruvic acid, L-alanyl glycine, and L-serine. Acid is not produced from D-glucose.

The type strain was isolated from the entrance floor of the JPL-SAF, Pasadena, CA, USA.

DNA G+C content (mol%): not reported.

Type strain: SAFN-007, ATCC BAA-1211, NBRC 101214.

EMBL/GenBank accession number (16S rDNA) of the type strain: AY167820 (SAFN-007).

59. **Paenibacillus peoriae** (Montefusco, Nakamura and Labeda

1993) Heyndrickx, Vandemeulebroecke, Scheldeman, Kersters, De Vos, Logan, Aziz, Ali and Berkeley 1996b, 999^{VP} (*Bacillus peoriae* Montefusco, Nakamura and Labeda 1993, 389)

pe.o'ri.ae. N.L. gen. n. *peoriae* of Peoria, named after Peoria, Illinois, where the organism was studied.

Grows on routine media such as nutrient agar producing butyrous, thin, smooth, circular, translucent colonies about 2 mm in diameter after incubation for 2 to 3 d at 30°C. Facultatively anaerobic, generally reduces nitrate to nitrite. Hydrolyzes pectin, pullulan, starch, and xylan. Acid and gas are produced from sugars. Acetylene reduction, an indication of nitrogen fixation, has been detected in some strains of this species (von der Weid et al., 2002). Major fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$, and $C_{17:0}$ anteiso.

Isolated from soil and fodder.

DNA G+C content (mol%): 46 (Bd).

Type strain: DSM 8320, LMG 14832.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB073186 (DSM 8320).

60. **Paenibacillus phyllosphaerae** Rivas, Mateos, Martínez-Molina and Velázquez 2005c, 745^{VP}

phyl.lo.sphae'rae. Gr. neut. n. *phyllon* leaf; L. fem. n. *sphaera* ball, sphere; N.L. gen. fem. n. *phyllosphaerae* of the phyllosphere.

Cells are Gram-variable, aerobic or facultatively anaerobic, spore-forming rods, motile with peritrichous flagella. Forms ellipsoidal spores in swollen sporangia in subterminal position. Chemo-organotrophic and xylanolytic. Colonies on yeast extract-glucose medium are circular, flat, whitish-cream, opaque, and 1–3 mm in diameter after 48 h growth at 28°C. Growth occurs between 10 and 37°C (optimal growth temperature is 28°C). The optimal pH for growth is 7. Oxidase- and catalase-positive. No growth in the presence of 5% NaCl. The major quinone is MK-7. The main fatty acid is $C_{15:0}$ anteiso. Gas is not produced from D-glucose, although a number of sugars are used as carbon sources. Xylanase, cellulase, amylase, and β -galactosidase are actively produced. Caseinase, arginine dihydrolase, indole, lysine decarboxylase, ornithine decarboxylase, urease, phenylalanine deaminase, tryptophan deaminase, hydrogen sulfide, and acetoin (Voges–Proskauer medium) reactions are negative. Nitrate is reduced to nitrite.

Isolated from the phyllosphere of *Phoenix dactylifera* in Palma de Mallorca (Spain).

DNA G+C content (mol%): 50.7 (T_m).

Type strain: PALXIL04, LMG 22192, CECT 5862.

EMBL/GenBank accession number (16S rDNA) of the type strain: AY598818 (PALXIL04).

61. **Paenibacillus popilliae** (Dutky 1940) Pettersson, Rippere, Yousten and Priest 1999, 539^{VP} (*Bacillus popilliae* Dutky 1940, 68)

po.pil'li.ae. N.L. n. *Popillia* generic name of the Japanese beetle; N.L. gen. n. *popilliae* of *Popillia*.

Cells are rods (0.5–0.8 by 1.3–5.2 µm), Gram-variable to Gram-negative in exponential phase and Gram-positive when sporulating. Nutritionally fastidious, requires J-broth (Gordon et al., 1973) or MYGPG (Costilow and Coulter, 1971) medium. On these media, forms cream-colored colonies less than 1 mm in diameter. Sporulation in laboratory media is poor. Spores are produced *in vivo* during growth in susceptible insect larvae. Spores are usually accompanied by a parasporal crystal. Facultatively anaerobic, does not reduce nitrate. Catalase-negative. Most strains grow in 2% NaCl or 150 µg/ml vancomycin, which distinguishes the species from *Paenibacillus lentimorbus*; however, strains isolated in South America are vancomycin-sensitive (Harrison et al., 2000). Does not grow in media containing 5% NaCl. Causative agent of type A milky disease in Japanese beetle (*Popillia japonica* Newman) and related scarab larvae which is characterized by increasing milky whiteness of the almost translucent grub as the bacterium grows and sporulates in the hemolymph. Major fatty acids are C_{15:0} and C_{16:0}^{anteiso}.

Isolated from diseased larvae of Japanese beetle.

DNA G+C content (mol%): 41 (T_m).

Type strain: ATCC 14706, DSM 2047, KCTC 3766, LMG 17744.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB073198 (ATCC 14706).

Additional remarks: Strains named as *Paenibacillus popilliae* are phylogenetically heterogeneous.

62. **Paenibacillus rhizosphaerae** Rivas, Gutiérrez, Abril, Mateos, Martínez-Molina, Ventosa and Velázquez 2005a, 1307^{VP}

rhi.zo.sphae'rae. Gr. fem. n. *rhiza* root; L. fem. n. *sphaera* -ae ball, any globe, sphere; N.L. gen. fem. n. *rhizosphaerae* of the rhizosphere.

Cells are Gram-positive aerobic rods (0.9–1.0 by 3.0–3.1 µm), motile by means of peritrichous flagella. Spores are subterminal and cause slight swelling of the sporangia. Colonies grown on nutrient agar (for 48 h at 28°C) are circular, convex, cream-colored, opaque, and usually 1–3 mm in size. Growth occurs at 10–37°C and pH 5–9. The optimum growth temperature is 28°C and the optimum pH is 7. Grows without NaCl and with up to 5.0% (w/v) NaCl. Oxidase- and catalase-positive. Gas is not produced from glucose. Acid is produced from various carbohydrates. Gelatinase, urease, and hydrogen sulfide are not produced. The predominant fatty acids are C_{15:0}^{anteiso}, C_{16:0}^{anteiso}, and C_{16:0}^{iso}.

The type strain was isolated from the rhizosphere of the legume *Cicer arietinum* in Argentina.

DNA G+C content (mol%): 50.9 (T_m; type strain).

Type strain: CECAP06, LMG 21955, CECT 5831.

EMBL/GenBank accession number (16S rDNA) of the type strain: AY751754 (CECAP06).

63. **Paenibacillus sanguinis** Roux and Raoult 2004, 1052^{VP}

san'gui.nis. L. masc. gen. n. *sanguinis* of blood, referring to the fact that the type strain was isolated from a blood sample.

Gram-positive, facultatively anaerobic rods (0.5 by 2.0–3.0 µm), motile by peritrichous flagella. Ellipsoidal endospores are formed in swollen sporangia. Colonies are grayish, translucent, shiny, regular circles, and 1 mm in diameter after 24 h incubation at 30°C (the medium was not reported). Catalase- and oxidase-negative. Optimal growth occurs at 30–37°C, but no growth occurs at 50°C. Growth does not occur in the presence of 5% (w/v) NaCl. Nitrate is not reduced and gelatin is not liquefied. Acid is produced from various carbohydrates.

The type strain was isolated from blood culture.

DNA G+C content (mol%): not reported.

Type strain: 2301083, CIP 107938, CCUG 48214.

EMBL/GenBank accession number (16S rDNA) of the type strain: AY323609 (2301083).

64. **Paenibacillus sepulcri** Šmerda, Sedláková, Páková, Krejčí and Havel 2006, 2343^{VP}

se.pul'cri. L. gen. n. *sepulcri* from a tomb, pertaining to the place of isolation of the type strain.

Cells are Gram-variable, facultatively anaerobic, spore-forming rods. Spores are oval, subterminally in swollen sporangia. Moderately psychrotolerant. The temperature range for growth is 10–30°C and the optimum is 25°C; no growth occurs at 37°C. Grows at pH 6.0–8.0; the optimum is between pH 7.2 and 7.4. Tolerates up to 2% NaCl, but not 3% NaCl. Colonies on nutrient agar are circular, smooth, slightly convex with complete edges, and colorless. Oxidase-positive. Acid is produced from various carbohydrates. Phylogenetically, the most closely related species is *Paenibacillus mendelii*. The predominant menaquinone is MK-7. The cell wall contains *meso*-DAP of the A1γ type with C_{15:0}^{anteiso} as major fatty acid component.

Isolated from the biodeteriorated mural paintings in the Servilia tomb (Spain).

DNA G+C content (mol%): 50 (HPLC).

Type strain: CCM 7311, LMG 19508.

EMBL/GenBank accession number (16S rDNA) of the type strain: DQ291142 (CCM 7311).

65. **Paenibacillus stellifer** Suominen, Spröer, Kämpfer, Rainey, Lounatmaa and Salkinoja-Salonen 2003, 1373^{VP}

stel'li.fer. L. masc. adj. *stellifer* star-bearing/starry, referring to the presence of star-shaped spores.

Gram-positive, facultatively anaerobic rods (0.6–0.8 by 2.5–5.0 µm), motile by means of peritrichous flagella. In swollen sporangia, terminally ellipsoidal spores are formed with spikes in electron micrographs of thin sections that are actually ribs connecting the poles of the spore. Spores as well as vegetative cells have pilus-like appendages. The temperature range for growth is 15–40°C. Does not reduce nitrate to nitrite. Hydrolyzes starch with the formation of cyclodextrins. Produces acid from various sugars. The temperature range for growth is 15–40°C. Non-hemolytic. Catalase-positive and oxidase-negative. Nitrate is not reduced to nitrite or nitrogen. Some biochemical characteristics are reported by Suominen et al. (2003) as being similar to those of *Paenibacillus durus*/*Paenibacillus azotofixans* without

the exact data being provided, which makes a correct interpretation difficult. The major fatty acid is C_{16:0} (34–45% total fatty acids) and the ratio of C_{15:0} iso:anteiso (28°C) is 2.3–2.5. Produces cyclodextrins from potato starch.

Isolated from food packaging paper and board.

DNA G+C content (mol%): 55.6 (HPLC).

Type strain: IS 1, CCUG 45566, DSM 14472.

EMBL/GenBank accession number (16S rDNA) of the type strain: AJ316013 (IS 1).

66. **Paenibacillus terrae** Yoon, Oh, Yoon, Kang and Park 2003, 300^{VP}

ter'rae. L. gen. n. *terrae* of the earth.

Cells are Gram-variable, facultatively anaerobic rods (1.3–1.8 by 4.0–7.0 µm), motile by means of peritrichous flagella on TSA. Ellipsoidal spores are formed in swollen sporangia. Colonies are cream-colored, irregular in shape, thin, and translucent on TSA. Growth occurs at 10–40°C with an optimum at 30°C. Optimal pH for growth is 6.5–8.0; no growth at pH 4.0. Grows optimally in the presence of 0–2% (w/v) NaCl and growth still occurs in presence of 3% (w/v), but not in the presence of 4% (w/v) NaCl. Oxidase-negative. Reduces nitrate to nitrite; one strain has been reported to denitrify (Horn et al., 2005). Hydrolyzes esculin, casein, gelatin, and starch, but not urea. Produces acid, but not gas, from a range of sugars. Major fatty acid is C_{15:0} anteiso'. Predominant menaquinone is MK-7.

Isolated from a soil sample from Taejon City, Korea.

DNA G+C content (mol%): 47 (HPLC).

Type strain: AM141, KCCM 41557, JCM 11466.

EMBL/GenBank accession number (16S rDNA) of the type strain: AF391124 (AM141).

67. **Paenibacillus thiaminolyticus** (ex Kuno 1951) Shida, Takagi, Kadowaki, Nakamura and Komagata 1997a, 297^{VP} ("Bacillus thiaminolyticus" ex Kuno 1951, 364; *Bacillus thiaminolyticus* Nakamura 1990, 245)

thi.am.in.o.ly'tic.us. N.L. n. *thiaminum* thiamine; N.L. adj. *lyticus* dissolving; N.L. adj. *thiaminolyticus* decomposing thiamine.

Cells are Gram-positive, facultatively anaerobic, motile rods (0.5–1.0 by 2.0–3.0 µm). Ellipsoidal spores are formed in swelling sporangia. Agar colonies are translucent, thin, smooth, and entire, measuring 1.0–2.0 mm in diameter. Optimal temperature for growth is 28°C with 20°C and 45°C as respective minimum and maximum. No growth is observed at pH 5.6 or 5.7. Most strains grow in media containing 5% NaCl, but are inhibited by 7% NaCl. Nitrate is usually reduced to nitrite. Hydrolyzes chitin, casein, pullulan, and starch. Decomposes tyrosine and thiamine. Acid, but no gas, is produced from sugars. Major fatty acids are C_{15:0} anteiso', C_{15:0} iso', and C_{17:0} anteiso'.

Isolated from human fecal material and honeybee larvae.

DNA G+C content (mol%): 52–54 (Bd).

Type strain: DSM 7262, NRRL B-4156, IFO 15656.

EMBL/GenBank accession number (16S rDNA) of the type strain: AJ320490 (DSM 7262).

68. **Paenibacillus timonensis** Roux and Raoult 2004, 1053^{VP}

ti.mo.nen'sis. N.L. masc. adj. *timonensis* pertaining to the Hôpital de la Timone, where the type strain was isolated.

Gram-positive, facultatively anaerobic rods (0.5 by 2.0 µm). Ellipsoidal endospores are formed in swollen sporangia. Colonies are grayish, translucent, shiny, 1.5 mm in diameter, regularly shaped, and low convex after incubation for 24 h at 30°C. Motile by peritrichous flagella. Catalase-positive, but oxidase-negative. Optimal growth occurs at 30–37°C; also grows at 50°C. Growth does not occur in the presence of 5% (w/v) NaCl. Nitrate is reduced weakly, but gelatin is not liquefied. Acid is produced from various carbohydrates.

The type strain was isolated from blood culture.

DNA G+C content (mol%): not reported.

Type strain: 2301032, CIP 108005, CCUG 48216.

EMBL/GenBank accession number (16S rDNA) of the type strain: AY323610 (2301032).

69. **Paenibacillus turicensis** Bosshard, Zbinden and Altwegg 2002, 2247^{VP}

tu.ri.cen'sis. L. adj. *turicensis* referring to *Turicum*, the Latin name of Zurich, where the organism was first isolated.

Cells are Gram-positive, facultatively anaerobic, motile rods (0.5–1.1 by 5–3 µm). Oval spores are terminal to sub-terminal in the sporangia. Grows on sheep blood agar producing non-hemolytic, grayish-white colonies, convex with regular margins. Grows poorly on Luria–Bertani medium. Growth occurs at 15–48°C with an optimum at 37 to 42°C. Growth occurs between pH 5.5 and 9.5 with an optimum at pH 7. Grows in the presence of up to 5% NaCl and 0.1% lysozyme. Catalase- and oxidase-negative. Unable to reduce nitrate. Positive for β-galactosidase and Voges–Proskauer reaction. Ferments a variety of sugars with the production of acid, but no gas. A distinctive feature is the variability of the 16S rRNA genes. Major fatty acids are C_{15:0} anteiso', C_{16:0}' and C_{14:0}'.

Isolated from the valve of a cerebrospinal shunt.

DNA G+C content (mol%): not reported.

Type strain: MOL722, DSM 14349.

EMBL/GenBank accession number (16S rDNA) of the type strain: AF378694 (MOL722).

70. **Paenibacillus validus** (Bredemann and Heigener 1935) Ash, Priest and Collins 1995, 197^{VP} (Effective publication: Ash, Priest and Collins 1993, 259) emend. Heyndrickx, Vandemeulebroecke, Scheldeman, Hoste, Kersters, De Vos, Logan, Aziz, Ali, Berkeley 1995, 667 ("Bacillus validus" ex Bredemann and Heigener 1935; *Bacillus validus* Nakamura 1984b, 225)

val'i.dus. L. adj. *validus* strong, vigorous.

Cells are rod-shaped (0.5–1.0 by 5.0–7.0 µm). Colonies on nutrient agar are grayish-white, translucent, smooth, circular, and entire, 1–2 mm in diameter. Growth occurs optimally at 28–30°C with 5–10 and 45–50°C as respective minimum and maximum ranges. Growth is inhibited by 3% NaCl. Strictly aerobic. Does not reduce nitrate to nitrite. Acid, but no gas, is produced from sugar fermentation. Selective growth on phenanthrene has resulted in isolation of *Paenibacillus validus* strains (Daane et al., 2002). Major fatty acids are C_{15:0} anteiso', C_{16:0} iso', and C_{16:0}'.

Isolated from soil and estuarine sediments.

DNA G+C content (mol%): 50–52 (Bd).

Type strain: JCM 9077, ATCC 43897, DSM 3037, LMG 11161.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB073203 (JCM 9077).

Additional remarks: This species represents DNA hybridization group 10 of *Bacillus circulans sensu lato* (Nakamura and J. Swezey, 1983). It is synonymous with *Paenibacillus gordonae* Heyndrickx, Vandemeulebroecke, Scheldman, Hoste, Kersters, De Vos, Logan, Aziz, Ali and Berkeley (1995).

71. **Paenibacillus wynnii** Rodríguez-Díaz, Lebbe, Rodelas, Heyman, De Vos and Logan 2005, 2097^{VP}

wynn'i.i. N.L. gen. n. *wynnii* of Wynn, in honor of Dr David Wynn-Williams, the Antarctic microbiologist who developed Mars Oasis as a research site.

Gram-negative, motile, facultatively anaerobic, spore-forming curved rods (0.5–0.7 by 3–5 µm) with slightly tapered ends, occurring as single cells or in pairs. Endospores are ellipsoidal or oval and lay paracentrally and subterminally in sporangia that may be swollen. On nutrient agar at 20°C, the maximum colony diameter observed after 3 d is 2 mm. Colonies are circular, convex, and glossy with entire margins. Smaller colonies are transparent and whitish, whereas larger colonies are pale yellow–orange with whitish margins and darker centers. They bear a watery biomass, but may be mucoid. Older colonies are firmly attached to the agar. The optimum temperature for growth is 20°C; some strains grow at 37°C, but no growth is observed at 40°C. Growth is observed at 4°C in broth within 7 d. Optimal pH for growth lies between 7.0 and 8.0; pH 6.0–6.5 and pH 7.0–8.0 are respective minima and maxima. Catalase-positive and oxidase-negative. Does not tolerate 3% NaCl in the medium. Growth on skimmed milk agar plates is scarce and casein is not hydrolyzed. Starch is hydrolyzed. Fixes nitrogen as demonstrated by the presence of the *nifH* gene in all strains and acetylene reduction in most of them (partial sequence of the *nifH* gene is available in EMBL under accession number AJ867247). Voges–Proskauer reaction and gelatin hydrolysis reactions are negative. Reduces nitrate. Acid without gas is produced from various carbohydrates. The main cellular fatty acids are C_{15:0 anteiso} and C_{16:0*}, each present in about 33% of the total fatty acid content.

The type strain and at least seven other strains were from a soil sample collected from four different locations at the Mars Oasis, Antarctica.

DNA G+C content (mol%): 44.6 (HPLC).

Type strain: LMG 22176, DSM 18334, CIP 108306.

EMBL/GenBank accession number (16S rDNA) of the type strain: AJ633647 (LMG 22176).

72. **Paenibacillus xinjiangensis** Lim, Jeon, Park, Xu, Jiang and Kim 2006b, 2581^{VP}

xin.ji.ang.en'sis. N.L. masc. adj. *xinjiangensis* pertaining to Xinjiang in China, where the type strain was isolated.

Cells are Gram-positive, strictly aerobic, spore-forming, motile rods (0.8–1.2 by 2.0–3.2 µm). Colonies are smooth, circular to slightly irregular, slightly convex, and cream-colored on TSA. Growth occurs at 10–40°C with an optimum at 30–35°C in media containing 0–3% (w/v) NaCl (opti-

mum 0–1%) and pH 6.5–9.8 (optimum pH 8.0–8.5). Catalase-positive and oxidase-negative. Nitrate is not reduced to nitrite. Hydrolysis of esculin is positive, but casein, starch, Tweens 20 and 80, L-tyrosine, hypoxanthine, xanthine, and urea are not hydrolyzed. Acids are produced from various carbohydrates. Cell wall contains *meso*-DAP (A1γ type). The predominant menaquinone is MK-7. The major cellular fatty acids on TSA are C_{15:0 anteiso} (48.61%), C_{16:0} (14.43%), C_{16:0 iso} (9.65%), and C_{15:0 iso} (9.32%).

The type strain was isolated from Xinjiang province, China.

DNA G+C content (mol%): 47.0 (HPLC).

Type strain: B538, KCTC 3952, DSM 16970.

EMBL/GenBank accession number (16S rDNA) of the type strain: AY839868 (B538).

73. **Paenibacillus xylanilyticus** Rivas, Mateos, Martínez-Molina and Velázquez 2005b, 406^{VP}

xy.la.ni.ly'ti.cus. N.L. neut. n. *xylanum* xylan; Gr. masc. adj. *lutikos* able to loose, dissolving; N.L. masc. adj. *xylanilyticus* xylan-dissolving.

Cells are Gram-positive, facultatively anaerobic, spore-forming rods (1.5–1.55 by 3.9–4 µm), motile by peritrichous flagella. Subterminal oval endospores are formed in slightly swollen sporangia. Xylanolytic, colonies grown for 48 h at 37°C on YNBX agar (6.7 g/l yeast extract, 7 g/l xylan, 20 g/l agar) are circular, convex, cream-colored, opaque, and usually 1–3 mm in diameter. Optimum growth temperature is 37°C and optimum pH is 7. Oxidase-negative. Nitrate is reduced to nitrite. Does not produce gas from glucose. Acid is produced from various carbohydrates. Produces xylanases, gelatinase, amylase, and β-galactosidase, but not urease, caseinase, phenylalanine deaminase, lysine decarboxylase, arginine dihydrolase, ornithine decarboxylase, tryptophan deaminase, tyrosinase, indole, dihydroxyacetone, hydrogen sulfide, or acetoin. The predominant fatty acids are C_{15:0 anteiso} and C_{16:0*}.

The type strain was isolated from air in a research laboratory, Salamanca University, Spain.

DNA G+C content (mol%): 50.5 (*T_m*).

Type strain: XIL14, LMG 21957, CECT 5839.

EMBL/GenBank accession number (16S rDNA) of the type strain: AY427832 (XIL14).

The following species were described after the submission deadline.

Paenibacillus fonticola Chou, Chou, Lin, Sheu, Sheu, Arun, Young and Chen 2007, 1348^{VP}

fon.ti.co'la. L. masc. n. *fons fontis* a spring, fountain; L. suff. *-cola* (from L. masc. or fem. n. *incola*) an inhabitant of a place, a resident; N.L. n. *fonticola* an inhabitant of a fountain.

The type strain was isolated from a water sample collected from Jhonglun warm spring, Hiayi County, Taiwan.

DNA G+C content (mol%): 49.2 (HPLC).

Type strain: ZL, BCRC 17579, LMG 23577.

EMBL/GenBank accession number (16S rDNA) of the type strain: DQ453131 (ZL).

Paenibacillus forsythiae Ma and Chen 2008, 321^{VP}

for.sy'thi.ae. N.L. gen. n. *forsythiae* of Forsythia, referring to the plant *Forsythia mira*, the source of the rhizosphere soil from which the type strain was isolated.

The type strain was isolated from rhizosphere soil of the plant *Forsythia mira* in the Beijing region, China.

DNA G+C content (mol%): 50.4 (T_m).

Type strain: T98, CCBAU 10203, DSM 17842.

EMBL/GenBank accession number (16S rDNA) of the type strain: DQ338443 (T98).

Paenibacillus ginsengarvi Yoon, Ten and Im 2007, 1812^{VP}
gin.seng.ar'vi. N.L. n. *ginsengum* ginseng; L. n. *arvum* a field; N.L. gen. n. *ginsengarvi* of a ginseng field, the source of the type strain).

The type strain was isolated from soil from a ginseng field in Pocheon Province, South Korea.

DNA G+C content (mol%): 48.1 (HPLC).

Type strain: Gsoil 139, KCTC 13059, DSM 18677.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB271057 (Gsoil 139).

Paenibacillus ginsengisoli Lee, Ten, Baek, Im, Aslam and Lee 2007c, 1372^{VP} (Effective publication: Lee, Ten, Baek, Im, Aslam and Lee 2007b, 133.)

gin.sen.gi.so'li. N.L. n. *ginsengum* ginseng; L. n. *solum* soil; N.L. gen. n. *ginsengisoli* of soil of a ginseng field, the source of the organism.

The type strain was isolated from soil of a ginseng field in Pocheon province, South Korea.

DNA G+C content (mol%): 50.7.

Type strain: Gsoil 1638, KCTC 13931, LMG 23406.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB245382 (Gsoil 1638).

Paenibacillus humicus Vaz-Moreira, Faria, Nobre, Schumann, Nunes and Manaia 2007, 2270^{VP}

hu'mi.cus. L. n. *humus* earth, soil and, in earth sciences or agriculture, humus; L. suff. *-icus -a -um* suffix used with the sense of belonging to; N.L. masc. adj. *humicus* pertaining to humus.

The type strain was isolated from final compost produced from poultry litter.

DNA G+C content (mol%): 58. (HPLC)

Type strain: PC-147, DSM 18784, NBRC 102415.

EMBL/GenBank accession number (16S rDNA) of the type strain: AM411528 (PC-147).

Paenibacillus provencensis Roux, Fenner and Raoult 2008, 685^{VP}

pro.ven.cen'cis. N.L. masc. adj. *provencensis* pertaining to Provence, the region of France where the type strain was isolated.

The type strain was isolated from human cerebrospinal fluid.

DNA G+C content (mol%): not reported.

Type strain: 4401170, CIP 109358, CCUG 53519.

EMBL/GenBank accession number (16S rDNA) of the type strain: EF212893.

Paenibacillus sabinae Ma, Xia, Liu and Chen 2007a, 9^{VP}
sa'bi.nae. N.L. gen. n. *sabinae* of Sabina, referring to the plant *Sabina squamata*, the source of the rhizosphere soil from which the type strain was isolated.

The type strain was isolated from the rhizosphere soil of *Sabina squamata* planted in Beijing, China.

DNA G+C content (mol%): 51.9 (T_m).

Type strain: T27, CCBAU 10202, DSM 17841.

EMBL/GenBank accession number (16S rDNA) of the type strain: DQ338444 (T27).

Paenibacillus soli Park, Kim, An, Yang, Oh, Chung and Yang 2007, 149^{VP}

so'li. L. neut. gen. n. *soli* of soil, the source of the organism.

The type strain was isolated from a soil sample from a ginseng field in the Republic of Korea.

DNA G+C content (mol%): 56.6–57.0.

Type strain: DCY03, KCTC 13010, LMG 23604.

EMBL/GenBank accession number (16S rDNA) of the type strain: DQ309072.

Paenibacillus taiwanensis Lee, Kuo, Tai, Yokota and Lo 2007a, 1353^{VP}

tai.wan.en'sis. N.L. masc. adj. *taiwanensis* of Taiwan, where the type strain was isolated.

The type strain was isolated in 2000 from farmland soil in Wu-Feng, Taiwan.

DNA G+C content (mol%): 44.6 (HPLC).

Type strain: G-soil-2-3, BCRC 17411, IAM 15414, LMG 23799, DSM 18679.

EMBL/GenBank accession number (16S rDNA) of the type strain: DQ890521.

Paenibacillus terrigena Xie and Yokota 2007, 71^{VP}

ter.ri.ge'na. L. n. *terrigena* (nominative in apposition) born of, or from, the earth, earth-born.

The type strain was isolated from coastal soil from Chiba, Japan.

DNA G+C content (mol%): 48.1 (HPLC).

Type strain: A35, IAM 15291, CCTCC AB206026.

EMBL/GenBank accession number (16S rDNA) of the type strain: AB248087.

Paenibacillus urinalis Roux, Fenner and Raoult 2008, 685^{VP}
u.ri.na'lis. L. masc. adj. *urinalis* pertaining to urine, urinary.

The type strain was isolated from a human urine sample.

DNA G+C content (mol%): not reported.

Type strain: 5402403, CIP 109357, CCUG 53521.

EMBL/GenBank accession number (16S rDNA) of the type strain: EF212892.

Paenibacillus woosongensis Lee and Yoon 2008, 615^{VP}

woo.song.en'sis. N.L. masc. adj. *woosongensis* of Woosong, the Korean name for the university in Korea at which the organism was isolated.

The type strain was isolated from forest soil at Daejeon in Korea.

DNA G+C content (mol%): 51.7 (HPLC).

Type strain: YB-45, KCTC 3953, DSM 16971.

EMBL/GenBank accession number (16S rDNA) of the type strain: AY847463 (YB-45).

Paenibacillus zanthoxyli Ma, Zhang and Chen 2007b, 876^{VP}
zan'th.ox.yli. N.L. gen. n. *zanthoxyli* of *Zanthoxylum*, referring to the plant *Zanthoxylum simulans*, the source of the rhizosphere soil from which the type strain was isolated.

The type strain was isolated from the rhizosphere soil of *Zanthoxylum simulans* planted in Beijing, China.

DNA G+C content (mol%): 53.2 (T_m).

Type strain: JH29, CCBAU 10243, DSM 18202.

EMBL/GenBank accession number (16S rDNA) of the type strain: DQ471303 (JH29).

Genus II. *Ammoniphilus* Zaitsev, Tsitko, Rainey, Trotsenko, Uotila, Stackebrandt and Salkinoja-Salonen 1998, 161^{VP}

FRED A. RAINEY

Am.mo.ni.phil'us. N.L. neut. n. *ammonium* ammonia (NH₃); Gr. adj. *philos* loving, friendly to; N.L. masc. n. *Ammoniphilus* ammonia lover.

Straight or slightly curved rods. Motile by peritrichous flagella. Endospores are formed. Gram reaction is variable. Cell wall consists of two electron-dense layers and electron-dense granules. **Obligate aerobe.** Catalase- and oxidase-positive. **Chemo-organotroph.** Produce H₂S from cysteine. Nitrate is not reduced. Indole-negative. High concentrations of ammonium ions required for growth. Growth is optimal at ≥0.07 M NH₄⁺. Oxalate is used as the sole organic source for carbon and energy. **Obligate oxalotroph.** Temperature optimum for growth is 28–30°C; pH optimum for growth is 8.0–8.5. Cell wall contains *meso*-diaminopimelic acid. The major menaquinone is MK-7. Phylogenetically this genus belongs to the Bacilli lineage of Gram-positive bacteria. Isolated from *Rumex acetosa* roots and decaying pinewood.

DNA G+C content (mol%): 42–46 (HPLC).

Type species: *Ammoniphilus oxalaticus* Zaitsev, Tsitko, Rainey, Trotsenko, Uotila, Stackebrandt and Salkinoja-Salonen 1998, 161^{VP}.

Further descriptive information

The genus *Ammoniphilus* was described on the basis of properties of nine strains from a collection of fifty-eight strains. The strains used for the description were RAOx-FS^T, RAOx-RS, RAOx-1^T, RAOx-PF, RAOx-PM, RAOx-FF, RAOx-RF, RAOx-RM (isolated from the rhizosphere of sorrel [*Rumex acetosa*]), and DWOx-RM (isolated from decaying pinewood). On OM-2 medium, colonies are visible after 2 d. The colonies of the different strains show variation in color and morphology after 4–8 days incubation. Strains RAOx-1^T, RAOx-PM, RAOx-FF, and RAOx-RF have light brown colonies that are circular, convex, have an entire margin and smooth surface. Strains RAOx-RM and DWOx-RM have colonies that are light brown in the center and bright-beige around the edges while those of RAOx-PF are mucoid and bright beige. Strains RAOx-FS^T and RAOx-RS have white colonies (0.5–2 mm in diameter). The cells of the strains of this genus are motile, straight or slightly curved rods. Cells vary in length (1.0–8.0 μm), can be single, and sometimes in pairs or chains. Strains stain Gram-negative in young cultures and Gram-positive for cultures in exponential or stationary phases of growth. The cell wall of these strains has two electron-dense layers, which is atypical for Gram-positive bacteria. The endospores, which are stable at 80°C for 10 min, are located centrally or subterminally in slightly or non-swollen sporangia. Strains RAOx-1^T and RAOx-FS^T have been shown to have *meso*-diaminopimelic acid in their cell walls. All nine strains examined have MK-7 as the major menaquinone. The major fatty acids found in all strains are C_{16:0} (22–29%), C_{16:1 ω7c} (13–36%), and -C_{15:0 anteiso} (8–37%). The amounts of these fatty acids vary between strains. Smaller amounts of C_{14:0 iso}, C_{14:0}, C_{15:0 iso}, C_{15:0}, C_{16:0 iso}, and C_{17:0 anteiso} are found in all strains.

Growth is strictly aerobic with none of the nine strains tested growing under anaerobic conditions. Strains RAOx-FS^T and RAOx-RS grow slowly when compared to the other seven rapidly growing strains and do not grow at ≤14°C. Strains RAOx-

FS^T and RAOx-RS differ from the other strains in that they grow with 5% NaCl, require ammonium oxalate (at least 5 g/l) for growth and do not grow on mixtures of formate and glycolate or methanol and glycolate. The strains of this genus are obligately oxalotrophic, and growth is not supported by acetate, adipate, adonitol, alanine, L-arabinose, L-asparagine, L-aspartate, D-cellobiose, citrate, dulcitol, ethanol, formate, fructose, fumarate, D-galactose, gluconate, glutamate, D-glucose, glycerol, glycerol, β-glycerophosphate, *meso*-inositol, 2-oxoglutarate, L-lactate, lactose, L-leucine, D-lyxose, malate, maleate, malonate, maltose, D-mannitol, D-mannose, DL-methionine, DL-norleucine, β-phenylalanine, L-proline, L-pyruvate, raffinose, L-rhamnose, D-ribose, sarcosine, L-serine, D-sorbitol, succinate, sucrose, DL-threonine, L-tryptophan, L-tyrosine, L-valine, and D-xylose. The strains do not grow on complex media such as nutrient agar, malt extract peptone agar, potato dextrose agar, or trypticase soy agar. Replacement of ammonium oxalate by ammonium sulfate and yeast extract, malt extract, peptone or tryptone did not support growth of any of the nine strains. Some strains show weak growth on glycolate or mixtures of formate and glycolate or methanol and glycolate. These strains all grow optimally at high concentrations of oxalate (20 g/l) and good growth occurs in saturated ammonium oxalate solutions (60 g/l). All of the strains require NH₄⁺ for growth and can utilize thiosulfate, sulfite, sulfide, DMSO, methionine, cysteine, glutathione, and thiouridine as sulfur sources.

Strains RAOx-FS^T and RAOx-RS are at the low end of the mol% G+C range with values of 42. The other seven strains have mol% G+C values in the range 45–46.

Enrichment, isolation and growth conditions

The oxalate utilizing strains of the genus *Ammoniphilus* were isolated from decaying pinewood and the rhizosphere of sorrel (*Rumex acetosa*) using OM-2 medium. Medium OM-2 contains per liter: 10–20 g of (NH₄)₂C₂O₄ (ammonium oxalate), 10 g of NaHCO₃, 10 g of NaH₂PO₄·2H₂O, 0.7 g of NaCl, 0.57 g of KCl, 0.1 g of MgCl₂·6H₂O, 0.01 g of CaCl₂·2H₂O, and 1 g of Na₂S₂O₃·5H₂O. Adjusted to pH 6.8–7.0. (NH₄)₂C₂O₄, NaHCO₃, and NaH₂PO₄·2H₂O should be dissolved completely and in the order listed. The medium will be pH 8.5–9.0 after autoclaving. Bacto Agar at 1.5–2.0% (w/v) is used to prepare solid medium. For enrichment cultures, 5 g of plant roots or 10 g of decaying wood was added to 100 ml of OM-2 medium in 500-ml flasks and incubated without shaking at 28°C for 20 d. Ten-ml aliquots of enrichment cultures showing ammonia production were transferred to 90 ml of OM-2 medium in a 500-ml flask incubated and shaken at 180 r.p.m. When turbidity was observed, the culture was diluted and plated on OM-2 agar and incubated at 28°C until colonies appeared. Strains were routinely cultured on OM-2 medium. For substrate utilization tests, OM-2 medium contained ammonium sulfate (6 g/l) instead of ammonium oxalate. To examine the utilization of nitrogen sources, ammonium oxalate was replaced by sodium oxalate (10 g/l).

Taxonomic comments

The species of the genus *Ammoniphilus* belong to a distinct phylogenetic lineage within the Bacilli that includes the closely related genus *Oxalophagus*. The 16S rRNA gene sequences of *Ammoniphilus oxalaticus* and *Ammoniphilus oxalivorans* share 98.6% similarity. The closest relative is *Oxalophagus oxalicus* with around 97% 16S rRNA gene sequence similarity. Species of the genera *Bacillus* and *Aneurinibacillus* share less than 91% sequence similarity. The strains of the *Ammoniphilus* species have high 16S rRNA gene sequence similarities. 16S rRNA gene sequences (with >98.7% sequence similarity) are available for strains RAOx-FS^T (Y14580), RAOx-1^T (Y14578), and RAOx-FF (Y14579). Strains RAOx-1^T and RAOx-FF have the most similar sequences (99.3% identical). The closest phylogenetic relative of the strains of this genus is *Oxalophagus oxalicus* (96.0–96.7% 16S rRNA gene sequence similarity). DNA–DNA hybridization studies demonstrated the distinct species status of strains RAOx-FS^T and RAOx-1^T (reassociation value of 39.7%). The nine strains have been assigned to two species of the genus *Ammoniphilus*. Strains RAOx-1^T, RAOx-PF, RAOx-PM, RAOx-FF, RAOx-RE, RAOx-RM, and DWOx-RM belong to the species *Ammoniphilus oxalaticus* while the species *Ammoniphilus oxalivorans* comprises strains RAOx-FS^T and RAOx-RS.

Differentiation of the genus *Ammoniphilus* from other genera

The species of the genus *Ammoniphilus* can be differentiated from other genera on the basis of their phylogenetic position as well as phenotypic and physiological characteristics. *Ammoniphilus* is most closely related to the single species genus *Oxalophagus* to which it has 96.5% 16S rRNA gene sequence similarity. The next closest relatives are species of the genera *Bacillus* and *Aneurinibacillus* at 16S rRNA gene sequence similarity levels of below 91%. Although the 16S rRNA gene sequence similarity between the strains of the genera *Ammoniphilus* and *Oxalophagus* is high and in most cases would indicate membership in the same genus, there are very distinct physiological differences between these organisms that warrant separate genus status. In contrast to the genus *Oxalophagus*, which is catalase-negative and a strict anaerobe, strains of the genus *Ammoniphilus* are strictly aerobic and catalase-positive. The mol% G+C content of the DNA also differs between these taxa, with the value for *Oxalophagus* (35.4–37.2) being lower than that for *Ammoniphilus* strains (42–46). The use of oxalate as a sole carbon and energy source and the inability to use other organic substrates differentiates the genus *Ammoniphilus* from the distantly related species of the genus *Bacillus*. The strict requirement for NH₄⁺ ions differentiates this genus from all other spore-forming taxa in the Bacilli lineage.

List of species of the genus *Ammoniphilus*

1. ***Ammoniphilus oxalaticus*** Zaitsev, Tsitko, Rainey, Trotsenko, Uotila, Stackebrandt and Salkinoja-Salonen 1998, 161^{VP}
o.xa.la'ti.cus. N.L. adj. *oxalaticus* pertaining to oxalate.

Straight or slightly curved rods. Cells are 1.0–8.0 µm in length and 0.6–1.1 µm in diameter. Cells occur singly, in pairs, or in short or long chains. Endospores are oval, centrally or subterminally located in either swollen or non-swollen sporangia, and moderately heat resistant to 80°C. Colonies on OM-2 agar after 4–8 d incubation are up to 5 mm in diameter, light brown or bright beige, convex, circular with entire margins, and smooth or mucoid. Obligate oxalotroph. Some strains grow poorly in 0.03 M NH₄⁺ and not at all in ≤0.02 M NH₄⁺. Growth occurs in the presence of ammonium oxalate (up to 100 g/l), with good growth occurring at 5–40 g/l, poor growth at 3–4 g/l, and no growth at ≤2 g/l. Glycolate is used by some strains as a carbon and energy source. Weak growth is supported by mixtures of formate and glyoxylate or methanol and glyoxylate. No growth occurs with other organic acids, sugars, or alcohols. Mesophilic, optimum temperature for growth is 28–30°C. Most strains grow at 10–40°C, pH 6.8–9.5, and are tolerant to 4% NaCl. Some strains slowly hydrolyze starch, gelatin, and urea. All strains form H₂S from cysteine but not from thiosulfate. Nitrates, nitrites, or urea are not utilized as sole nitrogen sources. No reduction of nitrate to nitrite or N₂; vitamins are not required; indole is not produced. The major cellular fatty acids are C_{16:0} (22–29%), C_{16:1 ω7c} (28–36%), and *anteiso*-C_{15:0} (8–15%). Isolated from the rhizosphere of sorrel (*Rumex acetosa*) and decaying pinewood.

DNA G+C content (mol%) of the type strain: 46.0 (HPLC).

Type strain: RAOx-1, ATCC 700649, CIP 105538, DSM 11538, HAMBI 2283.

GenBank accession number (16S rRNA gene): Y14578.

2. ***Ammoniphilus oxalivorans*** Zaitsev, Tsitko, Rainey, Trotsenko, Uotila, Stackebrandt and Salkinoja-Salonen 1998, 161^{VP}
o.xa.li.vo'rans. N.L. neut. n. *oxalatum* oxalate; L. part. pres. *vorans* eating; N.L. part. adj. *oxalivorans* oxalate-eating.

Straight or slightly curved rods. Cells are 1.0–1.4 µm in length and 0.7–1.1 µm in diameter. Cells occur singly, in pairs or in short or long chains. Endospores are oval, and centrally or subterminally located in either slightly swollen or non-swollen sporangia. Colonies on OM-2 agar after 4–8 d incubation are up to 2 mm in diameter, white, convex, and circular with entire margins and smooth. Obligate oxalotroph. Grows poorly in 0.03–0.6 M NH₄⁺ and not at all in ≤0.02 M NH₄⁺. Growth occurs in ammonium oxalate (up to 100 g/l) with good growth occurring in 5–60 g/l. No growth occurs on ≤4 g/l ammonium oxalate, on glycolate, organic acids, sugars, or alcohols, or on mixtures of formate and glyoxylate or methanol and glyoxylate. Mesophilic, grows in range 20–38°C with optimum growth temperature at 28–30°C. The pH range for growth is 6.8–9.5, and strains are tolerant to 5% NaCl. Starch and gelatin are hydrolyzed. H₂S is formed from cysteine but not from thiosulfate. Nitrates, nitrites, or urea are not utilized as the sole nitrogen sources. No reduction of nitrate to nitrite or N₂; vitamins not required; urease- and indole-negative. The major cellular fatty acids are C_{16:0} (26–28%), C_{16:1 ω7c} (13%) and *anteiso*-C_{15:0} (36–37%). Isolated from the rhizosphere of sorrel (*Rumex acetosa*).

DNA G+C content (mol%) of the type strain: 42.0 (HPLC).

Type strain: RAOx-FS, ATCC 700648, CIP 105539, DSM 11537, HAMBI 2284.

GenBank accession number (16S rRNA gene): Y14580.

Genus III. **Aneurinibacillus** Shida, Takagi, Kadowaki and Komagata 1996a, 945^{VP} emend. Heyndrickx, Lebbe, Vancanneyt, Kersters, De Vos, Logan, Forsyth, Nazli, Ali and Berkeley 1997, 814

NIALI A. LOGAN AND PAUL DE VOS

A. neu. ri. ni. ba. cil' lus. N.L. n. *aneurinum* thiamine; L. dim. n. *bacillus* small rod; N.L. masc. n. *Aneurinibacillus* thiamine-decomposing small rod.

Gram-positive, rod-shaped cells, 0.5–1.0 µm by 2.0–6.0 µm, and motile by peritrichous flagella. **Ellipsoidal spores**, one per cell, are **borne centrally, paracentrally, and subterminally and may swell the sporangia**. **Strictly aerobic**, but one species is microaerophilic. Grow on routine media such as nutrient agar and trypticase soy agar. Decompose thiamine. Catalase-positive, weakly positive or negative. Variable for nitrate reduction and hydrolysis of casein, gelatin, starch, and Tween 80. Urea is not hydrolyzed and indole is not produced. **Growth temperature range is from 20 to 65°C**. Growth occurs at pH 5.5 to 9.0. Growth occurs in the presence of 2–5% NaCl; some strains grow weakly at 7% NaCl. **Few carbohydrates are assimilated and acid is produced weakly, if at all, from them; amino acids and some organic acids are used as carbon sources**. The major cellular fatty acid components (ranges as percentages of total are given in parentheses) are C_{15:0 iso} (41.9–66.8), C_{17:0 iso} (1–23.8), C_{16:0} (1.8–8.5), and C_{16:0 iso} (0.5–6.6). The major quinone is menaquinone 7. A specific S-layer protein is present.

DNA G+C content (mol%): 42–47.

Type species: Aneurinibacillus aneurinilyticus (ex Aoyama 1952) Heyndrickx, Lebbe, Vancanneyt, Kersters, De Vos, Logan, Forsyth, Nazli, Ali and Berkeley 1997, 815^{VP} (*Bacillus aneurinolyticus* Shida, Takagi, Kadowaki, Yano, Abe, Udaka and Komagata 1994b, 146; *Aneurinibacillus aneurinolyticus* Shida, Takagi, Kadowaki and Komagata 1996a, 945).

Further descriptive information

Phylogeny. *Aneurinibacillus* belongs to the family *Bacillaceae* and is very closely related to the genus *Brevibacillus*. Both genera originated from a taxonomic rearrangement of *Bacillus* (Shida et al., 1996a). A phylogenetic tree, based on 16S rRNA gene sequences, comprising the type strains of *Aneurinibacillus* species is given in Figure 29.

The rod-shaped cells of *Aneurinibacillus* species are usually round-ended, and occur singly, in pairs, and in chains. Cell diameters range from 0.7 to 1.0 µm and lengths range from 3.0 to 6.0 µm, but the cells of particular strains are usually quite regular in size, and individual species normally have dimensions within fairly narrow limits. The spores are ellipsoidal, lie centrally, paracentrally, or subterminally, and swelling of the sporangia may be slight, moderate, or substantial, and vary within a strain (Figure 27).

Information on cell-wall composition is not available for *Aneurinibacillus* species, but *Aneurinibacillus thermoaerophilus* S-layer structure and biosynthesis have been studied intensively for a sugar beet extraction-juice isolate and a culture collection strain previously classified as *Bacillus brevis* (Kneidinger et al., 2001a, 2001b; Schäffer et al., 1999; Wugeditsch et al., 1999).

Colonies of the two mesophilic species of *Aneurinibacillus* species are flat, 0.5–3 mm in diameter after 48 h on nutrient agar at

FIGURE 27. Photomicrograph of the type strain of *Aneurinibacillus aneurinilyticus* viewed by phase-contrast microscopy, showing ellipsoidal, paracentral, and subterminal spores that usually swell the sporangia. Bar = 2 µm. Photomicrograph prepared by N.A. Logan.

37°C, round or irregular in shape, with slightly crenate edges, and glossy, translucent, and creamy or yellowish gray in appearance; they become whitish and opaque as their component cells sporulate. Colonies of the thermophilic species may be larger, up to 10 mm in diameter, show a tendency to swarm across the surface of the agar, and have matt surfaces.

Aneurinibacillus species are heterotrophic and neutrophilic and will grow well on routine media such as nutrient agar or trypticase soy agar; growth may be enhanced by the addition of a small amount of yeast extract. Most strains will grow on blood agar. They will use some amino acids, carbohydrates, and organic acids as sole sources of carbon and energy. Utilization of carbohydrates may be accompanied by the production of small amounts of acid, and utilization of amino acids and organic acids may be accompanied by the production of small amounts of alkali but, generally speaking, these are not easily detected by routine test methods and some characters may prove to be inconsistent when retested. Growth temperatures range from about 20 to 50°C for the mesophiles (optima around 30–37°C) and from 40 to 60°C for the thermophilic species *Aneurinibacillus thermoaerophilus*.

Habitats. The first isolates of *Bacillus aneurinolyticus* were obtained from human feces (Aoyama, 1952); later isolations were made from human, bovine, chicken, dog, and rat feces, Japanese soil, and turban shells from the Japan Sea. The type strain of *Bacillus migulanus* was isolated from garden soil as a gramicidin producer. The original strains of the thermophilic species *Aneurinibacillus thermoaerophilus* were isolated from the

high-temperature stages of beet sugar extraction and refining (Meier-Stauffer et al., 1996) and *Aneurinibacillus thermoaerophilus*, or a close relative of this species, was found to be a prominent member of the flora of hot synthetic compost (Dees and Ghiorse, 2001). The single isolate that represents *Aneurinibacillus danicus* was isolated at 45°C from a natural gas fermenter in Denmark. The geothermal soils of the Antarctic volcanoes Mount Melbourne and Mount Rittmann yielded strains of a novel, moderately thermophilic, and moderately acidophilic species, *Aneurinibacillus terranovensensis*, which were isolated in small numbers along with *Bacillus fumarioli* (Allan et al., 2005; Logan et al., 2000). There are no reports of *Aneurinibacillus* species being isolated in association with infections of humans, other animals, or plants.

Enrichment and isolation

Enrichment and selective isolation methods developed especially for *Aneurinibacillus* species have not been reported. The original strains of *Aneurinibacillus aneurinilyticus* were isolated from human feces by Aoyama (1952) by adding 1 g feces to "broth", heating at 80°C for 30 min, then incubating at 37°C for 3 d. Broth (1 ml) was then added to a buffered solution (pH 7.0) of thiamin, incubated at 37°C for 30 min, and examined for evidence of thiamine degradation using the permutit-thiochrome method. Strains that could decompose thiamine were then isolated on plates of chocolate blood agar. Abe and Kimoto (1984) isolated further strains from human, bovine, chicken, dog, and rat feces, soil, and seashells, but the isolation procedure was not reported. Abe et al. (1986) described a procedure for detecting thiaminase-producing colonies: cells of the organisms under test were diluted with physiological saline and spread on a plate of nutrient agar containing 0.1% yeast extract so as to obtain no more than 100 colonies per plate, then incubated at 37°C for 4 d. The plates were then overlaid with 8 ml molten soft agar at 50–55°C containing, for detection of "*Bacillus aneurinolyticus*": thiamin, 0.8 g; agar, 5 g; 25 mM Tris/HCl buffer, 1000 ml. After the soft agar had set, the plate was covered and incubated at 60°C for 2 h, then 16 ml freshly prepared diazo-reagent was poured onto the agar surface, left for 5–10 min at room temperature, then poured off. A yellow halo surrounding the colony against a reddish-pink background revealed zones of thiamin decomposition. The diazo-reagent was prepared from three solutions: (i) 0.6 g *p*-amino-acetophenone dissolved in 9 ml concentrated HCl (11.6M), diluted with water to 100 ml, and stored in a brown bottle; (ii) 23 g sodium nitrite dissolved in 100 ml water and stored in a brown bottle; (iii) 20 g sodium hydroxide and 28 g sodium bicarbonate dissolved in 350 ml water. The solutions could be stored at room temperature for several weeks. The reagent was prepared by adding 0.2 ml sodium nitrite solution to 0.8 ml *p*-amino-acetophenone solution in a glass tube followed by 10 ml distilled water, then 6 ml sodium hydroxide/sodium bicarbonate buffer, which was poured gradually into the tube; the mixture was poured onto the plate immediately.

Edwards and Seddon (2000) described an isolation method for detecting colonies of gramicidin-producing *Bacillus brevis* from field trial experiments; the method utilized the ability of this strain to decompose tyrosine, so producing light-brown colonies surrounded by haloes on tyrosine agar. Isolates producing gramicidin could then be identified by paper chromatography. The type strain of *Aneurinibacillus migulanus* was isolated as a

gramicidin-producing strain (Takagi et al., 1993). Tyrosine utilization is found in both mesophilic *Aneurinibacillus* species and *Brevibacillus* species (as well as many organisms outside these genera), so although this method is by no means specific or selective, it is potentially of assistance in detecting colonies of strains belonging to these two genera. Tyrosine agar contains: nutrient broth (Oxoid), 6.6 g; tyrosine, 5 g; agar, 15 g; water, 1000 ml. After autoclaving, it is stirred continuously with a magnetic stirrer (to reduce the size of the tyrosine crystals) until it has reached 50°C, whereupon it is poured immediately, giving an opaque, off-white, solid medium. *Aneurinibacillus thermoaerophilus* was originally isolated by smearing sugar beet extraction juice onto plates of TYG agar and incubating in air at about 60°C; colonies were purified by plating on the same medium. TYG agar contains: Bacto Tryptone (Difco), 5 g; yeast extract, 2.5 g; glucose, 1 g; agar, 22 g; water, 1000 ml. Dees and Ghiorse (2001) isolated a close relative of *Aneurinibacillus thermoaerophilus* from dilutions of hot synthetic compost by plating on a variety of routine media such as nutrient broth, plate count agar, and trypticase soy agar that were diluted to 1/10 of the manufacturer's recommended concentration and then amended with bacteriological agar to solidify.

Wakisaka and Koizumi (1982) noted that some aerobic endospore-formers that appeared to form minor components of soil floras showed slow and/or uneven germination compared with the more frequently encountered *Bacillus* species such as *Bacillus cereus*, *Bacillus megaterium*, *Bacillus sphaericus*, and *Bacillus subtilis*. Members of these minor populations were isolated with difficulty by the standard dilution-plate technique, but could be enriched by first removing the rapidly germinating, fast-growing members of the predominant flora. This approach has not been tried for the isolation of *Aneurinibacillus*, but it may well be of assistance (for details, see the treatment of *Brevibacillus*).

Aneurinibacillus terranovensensis was isolated from volcanic soils of Mount Melbourne and Mount Rittmann, northern Victoria Land, Antarctica. Soil (1 g quantities) was added to 9 ml *Bacillus fumarioli* broth (BFB) in duplicate at pH 5.5, and one of each pair was heat-treated at 80°C for 10 min to kill vegetative cells. All broths were incubated at 50°C in water baths and inspected daily. Cultures that became turbid were subcultured by streaking onto plates of *Bacillus fumarioli* agar (BFA). Colonies appearing on streak plates were screened for vegetative and sporangial morphologies by phase-contrast microscopy; spore-forming rods were streak-purified and then transferred to slopes of the same medium for storage at 4°C after incubation and confirmation of sporulation by microscopy. BFB contains 4 g yeast extract, 2 g (NH₄)₂SO₄, 3 g KH₂PO₄, and 4 ml/l of each of solutions A and B [A, 125 g (NH₄)₂SO₄ and 50 g MgSO₄·7H₂O per liter; B, 62.5 g CaCl₂·2H₂O per liter], adjusted to pH 5.5. BFA was prepared by adding 5 mg MnSO₄·4H₂O and 18 g/l agar to BFB prior to autoclaving.

Maintenance procedures

Aneurinibacillus strains may be preserved on slopes of a suitable growth medium that encourages sporulation, such as nutrient agar or trypticase soy agar containing 5 mg/l MnSO₄·7H₂O. Slopes should be checked microscopically for spores, before sealing to prevent drying out, and stored in a refrigerator; spores should remain viable on such sealed slopes for many years. For longer-term preservation, lyophilization and liquid nitrogen may be used, as long as cryoprotectants are added.

Procedures for testing special characters

Members of the genus *Aneurinibacillus* tend to be unreactive in routine biochemical tests and no special characters have been described for their differentiation; hence, their identification is difficult. They are largely unreactive in the carbohydrate utilization tests of the API 50CHB gallery (bioMérieux) and insufficiently variable in the API 20E and supplementary tests, so that the two mesophilic species in this genus are largely inseparable by these means. The API Biotype 100 gallery, which was developed as a research product for differentiating enterobacteria, proved to be of great value in differentiating species of *Brevibacillus* and *Aneurinibacillus* (Heyndrickx et al., 1997; Logan et al., 2002); it contained 99 tests for the assimilation of carbohydrates, organic acids, and amino acids, and one control tube. It was inoculated with a suspension in one of two semisolid media that differed in the number of growth factors they contained and, after incubation, the tubes were examined for turbidity. This system was adapted by using a suspension medium containing phenol red and examining the tubes for evidence of acid or alkali production (A. H. A. Albaser and N. A. Logan, unpublished results). For further guidance, the reader is referred to *Procedures for testing special characters* in the treatment of *Brevibacillus*.

Differentiation of members of the genus *Aneurinibacillus* from other genera

The genus *Aneurinibacillus* contains aerobic, endospore-forming rods that may be confused with members of other genera of aerobic endospore-formers, including *Bacillus*. The most characteristic feature of *Aneurinibacillus* species is their lack of reactivity in routine biochemical tests and their tendency to form swollen sporangia; however, members of the genus *Brevibacillus* have similar characteristics, and distinction of these two genera cannot be achieved easily on the basis of routine phenotypic tests.

Taxonomic comments

Bacillus aneurinolyticus was described by Aoyama (1952) as a thiamine-decomposing organism from human feces, but was omitted from the Approved Lists of Bacterial Names (Skerman et al., 1980) owing to a paucity of representative strains. Gordon et al. (1973) studied four strains, but they felt their experience with them was insufficient to allow delineation of the species, and Logan and Berkeley (1981) were unable to separate their strains of *Bacillus aneurinolyticus* from *Bacillus brevis*. The species was revived by Shida et al. (1994b) on the basis of a polyphasic analysis of 21 strains. Phenotypically, this organism was known to resemble *Bacillus brevis* and related taxa (Claus and Berkeley, 1986) and studies on the 16S rRNA gene sequences of the type strains of these two species suggested that *Bacillus aneurinolyticus* represented a distinct evolutionary line close to that of *Bacillus brevis* (Ash et al., 1991) or that it diverged early from the *Bacillus brevis* line (Farrow et al., 1992, 1994). Following DNA relatedness studies and chemotaxonomic analyses, the taxonomy of *Bacillus brevis* was modified by assigning some *Bacillus brevis*-group strains to the novel species *Bacillus agri* and *Bacillus centrosporus* (Nakamura, 1993), *Bacillus migulanus*, *Bacillus choshinensis*, and *Bacillus parabrevis* (Takagi et al., 1993), and *Bacillus reuszeri*, *Bacillus formosus*, and *Bacillus borstelensis* (Shida et al., 1995). The thermophilic species *Bacillus*

thermoaerophilus was described to include sugar beet isolates and *Bacillus brevis* strain ATCC 12990 (MeierStauffer et al., 1996). In the same year, Shida et al. (1996b) reported the findings of a SDS-PAGE study that supported the divergence of the *Bacillus brevis* and *Bacillus aneurinolyticus* groups, but although the *Bacillus aneurinolyticus* group species, *Bacillus aneurinolyticus* and *Bacillus migulanus*, were distinguishable by this technique, when the analysis was restricted to the type strains of individual species of the *Bacillus brevis* and *Bacillus aneurinolyticus* groups, they were not always well separated by this method. Similar problems were encountered by Logan et al. (2002). Shida et al. (1996a) created two new genera on the basis of 16S rRNA gene sequence analysis (type strains only) to contain the above-mentioned and allied species: *Aneurinibacillus* accommodated *Aneurinibacillus aneurinolyticus* and *Aneurinibacillus migulanus*, whereas *Brevibacillus* accommodated *Brevibacillus brevis* and the species derived from it (see above), *Brevibacillus laterosporus*, and *Brevibacillus thermoruber*. Meier-Stauffer et al. (1996) proposed *Bacillus thermoaerophilus* in the same year and suggested that it might, along with *Bacillus aneurinolyticus* and *Bacillus migulanus*, represent the core of a new genus, but it was not included in either of the Shida et al. (1996a, 1996b) studies.

Heyndrickx et al. (1997) carried out a polyphasic taxonomic study on 37 strains belonging to *Aneurinibacillus* and *Brevibacillus*, using amplified rDNA restriction analysis (ARDRA), fatty acid methyl ester analysis, SDS-PAGE of whole-cell proteins, pyrolysis mass spectrometry, assimilation tests, and other routine phenotypic tests. Two of the species, *Aneurinibacillus aneurinolyticus* (the type species) and *Aneurinibacillus migulanus*, were found to be quite similar phenotypically and genotypically, but distinguishable from each other by a small number of phenotypic characters. ARDRA revealed that *Aneurinibacillus aneurinolyticus*, *Aneurinibacillus migulanus*, and *Bacillus thermoaerophilus* formed a cluster that was quite separate from the *Brevibacillus* one, supporting the distinction of both genera, and they transferred *Bacillus thermoaerophilus* to *Aneurinibacillus*. The species epithet *aneurinolyticus* was corrected to *aneurinilyticus* at this time.

However, because *Aneurinibacillus* strains are unreactive in many of the conventionally formulated biochemical tests upon which routine identification schemes are based, identifications rely too heavily on negative test results. Distinction between most *Aneurinibacillus* and *Brevibacillus* species is thus not possible using the currently available *Bacillus* identification schemes and their separation remains difficult even with much wider selections of phenotypic tests; also, another unreactive species, *Bacillus badius*, may be easily misidentified as a member of these genera (Heyndrickx et al., 1997; Logan et al., 2002). The original recognition of the two mesophilic *Aneurinibacillus* species was based mainly upon DNA relatedness studies, molecular probing, and chemotaxonomic analyses of the relatively few available isolates (Shida et al., 1994b), using databases that remain restricted largely to reference laboratories. Such an approach to identification is unsuitable for such unreactive organisms encountered only occasionally in routine laboratories and isolates suspected of being *Aneurinibacillus* or *Brevibacillus* species may require referral to a reference laboratory.

Given these problems of identification, Goto et al. (2004) examined the hypervariable (HV) region corresponding to the 5' end of the 16S rRNA gene (nucleotide positions 70–344 in

Bacillus subtilis numbering) in 29 strains received at the culture collections as *Brevibacillus brevis*, along with strains of *Aneurinibacillus* and *Brevibacillus* species and other, unnamed, *Brevibacillus* strains. The HV region marker had already proved to be useful taxonomically for the genera *Alicyclobacillus*, *Bacillus*, and *Paenibacillus*. They found that 14 *Brevibacillus brevis* and three *Brevibacillus* spp. strains clustered in *Aneurinibacillus*: two with *Aneurinibacillus migulanus* and 14 with *Aneurinibacillus thermoaerophilus*. One strain did not cluster with any of the existing

Aneurinibacillus strains and was proposed as the novel species *Aneurinibacillus danicus*.

More reliable species differentiation and identification may be based in the future on genomic sequences of well selected so-called housekeeping genes.

Acknowledgements

We thank Abdul Hadi Ali Albaser for his assistance with phenotypic profiling of *Aneurinibacillus* species, and Raymond Allan for his data on *Aneurinibacillus terranovensensis*.

a.neu.ri.no.ly'tic.us. N.L. n. *aneurinum* thiamine; N.L. adj. *lyticus* dissolving; N.L. adj. *aneurinolyticus* decomposing thiamine.

Colonies on nutrient agar after 48 h at 37°C are flat, 0.5–2 mm in diameter, round or irregular in shape, with slightly crenate edges, glossy, translucent, and creamy grayish. Vegetative cells are 0.7–0.9 µm by 3.0–5.0 µm. Colonies become whitish and opaque as their component cells sporulate. Spores are ellipsoidal, paracentral, and subterminal and may swell the sporangia. Catalase weakly positive. Growth temperatures range from 20 to 50°C. Grows at pH 5.0–9.0. Optimum temperature for growth is 37°C; optimum pH for growth is pH 7.0. Nitrate is reduced to nitrite. Casein, gelatin, and Tweens 20, 40, 60, and 80 are not hydrolyzed. Utilization of some organic compounds and other characteristics are shown in Table 50 and Table 51.

The major cellular fatty acid components (ranges as percentages of total) are C_{14:0 iso} (1.4–8.8%), C_{14:0} (1.6–4.0%), C_{15:0 iso} (41.9–66.3%), C_{16:0 iso} (0.5–4.2%), C_{16:1 ω11c} (8.0–13.5%), C_{16:0} (2.2–8.5%), C_{17:1 ω10c iso} (1.5–3.4%), C_{17:0 iso} (1.0–3.4%), H C_{15:1 iso} and/or I C_{15:1 iso} and/or 3-OH C_{13:0} (0.9–2.8%), C_{16:1 ω7c} and/or 2-OH C_{15:0 iso} (2.7–10.3%), and I C_{17:1 iso} and/or B C_{17:1 anteiso} (1.0–3.5%). Isolated from human, bovine, chicken, dog, and rat feces, soil, and sea shells.

DNA G+C content (mol%): 41.1–43.4 (HPLC); that of the type strain is 42.9.

Type strain: DSM 5562, LMG 15531, ATCC 12856, CIP 104007, NRRL NRS-1589.

EMBL/GenBank accession number (16S rRNA gene): X94194 (DSM 5562).

- Aneurinibacillus danicus*** Goto, Fujita, Kato, Asahara and Yokota 2004, 425^{VP}

da'ni.cus. N.L. adj. *danicus* Danish, pertaining to Denmark.

Strictly aerobic, Gram-variable, motile rods, 0.8–1.0 µm by 4.0–6.0 µm. Ellipsoidal spores are borne subterminally in swollen sporangia. Description is based upon a single isolate. Colonies on nutrient agar are circular, entire, smooth, flat, translucent, and white, and they are 5–10 mm in diameter after 48 h. The temperature range for growth is 35–55°C and the temperature for optimum growth is 45–50°C. Optimum pH for growth is 6.5–7.0; growth occurs at pH 6.0–7.5, but not at pH 5.5 or 9.5. Growth is weak in 2% NaCl and is inhibited by 5% NaCl. Catalase- and oxidase-positive. Urease, citrate utilization,

and nitrate reduction are negative. Casein, esculin, gelatin, and DNA are hydrolyzed, tyrosine is weakly hydrolyzed, and arbutin and starch are not hydrolyzed. Acid is produced from a range of carbohydrates (see Table 50). The major fatty acids are C_{15:0 iso}, C_{16:0}, and C_{17:0 iso}. The main quinone is menaquinone 7. Isolated from a natural gas fermenter.

DNA G+C content (mol%): 46.7 (HPLC).

Type strain: NCIMB 13288, IAM 15048.

EMBL/GenBank accession number (16S rRNA gene): AB112725 (NCIMB 13288).

- Aneurinibacillus migulanus*** (Takagi, Shida, Kadowaki, Komagata and Udaka 1993) Shida, Takagi, Kadowaki and Komagata 1996a, 945^{VP} (*Bacillus migulanus* Takagi, Shida, Kadowaki, Komagata and Udaka 1993, 229)

mi.gu.la'nus. N.L. adj. *migulanus* referring to the German bacteriologist W. Migula, who contributed to bacterial taxonomy.

Colonies on nutrient agar after 48 h at 37°C are flat, 2–3 mm in diameter, with crenate edges, translucent, yellowish gray, and glossy. Vegetative cells are 0.5–1.0 µm by 2.0–6.0 µm. Colonies become creamy white and opaque as their component cells sporulate. Spores are ellipsoidal, paracentral, and subterminal and may swell the sporangia. Catalase-positive. Growth temperatures range from 20 to 50°C. Grows at pH 5.5–9.0. Nitrate is reduced to nitrite. Gelatin and starch are hydrolyzed. Casein and Tween 20, 40, 60, and 80 are not hydrolyzed. A range of carbohydrates, amino acids, and organic acids are used as carbon sources (see Table 50 and Table 51).

The major cellular fatty acid components (ranges as percentages of total) are C_{14:0 iso} (8.3–9.6%), C_{14:0} (1.8–2.0%), C_{15:0 iso} (48.3–48.9%), C_{15:0 anteiso} (1.3%), C_{15:1 ω6c} (0.8–1.0%), C_{15:0} (2.3–3.3%), C_{16:1 ω7c} alcohol (1.4%), H C_{16:1 iso} (1.3–1.7%), C_{16:0 iso} (6.5–6.6%), C_{16:1 ω11c} (6.4–6.6%), C_{16:1 ω5c} (1.1–1.2%), C_{16:0} (3.4–3.6%), C_{17:1 ω10c iso} (1.7–2.2%), C_{17:0 iso} (2.1%), C_{17:1 ω10c} (1.4–1.7%), H C_{15:1 iso} and/or I C_{15:1 iso} and/or 3-OH C_{13:0} (1.3–1.6%), C_{16:1 ω7c} and/or 2-OH C_{15:0 iso} (4.8–5.0%), and I C_{17:1 iso} and/or B C_{17:1 anteiso} (2.4–2.5%). Isolated from garden soil.

DNA G+C content (mol%): 42.5–43.2 (HPLC); that of the type strain is 42.5.

Type strain: DSM 2895, LMG 15427, ATCC 9999, CIP 103841, NCTC 7096.

EMBL/GenBank accession number (16S rRNA gene): X94195 (DSM 2895).

- Aneurinibacillus terranovensensis*** Allan, Lebbe, Heyrman, De Vos, Buchanan and Logan 2005, 1048^{VP}

terr.a.no.ven'sis. N.L. adj. *terranovensensis* referring to Terra Nova Bay Station (Italy), northern Victoria Land, Antarctica, where the strains were first isolated.

^fType strain gives a positive reaction.

^gFatty acid data for *Aneurinibacillus terranovensis* are for cells grown on 1/2 BFA.

FIGURE 28. Photomicrograph of the type strain of *Aneurinibacillus terranovensis* viewed by phase-contrast microscopy, showing ellipsoidal, paracentral, and subterminal spores in very swollen sporangia. Bar = 2 μ m. Photomicrograph prepared by N.A. Logan.

Cells are Gram-positive, becoming Gram-negative after 48 h, motile, round-ended rods (0.8–1 μ m by 2–8 μ m),

occurring singly, in pairs, and in chains. Endospores are ellipsoidal, occurring paracentrally and subterminally in very swollen sporangia (Figure 28). After 48 h incubation on 1/2 BFA (pH 5.5) at 40°C, colonies are circular, flat, up to 1.5 mm in diameter, and cream-colored with a slightly glossy appearance and butyrous consistency. Minimum growth temperature lies between 20 and 25°C, with the optimum temperature for growth being between 37 and 45°C, and the maximum growth temperature lying between 50 and 55°C. Growth may occur between pH 3.5 and 7.0 and the optimum pH for growth lies between pH 5.0 and 5.5. Growth is inhibited by 2–3% NaCl. The organisms are microaerophilic and weakly positive for catalase. Gelatin is hydrolyzed slowly. Starch is hydrolyzed weakly. No growth occurs on casein agar. In the API 20E strip reactions, arginine dihydrolase, the Voges–Proskauer reaction, and nitrate reduction are positive. Citrate utilization is variable. A small range of carbohydrates, amino acids, and organic acids is utilized as sole carbon sources by all strains in the API Bio-type 100 gallery (see Table 50 and Table 51). Utilization of a wider range of such substrates shows variation between strains, but the type strain utilizes *trans*-aconitate, citrate, fumarate, D-galactose, D-glucosamine, α -lactose, L-malate, and quininate; although no acid production is seen, alkaline reactions are observed from various organic compounds

Table 50). The major cellular fatty acids (from cells grown on 1/2 BFA) are $C_{15:0 \text{ anteiso}}$ and $C_{15:0 \text{ iso}}$, accounting for approximately 41 and 46% of the total fatty acid content, respectively. The following fatty acids are present in smaller amounts (at least 1.0%): $C_{14:0}$, $C_{14:0 \text{ iso}}$, $C_{16:0}$, $C_{16:0 \text{ iso}}$, and $C_{16:1 \omega 7c}$ alcohol. Isolated from volcanic soils in northern Victoria Land, Antarctica.

DNA G+C content (mol%): 43.2–44.6; that of the type strain is 43.2 (HPLC).

Type strain: LMG 22483, CIP 108308.

EMBL/GenBank accession number (16S rRNA gene): AJ715378 (LMG 22483).

5. *Aneurinibacillus thermoaerophilus* (Meier-Staufffer, Busse, Rainey, Burghardt, Scheberl, Hollaus, Kuen, Makristathis, Sleytr and Messner 1996) Heyndrickx, Lebbe, Vancanneyt, Kersters, De Vos, Logan, Forsyth, Nazli, Ali and Berkeley 1997, 816^{VP} (*Bacillus thermoaerophilus* Meier-Staufffer, Busse, Rainey, Burghardt, Scheberl, Hollaus, Kuen, Makristathis, Sleytr and Messner 1996, 540)

ther.mo.aer.o'phi.us. Gr. adj. *thermos* hot; Gr. masc. n. *aer* air; Gr. adj. *philos* loving; N.L. adj. *thermoaerophilus* loving heat air, i.e., thermophilic and aerobic.

Colonies on nutrient agar after 24 h at 55°C are flat, 1–10 mm in diameter, irregular in shape, with a tendency to swarm across the surface of the agar; they are matt, translucent, and creamy grayish in appearance, becoming whitish and opaque in their centres. Vegetative cells are Gram-positive, motile by peritrichous flagella, and 1.0–1.2 µm by 3.5–5.5 µm. Central and paracentral spores are formed in swollen sporangia. Strictly aerobic. Catalase production variable. Growth temperatures range from 40 to 60°C and growth occurs from pH 7.0 to 8.0. Growth occurs in presence of 3% NaCl, but not 5% NaCl. Hydrolyzes casein, gelatin, and Tween 80. Produces acid from a small range of carbohydrates. Nitrate is not reduced. A range of amino acids, carbohydrates, and organic acids is assimilated as carbon sources in the API Biotype 100 System. The major cellular fatty acid components (ranges as percentages of total) are $C_{15:0 \text{ iso}}$ (50.3–66.8%), $C_{15:0 \text{ anteiso}}$ (0–10.3%), $C_{15:0}$ (0.9–3.4%), $C_{16:0 \text{ iso}}$ (3.5–4.1%), $C_{16:0}$ (1.8–2.5%), $C_{17:0 \text{ iso}}$ (23.4–23.8%), and $C_{17:0 \text{ anteiso}}$ (0–8.3%). Isolated from sugar beet extraction juice.

DNA G+C content (mol%): 46.3–46.7 (HPLC); that of the type strain is 46.7.

Type strain: DSM 10154, LMG 17165.

EMBL/GenBank accession number (16S rRNA gene): X94196 (DSM 10154).

Genus IV. *Brevibacillus* Shida, Takagi, Kadowaki and Komagata 1996a, 942^{VP}

NIALL A. LOGAN AND PAUL DE VOS

Bre.vi.ba.cil'lus. L. adj. *brevis* short; L. dim. n. *bacillus* small rod; N.L. masc. n. *Brevibacillus* short, small rod.

Gram-positive, Gram-variable, or Gram-negative, rod-shaped cells, 0.7–1.0 µm × 3.0–6.0 µm. Motile by means of peritrichous flagella. **Ellipsoidal spores are formed and swell the sporangia.** Most species grow on routine media such as nutrient agar and trypticase soy agar producing flat, smooth, yellowish-gray colonies. One species produces red pigment. **Most species are strictly aerobic, but one species is microaerophilic and one species is facultatively anaerobic.** Most species are catalase-positive. Oxidase reaction varies between species. Voges–Proskauer reaction is negative. Nitrate reduction and casein, gelatin, and starch hydrolysis varies between species. Growth is inhibited by 5% NaCl. Optimum growth occurs at pH 7.0. **Carbohydrates may be assimilated, but acid is produced weakly if at all from them by most species.** Some amino acids and organic acids may be used as carbon and energy sources. The major cellular fatty acids are $C_{15:0 \text{ ante}}$ and $C_{15:0 \text{ iso}}$.

DNA G+C content (mol%): 40.2–57.4.

Type species: *Brevibacillus brevis* (Migula 1900) Shida, Takagi, Kadowaki and Komagata 1996a, 943^{VP} (*Bacillus brevis* Migula 1900, 583.).

Further descriptive information

Phylogeny. *Brevibacillus* belongs to the family *Paenibacillaceae* and a phylogenetic tree covering the present species that are represented by their type strain is given in Figure 29 as a 16S rDNA sequence based neighbor-joining tree.

Differential characteristics for members of the genus *Brevibacillus* are given in Table 52. The rod-shaped cells of *Brevibacillus* species are usually round-ended, and occur singly, in pairs, and in chains. Cell diameters range from 0.7–1.0 µm and lengths

FIGURE 29. Phylogenetic neighbor-joining tree of type strains of *Brevibacillus* and *Aneurinibacillus* species based on 16S rDNA sequences. Bootstrap values are given at the branching points based on 1000 recalculations. Strain numbers with their respective EMBL accession numbers are given in parentheses.

from 3.0–6.0 µm, but the cells of a particular strain are usually quite regular in size, and individual species normally have dimensions within fairly narrow limits. Most of the species of *Brevibacillus* do not have distinctive sporangial morphologies; the spores are ellipsoidal, lie subterminally or perhaps terminally, and swell the sporangia slightly or moderately (Figure 30 and Figure 31). The notable exception is the unique sporangia

^aSymbols: +, >85% positive; d, results differ between strains (16–84% positive); -, 0–15% positive; +/v, positive or variable reaction within a strain; +/v/-, positive, variable or negative reaction within a strain; v, reaction varies within a strain; w, weak reaction; d/w, positive or weak positive reaction; +/w, positive or weak positive reaction; d/w, results differ between strains, but positive reactions are weak; no entry indicates that no data are available.

^bData from Manachini et al. (1985), Goto et al. (2004), Heyndrickx et al. (1997), Allan et al. (2005), Albaser and Logan (unpublished results).

^cData for this species (other than growth temperature tests) were obtained by incubating at 40 °C, and (excepting acid and alkali production from carbon sources – see^f below) were obtained at pH 5.5.

^dData for this species were obtained by incubating at 45 °C.

^e*Brevibacillus levickii* is microaerophilic.

^fData for *Brevibacillus limnophilus* are from Goto et al. (2004); data for *Brevibacillus thermoruber* are from Manachini et al. (1985); data for *Brevibacillus levickii* are from Allan et al. (2005) and inoculum was at pH 7, although this is supra-optimal for this species. Data for all other species are from Albaser and Logan (unpublished results), and the method of testing is described in the section *Procedures for testing special characters*.

FIGURE 30. Photomicrograph of type strain of *Brevibacillus brevis* viewed by phase-contrast microscopy, showing ellipsoidal, subterminal spores that usually swell the sporangia. Bar = 2 μ m. Photomicrograph prepared by N.A. Logan.

FIGURE 31. Photomicrograph of type strain of *Brevibacillus levickii* viewed by phase-contrast microscopy, showing ellipsoidal, subterminal and terminal spores in swollen sporangia. Bar = 2 μ m. Photomicrograph prepared by N.A. Logan.

FIGURE 32. Composite photomicrograph of type strain of *Brevibacillus laterosporus* viewed by phase-contrast microscopy. The ellipsoidal spores are cradled in parasporal bodies, are borne paracentrally and subterminally, and are displaced laterally so that the sporangia are swollen into spindle shapes. Bar = 2 μ m. Photomicrograph prepared by N.A. Logan.

gial morphology of *Brevibacillus laterosporus* which produces parasporal bodies (PBs) which laterally displace the spore in the sporangium (Figure 32), and which remain attached to the free spore (see below); the ellipsoidal spores of this species may lie centrally, paracentrally, or subterminally, and they characteristically swell the sporangia into spindle shapes.

Information on cell-wall composition is available for only two *Brevibacillus* species, *Brevibacillus brevis* and *Brevibacillus laterosporus*. They have the type of cross-linkage that is seen in the majority of *Bacillus* species for which it is known (see Table 2 in *Bacillus* section). A peptide bond is formed between the diamino acid in position 3 of one subunit and the D-Ala in position 4 of the neighboring peptide subunit so that no interpeptide bridge is involved. The diamino acid in most *Bacillus* species is *meso*-

FIGURE 33. Glossy colonies of the type strain of *Brevibacillus brevis* grown on trypticase soy agar for 24–36 h. Bar = 2 mm. Photograph prepared by N.A. Logan.

diaminopimelic acid (*meso*-DAP), and this cross-linkage is usually known as DAP-direct (Schleifer and Kandler, 1972).

Colonies of *Brevibacillus* species are usually smooth, moist, and glossy. Their elevations are flat to slightly raised, consistencies are butyrous, and shapes vary from round to irregular (Figure 33 and Figure 34). Diameters commonly range from 1–3 mm, but sizes up to 8 mm may occur. Colony color commonly ranges from buff or creamy-gray to off-white. *Brevibacillus thermoruber* produces spreading colonies and a red, nondiffusible pigment.

Brevibacillus species are heterotrophic and neutrophilic and will grow well on routine media such as nutrient agar or trypticase soy agar. Growth may be enhanced by the addition of a small amount of yeast extract. Most strains will grow on blood agar. They will use some amino acids, carbohydrates, and organic acids as sole sources of carbon and energy (see Table 53). Utilization of carbohydrates may be accompanied by the production of small amounts of acid, and utilization of amino acids and organic

FIGURE 34. Type strain of *Brevibacillus laterosporus* grown on trypticase soy agar for 24–36 h, showing creamy-white and smooth colonies with irregular margins. Bar = 2 mm. Photograph prepared by N.A. Logan.

acids may be accompanied by the production of small amounts of alkali, but, these generally are not easily detected by the routine test methods, and some characters may prove to be inconsistent when retested. Growth temperatures vary considerably, and the descriptions of the individual species should be consulted.

Habitats. Most *Brevibacillus* strains have been isolated from the natural environment, particularly soils, where they appear to be saprophytes, but there have been some isolations from human clinical specimens and from human illness, and *Brevibacillus laterosporus* has long been associated with insect pathogenicity. As with *Bacillus*, the spores of these organisms may readily survive distribution from these natural environments to a wide variety of other habitats, and some strains have been found as contaminants in foods and pharmaceutical products. For more information on endospores in the environment, see the chapter on *Bacillus*. *Brevibacillus* species may be isolated following heat treatment of specimens in order to select for endospores. Although the presence of their spores in a given environment does not necessarily indicate that the organisms are metabolically active there, repeated and independent isolations from such a habitat make it reasonable to assume that vegetative *Brevibacillus* cells are, or have been, active there. Isolates identified as *Bacillus brevis* prior to the allocation of many strains bearing this name into the new and revived species *Brevibacillus agri*, *Brevibacillus borstelensis*, *Brevibacillus centrosporus*, *Brevibacillus choshinensis*, *Brevibacillus formosus*, *Brevibacillus* (now *Aneurinibacillus*) *migulanus*, *Brevibacillus parabrevis*, *Brevibacillus reuszeri*, *Aneurinibacillus danicus*, and strains assigned to *Bacillus brevis* by authors unaware that these nomenclatural changes had been proposed (between 1995 and 2004), may or may not be authentic strains of this species or even members of the genus. This should be borne in mind when reading the accounts of habitats in which strains have been found. Isolations of strains identified as *Bacillus brevis* have been reported from tannery processing (Birbir and Ilgaz, 1996), black crusts on open-air stone monuments in Italy (Turtura et al., 2000), and soil contaminated with hexachlorocyclohexane. A *Bacillus brevis* strain secreting an extracellular cellulase was found in another soil (Singh and Kumar, 1998), and Wenzel et al. (2002) found a cellulolytic *Brevibacillus brevis* in the gut of the termite *Zootermopsis angust-*

collis. Isolates identified as *Brevibacillus brevis* have been reported from the airborne dust of schools and children's daycare centers (Andersson et al., 1999), food packaging products of paper and board (Pirttijarvi et al., 2000), the submerged rhizosphere of the seagrass *Vallisneria americana* (wild celery) in an estuarine environment (Kurtz et al., 2003), and in the humus of Norway spruce (*Picea abies*) (Elo et al., 2000).

The sources of the type strains of the species *Brevibacillus agri*, *Brevibacillus borstelensis*, *Brevibacillus choshinensis*, *Brevibacillus formosus*, *Brevibacillus ginsengisoli*, and *Brevibacillus reuszeri* were soils. Foodstuffs are readily contaminated by soil organisms; *Brevibacillus centrosporus* has been isolated from spinach and *Brevibacillus parabrevis* from cheese. *Brevibacillus centrosporus* has also been found in estuarine seagrass rhizosphere (Kurtz et al., 2003). Strains of *Brevibacillus invocatus* and *Brevibacillus agri* were repeatedly isolated from a pharmaceutical fermenter plant and its antibiotic raw product over a period of several months (Logan et al., 2002). *Brevibacillus agri* has also been isolated from sterilized milk, a gelatin processing plant, clinical specimens, and a public water supply where it was implicated in an outbreak of waterborne illness (Logan et al., 2002). *Brevibacillus centrosporus* was isolated from a bronchio-alveolar lavage, *Brevibacillus parabrevis* was found in a breast abscess, and both species have been isolated from human blood (Logan et al., 2002). The original strain of the thermophilic species *Brevibacillus thermoruber* was isolated from mushroom compost (Craveri et al., 1966; Gucciardi et al., 1968), *Brevibacillus borstelensis* or a close relative of this species was found to be a prominent member of the flora of hot synthetic compost (Dees and Ghiorse, 2001), and a hydrogen sulfide decomposing strain of *Brevibacillus formosus* has been isolated from pig feces compost (Nakada and Ohta, 2001). The geothermal soil of the northwest slope of Mount Melbourne, a volcano in Antarctica, yielded strains of a moderately thermophilic and moderately acidophilic species, *Brevibacillus levickii*, that were isolated in small numbers along with *Bacillus fumarioli* (Allan et al., 2005; Logan et al., 2000).

The specific epithet of *Brevibacillus laterosporus* is derived from the organism's unique sporangial morphology. It produces parasporal bodies (PBs) that displace the spore laterally in the sporangium (Figure 32); these bodies have been described as resembling canoes or the keels of ships. Montaldi and Roth (1990) examined sporangia by thin-section transmission electron microscopy and found three kinds of PB: i) a large one, associated with the spore, and of similar volume to it, with a lamellar structure of sequentially smaller layers, ii) a smaller globular or angular one of 100–200 nm in diameter that appeared at the same time as the lamellar PB but which was not attached to the spore in any way, and iii) a striated, rod-shaped PB with diameter of at least 200 nm. *Brevibacillus laterosporus* was originally isolated from water (Laubach, 1916), but McCray (1917) isolated other strains with sporangial morphologies similar to the Laubach et al. strain from the diseased larvae of bees. White (1920), who had named his bee larvae isolates as *Bacillus orpheus* in 1912 but had not described them, recognized the similarity between the two species. *Bacillus orpheus* is thus a synonym of *Brevibacillus laterosporus*. Endosporeformers named *Bacillus pulvifaciens* by Katznelson (1950) were isolated from diseased honeybee larvae (including cases of powdery scale). Gordon et al. (1973) thought that they might form a connection between *Bacillus larvae* and *Bacillus laterosporus* and

^aSymbols: +, >85% positive; d, results differ between strains (16–84% positive); -, 0–15% positive; +/v, positive or variable reaction within a strain; +/v/-, positive, variable or negative reaction within a strain; v, reaction varies within a strain; w, weak reaction; +/w, positive or weak positive reaction; d/w, results differ between strains, but positive reactions are weak; no entry indicates that no data are available.

^b*Brevibacillus brevis*, *Brevibacillus agri*, *Brevibacillus borstelensis*, *Brevibacillus centrosporus*, *Brevibacillus choshinensis*, *Brevibacillus formosus*, *Brevibacillus invocatus*, *Brevibacillus laterosporus*, *Brevibacillus levickii*, *Brevibacillus parabrevis*, and *Brevibacillus reuszeri* were negative for utilization of: L-arabinose, D-arabitol, dulcitol, L-fucose, lactulose, lyxose, melibiose, 1-O-methyl-α-galactopyranoside, 3-O-methyl-D-glucopyranose, raffinose, sorbose, xylitol, D-xylose, histamine, trigonelline, tryptamine, 5-aminovalerate, betain, caprate, *m*-coumarate, gentisate, glutarate, 3-hydroxybenzoate, 4-hydroxybenzoate, itaconate, 3-phenylpropionate, protocatechuate, D-tartrate, L-tartrate, tricarballoylate.

^cData for this species (other than growth temperature tests) were obtained by incubating at 40°C, and (excepting acid and alkali production from carbon sources – see ¹ below) were obtained at pH 5.5.

^dData for this species were obtained by incubating at 45°C.

included them as unassigned strains in their listing of the latter species, however, Nakamura (1984a) revived *Bacillus pulvifaciens* as a distinct species. *Bacillus pulvifaciens* was later transferred to *Paenibacillus*. Heyndrickx et al. (1996a) showed that *Paenibacillus pulvifaciens* was a later subjective synonym of *Paenibacillus larvae* and proposed that the two species should become subspecies of *Paenibacillus larvae* because they represent distinct pathovars. In a recent taxonomic proposal, this subspecies distinction was again abandoned (Genersch et al., 2006). Although the strains of *Brevibacillus laterosporus* originally named *Bacillus orpheus* were isolated from diseased bees, it was not clear that they were clinically significant and this species is now considered to be a secondary invader. Falcon (1971) noted that *Bacillus laterosporus* had been isolated along with other bacteria in association with a natural epizootic of high mortality affecting Cabbage Moth (*Mamestra brassicae*) caterpillars on cabbage. Some *Bacillus laterosporus* strains have been convincingly shown to be pathogenic for mosquito and blackfly (*Simulium*) larvae (Favret and Yousten, 1985). Their pathogenicities are very low, and apparently are toxin-mediated but not associated with their spores. Subsequently, other strains (one of them isolated from dead insects) were found to produce crystalline inclusions during sporulation (Smirnova et al., 1996) which were toxic for larvae of the mosquito species *Aedes aegypti* and *Anopheles stephensi*, and toxic to a lesser extent for *Culex pipiens* (Orlova et al., 1998). *Bacillus laterosporus* and *Brevibacillus laterosporus* have also been isolated from a case of endophthalmitis following penetrating injury (Yabbara et al., 1977), sweet curdling milk spoilage (Heyndrickx and Scheldeman, 2002), bread dough (Bailey and von Holy, 1993), spontaneously fermenting soybeans (Sarkar et al., 2002), food packaging paper and board products (Pirttijarvi et al., 2000), tannery processing (Birbir and Ilgaz, 1996), sea water (Barsby et al., 2002), and from an estuarine seagrass rhizosphere (Kurtz et al., 2003). Garabito et al. (1998) identified some of their isolates from salterns and saline soils as *Brevibacillus laterosporus* but found that these strains showed different substrate utilization patterns from that of the type strain of this species.

Brevibacillus strains, especially of *Brevibacillus brevis*, *Brevibacillus choshinensis*, and *Brevibacillus laterosporus*, have attracted considerable interest owing to their production or transformation of valuable compounds, or their potentials as biocontrol agents. The characteristically very high productivity of heterologous polypeptides and proteins by "*Bacillus brevis*" and *Brevibacillus brevis* strains have been harnessed for the production of human growth hormone (Kajino et al., 1997), human interleukin-2 (Takimura et al., 1997), cholera toxin B subunit for use as a mucosal adjuvant (Goto et al., 2000), a thermostable alkaline protease for use as a laundry detergent additive (Banerjee et al., 1999), acetolactate decarboxylase to prevent diacetyl formation during the accelerated maturation of beer (Outtrup and Jørgensen, 2002), and artificially designed gelatins (Kajino et al., 2000). *Brevibacillus choshinensis* has been used for the production of recombinant chicken interferon- γ as a growth-promoting agent for poultry (Yashiro et al., 2001) and for the production of recombinant human epidermal growth factor multimers and their transformation into the monomeric, native form (Miyachi et al., 1999).

An unidentified *Brevibacillus* strain isolated from petroleum-contaminated soil was found to be capable of degrading

petroleum hydrocarbons (Grishchenkov et al., 2000). A strain identified as *Bacillus brevis* was isolated from soil contaminated with hexachlorocyclohexane where it degraded this polluting pesticide (Gupta et al., 2000). Another strain of this species was found to degrade the insecticide teflubenzuron (Finkelstein et al., 2001). A strain of *Brevibacillus laterosporus* was able to break down polyvinyl alcohol to acetate (Lim and Park, 2001). An isolate closely related to *Brevibacillus thermoruber* has been found to depolymerize xanthan (Nankai et al., 1999).

Brevibacillus brevis produces the broad-spectrum, topically useful peptide antibiotic gramicidin S, which attacks the lipid bilayer of the inner membranes of susceptible organisms (Prenner et al., 1999). *Brevibacillus laterosporus* was the original source of the immunosuppressive drug spergualin (Takeuchi et al., 1981), synthetic analogs of which may be used as anti-tumor drugs and to prevent or treat tissue rejection (Allison, 2000). Other antibiotics produced by *Brevibacillus laterosporus* include laterosporamine (Shoji et al., 1976), the anti-*Candida* basiliskamides, and tupuseleiamides (Barsby et al., 2002). *Brevibacillus* strains with antifungal properties are potentially valuable biocontrol agents. These include a *Bacillus brevis* strain active against fusarial wilt of pigeon pea (Bapat and Shah, 2000), *Brevibacillus brevis* antagonistic to *Botrytis cinerea* (Edwards and Seddon, 2001), and a *Brevibacillus laterosporus* effective against four foliar necrotrophic pathogens of wheat (Alippi et al., 2000).

Enrichment and isolation

For most species, enrichment and selective isolation methods have not been reported. An isolation method for detecting colonies of the fungicidal, gramicidin-producing *Bacillus brevis* Nagano strain was developed by Edwards and Seddon (2000) for the recovery of this organism from plants and soil in field trial experiments. It utilized the ability of this strain to decompose tyrosine, producing light-brown colonies surrounded by haloes on tyrosine agar. The Nagano strain and any other isolates producing gramicidin could then be identified by paper chromatography of ethanolic extracts with detection by ninhydrin. Tyrosine agar contains nutrient broth (Oxoid), 6.6g; tyrosine, 5g; agar, 15g; water, 1000ml. After autoclaving, it is continuously stirred with a magnetic stirrer (to reduce the size of the tyrosine crystals) until it has reached 50°C, whereupon it is poured immediately, resulting in an opaque, off-white, solid medium. Tyrosine utilization is found among other *Brevibacillus* species and in many organisms outside this genus, so this method is by no means specific for *Brevibacillus brevis*. *Brevibacillus laterosporus* may be isolated from larval remains in outbreaks of European foulbrood in honeybees where they are considered to be secondary invaders (Alippi, 1991). Wakisaka and Koizumi (1982) noted that some aerobic endosporeformers that appeared to form minor components of soil floras, including *Bacillus brevis* and *Bacillus laterosporus*, showed slow and/or uneven germination compared with the more frequently encountered *Bacillus* species such as *Bacillus cereus*, *Bacillus megaterium*, *Bacillus sphaericus*, and *Bacillus subtilis*. Members of these minor populations were isolated with difficulty by the standard dilution-plate technique, but could be enriched by removing the rapidly germinating, fast-growing members of the predominant flora even though the latter might outnumber the minor flora by 100- to 1000-fold. The dried soil sample (0.5g) was suspended in 5ml of sterile saline and stirred with

three to five 4 mm diameter glass beads for 1 min, then placed in a vacuum desiccator for 30 min to eliminate air. The mixture was then heated at 65°C for 10 min to destroy vegetative bacteria and prompt spore germination; 1 ml of this suspension was combined with 1 ml of germination medium and incubated for 2–3 h at 30°C with gentle shaking (90 r.p.m.) followed by heating it at 65°C for 10 min to kill the newly emerged and vulnerable vegetative cells of the predominant members of the flora. After cooling, the suspension was serially diluted, and 0.5 ml quantities (of 1-, 10- and 100-fold dilutions, usually) were plated on Gly IM medium (see below), followed by incubation at 30°C for 2–12 days to recover the members of the minor population. Germination medium contained: glucose, 10 g; Casamino acids, 5 g; beef extract, 3 g; yeast extract, 1 g; DL-alanine, 1 g; water, 1000 ml; pH 6.8. Autoclave at 110°C for 15 min. Gly IM agar contained: NaCl, 3 g; beef extract, 2.5 g; polypeptone, 2.5 g; yeast extract, 2.5 g; soluble starch, 2 g; glycerol, 2 g; agar, 12.5 g; water, 1000 ml; pH 6.8.

Brevibacillus ginsengisoli was originally isolated from ginseng field soil. The sample was suspended in 50 mM phosphate buffer (pH 7.0), and the suspension was spread on one-fifth-strength modified R2A agar plates (tryptone, 0.25 g; peptone, 0.25 g; yeast extract, 0.25 g; malt extract, 0.125 g; beef extract, 0.125 g; Casamino acids, 0.25 g; soytone, 0.25 g; glucose, 0.5 g; soluble starch, 0.3 g; xylan, 0.2 g; $C_3H_3NaO_3$, 0.3 g; K_2HPO_4 , 0.3 g; $MgSO_4$, 0.05 g; $CaCl_2$, 0.05 g; agar, 15 g; water) after being serially diluted with 50 mM phosphate buffer (pH 7.0). The plates were incubated for 1 month at room temperature in an anaerobic chamber. The headspace was substituted with a gas mixture comprising $N_2/CO_2/H_2$ (80:15:5, by vol). Single colonies on the plates were purified by transferring them onto new plates that were incubated using the modified R2A agar or half-strength modified R2A agar under anaerobic conditions. The organism was routinely cultured on R2A agar at 30°C.

Brevibacillus levickii was isolated from geothermal soil samples collected from the northwest slope of Mount Melbourne, northern Victoria Land, Antarctica. 1 g quantities of soil were added to 9 ml *Bacillus fumarioli* broth (BFB) in duplicate at pH 5.5, and one of each pair was heat treated at 80°C for 10 min to kill vegetative cells. All broths were incubated at 50°C in waterbaths and inspected daily. Cultures which became turbid were subcultured by streaking onto plates of *Bacillus fumarioli* agar (BFA). Colonies appearing on streak plates were screened for vegetative and sporangial morphologies by phase-contrast microscopy, and sporeforming rods were streak purified and then transferred to slopes of the same medium for storage at 4°C after incubation and confirmation of sporulation by microscopy. The recipe for BFB is given under *Enrichment and isolation* in *Aneurinibacillus*, above.

Procedures for testing special characters

From the point of view of routine diagnostic laboratories, the aerobic endosporeformers comprise two groups, the reactive ones that will give positive results in various routine biochemical tests (and which are therefore more amenable to identification by traditional methods and modern developments of such approaches) and the nonreactive ones which give few if any positive results in such tests. Members of the genus *Brevibacillus* fall into the latter category. No special characters have been

described for their differentiation, so their identification is difficult. They are largely unreactive in the carbohydrate utilization tests of the API 50CHB gallery (bioMérieux, Marcy l'Étoile, France) and insufficiently variable in the API 20E and supplementary tests so that species in this genus are largely inseparable by these means. *Bacillus laterosporus* is an exception and does give useful results in this system. The API Biotype 100 gallery (bioMérieux), which was developed as a research product for differentiating enterobacteria, proved to be of great value in differentiating species of *Brevibacillus* and *Aneurinibacillus* (Allan et al., 2005; Heyndrickx et al., 1997; Logan et al., 2002); it contained 99 tests for the assimilation of carbohydrates, organic acids, and amino acids, and one control tube. It was inoculated with a suspension in one of two semi-solid media which differed in the number of growth factors they contained. After incubation, the tubes were examined for turbidity. Rigorous standardization of the suspension densities was essential. This system was adapted by using a suspension medium containing phenol red and examining the tubes for evidence of acid or alkali production (Albaser and Logan, unpublished results). The medium contained: KH_2PO_4 , 1.5 g; $MgSO_4 \cdot 7H_2O$, 0.1 g; $CaCl_2 \cdot 2H_2O$, 0.125 g; $MnSO_4 \cdot 4H_2O$, 2.5 mg; phenol red 1 g; distilled water, 1000 ml; vitamin solution, 1 ml; pH 7.5. The vitamin solution contained: biotin 5 mg; thiamine, 5 mg; riboflavin, 5 mg; pyridoxal phosphate, 5 mg; pantothenate, 5 mg; nicotinic acid, 5 mg; *p*-aminobenzoic acid, 1 mg; folic acid, 0.5 mg; vitamin B_{12} , 0.5 mg; thioctic acid, 0.5 mg; deionized water, 50 ml. Several other commercially available biotyping kits have been investigated but do not give useful data for differentiating *Brevibacillus* species. Some of the special characters described in the section *Procedures for testing special characters* of *Bacillus* (see above) are applicable to *Brevibacillus*. It is strongly recommended that the original and emended descriptions of the more recently described species are consulted wherever possible and that cultures of those organisms are obtained for comparison when trying to distinguish between *Brevibacillus* species. It should be appreciated that 16S rDNA sequencing is not always reliable as a stand-alone tool for identification (see Logan et al., 2002, for example) and that a polyphasic taxonomic approach is advisable for the identification of some of the more rarely encountered species and the confident recognition of new taxa. Nomenclatural types exist for a good reason and are usually easily available. There is no substitute for direct laboratory comparisons with authentic reference strains. It must also be remembered that cultures labeled *Brevibacillus brevis* in various laboratory collections around the world may not be authentic strains of this species if they were deposited prior to the extensive splitting of this species in the mid-1990s; the use of authentic type strains is therefore essential.

Taxonomic comments

Bacillus brevis was described by Migula in 1900, and the species attracted much interest in the early 1940s due to the production of the antibiotic gramicidin. Molluscicidal activity (Singer et al., 1988) and protein overproduction (Udaka et al., 1989) were subsequently reported for some strains. Because of such interest in potential applications, numerous isolations were made, but many isolates were found to differ from the reference strains, some in particular being thermophilic, and so the delineation

of the species became uncertain. Following DNA–DNA reassociation studies and chemotaxonomic analyses, the taxonomy of *Bacillus brevis* was modified by assigning some *Bacillus brevis* strains to the new or revived species *Bacillus agri* and *Bacillus centrosporus* (Nakamura, 1993), *Bacillus migulanus*, *Bacillus choshinensis*, *Bacillus parabrevis*, and *Bacillus galactophilus* (Takagi et al., 1993) and *Bacillus reuszeri*, *Bacillus formosus*, and *Bacillus borstelensis* (Shida et al., 1995), but *Bacillus galactophilus* was later recognized to be a synonym of *Bacillus agri* (Shida et al., 1994a).

Studies on the 16S rDNA sequences of the type strain of *Bacillus brevis* suggested that *Bacillus aneurinolyticus* represents a distinct evolutionary line close to that of *Bacillus brevis* (Ash et al., 1991) or that it diverged early from the *Bacillus brevis* line (Farrow et al., 1992, 1994). On the basis of a 16S rDNA gene sequence analysis of the type strains only, Shida et al. (1996a) proposed the new genera *Brevibacillus* and *Aneurinibacillus*. The former accommodated *Brevibacillus brevis* and the seven species mentioned above that were derived from it, along with *Brevibacillus laterosporus* and the thermophile *Brevibacillus thermoruber*. *Aneurinibacillus* contained "*Bacillus aneurinolyticus*" and two other species. An earlier SDS-PAGE study supported this divergence of the *Bacillus brevis* and *Bacillus aneurinolyticus* groups (Shida et al., 1996b), but the individual species of the *Bacillus brevis* group were not always well separated by this method, a problem also noticed by Logan et al. (2002). The latter authors also found that 16S rDNA sequence analysis showed low discrimination potential for the species *Brevibacillus brevis*, *Brevibacillus choshinensis*, *Brevibacillus formosus*, *Brevibacillus parabrevis*, and *Brevibacillus reuszeri*, and that most species of the genus were difficult to separate by routine phenotypic tests. A further species, *Brevibacillus invocatus*, was proposed by Logan et al. (2002), who emphasized the difficulties of distinguishing between species of this genus. In the light of these problems of identification, Goto et al. (2004) examined the hypervariable (HV) region corresponding to the 5' end of 16S rDNA (nucleotide positions 70–344 in *Bacillus subtilis* numbering) in 52 strains of aerobic endosporeformers, 31 of which were received as *Brevibacillus*, and 3 as unidentified *Brevibacillus* species. The HV region marker had already proved to be taxonomically useful in *Alicyclobacillus*, *Bacillus*, and *Paenibacillus*, and tentative identifications by this approach were then confirmed by DNA–DNA hybridizations. They found that 14 *Brevibacillus brevis* and three *Brevibacillus* species strains clustered in *Aneurinibacillus* and proposed one of these strains as the new species *Aneurinibacillus danicus*. Of the remaining 17

strains received as *Brevibacillus brevis*, five identified as *Bacillus methanolicus*, two strains clustered close to this species but showed less than 70% DNA homology with the type strain, and one identified as *Bacillus oleronius*. Only two strains clustered with *Brevibacillus brevis*, and they showed less than 60% DNA homology with the type strain of this species. Of the remainder, three strains identified as *Brevibacillus agri*, two as *Brevibacillus parabrevis*, and 1 strain which did not cluster with an existing species of the genus was proposed as the new species *Brevibacillus limnophilus*.

Thus strains which might previously have been assigned to *Bacillus brevis* now represent some 12 mesophilic species in *Brevibacillus*. Their distinctions are based mainly upon DNA relatedness studies, molecular probing, and chemotaxonomic analyses of the relatively few available isolates using databases which are largely restricted to reference laboratories and unsuitable for organisms encountered only occasionally in routine laboratories. Distinction of most *Brevibacillus* species is not possible using the currently available *Bacillus* identification schemes, and separation remains difficult even with much wider selections of phenotypic tests (Heyndrickx et al., 1997; Logan, 2002). Also, another unreactive species, *Bacillus badius*, and species of *Aneurinibacillus* may easily be misidentified as a member of this genus. It is unfortunate that the extensive splitting proposed by the various recent taxonomic studies has not revealed characteristic phenotypic profiles that would be of value in the routine laboratory. It has been questioned whether the current taxonomy of *Brevibacillus* best serves the needs of the diagnostic bacteriologist and whether certain species might better be merged to give a more practically useful classification of this genus (Logan et al., 2002). However, new genotypic approaches based on sequences of so-called housekeeping genes may provide more straightforward (genomic) differentiation and identification.

Maintenance procedures

Brevibacillus strains may be preserved on slopes of a suitable growth medium that encourages sporulation, such as nutrient agar or trypticase soy agar containing 5 mg/l of $\text{MnSO}_4 \cdot 7\text{H}_2\text{O}$. Slopes should be checked microscopically for spores before sealing (to prevent drying out) and storage in a refrigerator; on such sealed slopes the spores should remain viable for many years. For longer term preservation, lyophilization and liquid nitrogen may be used, as long as cryoprotectants are added.

List of the species of the genus *Brevibacillus*

1. ***Brevibacillus brevis*** (Migula 1900) Shida, Takagi, Kadowaki and Komagata 1996a, 943^{VP} (*Bacillus brevis* Migula 1900, 583.)

bre'vis. L. adj. *brevis* short.

Strictly aerobic, Gram positive or Gram variable, motile, rod-shaped cells, 0.7–0.9 μm \times 3.0–5.0 μm , occurring singly and in pairs. The ellipsoidal spores are borne subterminally and swell the sporangia (Figure 30). Grows on routine media such as nutrient agar and trypticase soy agar, pro-

ducing glossy, butyrous, cream-colored colonies, 1–3 mm in diameter after 24–36 h (Figure 33). Growth at 30°C may initially be slow, with more rapid growth following 24 h incubation. Catalase- and oxidase-positive. Nitrate reduction positive for most strains. Casein, DNA, gelatin, and Tween 60 are hydrolyzed; starch and urea are not hydrolyzed. Hydrolysis of Tween 80 is variable. Hydrogen sulfide and indole are not produced. Most strains do not grow at 20° or below, or above 50°C. No growth occurs at pH 5.5 and most

strains do not grow at pH 9.0. D-Fructose, D-glucose, glycerol, maltose, mannitol, ribose, trehalose, and a few other carbohydrates are assimilated, and acid is produced weakly, if at all, from them. Amino acids and some organic acids are used as carbon and energy sources.

Isolated mainly from soil; also found in airborne dust, milk, rhizospheres, and paper products.

DNA G+C content (mol%): 48.7 (HPLC).

Type strain: ATCC 8246, BCRC 14682, CCM 2050, CCUG 7413, CIP 52.86, DSM 30, HAMBI 1883, NBRC 15304, JCM 2503, LMG 7123, NCCB 48009, NCIMB 9372, NCTC 2611, NRRL B-14602, NRRL NRS-604, VKM B-503, W.W. Ford 27B.

GenBank accession number (16S rRNA gene): AB101593, AB271756, D78457, X60612.

2. **Brevibacillus agri** (Laubach 1916) Shida, Takagi, Kadowaki and Komagata 1996a, 943^{VP} (*Bacillus agri* (ex Laubach, Rice and Ford 1916) Nakamura 1993, 23; *Bacillus galactophilus* Takagi, Shida, Kadowaki, Komagata and Udaka 1993, 229.) ag'ri. L. gen. n. *agri* of a field.

Strictly aerobic, Gram positive, motile, rod-shaped cells, 0.5–1.0 µm × 2.0–5.0 µm. The ellipsoidal spores swell the sporangia. Grows on routine media such as nutrient agar and trypticase soy agar, producing nonpigmented, translucent, thin, smooth, circular, entire colonies of about 2 mm in diameter. Catalase-positive, oxidase-negative. Nitrate reduction negative. Casein and gelatin are hydrolyzed; starch and urea are not hydrolyzed. Minimum growth temperature varies between 5 and 20°C, optimum temperature for growth is 28°C, and maximum growth temperature is 40°C. Growth occurs at pH 5.6 and no growth occurs at pH 9.0. Grows in presence of 2% but not 3% NaCl. D-Fructose, D-glucose, glycerol, maltose, D-mannitol, D-trehalose, and a few other carbohydrates are assimilated, and acid is produced weakly, if at all, from them. Amino acids and some organic acids are used as carbon and energy sources.

Isolated from soil, water, clinical specimens, sterilized milk, and pharmaceutical manufacturing plants.

DNA G+C content (mol%): 53.5 (HPLC).

Type strain: ATCC 51663, CCUG 31345, CIP 104002, DSM 6348, NBRC 15538, JCM 9067, LMG 15103, NRRL NRS-1219.

GenBank accession number (16S rRNA gene): AB112716, D78454.

3. **Brevibacillus borstelensis** (Stührk 1935) Shida, Takagi, Kadowaki and Komagata 1996a, 945^{VP} (*Bacillus borstelensis* Shida, Takagi, Kadowaki, Udaka, Nakamura and Komagata 1995, 98.)

bor.stel.en'sis. N.L. adj. *borstelensis* referring to Borstel, Germany, where it was isolated.

Strictly aerobic, Gram positive, motile, rod-shaped cells, 0.5–0.9 µm × 2.0–5.0 µm. The ellipsoidal spores swell the sporangia. Grows on routine media such as nutrient agar and trypticase soy agar, producing flat, smooth, circular, entire colonies. One of the 16 strains contributing to the original description produced brown-red pigmentation on nutrient agar. Catalase-positive, oxidase-negative. Nitrate is reduced. Casein and gelatin are hydrolyzed; starch and urea are not hydrolyzed. Growth occurs at 20°C, the maximum is 50°C,

and the optimum temperature for growth is 30°C. Growth occurs at pH 5.5 and 5.6. Growth does not occur in the presence of 2% NaCl. D-Fructose, ribose, and a few other carbohydrates are assimilated, and acid is produced weakly, if at all, from them. D-Mannitol and D-trehalose are not assimilated. Amino acids and some organic acids, but not citrate, are used as carbon and energy sources.

Isolated from soil.

DNA G+C content (mol%): 51.3 (HPLC).

Type strain: ATCC 51668, CIP 104545, DSM 6347, NBRC 15714, JCM 9022, LMG 16009, NRRL NRS-818.

GenBank accession number (16S rRNA gene): AB112721, D78456.

4. **Brevibacillus centrosporus** (Laubach 1916) Shida, Takagi, Kadowaki and Komagata 1996a, 943^{VP} (*Bacillus centrosporus* ex Laubach, Rice and Ford 1916) Nakamura 1993, 24.)

cen.tro.spor'us. L. n. *centrum* the center; N.L. n. *spora* spore; N.L. adj. *centrosporus* with a central spore.

Strictly aerobic, Gram positive, motile, rod-shaped cells, 0.5–1.0 µm × 2.0–6.0 µm. The ellipsoidal spores swell the sporangia. Despite the species name, the spores do not tend to lie centrally in the sporangia. Grows on routine media such as nutrient agar and trypticase soy agar, producing nonpigmented, translucent, thin, smooth, circular, entire colonies 2–3 mm in diameter. Catalase-positive, oxidase-negative. Nitrate is reduced to nitrite by some strains. Casein, gelatin, starch, and urea are not hydrolyzed. Minimum temperature for growth is 10°C, maximum is 40°C, and the optimum temperature for growth is 28°C. Growth does not occur at pH 5.6. Growth does not occur in the presence of 3% NaCl. D-Glucose, D-mannitol, ribose, and a few other carbohydrates are assimilated, and acid is produced weakly, if at all, from them. D-Fructose and trehalose are not assimilated. Some amino acids and organic acids are used as carbon and energy sources.

Isolated from child's feces, clinical specimens, spinach, and estuarine seagrass rhizosphere.

DNA G+C content (mol%): 49.8 (HPLC).

Type strain: ATCC 51661, CCUG 31347, CIP 104003, DSM 8445, NBRC 15540, JCM 9071, LMG 15106, NRRL NRS-664.

GenBank accession number (16S rRNA gene): AB112719, D78458.

5. **Brevibacillus choshinensis** (Takagi, Shida, Kadowaki, Komagata and Udaka 1993) Shida, Takagi, Kadowaki and Komagata 1996a, 943^{VP} (*Bacillus choshinensis* Takagi, Shida, Kadowaki, Komagata and Udaka 1993, 229.)

cho.shi.nen'sis. N.L. adj. *choshinensis* referring to Choshi, Japan, where it was isolated.

Strictly aerobic, Gram positive, motile, rod-shaped cells, with cell diameters greater than 0.5 µm and cell lengths greater than 3.0 µm. The ellipsoidal spores swell the sporangia and lie subterminally to terminally. Grows on routine media such as nutrient agar and trypticase soy agar, producing pale yellow colonies. Catalase- and oxidase-positive. Nitrate reduction negative. Casein, gelatin, starch, and urea are not hydrolyzed. Growth occurs at 15°C, but not at 50°C. Growth does not occur at pH 5.5 and pH 9.0. Does not grow in presence of 2% NaCl. Strains are very unreactive and very few carbohydrates are assimilated by some strains while

acid is produced weakly, if at all, from them. Glycerol is not assimilated. A very few amino acids, citrate, and some other organic acids may be used as carbon and energy sources.

Isolated from soil.

DNA G+C content (mol%): 48.2 (Takagi et al., 1993)–49.8 (Logan et al., 2002) (both HPLC).

Type strain: HPD52, ATCC 51359, CIP 103838, DSM 8552, NBRC 15518, JCM 8505, LMG 15968, NCIMB 13345, NRRL B-23247.

GenBank accession number (16S rRNA gene): AB112713, D78459.

6. **Brevibacillus formosus** (Heigener 1935) Shida, Takagi, Kadowaki and Komagata 1996a, 943^{VP} (*Bacillus formosus* Shida, Takagi, Kadowaki, Udaka, Nakamura and Komagata 1995, 98.)

for.mo'sus. L. adj. *formosus* beautiful.

Strictly aerobic, Gram positive, motile, rod-shaped cells, 0.5–0.9 μm × 2.0–5.0 μm. The ellipsoidal spores swell the sporangia. Description is based on the study of three strains. Grows on routine media such as nutrient agar and trypticase soy agar, producing colonies that are unpigmented, flat, smooth, circular and entire. Catalase-positive, oxidase-negative. Nitrate is reduced to nitrite. Casein and gelatin are hydrolyzed; starch and urea are not hydrolyzed. Growth occurs at 10°C and at 45°C, but not at 50°C; the optimum temperature for growth is 30°C. Growth occurs at pH 5.5 and 5.6. Growth does not occur in the presence of 2% NaCl. D-Glucose, D-fructose, glycerol, and other carbohydrates are assimilated, and acid is produced weakly, if at all, from them. A range of amino acids and organic acids may be used as carbon and energy sources.

Isolated from soil.

DNA G+C content (mol%): 47.2 (HPLC).

Type strain: F12, ATCC 51669, CIP 104544, DSM 9885, NBRC 15716, JCM 9169, LMG 16010, NRRL NRS-863.

GenBank accession number (16S rRNA gene): AB112712, D78460.

7. **Brevibacillus ginsengisoli** Baek, Im, Oh, Lee, Oh and Lee 2006, 2667^{VP}

gin.sen.gi.so'li. N.L. n. *ginsengum* ginseng; L. n. *solum* soil; N.L. gen. n. *ginsengisoli* of the soil of a ginseng field, the source of the organism.

Cells are Gram positive, aerobic or facultatively anaerobic, motile, slightly curved rods, 0.3–0.5 μm in diameter and 3.5–5.0 μm in length after 2 days culture on R2A agar. Colonies grown on R2A agar for 2 days are smooth, circular, glossy, white, and convex. Central and subterminal oval spores are formed in swollen sporangia. Grows well at 20–42°C and pH 5.0–8.5, but does not grow at 4 or 45°C. Growth occurs in the absence of NaCl and in the presence of 2.0% (w/v) NaCl but not 4% (w/v) NaCl. Grows anaerobically in denitrifying conditions. Casein and gelatin are hydrolyzed. Xylan, chitin, starch, cellulose, and DNA are not degraded. Urease, β-glucosidase, protease, and malic acid assimilation are positive in tests using API 20E and API 20NE strips. Reactions for ONPG hydrolysis, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, citrate utilization, hydrogen sulfide production, tryptophan deaminase, indole production, acetoin production, and adipic acid assimilation are negative. Utilizes a small number of carbohydrates, amino acids, and

organic acids as carbon sources. In addition to those shown in the tables, the following carbon sources are utilized in the API 50 CH and ID 32GN tests: L-histidine, salicin, and valeric acid. Utilization tests are negative for the following substrates: amygdalin, arbutin, D-arabinose, D-arabitol, D-fucose, D-lyxose, dulcitol, erythritol, L-fucose, glycogen, inulin, D-mannose, D-melibiose, methyl-α-D-mannopyranoside, methyl-β-D-xylopyranoside, D-raffinose, L-sorbose, D-tagatose, D-turanose, xylitol, L-xylose, capric acid, 3-hydroxybenzoic acid, 4-hydroxybenzoic acid, itaconic acid, propionic acid, sodium malonate, and suberic acid. MK-7 is the predominant respiratory quinone. The major cellular fatty acids are C_{15:0 iso}, C_{14:0 iso}, and C_{15:0 ante}.

Isolated from soil from a ginseng field in Pocheon Province, South Korea.

DNA G+C content (mol%): 52.1 (HPLC).

Type strain: Gsoil 3088, KCTC 13938, LMG 23403.

GenBank accession number (16SrRNA): AB245376.

8. **Brevibacillus invocatus** Logan, Forsyth, Lebbe, Goris, Heyndrickx, Balcaen, Verhelst, Falsen, Ljungh, Hansson and De Vos. 2002, 964^{VP}

in.vo.ca'tus. L. adj. *invocatus* uninvited, referring to the isolation of strains of this organism as contaminants of an industrial fermentation.

Gram negative, motile, rod-shaped cells, 0.5–1.0 μm × 2.0–6.0 μm. Strictly aerobic. The ellipsoidal spores are borne subterminally and occasionally terminally, and swell the sporangia. Grows on routine media such as nutrient agar and trypticase soy agar. Growth at 30°C is initially slow, with more rapid growth following 24 h incubation; after 3–4 days the slightly umbonate colonies are 1–8 mm in diameter, with slightly irregular margins. Colonies are brownish-yellow, some with a single whitish concentric zone at the margin, and they are butyrous and have silky surfaces; the centers are opaque and the edges translucent. Catalase-positive. Nitrate reduction negative. Casein, gelatin, starch, and urea are not hydrolyzed; indole is not produced. Growth temperatures range from 15–35°C. Growth occurs between pH 6.0 and 8.5. Few carbohydrates are assimilated, only weakly, and acid is not produced from them; some amino acids and organic acids are used as carbon sources.

Isolated from a pharmaceutical fermentation plant and its antibiotic raw product.

DNA G+C content (mol%): 49.7 (HPLC).

Type strain: B2156, CIP 106911, JCM 12215, LMG 18962, NCIMB 13772.

GenBank accession number (16SrRNA): AB112718.

9. **Brevibacillus laterosporus** (Laubach 1916) Shida, Takagi, Kadowaki and Komagata 1996a, 945^{VP} (*Bacillus laterosporus* Laubach 1916, 505.)

la.te.ro.spor'us. L. n. *latus*, *lateris* the side; N.L. n. *spora* spore; N.L. adj. *laterosporus* with lateral spores.

Gram positive, Gram negative, and Gram variable, motile, rod-shaped cells, 0.5–0.9 μm × 2.0–5.0 μm. Facultatively anaerobic. Strains of this species commonly exhibit distinctive sporangial morphologies. The ellipsoidal spores are cradled in parasporal bodies (PBs) that have been described as C-shaped, or resembling canoes or the keels of

ships. The spores, with their attached PBs, are borne centrally, paracentrally, and subterminally and are displaced laterally in the sporangia by the PBs, so that the sporangia are swollen into spindle shapes (Figure 32). Other species of aerobic endosporeforming bacteria may produce spores that lie laterally, but the PBs, which tend to remain firmly adherent to the spore after sporangial lysis, appear to be unique to this species. The proportion of sporangia containing PBs may vary with the strain and growth conditions. Grows on routine media such as nutrient agar and trypticase soy agar. Colonies are 1–3 mm in diameter, creamy-white, and smooth, and may have slightly irregular margins (Figure 34). Catalase-positive. Nitrate is reduced. Casein and gelatin are hydrolyzed, and starch and urea are not hydrolyzed; indole is not produced. Growth temperatures range from minima between 15 and 20°C to maxima between 35 and 50°C, with optima around 30°C. Growth does not occur at pH 5.7 but does occur at pH 6.8. D-Fructose, D-glucose, glycerol, maltose, D-mannitol, D-mannose, D-ribose, trehalose, and several other carbohydrates are assimilated, and acid is produced from them in larger quantities, so it is more readily detected than is the case with most other species of *Brevibacillus*. Some amino acids and organic acids are also used as carbon and energy sources. Some strains are pathogenic for mosquito and blackfly larvae. Parasporal toxin crystals, visible by electron microscopy, may be produced by some strains.

Isolated from soil, salterns, tap water, diseased honey bee larvae, other insects, foods, paper products, marine environments, and an eye infection.

DNA G+C content (mol%): 40.2 (T_m), 40.5 (Bd).

Type strain: ATCC 4517, ATCC 64, ATCC 8248, CCM 2116, BCRC 10607, CCUG 7421, CFBP 4222, CIP 52.83, DSM 25, HAMBI 1882, IAM 12465, NBRC 15654, JCM 2496, LMG 6931, LMG 16000, NCCB 75013, NCCB 48016, NCIMB 8213, NCIMB 9367, NCTC 6357, NRRL NRS-314, NRRL NRS-340, VKM B-499.

GenBank accession number (16S rRNA gene): AB112720, D16271, X60620.

10. **Brevibacillus levickii** Allan, Lebbe, Heyrman, De Vos, Buchanan and Logan 2005, 1048^{VP}

le.vic.ki'i. N.L. gen. n. *levickii* of Levick, named after G. Murray Levick, surgeon and biological scientist of Captain R.F. Scott's Northern Party, the first scientific expedition to visit the vicinity of Mt. Melbourne in 1912.

Microaerophilic and weakly catalase-positive. Cells are Gram positive, becoming Gram negative after 48 h, motile, round-ended rods (0.7–0.8 µm × 2–5 µm) occurring singly, in pairs, and in chains. Endospores are ellipsoidal, occurring subterminally or terminally in swollen sporangia (Figure 31). After 48 h incubation at 40°C on 1/2 BFA (pH 5.5), colonies are circular, flat, up to 3.0 mm in diameter, and cream-colored with a matt appearance. Colony consistency becomes tough and difficult to break with a loop. Minimum growth temperature lies between 15 and 20°C, with the optimum temperature for growth being between 40 and 45°C, and the maximum growth temperature lying between 50 and 55°C. Growth occurs between pH 4.5 and 6.5 and the optimum pH for growth

lies between pH 5.0 and 5.5. Horse blood agar is partially hemolyzed. Gelatin is hydrolyzed, starch hydrolysis is weak, and casein hydrolysis is weak and variable. In the API 20E strip reactions for arginine dihydrolase, citrate utilization and Voges–Proskauer reaction are positive. Nitrate reduction is variable. A range of carbohydrates, amino acids, and organic acids is assimilated in the API Biotype 100 gallery as sole carbon sources. The major cellular fatty acid is C_{15:0 ante}, accounting for approximately 74 % of the total fatty acid content. The following fatty acids are present in smaller amounts (at least 1 %): C_{14:0 iso}, C_{15:0 iso}, C_{16:0}, C_{16:0 iso}, summed feature 4 (C_{17:1 iso} and/or C_{17:1 ante}), and C_{17:0 ante}.

Isolated from geothermal soil collected from the northwest slope of Mt. Melbourne, northern Victoria Land, Antarctica.

DNA G+C content (mol%): 50.3 (HPLC).

Type strain: B-1657, CIP 108307, LMG 22481.

GenBank accession number (16S rRNA gene): AJ715378.

11. **Brevibacillus limnophilus** Goto, Fujita, Kato, Asahara and Yokota 2004, 426^{VP}

lim.no'phi.us. Gr. n. *limnos* lake; Gr. adj. *philos* loving or friendly to; N.L. masc. adj. *limnophilus* lake-loving.

Strictly aerobic, Gram variable, motile rods, 0.5–0.6 µm × 2.2–4.0 µm. Ellipsoidal spores are borne subterminally in swollen sporangia. Description is based upon a single isolate. Colonies on nutrient agar are circular, entire, smooth, convex, translucent, and whitish-beige, and they are 3–4 mm in diameter after 48 h. The temperature range for growth is 20–45°C, and the temperature for optimum growth is 30–35°C. Optimum pH for growth is 7.0–7.5, growth occurs at pH 6.5–8.0 and does not occur at pH 6.0 or 8.5. Growth is weak in the presence of 2% NaCl and is inhibited by 5% NaCl. Catalase-positive and oxidase-negative. Urease, citrate utilization, and nitrate reduction are negative. Esculin is hydrolyzed, DNA is weakly hydrolyzed, and arbutin, casein, gelatin, starch, and tyrosine are not hydrolyzed. Acid is produced from L-arabinose, D-fructose, glycerol, rhamnose (weakly), and ribose. The major fatty acids are C_{15:0 iso}, C_{16:0} and C_{17:0 iso}. The main quinone is menaquinone 7.

This organism was deposited in the ARS Culture collection as "*Bacillus limnophilus*" by Porter in 1940 and identified by Smith et al. (1952) as "*Bacillus brevis*".

Source of the type strain not reported; *Bacillus limnophilus* was described by Stührk (1935). Goto et al. (2004) did not refer to the original description, but they did indicate that the name they proposed was a revival for the strain that was deposited with this name in the ARS Culture Collection by Porter in 1940. Smith et al. (1952) considered it to be a synonym of *Bacillus brevis*.

DNA G+C content (mol%): 51.9 (HPLC).

Type strain: DSM 6472, NRRL NRS-887.

GenBank accession number (16S rRNA gene): AB112717.

12. **Brevibacillus parabrevis** (Takagi, Shida, Kadowaki, Komagata and Udaka 1993) Shida, Takagi, Kadowaki and Komagata 1996a, 943^{VP} (*Bacillus parabrevis* Takagi, Shida, Kadowaki, Komagata and Udaka 1993, 229.)

pa.ra.bre'vis. Gr. prep. *para* alongside of, like; N.L. adj. *brevis* short; N.L. *parabrevis brevis*-like, referring to *Bacillus* (now *Brevibacillus*) *brevis*.

Strictly aerobic, Gram positive or Gram variable, motile, rod-shaped cells, 0.5–0.9 µm × 2.0–4.0 µm. The ellipsoidal spores are borne subterminally to terminally and swell the sporangia. Grows on routine media such as nutrient agar and trypticase soy agar, producing flat, smooth, yellowish-gray colonies. Catalase- and oxidase-positive. Nitrate reduction positive. Casein, DNA, gelatin, Tween 60, and Tween 80 are hydrolyzed; starch, and urea are not hydrolyzed. Hydrogen sulfide and indole are not produced. Growth occurs at 20°C, some strains grow at 15°C and most at 50°C, but no growth occurs at 55°C. Most strains will not grow at pH 5.5 or pH 9.0. Most strains will grow in presence of 2% NaCl, but not with 5% NaCl. D-Glucose, glycerol, maltose, D-mannitol, trehalose, and other carbohydrates are assimilated, but acid is produced weakly, if at all, from them. D-Fructose is not assimilated. Some amino acids and organic acids are used as carbon and energy sources.

Source of type strain not reported; other strains found in clinical specimens and cheese.

DNA G+C content (mol%): 51.8 (Takagi et al., 1993)–52.2 (Logan et al., 2002) (both HPLC).

Type strain: ATCC 10027, CIP 103840, DSM 8376, NBRC 12334, JCM 8506, LMG 15971, NCIMB 13346, NRRL NRS-605, NRRL NRS-815.

GenBank accession number (16S rRNA gene): AB112714, D78463.

13. **Brevibacillus reuszeri** (Shida, Takagi, Kadowaki, Udaka, Nakamura and Komagata 1995) Shida, Takagi, Kadowaki and Komagata 1996a, 943^{VP} (*Bacillus reuszeri* Shida, Takagi, Kadowaki, Udaka, Nakamura and Komagata 1995, 98.)
reus.ze'ri. N.L. gen. n. *reuszeri* of Reuszer, referring to H.W. Reuszer, who isolated the organism.

Strictly aerobic, Gram positive, motile, rod-shaped cells, 0.5–0.9 µm × 2.0–5.0 µm. The ellipsoidal spores swell the sporangia. Grows on routine media such as nutrient agar and trypticase soy agar, producing unpigmented, flat, smooth, circular, entire colonies. Catalase-positive, oxidase-negative. Nitrate is not reduced to nitrite. Casein, gelatin, starch, and urea are not hydrolyzed. Growth occurs at 10°C and at 45°C, and the optimum temperature for growth is 30°C. Growth occurs at pH 5.5 and 5.6. Growth occurs in the presence of 2% NaCl but not with 3% NaCl. D-Fructose, D-glucose, D-mannitol, and a few other carbohydrates are assimilated, and acid is produced weakly, if at

all, from them. Shida et al. (1995) found that this organism produced acid from glycerol and maltose, but Logan et al. (2002) found that neither was assimilated. Some amino acids and organic acids are used as carbon and energy sources.

Isolated from soil.

DNA G+C content (mol%): 46.5 (HPLC).

Type strain: H.W. Reuszer Army strain 39, ATCC 51665, CIP 104543, DSM 9887, NBRC 15719, JCM 9170, LMG 16012, NRRL NRS-1206.

GenBank accession number (16S rRNA gene): AB112715, D78464.

14. **Brevibacillus thermoruber** (Guicciardi, Biffi, Manachini, Craveri, Scolastico, Rindone and Craver 1968) Shida, Takagi, Kadowaki and Komagata 1996a, 945^{VP} (*Bacillus thermoruber* (ex Guicciardi, Biffi, Manachini, Craveri, Scolastico, Rindone and Craver 1968) Manachini, Fortina, Parini and Craveri 1985, 495.)

ther'mo.ru.ber. Gr. n. *therme* heat; L. adj. *ruber* red; N.L. masc. adj. *thermoruber* heat-loving and red-pigment producing.

Moderately thermophilic, strictly aerobic, Gram positive, motile, rod-shaped cells, 0.8–1.0 µm × 2.5–4.8 µm. The ellipsoidal spores are borne terminally and subterminally and swell the sporangia. Description is based upon study of a single isolate. Requires biotin or thiamin for growth. Grows on glucose yeast extract agar, producing colonies that are spreading, smooth, shiny and red, with glossy, mucilaginous surfaces. The red pigment is endocellular and nondiffusible. Grows on routine media supplemented with yeast extract; biotin or thiamine required for growth. Growth in glucose-yeast extract broth is homogeneous. Catalase-negative or weakly positive. Nitrate is not reduced to nitrite. Casein, gelatin, and starch are hydrolyzed. Growth occurs between 34°C and 58°C, and the optimum temperature for growth is 45–48°C. No growth occurs in the presence of 5% NaCl. D-Fructose, D-glucose, D-mannitol, D-trehalose, and other carbohydrates are utilized as sole carbon sources according to Manachini et al. (1985), but Logan et al. (2002) were unable to reproduce these results.

Isolated from mushroom compost.

DNA G+C content (mol%): 57.0 ± 0.8 (HPLC).

Type strain: BT2, MIM 30.8.38, CIP 105255, CIP 105298, DSM 7064, HAMB1 2105, LMG 16910.

GenBank accession number (16S rRNA gene): AB112722, Z26921.

Genus V. **Cohnella** Kämpfer, Rosselló-Mora, Falsen, Busse and Tindall 2006, 784^{VP}

PETER KÄMPFER, HANS-JÜRGEN BUSSE AND BRIAN J. TINDALL

Cohn.el'la. N.L. fem. dim. n. *Cohnella* named after Ferdinand Cohn, a German microbiologist who first described the bacterial genus *Bacillus* in 1872.

Spore-forming rods. Nonmotile. Gram-positive. **Aerobic.** Oxidase-positive. Good growth after 24 h on complex media such as trypticase soy agar and nutrient agar at 25–30°C. **Thermotolerant**; good growth occurs at 55°C. The major menaquinone is MK-7. The predominant polar lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidyle-

thanolamine, and lysyl-phosphatidylglycerol. In addition, two unknown phospholipids, and four unknown amino-phospholipids are present. The main fatty acids are C_{16:0 iso}, C_{15:0 anteiso} and C_{16:0}. Fatty acids in minor amounts are C_{14:0}, C_{15:0}, C_{17:0 iso}, C_{17:1 iso}, and C_{17:0 anteiso}.

DNA G+C content (mol%): 57–59.

Type species: Cohnella thermotolerans Kämpfer, Rosselló-Mora, Falsen, Busse and Tindall 2006, 784^{VP}.

Further descriptive information

The 16S rRNA gene (1486 bp) of *Cohnella thermotolerans* showed the greatest degree of similarity to “*Paenibacillus hongkongensis*” (GenBank accession no. AF433165; 96.58%), described by Teng et al. (2003), but this name was not validly published. Significantly lower sequence similarities (<94.5%) were found with all other species of the genus *Paenibacillus* with validly published names (Kämpfer et al., 2006). A phylogenetic tree is shown in Figure 35.

As currently circumscribed, the genus contains only two species, *Cohnella thermotolerans* and *Cohnella hongkongensis*. Both species descriptions are based on single strains. The type strain of *Cohnella thermotolerans* was isolated on blood agar at 37°C during a routine hygienic control in a starch producing company. On trypticase soy (TS) agar, the strain was able to grow at 20–55°C, but not at 10 or 60°C. Growth at 30°C was also observed on nutrient agar and the R2A medium of Reasoner and Geldreich (1985), but not on *Salmonella-Shigella* (SS) agar. The type strain of *Cohnella hongkongensis*—originally described as “*Paenibacillus hongkongensis*” by Teng et al., (2003)—was also isolated from a blood agar culture of a 9-year-old Chinese boy with neutropenic fever and pseudobacteremia. This strain was also able to grow on complex media. On horse blood agar, the strain produced gray colonies after 24 h incubation at ambient air temperature. At 50°C it produced pinpoint colonies after 72 h incubation.

Both type strains of the *Cohnella* species display a complex polar lipid profile, which consists of diphosphatidylglycerol, phosphatidylglycerol, phosphatidylethanolamine, lysyl-phosphatidylglycerol, two unknown phospholipids, and four unknown amino-phospholipids.

The fatty acid profiles of the *Cohnella* strains (given in the species description) are similar to those of other *Paenibacillus* species, however, the amounts of C_{16:0 iso} (45.5% in *Cohnella thermotolerans*), or C_{16:0} (25.3% in *Cohnella hongkongensis*) are very high (Kämpfer et al., 2006). Such high amounts of C_{16:0 iso} have not been reported to date for *Paenibacillus* species. Members of the genus *Thermobacillus*, described by Touzel et al. (2000) show a similar fatty acid content to *Cohnella thermotolerans* with respect to C_{16:0} and C_{17:0}, but not for the other fatty acids. Kämpfer (2002) compiled fatty acid data of *paenibacilli* and found that the major fatty acids of the genus *Paenibacillus* (with ranges as percentages of total given in parentheses), as currently defined, are C_{15:0 anteiso} (36–80%), C_{16:0 iso} (0.5–6%), and C_{15:0 iso} (1–12%), and C_{17:0 anteiso} (6.7%). The differences in the relative amounts of C_{16:0 iso} and C_{16:0}, as well as the differences of more than 10% in the mol% G+C content of the DNA, may be indicative of properties that allow one not only to distinguish the two species, but (potentially) differentiate higher taxa. However, finding additional species that show similar 16S rDNA sequences and chemotaxonomic properties would be needed to test this hypothesis. Additional potential members of the genus *Cohnella* as suggested by high similarities in 16S rRNA gene sequences, which are deposited with gene banks, are apparently present in several institutional culture collections such as *Paenibacillus* sp. GP25–12 (94.6–95.4% 16S rRNA gene sequence similarity; accession no AM162342), *Cohnella* sp. T (95.2–97.3% 16S rRNA gene sequence similarity; accession no DQ333896), “*Cohnella ginsengisoli*” GR21–5 (94.4–94.9% 16S rRNA gene sequence

similarity; accession no EF368010), “*Paenibacillus panacarvi*” Gsoil 349; (94.4–94.6% 16S rRNA gene sequence similarity; accession no AB271056), and *Bacillus* sp. GL1 (94.3–94.9% 16S rRNA gene sequence similarity; accession no AB024598; Nankai et al., 1999). Other strains might be also affiliated with the genus *Cohnella* but 16S rRNA gene sequences alone do not provide sufficient evidence because these strains share sequence similarities higher than 94% with only one of the established *Cohnella* species.

Enrichment and isolation procedures

No specific isolation medium has been described so far. Good growth occurs on complex media such as nutrient agar and trypticase soy agar (BBL).

Maintenance procedures

Cohnella cultures may be lyophilized by common procedures used for many bacteria. In addition, cultures can be maintained by serial transfers on solid complex media (although this is the least satisfactory of long-term storage methods). Growth on agar slants in screw-capped tubes can be kept at 4°C for about 2–4 weeks. Long-term preservation of liquid cultures supplemented with 5% dimethyl sulfoxide is recommended in liquid nitrogen in the liquid phase at –196°C.

Differentiation of the genus *Cohnella* from other genera

Members of the genus *Cohnella* may be distinguished from other genera by a combination of the cell-wall peptidoglycan, polar lipid, menaquinone, and fatty acid composition, and also the ability to grow at relatively high temperatures.

Taxonomic comments

In the field of reclassification of the bacilli, there is still a discussion as to what constitutes the genus *Bacillus* and whether other genera created over the years should be either further split or combined. In creating the genus *Cohnella* it was important to show that it could be clearly distinguished from the members of the genus *Bacillus* and also from members of the genus *Paenibacillus* (Kämpfer et al., 2006). One solution is to define the properties of the type species of these genera (i.e., *Bacillus* and *Paenibacillus*) and to create new genera where clear differences are to be found based on a combination of 16S rDNA sequence data, chemical composition, physiology, and biochemical properties.

The chemical composition of members of the bacilli is heterogeneous. This has been well documented (Minnikin and Goodfellow, 1981; O’Leary and Wilkinson, 1988). However, in recent years much emphasis has been put on the use of fatty acid composition. Although some differentiation is possible, fatty acid composition appears to be of limited value in further differentiating within the bacilli. In the case of respiratory lipoquinones, menaquinones dominate, with isoprenoid chain lengths from 6–9. The most commonly encountered menaquinone is MK-7. Closer examination of the polar lipids indicates a greater degree of variation, although this method has not been widely applied in recent years. As regards the members of *Bacillus* group 1 (Ash et al., 1991), there is chemical heterogeneity within the group (Minnikin and Goodfellow, 1981; O’Leary and Wilkinson, 1988). However, *Bacillus subtilis*—the type species of the genus *Bacillus*—produces diphosphatidylglycerol, phosphatidylglycerol, phosphatidylethanolamine, an amino-

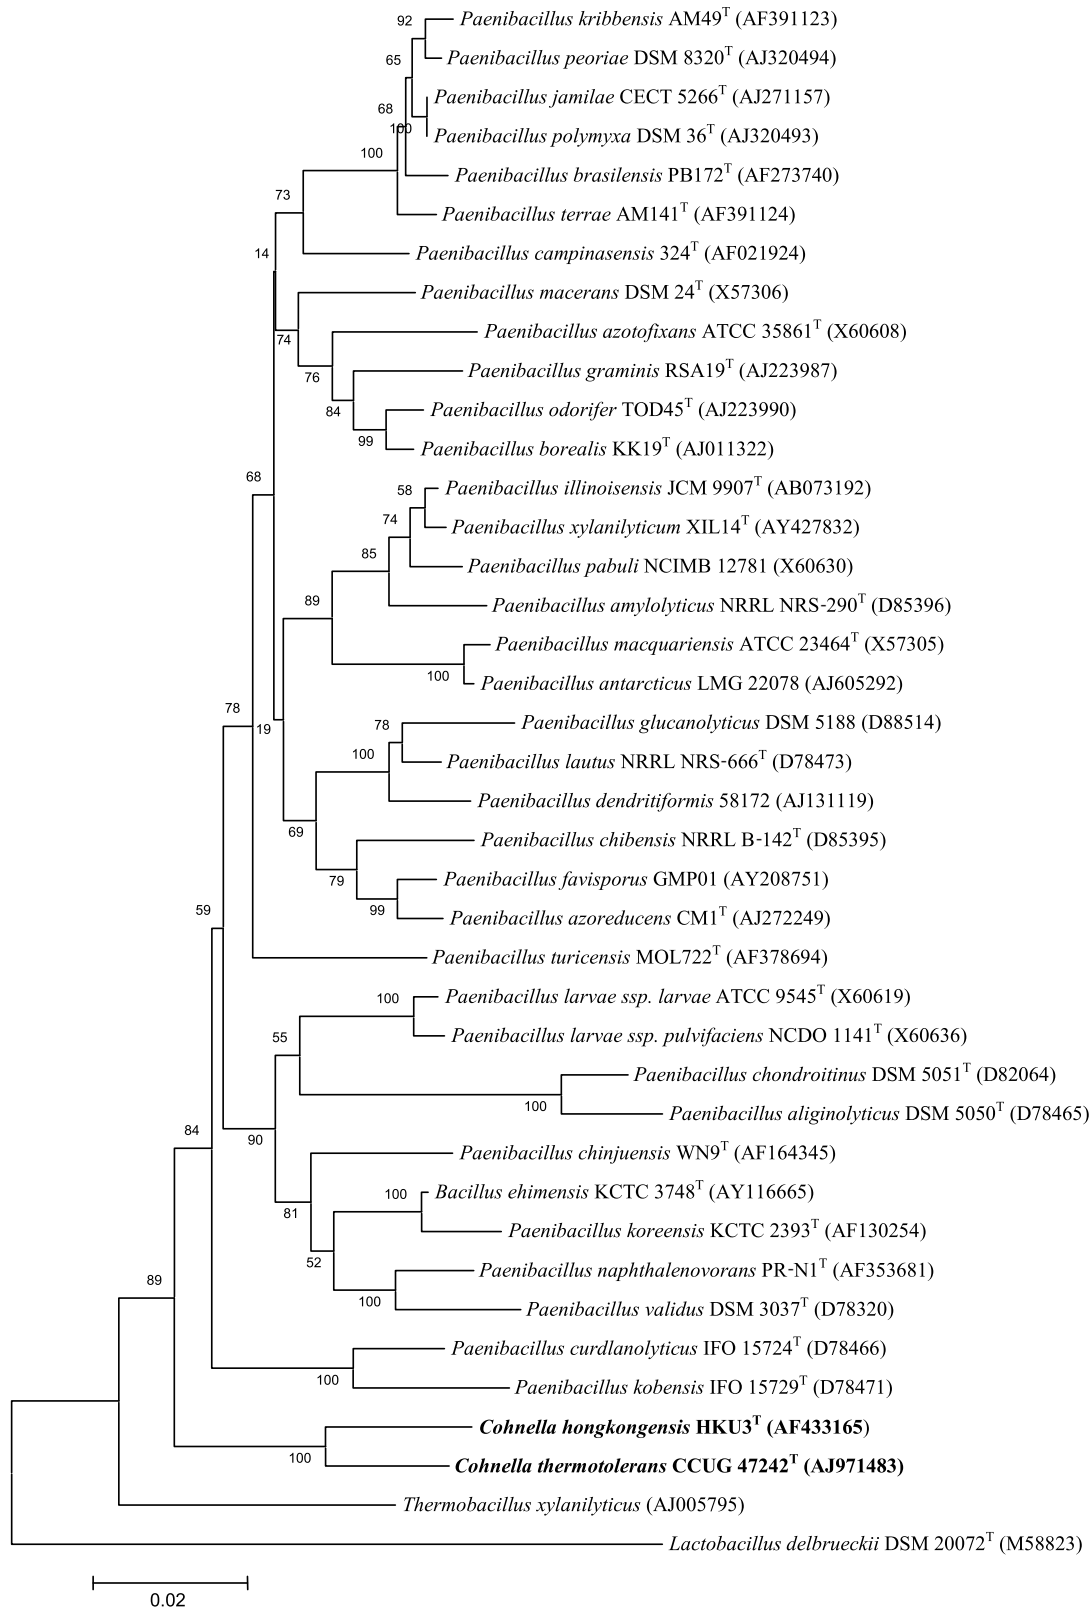

FIGURE 35. Phylogenetic analysis based on 16S rRNA gene sequences available from the European Molecular Biology Laboratory database (accession no.s are given in parentheses) constructed after multiple alignment of data by CLUSTAL_X (Thompson et al., 1997). Distances (distance options according to the Kimura-2 model) and clustering with the neighbor-joining method were performed by using the software packages MEGA (Molecular Evolutionary Genetics Analysis) version 2.1 (Kumar et al., 2001). Bootstrap values based on 1000 replications are listed as percentages at the branching points. (Data from Kämpfer et al., 2006).

acylphosphatidylglycerol, and a glycolipid that has been identified as a β -gentiobiosyldiacylglycerol (Minnikin and Goodfellow, 1981). Species sharing this polar lipid pattern, together with MK-7 and the fatty acid pattern listed in Table 54 should, in the future, constitute the "core" of the genus *Bacillus*.

On the other hand, it is still an open question which degree of variability (if any) within the polar lipid pattern will be acceptable to allow affiliation with the "core" of the genus *Bacillus*. *Bacillus herbersteinensis* (Wieser et al., 2005), for instance, which shows a high degree of 16S rDNA sequence similarity, shares with *Bacillus subtilis* the same quinone system, diamino-pimelic acid in the cell wall, a rather similar fatty acid profile, and the majority of characteristics within the polar lipid patterns, however, it can be distinguished by its lack of phosphatidylethanolamine and an unknown aminophospholipid. It is hoped that the affiliation of *Bacillus herbersteinensis* lies with the *Bacillus* "core" and assignment to the genus *Bacillus*, or to a novel genus can be unambiguously answered by analyses of other representatives of taxa that show similar high degrees of 16S rDNA sequence similarity.

In contrast to the polar lipids of type species of the genus *Bacillus*, the polar lipid composition of the type species of the genus *Paenibacillus*, *Paenibacillus polymyxa*, is clearly different. The single glycolipid present does not have the same R_f value as β -gentiobiosyldiacylglycerol. Although the major phospholipids present are diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylethanolamine, they only serve (together with the presence of menaquinones and iso/anteiso fatty acids) to confirm that this species belongs to the bacilli. The presence of a number of unidentified phospholipids serves to differentiate this species from other taxa. Preliminary work on the polar lipid composition of the genus *Paenibacillus* indicates that this group is also heterogeneous (Minnikin and Goodfellow, 1981; O'Leary and Wilkinson, 1988), and only those species sharing a similar chemical composition to the type species should be retained in the genus *Paenibacillus* in the future.

In the case of members of the genus *Cohnella*, the chemical composition also centres on the presence of menaquinones (MK-7), the dominance of iso and anteiso fatty acids, and the presence of diphosphatidylglycerol, phosphatidylglycerol,

*Data for *Cohnella thermotolerans* and *Cohnella hongkongensis* are based on the type strains (Kämpfer et al., 2006). Data for *Bacillus subtilis* and *Paenibacillus polymyxa* were taken from Kämpfer (2002) and are compiled from several species descriptions.

and phosphatidylethanolamine as the predominant phospholipids. Among the polar lipids, however, both strains share the same properties of having a number of phospholipids and amino-phospholipids that are not present in either of the type species of the genus *Bacillus* or *Paenibacillus*. The ability to synthesize such lipids (including other amino acid derivatives) must also be seen in a taxonomic and evolutionary context, being particularly prevalent in this branch of the Gram-positive Bacteria. This and previous work clearly indicate the value of chemotaxonomy within the bacilli, and further support the need for including such studies in all future taxonomic work on this group. This conclusion is also consistent with the remarks of the *ad hoc* committee (Murray et al., 1990; Wayne et al., 1987), which emphasized the need to carry out more chemotaxonomic work, particularly when defining new genera and families.

List of species of the genus *Cohnella*

- 1. *Cohnella thermotolerans*** Kämpfer, Rosselló-Mora, Falsen, Busse and Tindall 2006, 784^{VP}
ther.mo.to'ler.ans. Gr. n. *therme* heat; L. pres. part. *tolerans* tolerating; N.L. part. adj. *thermotolerans* able to tolerate high temperatures.

The description is as given for the genus, with the following additional characteristics. Good growth occurs after 24 h on TS agar and nutrient agar at 25–30°C; good growth occurs also at 55°C. The fatty acid profile of the type strain is comprised of C_{16:0} iso (45.5%), C_{15:0} anteiso (28.4%), C_{17:0} anteiso (6.7%), C_{16:0} (6.6%), C_{18:1} ω 7c (4.0%), C_{15:0} iso (3.2%), C_{14:0} iso (2.1%), C_{15:0} (1.4%), C_{17:0} iso (1.1%), C_{14:0} (1.0%), and C_{17:1} ω 6c (1.0%). Esculin and *p*-nitrophenyl (pNP)- β -D-glucopyranoside are hydrolyzed. The following are utilized as sole carbon sources: arbutin, L-arabinose (weakly),

D-cellobiose, D-fructose, D-galactose, gluconate, D-glucose, D-maltose, D-mannose, α -D-melibiose, L-rhamnose (weakly), and D-ribose.

No acid production occurs from glucose, lactose, sucrose, D-mannitol, sulcitol, salicin, adonitol, inositol, sorbitol, L-arabinose, raffinose, rhamnose, maltose, D-xylose, trehalose, cellobiose, methyl-D-glucoside, erythritol, melibiose, D-arabitol, and D-mannose. No hydrolysis occurs of pNP- β -D-galactopyranoside, pNP- β -D-glucuronide, pNP- α -D-glucopyranoside, pNP- β -D-xylopyranoside, bis-pNP-phosphate, pNP-phenyl-phosphonate, pNP-phosphoryl-choline, 2-deoxythymidine-5'-pNP-phosphate, L-alanine- *p*-nitroanilide (pNA), L-glutamate-gamma-3-carboxy-pNA, and L-proline-pNA. The following carbon source are not utilized: N-acetyl-D-galactosamine, N-acetyl-D-glucosamine, sucrose,

salicin, D-trehalose, D-xylose, adonitol, *l*-inositol, maltitol, D-mannitol, D-sorbitol, putrescine, acetate, propionate, *cis*-aconitate, *trans*-aconitate, adipate, 4-aminobutyrate, azelate, citrate, fumarate, glutarate, DL-3-hydroxybutyrate, itaconate, DL-lactate, L-malate, mesaconate, oxoglutarate, pyruvate, suberate, L-alanine, β -alanine, L-aspartate, L-histidine, L-leucine, L-ornithine, L-phenylalanine, L-proline, L-serine, L-tryptophan, 3-hydroxybenzoate, 4-hydroxybenzoate, and phenylacetate.

DNA G+C content (mol%): 59 (HPLC).

Type strain: CCUG 47242, CIP 108492, DSM 17683).

GenBank accession number (16S rRNA gene): AJ971483.

2. **Cohnella hongkongensis** Kämpfer, Rosselló-Mora, Falsen, Busse and Tindall 2006, 784^{VP} (*Paenibacillus hongkongensis* Teng, Woo, Leung, Lau, Wong and Yuen 2003, 33.)

hong.kong.en'sis. N.L. fem. adj. *hongkongensis* pertaining to Hong Kong.

The description is as given for the genus, with the following additional characteristics. Good growth occurs after 24 h on horse-blood agar at 37°C; good growth occurs also at 50°C, but not at 65°C. The fatty acid profile of the type

strain is composed of C_{16:0 iso} (11.9%), C_{15:0 anteiso} (31.2%), C_{17:0 anteiso} (2.6%), C_{16:0} (25.3%), C_{15:0 iso} (8.1%), C_{13:0 anteiso} (0.8%), C_{14:0 iso} (2.3%), C_{15:0} (8.0%), C_{16:1 ω 11c} (0.9%), C_{17:0 iso} (1.9%), C_{14:0} (5.0%), and C_{17:0} (1.2%).

The type strain utilizes the following carbon sources after 7 d: *N*-acetyl-D-galactosamine, *N*-acetyl-D-glucosamine, arbutin, L-arabinose (weakly), D-cellobiose, D-fructose, D-galactose, gluconate, D-glucose, D-maltose, D-mannose, α -D-melibiose, L-rhamnose, and D-ribose. The following carbon source are not utilized: sucrose, salicin, D-trehalose, D-xylose, adonitol, *l*-inositol, maltitol, D-mannitol, D-sorbitol, putrescine, acetate, propionate, *cis*-aconitate, *trans*-aconitate, adipate, 4-aminobutyrate, azelate, citrate, fumarate, glutarate, DL-3-hydroxybutyrate, itaconate, DL-lactate, L-malate, mesaconate, oxoglutarate, pyruvate, suberate, L-alanine, β -alanine, L-aspartate, L-histidine, L-leucine, L-ornithine, L-phenylalanine, L-proline, L-serine, L-tryptophan, 3-hydroxybenzoate, 4-hydroxybenzoate, and phenylacetate.

DNA G+C content (mol%): 47.6 (T_m).

Type strain: HKU3, CCUG 49571, CIP 107898, DSM 17642.

GenBank accession number (16S rRNA gene): AF433165.

Genus VI. **Oxalophagus** Collins, Lawson, Willems, Cordoba, Fernandez-Garayzabal, Garcia, Cai, Hippe and Farrow 1994a, 822^{VP}

FRED A. RAINEY

Ox.sa.lo'pha.gus. Gr. n. *oxalis* wood sorrel (from which the name of oxalic acid is derived); Gr. masc. n. *phagos* glutton; N.L. masc. n. *Oxalophagus* oxalate eater.

Cells are Gram-positive, straight rods. Endospores are formed. Oval spores, located subterminally to centrally. Strictly anaerobic. Catalase-negative. Cytochromes are not produced. Oxalate and oxamate are decarboxylated to formate. Acetate is assimilated for cell carbon synthesis. No growth occurs with other organic acids, sugars, or alcohols. Member of the family *Paenibacillaceae* based on 16S rRNA gene sequence comparisons.

DNA G+C content (mol%): 36.3.

Type species: **Oxalophagus oxalicus** (Dehning and Schink, 1989) Collins, Lawson, Willems, Cordoba, Fernandez-Garayzabal, Garcia, Cai, Hippe and Farrow 1994, 822^{VP} (*Clostridium oxalicum* Dehning and Schink 1989, 83.).

List of species of the genus *Oxalophagus*

1. **Oxalophagus oxalicus** (Dehning and Schink 1989) Collins, Lawson, Willems, Cordoba, Fernandez-Garayzabal, Garcia, Cai, Hippe and Farrow 1994, 822^{VP} (*Clostridium oxalicum* Dehning and Schink 1989, 83.)

ox.a'li.cus. N.L. n. *acidum oxalicum* oxalic acid; N.L. masc. adj. *oxalicus* referring to the metabolism of oxalic acid.

Cells are straight rods, with rounded ends, occurring singly or in pairs, 2.5–4.8 μ m long and 0.7–0.9 μ m wide. Endospores are oval, 1.2–1.4 \times 0.9 μ m, subterminal to central and heat resistant. Motile by peritrichous flagella. Gram-positive. No cytochromes. Strictly anaerobic. Chemo-organotroph. Oxalate and oxamate decarboxylated to formate. Acetate assimilated for cell carbon synthesis. Nitrate, sulfate, sulfite, thiosulfate, and sulfur are not reduced. No growth with malonate, succinate (both

20 mM), glutamate, aspartate, glycine, fumarate + formate, glycerol, ethylene glycol, pyruvate, malate, citrate, acetoin, betaine, 1,2-propanediol, trimethoxybenzoate (all 10 mM), lactate, glycolate, methanol (all 5 mM), glyoxylate, hexamethylenetetramine, glucose, fructose, xylose, arabinose (all 2 mM), yeast extract, Casamino acids (both 0.1%), and H₂/CO₂ as substrates. Indole and catalase are not formed. Urea, gelatin, and esculin are not hydrolyzed. Growth occurs between 16–34°C, optimum 28–30°C. pH range for growth is 5.3–8.5, optimum 7.0. Enriched from pasteurized samples. The type strain was isolated from anoxic freshwater sediment.

DNA G+C content (mol%): 36.3 (T_m).

Type strain: Alt Ox1, ATCC 49686, DSM 5503.

GenBank accession number (16S rRNA gene): X77840, Y14581.

Genus VII. *Thermobacillus* Touzel, O'Donohue, Debeire, Samain and Breton 2000, 318^{VP}

JEAN PIERRE TOUZEL AND GÉRARD PRENSIER

Ther.mo.ba.cil'lus. Gr. adj. *thermos* hot; N.L. dim. n. *bacillus* small rod; N.L. masc. n. *Thermobacillus* small thermophilic rod.

Cells straight rods with tapered ends 0.4–0.5 by 2.0–2.8 μm (Figure 36). Nonmotile. Ellipsoidal **endospores** are formed in swollen sporangia. **Aerobic**. Cells stain Gram-negative although the phylogenetic position is Gram-positive. Cell-wall structure is clearly of the Gram-positive type. Colonies are irregular, flat, with undulate margins. Catalase-positive and oxidase- and urease-negative. Growth occurs in the presence of 3% NaCl. Starch and esculin are hydrolyzed whereas gelatin and casein are not. Utilizes cellobiose, fructose, galactose, lactose, mannose, melezitose, melibiose, raffinose, trehalose, tributyrin, and xylose as sole carbon source for growth. Substrates which are not utilized are adonitol, casein, citrate, dextrin, dulcitol, erythritol, gelatin, inulin, salicin, sorbitol, and succinate. Nitrate is not reduced. **Thermophilic**. Grows optimally at 55°C; maximum temperature for growth is 63°C. Grows at pH 6.5–8.5; optimal pH is 7.8. **Carbon dioxide is required**. Produces large quantities of a xylan-inducible xylanase in the culture medium. The menaquinone is MK 7. The major fatty acid is C_{16:0 iso}. On the basis of 16S rRNA analysis, the genus *Thermobacillus* is closely related to members of the genus *Paenibacillus* (Ash et al., 1994).

Isolated from farm soil in the north of France.

DNA G+C content (mol%): 57.5.

Type species: Thermobacillus xylanilyticus Touzel, O'Donohue, Debeire, Samain and Breton 2000, 319^{VP}.

Further descriptive information

The type strain is XE, which was isolated from farm soil in northern France and has been deposited with the French

Collection Nationale de Cultures Microbiennes as a patent strain (CNCM-I1017).

Enrichment and isolation procedures

Thermobacillus xylanilyticus was isolated from a farm soil underlying a former manure heap in France. It is considered to be common in hot environments where plant organic matter is decaying. It is easily enriched and isolated after successive transfers in a xylan-based medium under aerobic, thermophilic (55°C) conditions in tightly closed vials that favor CO₂ accumulation (Touzel et al., 2000).

Maintenance procedures

Thermobacillus grows well in tightly closed 125 ml penicillin vials containing 10 ml liquid medium (Touzel et al., 2000) with a gas phase of air/CO₂ (90:10). The cultures are incubated overnight at 55°C on a rotary shaker. Such cultures remain viable for about 1 year when kept at 4°C. Long-term preservation is maintained in a mechanical freezer (–80°C) with 25% glycerol.

Differentiation of the genus *Thermobacillus* from other genera

Thermobacillus can be phylogenetically differentiated from *Paenibacillus* by 16S rDNA sequence comparison. Other features that distinguish these two genera include: motility, major fatty acid, and mol% G+C content of the DNA.

FIGURE 36. Electron micrograph of thin sections of *Thermobacillus xylanilyticus* grown in liquid medium. (A) Detail of the cell-wall structure typical of Gram-positive bacteria; bar = 0.2 μm. (B) General view of a sporulating cell; bar = 0.4 μm.

List of species of the genus *Thermobacillus*

1. ***Thermobacillus xylanilyticus*** Touzel, O'Donohue, Debeire, Samain and Breton 2000, 319^{VP}
 xy.la.ni.ly'ti.cus. Gr. n. *xylon* wood; N.L. n. *xylanum* xylan, a plant polysaccharide; Gr. adj. *lutikos* dissolving; N.L. adj. *xylanilyticus* hydrolyzing xylan.

Pas.teu'ri.a. N.L. gen. n. *Pasteuria* of Pasteur, named after Louis Pasteur, French savant and scientist.

Gram-positive, endospore-forming bacteria. Propagation following germination within a nematode or cladoceran host proceeds through the formation of rounded to elliptical (termed "cauliflower-like" by Metchnikoff, 1888) vegetative microcolonies from which "daughter" microcolonies may be formed. The sporogenous cells at the periphery of the colonies are usually attached by narrow "sacrificial" intercalary hyphae that lyse, resulting in developing sporangia arranged in clumps of eight or more, but more often in quartets, triplets, or doublets and, finally, as single teardrop-shaped or cup-shaped or rhomboidal mature sporangia. The rounded end of the sporangium encloses a single refractile endospore (1.0–3.0 μm in major dimension), an oblate spheroid, ellipsoidal or almost spherical in shape, usually resistant to desiccation and elevated temperatures (one species has somewhat limited heat tolerance). Nonmotile. Sporangia and microcolonies are endoparasitic in the bodies of freshwater, plant, and soil invertebrates. Axenic cultivation has not been documented, but it can be grown in the laboratory with its invertebrate host. The pathogen is horizontally transmitted via soil or waterborne spores. Infected hosts fail to reproduce.

DNA G+C content (mol%): not known.

Type species: Pasteuria ramosa Metchnikoff 1888, 166^{AL}.

Further descriptive information

A complex of errors initially confused our understanding of the genus *Pasteuria* Metchnikoff (1888). Stated briefly, Metchnikoff (1888) described an endospore-forming bacterial parasite of cladocerans, which he named *Pasteuria ramosa*. Metchnikoff presented drawings and photomicrographs of the life stages of this parasite as they occurred in the hemolymph of the water fleas *Daphnia pulex* Leydig and *Daphnia magna* Straus. He was, however, unable to cultivate the organism *in vitro*. Subsequent workers (Henrici and Johnson, 1935; Hirsch, 1972; Staley, 1973), who were looking in cladocerans for Metchnikoff's unique bacterium, reported on a different bacterium with only superficial resemblance to certain life stages of *Pasteuria ramosa*. Their investigations led to the axenic cultivation of a budding bacterium that is occasionally found on the exterior surfaces of *Daphnia* species. Unlike the organism described

by Metchnikoff, this bacterium divides by budding. It forms a major non-prosthecate appendage (a fascicle), it does not form endospores, it is not mycelial or branching, its staining reaction is Gram-negative, and it is not an endoparasite of cladocerans.

After searching for, but not finding, the bacterial endoparasite in water fleas as described by Metchnikoff, the erroneous conclusion was reached that this budding bacterium that occurs on the surfaces of *Daphnia* species was the organism Metchnikoff had described in 1888. As a result, a budding bacterium (strain ATCC 27377) was mistakenly designated (Staley, 1973) as the type culture for *Pasteuria ramosa* Metchnikoff (1888), the type (and, then, sole) species of the genus *Pasteuria*. This confusion between Metchnikoff's described cladoceran parasite and the quite different budding bacterium was resolved by Starr et al. (1983). The budding bacterium (with strain ATCC 27377 as its type culture) was named *Planctomyces staleyi* Starr, Sayre and Schmidt (1983), now named *Pirellula staleyi* (Butler et al., 2002). Conservation of the original descriptions of the genus *Pasteuria* and *Pasteuria ramosa*, as updated, was recommended (Starr et al., 1983) and approved (Judicial-Commission, 1986). Unfortunately, vestiges of this nomenclatural disorder remained for some time. For example, certain evolutionary and taxonomic inferences (Woese, 1987) regarding the genus *Pasteuria* were based upon data concerning bacteria belonging to the *Blastocaulis-Planctomyces* group of budding and non-prosthecatly appendaged bacteria rather than the mycelial and endospore-forming invertebrate parasites that actually comprise the genus *Pasteuria*. A *Pasteuria ramosa*-like strain was discovered infecting the cladoceran *Moina rectirostris*, a member of the Daphniidae (Sayre et al., 1979), and this strain was used in the emendation of the species (Starr et al., 1983). Ebert et al. (1996), however, proposed that the *Daphnia*-parasitic *Pasteuria ramosa* that they had characterized from the same host as Metchnikoff (1888) be designated the neotype for *Pasteuria ramosa* Metchnikoff (1888) and that the *Moina* isolate be compared directly to the neotype in future studies.

Confusion of a different kind occurred in the nomenclature of the bacterial endoparasite of nematodes when Cobb (1906) erroneously reported the numerous highly refractive bodies infecting specimens of the nematode *Dorylaimus bulbiferous*

as “perhaps monads” of a parasitic sporozoan. The incorrect placement in the protozoa of an organism now known to be a bacterial parasite of nematodes has persisted for nearly 70 years. Another incorrect placement was suggested by Micoletzky (1925), who found a nematode parasite similar in size and shape to those reported by Cobb. Micoletzky suggested that this organism belonged to the genus *Duboscqia* Perez (1908), another sporozoan group (Perez, 1908). Later, Thorne (1940) presented a detailed description of a new parasite from the nematode *Pratylenchus pratensis* (syn. *Pratylenchus brachyurus*, see Sayre et al., 1988). Thorne assumed that this organism was similar to the nematode parasite described by Micoletzky, thereby assigning it to the microsporidian genus *Duboscqia*, as *Duboscqia penetrans*.

Thorne’s description and nomenclature persisted until 1975 even though other investigators (Canning, 1973; Williams, 1960), who had examined this nematode parasite in some detail, questioned this placement. It was not until the nematode parasite was re-examined using electron microscopy that its true affinities to bacteria rather than to protozoa were recognized and the name *Bacillus penetrans* (Thorne, 1940) Mankau (1975) was applied to it (Imbriani and Mankau, 1977; Mankau, 1975).

However, *Bacillus penetrans* was not included in the Approved Lists of Bacterial Names (Skerman et al., 1980), therefore it had no nomenclatural standing. Although this micro-organism forms endospores of the sort typical of the genus *Bacillus* Cohn (1872), its other traits (e.g., mycelial habit, endoparasitic associations with plant-parasitic nematodes) suggested that it did not belong in the genus *Bacillus*. Rather, it is closely related to *Pasteuria ramosa* (see Table 55 and Figure 37) and it has more properly been assigned (Sayre and Starr, 1985) to the genus *Pasteuria* Metchnikoff (1888) as *Pasteuria penetrans*.

The developmental stages that occur before sporulation are similar for all *Pasteuria* spp. Except for *Thermoactinomyces* spp., the mycelial-like proliferation during development is not found in any other endospore-forming bacteria. The morphological changes that occur during sporulation appear to be generally similar for all of the endospore-forming bacteria (Atibalentja et al., 2004a, 2004b; Chen et al., 1997b; Ebert et al., 1996, 2004; Giblin-Davis et al., 2003a, 2003b; Metchnikoff, 1888; Sayre and Starr, 1985).

Recent molecular work with 16S rRNA gene sequences support *Pasteuria* as a monophyletic clade comprising well supported lineages (Anderson et al., 1999; Atibalentja and Noel,

TABLE 55. Common characteristics of *Pasteuria ramosa* Metchnikoff (1888), *Pasteuria penetrans sensu stricto* emend. Starr and Sayre (1988a), *Pasteuria thornei* Starr and Sayre (1988a), *Pasteuria nishizawae* Sayre, Wergin, Schmidt and Starr (1991) emend. Noel, Atibalentja and Domier (2005), and “*Candidatus Pasteuria usgae*” Giblin-Davis, Williams, Bekal, Dickson, Brito, Becker and Preston (2003b)

Characteristic	Description
<i>Morphological similarities as observed by light microscopy:</i>	
Vegetative cells	Microcolonies consist of dichotomously branched mycelium. Diameter of mycelial filaments similar. Mycelial filaments are seen in host tissues only during early stages of infection. Daughter microcolonies seem to be formed by lysis of “sacrificial” intercalary cells. Nearly all vegetative mycelium eventually lyses, leaving only sporangia and endospores.
Endospores	Terminal hyphae or peripheral cells of the colony elongate and swell, giving rise to sporangia. A single endospore is produced within each sporangium. Endospores are in the same general size range. Refractivity of endospores, as observed on the light microscope, increases with maturity.
Staining reaction	Gram-positive
<i>Ultrastructural similarities:</i>	
Vegetative cells	Mycelial cell walls are typical of Gram-positive bacteria. Mycelial filaments divided by septa. Double-layered cell walls. Where they occur, mesosomes are similar in appearance and seem to be associated with division and septum formation.
Endospores	Typical endogenous spore formation. Identical sequences in endospore formation: (a) septa form within sporangia; (b) sporangium cytoplasm condenses to form forespore; (c) endospore walls form; (d) final endospore matures; and (e) “light” areas adjacent to endospore give rise to extraspore fibers.
Similar sequences of life stages	Microcolonies. Fragmentation of microcolonies. Quartets of sporangia. Doublets of sporangia. Single sporangia. Free endospores.
Host–bacterium relationships	All parasitize invertebrates. Colonies first observed in the host are sedentary and located in the host’s musculature. Growth in muscle tissue eventually leads to fragmentation and entry of microcolonies into the coelom or pseudocoelom of the respective host. Microcolonies carried passively by body fluids. Colonization of hemolymph or pseudocoelomic fluid by the parasite is extensive. Host ranges are very narrow: <i>Pasteuria ramosa</i> occurs only in cladoceran water fleas, <i>Pasteuria penetrans sensu stricto</i> in the root-knot nematode <i>Meloidogyne incognita</i> , <i>Pasteuria thornei</i> in the lesion nematode <i>Pratylenchus brachyurus</i> , <i>Pasteuria nishizawae</i> in <i>Heterodera</i> and <i>Globodera</i> , and “ <i>Candidatus Pasteuria usgae</i> ” in <i>Belonolaimus</i> . Host is completely utilized by the bacteria; in the end, the host becomes little more than a bag of bacterial endospores.
Survival mechanisms	Survive in field soil and at bottom of ponds. Resist desiccation. Loss of infectivity after 5 min at 70°C may indicate moderate resistant to heat.

FIGURE 37. Drawings of *Pasteuria penetrans sensu stricto* (left) based on electron micrographs are compared with those of *Pasteuria ramosa* (right) as drawn by Metchnikoff (1888). Starting at the top of the left column is a vegetative colony of *Pasteuria penetrans* followed by daughter colonies, quartets of sporangia, doublets of sporangia, single sporangia and, finally, at the bottom the mature endospore within the old sporangial wall. The drawings of *Pasteuria ramosa* on the right are placed in order of their occurrence in the life cycle of the parasite as reported by Metchnikoff (1888). (Reproduced by permission from R.M. Sayre, W.P. Wergin and R.E. Davis. (1977). *Can. J. Microbiol.* 23: 1573–1579).

2008; Atibalentja et al., 2000; Bekal et al., 2001; Bishop et al., 2007; Ebert et al., 1996; Giblin-Davis et al., 2003b; Preston et al., 2003; Sturhan et al., 2005). Further genomic comparisons have been made through the sequences of sporulation and other genes in different isolates of *Pasteuria penetrans* and *Pasteuria ramosa* (Bird et al., 2003; Charles et al., 2005; Preston et al., 2003; Schmidt et al., 2004; Trotter and Bishop, 2003). A phylogenetic tree (Atibalentja and Noel, 2008) comparing 16S rRNA

FIGURE 38. Phylogenetic position of *Pasteuria* spp. inferred from maximum-parsimony analysis of 16S rRNA gene sequences. The accession numbers of the *Pasteuria* sequences used were as follows: “*Pasteuria goettingiana*”, AF515699; “*Pasteuria hartismerei*”, AJ878853; *Pasteuria nishizawae*, AF134868; *Pasteuria penetrans*, AF077672; *Pasteuria* sp. parasitic on nematodes of the family Plectidae, AY652776; *Pasteuria ramosa*, U34688; and “*Candidatus Pasteuria usgae*”, AF254387. The accession numbers for the other sequences were as in Atibalentja et al. (2000). *Anacystis nidulans* (Cyanobacteria) and *Escherichia coli* (Proteobacteria) were used as outgroup taxa. Bootstrap proportions (10,000 replications) are shown, wherever possible, for nodes that are relevant for *Pasteuria* spp. The figures not shown are 98, 96, 53, 87, and 93, respectively, for branches leading to *Pasteuria* sp. on Plectidae, “*Pasteuria hartismerei*”, “*Pasteuria goettingiana*”, *Pasteuria nishizawae*, and *Pasteuria penetrans*. Bootstrap support was 100% for each of the branches leading to *Alicyclobacillus cycloheptanicus* and *Alicyclobacillus acidoterristris*. The alignment of the 16S rRNA gene sequences was performed with CLUSTAL X (Thompson et al., 1997) and phylogenetic analyses were conducted with PAUP* 4.0b10 (Swofford, 2003). “*Pasteuria goettingiana*”, “*Pasteuria hartismerei*” and “*Candidatus Pasteuria usgae*” are most likely common in environmental samples but require isolation and deposition of type cultures before validation of their names. From Atibalentja and Noel (2008).

sequences has been updated to depict the close relationship of *Pasteuria* spp. to other genera of the Firmicutes (Figure 38).

Comparison of *spoIIAB* gene sequences amplified by PCR from DNA from different isolates (biotypes) of *Pasteuria penetrans* identified single nucleotide polymorphisms or SNPs, indicating genetic heterogeneity within populations obtained from both individuals, as well as populations of *Meloidogyne* spp. (Nong et al., 2007). DNA sequences from three different loci derived from a single-spore isolate of *Pasteuria penetrans* were identical, supporting the need for clonal populations for definitive studies on host preference (Trotter et al., 2004).

To clarify the characteristics of the genus *Pasteuria*, the meanings of the terms “endospore” and “sporangium” must be modified slightly from their usual definition in order to be applicable to this genus. Metchnikoff observed the several stages of endosporogenesis that occurred in *Pasteuria ramosa*. In his discussion, he noted within each sporangium a single refractile body that stained with difficulty; he called this structure, as we do today, an endospore. The *Pasteuria* endospore is not entirely typical of those found in *Bacillus* or *Clostridium*.

FIGURE 39. Scanning electron micrograph of endospores of *Pasteuria penetrans sensu stricto* attached to a juvenile of a root-knot nematode that has partially penetrated a tomato root. The endospores carried on the juvenile will germinate inside the plant and penetrate the developing nematode, completing their life cycle in their host. On decay of the plant root in soil, the endospores developed within the parasitized nematode are released. Bar = 10 μ m.

FIGURE 40. Scanning electron micrograph of an endospore of *Pasteuria penetrans sensu stricto* on cuticle of a second-stage juvenile of *Meloidogyne incognita*. This endospore has retained its exosporium, resulting in the appearance of a crinkled surface. Bar = 10 μ m.

For one thing, the *Pasteuria* endospore has a mass of fibrous outgrowths emanating from the central body or core. These microfibrillar strands (usually called parasporal fibers, peripheral fibers, or perisporium), which surround the central body of the endospore, are structures comprised of glycoproteins that are presumed to function as adhesins involved in attachment of the endospore to its invertebrate host (Figure 40) (Brito et al., 2004; Davies et al., 1994; Persidis et al., 1991; Preston et al., 2003; Schmidt et al., 2004). A monoclonal antibody that recognizes a glycan-containing epitope associated with adhesins on the surfaces of endospores of *Pasteuria penetrans* (Brito et al., 2003; Schmidt et al., 2003) detects this epitope in extracts of endospores from other species of infected nematodes (Preston et al., 2003), as well as *Pasteuria ramosa* (Schmidt et al., 2008). The epitope was not detected in extracts of endospores obtained from a number of *Bacillus* spp. that were tested, but is common to endospores of all *Pasteuria* spp. that have been evaluated.

Albeit an integral part of the endospore, the parasporal fibers are arrayed differently in the different *Pasteuria* spp. discussed herein. It is difficult to include these somewhat amorphous fibrous masses in any precise measurements of endospores. For this reason, the measurements reported herein include only the major and minor axes of the central body of the endospore,

the endospore proper, and explicitly exclude the parasporal fibers. Measurements and descriptions of parasporal fibers are presented separately.

The attachment of endospores to their invertebrate hosts is mediated by the adhesins in their parasporal fibers. The attached endospore is often overlaid by seemingly nonfunctional remnants of the old sporangium (Figure 40). The presence or absence of these sporangial remnants may be due in part to the length of time the sporangium has been subjected to degradative processes in the soil or the amount of abrasion received as the nematode host moves through its environs (Figure 41). When such sporangial material was significant, it was included in the measurements of the endospores reported herein. Even though sporangial material is sometimes seen, we have adopted the convention of calling the infectious unit on the nematode exterior cuticle surface an endospore. *Pasteuria* endospores, at least in the case of the nematode parasites, also differ from those of *Bacillus* in that the former produce a germ tube that penetrates the nematode cuticle and initiates bacterial colonization within the nematode body.

The type-descriptive material (Sayre and Starr, 1985) of *Pasteuria penetrans* (*ex* Thorne (1940) Sayre and Starr (1985) refers

FIGURE 41. Endospore of *Pasteuria penetrans sensu stricto* attached to the cuticle along the lateral field of the juvenile of a root-knot nematode. The exosporium has been sloughed, exposing the central dome of the endospore; the peripheral fibers can be distinguished. Bar = 0.5 μ m.

to the bacteria occurring on the root-knot nematode *Meloidogyne incognita*. Hence, the name *Pasteuria penetrans* must refer to that organism (Starr and Sayre, 1988a). This morphotype, however, has been isolated from other *Meloidogyne* spp. and comprises several genotypes that may defy or challenge easy species definition (Sturhan et al., 2005). Some other observed members of *Pasteuria* are demonstrably different from *Pasteuria penetrans* using a Linnaean species concept (typological) with molecular corroboration and should be assigned to other taxa. The first such assignment was made for the bacterium from the lesion nematode *Pratylenchus brachyurus*, to which the name *Pasteuria thornei* Starr and Sayre (1988a) was affixed (Starr and Sayre, 1988a). Because the obligate endoparasitic nature of *Pasteuria* currently prevents cultivation of axenic type strains, “*Candidatus*” status has been proposed for each new provisional species designation in this genus (Giblin-Davis et al., 2003b; Murray and Stackebrandt, 1995; Murray and Schleifer, 1994; Stackebrandt et al., 2002). All of the previously named species in the genus *Pasteuria* Metchnikoff (1888) (Skerman et al., 1980) have nomenclatural standing and remain as species with validly published names.

The species that remain valid include *Pasteuria ramosa* Metchnikoff (1888) [Skerman et al. (1980) as emended by Starr et al. (1983) serving as type; see Judicial Commission (1986), Wayne (1986)], *Pasteuria penetrans* (ex Thorne, 1940) [Sayre and Starr (1985) description and illustrations serving as type;

Validation List no. 20; (Sayre and Starr, 1986)], *Pasteuria thornei* [Sayre et al. (1988) and Starr and Sayre (1988a) description and illustrations serving as type; Validation List no. 26; (Starr and Sayre, 1988b)], and *Pasteuria nishizawae* [Sayre et al. (1991) as emended by Noel et al. (2005) description and illustrations serving as type; Validation List no. 41; (Sayre et al., 1992)]. We concur with the proposal of Ebert et al. (1996) to accept the *Daphnia* parasite that they isolated and studied, and whose 16S rRNA gene has been sequenced, as the neotype for *Pasteuria ramosa* and the genus *Pasteuria*. Unfortunately, 16S rRNA gene sequence data are not available for *Pasteuria thornei* and this species of *Pasteuria* must be rediscovered before a more complete characterization can be made.

Enrichment and isolation procedures

Attempts to devise methods for *in vitro* cultivation of *Pasteuria penetrans* using defined media have proven difficult, but some success has been reported (Bishop and Ellar, 1991; Hewlett et al., 2006). The cultivation of *Pasteuria penetrans* outside of its nematode host has been reported by an independent commercial enterprise, but complexities and undisclosed composition of the media used have precluded their application and confirmation in other laboratories. The distinctive morphology and unique relationship to invertebrate hosts shared by *Pasteuria* spp. (see Table 55) suggest that this commonality may be the harbinger of similarities in their physiological requirements for endospore germination, vegetative growth, sporulation, and their eventual axenic cultivation. Based on microscopic observations, the physiological and physical requirements for their growth *in vivo* would appear to be similar. Summarized briefly, vegetative growth of *Pasteuria* spp. seems linked through the environment provided in the coelom/pseudocoelom of their different invertebrate hosts. The hemolymph of the cladoceran or the pseudocoelomic fluid of the nematode allows for the exchange of nutrients and waste products. Also, the coelom/pseudocoelom provides space for mycelial colony development. These colonies fragment after they reach a critical size. Finally, it is reasoned that various factors, possibly the accumulation of bacterial biomass and metabolites, as well as the onset of senility in the invertebrate hosts, trigger sporulation of the bacteria. The similar physical conditions found in the separate host species suggests that the bacteria might have common nutritional requirements; hence, when the requirements for axenic cultivation of one *Pasteuria* sp. become known, they may, with slight modification, apply to other species. The unique host specificities of different *Candidatus* species (Giblin-Davis et al., 2004; Giblin-Davis et al., 2003a; Sturhan et al., 2005), as well as biotypes of *Pasteuria penetrans* defined by a marked preference for different *Meloidogyne* spp. (Oostendorp et al., 1990; Stirling, 1985), supports a role for the host in conferring virulence and host specificity. The host may play an active role in the maturation of endospores and endow it with adhesins that serve as virulence factors through their recognition of receptors on the cuticle of the host and the attachment that is required for infection (Preston et al., 2003).

Since isolation and cultivation of *Pasteuria ramosa*, apart from in its cladoceran host, has not yet been achieved, this bacterium is usually studied in field samples of the infected invertebrate host. The following procedures may increase the chances of finding *Pasteuria ramosa* in its natural habitat.

1. Cladocerans should be collected during the warmest part of the growing season. The parasite is most often found in *Daphnia magna*, but also in other *Daphnia* spp. (Ebert, 2005).
2. Because the frequency of occurrence of the parasite in a cladoceran population may be low (less than 10%), a large number of living specimens needs to be examined to increase the odds for detection. Prevalence, however, may reach up to 100% of all the adult hosts (Duncan and Little, 2007).
3. The internal parasites are most easily identified by using an inverted microscope at magnifications of $\times 100$ –250. Infected *Daphnia* are typically large and much less transparent than uninfected animals. The parasite fills the entire body cavity.

Although axenic cultivation of *Pasteuria penetrans* has been reported but not confirmed, investigations have been limited to studies on naturally or artificially infected nematode hosts (Bekal et al., 1999; Chen et al., 1997a; Chen and Dickson, 1998; Imbriani and Mankau, 1977; Mankau, 1975; Mankau and Imbriani, 1975; Sayre et al., 1983, 1988; Sayre and Wergin, 1977; Starr and Sayre, 1988a) and exploration of the bacterium's potential as a biological control agent against plant-parasitic nematode populations (Chen and Dickson, 1998). Consequently, the studies have depended on finding, maintaining, and manipulating nematode populations infected with these bacteria. Because of this direct dependence on host–nematode populations, the procedures and methods used for maintaining members of the nematode-associated *Pasteuria* are by-and-large those used in maintaining the nematodes (Southey, 1986; Zuckerman et al., 1984).

A few generalizations about *Pasteuria* spp. follow:

1. The group of nematodes that are parasitized by *Pasteuria* spp. is widespread and diverse. The bacterial parasite has been reported from about 116 nematode genera and 323 nematode species. *Pasteuria* spp. have been reported in a dozen states of the United States, as well as roughly 51 countries on five continents and on various islands in the Atlantic, Pacific, and Indian Oceans (Chen and Dickson, 1998; Ciancio et al., 1994; Sayre and Starr, 1988; Sturhan, 1988).
2. Members of nematode-associated *Pasteuria* will most likely be found in soils where nematode populations have been consistently high and are causing crop damage (in the case of plant-parasitic nematodes only). However, numerous nematode suppressive soils have been identified where *Pasteuria* causes a precipitous drop in plant nematode numbers (Chen and Dickson, 1998). Planting of susceptible crops is necessary for maintenance of the nematode populations and multiplication of *Pasteuria* spp. *Pasteuria* spp. may also be associated with plant nematodes in greenhouse situations.
3. To find the bacterial endospores, nematodes are extracted from the suspected soil, e.g., by a centrifugal-flotation method (Jenkins, 1964). Increasing the sucrose concentration used for extraction of nematodes results in a higher percentage recovery of endospore-filled specimens (Oostendorp et al., 1991). Other separation methods, relying on the nematode's mobility (e.g., Baermann, 1917), may not yield those nematodes that are heavily encumbered with endospores or endospore-filled bodies since such nematodes are partially immobilized. Addition of healthy nematodes to soils, together with subsequent extraction and examination, is the most commonly used bioassay for determining the presence of members of the genus *Pasteuria* in soil. Attachment assays have been developed that allow estimations of the number of endospores per gram of soil and the extent to which soils are suppressive for plant nematodes (Chen and Dickson, 1998; Oostendorp et al., 1990). Also, methods have been developed for the quantification of *Pasteuria* endospore concentrations in tomato root material (Chen et al., 1996), the extraction and purification of endospores (Chen et al., 2000), and for determining suppressive soils caused by *Pasteuria* (Chen et al., 1997a; Dickson et al., 1994; Stirling, 1984; Walia et al., 2004). PCR-based methods have been developed for amplifying and sequencing 16S rRNA genes from soil samples and single nematodes (Atibalentja et al., 2004b; Duan et al., 2003). Immunoassays using polyclonal (Costa et al., 2006; Fould et al., 2001) and monoclonal (Schmidt et al., 2003) antibodies directed against endospore surface proteins have been developed for the detection and quantification of bacterial endospores in soil and tissue samples. PCR-based assays for sporulation and other genes have been developed for the identification and quantification of the vegetative cells in plant tissues (Schmidt et al., 2004).
4. Occurrence of endospores on the surfaces of nematodes is most easily observed by means of an inverted microscope at $\times 250$ –400 magnification. Several stains, e.g., crystal violet, cotton blue, Brilliant Blue G, etc., are useful for visualizing external spores. The endospores also may be readily identified with a fluorescent immunoassay and monoclonal antibodies that recognize adhesin-related epitopes (Davies et al., 1994; Schmidt et al., 2003). The application of immunoassays avoids potential misidentification of endospores of *Paenibacillus* spp. that may be associated with entomopathogenic rhabditid nematodes (El-Borai et al., 2005; Enright et al., 2003).
5. Direct confirmation of the presence of members of the *Pasteuria* group inside the nematode can be made by microscopic examination of the pseudocoelom of nematodes, also at $\times 250$ –400 magnification. Both juveniles and adults should be examined for the characteristic mycelial colonies and endospores. Treating nematodes with methyl blue and lactophenol stain works well for visualizing the various developmental stages within the nematode pseudocoelom (Serracin et al., 1997). In uninfected nematodes, the anterior region of the esophagus is clear, with internal structures visible; when filled with endospores, the region will not be clear and internal structures will be masked by the bacterium.
6. Detection of the bacterium in the sedentary endoparasitic nematodes depends on manual (Thorne, 1940) and/or enzymic (Dickson et al., 1970) removal of root-tissues from around the female nematodes. The freed females are placed on glass slides, crushed, and their body contents are examined microscopically for vegetative stages and endospores of the bacterium.

Maintenance procedures

Since the recently reported method of axenic cultivation is proprietary and has not been optimized or confirmed, *Pasteuria* spp. are maintained by co-cultivation with their respective invertebrate host.

Pasteuria ramosa can be grown in the laboratory in clonal cultures of *Daphnia magna*. (Ebert et al., 2004). An endospore-filled body of *Daphnia magna* is shown in Figure 42. *Daphnia* are maintained on a diet of chemostat-grown unicellular green

FIGURE 42. Photomicrograph of *Daphnia magna* showing body cavity filled with endospores of *Pasteuria ramosa*.

algae *Scenedesmus* sp. At 20°C, an infected *Daphnia magna* produces several million *Pasteuria* spores within about 40 d.

Endospores used to inoculate healthy *Daphnia magna* are obtained from two sources: (a) the crushed bodies of living or dead parasitized cladocerans in late-stage infections; and (b) sediments from the bottoms of aquaria (or ponds) in which dead and parasitized cladocerans have accumulated. Frozen cadavers can also be used. The infection rate is dose-dependent. High infection rates can be reached by adding 10,000 endospores to jars with 20 ml water and a single *Daphnia magna* in each jar (Regoes et al., 2003). Resistance of *Daphnia magna* clones to *Pasteuria ramosa* is widespread (Carius et al., 2001; Decaestecker et al., 2003; Little and Ebert, 1999) and may be the most common reason for a failure to cultivate the bacterium. Furthermore, there are strong host clone–parasite isolate interactions (Carius et al., 2001).

Nematode-associated *Pasteuria* can be maintained in a system consisting of the immediate nematode host and its host plant. A good example is the system consisting of *Pasteuria penetrans*–*Meloidogyne incognita* and tomato plants (Sayre and Wergin, 1977). To initiate and increase a bacterial population, dried bacterial endospore preparations (e.g., Stirling and Wachtel, 1980) are mixed into soils that are heavily infested with juveniles of *Meloidogyne incognita*. The juveniles become encumbered with the bacterial endospores as they move through the soil in a random fashion (Figure 39). The endospores adhering to the nematode cuticle are carried by the juvenile into tomato roots, where germination occurs after the nematode initiates feeding. An endospore penetrates the cuticle by means of a single germ tube (Figure 43), which extends into the pseudocoelomic cavity. The bacterium then enters into its vegetative endoparasitic developmental stages (Figure 44 and Figure 45). Finally, bacteria form in the mature and moribund host nematodes and in sporangia that contain endospores (Figure 46, Figure 47, and Figure 48). In summary, the developmental stages of the bacterium include recognition and attachment to a susceptible host nematode, infection of the

FIGURE 43. Section through a germinated endospore of *Pasteuria penetrans sensu stricto*; the penetrating germ tube follows a sinuous path as it travels the cuticle and hypodermis of the nematode. Bar = 0.5 μ m.

FIGURE 44. Section of a mycelial colony of *Pasteuria penetrans sensu stricto* in the pseudocoelom of the nematode. The septate hyphae appear to bifurcate at the margins of the colony. Bar = 0.5 μ m.

FIGURE 45. Hyphal cells of *Pasteuria penetrans sensu stricto* are bounded by a compound wall consisting of a double membrane. A mesosome is associated with the septum. Bar = 0.5 μ m.

FIGURE 46. An early stage of endospore development in *Pasteuria penetrans sensu stricto* is shown in this median section through a sporangium. An electron-opaque body has formed with the forespore; the body is surrounded by membranes that will condense and contribute to the multilayered wall of the mature endospore. Bar = 0.5 μm .

FIGURE 47. Section through a sporangium of *Pasteuria penetrans sensu stricto* with an almost mature endospore. The lateral regions (light areas) will differentiate into parasporal fibers. Bar = 0.5 μm .

FIGURE 48. Median section through a sporangium of *Pasteuria penetrans sensu stricto* containing a fully mature endospore. Final stages of endospore differentiation include formation of an encircling membrane or exosporium and emergence of parasporal fibers within the granular material that lies laterally around the spore. Bar = 0.5 μm .

host nematode via a germ tube, followed by vegetative growth, sporulation, and maturation within the host pseudocoelom.

Endospores of *Pasteuria penetrans* growing inside *Meloidogyne incognita* can be harvested by two methods. The simplest procedure is to allow the nematode-infested plant roots to decay *in situ* in soil; during such decay, about 2×10^6 endospores are released from each female nematode. The soil containing the endospores is air-dried, mixed, and stored. Such preparations have yielded bacterial endospores that can attach to the juvenile of their respective host nematode even after several years in storage (Mankau, 1973). A second method for obtaining a more concentrated preparation of the bacterial endospores has been demonstrated (Stirling and Wachtel, 1980). Freshly hatched juveniles of *Meloidogyne incognita* may be encumbered with endospores by placing them in aqueous suspensions containing endospores. A centrifuge method can be used to help obtain consistent attachment of endospores to host nematodes (Hewlett and Dickson, 1993). These encumbered juveniles are then allowed to penetrate roots of tomato seedlings. After the life cycle of the nematode is completed in soil, the galled roots are harvested, washed, air-dried, ground into a fine powder, and stored. Such preparations have provided adequate sources of endospores for use in bioassays and other procedures. A more efficient and rapid method of obtaining endospore-filled female nematodes is by using an enzyme (cellulase and/or pectinase) preparation (Brito et al., 2003; Chen et al., 2000; Schmidt et al., 2004). Purification can be achieved by selective filtration steps and centrifugation in sucrose or renografin (sodium diatrizoate) gradients (Chen et al., 2000).

Pasteuria thornei and "*Candidatus Pasteuria usgae*" can be maintained in similar systems, except that the bacteria must be maintained on the migratory endoparasitic host nematode *Pratylenchus brachyurus* or the ectoparasitic nematode *Belonolaimus longicaudatus*, respectively. *Pratylenchus brachyurus* may be collected from roots of infected hosts, whereas *Belonolaimus longicaudatus* may be collected from around roots of infected plants. Numerous bacterial endospores are liberated upon decay of the plant roots and the cadavers of infected nematodes. Healthy juveniles or adults of either nematode migrating through such soils can become encumbered with endospores of their respective bacterial parasite and repeat the developmen-

tal cycle, with not only maintenance of the bacterium, but also a net increase in the endospore content of the soil.

At present, the only method of producing endospores of *Pasteuria nishizawae* is to collect infected females and cysts. This is difficult due to the fragile nature of infected cysts and the difficulty in identifying them. At a certain stage, the infected cysts are usually a grayish-green color, but this coloration is often difficult to observe. Infected females cannot be readily identified without crushing them.

A number of investigators have cultivated members of *Pasteuria* in three-membered systems consisting of plant-tissue cultures, gnotobiotically reared nematodes, and the desired bacterium free of contaminating microbes (Bekal et al., 1999; Chen and Dickson, 1998). Once perfected, these cultural methods are useful for maintenance of these bacteria, at least until methods for their axenic cultivation become generally available.

Differentiation of the genus *Pasteuria* from other genera

Table 55 summarizes the characteristic features of species of the genus *Pasteuria*.

Taxonomic comments

De Toni and Trevisan (1889) provided the first generic diagnosis of *Pasteuria*; it followed quickly and closely the original description of *Pasteuria ramosa* by Metchnikoff (1888). However, some other early investigators, particularly those interested in taxonomic coherence, not having observed this enigmatic organism and relying solely on descriptions, rejected both the generic and specific concepts (Lehmann and Neumann, 1896; Migula, 1904). Laurent (1890) suggested that a bacteroid-forming species from nodules on leguminous plants, together with *Pasteuria ramosa*, comprised the new family he erected, *Pasteuriaceae*. Similarly, Vuillemin (1913) believed that a generic relationship existed between *Nocardia* and *Pasteuria*. De Toni and Revisan (1889) speculated that *Pasteuria ramosa*, because of its ability to form endospores, should be placed in the subtribe *Pasteurieae* of the tribe *Bacilleae*. The unusual morphology of *Pasteuria ramosa* became the basis for numerous suppositions about its affinities to other bacterial groups (Buchanan, 1925). This speculative process continued up until recently (Sayre et al., 1983; Sayre and Starr, 1985, 1988; Starr and Sayre, 1988a). The advent of 16S rRNA gene analyses indicated that *Pasteuria* is a deep lineage within the *Bacillales* (Atibalentja et al., 2000; Ebert et al., 1996). Although it has been classified within the “*Alicyclobacillaceae*” (Garrity et al., 2005), the low sequence similarity of 85% and its distinctive phenotype suggests that it would be more properly classified within its own family, the *Pasteuriaceae*.

A significant change made since the 9th edition of the *Manual* is the reduction in the confusion between Metchnikoff's Gram-positive, endospore-forming, mycelial cladoceran parasite with certain Gram-negative, budding, non-prosthecatly appendaged aquatic bacteria. Conservation of *Pasteuria ramosa sensu* Metchnikoff (1888) on the basis of type-descriptive material, as well as rejection of ATCC 27377 as the type of *Pasteuria ramosa* Metchnikoff (1888) because it actually is a quite different organism (*Planctomyces staley* Starr, Sayre and Schmidt (1983), have been recommended (Starr et al., 1983) and approved (Judicial-Commission, 1986). The detailed drawings, photomicrographs, and lengthy description offered by Metchnikoff (1888) provided a sound basis for comparing his species with the current cladoceran parasites. As stated

above, a *Pasteuria ramosa*-like strain was discovered infecting *Moina rectoris* (Sayre et al., 1979) that was used in the emendation of the species (Starr et al., 1983). We support the proposal of Ebert et al. (1996) that the *Daphnia*-parasitic *Pasteuria ramosa* characterized from the same host as Metchnikoff (1888) from Europe be designated the neotype for *Pasteuria ramosa* Metchnikoff (1888) and that the *Moina* isolate of Sayre et al. (1979) be compared directly to the neotype in future studies.

One reason investigators (Henrici and Johnson, 1935; Hirsch, 1972) have been interested in re-examining *Pasteuria ramosa* stems from the questions raised by Metchnikoff's assertion that the bacterium divides longitudinally. Metchnikoff suggested that cells of *Pasteuria ramosa* undergo a longitudinal fission, giving rise to a branched structure in which the two daughter cells remain attached at their tips. Based on a hypothesis about the evolution of division patterns in bacteria, he concluded that *Pasteuria ramosa*, a fairly primitive bacterium in his view, divided longitudinally.

Observations on the *Pasteuria ramosa*-like parasite of *Moina* (Sayre et al., 1979) indicated that cleavage indeed occurs in three planes, as evidenced by the spherical mycelial colonies. However, no common plane of division was found, as illustrated in drawing 2 of the Metchnikoff (1888) paper, starting at the surface of the cauliflower-like growth and ending at its interior. The prominent bifurcations in the mycelium (Figure 49), which Metchnikoff also observed and which may have prompted his longitudinal fission theory, are not products of atypical fission but rather are probably the branched distal or terminal cells of the mycelium undergoing rapid enlargement during formation of endogenous spores. These terminal cells develop into sporangia.

Of some historical interest are a few scattered reports in the literature about organisms similar in appearance to *Pasteuria ramosa*. In these reports, each author came to a different taxonomic decision about the organism, as follows: *Torula* or other yeast species (Ruehberg, 1933); two different genera of the microsporidia (Jirovec, 1939; Weiser, 1943), and a haplosporidium (*Dermocystidium daphniae* Jirovec (1939) and a possible intermediate stage in the life cycle of a *Dermocystidium* sp. (Sterba and Naumann, 1970). These results prob-

FIGURE 49. Cross-section of a fragmenting mycelium of *Pasteuria ramosa* in the body cavity of a cladoceran. Bar = 2.0 μ m.

ably stem from the inability of these investigators to cultivate the particular organism they observed, taken together with their dependence solely on morphology and staining reactions as the basis for their descriptions and classifications. Surprisingly, Metchnikoff (1888), the first person to report on *Pasteuria*, recognized it correctly as a bacterium, whereas the later workers did not and, moreover, were apparently unaware of Metchnikoff's work.

Until rather recently, taxonomic studies of *Pasteuria* were carried out mainly by nematologists. Cobb (1906) erroneously designated such microbes as protozoan parasites of nematodes. At first glance, it would appear from the literature that subsequent workers (Steiner, 1938; Thorne, 1940) had independently come to the same conclusion. However, their conclusions were probably by consensus. Members of *Pasteuria* were then, and largely still are, essentially known only to the community of plant nematologists. When Thorne described *Duboscqia penetrans* as a protozoan, he could not have realized its bacterial nature because electron microscopes were not then available. Later, Williams (1960) studied a similar organism in a population of root-knot nematodes from sugarcane, presented an interpretation of its life stages, and indicated some reservations about Thorne's identification. Canning (1973) also doubted the identification as a protozoan and stressed the organism's fungal characteristics. Finally, Mankau (1975) and Imbriani and Mankau (1977) established the bacterial nature of the organism and brought its attendant taxonomic problems to the attention of bacteriologists. Some results of the ensuing interdisciplinary enterprise are summarized elsewhere (Sayre and Starr, 1988; Sayre et al., 1988; Starr and Sayre, 1988a).

List of species of the genus *Pasteuria*

1. ***Pasteuria ramosa*** Metchnikoff 1888, 166^{AL} [Nom. Cons. Opin. 61 Jud. Comm. 1986, 119. Not *Pasteuria ramosa* in the sense of Henrici and Johnson 1935, Hirsch 1972, and Staley 1973; see Starr et al. (1983) and Judicial Commission (1986)]
ra.mo'sa. L. fem. adj. *ramosa* much-branched.

Gram-positive. Sporangia and microcolonies are parasitic in the hemocoel of cladocerans, water fleas of the genera *Daphnia* and *Moina*. Usually occur attached to one another at pointed ends of the teardrop-shaped sporangia, forming quartet, triplet, and doublet configurations. The rounded end of the sporangium encloses a single refractile endospore, having axes of $1.37\text{--}1.61 \times 1.20\text{--}1.46\mu\text{m}$, narrowly elliptic in cross-section. Endospores are $4.2\text{--}5.4 \times 4.9\text{--}6.0\mu\text{m}$. Nonmotile. Endospores are resistant to desiccation, but with only limited heat tolerance. They have been recovered from 30-year-old pond sediments (Decaestecker et al., 2004). Vegetative stages are cauliflower-like, septate, mycelial growths that branch dichotomously and fragment to form microcolonies. Has not been cultivated axenically, but can be grown in the laboratory with the invertebrate host. The type-descriptive material consists of descriptions and illustrations in Metchnikoff's original publication (Metchnikoff, 1888) and elsewhere (Ebert et al., 1996; Sayre et al., 1979, 1983; Starr and Sayre, 1988a; Starr et al., 1983).

DNA G+C content (mol%): not reported.

Type strain: descriptions and illustrations serving as type.

GenBank accession number (16S rRNA gene): AY762091 (Ebert et al., 1996).

Acknowledgements

This chapter is dedicated to the memory of Dr Richard Sayre and his wife, Diane, who perished on 10 June 1998 in a boating accident in the Galapagos Islands.

We thank R. E. Davis for calling our attention to the genus *Pasteuria* and for his help in initiating its study. Thanks also go to W. P. Wergin, J. R. Adams, C. Pooley, R. Reise, and S. Ochs for sustained technical advice and assistance, particularly in the preparation of the figures involving transmission and scanning electron microscopy. Thanks are due R. L. Gherna for supplying strain ATCC 27377. We are grateful to J. M. Schmidt for her corroboration during the period when the taxonomic confusion between *Pasteuria* and *Planctomyces* was being corrected. Skillful bibliographic and redactional assistance was provided by P. B. Starr.

Differentiation and characteristics of the species and *Candidatus* species of the genus *Pasteuria*

The differential characteristics of nominal *Pasteuria* and *Candidatus* species are given in Table 56.

2. ***Pasteuria nishizawae*** Sayre, Wergin, Schmidt and Starr 1992, 327^{VP} (Effective publication: Sayre, Wergin, Schmidt and Starr 1991, 562.) (emend. Noel, Atibalentja and Domier 2005, 1683.)

ni.shi.za'wae. N.L. gen. n. *nishizawae* of Nishizawa, named after Tutomu Nishizawa, a Japanese nematologist who discovered and first investigated bacterial parasites of cyst-forming nematodes.

Gram-positive vegetative cells, forms endospores. Obligate endoparasitic bacterium of the pseudocoelom of *Heterodera glycines* (soybean cyst nematode). Microcolony shape is cauliflower-like initially and later fragments into clusters of elongated grape-like immature sporangia occurring in configurations of octets, quartets, and doublets. Sporangia are cup-shaped with diameters and heights (under the light microscope) of 5.3 and 4.3 μm , respectively, and (under the transmission electron microscope) of 4.4 and 3.1 μm , respectively. Sporangial wall and mother cell matrix disintegrate at maturity leaving the exosporium as the outermost layer of the endospore. The surface of the exosporium is velutinous to hairy. The stem cell is observed occasionally. The central body is oblate spheroid, ellipsoid to narrowly elliptical. Orientation of major axis to sporangium base is horizontal with diameter and height of 2.1 and 1.7 μm , respectively (when viewed under the light microscope) or 1.6 and 1.3 μm , respectively (when viewed by transmission electron microscopy). The epicortical layer entirely surrounds the cortex. A laminar inner spore coat with alternating layers of dense and light materials occurs

Matrix, at maturity	Persists as fine granular material	Persists, numerous strands are formed and partial collapse may occur	Becomes coarsely granular; lysis occurs; sporangial wall collapses; base is vacuolate	Persists, but more granular; some strands are formed and partial collapse may occur	Same as <i>P. penetrans</i>
Host	Cladocerans (<i>Daphnia</i> , <i>Moina</i>)	Cyst nematodes (<i>Heterodera glycines</i>)	Nematodes <i>Meloidogyne</i> spp.)	Nematodes (<i>Pratylenchus brachyurus</i>)	Nematodes (<i>Belonolaimus longicaudatus</i>)
Completes life cycle in nematode juveniles	-	No, only in female and cyst	Mostly only in female, occasionally seen in 2nd stage juvenile ^b	Yes, in 2nd, 3rd, and 4th stage juveniles and adult	3rd, 4th stage juveniles and adults
Location in host	Hemocoel and musculature; sometimes found attached to coelom walls	Pseudocoelom and musculature; no attachment to pseudocoelom walls seen	Pseudocoelom and musculature; no attachment to pseudocoelom walls seen	Pseudocoelom and musculature; no attachment to pseudocoelom walls seen	Pseudocoelom and musculature; no attachment to pseudocoelom walls seen
Attachment of spores on host	Spores not observed to attach or accumulate on surface of cladoceran	Spores accumulate on juveniles, rare on male	Spores accumulate in large numbers on cuticular surface	Spores accumulate in large numbers on cuticular surface	Spores accumulate in large numbers on cuticular surface
Mode of penetration of host	Not known; suspected to occur through gut wall	Direct penetration of nematode cuticle by germ tube	Direct penetration of nematode cuticle by germ tube	Direct penetration suspected but not seen	Direct penetration of nematode cuticle by germ tube
Source of host	Pond mud, freshwater	Soil, plants	Soil, plants	Soil, plants	Soil, plants

^aMeasurements are based on preparations examined by transmission electron microscopy. Somewhat different apparent sizes are obtained by phase-contrast light microscopy and scanning electron microscopy.
^bRarely seen in males but, when observed, thought to be sex-reversed males (Hatz and Dickson, 1992).

between the outer spore membrane and the epicortical layer. The outer spore coat consists of several layers of electron-dense materials and is surrounded laterally and ventrally by micro-projections. Including the microprojections, the outer spore coat is thickest at the top of the central body and then tapers gradually to 0.2 µm at the spore equator and to 0.1 µm or less around a 0.3 µm wide basal pore. Parasporal structures consist of long primary fibers arising laterally from the outer spore coat and bending downwards to yield numerous secondary fibers arrayed ventrally. Depending upon the extent of invagination of the basal adhesion layer, additional partial hirsute layers may be present on the obverse face of the central body. Spores attach to second-stage juveniles in the soil, but rarely to males in the soil. The cuticle and body wall are penetrated by the germ tube that develops after the infective second-stage juvenile penetrates the host plant root. The life cycle is completed only in the pseudocoelom of females, but may also be completed in the cyst (female cadaver). The only confirmed host is *Heterodera glycines*. Attachment of endospores to second-stage juveniles of *Globodera rostochiensis* (potato cyst nematode) with endospores obtained from *Heterodera elachista* (upland rice nematode), *Heterodera lespedezae* (lespedeza cyst nematode), *Heterodera schachtii* (sugarbeet cyst nematode), and *Heterodera trifolii* (clover cyst nematode) indicates that these nematode species may be hosts. Completion of the life cycle of *Pasteuria nishizawae* in these nematode species has not been confirmed.

DNA G+C content (mol%): not reported.

Type strain: descriptions and illustrations serving as type.

GenBank accession number (16S rRNA gene): AF134868 and AF516396.

3. ***Pasteuria penetrans*** (ex Thorne 1940) Sayre and Starr 1986, 355^{VP} (Effective publication: Sayre and Starr 1985, 163.) (emend. Sayre, Starr, Golden, Wergin and Endo 1988, 28; *Duboscqia penetrans* Thorne 1940, 51.)

pen'e.trans. L. part. adj. *penetrans* penetrating, entering.

Gram-positive vegetative cells. Mycelium is septate; hyphal strands, 0.2–0.5 µm in diameter, branch dichotomously. The sporangia, formed by expansion of hyphal tips, are cup shaped, approximately 2.26–2.60 µm in height with a diameter of 3.0–4.0 µm. Each sporangium is divided into two unequal sections. The smaller proximal body is not as refractile as the larger, rounded, cup-shaped portion, which encloses an ellipsoidal endospore broadly elliptic in section having axes of 0.99–1.21 × 1.30–1.54 µm. Endospores seem to be of the kind typical of the genus *Bacillus*; they are resistant to both heat and desiccation. Nonmotile. Sporangia and vegetative cells are found as parasites in the pseudocoelomic cavities of *Meloidogyne* spp. The epithet is now restricted to members of *Pasteuria penetrans* with cup-shaped sporangia and ellipsoidal endospores broadly elliptic in section occurring primarily as parasites of *Meloidogyne* spp. Has not been cultivated axenically; the type-descriptive material consists of the text and photographs in Sayre and Starr (1985) and Starr and Sayre (1988a). *Pasteuria penetrans* differs from other described members of *Pasteuria* in host specificity, in size and shape of sporangia and endospores, and in other morphological and developmental characteristics.

The influence of temperature on the development of *Pasteuria penetrans* in *Meloidogyne* spp. has been observed in growth chambers (Hatz and Dickson, 1992; Serracin et al., 1997; Stirling, 1981). The parasite's greatest endospore

attachment rate to second-stage juveniles was at 30°C and the bacterium developed more quickly within its nematode host at 30 and 35°C than at 25°C. Development time quickly decreases as temperature decreases, e.g., at 35, 28, and 21°C, mature endospores were detected at 28, 35, and >90 d, respectively (Hatz and Dickson, 1992; Serracin et al., 1997).

DNA G+C content (mol%): not reported.

Type strain: descriptions and illustrations serving as type.

GenBank accession number (16S rRNA gene): AF077672 and AF375881 (Anderson et al., 1999).

4. ***Pasteuria thornei*** Starr and Sayre 1988, 328^{VP} (Effective publication: Starr and Sayre 1988a, 28.)

thor'ne.i. M.L. gen. n. *thornei* of Thorne, named after Gerald Thorne, a nematologist from the United States, who described and named this parasite of *Pratylenchus* as a protozoan parasite.

Gram-positive vegetative cells. Mycelium is septate; hyphal strands, 0.2–0.5 µm in diameter, branch dichotomously. Sporangia, formed by expansion of hyphal tips, are rhomboidal in shape, approximately 2.22–2.70 µm in diameter and 1.96–2.34 µm in height. Each sporangium is divided into two almost equal units. The smaller unit, proximal to the mycelium, is not refractile and contains a granular matrix interspersed with many fibrillar strands. The refractile apical unit is cone shaped; it encloses an ellipsoidal endospore, sometimes almost spherical, having axes of 0.96–1.20 × 1.15–1.43 µm, with cortical walls about 0.13 µm in thickness. A sublateral epicortical wall gives the endospore a somewhat triangular appearance in cross-section. The tapering outer cortical wall at the base of the endospore forms an opening approximately 0.13 µm in diameter. Sporangia and endospores are found as parasites of lesion nematodes (*Pratylenchus* spp.). Has not been cultivated axenically; the type-descriptive material consists of the text and photographs in Starr and Sayre (1988a) and Sayre et al. (1988). *Pasteuria thornei* differs from *Pasteuria penetrans* and other members of *Pasteuria* in host specificity, size and shape of sporangia and endospores, and other morphological and developmental traits.

DNA G+C content (mol%): not reported.

Type strain: descriptions and illustrations serving as type.

GenBank accession number (16S rRNA gene): not reported.

5. ***“Candidatus Pasteuria usgae”*** Giblin-Davis, Williams, Bekal, Dickson, Brito, Becker and Preston 2003b, 197

us'gae. N.L. gen. n. *usgae* of U.S.G.A., the acronym for the United States Golf Association, in gratitude for their financial support to study this potential biological control agent against *Belonolaimus longicaudatus* in turfgrass ecosystems.

Organism is nonmotile with Gram-positive vegetative cells. Mycelium is septate; hyphal strands branch dichotomously with expansion of hyphal tip forming sporangium. With scanning electron microscopy, peripheral fibers of the mature endospore protrude around the exposed spherical outer coat of the spore creating a crenate border as opposed to other species of *Pasteuria* described from nematodes that have no scalloped border. The sporangium and central body diameters were on average at least 0.5 and 0.7 µm wider than these respective measurements for the other described species of *Pasteuria*. In lateral view with transmission electron microscopy, the shape of the central body is a rounded-rectangle to a rounded-trapezoid in transverse section that contrasts with the circular shape for

Pasteuria ramosa, the horizontally oriented elliptical shapes for *Pasteuria penetrans* and *Pasteuria nishizawae*, and the rounded-square shape for *Pasteuria thornei*. The outer spore coat is thickest laterally, thinner on top and thinnest across the bottom of the spore, being 7–8 times thicker laterally than along the bottom. These measurements contrast with all other described species having outer spore coats with relatively uniform thickness. No basal ring exists around the pore opening as in *Pasteuria penetrans*. The outer coat wall thickness at its thickest point is >15% (both walls >30%) of the diameter of the central body compared with 3 to <13% (both walls 6 to <25%) for the other described species of *Pasteuria*. The epicortical wall remnant of the mature endospore occurs between the cortex and the inner spore coat in a sublateral band, similar to *Pasteuria thornei* but different from the other three described species. The epicortical wall in the other described species is as follows: completely concentric in *Pasteuria ramosa* and *Pasteuria nishizawae*, and lateral in *Pasteuria penetrans*.

Obligate endoparasitic bacterium of the pseudocoelom of *Belonolaimus longicaudatus* that cannot be cultivated on cell-free media. Cultivated only by attachment of endospores to *Bacillus longicaudatus* and co-cultivation on excised axenic root or greenhouse plant cultures. Transmission occurs horizontally. Host infection is via cuticular penetration by attached endospores that occurs on all stages of *Belonolaimus longicaudatus* except eggs. Sporogenesis, which leads to the death of the host, occurs in the pseudocoelom of J3 through adult stage nematodes. Sporogenesis is typical of other nematode-specific *Pasteuria*. Host range appears to be limited to *Belonolaimus longicaudatus*, although attachment of endospores has been observed on *Bacillus euthychilus*, but not other soil-inhabiting nematodes.

DNA G+C content (mol%): not reported.

Type strain: descriptions and illustrations serving as type.

GenBank accession number (16S rRNA gene): AF254387.

Further information

***Pasteuria ramosa*.** When using light microscopy, the earliest visible growth stages of *Pasteuria ramosa* in the water fleas *Daphnia magna* and *Moina rectirostris* Leydig 1860 are the cauliflower-like microcolonies usually found on the inner wall of the invertebrate's carapace Ebert et al., (1996), Sayre et al., 1979; Figure 50). The next detectable stage consists of quartets of sporangia carried in the hemolymph throughout the body of the cladoceran. Later, as the parasite develops, the hemolymph is noticeably clouded by the myriad immature sporangia of *Pasteuria ramosa*, mainly singles or doublets.

Electron micrographs of the "cauliflower" stage reveal circular patterns of septate hyphal strands of an actinomycete-like organism (Figure 49). The hyphae measure approximately 0.67 μm in width and their wall, which is fairly homogeneous in density, is 14.5–15 nm thick. The periplasmic region between the wall and the cell membrane is about 8.7–9.0 nm in width. The cell membrane measures 5.8 nm in thickness. Mesosomes (circular membrane complexes) are often found associated with the septa (Sayre et al., 1979; Figure 51).

The distal or terminal mycelial cells of the microcolonies enlarge to form teardrop-shaped sporangia that, when viewed by light microscopy, measure approximately 4.8–5.7 \times 3.3–4.1 μm in diameter. Similar materials prepared for transmission electron microscopy and sectioned gave measurements of 3.40–4.35 μm in height and 2.12–2.77 μm in diameter. Early in this process, two septa form; these septa divide the sporangium into anterior, mid-

FIGURE 50. Cauliflower-like, branching, mycelial colony of *Pasteuria ramosa* attached to the inner walls of the carapace of the cladoceran *Moina rectirostris*. Bar = 10 μm .

dle, and stem sections (Metchnikoff, 1888; Figure 52). The partitioning is reflected in the outer wall of the sporangia (Figure 53).

The anterior section, the upper two-thirds of the sporangium, gives rise to the forespore. Within the anterior section, granular material condenses to form an electron-dense endospore, slightly ellipsoidal to almost spherical in shape, having axes measuring 1.37–1.61 \times 1.20–1.46 μm . It comprises a multilayered central cytoplasm containing numerous doubled fibrillar strands (Figure 54). Structural changes also occur within the median section, where electron-transparent areas appear to expand and attach laterally to the multilayered endospore wall

to form fibrous appendages. The mode of penetration of spores into host cladocerans is not known.

Parasitized water fleas (*Moina rectoris*) taken from a pond in College Park, MD, USA, were found to yield about 2×10^5 *Pasteuria ramosa* sporangia per host individual. Generally, the parasite was found in mature females with no young in their egg pouches. *Daphnia* species, reported previously (Metchnikoff, 1888) as hosts of this organism, were not parasitized by this bacterial strain (Sayre et al., 1979). Neither sporangia from crushed water fleas nor sediments from the rearing aquaria of parasitized *Moina rectoris* (Sayre and Wergin, 1977) resulted in infection when added to healthy populations of *Daphnia magna* or *Daphnia pulex*. These two *Daphnia* species were listed by Metchnikoff (1888) as hosts for *Pasteuria ramosa*. However, because *Moina rectoris* is in the same family (Daphniidae) as these two *Daphnia* spp., this result may suggest only a very marked host specificity in the particular strain of *Pasteuria ramosa* available to us, perhaps at the level of a *forma specialis*, the situation in which one form of a parasite reproduces only in one host species and not in others that are closely related taxonomically. Recent work on *Pasteuria ramosa* from populations of *Daphnia magna* demonstrated strong specificity (Carius et al., 2001). The type-descriptive material of this taxon (Metchnikoff, 1888) is attached to the form on *Daphnia* species. If later work should show differences warranting separation at the specific
