

FIGURE 54. Mature sporangium of *Pasteuria ramosa* containing an endospore, made up of multilayered spore walls (mw), cortex (c), and cytoplasm with stranded inclusions (st). Septum (s) separates the stem from the middle section. The function of the fibrous appendages (wi; wing-shaped light areas) is not known. Bar = 0.5 μm .

or subspecific level, the taxon on *Moina* would of course have to be given a different name from *Pasteuria ramosa*.

The influence of water temperature on the occurrence of *Pasteuria ramosa* in *Moina rectirostris* in nature was observed over a 3-year period. The parasite was not found until the surface water temperature in the pond reached 26°C or higher, usually about mid-July in the College Park (MD, USA) area. The apparent temperature requirement was confirmed in laboratory tests in which water in the aquaria was held at constant temperatures; the parasite was found in 6 and 3 d at 26° and 31°C, respectively, but not at all at 21°C. *Pasteuria ramosa* from *Daphnia magna* can be cultured from 15 to 25°C (Ebert et al., 1996).

Although endospores of *Pasteuria ramosa* appear to withstand desiccation, they have only limited resistance to heat. Air-dried sporangia, which were stored for 6 months, were capable of infecting healthy populations of cladocerans. However, when air-dried aquarium sediments were heated to 40, 60, or 80°C for 10 min and then added to cultures of healthy cladocerans, they failed to develop after treatment at 80°C (Sayre et al., 1979). Endospores from *Pasteuria ramosa* from *Daphnia* populations can survive in pond sediments for decades (Decaestecker et al., 2004).

***Pasteuria penetrans*.** Members of nematode-associated *Pasteuria* share several morphological, ultrastructural, and ecological features Sayre and Starr, 1985; Starr et al., 1983; Starr and Sayre, 1988a; Table 55; Figure 37): all are Gram-positive; all form endospores; all form mycelia, septate and dichotomously branched, vegetative cells; and all parasitize invertebrates (Table 55). The members of the *Pasteuria penetrans* group differ in many respects from *Pasteuria ramosa*: colony shape, shape and size of sporangia (Figure 55) and endospores, and host relations (Table 56). Upon recognition (Sayre and Starr, 1985) of its relationship to the genus *Pasteuria*, the first of these nematode parasites to receive such taxonomic attention was renamed *Pasteuria penetrans sensu stricto* (i.e., in the strict sense) was limited in scope to the bacterium parasitic on *Meloidogyne* spp. and particularly *Meloidogyne incognita* (Starr and Sayre, 1988a). A second species, *Pasteuria thornei*, was erected for parasites of the lesion nematodes of the genus *Pratylenchus* and particularly *Pasteuria brachyurus* (Starr and Sayre, 1988a).

Much of the following information stems from studies of *Pasteuria penetrans*. *Pasteuria thornei*, which has received much less study than its relative, is similar in most respects examined (transmission electron micrographs of sporangia of *Pasteuria thornei* at various stages are shown in Figure 56, Figure 57, and Figure 58); where substantial differences have been observed, they are noted below. Cross-sections viewed by transmission electron microscopy (Imbriani and Mankau, 1977; Sayre and Starr, 1985; Sayre and Wergin, 1977; Starr and Sayre, 1988a) reveal that the endospore of *Pasteuria penetrans sensu stricto* consists of a central, highly electron-opaque core surrounded by an inner and an outer wall composed of several distinct layers (Figure 48). When observed with the transmission electron microscope, the peripheral matrix of the spore is fibrillar. Fine microfibrillar strands, about 1.5 nm thick, extend outward and downward from the sides of the endospore to the cuticle of the nematode, where they become more electron-dense.

A mature endospore of *Pasteuria penetrans sensu stricto* attaches to the surface of a nematode so that a basal ring of wall material lies flatly against the cuticle. A median section through the endospore

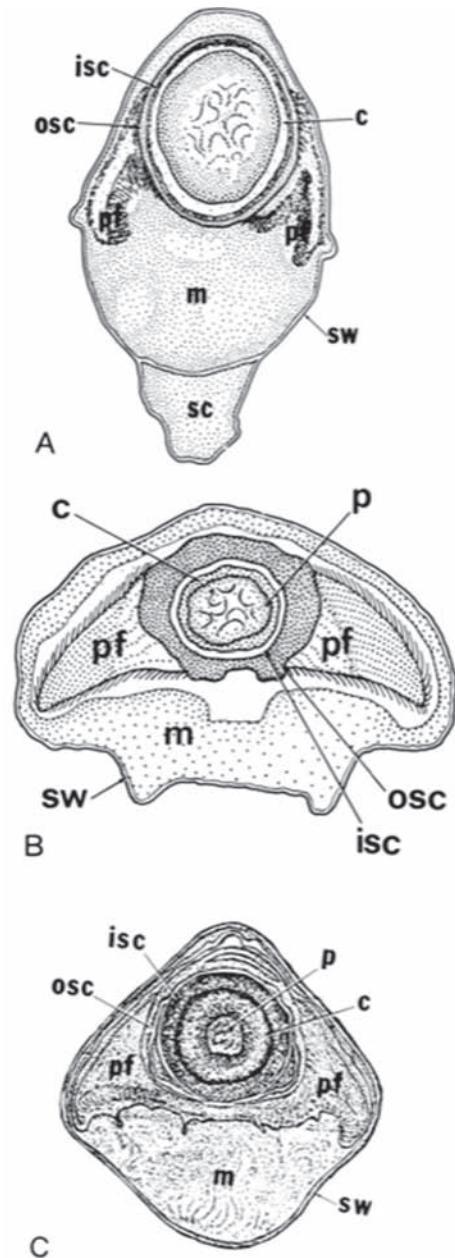

FIGURE 55. Drawings of sections through typical mature sporangia of three *Pasteuria* species emphasizing ultrastructural features useful in identification. A, *Pasteuria ramosa*, parasite of cladoceran water fleas. B, *Pasteuria penetrans sensu stricto*, parasite of *Meloidogyne incognita*. C, *Pasteuria thornei*, parasite of *Pratylenchus brachyurus*. Labels: protoplast (p) containing stranded inclusions; multilayered structures including a cortex (c) and inner (isc) and outer (osc) spore coats; parasporal fibers (pf); granular matrix (m); sporangial wall (sw); in *Pasteuria ramosa*, a stem cell (sc) remains attached to the sporangium.

and perpendicular to the surface of the nematode bisects this basal ring. As a result, the ring appears as two protruding pegs, which are continuous with the outer layer of the spore wall and rest on the cuticular surface of the nematode (Figure 43).

The peripheral fibers of the endospore also are closely associated with the nematode's cuticle. These fibers, which encircle the endospore, lie along the surface of the nematode and follow the irregularities of the cuticular annuli. They seem not

FIGURE 56. Transmission electron micrograph of *Pasteuria thornei* parasitizing a juvenile of the lesion nematode *Pratylenchus brachyurus*, showing simultaneous occurrence of vegetative microcolonies (MC) and sporangia (SP) of the bacterium in the nematode's pseudocoelomic cavity. Bar = 1.0 μm .

FIGURE 57. Section of immature sporangium of *Pasteuria thornei* showing the developing septum (SE) separating the polar area that condenses into an endospore from the parasporal matrix; the light areas sublateral to the polar area will develop into parasporal fibers. Bar = 0.5 μm .

to penetrate the cuticle. The germ tube of the endospore of *Pasteuria penetrans* emerges through the central opening of the basal ring, penetrates the cuticle of the nematode, and enters the hypodermal tissue (Figure 43). Hyphae were initially encountered beneath the cuticle of the nematode near the site of germ-tube penetration. From this site, they apparently penetrate the hypodermal and muscle tissues and enter the pseudocoelom.

FIGURE 58. Lateral view of a mature sporangium of *Pasteuria thornei* showing inner sublateral cortical wall (arrows) that gives the endospore an angular appearance. The basal cortical wall for the endospore thins to provide a germinal pore. The basal portion of the sporangium contains an irregular granular matrix intermingled with fibrillar strands. Bar = 0.5 μm .

Mycelial colonies of *Pasteuria penetrans* up to 10 μm in diameter are formed in the pseudocoelom, where they are observed after the diseased juvenile penetrates plant roots (Figure 44). The hyphae comprising the colony are septate. A hyphal cell, which is 0.40–0.50 μm in cross-section, is bounded by a compound wall, 0.12 μm thick, composed of an outer and an inner membrane. The inner membrane of the wall forms the septation and delineates individual cells. In addition, this membrane is continuous with a membrane complex or mesosome that is frequently associated with the septum (Figure 45). Because of the sinuous and branching growth habit, cell length cannot be determined from thin section electron micrographs.

Sporulation of *Pasteuria penetrans* occurs in a developmental pattern that is similar to that observed in axenic cultures of *Bacillus* spp., e.g., *Bacillus subtilis*. During the controlled and semi-synchronous growth of *Meloidogyne arenaria* race 1 infected with a line (P20) of *Pasteuria penetrans*, endospore maturation was coincident with the formation of spore-associated adhesin, as determined by a specific monoclonal antibody (Brito et al., 2003).

Sporulation of *Pasteuria penetrans* is initiated in the female nematode. As the process begins, the terminal hyphal cells of the mycelium bifurcate and enlarge from typical hyphal cells to ovate cells measuring 2.0 \times 4.0 μm . Structure and content of the cytoplasm change from a granular matrix, which contains numerous ribosomes as found in the hyphal cells, to one lacking particulate organelles. During these changes, the developing sporangia separate from their parental hyphae, which cease to grow and eventually degenerate.

After these early structural alterations, a membrane forms within the sporangium and separates the upper third of the cell or forespore from its lower or parasporal portion (Figure 46). The granular matrix confined within the membrane then condenses into an electron-opaque body, 0.6 µm in diameter, which eventually becomes encircled by a multilayered wall. The resulting discrete structure is an endospore.

Coincident with the formation of an endospore in *Pasteuria penetrans* is the emergence of parasporal fibers. These fine fibers, which form around the base of the spore, differentiate from an electron-translucent, granular substance. They appear to connect with and radiate from the external layer of the wall of the endospore (Figure 47). During development of the parasporal fibers, the formation of another membrane, the exosporium, isolates the newly formed endospore within the sporangium. At this later stage of spore development, the granular content of the paraspore becomes less dense, degenerates, and disappears. As a result, the mature sporangium contains a fully developed endospore enclosed within the exosporium (Figure 48).

The cell wall of the sporangium of *Pasteuria penetrans* remains intact until the remnants of the infected nematode are disrupted, after which event the endospores are released. The exosporium apparently remains associated with the endospore

until contact is made with a new nematode and the infection cycle restarts. The vermiform juvenile stages of the nematodes are encumbered by the parasite as they migrate through soils infested by the endospores of *Pasteuria penetrans sensu stricto* and the infectious cycle is repeated.

Much morphological, ultrastructural, developmental, and host diversity is evident in *Pasteuria* (Giblin-Davis et al., 2001; Sayre and Starr, 1985; Sayre et al., 1988). We believe this diversity speaks for the existence of many taxa within the group. *Pasteuria thornei*, *Pasteuria nishizawae*, and “*Candidatus Pasteuria usgae*” represent three cases where novel species have been proposed on substantial morphological, morphometric, host range, and molecular grounds (Table 56) (Giblin-Davis et al., 2001; Giblin-Davis et al., 2003b; Sayre et al., 1988; Starr and Sayre, 1988a). Other organisms – “*Pasteuria hartismerei*”. *Pasteuria hartismerei* Bishop, Gowen, Pembroke and Trotter (2007) was described from *Meloidogyne ardenensis* on the basis that the endospores lacked a basal ring on their ventral side and they had a unique clumping nature inside their host (Bishop et al., 2007). Also, a unique 16S rRNA sequence was obtained which differs from that of other described *Pasteuria*. This taxon will become a *Candidatus* species when validated according to the *International Code of Nomenclature of Bacteria* (1992) (Euzéby, 1998).

Family VI. **Planococcaceae** Krasil'nikov 1949, 328^{AL}

WOLFGANG LUDWIG, KARL-HEINZ SCHLEIFER AND WILLIAM B. WHITMAN

Plan.o.coc.ca'ce.ae. N.L. masc. n. *Planococcus* type genus of the family; L. suff. *-aceae* ending denoting family; N.L. fem. pl. n. *Planococcaceae* the *Planococcus* family.

The family *Planococcaceae* is circumscribed for this volume on the basis of phylogenetic analyses of the 16S rRNA sequences and includes the genus *Planococcus* and its close relatives, *Caryophanon*, *Filibacter*, *Jeotgalibacillus*, *Kurthia*, *Marinibacillus*, *Planomicrobium*, *Sporosarcina*, and *Ureibacillus*. Cells are cocci or rods, sometimes forming filaments or trichomes. Usually strictly

aerobic heterotrophs, although some species are facultatively aerobic. Motile by flagella or gliding. Catalase-positive, oxidase-positive or negative. May or may not form endospores. The dominant fatty acids are usually C_{15:0 iso} or C_{15:0 anteiso}.

DNA G+C content (mol%): 34–48.

Type genus: **Planococcus** Migula 1894, 236.

Genus I. **Planococcus** Migula 1894, 236^{AL}

SISINTHY SHIVAJI

Plan.o.coc'cus. Gr. n. *planos* wanderer; Gr. n. *coccus* a grain, berry; N.L. masc. n. *Planococcus* motile coccus.

Cells coccoid, 1.0–1.2 µm in diameter, occurring singly, in pairs, in groups of three, or as tetrads or clumps of cells. Gram-positive to Gram-variable. **Motile**. The cells have one or two flagella. Chemo-organotrophic, respiratory metabolism. **Aerobic. Catalase-positive. Lack endospores**. Colonies are circular, slightly convex, smooth, glistening, and **yellow-orange in color**. Halotolerant; can tolerate 1–17% NaCl and are occasionally halophilic. Most strains are oxidase-negative and hydrolyze gelatin but not starch. Do not reduce nitrate. Growth factors are usually not required. Either psychrophilic or mesophilic. Distributed in sea water, marine clams, fish, shrimp, prawns, cyanobacterial mats, freshwater ponds, sulfur springs, and glacial soil.

DNA G+C content (mol%): 39–48 (*T_m*, Bd).

Type species: **Planococcus citreus** Migula 1894, 236^{AL}.

Further descriptive information

Planococcus species have been isolated using various kinds of media such as sea water agar (1.0% beef extract, 1.0% peptone, 2.0% agar, tap water 250 ml and sea water 750 ml; pH 7.2), nutrient agar containing 1–5% NaCl, Zobell marine agar 2216 (Difco Laboratories, Detroit, USA) or antarctic bacterial medium (0.5% peptone, 0.2% yeast extract, and 1.5% agar, pH 6.4) with 1.5% NaCl or in the absence of salt. Cells are coccoid, motile, and possess one or two flagella; a few cells possess three to four flagella. The flagella are often irregular, but some show a regular sine curve. Motile cells occur in both liquid and solid media.

The fine structure of the cells of planococci is similar to that of other Gram-positive, catalase-positive cocci (Novitsky and Kushner, 1976). The cell wall of *Planococcus citreus* is double layered, and its thickness varies with the age of the culture from 25–35 nm. Cell wall peptidoglycan is of the L-Lys-D-Glu type (Alam et al., 2003; Mayilraj et al., 2005; Reddy et al., 2002; Schleifer and Kandler, 1970). C_{15:0 ante} is the predominant fatty acid (Alam et al., 2003; Engelhardt et al., 2001; Junge et al., 1998; Mayilraj et al., 2005; Nakagawa et al., 1996; Reddy et al., 2002; Romano et al., 2003; Thirkell and Summerfield, 1980) followed by C_{17:0 ante} and C_{16:0 iso}. Strains of psychrophilic *Planococcus antarcticus* possess significant amounts of C_{15:1} and C_{18:1} (Reddy et al., 2002).

All species produce a yellow-orange, water-insoluble but methanol-soluble carotenoid pigment. In methanol, the pigments exhibited three absorption maxima at about 440, 465, and 488 nm, a characteristic feature of carotenoids. The concentration of sea salt in the medium and the age of the culture appear to influence the quantity of the pigment synthesized and the type of carotenoid (Thirkell and Summerfield, 1980). Hydrostatic pressure of 20–40 MPa has no influence on the growth and pigment production of *Planococcus citreus* (Courington and Goodwin, 1955; Oppenheimer and Zobell, 1952).

MK-7 and MK-8 are the menaquinones that are normally present (Alam et al., 2003; Jeffries, 1969; Mayilraj et al., 2005; Reddy et al., 2002; Yamada et al., 1976). In *Planococcus kocurii* and *Planococcus maritimus*, in addition to MK-7 and MK-8, MK-6 is also present (Hao and Komagata, 1985; Yoon et al., 2003), and in *Planococcus rifietoensis* only MK-8 is present (Romano et al., 2003). The phospholipid pattern of planococci is similar to that of *Sporosarcina* and contains a large amount of cardiolipins (Thirkell and Summerfield, 1977; Yamada et al., 1976) including phosphatidylglycerol (PG), diphosphatidylglycerol (DPG), and phosphatidylethanolamine (PE) as in *Planococcus antarcticus*, *Planococcus maritimus*, and *Planococcus stackebrandtii* (Mayilraj et al., 2005; Reddy et al., 2002; Yoon et al., 2003). In *Planococcus rifietoensis*, PE is replaced by phosphocholine (Romano et al., 2003). All the reported species are halotolerant (7–17% NaCl) and *Planococcus maitriensis* is halophilic (Alam et al., 2003; Novitsky and Kushner, 1976).

A serological examination of *Planococcus citreus* has shown no antigenic relationship to staphylococci and micrococci (Oeding, 1971). Sensitivity to antibiotics has not been studied in all the species of *Planococcus*. *Planococcus citreus*, *Planococcus maritimus*, *Planococcus maitriensis*, and *Planococcus antarcticus* are sensitive to tetracycline and chloramphenicol. The last three species were also sensitive to streptomycin, lincomycin, and bacitracin but varied in their sensitivity to erythromycin, penicillin G, gentamicin, rifampin, and ampicillin (Alam et al., 2003; Jeffries, 1969; Kocur et al., 1970; Novitsky and Kushner, 1976; Reddy et al., 2002; Yoon et al., 2003).

Planococci have been isolated from various terrestrial, aquatic, and marine habitats such as sea water (Yoon et al., 2003; Zobell and Upham, 1944), fish-brining tanks (Georgala, 1957), marine

clams and fish (Hao and Komagata, 1985; Novitsky and Kushner, 1976), shrimp (Alvarez, 1982), antarctic soil (Shivaji et al., 1988), antarctic cyanobacterial mats (Alam et al., 2003; Reddy et al., 2002), sulfur spring (Romano et al., 2003), and glacial soil (Mayilraj et al., 2005).

Enrichment and isolation procedures

Various media listed above may be used for the isolation of planococci. Enrichment may be facilitated by using sea water agar or nutrient agar containing 5–7% NaCl.

Maintenance procedures

Planococci cultures can be stored in screw-capped tubes or on plates containing semisolid medium. Tubes and plates are inoculated and, after overnight growth at optimum temperature, stored at 4°C. Cultures are lyophilized for long-term preservation.

Differentiation of the genus *Planococcus* from other genera

Table 57 indicates the characteristics of *Planococcus* that distinguish it from other genera of morphologically or physiologically similar taxa.

Taxonomic comments

The genus *Planococcus* was first proposed more than hundred years ago to include Gram-positive motile cocci (Kocur et al., 1970; Migula, 1894). Despite this clear-cut criterion based on cell shape and motility (motile cocci), the genus *Planococcus* still included species which were either coccoid (*Planococcus citreus* and *Planococcus halophilus*) or rod-shaped (*Planococcus okeanokoites* and *Planococcus mcmeekinii*) (Junge et al., 1998; Migula, 1894; Nakagawa et al., 1996; Novitsky and Kushner, 1976; Zobell and Upham, 1944). In addition, motile cocci were also included in the genus *Micrococcus* (Hao and Komagata, 1985), but such motile cocci differed from species of the genera

Micrococcus and *Staphylococcus* in their motility and DNA base composition (Hao and Komagata, 1985). Taking these phenotypic traits into consideration, Boháček et al. (1967) separated the motile from the nonmotile cocci and subsequently, on the basis of DNA base composition, Kocur et al. (1970) divided the motile cocci into two groups. Group I included strains with a low mol% G+C content of DNA (39.6–42.2 mol%) and were identified as *Planococcus kocurii* (Hao and Komagata, 1985). Group II included strains with high mol% G+C content of DNA (48–52.1 mol%) and were identified as *Planococcus citreus* (Migula, 1894). Subsequent phylogenetic analysis based on 16S rRNA gene sequences confirmed that these *Planococcus* species are distinct from other cocci (Farrow et al., 1992; Farrow et al., 1994a) and exhibit no specific relationship to the genera *Micrococcus* and *Staphylococcus* (Stackebrandt and Woese, 1979). However, phylogenetically they appear to be related to the genera *Bacillus* and *Sporosarcina* (Boháček et al., 1968b; Pechman et al., 1976; Stackebrandt and Woese, 1979) and chemotaxonomic characteristics such as mol% G+C content in the DNA and cell wall composition support these observations (Boháček et al., 1968b; Kocur et al., 1970; Schleifer and Kandler, 1970) but planococci are nonsporeforming and thus are distinctly different. Phylogenetic analysis of *Planococcus mcmeekinii*, *Planococcus okeanokoites*, *Planococcus kocurii*, and *Planococcus citreus* based on 16S rRNA gene sequences indicated that the four species formed two distinct phylogenetic clusters (Yoon et al., 2001a). One of the clusters included *Planococcus okeanokoites* and *Planococcus mcmeekinii*. Both these species have MK-8 as the predominant menaquinone and MK-7 as the minor component (Nakagawa et al., 1996). *Planococcus citreus* and *Planococcus kocurii* constituted the second cluster. These two species differ in their menaquinone composition, with *Planococcus citreus* having MK-6, MK-7, and MK-8 and *Planococcus kocurii* having MK-7 and MK-8 (Hao and Komagata, 1985). Subsequent studies confirmed the preceding phylogenetic affiliations (Alam et al., 2003; Mayilraj et al., 2005; Reddy et al., 2002) and clearly

TABLE 57. Characteristics differentiating the genus *Planococcus* from other morphologically or biochemically similar taxa^a

Characteristics	<i>Planococcus</i>	<i>Sporosarcina</i>	<i>Micrococcus</i>	<i>Planomicrobium</i> ^b
Spores	–	+	–	–

^cData from Boháček et al. (1968b, 1968a); Kocur et al. (1970).

^dData from Schleifer and Kandler (1970); Novitsky and Kushner (1976).

^eData from Jeffries (1969); Yamada et al. (1976).

^fData from Komura et al. (1975).

^gData from Morrison et al. (1971).

indicated a robust phylogenetic relationship between *Planococcus citreus*, *Planococcus kocurii*, *Planococcus antarcticus*, *Planococcus maritimus*, *Planococcus rifietoensis*, *Planococcus maitriensis* and *Planococcus columbae* but *Planococcus stackebrandtii* (Alam et al., 2003; Hao and Komagata, 1985; Mayilraj et al., 2005; Migula, 1894; Reddy et al., 2002; Romano et al., 2003; Suresh et al., 2007; Yoon et al., 2003) proved to be an exception and it grouped with *Planomicrobium psychrophilus* with a low bootstrap value. Thus, based on the phylogenetic inference, morphological features, and chemotaxonomic properties, it was suggested

that *Planococcus okeanokoites* and *Planococcus mcmeekinii* be classified into the new genus *Planomicrobium*, separating it from *Planococcus* as represented by *Planococcus citreus* and *Planococcus kocurii* (Yoon et al., 2001a). All of the eight species of *Planococcus* listed above are Gram-positive, motile, coccoid, orange-yellow in color, halotolerant and catalase-positive.

Differentiation and characteristics of the species of the genus *Planococcus*. The differential characteristics of the species of *Planococcus* are indicated in TABLE 58. Other characteristics of the species are presented in TABLE 59 and Table 60.

(2005).List of species of the genus *Planococcus*1. ***Planococcus citreus*** Migula 1894, 236^{AL}ci'tre.us. L. masc. adj. *citreus* lemon yellow.

The cell and colony morphology are as given for the genus. Physiological and biochemical characteristics are listed in Table 58, Table 59, and Table 60.

DNA G+C content (mol%): 48–52 (T_m , Bd).

Type strain: ATCC 14404, CCM 316, CIP 81.74, DSM 20549, JCM 2532, LMG 17319, NBRC 15849, NCIMB 1493, VKM B-1307.

GenBank accession number (16S rRNA gene): X62172.

2. ***Planococcus antarcticus*** Reddy, Prakash, Vairamani, Prabhakar, Matsumoto and Shivaji 2002, 1437^{VP} (Effective publication: Reddy, Prakash, Vairamani, Prabhakar, Matsumoto and Shivaji 2002, 260.)an.tarc'ti.cus. L. masc. adj. *antarcticus* pertaining to Antarctica.

The cell and colony morphology are as given for the genus. Physiological and biochemical characteristics are listed in Table 58, Table 59, and Table 60. This was the first psychrophilic species of *Planococcus* isolated, and it has significant quantities of C_{15:1}, C_{16:1 iso} and C_{18:1} (Table 60).

DNA G+C content (mol%): 41.5 (T_m).

Type strain: CMS 26or, MTCC 3854, DSM 14505.

GenBank accession number (16S rRNA gene): AJ314745.

3. ***Planococcus columbae*** Suresh, Mayilraj, Bhattacharya and Chakrabarti 2007, 1269^{VP}.co.lum'ba.e. L. gen. n. *columbae* of a pigeon, *Columba livia*.

The cell and colony morphology are as given for the genus. Physiological and biochemical characteristics are listed in Table 58, Table 59, and Table 60.

DNA G+C content (mol%): 50.5 (T_m).

Type strain: PgEx 11, ATCC 7251, DSM 17517.

4. ***Planococcus kocurii*** Hao and Komagata 1986, 573^{VP} (Effective publication: Hao and Komagata 1985, 452.)ko.cu'ri.i. N.L. masc. gen. n. *kocurii* named in honor of Miloslav Kocur, a Czechoslovakian bacteriologist.

The cell and colony morphology are as given for the genus. Physiological and biochemical characteristics are listed in Table 58, Table 59, and Table 60.

DNA G+C content (mol%): 39.6–42.9 (T_m).

Type strain: HK 701, AJ 3345, ATCC 43650, CCM 1849, DSM 20747, IAM 12847, JCM 2569, LMG 17320, NBRC 15850, NCIMB 629.

GenBank accession number (16S rRNA gene): X62173.

5. **Planococcus maitriensis** Alam, Singh, Dube, Reddy and Shivaji 2003, 307^{VP} (Effective publication: Alam, Singh, Dube, Reddy and Shivaji 2003, 509.)

mai.tri.en'sis. N.L. masc. adj. *maitriensis* pertaining to the Indian station Maitri in Antarctica.

The cell and colony morphology are as given for the genus. Physiological and biochemical characteristics are listed in Table 58, Table 59, and Table 60.

DNA G+C content (mol%): 39 (T_m).

Type strain: S1, MTCC 4827, DSM 15305.

GenBank accession number (16S rRNA gene): AJ544622.

6. **Planococcus maritimus** Yoon, Weiss, Kang, Oh and Park 2003, 2016^{VP}

ma.ri'ti.mus. L. masc. adj. *maritimus* living near the sea.

The cell and colony morphology are as given for the genus. Physiological and biochemical characteristics are listed in Table 58, Table 59, and Table 60. This species is tolerant to 17% NaCl.

DNA G+C content (mol%): 48 (HPLC).

Type strain: TF-9, JCM 11543, KCCM 41587.

GenBank accession number (16S rRNA gene): AF50,0007.

7. **Planococcus rifietoensis** Romano, Giordano, Lama, Nicolaus and Gambacorta 2003, 1701^{VP} (Effective publication:

corrig. Romano, Giordano, Lama, Nicolaus and Gambacorta 2003, 364.)

ri.fie.to.en'sis. N.L. masc. adj. *rifietoensis* pertaining to Rifieto Spring in Italy.

The cell and colony morphology are as given for the genus. Physiological and biochemical characteristics are listed in Table 58, Table 59, and Table 60.

DNA G+C content (mol%): 47.9 (HPLC).

Type strain: M8, ATCC BAA-790, DSM 15069.

GenBank accession number (16S rRNA gene): AJ493659.

8. **Planococcus stackebrandtii** Mayilraj, Prasad, Suresh, Saini, Shivaji and Chakrabarti 2005, 93^{VP}

sta.cke.brand.ti'i. N.L. gen. n. *stackebrandtii* of Stackebrandt, to honor Erko Stackebrandt, a German microbiologist.

The cell and colony morphology are as given for the genus. Physiological and biochemical characteristics are listed in Table 58, Table 59, and Table 60.

DNA G+C content (mol%): 40 (T_m).

Type strain: K22-03, DSM 16419, JCM 12481, MTCC 6226.

GenBank accession number (16S rRNA gene): AY437845.

Acknowledgements

S. Shivaji thanks Dr G. S. N. Reddy for his inputs at the proof level.

Genus II. **Caryophanon** Peshkoff 1939, 244^{AL}

DAGMAR FRITZE AND DIETER CLAU

Ca.ry.o'pha.non. Gr. n. *karyon* nut, kernel, nucleus; Gr. adj. *phaneros* bright, conspicuous; N.L. neut. n. *Caryophanon* that which has a conspicuous nucleus.

Slightly curved to straight **multicellular rods** (trichomes) with rounded or slightly tapered ends. Cell diameter is 1.0–3.5 µm and length is 4–20 µm or more. Several trichomes may form short chains. Asporogenous, nonbranching. Gram-positive. Motile by means of peritrichous flagella. After isolation in pure culture, the typical cell morphology may be preserved only in liquid media containing cow dung. Strictly aerobic. Chemo-organotrophic with presumed respiratory metabolism. Carbohydrates are not used as substrates. Acetate and other organic acids are the only major carbon sources used. Biotin is required and thiamine is stimulatory. Catalase-positive; cytochrome oxidase-negative; indole not produced. Found **associated with cattle dung. Not known to be pathogenic.**

DNA G+C content (mol%): 41–46 (T_m).

Type species: Caryophanon latum Peshkoff 1939, 244^{AL}.

Further descriptive information

The original false interpretation of cross-walls, nuclear material and cytoplasm in stained trichomes led to the name *Caryophanon* (Peshkoff, 1939). The true nature of the trichomes was shown by Pringsheim and Robinow (1947) by improved cytological techniques. Studies on both species have been reviewed by Trentini (1978). Since then only a few studies have been published in which *Caryophanon* strains have been used or at least cited (only 11 retrieved in search). A table of diagnostic characters is given in Table 61 and physiological properties are given in Table 62.

The close phylogenetic relationship between *Caryophanon* and members of the genus *Bacillus* and related genera, in particular

^bLiterature data available for species only.

^cOwn data; physiological tests were performed according to Gordon et al. (1973); Gordon's J-medium with glucose replaced by propionate was used as the basic medium; urease was tested using urease test broth (BBL 11797); motility was tested on soft agar (0.1% yeast extract, 0.01% K₂HPO₄, 0.2% agar); Tween-80 was tested according to Cowan and Steel (1974). Anaerobic growth was tested in anaerobic agar (BBL 210926) and casein-peptone soymeal-peptone glucose agar (Merck CASO Broth 105459 plus 1.5% agar).

^dMotility lost on culture media.

the round-spore-forming *Bacillus* species, was described by Stackebrandt et al. (1987). Placement of both *Caryophanon* species within the Gram-positive aerobic endospore-forming bacteria, in particular within rRNA group 2 (Ash et al., 1991), was confirmed by Farrow et al. (1994a) and by our own re-analysis. When comparing sequences of the type strain of *Caryophanon tenue* as determined by Farrow et al. (1994a) and by our own analysis, a similarity of 99.6% was determined. However, a comparison of sequences determined for the type strain of *Caryophanon latum* in both studies revealed that sequence similarities differed by more than 3% (Figure 59).

Caryophanon grows in the form of trichomes. To correctly interpret the term trichome, the applicable definition of Starr and Skerman (1965) is given here: "the designation trichome, frequently misused, is intended to mean the assemblage of cells in uniseriately multicellular bacteria, irrespective of their mode of movement, in which adjacent cells have a relatively large area of close contact". Endospores, sheaths or capsules are not formed. However, Trentini and Gilleland (1974) reported that one or two superficial wall layers containing protein are present in cells of *Caryophanon latum*. Mesosomes, nucleidosomes, and analogs of mitochondria have been described by Shadrina et al. (1982).

Under optimal growth conditions, individual cells of *Caryophanon latum* exhibit a disk-like shape within a trichome. Cells are larger in width than in length, showing cross wall formation at various stages of closure. In *Caryophanon tenue*, cells within trichomes are slightly larger in length than in width. They lack the multiple septation typical of *Caryophanon latum* and show mostly only one cross septum in a trichome (Peshkov and Marek, 1972).

The size of trichomes of *Caryophanon latum* in enrichment cultures varies between 2.3×6.0 and $3.5 \times 20 \mu\text{m}$. The cell number within trichomes ranges from 4 in the shorter to 15 in the

longer ones. The dimensions of *Caryophanon tenue* trichomes range between 1.0×4.0 and $2.0 \times 10.0 \mu\text{m}$ and numbers of cells within trichomes usually range from 2 to 3.

On artificial media, the morphology of trichomes may differ greatly from that in enrichment cultures. Cells may be deformed, thinner, longer, or crooked. In older cultures, strains of *Caryophanon latum* often form small, spheroidal forms. It has been postulated that these are part of a normal life cycle. According to Kele (1970), these are degenerate structures. Changes in the cell morphology of both *Caryophanon* species during longer cultivation on agar media have been described by Peshkov et al. (1978).

Various solid media adjusted to pH 7.5–8.5 have been described for growing strains of *Caryophanon*. Clarified manure extract agar¹ (Peshkov, 1967), cow dung agar² (Smith and Trentini, 1972), peptone-yeast extract-acetate agar (Pringsheim and Robinow, 1947), cow dung agar with lactalbumin hydrolysate (Moran and Witter, 1976), or a semisynthetic medium³ (Smith and Trentini, 1973; Trentini, 1978) support good growth of most strains of *Caryophanon latum* and *Caryophanon tenue*. However, with most of these media, the true enrichment morphology of most strains of *Caryophanon latum* cannot be maintained. For both species, biotin has been found to be essential for growth, whereas thiamine seems to be stimulatory.

Growth in liquid media like dung extract generally is scant. A defined liquid medium for *Caryophanon latum* has been developed by Kele and McCoy (1971). They noted that after some subcultures, nonmotile laboratory strains became actively motile and developed normal morphology. However, this medium did not support high density populations and some of the strains tested failed to grow.

Because growth in liquid media is scant, detailed studies of the effects of temperature and pH on growth of *Caryophanon latum* have been performed only with agar cultures (Moran and Witter, 1976). When measuring colony growth rate, an optimum for these parameters was found at pH 8.0 and 35°C. Detailed data for minimum and maximum growth temperatures for both *Caryophanon* species cannot be found in literature. With strains of *Caryophanon latum*, growth occurs at 10 and 37°C, but not at 45°C and at pH values between 6 and 8, with optimum growth at pH 7.5–8.0 (Weeks and Kelley, 1958). Data on the influence of temperature or pH on growth of *Caryophanon tenue* are not available.

FIGURE 59. Neighbor-joining tree showing the 16S rRNA gene sequence similarity of the type strains of *Caryophanon latum* and *Caryophanon tenue* (X70314 and X70315, deposited by Farrow et al., 1994a; AJ491302 and AJ491303, own deposits) in comparison with closest relatives belonging to the *Bacillus* rRNA group 2. The sequence of *Kurthia zopfii* was used to root the dendrogram. Bar = 0.05 sequence divergence.

¹ Clarified manure extract agar (Peshkov, 1967; modified). Clarified cow manure extract, 250.0 ml; peptone from casein, 5.0 g; sodium acetate trihydrate, 2.3 g; distilled water, 750.0 ml; agar, 15.0 g. Adjust to pH 7.8–8.0 and sterilize the medium at 121°C for 15 min. To prepare the manure extract, 250 g fresh cow dung is mixed with 750 ml distilled water, sterilized for 15 min at 120°C, and filtered through several layers of gauze. The filtrate is centrifuged at 3300 g for 15 min and the supernatant is frozen at 20°C. Due to the freezing step, colloidal particles form larger aggregates which, after thawing, can be removed by centrifugation at 3300 g. The clarified extract is stored frozen.

² Cow dung agar (Smith and Trentini, 1972). Fresh cow dung, 250 g; distilled water, 750 ml; agar, 15 g. Before agar is added, dung and water are mixed for a few minutes in a blender to break up large dung particles and to ensure thorough dispersion. Sterilize at 121°C for 15 min.

³ Semisynthetic medium for *Caryophanon latum* (Trentini, 1978). Lactalbumin hydrolysate, 10.0 g; sodium acetate, 5.0 g; MgCl₂ · 6H₂O, 20.3 mg; CaCl₂, 11.1 mg; Cu₂(SO₄)₃, 0.4 mg; FeSO₄, 0.152 mg; biotin, 0.02 mg; thiamine-HCl, 0.05 mg; nitrotriacetic acid, 19.1 mg; double-distilled water, 1000.0 ml. Adjust the medium with anhydrous Na₂CO₃ to pH 7.5 before autoclaving. The pH of the medium should be around 8.0 after sterilization.

In cell walls of *Caryophanon latum*, the peptidoglycan type is A4 α (Lys-D-Glu) (Stackebrandt et al., 1987). For *Caryophanon tenue*, no data on cell wall composition are available. Cell walls are sensitive to lysozyme: septal peptidoglycan is split very quickly, whereas wall peptidoglycan is more resistant (Trentini and Murray, 1975).

Menaquinones with six isoprene units (MK-6) are the major isoprenologues in *Caryophanon latum* and *Caryophanon tenue* (Collins and Jones, 1981).

The fatty acid composition data for strains of *Caryophanon latum* and *Caryophanon tenue* are shown in Table 63.

Studies on the fine structure of *Caryophanon latum* and *Caryophanon tenue* have been published by Peshkov and Marek (1972).

Caryophanon latum and *Caryophanon tenue* are strictly aerobic species. According to Provost and Doetsch (1962), *Caryophanon latum* forms a yellowish, nondiffusible pigment on several media that shows a strong absorption peak at 430 nm and which is presumed to be a carotenoid. Pigment formation is inhibited by diphenylamine. In older cultures and in cultures with unbalanced nutrition, *Caryophanon latum* synthesizes large quantities of poly- β -hydroxybutyric acid from butyrate and acetate (Provost and Doetsch, 1962; Shekhovtsov and Zharikova, 1978).

According to Provost and Doetsch (1962), acetate has been found to be the major carbon source for *Caryophanon latum*, followed by butyrate. With the exception of β -hydroxybutyrate, numerous other fatty acids, tricarboxylic acids, sugars, sugar alcohols, amino acids, and aliphatic alcohols cannot be used as substrates. However, Rowenhagen (1987) has shown that a number of additional fatty acids (e.g., propionate, valerate, capronate, and stearate) are oxidized by several strains of both *Caryophanon* species. Strains of *Caryophanon tenue* preferred valerate and capronate to acetate. It seems that each strain is specialized to one or two fatty acids as a result of a competitive pressure of other *Caryophanon* strains in the same habitat.

The DNA base composition of 36 strains of *Caryophanon latum* collected from Canada, England, Germany, Scotland,

USA, and the former USSR formed a tight group with G + C contents of 44.0–45.6 mol% (T_m), whereas three isolates of *Caryophanon tenue* clustered with 41.2–41.6 mol% G + C (T_m). DNA–DNA hybridization studies revealed intragroup relatedness values of 78–94% (*Caryophanon latum*) and 82–94% (*Caryophanon tenue*). *Caryophanon latum* and *Caryophanon tenue* showed intergroup relatedness values of only 13–30% (Adcock et al., 1976). The genome size of *Caryophanon tenue* is 900–1000 \times 10⁶ Da.

Phages have been isolated for both *Caryophanon* species. They were specific for *Caryophanon latum* or for *Caryophanon tenue* or were active against both species (Trentini, 1978).

According to Provost and Doetsch (1962) and W.C. Trentini (unpublished results), *Caryophanon latum* and *Caryophanon tenue* show a similar antibiotic sensitivity pattern to 45 antibiotics. Both species are resistant to streptomycin, polymyxin B, nalidixic acid, and several sulfa drugs. To isolate *Caryophanon latum*, cow dung agar containing 80 μ g/ml streptomycin sulfate can be used.

Caryophanon latum and *Caryophanon tenue* are not known to be pathogenic.

Caryophanon latum and *Caryophanon tenue* were both isolated from fresh cattle dung. In most successive studies, *Caryophanon latum* was found only in cattle manure or cattle manure-contaminated materials like bedding straw, barn dust, or barnyard soil. It was absent from freshly voided droppings and old, dried samples. Reports that *Caryophanon latum* has been isolated from other sources could not be verified. *Caryophanon latum* has not been found as part of the natural flora of the intestinal tract of cattle (Trentini, 1978) and seems to be a natural, specific, and temporary coprophilic resident of cattle dung. It seems to be dispersed to new droppings by contaminated air and by flying insects (Trentini, 1978; Trentini and Machen, 1973). Whether the habitat of *Caryophanon tenue* is also restricted like that of *Caryophanon latum* is not known.

Drozd et al. (1987) described a case of concrete corrosion caused by a *Caryophanon* species.

^aNote: Analysis through the MIDI system; as *Caryophanon* does not grow on the standard medium used for culturing organisms for fatty acid analysis, medium no. 34 from the DSMZ catalogue designed for *Caryophanon* was used; data are therefore not directly comparable with other data; values lower than 0.36% are not recorded by the system; values for anteiso-11:0, iso-13:0, iso-15:1 at 5, iso-18:0, 18:0 and 20:4 ω 6,9,12,15*c* are lower than 1% or not detectable; values for 17:0 are 1.68% for DSM 484, but are lower than 1% or not detectable for all other strains; data produced at the DSMZ.

Enrichment and isolation procedures

Caryophanon strains can be isolated only after an enrichment step. According to Pringsheim and Robinow (1947) and Weeks and Kelley (1958), samples of fresh cow dung are collected, placed in closed bottles, and kept at room temperature. After 1 to 2 d, when *Caryophanon* has multiplied in the sample, a loopful of dung is suspended in a few drops of tap water. Samples that are microscopically rich in *Caryophanon latum* are streaked on cow dung agar or peptone-yeast extract-acetate agar. Small sized granular colonies of the large bacterium, among those of other organisms, are visible after about 24 h. With the aid of a dissecting microscope colonies can be picked with a capillary pipette or needle and checked microscopically for the presence of *Caryophanon*. Pure cultures are obtained by repeated re-streaking on agar plates. Provost and Doetsch (1962) isolated *Caryophanon latum* by the following method. Fresh cow dung samples are incubated at room temperature in glass bottles and covered with aluminum foil. After 1 d, wet mount preparations are examined microscopically for typical trichomes. Part of a positive sample is sterilized at 121°C for 15 min and is then inoculated with several loops of material taken from the remaining portion. After incubation for 24 h at room temperature, the inoculated dung sample usually shows high numbers of trichomes. About 2 g enriched sample is suspended in 10 ml water. The suspension is forced through several layers of gauze to remove large particles. The filtrate is centrifuged at 50 g for 8 min and the sediment is resuspended in water. This process is repeated 10 times. The resulting sediment is streaked on plates of peptone-yeast extract-acetate agar. After about 24 h at room temperature, the plates are examined for minute, granular colonies using a dissecting microscope. Material from colonies is checked microscopically for the presence of *Caryophanon*. Pure cultures are obtained by repeated streaking.

Smith and Trentini (1972) used cow dung-streptomycin agar for the effective isolation of *Caryophanon latum*. Their isolation method is based on differential low-speed centrifugation followed by filtration and plating on cow dung agar containing 80 µg/ml filter-sterilized streptomycin sulfate. Positive colonies are purified by re-streaking on cow dung agar without streptomycin.

Whereas *Caryophanon latum* can be detected easily because of its typical morphology (Figure 60), the presence of *Caryophanon tenue* in cow dung or enrichment samples is more difficult to detect. Often, its trichomes are only slightly bigger in width and length than other rod-shaped bacteria developing in the enrichment cultures. To detect *Caryophanon tenue*, it is best to prepare samples on slides covered with 1.0 ml 5% or 10% (w/v) gelatin and dried at about 50°C to enhance the contrast of cross septa and to look for trichomes with only one or two cross septa per cell (Figure 61). Methods for the specific isolation of *Caryophanon tenue* have not been described up to now. Cultures have been isolated apparently by random.

Maintenance procedures

Caryophanon cultures can be maintained on clarified manure extract agar¹ or cow dung agar². After incubation at about 25°C for 48 h, *Caryophanon* strains survive storage at 4°C for

FIGURE 60. *Caryophanon latum* strain Lenglern; clarified manure extract agar; 30°C; microscopic slides covered with 0.5 ml of 5% (w/v) gelatin and dried at 50°C; bar = 10 µm.

FIGURE 61. *Caryophanon tenue* strain Uelzen; clarified manure extract agar; 30°C; microscopic slides covered with 0.5 ml of 5% (w/v) gelatin and dried at 50°C; bar = 10 µm.

at least 4 weeks. For long-term storage, isolates can be readily freeze-dried or kept in or above liquid nitrogen by standard methods.

In enrichment cultures, the numbers of *Caryophanon latum* rapidly fall to zero after about 2 d at room temperature. However, actively moving trichomes can usually be maintained for some weeks by keeping the enrichment cultures (cow dung mixed with some water) at about 4°C after incubation for 1 to 2 d at room temperature.

Differentiation from closely related taxa

The two species of the genus are still today mainly defined morphologically; thus, differentiation from other bacterial genera present in cow manure is possible through their trichomous appearance. Differentiation from other trichome-forming bacteria is by the presence of flagella (Figure 62) and the absence of gliding movement.

FIGURE 62. *Caryophanon tenue* strain Uelzen; clarified manure extract agar; 30°C; negative staining, uranyl acetate; bar = 10 µm.

Taxonomic comments

Whereas the data presented for *Caryophanon latum* are mostly based on several strains, those for *Caryophanon tenue* are generally based on a single isolate.

Acknowledgements

Dr R.M. Kroppenstedt (DSMZ) is thanked for doing FAME analysis, Dr M. Madkour (University of Göttingen, Institute for Microbiology and Genetics) is thanked for taking electron micrographs, J. Swiderski (DSMZ) is thanked for constructing the 16S rRNA gene sequence dendrogram, and C. Wahrenburg (DSMZ) is thanked for doing the physiological tests.

GenBank accession number (16S rRNA gene): X70315 (Farrow et al., 1994a), AJ491303.

Genus III. *Filibacter* Maiden and Jones 1985, 375^{VP} (Effective publication: Maiden and Jones 1984, 2957.)

ERKO STACKEBRANDT

Fi.li.bac'ter. L. n. *filum* a thread; N.L. masc. n. *bacter* masculine form of Gr. neut. n. *batron* a rod; N.L. masc. n. *Filibacter* thread rod.

Filaments composed of cylindrical cells, straight or curved. Filaments are neither sheathed nor branched. Gram stain negative. Cell junctions clearly marked by constrictions. **Filaments are flexible**, but do not show active flexing. **Motile by gliding.** Resting stages not observed. Nonspore-forming. Strictly aerobic, catalase and oxidase-positive. The mol% of the DNA is 44. **Peptidoglycan contains lysine. Murein type L-lysine-D-glutamic acid, variation A4.** **Major respiratory lipoquinone is menaquinone MK-7. Membrane fatty acids are dominated by C_{15:0} anteiso and C_{17:0} anteiso.** **Cytochromes are predominantly of the c type** while b-type cytochromes occur in lesser amounts. Phylogenetically, a member of *Bacillus* RNA group 2, subphylum *Clostridium-Bacillus*, phylum of Gram-positive bacteria. *Bacillus globisporus*, *Bacillus pasteurii*, and *Bacillus psychrophilus* are close phylogenetic neighbors.

Type species: ***Filibacter limicola*** Maiden and Jones 1985, 375^{VP} (Effective publication: Maiden and Jones 1984, 2957).

Further descriptive information

As the genus currently contains a single species only, the description of the genus is that of the species. Only the type strain ISS101^T (NCIMB 11923^T, DSM 13886^T) has been analyzed in detail. Morphological, cultural, and most of the physiological data were taken from Maiden and Jones (1984).

Filaments of up to 150 µm in length are multicellular, the cells being 3–30 µm in length. Within longer cells, septa without constrictions can be seen (Maiden and Jones, 1984). The study by Clausen et al. (1985) pointed out that Gram-negative staining behavior does not necessarily indicate the presence of the typical Gram-negative wall morphology. Electron micrographs of thin sections of glutaraldehyde fixed cells of *Filibacter limicola* showed a five-layered cell wall, including an electron-dense peptidoglycan layer of approximately 12.5 nm thickness and a surface (S) layer. An outer membrane, which is typical of Gram-negative bacteria, was absent. The cell wall of *Filibacter limicola* is about

40 nm thick, and thus within the range of 20–80 nm typical for a Gram-positive cell wall (Glauert and Thornley, 1969). Neither sheaths nor capsules were observed. Electron micrographs of unfixed cells and filaments indicated the presence of fibrillar material which often appeared as a capsule-like structure around the cells. Safranin stain of *Filibacter limicola* cells was even. Upon staining with Sudan Black one particle per cell was stained. Polyhydroxybutyrate and volutin tests were negative (Maiden and Jones, 1984) and no intracellular sulfur globules were deposited when cells were grown in the presence of sulfide.

The growth habits of *Filibacter limicola* on solid media are similar to those of *Vitreoscilla stercoraria*, in that cells spread widely over the surface of agar producing whorls of growth and spiral colonies. This distinctive growth was interpreted as gliding (Maiden and Jones, 1984). Some filaments were reported to move slowly (5 µm/min). In wet mounts, the strain was usually immotile, but often showed vibrating movements, unlike Brownian motion. As reported by Maiden and Jones (1984), occasionally cells 10–20 µm long were seen to rotate slowly through 360° with one end appearing to be attached to the glass. Under these conditions, only rarely, was gliding motility observed.

Filibacter limicola is strictly aerobic, growing well at the surface (3–4 mm) in shake cultures. In tubes with an agar plug cells grew faintly at the surface of semi-solid agar. The organism is catalase and oxidase-positive. The cytochrome spectrum of *Filibacter limicola* showed a Soret peak at 409 nm in the oxidized state, which increased and was shifted to 417 nm when reduced. The reduced spectrum also showed the characteristic cytochrome *c* beta (522 nm) and alpha peaks (552 nm). Small shoulders in the alpha and beta peaks occurring in reduced minus oxidized difference spectra of the alpha and beta peaks indicated the presence of minor amounts of *b*-type cytochromes.

Filibacter limicola grows well on Tryptone soy broth (TSB) (Oxoid CM129) with a generation time of 6.6 h. It also grows with Casamino acids or the complete amino acid mixture in the presence of vitamins (Maiden and Jones, 1984). Good growth also occurred on Anaerobe Agar (BBL, Becton–Dickinson) and in CASO (casein-peptone soymeal-peptone; Merck 5458), supplemented with inosine. No growth occurred in the absence of vitamins. One of the most salient metabolic properties of this organism is its inability to utilize organic compounds in the absence of amino acids. These results were confirmed in the DSMZ laboratories. Many of the organic compounds tested in the presence of amino acids were inhibitory. The only compounds which enhanced yields were acetate, butyrate, and glycerol at 2 mg carbon atom/l with amino acids at 36.3 carbon atom/l. Stimulation of growth decreased at higher substrate concentrations and lower amino acid concentrations.

Of the amino acids that supported growth, combinations of those of the following families were found stimulating: the glutamate family (glutamate, glutamine, arginine, proline) plus aspartate (aspartate, asparagine, lysine, threonine, isoleucine, methionine) or serine (serine, glycine, cysteine) families, and the aspartate family plus the pyruvate (alanine, valine, leucine), serine (serine, glycine, cysteine) or aromatic (tryptophan, phenylalanine, tyrosine) families. The requirements for and interdependence of particular combinations of amino acids from different families may be due to coupled oxidation-reduction reactions such as in the Stickland reaction in anaerobes. No sin-

gle amino acid or mixture of amino acids from a single biosynthetic family supported growth. Histidine and members of the aromatic family (in most cases) were reported inhibitory. More detailed information on the mutual influence of amino acid families on support and inhibition of growth has been given by Jones and Maiden (1984).

Physiological reactions of strain DSM 13886^f towards the substrate panel provided by the API 20 NE (API BioMérieux, Marcy l'Etoile, France) confirmed the positive urease reaction and gelatin hydrolysis described by Maiden and Jones (1984); in addition, the strain was found to reduce nitrate and to cleave *p*-nitro-phenyl-β-D-galactopyranoside. None of the other substrates of the API 20 NE panel, none of carbohydrates (sugars and acids) provided by the API 50 CHE panel, as well as those carbohydrates used for the differentiation of *Bacillus* species (Gordon et al., 1973), supported growth within 8 days.

Filibacter limicola has only been isolated once, from sediments of Blelham Tarn, a eutrophic freshwater lake in the English Lake District (Maiden, 1983). This lake was selected for enrichment studies because here the greatest numbers and variety of filamentous bacteria had been observed (Godinho-Orlandi and Jones, 1981). The nutrition with respect to amino acids as substrates for carbon sources resembles that of the gliding organism *Vitreoscilla stercoraria*, a strain of which has also been isolated from the same source. The ecological role has been discussed by Maiden and Jones (1984). As compared to the amino acid concentration in surface waters, that of sediments is 10³ times higher [35 µg/l ((Sepers, 1981)] and 35 mg/l glycine equivalents ((Simon and Jones, 1982), respectively], and the selective use of amino acids may reflect their relative abundance in the sediment. *Filibacter limicola* shows a positive urease reaction; urea may originate as a product of decomposing phytoplankton (Satoh, 1980).

Enrichment and isolation procedures

For isolation, sediment cores are sampled and treated according to Maiden and Jones (1984). Sediment was sampled using a Jenkins surface mud-sampler (Ohnstadt and Jones, 1982). The top 1–2 cm layer of a deep-water sample (13–14 m in depth) was diluted with filtered lake water, mixed vigorously with a vortex mixer, and used for the inoculation of isolation media. The highest number of colonies containing filamentous bacteria was observed on MYP plates at 10°C. MYP medium has the following composition (mg/l): yeast extract (Difco), 10; peptone (Oxoid L37), 100; K₂HPO₄, 28; MgCl₂·6H₂O, 127; KNO₃, 4; (NH₄)₂SO₄, 60; MnSO₄·4H₂O, 8; Ferric citrate, 6. The pH of the medium was adjusted with 1 M KHCO₃ before autoclaving and the final pH was 7.0–7.2. Filaments developed after 14 d incubation. Good growth, but less abundant growth, also occurred on CASO agar and Tryptone soy agar at 20°C. During incubation, plates were examined by eye, and through a dissecting microscope at a magnification of 32x. Small agar blocks containing filaments occurring away from the inoculation sample were excised, transferred to fresh agar, and subcultured until pure cultures were obtained.

Maintenance procedures

Cultures may be grown at 20°C on the isolation media, indicated under Enrichment (MYP, Oxoid CM129, Oxoid CM 131).

Cultures, grown at 20°C, can be maintained at 10°C for some weeks. Long-term preservation can be done by lyophilization or storage in liquid nitrogen.

Special characters

Because of the morphological similarity between *Filibacter limicola* and *Vitreoscilla stercoraria*, affiliation of new *Filibacter* isolates should include 16S rDNA sequence analysis and/or determination of chemotaxonomic properties, such as the presence of the L-lysine-D-glutamic acid peptidoglycan type (Schleifer and Kandler, 1972) and the isoprenoid type MK-7 (Collins, 1994). Verification of isolates which are genomically highly related to the type strain ISS101 (DSM 13886^T, NCIMB 11923^T) should be done by RiboPrint™ analysis. The pattern of strain DSM 13886 (Figure 63) is distinct and clearly different from those of *Bacillus* species, shown to be phylogenetic neighbors by 16S rDNA analysis, e.g., *Bacillus pasteurii*, *Bacillus globisporus*, and *Bacillus psychrophilus*.

Differentiation of *Filibacter* from other taxa

Filibacter limicola resembles *Vitreoscilla stercoraria* in superficial morphological properties, such as the formation of Gram-negative, unpigmented, multicellular, and gliding filaments (see *Special characters* for differentiation of *Filibacter* from other gliding bacteria). The genomic and chemotaxonomic characters of *Filibacter* give evidence for a close relationship with members of the *Bacillus* rRNA group 2 (Ash et al., 1991), which, in addition to members of the genus *Bacillus* and *Sporosarcina*, contains non-sporeforming organisms, presently classified in *Caryophanon*, *Planococcus* and *Kurthia* (Claus et al., 1991). However, none of these taxa is as closely related to any *Sporosarcina* species as *Filibacter limicola* is to *Sporosarcina pasteurii*, *Sporosarcina globispora* and *Sporosarcina psychrophila* (Yoon et al., 2001b). An intense search for endospores in *Filibacter limicola*, using a broad range of techniques which have triggered spore formation in *Bacillus* species (Gordon et al., 1973), has failed (Maiden and Jones, 1984; studies of the DSMZ identification service).

The compilation of the main differential morphological, physiological, and biochemical properties (Table 64) indicates that *Filibacter limicola* can easily be diagnosed as a unique taxonomic entity, even if formation of endospores may be described in future studies on this organism.

Taxonomic comments

The first evidence that *Filibacter limicola* is not a member of the *Flexibacteraceae*, as proposed in the species description (Maiden and Jones, 1984), originated from 16S rRNA oligonucleotide cataloging (Clausen et al., 1985). Comparison of the catalog of 16S rRNA fragments of *Filibacter limicola* with those of gliding organisms such as *Vitreoscilla stercoraria*, *Cytophaga johnsonae*, and *Flexibacter elegans* and representatives of Gram-positive organisms, indicated a phylogenetic relationship with members of the latter taxa, especially to the round-spore-forming *Bacillus pasteurii*, *Bacillus insolitus*, *Bacillus psychrophilus* (Stackebrandt and Woese, 1981), *Sporosarcina urea* (Pechman et al., 1976), and to the asporogenous species *Planococcus citreus* (Stackebrandt and Woese, 1979). The phylogenetic relationship was supported by several common phenotypic properties, such as the presence of lysine as the diagnos-

FIGURE 63. Riboprint™ patterns of the DNA of *Filibacter limicola* DSM and the type strains of *Sporosarcina urea* and related *Bacillus* species of RNA group 2. The pattern was generated by the Riboprint™ robot (Qualicon, Wilmington, DE), in which DNA was cleaved by *EcoRI*, the resulting fragments separated on a membrane, and fragments of the *rrn* operons were visualized by hybridization with a fluorescent *rrn* operon probe. The scale bar on top of the fragments indicates the length (in kb) of the fluorescence-positive fragments. Fresh material (agar colonies) was analyzed except for *Sporosarcina pasteurii* DSM33^T, for which frozen material was used.

tic amino acid in the peptidoglycan and the occurrence of MK-7 as the major isoprenoid quinone. In a subsequent study (Stackebrandt et al., 1987), the diversity of the phylogenetically coherent but morphologically diverse group, to which *Filibacter limicola* belongs, was extended by the inclusion of members of *Caryophanon* and *Sporosarcina globispora*. With the introduction of reverse transcriptase sequencing of 16S DNA the phylogenetic heterogeneity was fully explored (Ash et al., 1991) and the group containing *Filibacter limicola* and its nearest phylogenetic neighbors was defined as RNA group 2 of the genus *Bacillus* and related taxa. In addition to the organisms indicated above, members of the genus *Kurthia* were affiliated to this group (Farrow et al., 1994b). As the 16S rDNA sequence of *Filibacter limicola* NCIMB 11923^T (accession no. X70317) contained several ambiguous nucleotides and stretches of undetermined nucleotides, the almost complete sequence (1517 nucleotides) was redetermined for a new culture of strain NCIMB 11923^T, deposited in the DSMZ as DSM 12288^T (accession no. AJ292316). Though the two sequences showed only 95% similarity to each other, the phylogenetic position of the strains as members of RNA group 2 remained unchanged. The new sequence placed *Filibacter limicola* next to the species *Sporosarcina psychrophila*, *Sporosarcina pasteurii*, and *Sporosarcina globispora*. Depending upon the algorithm used (DeSoete, 1983; Felsenstein, 1993), *Bacillus pasteurii* grouped either with the other two *Sporosarcina* species (consensus tree using DNAPARS) or it branched below the lineage defined by *Filibacter limicola*, *Sporosarcina psychrophila* and *Sporosarcina globispora* [consensus tree using distance matrix analyses or maximum-likelihood (ML)]. Figure 64 displays the position of *Filibacter limicola* within RNA group 2 (ML algorithm) together with organisms analyzed recently, such as members of *Planococcus* (Ash et al., 1992), and various *Bacillus* species (Rheims et al., 1999).

List of species of the genus *Filibacter*

1. ***Filibacter limicola*** Maiden and Jones 1985, 375^{VP} (Effective publication: Maiden and Jones 1984, 2957.)
li.mi'co.la L.n. *limus* mud; L. suff. *cola* dweller; N.L. masc. n. *limicola* mud-dweller.

Filaments 1.1 μm × 8–150 μm, cells 1.1 μm × 3–30 μm, rarely less than three diameters in length. Gliding motility about 5 μm/min. Good growth at pH 7.0, no growth at pH 5.7. Optimal temperature 20°C, slow growth at 4°C and no growth above 26°C.

Sugars and organic acids not utilized, amino acids only are used as carbon and energy sources. Good growth on peptone-containing media. Gelatin hydrolysed, but casein and starch not hydrolysed. Nitrate reduction in CASO broth positive. *p*-Nitrophenyl-β-D-galactopyranoside hydrolysis and urease-positive.

DNA G+C content (mol%): 44 mol% (T_m).

Type strain: 1SS101, ATCC 43646, NCIMB 11923, DSM 13886.

GenBank accession number (16S rDNA): AJ292316.

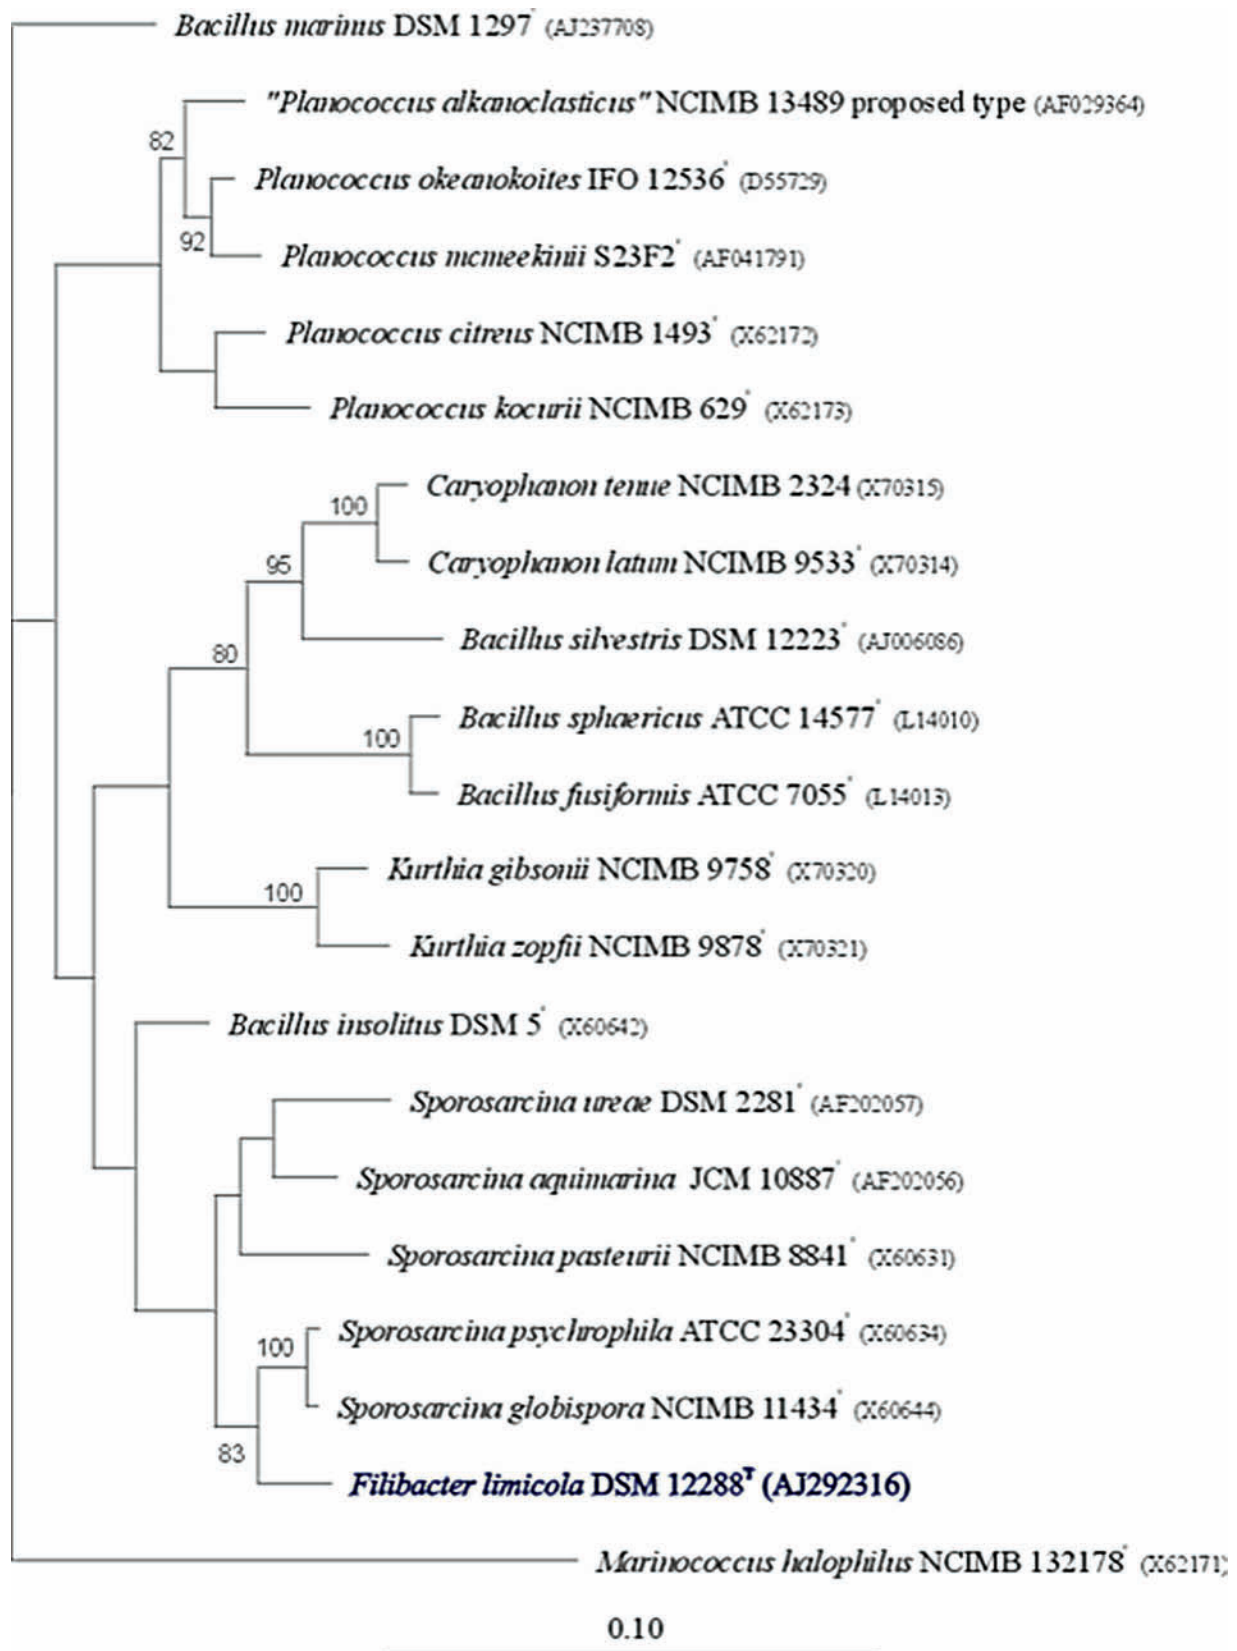

FIGURE 64. 16S rDNA sequence-based dendrogram displaying the phylogenetic position of *Filibacter limicola* and related taxa of *Bacillus* RNA group 2 by the maximum-likelihood algorithm (Felsenstein, 1993). Bootstrap values (expressed as percentages of 100 replications) of 75% and higher are indicated at the branch points. Scale bar = 10 inferred nucleotide substitutions per 100 nucleotides.

Genus IV. *Jeotgalibacillus* Yoon, Weiss, Lee, Lee, Kang and Park 2001c, 2092^{VP}

ELKE DE CLERCK AND PAUL DE VOS

Je.ot.ga.li.ba.cil'lus. N.L. n. *jeotgalum* (Korean n. *jeotga*) jeotgal, traditional Korean food; L. n. *bacillus* rod; N.L. masc. n. *Jeotgalibacillus* rod from jeotgal.

Rods 1.0–1.2 × 2.0–4.0 μm, but longer rods are often observed. Motile by peritrichous flagella. **Round endospores** are formed in swollen sporangia. Cells stain Gram-variable. **Cell wall peptidoglycan contains L-lysine at position 3 of the peptide subunit.** Facultatively anaerobic. Optimal growth temperature is 30–35°C. Optimal pH for growth is 7.0–8.0. Catalase- and oxidase-positive. Urease-negative. Nitrate is reduced to nitrite. **The predominant menaquinones are MK-7 and MK-8.** The major fatty acid is C_{15:0 iso}.

DNA G+C content (mol%): 44.

Type species: *Jeotgalibacillus alimentarius* Yoon, Weiss, Lee, Lee, Kang and Park 2001c, 2092^{VP}.

Further descriptive information

The genus *Jeotgalibacillus* contains a single species, *Jeotgalibacillus alimentarius*, which is phylogenetically related to members of *Bacillus* rRNA group 2 and forms a coherent cluster with *Marinibacillus marinus*.

Jeotgalibacillus alimentarius contains a single strain, YKJ-13. Most cells of strain YKJ-13 are 1.0–1.2 × 2.0–4.0 μm in a 3-d-old culture on Marine agar at 30°C, but longer rods may also be observed. MK-7 is the predominant menaquinone (62%), but a significant amount of MK-8 (35%) also occurs. The fatty acid profile is characterized by the predominance of C_{15:0 iso} (47.6%), followed by -C_{15:0 anteiso} (15.2%).

After incubation on Marine agar, colonies are smooth, glistening, irregular, flat-raised, and orange-yellow in color.

Optimal growth is observed at 30–35°C. Growth occurs at 10 and 45°C but not at 4 or 50°C. Strain YKJ-13 grows optimally at pH 7.0–8.0, and no growth occurs at pH values below 6.0. Optimal growth is observed in the presence of 3–12% NaCl (w/v); growth occurs with 19% NaCl and weakly with 20% NaCl, but not with more than 21% NaCl. Strain YKJ-13 grows under anaerobic conditions on Marine agar and shows catalase and oxidase activities, but no urease activity.

Esculin, casein, gelatin, and Tween 80 are hydrolyzed. No hydrolysis of hypoxanthine, starch, tyrosine, or xanthine is observed. Nitrate is reduced to nitrite.

Enrichment and isolation procedures

Jeotgalibacillus cells can be enriched in Marine broth at 30°C and harvested from Marine agar after incubation for 3 d.

Differentiation of the genus *Jeotgalibacillus* from other genera

Jeotgalibacillus is considered a member of *Bacillus* rRNA group 2 because of the formation of round endospores, the inclusion of L-lysine at position 3 of the peptide subunit of the peptidoglycan, and the abundance of C_{15:0 iso}, the major fatty acid. Those properties have been stated as characteristic for members of this group (Rheims et al., 1999; Shida et al., 1997; Stackebrandt et al., 1987). The menaquinone profile of *Jeotgalibacillus* has not been found among other members of *Bacillus* rRNA group 2. *Jeotgalibacillus* differs from the closest related genus, *Marinibacillus*, in its ability to grow anaerobically, and in its NaCl and growth temperature tolerances. Whereas *Marinibacillus* shows slight growth with 7% NaCl and no growth with 10% NaCl, *Jeotgalibacillus* grows with 20% NaCl. Moreover, *Jeotgalibacillus alimentarius* strain YKJ-13T is a mesophile, whereas *Marinibacillus marinus*, the only species within the genus *Marinibacillus*, is a psychrophile.

Taxonomic comments

In the tree-based neighbor-joining algorithm, strain YKJ-13 is phylogenetically related to members of *Bacillus* rRNA group 2 and forms a coherent cluster with *Marinibacillus marinus* DSM 1297^T. The relationship between strain YKJ-13, *Marinibacillus marinus* DSM 1297^T, and members of *Bacillus* rRNA group 2 is also found in trees generated by the maximum-likelihood and maximum-parsimony algorithms.

List of species of the genus *Jeotgalibacillus*

1. *Jeotgalibacillus alimentarius* Yoon, Weiss, Lee, Lee, Kang and Park 2001c, 2092^{VP}

a.li.men.ta'ri.us. L. adj. *alimentarius* relating to food.

Cell morphology, nutrition, and physiology are as described for the genus and as listed in Table 65.

DNA G+C content (mol%): 44 (HPLC).

Type strain: YKJ-13, JCM 10872, KCCM 80002.

GenBank accession number (16S rRNA gene): AF281158.

Genus V. *Kurthia* Trevisan 1885, 92^{AL} Nom. cons. Opin. 13 Jud. Comm. 1954, 152

RÜDIGER PUKALL AND ERKO STACKEBRANDT

Kurth'i.a. N.L. fem. gen. n. *Kurthia* named for H. Kurth, the German bacteriologist who described the type species.

In young cultures (12–24 h): **regular, unbranched rods** with rounded ends occurring in chains that are often parallel. The rods are ~0.6–1.2 μm in diameter and vary in length according to the stage of growth ~2–5 μm long; filaments (5–10 μm) may

occur. Older cultures (3–7 d) of **some species are composed of coccoid cells** formed by fragmentation of the rods, but short rods may be the dominant forms in such cultures; one species does not form coccoid cells. **Does not form endospores.**

^aSymbols: +, positive; -, negative; w, weakly positive; v, variable.

Gram-positive. Not acid-fast. The rods are usually motile by peritrichous flagella but nonmotile strains occur. **Strictly aerobic.** Optimum temperature 25–30°C or 20–25°C, one species grows up to 45°C. Grows well on peptone-yeast extract media at neutral pH, producing rhizoid colonies. Two species grow in 7% generally agree with previous reports on *Kurthia zopfii* and *Kurthia gibsonii* (Goodfellow et al., 1980), in that C_{15:0 ante} and C_{15:0 iso} acids are the major component. Detailed percentages are given in the species descriptions.

Phylogenetic position. The phylogenetic position of *Kurthia* was elucidated in comparison with non-spore-forming aerobic spherical and rod-shaped Gram-positive organisms with a DNA G+C content of less than 55 mol%. Members of *Filibacter* (Clausen et al., 1985), *Sporosarcina*, *Planococcus* and *Marinococcus* (Farrow et al., 1992; Ludwig et al., 1981), as well as *Kurthia*, *Caryophanon*, *Planococcus* and *Exiguobacterium* (Farrow et al., 1994a) were found to branch among members of the genus *Bacillus* (Ash et al., 1991; Stackebrandt et al., 1987; Stackebrandt and Swiderski, 2002). The genus *Bacillus* itself was found to contain several remotely related phylogenetic branches, many of which are today described as individual genera (see chapters on the family *Bacillaceae*). The core genus of *Bacillus* still forms a phylogenetically broad cluster, consisting of different groups (Ash et al., 1991), one of which, *Bacillus* group 2, embraces the round spore-forming bacilli (e.g., *Bacillus psychrodurans*, *Bacillus nedei*, *Bacillus psychrus*, *Bacillus sphaericus*, *Bacillus insolitus*, *Bacillus*

silvestris) and their non-spore-forming relatives (Stackebrandt et al., 1987).

With 16S rRNA gene sequence similarities ranging between 95.8 and 97.7%, the type strains of the three *Kurthia* species form a tight phylogenetic cluster (Figure 66). The branching is supported by high bootstrap values. *Kurthia* species are remotely related to the type strains of two *Bacillus* species, i.e., *Bacillus pycnus* JCM 11075^T and *Bacillus neidei* JCM 11077^T (94.2–96.2%). However, low bootstrap values indicate that the stability of their branching is not significant and may change with other sequences included in the database. These five species form a sister clade of a cluster consisting of species of *Bacillus*, *Sporosarcina*, *Filibacter*, and *Planococcus*.

Genes other than those encoding 16S rRNA have rarely been sequenced. An example is the suite of 11 biotin biosynthesis genes involved in the stepwise synthesis of biotin in *Kurthia* sp. DSM 10609 (Kiyasu et al., 2001; accession numbers AB045873–AB045875). Besides a chitinase gene of *Kurthia zopfii* (accession no. D63702), the *cpn60* (chaperonin 60) gene has partially been sequenced for all three type strains of *Kurthia* (accession nos AY123713, AY123714, AY123716).

Habitat (Keddie and Shaw, 1986). Although a number of strains of bacteria identified as “*Kurthia* species,” have been isolated from various clinical materials, most commonly from the feces of patients suffering from diarrhea, there is no evidence of pathogenicity in authentic members of the genus (see

FIGURE 65. Growth behavior of *Kurthia zopfii* NCIB 9878^T. (a) Rhizoid colony on yeast nutrient agar after 4 d incubation at 25°C; bar = 10 mm. (b) Yeast nutrient gelatin slant showing "bird's feather" type of growth; incubated 5 d at 20°C. *Kurthia zopfii* isolate: edge of colony on yeast nutrient agar incubated at 25°C. (c) After 24 h, showing long filaments composed of rods. (d) After 3 d, showing development of coccoid forms. Bar = 10 μm.

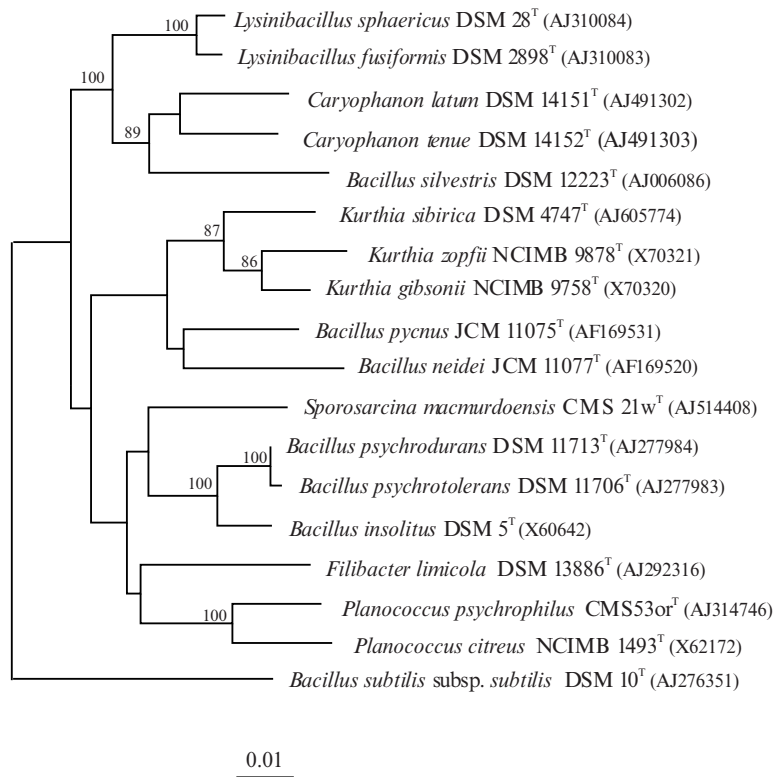

FIGURE 66. Neighbor-joining tree (Felsenstein, 1993) generated on the basis of 16S rRNA gene sequences showing the nearest neighbors of members of the genus *Kurthia*. Bootstrap value was calculated for 500 replicate trees. The bar corresponds to a 1% difference in nucleotide sequences.

Keddie, 1981, for references). *Kurthia zopfii* and *Kurthia gibsonii* are commonly isolated from meat (particularly after storage for a few days at 16°C (Gardner, 1969) and meat products; it is likely that the meat becomes contaminated with *Kurthia* in the abattoir (Keddie, 1981). The other common source of *Kurthia zopfii* and *Kurthia gibsonii* is feces of certain farm animals, especially of chickens and pigs, several hours to a few days after they have been voided (Keddie, 1981). There are also reports of presumptive *Kurthia* species being isolated from such diverse sources as "sloughing spoilage" of ripe olives, the gut of a crab, wet stored wood, dental plaque of beagle dogs and from air at an altitude greater than 10,000 feet (see Keddie, (1981) for references), but there is considerable doubt about the accuracy of identification of many of these isolates. However, authentic *Kurthia* species have been isolated occasionally from milk, soil and surface waters, presumably as a result of contamination with animal dung (Keddie, 1981). Recent reports describe *Kurthia* species in bottled drinking water (Jeena et al., 2006) and the nasal cavity of sea lions (Hernandez-Castro et al., 2005). *Kurthia* species were isolated from the stomach and intestinal contents of the Susuman mammoth (Belikova et al., 1980). Of 13 strains referred to by these authors as *Kurthia zopfii*, four had the characters of that species, three appeared to be *Kurthia gibsonii* and the remainder, mainly psychrophiles, were described as *Kurthia sibirica* (Belikova et al., 1986).

Isolation and enrichment procedures (Keddie and Shaw, 1986)

Species of the genus may be isolated by making use of their unusual cultural properties. Nutrient gelatin plates are inoculated heavily with a single, central streak of the material to be examined, or of a suspension or macerate of solid material in sterile water. The plates are incubated at 20°C with the lids upright and examined daily. Liquefaction of the gelatin around the streak soon occurs but in successful cultures filamentous outgrowths of *Kurthia* appear beyond this zone in 2–3 d. To obtain pure cultures, a small piece of nutrient gelatin containing outgrowths is streaked out on a suitable nutrient agar medium. Isolates are then examined for the characteristic properties of *Kurthia*: useful screening tests are colony form, morphology and Gram reaction, production of "bird's feather" growth on nutrient gelatin slants and aerobic growth in glucose nutrient agar shake cultures.

The composition of the nutrient gelatin medium used is important and, in particular, the concentration and brand of gelatin used; not all brands support the typical outgrowths. A nutrient gelatin (YNG; Keddie, 1981) of the following composition may be used (per liter of distilled water): meat extract (Lab Lemco powder, Oxoid), 4g; peptone (Difco), 5g; yeast extract (Difco), 2.5g; NaCl, 5g; gelatin (BDH Chemical Co., Poole,

UK), 100 g; pH 7.0. The medium is sterilized for 30 min (for quantities up to 100 ml). The medium should be inoculated with a reference strain of *Kurthia zopfii* (NCIB 9878) to test its ability to allow good outgrowth production. The gelatin manufactured by the BDH Chemical Co., Poole, England is satisfactory but, with some batches, a lower concentration than that stated may give more satisfactory outgrowths. Although all *Kurthia* strains tested grow well in yeast nutrient broth, YNB (YNG without gelatin), YNG prepared with some batches of gelatin has given poor growth. Dissolving the constituents of YNG in mineral base E (Owens and Keddie, 1969) to give MYNG (Shaw and Keddie, 1983b) overcomes this problem. A single central streak on a suitable nutrient agar often allows the detection and isolation of *Kurthia* and should be used in addition to the gelatin streak method in case rapid liquefaction of gelatin prevents the detection of *Kurthia*. YNA is inoculated with a single, central streak as described above. Yeast extract nutrient agar (YNA) has a composition similar to YNG but the gelatin is replaced by 12 g/l of Bacto-Agar (Difco). Plates are incubated at 25°C and each day the edge of the streak is scanned by low power (100×) microscope for the characteristic skein-like outgrowths of *Kurthia*. Pure cultures are obtained by picking carefully from outgrowths and streaking on YNA.

Maintenance procedures

Kurthia species grow well on media such as YNA (described above) at 25°C. YNA cultures should remain viable for at least

6 months at room temperature (20°C) provided they are not allowed to dry out. They may be preserved for long periods by lyophilization.

Differentiation of the genus *Kurthia* from other genera

The 16S rRNA gene sequence similarities, in combination with absence of endospores, strictly aerobic growth and bird's feather-like growth on gelatin nutrient agar unambiguously assign new Gram-positive isolates to the genus *Kurthia* (Table 66). Peptidoglycan of the Lys-Asp type is another characteristic trait.

Differentiation of the species of the genus *Kurthia*

DNA–DNA similarity studies of a few strains (some atypical) support the conclusion that *Kurthia zopfii*, *Kurthia gibsonii* and *Kurthia sibirica* are distinct species with DNA similarity values ranging between 20 and 40% (Cherevach et al., 1983). Chemotaxonomically the type strains of the species can be differentiated on the basis of qualitative and quantitative differences in their fatty acid profiles. The circumscription of the genus as given in the First Edition of Bergey's Manual of Systematic Bacteriology (Keddie and Shaw, 1986) was based on the characters of *Kurthia zopfii* and *Kurthia gibsonii*. Both species were shown to resemble each other closely in the numerical phenetic study of Shaw and Keddie (1983b). In order to compare the type strains of the three species on

^hPersonal data.

the same information basis, BIOLOG substrate panels were tested (Table 67).

In general, physiological reactions are weak, leading to many weak or doubtful positive reactions (Table 67; see also Keddie and Jones, 1992). Physiological similarities between *Kurthia zopfii* and *Kurthia gibsonii* support the phylogenetic adjacent position of the two type strains in the phylogenetic tree (Figure 66). Nevertheless these two species can be differentiated from each other by a few reactions, notably utilization of *N*-acetyl- β -D-glucosamine and γ -hydroxybutyric acid by *Kurthia zopfii*. *Kurthia sibirica* shows a more distinct metabolic pattern as it utilizes D-fructose, D-mannose and D-psicose, but fails to utilize uridine-5'-monophosphate, succinic acid monomethylester and pyruvic acid methyl ester. The riboprint patterns of the three type strains are distinct (Figure 67).

Clinical sources. Reports on the authenticity of *Kurthia* species isolated from various clinical sources (Faoagali, 1974; Severi, 1946; Yang et al., 1985) and most frequently from the feces of patients suffering from diarrhea (Elston, 1961; Jarumilinta et al., 1976) should be taken with caution as none of these strains may have been properly classified. Also, in all of these cases, the connection between the occurrence of the pre-

FIGURE 67. Diversity of normalized *Eco*RI ribotype patterns found within the type strains of the genus *Kurthia*. Automated ribotyping was carried out by using the RiboPrinter Microbial Characterization system (Qualicon). The analysis is based on the detection of polymorphism that exists within and around the *rm* operons of the strains.

sumptive *Kurthia* and the clinical condition was, at most, tenuous. Some organisms were considered to be "*Kurthia bessonii*" or "*Kurthia variabilis*", neither of which was included in the Approved Lists of Bacterial Names (Skerman et al., 1980) and are therefore not legitimate species.

List of species of the genus *Kurthia*

1. ***Kurthia zopfii*** (Kurth) Trevisan 1885, 92^{AL}. nom. cons. *Opin.* 13, *Jud. Comm.* 1954, 152 (*Bacterium zopfii* Kurth 1883, 98) *zop'fi*.i. M.L. gen. n. *zopfii* of Zopf, named for W. Zopf, a German botanist.

The description is based on the emended description of Shaw and Keddie (1983b) and personal data. Morphology and general characteristics are given in the generic description. Other characteristics are given in Table 66 and Table 67.

Polar lipids are available only for one strain (NCTC 404, Collins et al., 1979; Goodfellow et al., 1980). Major fatty acids are C_{15:0 iso} (42.9%) and C_{15:0 ante} (39.3%); C_{14:0} (1.7%), C_{14:0 iso} (6.8%), C_{16:1 ω₇EtOH} (1.5%), C_{16:1 ω₁₁c} (2.0%), and C_{16:0} (4.6%) occur in smaller amounts.

DNA G+C content (mol%): 36–38 (*T_m*) (Keddie, 1981; Shaw S. and Keddie, 1984).

Type strain: NCIB 9878 (DSM 20580).

GenBank accession number (16S rRNA gene): X70321.

2. ***Kurthia gibsonii*** Shaw and Keddie 1983b, 672 (Effective publication: Shaw and Keddie 1983b, 268.)

gib'son.i.i. M.L. gen. n. *gibsonii* of Gibson, named for T. Gibson.

The description is based on that of Shaw and Keddie (1983b) supplemented with personal data. Morphology and general characteristics are given in the generic description. Growth occurs at 40°C; acid is formed from butane-1-ol; n-octanoate, crotonate, DL-lactate, oxalacetate, and L-alanine are utilized. There is no production of H₂S. Other characteristics are given in Table 66 and Table 67.

Data on the isoprenoid quinones and polar lipids are available for four strains (Collins et al., 1979; Goodfellow et al., 1980). Major fatty acids are C_{14:0 iso} (8.9%), C_{15:0 iso} (26.8%), C_{15:0 ante} (31.1%) and C_{16:0 iso} (8.8%); C_{14:0} (1.2%), C_{15:0} (4.3%), C_{16:1 ω₁₁c} (4.1%), C_{16:0} (6.0%), C_{17:0 iso} (1.7%) and C_{17:0 ante} (4.6%) occur in smaller amounts. When supplied with a suitable source of amino acids cells require biotin and thiamine (Shaw and Keddie, 1983a).

DNA G+C content (mol%): 36–38 (*T_m*) (Keddie, 1981; Shaw S. and Keddie, 1984).

Type strain: NCIB 9758 (DSM 20636).

GenBank accession number (16S rRNA gene): X70320.

3. ***Kurthia sibirica*** Belikova, Cherevach and Kalakutskii 1988, 220^{VL} (Effective publication: Belikova, Cherevach and Kalakutskii 1986, 834.)

si.bi'ri.ca. M.L. fem. adj. *sibirica* (Siberian) from Siberia where it was found in a mammoth from which the bacteria were isolated.

The description is based on the original description of Belikova et al. (1986) supplemented with personal data. General characteristics are consistent with those given in the generic description. Other characteristics are given in Table 66 and Table 67.

Cells are regular rods with rounded ends, 0.6–1.0 μm in diameter. They vary in length with age: in young cultures from 5–10 μm or long filaments and in old cultures from 2–5 μm, but not coccoid. Colonies and smears are gray-cream or yellow, depending on culturing conditions. A yellow pigment, probably a carotenoid (absorption maxima ranging between 400 and 480 nm), is produced. Nutritional requirements are complex. It grows well in media containing peptone and yeast extract. Requires biotin, thiamine, pantothenate, nicotinic acid and pyridoxal-5-phosphate. Blood is hemolysed. Growth occurs between 5–37°C, fresh isolates may grow at 0–1°C, the optimum temperature for growth is in the 20–25°C range. Growth occurs in a pH ranging from 5.5–9.5. No growth occurs at 7% NaCl. Cells are phosphatase positive, urease and lecithinase negative, and do not hydrolyze starch. Acid is formed from fructose and glycerol. No acid is produced from glucose, ribose and ethanol. Major fatty acids are C_{15:0 iso} (65.4%), C_{15:0 ante} (12.2%) and C_{17:1 ω₁₀c} (6.5%); C_{14:0 iso} (2.0%) C_{16:1 ω₇EtOH} (1.4%) C_{16:0 iso} (1.1%) C_{16:1 ω₁₁c} (3.6%) C_{16:0} (2.4%) C_{17:0 iso} (2.5%) and C_{17:0 ante} (1.4%) occur in smaller amounts.

Kurthia sibirica is sensitive to penicillin (2 units), streptomycin (2 units), erythromycin (2 μg), novobiocin (5 μg) neomycin (5 μg), oleandomycin (5 μg), polymyxin B (300 μg) and to 0.1% chlorous triphenyltetrazole added to the medium.

Isolated from the intestinal tract and the stomach of a mammoth in the Magadan province of Siberia.

DNA G+C content (mol%): 37.

Type strain: 13-2 (VKM B-1549, ATCC 49154, DSM 4747).

GenBank accession number (16S rRNA gene): AJ605774.

Genus VI. ***Marinibacillus*** Yoon, Weiss, Lee, Lee, Kang and Park 2001c, 2092^{VP} emend. Yoon, Kim, Schumann, Oh and Park 2004, 1320

JEROEN HEYRMAN AND PAUL DE VOS

Ma.ri.ni.ba.cil'lus. L. adj. *marinus* of the sea; L. n. *bacillus* rod; N.L. masc. n. *Marinibacillus* rod of the sea.

Rod-shaped, **Gram-positive** (may be Gram-variable in older cultures) bacterium, 0.8–1.6 μm in diameter and 2.0–7.0 μm in length. Endospores are round to ellipsoidal and are located

centrally, terminally, or subterminally. The sporangia are not swollen or are only slightly swollen. Strains without the ability to form endospores have been isolated. **Cell wall peptidoglycan**

contains L-lysine at position 3 of the peptide subunit. Filaments present. Motile by single polar flagellum or peritrichous (degenerated) flagella. Obligately aerobic. **Strains require sea water or marine agar for growth.** The optimum NaCl concentration for growth varies between 1.2 and 3%, while growth in 10% NaCl is variable. Strains are **psychrophilic or psychrotolerant with growth at 1–4°C**; some strains may grow up to 39°C whereas others do not grow above 4–8°C. Catalase-positive. No reduction of nitrate to gas is observed. **The predominant menaquinone is MK-7** and the predominant fatty acids are C_{15:0 iso} and C_{15:0 ante}.
DNA G+C content (mol%): 33.9–41.8.

Type species: Marinibacillus marinus (Rüger and Richter 1979) Yoon, Weiss, Lee, Lee, Kang and Park 2001b, 2092^{VP} (*Bacillus globisporus* subsp. *marinus* Rüger and Richter 1979, 196; *Bacillus marinus* Rüger 1983, 157 emend. Rüger, Fritze and Spröer 2000, 1310.).

Further descriptive information

Colonies on sea water agar are round with entire margin, flat to raised, colorless, mostly translucent; light orange pigment may be formed. Colony diameter of 2–3 mm may be obtained after three days while a diameter of 1–2 mm is reached after 2 weeks of incubation on sea water medium.

Strains of *Marinibacillus marinus* have been isolated from sediments of the Iberian deep-sea, the tropical Atlantic, and the Arctic and Antarctic Oceans. Taking into consideration the known deep-water circulation in the polar and tropical sectors of the Atlantic Ocean (Hollister and McCave, 1984; Mantayla and Reid, 1983), it is assumed that the origin of *Marinibacillus marinus* was in the Antarctic and that the species spread from there to the north. The ability to form endospores as a survival strategy may not be necessary in environments with long periods of uniform environmental conditions, like the deep-sea. This may explain why endospores could be detected in only a few of the *Marinibacillus marinus* isolates. Additional information on the biochemical characteristics of *Marinibacillus* species can be found in Rüger, 1983; Rüger et al., (2000), and Yoon et al., (2001b), (2004).

Enrichment and isolation procedures

Strains grow on sea water medium and/or Marine Agar. Good growth occurs between 2 d and 2 weeks of incubation, but the extremely psychrophilic strains require longer incubation times of up to 4 weeks at 4°C.

Differentiation of the genus *Marinibacillus* from other genera

Sequence analysis of the 16S rDNA revealed the closest phylogenetic relation of the type strain of *Marinibacillus marinus* to be the type strain of *Jeotgalibacillus alimentarius*, the only species within the genus *Jeotgalibacillus* (95.7% similarity). However, there are some physiological differences. Whereas *Marinibacillus marinus* shows slight growth at 7% NaCl and no growth at 10% NaCl, *Jeotgalibacillus alimentarius* grows at 20% NaCl. *Marinibacillus marinus* is a psychrophile, while *Jeotgalibacillus alimentarius* is a mesophile. Also, some chemotaxonomic properties are important to distinguish *Marinibacillus* from *Jeotgalibacillus*. Whereas *Marinibacillus* has C_{15:0 ante} as the predominant fatty acid, *Jeotgalibacillus* is characterized by the predominance of C_{15:0 iso}. Furthermore, the menaquinone profile of *Jeotgalibacillus* is characterized by the predominance of MK-7 (62%) followed by MK-8 (35%), whereas *Marinibacillus* has 87% MK-7 and no MK-8. Other round spore-forming bacilli, originally belonging to rRNA group 2, can be discriminated from *Marinibacillus* rather easily by comparative 16S rDNA analysis.

Taxonomic comments

The genus *Marinibacillus* now encompasses two species, *Marinibacillus marinus* and *Marinibacillus campisalis*, which both can be regarded as illegitimate because they belong to a genus of which the type species was not validly published. The first species was originally described as *Bacillus globisporus* subsp. *marinus* (Rüger and Richter, 1979) and later elevated to the species level as *Bacillus marinus* (Rüger, 1983). An emended description of the species has been formulated (Rüger et al., 2000) and a reclassification to *Marinibacillus marinus* was proposed (Yoon et al., 2001c).

Marinibacillus is phylogenetically related to members of *Bacillus* rRNA group 2 and forms a coherent cluster with *Jeotgalibacillus*. The phylogenetic relationship between *Marinibacillus*, *Jeotgalibacillus*, and members of *Bacillus* rRNA group 2 is found with the tree-based neighbor-joining algorithm and in trees generated by the maximum-likelihood and maximum-parsimony algorithms. Species of the *Bacillus* rRNA group 2 may deserve to be separated at the generic level from the genus *Bacillus*. The genera *Sporosarcina* (Yoon et al., 2001b), *Jeotgalibacillus* (Yoon et al., 2001c), and *Marinibacillus* (Yoon et al., 2001c) can be considered as a next step in the further splitting of the former genus *Bacillus sensu* Claus and Berkeley (1986).

List of species of the genus *Marinibacillus*

1. ***Marinibacillus marinus*** (Rüger and Richter 1979) Yoon, Weiss, Lee, Lee, Kang and Park 2001c, 2092^{VP} (*Bacillus globisporus* subsp. *marinus* Rüger and Richter 1979, 196; *Bacillus marinus* Rüger 1983, 157 emend. Rüger, Fritze and Spröer 2000, 1310.) ma.ri'nus. L. adj. *marinus* of the sea.

Gram-positive rods, 0.8–1.1 × 2.0–7.0 µm. Filaments present. Single or in pairs. Motile strains are peritrichously flagellated or show degenerated flagella. The spores are terminally or subterminally located. Cells without the ability to form spores have been isolated. Colonies on sea water agar are round with entire margin, flat to raised, colorless, mostly translucent with

a diameter of 1–2 mm after 2 weeks of incubation. Growth occurs at 1–4°C. The highest maximum growth temperature was 30°C and numerous strains did not grow at temperatures exceeding 4 or 8°C. Catalase-positive, aerobic acid production from glucose-positive in MOF medium. Further detailed biochemical characterization is given in Table 68.

DNA G+C content (mol%): 38 (HPLC).

Type strain: 581, ATCC 29841, CCUG 28884, CIP 103308, DSM 1297, LMG 6930, NCMB 2140, NRRL B-14321.

EMBL/GenBank accession number (16S rDNA): AB021190, AJ237708. This suggested change is unclear to me: it is well

^aSymbols: +, property of the species; -, not a property of the species; w, weakly positive reaction; D, variable reaction. Data from Ruger et al., (2000) and Yoon et al., (2001c), (2004).

^bData in the literature show some contradictions.

known that there are often various 16S sequences available of the same strain - in this case the type strain -, but they do not always have the same quality. Although there might even be more than one sequence of good quality we have preferred

here to give only one accession number with the indication between brackets of the subculture that has been reported to link with that particular accession number. This is the reason why only one accession number has been mentioned.

2. **Marinibacillus campisalis** Yoon, Kim, Schumann, Oh and Park 2004, 1320^{VP}

cam.pi.sa'lis. L. n. *campus* field; L. gen. n. *salis* of salt; N.L. gen. n. *campisalis* of the field of salt.

Contains only one strain. Cells are rods, 1.3–1.6 × 2.5–4.0 μm. Gram-positive, but Gram-variable in older cultures. Round to ellipsoidal endospores lie centrally or subterminally in slightly swollen sporangia. Colonies are smooth, glistening, circular to slightly irregular, flat to raised, light orange–yellow in color and 2–3 mm in diameter after 3 d incubation on marine agar. Growth occurs at 4°C; maximum growth temperature is 39°C. Optimal pH for growth is 7.0–8.0; no growth occurs at pH 4.5.

Optimal growth occurs in the presence of 2–3% (w/v) NaCl. Growth occurs in the presence of 15% NaCl, but not 16% NaCl. Xylan is not hydrolyzed. Acid is produced from D-fructose and melibiose and weakly produced from D-melezitose. Acid is not produced from adonitol, D-galactose, myo-inositol, D-ribose, or stachyose. Other characteristics are given in Table 68. The peptidoglycan type is A1 (L-Lys direct). The predominant menaquinone is MK-7. The major fatty acid is C_{15:0 ante}. Isolated from marine solar saltern in Korea.

DNA G+C content (mol%): 41.8 (HPLC).

Type strain: SF-57, JCM 11810, KCCM 41644.

EMBL/GenBank accession number (16S rDNA): AY190535.

Genus VII. **Planomicrobium** Yoon, Kang, Lee, Lee, Kho, Kang and Park 2001a, 1518^{VP}

JUNG-HOON YOON, BYUNG-CHUN KIM AND YONG-HA PARK

Pla.no.mi.cro'bi.um. Gr. n. *planos* wanderer; Gr. adj. *micros* small; Gr. n. *bios* life; N.L. neut. n. *microbium* microbe; N.L. neut. n. *Planomicrobium* motile microbe.

Rods or rods to cocci/short rods in liquid culture and on plates usually 1.0–2.0 μm. Spores are not formed. **Gram-positive to Gram-variable. Motile by means of a single polar flagellum or peritrichous flagella.** Aerobic. Colonies on plates are circular, smooth, and **yellow to orange or pale orange** in color. Nitrate is or is not reduced to nitrite. Catalase-positive. Oxidase-negative or positive. Urease-negative. Hydrolysis of esculin, casein, starch, and Tween 80 are negative or positive. Hydrolysis of gelatin is positive. The menaquinone profile is characterized by the predominance of MK-8 followed by MK-7, or by the predominance of MK-8 followed by MK-7 and MK-6. The cellular fatty acids are mainly unsaturated and branched fatty acids (Table 69). The cellular phospholipids

are phosphatidylethanolamine, phosphatidylglycerol, and bisphosphatidylglycerol. In the 16S rRNA gene sequences, two sequence signatures, cytosine and guanine, are present at positions 183 and 190 (*Escherichia coli* numbering), respectively (Dai et al., 2005).

DNA G+C content (mol%): 34.8–47 (HPLC, T_m).

Type species: **Planomicrobium koreense** Yoon, Kang, Lee, Lee, Kho, Kang and Park 2001a, 1518^{VP}.

Further descriptive information

Phylogenetic analysis shows that *Planomicrobium* forms a distinct cluster containing four species previously described as *Planococcus* species, and the relationship between this cluster

^bData from Engelhardt et al. (2001) for *Planomicrobium alkanoclasticum* cultured on sea water agar (NCIMB medium 209); Yoon et al. (2001a) for *Planomicrobium koreense*, *Planomicrobium mcmeekinii*, and *Planomicrobium okeanokoites* cultured on marine agar; Reddy et al. (2002) for *Planomicrobium psychrophilum*; and Dai et al. (2005) for *Planomicrobium okeanokoites* cultured in marine broth.

and other species described as *Planococcus* is supported by bootstrap analysis at a confidence level of 100%. The 16S–23S internally transcribed spacer (ITS) sequence similarity and DNA–DNA relatedness values between *Planomicrobium koreense* and the type strains of other *Planococcus* species are in the range 74.6–83.2% and 10.4–20.5%, respectively. Cell wall peptidoglycan type is L-Lys-D-Glu or L-Lys-D-Asp. *Planomicrobium alkanoclasticum* MAE2 (basonym: *Planococcus alkanoclasticus*) degrades linear and branched alkanes from C11–C33 (Engelhardt et al., 2001). *Planomicrobium okeanokoites* IFO 12536 (basonym: *Flavobacterium okeanokoites*) produces *FokI* restriction endonuclease recognizing the nonpalindromic pentadeoxyribonucleotide 5'-GGATG-3':5'-CATCC-3' in duplex DNA and cleaving 9 and 13 nucleotides away from the recognition site, and adenine-N6-specific DNA-methyltransferase M.*FokI*, an adenine-N6-specific DNA-methyltransferase which specifically methylates both adenine residues within 5'-GGATG-3':5'-CATCC-3' sequences (Landry et al., 1989; Sugisaki and Kanazawa, 1981). Members of the genus *Planomicrobium* are currently represented by six species including four species reclassified from *Planococcus* (*Planomicrobium okeanokoites*, *Planomicrobium mcmeekinii*, *Planomicrobium psychrophilum*, and *Planomicrobium alkanoclasticum*), and two isolates (*Planomicrobium*

koreense and *Planomicrobium chinense*). Characteristics that are useful in differentiating members of the genus *Planomicrobium* are given in Table 70.

Enrichment and isolation procedures

Members of the genus *Planomicrobium* have been isolated from specimens related to marine environment such as seafood, coastal sediments, and Antarctic sea ice. For the isolation of *Planomicrobium*, media containing NaCl, marine agar (MA, Difco), or artificial sea water basal medium with 1% peptone and 0.5% yeast extract (Eguchi et al., 1996) may be used.

Maintenance procedures

Members of the genus *Planomicrobium* may be maintained on marine agar for short term storage at 4°C. Freeze-drying is recommended for long term storage of members of this genus.

Taxonomic comments

Based on 16S rRNA gene sequence data, the closest relative of *Planomicrobium* is *Planococcus*. *Planomicrobium* is distinguishable from *Bacillus* species and the other genera belonging to the *Bacillus* rRNA group 2 by menaquinone type and lack of spore formation (Rheims et al., 1999).

List of species of the genus *Planomicrobium*

is inhibited at pH 5.5 and 10. Growth occurs in the presence of 0–6% NaCl but weakly in the presence of 7% NaCl and does not occur in the presence of more than 8% NaCl. The optimal concentration of NaCl for growth is 1–4%.

Acid is produced from esculin, cellobiose, maltose, lactose, melibiose, and 5-ketogluconate. No acid is produced from

glycerol, erythritol, D-arabinose, L-arabinose, ribose, D-xylose, L-xylose, adonitol, β -methyl-D-xyloside, galactose, fructose, mannose, sorbose, rhamnose, dulcitol, inositol, mannitol, sorbitol, α -methyl-D-mannoside, α -methyl-D-glucoside, N-acetylglucosamine, amygdalin, arbutin, salicin, sucrose, trehalose, inulin, melezitose, raffinose, starch, glycogen, xylitol, gentiobiose, D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, gluconate, or 2-ketogluconate. Isolated from the Korean traditional fermented seafood jeotgal.

DNA G+C content (mol%): 47 (HPLC).

Type strain: JG07, CIP 107134, JCM 10704, KCTC 3684.

GenBank accession number (16S rRNA gene): AF144750.

2. **Planomicrobium alkanoclasticum** (Engelhardt, Daly, Swannell and Head 2001) Dai, Wang, Wang, Liu and Zhou 2005, 702^{VP} (*Planococcus alkanoclasticus* Engelhardt, Daly, Swannell and Head 2001, 245.)

al.kan.o.cla'sti.cum. N.L. n. *alkanum* alkane; Gr. adj. *clastos* broken; N.L. neut. adj. *alkanoclasticum* breaking alkanes.

The following description is taken from the original paper. Cells are rods that are 0.4–0.8 μ m wide and 1.7–2.6 μ m long. Gram-positive, though Gram stain reaction may be variable. Chemo-organotroph with respiratory metabolism. Colonies on marine agar or nutrient agar with 0.8% NaCl are orange pigmented. Temperature range for growth is 15–41 $^{\circ}$ C. Obligate requirement for NaCl but will not grow at NaCl concentrations of 6% or greater.

Produce DNase and phosphatase. Negative tests were obtained for the utilization of α -cyclodextrin, β -cyclodextrin, dextrin, glycogen, inulin, mannan, N-acetyl-D-glucosamine, N-acetyl-D-mannosamine, amygdalin, L-arabinose, D-arabitol, arbutin, cellobiose, D-fructose, L-fucose, D-galactose, D-galacturonic acid, gentiobiose, D-gluconic acid, α -D-glucose, *m*-inositol, α -D-lactose, lactulose, maltose, maltotriose, D-mannitol, D-mannose, D-melezitose, D-melibiose, α -methyl-D-galactoside, β -methyl-D-galactoside, 3-methyl glucose, α -methyl-D-glucoside, β -methyl-D-glucoside, α -methyl-D-mannoside, palatinose, D-psicose, D-raffinose, L-rhamnose, D-ribose, salicin, seduheptulosan, D-sorbitol, stachyose, sucrose, D-tagatose, D-trehalose, turanose, xylitol, D-xylose, acetic acid, α -hydroxybutyric acid, β -hydroxybutyric acid, γ -hydroxybutyric acid, *p*-hydroxyphenylacetic acid, α -ketoglutaric acid, α -ketovaleric acid, lactamide, D-lactic acid methyl ester, L-lactic acid, D-malic acid, L-malic acid, methyl pyruvate, monomethylsuccinate, propionic acid, pyruvic acid, succinamic acid, succinic acid, N-acetyl L-glutamic acid, alaninamide, D-alanine, L-alanine, L-alanyl-glycine, L-asparagine, L-glutamic acid, glycyl-L-glutamic acid, L-pyroglytamic acid, L-serine, putrescine, 2,3-butanediol, glycerol, adenosine, 2'-deoxyadenosine, inosine, thymidine, uridine, adenosine-5'-monophosphate, thymidine-5'-monophosphate, uridine-5'-monophosphate, fructose-6-phosphate, glucose-1-phosphate, glucose-6-phosphate, and DL- α -glycerol. Isolated from intertidal beach sediment.

DNA G+C content (mol%): 45.3 \pm 0.4% (HPLC, n. 4).

Type strain: MAE2, CIP 107718, NCIMB 13489.

GenBank accession number (16S rRNA gene): AF029364.

3. **Planomicrobium chinense** Dai, Wang, Wang, Liu and Zhou 2005, 701^{VP}

chin.en'se. N.L. neut. adj. *chinense* from China.

Cells are coccoid or short rods, $0.8 \times 1.0 \mu\text{m}$. Gram-positive. Motile by polar flagella. Strictly aerobic. Colonies are smooth, circular, low-convex, and yellow to orange in color when cultivated on MA. Temperature range for growth is $10\text{--}45^\circ\text{C}$, but growth does not occur at 46°C . The optimal growth temperature is $30\text{--}35^\circ\text{C}$. Optimal pH for growth is $6.0\text{--}7.0$; no growth occurs below pH 5.0 or above pH 10.0.

Acid is not produced from sucrose, raffinose, lactose, arabinose, cellobiose, xylose, rhamnose, melibiose, mannose, or mannitol. Citrate does not support growth.

Isolated from coastal sediment from the Eastern China Sea in Fujian Province, China.

DNA G+C content (mol%): 34.8 (T_m).

Type strain: DX3-12, AS 1.3454, JCM 12466.

GenBank accession number (16S rRNA gene): AJ697862.

4. **Planomicrobium mcmeekinii** (Junge, Gosink, Hoppe and Staley 1998) Yoon, Kang, Lee, Lee, Kho, Kang and Park 2001a, 1519^{VP} (*Planococcus mcmeekinii* Junge, Gosink, Hoppe and Staley 1998, 312.)

mc.mee.kin'i.i. N.L. gen. n. *mcmeekinii* of McMeekin named after Thomas A. McMeekin, Australian microbiologist.

Cells are rod-shaped, $0.8\text{--}1.2 \times 0.8\text{--}10 \mu\text{m}$ long, and occur singly. Gram-positive. Aerobic. Colonies are pale orange, circular, convex, undulate on SWCm agar (Irgens et al., 1989). Growth from $0\text{--}37^\circ\text{C}$. Tolerate up to 14% NaCl. Oxidative and fermentative glucose metabolism in MOF medium of Leifson. Halotolerant. No sodium requirement.

Utilize propionate, pyruvate, acetate, and malate as sole carbon source. Isolated from Antarctic sea ice.

DNA G+C content (mol%): 35 (HPLC).

Type strain: S23F2, ATCC 700539, CIP 105673.

GenBank accession number (16S rRNA gene): AF041791.

5. **Planomicrobium okeanokoites** (Zobell and Upham 1944) Yoon, Kang, Lee, Lee, Kho, Kang and Park 2001a, 1518^{VP} (*Flavobacterium okeanokoites* ZoBell and Upham 1944; *Planococcus okeanokoites* Nakagawa, Sakane and Yokota 1996, 869.)

o.ke.a.no.ko.i'tes. Gr. masc. n. *okeanos* the ocean; Gr. fem. n. *choite* bed; N.L. fem. gen. n. *okeanokoites* of the ocean bed.

Cells are rods $0.4\text{--}0.8 \times 1.0\text{--}20 \mu\text{m}$ long. Most cells are less than $2.8 \mu\text{m}$ long. Gram-positive to Gram-variable in medium containing NaCl. Gram-negative in medium without NaCl. Motile by means of peritrichous flagella. Strict aerobes. The color of the cell mass is usually bright yellow to bright orange. Chemo-organotrophs. Metabolism is respiratory. The optimum temperature range for growth is $20\text{--}37^\circ\text{C}$. The optimum level of salinity for growth is 3–5% NaCl. No growth occurs in the presence of more than 7% NaCl.

The following tests are positive: arginine dihydrolase, lysine decarboxylase, and ornithine decarboxylase. The following tests are negative: methyl red, Voges–Proskauer reaction, indole production, phenylalanine deaminase, hydrolysis of

cellulose, and decomposition of tyrosine. Acid is not produced from D-galactose, L-arabinose, D-xylose, sucrose, maltose, lactose, or mannitol in Hugh–Leifson O-F medium. The molar ratio of the amino acids glutamic acid, lysine, alanine, and aspartic acid in the cell wall is 1:1:2:1. Isolated from marine mud.

DNA G+C content (mol%): 46.3 (HPLC).

Type strain: ATCC 33414, CCM 320, CIP 105082, NBRC 12536, LMG 4030, NCIMB 561, VKM B-1175.

GenBank accession number (16S rRNA gene): D55729.

6. **Planomicrobium psychrophilum** (Reddy, Prakash, Vairamani, Prabhakar, Matsumoto and Shivaji 2002) Dai, Wang, Wang, Liu and Zhou 2005, 702^{VP} (*Planococcus psychrophilus* Reddy, Prakash, Vairamani, Prabhakar, Matsumoto and Shivaji 2002, 260.)

psy.chro.phi'lum. Gr. n. *psychros* cold; Gr. adj. *philos* loving; N.L. neut. adj. *psychrophilum* cold-loving.

Cells are rod-shaped, single, and Gram-positive. Colonies on peptone–yeast extract medium are orange, smooth, convex, circular, and 1–2 mm in diameter. Growth occurs at $2\text{--}30^\circ\text{C}$. The optimal growth temperature is 22°C . Cultures can grow at pH 6–12, optimum growth at pH 7, and they tolerate up to 12% NaCl. Pigment is insoluble in water but soluble in methanol and exhibits absorption maxima at 440, 465, and 487.5 nm. Pigment synthesis is not dependent on the growth phase or the growth conditions.

Can hydrolyze esculin. Lipase, β -galactosidase, and arginine dihydrolase-positive, but negative with respect to phosphatase, indole production, the methyl red and Voges–Proskauer tests, and levan formation. Can utilize rhamnose, melibiose, trehalose, xylose, glycerol, lysine, sodium acetate, sodium succinate, inositol, glutamic acid, and pyruvate, but not glucose, lactose, sorbose, arabinose, cellobiose, sucrose, fructose, mannose, mannitol, raffinose, ribose, lactose, lactic acid, adonitol, maltose, glucosamine, sorbitol, melizitol, β -hydroxybutyric acid, dulcitol, dextran, PEG, glycine, sodium citrate, cellulose, inulin, alanine, phenylalanine, methionine, glutamine, arginine, serine, potassium hydrogen phthalate, myristic acid, creatinine, tyrosine, or glycogen as the sole carbon source. Further, it does not produce acid or gas from sucrose, cellobiose, lactose, sodium glutamate, or sodium thioglycolate.

It is sensitive to penicillin, chlortetracycline, chloramphenicol, neomycin, streptomycin, novobiocin, tetracycline, bacitracin, furazolidone, colistin, kanamycin, lincomycin, cotrimoxazole, ampicillin, amoxycillin, trimethoprim, erythromycin, nalidixic acid, nystatin, gentamicin, and polymyxin B, but resistant to carbenicillin, tobramycin, oxytetracycline, nitrofurazone, and nitrofurantoin. Isolated from a cyanobacterial mat sample from McMurdo Dry Valleys, Antarctica.

DNA G+C content (mol%): 44.5 (T_m).

Type strain: CMS 53or, DSM 14507, MTCC 3812.

GenBank accession number (16S rRNA gene): AJ314746.

Genus VIII. **Sporosarcina** Kluver and van Niel 1936, 401^{AL} emend. Yoon, Lee, Weiss, Kho, Kang and Park 2001b, 1085

THE EDITORIAL BOARD

Spo.ro.sar.ci'na. Gr. n. *spora* a spore; L. fem. n. *sarcina* a package, bundle; N.L. fem. n. *Sporosarcina* a sporeforming package.

Endospore forming cocci or rods. Gram positive or variable. Most species are motile. **Strict or facultative aerobes.** Catalase positive. Most species are also oxidase and urease positive. Nitrate reduction to nitrite is variable. Optimum growth temperature and pH are 20–30°C and 6.5–8, respectively. Many species grow at low temperatures <10°C. Many species are also halotolerant and grow at <3–15% NaCl. Cell wall peptidoglycan contains L-lysine at position 3 of the peptide subunit and is the A4 α type. **The principal menaquinone is MK-7. Major fatty acid is C_{15:0 ante}.**

DNA G + C content (mol%): 38–46.5.

Type species: **Sporosarcina ureae** (Beijerinck 1901) Kluver and van Niel 1936, 401^{VP} (*Planosarcina ureae* Beijerinck 1901, 52).

Further descriptive information

Coherent clustering of the nine species of *Sporosarcina* is suggested by sequence analyses of the 16S rRNA gene. One study found that *Sporosarcina saromensis* forms a cluster with the type strains for *Sporosarcina aquimarina* (97.3% similarity), *Sporosarcina globispora* (96.9%), *Sporosarcina psychrophila* (96.8%), *Sporosarcina ureae* (96.8%), *Sporosarcina pasteurii* (96.0%), and

Sporosarcina macmurdoensis (95.9%) (An et al., 2007). Another study found that *Sporosarcina koreensis* forms a cluster with the type strains for *Sporosarcina soli* (98.9%), *Sporosarcina globispora* (97.3%), *Sporosarcina aquimarina* (97.2%), and *Sporosarcina psychrophila* (96.9%) (Kwon et al., 2007).

Though similar in phenotypic and physiological characteristics, *Sporosarcina* species may also be distinguished on the basis of phenotypic differences (see Table 71). The cells of some species occur singly or in pairs (*Sporosarcina globisporus*, *Sporosarcina koreensis*, and *Sporosarcina macmurdoensis*), whereas others also form clusters or short chains (*Sporosarcina psychrophila* and *Sporosarcina soli*). Endospores can be terminal (*Sporosarcina aquimarina*, *Sporosarcina globispora*, *Sporosarcina koreensis*, *Sporosarcina pasteurii*, *Sporosarcina psychrophila*, and *Sporosarcina saromensis*), subterminal (*Sporosarcina macmurdoensis*), or central (*Sporosarcina soli*). Only two species are nonmotile (*Sporosarcina macmurdoensis* and *Sporosarcina soli*). All species tested are catalase positive. Only one species is negative for urease and oxidase (*Sporosarcina macmurdoensis*). While *Sporosarcina pasteurii* is positive for urease, it has not been tested for catalase and oxidase.

Isolation and enrichment procedures

Isolation is best achieved by plating soil or water dilutions on an appropriate agar. The growth of *Sporosarcina ureae* can be enhanced by addition of 3% urea. Two methods for isolating *Sporosarcina ureae* are described in detail in Claus et al. (1991) and include Claus's 1981 modification of Gibson's method and the method used by Pregerson in 1973. In the former, about 5 g of dried soil was suspended in 20 ml of sterile tap water, and the suspension was diluted 1:10 and 1:100. About 0.1 ml of each dilution was streaked on nutrient agar plates (peptone, 5 g; meat extract, 3 g; agar, 15 g; distilled water, 100 ml) supplemented with 30–100 g urea/liter. After incubation at 25°C for 3 or more days, colonies were visible under a dissecting microscope or by transmitted light. Colonies were checked microscopically for the sarcina morphology and restreaked on nutrient agar containing 1% urea for purification. Testing motility and endospore formation was used to confirm the provisional identification.

The second method used tryptic soy yeast extract agar (Difco Tryptic Soy Broth, 27.5 g; Difco Yeast Extract, 5.0 g; glucose, 5.0 g; Bacto Agar, 15.0 g; distilled water, 1000 ml), which was adjusted to pH 8.5 with NaOH before sterilization. After sterilization, a filter-sterilized urea solution was added to give a final concentration of 1% (Claus and Fahmy, 1986). If cells from picked colonies exhibited motile tetrads and/or packets under the microscope, the colonies were restreaked on the same medium for further purification.

Other species were isolated by a variety of methods. *Sporosarcina aquimarina* was isolated on trypticase soy agar (TSA) supplemented with artificial sea water (pH 7.5) (Yoon et al., 2001b). *Sporosarcina koreensis* and *Sporosarcina soli* were isolated upon dilution and plating of soil on TSA (30°C for 2 days) (Kwon et al., 2007). *Sporosarcina macmurdoensis* was isolated from a suspension of cyanobacterial mat after plating on ABM agar (0.5% peptone, 0.2% yeast extract, 1.5% agar, pH 7.2) (Reddy et al., 2003). *Sporosarcina saromensis* was isolated from surface water of Lake Saroma or marine sediment by plating on JCM57 medium (10 g of glucose, 1.0 g of asparagine, 0.5 g of K₂HPO₄, 2.0 g of yeast extract, 15 g of agar per liter of distilled water, pH adjusted to 7.3) or 1/10 diluted marine agar 2216 (An et al., 2007).

Maintenance procedures

Sporosarcina ureae vegetative cultures grown on nutrient agar are viable for up to a year when stored at 4–10°C in the dark. Endospores survive several years in screw-capped tubes under the same conditions (Claus and Fahmy, 1986). In general, strains of *Sporosarcina ureae* form spores in nutrient agar supplemented with urea (final concentration 0.2%) if incubated at 25°C. Addition of 50 mg of MnSO₄·H₂O per liter may enhance sporulation. Good sporulation can also be expected in the medium of MacDonald and MacDonald (1962) (see Claus and Fahmy, 1986).

Cryopreservation is recommended for long term storage. Cryoprotectants in use include skim milk (20%, w/v), serum containing 5% meso-inositol, glycerol (10%), and DMSO (5%).

Differentiation of the genus *Sporosarcina* from other species

The genus belongs to the family *Planococcaceae* and can be differentiated from other family members on the basis of its morphology, chemotaxonomic markers and 16S rRNA sequence. Species of *Sporosarcina* form coccoid or rod-shaped cells and round or oval endospores. Most species are motile. All species described so far possess MK-7 as the major menaquinone and an A4 α peptidoglycan type in the cell wall (Reddy et al., 2003).

Taxonomic comments

Nine species are currently assigned to the genus *Sporosarcina*. In the last edition of *Bergey's Manual of Systematic Bacteriology*, this genus comprised the type species, *Sporosarcina ureae*, and *Sporosarcina halophila* (Claus and Fahmy, 1986). However, subsequent 16S rRNA sequence analyses led to the reassignment of the latter species to a new genus, *Halobacillus* (Spring et al., 1996). Further analyses of *Bacillus* species discovered close relationships of *Bacillus globisporus*, *Bacillus psychrophilus*, and *Bacillus pasteurii* to *Sporosarcina ureae*, and these organisms were reclassified as *Sporosarcina globispora*, *Sporosarcina psychrophila*, and *Sporosarcina pasteurii*, respectively (Yoon et al., 2001b). Five additional species have also been isolated in soil and water samples.

List of species of the genus *Sporosarcina*

1. ***Sporosarcina ureae*** (Beijerinck 1901) Kluver and van Niel 1936, 401^{AL} (*Planosarcina ureae* Beijerinck 1901, 52.)
ure.ae. N.L. n. *urea* urea; N.L. gen. n. *ureae* of urea.

The description is the same as for the genus except as follows. Cells are spherical or oval cocci (1.0–2.5 μ m in diameter). They occur singly, in pairs, tetrads, and in packets of eight or more cells as a result of division in two or three perpendicular planes. Endospores are 0.5–1.5 μ m in diameter. Cells are motile, and flagella are randomly spaced. Colonies are gray or cream, becoming yellowish, orange, or brown depending upon the strain and medium. Negative for acid production from D-glucose and D-xylose. In nature, it may play an active role in urea decomposition. Other characteristics are described in Table 71.

DNA G + C content (mol%): 40–42 (T_m).

Type strain: ATCC 6473, DSM 2281, JCM 2577, LMG 17366, NBRC 12699, VKM B-595.

GenBank accession number (16S rRNA gene): AF202057.

2. ***Sporosarcina aquimarina*** Yoon, Lee, Weiss, Kho, Kang and Park 2001b, 1084^{VP}

a.qui.ma.ri'na. L. n. *aqua* water; L. adj. *marinus* of the sea; M.L. adj. *aquimarina* pertaining to sea water.

Cells are rods (0.9–1.2 μ m \times 2.0–3.5 μ m) that form round, terminal endospores in swollen sporangia in 3-day-old cultures on trypticase soy agar. Gram variable. Motile by means of a single polar flagellum. Colonies are light orange, smooth, circular to irregular, and raised on TSA. Grows in the presence of 13% NaCl but not in the presence of more than 14% NaCl. Growth occurs at 4 and 37°C, but not at 40°C. The opti-

mal growth temperature is 25°C. The optimal pH for growth is 6.5–7.0. Growth is inhibited below pH 5.0. Does not hydrolyze esculin, arbutin, casein, hypoxanthine, starch, Tween 80, and xanthine. Negative for deamination of arginine and production of indole. Acid is produced from *N*-acetylglucosamine, esculin, fructose, glycerol, 5-ketogluconate, ribose, and *D*-tagatose but not from erythritol, *D*-arabinose, *L*-arabinose, *D*-xylose, *L*-xylose, adonitol, β -methyl-*D*-xyloside, galactose, glucose, mannose, sorbose, rhamnose, dulcitol, inositol, mannitol, sorbitol, α -methyl-*D*-mannoside, α -methyl-*D*-glucoside, amygdalin, arbutin, salicin, cellobiose, maltose, lactose, melibiose, sucrose, trehalose, inulin, melezitose, raffinose, starch, glycogen, xylitol, gentiobiose, *D*-turanose, *D*-lyxose, *D*-fucose, *L*-fucose, *D*-arabitol, *L*-arabitol, gluconate, and 2-ketogluconate. The major fatty acid is $C_{15:0\text{ ante}}$. Isolated from sea water in Korea. Other characteristics are included in Table 71 and the genus description.

DNA G + C content (mol%): 40 (HPLC).

Type strain: SW28, JCM 10887, KCCM 41039.

GenBank accession number (16S rRNA gene): AF202056.

3. ***Sporosarcina globispora*** (Larkin and Stokes 1967) Yoon, Lee, Weiss, Kho, Kang, and Park 2001b, 1085^{VP} (*Bacillus globisporus* Larkin and Stokes 1967, 892.)

glo.bis'por.a. L. n. *globus* a sphere; N.L. n. *spora* a spore; N.L. fem. adj. *globispora* with spherical spores.

Cells are rods (usually 0.9–1.0 $\mu\text{m} \times 2.5$ –4.0 μm) with rounded ends. They occur singly or in pairs, stain uniformly, and are motile by means of peritrichous flagella. Gram positive or Gram variable. They form terminal to subterminal (sometimes slightly lateral), thick-walled, easily stained spores (1.0–1.1 μm in diameter). Colonies on nutrient agar are off-white, raised, and irregular with lobate to undulate margins. In glucose broth, growth occurs under anaerobic conditions. Growth is the same on nutrient agar, glucose agar, and tyrosine agar, but better on soybean agar and trypticase soy agar. No growth or scant growth on glucose nitrate agar and proteose-peptone acid agar. Moderate turbidity forms with sediment in nutrient broth. A small curd forms in litmus milk, which becomes slightly alkaline, after 3 weeks of growth. No indole production. Using ammonium salts as the source of nitrogen, cells form acid but not gas from glucose, lactose, sucrose, and glycerol but not from mannitol, arabinose, and xylose. However, no acid is formed from lactose in the presence of an organic nitrogen source. Negative for starch hydrolysis, acetylmethylcarbinol production, and citrate utilization. Maximum temperature for growth is 20–25°C. Grows and sporulates at 0°C. Isolated from soil and river water. Other characteristics are included in Table 71 and the genus description.

DNA G + C content (mol%): 39.7 (Bd), 39.8 (T_m).

Type strain: 785, Larkin and Stockes W 25, ATCC 23301, CCUG 7419, CIP 103266, DSM 4, HAMBI 471, NBRC 16082, JCM 10046, LMG 6928, NRRL NRS-1533, NRRL B-3396, VKM B-1435. *GenBank accession number (16S rRNA gene):* X54967, X68415.

4. ***Sporosarcina korensis*** Kwon, Kim, Song, Weon, Schumann, Tindall, Stackebrandt and Fritze 2007, 1697^{VP}

ko.re.en'sis. N.L. fem. adj. *korensis* referring to Korea, where the isolates were collected.

The species characteristics are the same as those of the genus except as follows. Cells are sporeforming rods (0.5–0.7 $\mu\text{m} \times 2.5$ –3.0 μm) occurring singly or in short chains. Gram positive. They form mainly oval, terminal endospores in swollen sporangia. Colonies are light orange (after 2 days on TSA at 30°C). Growth is strictly aerobic and does not occur in >7% NaCl. The growth temperature range is 15–40°C (optimum, 30°C), and growth pH range is 6.0–9.0 (optimum, 7.0; no growth at pH 5.7 or 10.0). Negative for anaerobic growth, formation of indole and dihydroxyacetone, in the Voges–Proskauer test, for phenylalanine deamination, and acid production from *D*-glucose, *L*-arabinose, *D*-xylose, and *D*-mannitol. No utilization of citrate or propionate. The major fatty acids are $C_{15:0\text{ iso}}$ and $C_{15:0\text{ ante}}$. The major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylethanolamine, an unidentified phospholipid, and two unidentified aminophospholipids. The type strain was isolated from upland soil in Suwon, Korea. Other characteristics are included in Table 71.

DNA G + C content (mol%): 46.5 (HPLC).

Type strain: F73, DSM 16921, KACC 11299.

GenBank accession number (16S rRNA gene): DQ073393.

5. ***Sporosarcina macmurdoensis*** Reddy, Matsumoto and Shivaji 2003, 1364^{VP}

mac.mur.do.en'sis. N.L. fem. adj. *macmurdoensis* pertaining to the McMurdo Region, Antarctica, where the isolates were collected.

Cells are single, nonmotile, rods and form subterminal spores. Gram positive. Colonies (2–3 mm in diameter) are white, circular, flat, and opaque. They tolerate a maximum of 3% (w/v) NaCl and grow at pH 6–9 (pH 7 is optimum for growth) and at psychrophilic temperatures (4–25°C; 18–20°C is optimal for growth). They do not hydrolyze esculin or reduce nitrate to nitrite. They are negative for lipase, β -galactosidase, arginine dihydrolase, arginine decarboxylase, lysine decarboxylase, indole production, methyl red test, and Voges–Proskauer test. Neither acid nor gas is produced from *L*-arabinose, *D*-fructose, *D*-galactose, lactose, *D*-mannose, *D*-mannitol, *L*-rhamnose, sucrose, or *D*-xylose. Utilizes dulcitol, *D*-fructose, *D*-galactose, *D*-glucose, *meso*-inositol, lactose, *D*-maltose, *D*-mannose, pyruvate, *D*-raffinose, *D*-xylose, and *L*-glutamic acid as sole carbon sources but not acetate, adonitol, *L*-arabinose, *D*-cellobiose, cellulose, citrate, dextran, glucose, *meso*-erythritol, fumaric acid, glycerol, inulin, lactic acid, *D*-mannitol, *D*-melibiose, melezitose, *L*-rhamnose, *D*-ribose, sorbitol, *D*-sorbose, sucrose, succinic acid, trehalose, thioglycollate, *L*-alanine, *L*-arginine, *L*-aspartic acid, *L*-asparagine, *L*-glutamine, *L*-lysine, *L*-histidine, *L*-isoleucine, *L*-leucine, *L*-lysine, *L*-methionine, *L*-phenylalanine, *L*-proline, *L*-serine, *L*-threonine, *L*-tyrosine, *L*-tryptophan, or *L*-valine. Sensitive to amikacin, ampicillin, amoxicillin, bacitracin, carbenicillin, cefazoline, cefaperazone, cephotaxime, chloramphenicol, chlorotetracycline, co-trimoxazole, ciprofloxacin, erythromycin, furazolidone, furoxone, gentamicin,

kanamycin, lomefloxacin, nalidixic acid, neomycin, nitrofurazone, nitrofurantoin, norfloxacin, novobiocin, nystatin, oxytetracycline, penicillin, polymyxin-B, rifampin, roxithromycin, streptomycin, tetracycline, tobramycin, trimethoprim and vancomycin, but resistant to cefuroxime, colistin, and lincomycin. Peptidoglycan type is L-Lys-D-Glu of the A4 α variant. The major fatty acids include C_{16:1 iso} in addition to C_{15:0 ante}. Other characteristics are included in Table 71 and the genus description.

DNA G + C content (mol%): 44 (T_m).

Type strain: CMS 21w, CIP 107784, DSM 15428, MTCC 4670.

GenBank accession number (16S rRNA gene): AJ514408.

6. **Sporosarcina pasteurii** (Miquel 1889) Yoon, Lee, Weiss, Kho, Kang and Park 2001b, 1085^{VP} (*Urobacillus pasteurii* Miquel 1889, 519; *Bacillus pasteurii* Chester 1898, 47.)

pas.teur'i.i. N.L. gen. n. *pasteurii* of Pasteur; named for Louis Pasteur, French chemist and bacteriologist.

Cells are rods, 0.5–1.2 × 1.3–4 μm. Colonies are usually circular and glossy and have variable opacity and size, depending on the medium. In liquid media, growth is turbid with slimy deposits but rarely a fragile pellicle. Cultures are very adept at converting urea to ammonium carbonate, but this activity frequently decreases upon transfer in artificial media. Requires alkaline medium (optimum pH ca. 9) containing NH₃ (1% NH₄Cl). Growth in culture medium is supported by casein hydrolyzate (pH 8.5–9.5), ammonia, thiamine, and for some strains, biotin, and nicotinic acid. Isolated from soil, sewage, and incrustations on urinals. Other characteristics are included in Table 71 and the genus description.

DNA G + C content (mol%): 38.4 (Bd), 38.5 (T_m).

Type strain: ATCC 11859, CCUG 7425, CIP 66.21, DSM 33, LMG 7130, NCCB 48021, NCIMB 8841, NCTC 4822, NRRL NRS-673, VKM B-513.

GenBank accession number (16S rRNA gene): X60631.

7. **Sporosarcina psychrophila** (Nakamura 1984) Yoon, Lee, Weiss, Kho, Kang, and Park 2001b, 1085^{VP} (*Bacillus psychrophilus* Nakamura 1984, 122.)

psy.chro'phil.a. Gr. adj. *psychros* cold; Gr. adj. *philos* liking, preferring; N.L. adj. *psychrophila* preferring cold.

Rod-shaped (0.5–1.0 μm × 3.0–7.0 μm). Cells occur singly and in chains. Gram positive. Motile. Round endospores produced in swollen sporangia. Colonies (1–2 mm in diameter) are nonpigmented, translucent, slightly raised, circular, entire, smooth, and slightly glossy. Grows anaerobically in the presence of glucose. Acetylmethylcarbinol, indole, and hydrogen sulfide are not produced. Arginine-, lysine-, and ornithine-decomposing enzymes are not produced. Acetate, fumarate, malate, and succinate, but not citrate, are utilized. No growth occurs at pH 5.6 or 5.7. Litmus milk is unchanged at 7 d. Temperature for growth ranges from 0–3°C to 30°C and is optimum at 25°C. Acid but no gas is produced from D-fructose, D-galactose, D-glucose, D-mannitol, maltose, D-ribose, sucrose, trehalose, and D-xylose. Isolated from soil and river water. Other characteristics are included in Table 71 and the genus description.

DNA G + C content (mol%): 44.1 (Bd).

Type strain: ATCC 23304, CCM 2117, BCRC 11738, CCUG 28886, CIP 103267, DSM 3, IAM 12468, NBRC 15381, JCM 9075, LMG 6929, NRRL B-3397, NRRL NRS-1530, W16A.

GenBank accession number (16S rRNA gene): D16277, X60634.

8. **Sporosarcina saromensis** An, Haga, Kasai, Goto and Yokata 2007, 1870^{VP}

sa.ro.men'sis. N.L. fem. adj. *saromensis* pertaining to Lake Saroma, where the type strain was collected.

Cells are sporeforming rods (0.8–1.0 μm × 2.0–3.2 μm). Gram positive. They form spherical, terminal endospores. Colonies are circular, convex, and beige on TSA medium containing 50% Herbst's artificial sea water. The growth temperature range is 5–40°C (optimum, 27°C; no growth at 45°C) and growth pH range is 5.5–9.0 (optimum, 6.5). Negative for formation of indole, H₂S, and acetoin, and tests for arginine hydrolase, lysine decarboxylase, ornithine decarboxylase, tryptophan deaminase, and citrate utilization. Acid is not produced from carbohydrates in the API 50CHI gallery. L-Lys-D-Glu is the cell wall peptidoglycan type. The major fatty acids are C_{15:0 iso} and C_{15:0 ante}. The major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylethanolamine. The type strain was isolated from surface water in Lake Saroma. A reference strain, HG711, was isolated from sediment in Nagasaka fishery harbor (Miyagi, Japan). Other characteristics are included in Table 71 and the genus description.

DNA G + C content (mol%): 46.0 (HPLC).

Type strain: HG645, IAM 15429, JCM 23205, KCTC 13119, MBIC08270, NBRC 103571.

GenBank accession number (16S rRNA gene): AB243859.

9. **Sporosarcina soli** Kwon, Kim, Song, Weon, Schumann, Tindall, Stackebrandt and Fritze 2007, 1697^{VP}

so'li. L. neut. gen. n. *soli* of soil, the source of the organism.

Cells are sporeforming rods (0.7–1.0 μm × 2.0–3.0 μm) occurring singly, in pairs, or occasionally in short chains. Gram positive. They form mainly round, central endospores in nonswollen sporangia. Colonies are light orange after 2 d on TSA at 30°C. The growth temperature range is 15–37°C (optimum, 30°C), and growth pH range is 7.0–9.0 (optimum, 8.0; no growth at 5.7 or 10.0). Negative for formation of indole and dihydroxyacetone, in the Voges-Proskauer test, for phenylalanine deamination, nitrate reduction, acid production from D-glucose, L-arabinose, D-xylose, and D-mannitol, and for hydrolysis of starch, casein, and Tween 80. No utilization of citrate or propionate. L-Lys-D-Glu is the peptidoglycan type. The major fatty acids are C_{15:0 iso} and C_{15:0 ante}. The major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylethanolamine, and an unidentified phospholipid. The type strain was isolated from upland soil in Suwon, Korea. Other characteristics are included in Table 71 and the genus description.

DNA G + C content (mol%): 44.5 (HPLC).

Type strain: strain I80, DSM 16920, KACC 11300.

GenBank accession number (16S rRNA gene): DQ073394.

Genus IX. **Ureibacillus** Fortina, Pukall, Schumann, Mora, Parini, Manachini and Stackebrandt 2001, 453^{VP}

DAGMAR FRITZE AND PAUL DE VOS

Ur.e.i.ba.cil'lus. N.L. n. *urea* urea; L. dim. n. *bacillus* a rod and also the name of a genus of aerobic endospore-forming bacteria; N.L. masc. n. *Ureibacillus* a ureolytic aerobic bacillus.

Gram-stain-negative, rod-shaped, motile bacterium, 0.5–0.7 µm in diameter and 1.0–6.0 µm in length. **Endospores** are **spherical**, subterminal or terminal in swollen sporangia. Aerobic. Cross-linkage of the **peptidoglycan is of the L-Lys-D-Asp type**. Phosphatidylglycerol, diphosphatidylglycerol, phospholipids, and glycolipids of unknown composition are found as polar lipids. C_{16:0 iso} is the major fatty acid component. The predominant menaquinones are either **MK-7 or a mixture of MK-8 and MK-9**.

DNA G+C content (mol%): 35.7–41.5.

Type species: Ureibacillus thermosphaericus (Andersson et al., 1996) Fortina, Pukall, Schumann, Mora, Parini, Manachini and Stackebrandt 2001, 453^{VP} (*Bacillus thermosphaericus* Andersson, Laukkanen, Nurmiaho-Lassila, Rainey, Niemelä and Salkinoja-Salonen 1996, 362.).

Further descriptive information

Colonies on CESP agar (see Fortina et al., (2001) for composition) are circular, with entire margins, transparent, and show swarming; for *Ureibacillus suwonensis*, no real colony formation has been observed. Growth occurs on complex media. For some strains, growth is limited to temperatures of 40 to about 65°C, with optimal growth at 50–60°C; others may grow at 35–37°C (*Ureibacillus thermosphaericus*). Strains may grow with 3% (w/v) NaCl in the medium and even up to 5% (w/v) NaCl at pH 9.0. Casein is never hydrolyzed and acetylmethylcarbinol formation is negative. Fatty acids that are present in substantial amounts are C_{15:0 iso}, C_{16:0 iso}, and C_{16:0}. Data from fatty acid analyses obtained after growth on non-standard media allow discrimination at the

intrageneric level (Fortina et al., 2001). Remarkable intrageneric differences are found in the menaquinone composition, which varies between almost exclusively MK-7 to a mixture of major amounts of MK-8 and MK-9 with minor fractions of MK-11, MK-10, and MK-7, and possibly a minor fraction of MK-6.

Taxonomic comments

The genus *Ureibacillus* was created to accommodate a number of thermophilic spore-formers that held a separate phylogenetic position in the genus *Bacillus* and of which a number of airborne strains were initially classified and described as *Bacillus thermosphaericus* (Andersson et al., 1995; Andersson et al., 1996); three further strains, isolated at a later date (Mora et al., 1998), were found to be the closest relatives of these airborne isolates. The distinctiveness of this new phylogenetic lineage is also supported by chemotaxonomic and phenotypic characteristics. On the basis of DNA–DNA hybridization data, the four strains (one of which was the original type strain of *Bacillus thermosphaericus*) studied by Fortina et al. (2001) clearly belonged to two different species, one of which complies with the type species *Ureibacillus thermosphaericus*. Species differentiation is only partially supported by ribotyping results. A third species was recently found in compost of cotton waste in Korea. Discrimination from members of other genera is on the basis of 16S rRNA gene sequence analysis, but also on the basis of the amino acid composition of peptide bridges in the peptidoglycan, and menaquinone and fatty acid compositions.

Hydrolysis of urea (reflected in the name *Ureibacillus*) could not be confirmed for any of the three species when using stringent test systems (Kim et al., 2006).

List of species of the genus *Ureibacillus*

- 1. *Ureibacillus thermosphaericus*** (Andersson, Laukkanen, Nurmiaho-Lassila, Rainey, Niemelä and Salkinoja-Salonen 1996) Fortina, Pukall, Schumann, Mora, Parini, Manachini and Stackebrandt 2001, 453^{VP} (*Bacillus thermosphaericus* Andersson, Laukkanen, Nurmiaho-Lassila, Rainey, Niemelä and Salkinoja-Salonen 1996, 362.)

ther.mo.sphae'ri.cus. Gr. adj. *thermos* hot; L. adj. *sphaericus* spherical; N.L. n. *thermosphaericus* the hot sphere.

Pleomorphic cells that vary during the incubation phase between cocci, short rods and extremely long rods. Motility is enhanced upon higher incubation temperature. Peritrichously inserted flagella. Strictly aerobic. Grows between 33 and 64°C. The spherical spores lay terminally in swollen sporangia. Colonies are circular, entire, flat, transparent, and swarming. Growth occurs in the presence of 5% NaCl and at pH 9.0. Negative for the following characters: anaerobic growth; Voges–Proskauer; indole production; nitrate reduction; starch, casein, and gelatin hydrolysis; and acid production from ara-

binose, ribose, xylose, glucose, maltose, mannose, rhamnose, trehalose, sucrose, and citrate. Unable to use sugars as carbon and energy source. Uses esculin, urea (see comment above), and malate. Peptidoglycan type is A4α-lysine-aspartic acid. The major menaquinone is MK-7, but MK-8 is also present as a minor component. The main fatty acid is C_{16:0 iso} (58–61%). The type strain was isolated from landfill air.

DNA G+C content (mol%): 35.7–39.2 (*T_m*).

Type strain: P-11, DSM 10633, KACC 10504.

EMBL/GenBank accession number (16S rRNA gene): AB101594 (P-11).

- 2. *Ureibacillus terrenus*** Fortina, Pukall, Schumann, Mora, Parini, Manachini and Stackebrandt 2001, 454^{VP}

ter.re'nus. L. adj. *terrenus* from earth, referring to the habitat of the organism.

Description is not well-documented, but characteristics are similar to those given for the genus and for *Ureibacillus*

thermosphaericus. In general, cells are Gram-stain-negative rods, forming endospores in swollen sporangia that lay terminal/subterminal. Not all strains grow at pH 9 or in media with 5% NaCl. The temperature range for growth is 42–65°C; does not grow at 37°C. Major menaquinones are MK-9 and MK-8, with MK-7 as a minor component. The type strain was isolated from soil.

DNA G+C content (mol%): 39.6–41.5 (T_m).

Type strain: TU1A, DSM 12654, LMG 19470.

EMBL/GenBank accession number (16S rRNA gene): AJ276403 (DSM 12654).

3. **Ureibacillus suwonensis** Kim, Lee, Weon, Kwon, Go, Park, Schumann and Fritze 2006, 665^{VP}

su.won.en'sis. N.L. masc. adj. *suwonensis* referring to Suwon Region in Korea, where the bacterium was first found.

Gram-stain-negative, spore-forming, motile (by means of peritrichously inserted flagella) rods (0.5–0.7 µm wide and 1.5–2.0 µm long), appearing singly and in chains.

Endospores are spherical to oval in subterminally or terminally swollen sporangia. Colonies appear to be smeared over the surface of solid media. Temperature for growth ranges from 35 to 60°C. Grows in the presence of 5% NaCl. Strictly aerobic. Catalase, oxidase, and arginine dihydrolase reactions are positive. Weak reaction for phenylalanine deamination. Strains test negative for the production of indole and dihydroxyacetone, and also in the Voges–Proskauer test. Nitrate reduction is not observed. Acid is not produced from glucose, arabinose, xylose, or mannitol. Esculin, starch, gelatin, casein, and urea are not hydrolyzed. The cross-linkage of peptidoglycan is as for the genus. The major cellular fatty acid is C_{16:0 iso} (65–66%). The major isoprenoid quinones are MK-9, MK-8 and MK-7. Isolated from cotton compost in Suwon, Korea.

DNA G+C content (mol%): 41.5 (HPLC).

Type strain: 6T19, KACC 11287, DSM 16752.

EMBL/GenBank accession number (16S rRNA gene): AY850379 (6T19).

Family VII. *Sporolactobacillaceae* fam. nov.

WOLFGANG LUDWIG, KARL-HEINZ SCHLEIFER AND WILLIAM B. WHITMAN

Spo.ro.lac.to.ba.cil.la'ce.ae. N.L. masc. n. *Sporolactobacillus* type genus of the family; suff. *-aceae* ending denoting family; N.L. fem. pl. n. *Sporolactobacillaceae* the *Sporolactobacillus* family.

The family *Sporolactobacillaceae* is circumscribed for this volume on the basis of phylogenetic analyses of the 16S rRNA sequences and includes the genus *Sporolactobacillus* and its close relatives. It is composed of Gram-positive rods. The cell walls contain

meso-diaminopimelate. Endospores are formed. Facultatively anaerobic or aerobic growth. Cells contain menaquinone as the major respiratory quinone. Mesophilic and thermophilic species.

Type genus: Sporolactobacillus Kitahara and Suzuki 1963, 69^{AL}.

Genus I. *Sporolactobacillus* Kitahara and Suzuki 1963, 69^{AL}

FUJITOSHI YANAGIDA AND KEN-ICHIRO SUZUKI

Spo.ro.lac.to.ba.cil'lus. Gr. n. *spora* seed; L. n. *lac*, *lactis* milk; L. dim. n. *bacillus* a small rod; N.L. masc. n. *Sporolactobacillus* sporing milk rodlet.

Cells are **straight rods**, 0.4–1.0 × 2.0–4.0 µm, occurring singly, in pairs, and, rarely, in short chains. **Endospores are formed** that are resistant to heating at 80°C for 10 min. **Gram-stain-positive**. Mostly motile by peritrichous flagella. Facultatively anaerobic or microaerophilic; good growth occurs on media containing glucose, but poor or no growth occurs in nutrient broth; D- or DL-lactic acid is produced homofermentatively; catalase negative; does not contain cytochromes. Mesophilic. Acid is produced from glucose, fructose, galactose, mannose, maltose, sucrose, and trehalose. The cell wall contains ***meso*-diaminopimelic acid (*meso*-DAP)**. The predominant isoprenoid quinone is a **menaquinone with seven isoprene units (MK-7)**. Ubiquinone is not detected. The cellular fatty acids comprise predominantly **12-methyl tetradecanoic acid (C_{15:0 ante})** and **14-methyl hexadecanoic acid (C_{17:0 ante})**, with 13-methyl tetradecanoic acid (C_{15:0 iso}) and 14-methyl pentadecanoic acid (C_{16:0 iso}) as minor components.

DNA G+C content (mol%): 43–50 (T_m).

Type species: Sporolactobacillus inulinus (Kitahara and Suzuki 1963) Kitahara and Lai 1967, 197^{AL} (*Lactobacillus* (*Sporolactobacillus*) *inulinus* Kitahara and Suzuki 1963, 69).

Further descriptive information

Although strains of *Sporolactobacillus* show resistance to heat at 80°C for 10 min, spores are rarely observed microscopically. Media for sporulation contain: 0.1% (w/v) yeast extract; 0.5% (w/v) meat extract; 1.0% (w/v) (NH₄)₂SO₄; 0.5% (w/v) α-methyl D-glucoside; 20% (v/v) tomato serum; and an excess of CaCO₃ (Kitahara and Lai, 1967; Kitahara and Toyota, 1972). However, Doores and Westhoff (1983) reported improved sporulation in the absence of tomato serum. Motility occurs by means of a small number of long peritrichous flagella.

The cell wall shows a Gram-positive type of structure with peptidoglycan of the *meso*-DAP direct linkage type. In spite of the presence of polysaccharides, teichoic acid is not found (Okada et al., 1976; Weiss et al., 1967). Isoprenoid quinones are exclusively menaquinones, predominantly MK-7 and small proportions of MK-6 and MK-5 (Collins and Jones, 1979; Yanagida et al., 1997). Cellular fatty acids consist mostly of anteiso- and

iso-branched acids (Uchida and Mogi, 1973; Yanagida et al., 1997). These chemotaxonomic characteristics are similar to those of members of the genus *Bacillus*.

Catalase is absent. Growth is observed under anaerobic cultivation. Very recently *Bacillus laevolacticus* was transferred to the genus *Sporolactobacillus* based on phylogenetic analysis (Hatayama et al., 2006). Hatayama and colleagues showed that strains of *Sporolactobacillus laevolacticus* did not have catalase activity, in contrast to data from previous studies (Nakayama and Yanoshi, 1967a; Yanagida et al., 1987a).

Carbohydrates are essential substrates for growth. Although acid is produced from a limited number of carbohydrates, species and subspecies of the genus vary in their substrate utilization patterns, as shown in Table 72. Lactic acid is produced from glucose by homofermentation.

Phylogenetically, the genus *Sporolactobacillus* is part of the family "*Sporolactobacillaceae*" of the order *Bacillales* based on 16S rRNA gene sequences. Previously, several DNA–DNA hybridization studies have shown low relatedness values of the type strain of *Sporolactobacillus inulinus* with *Bacillus coagulans* and with *Lactobacillus* species, including *Lactobacillus plantarum* (Dellaglio et al., 1975; Miller et al., 1971). Fox et al. (1977, 1980) and Stackebrandt et al. (1987) indicated a distant relationship between *Sporolactobacillus inulinus* and *Bacillus* species based on 16S rRNA oligonucleotide cataloging. Ash et al. (1991) classified the genus *Bacillus* into five groups by comparative analysis of nearly (95%) complete 16S rRNA primary sequences; *Sporolactobacillus inulinus* was separated phylogenetically from all of the *Bacillus* species. Suzuki and Yamasato (1994) determined 16S rRNA gene sequences of 16 strains of the spore-forming lactic acid bacteria and revealed that the isolates of Nakayama and Yanoshi (1967a, 1967b) formed one cluster with *Sporolactobacillus inulinus* and that the cluster could be further divided into five subclusters, namely four catalase negative subclusters and one positive subcluster. Andersch et al. (1994) proposed *Bacillus laevolacticus* for a group of catalase positive strains. Later, Hatayama et al. (2006) transferred *B. laevolacticus* to the genus *Sporolactobacillus* based on phylogenetic analysis of the 16S rRNA gene.

^bYanagida et al. (1997); *Sporolactobacillus laevolacticus* was not included in this study.

Enrichment and isolation procedures

Sample suspensions are incubated anaerobically at 30°C after a heat treatment of 10 min at 80°C to suppress non-spore-forming aerobic bacteria. After 4–7 d incubation, one drop of the turbid broth is spread on GYP agar containing 1% CaCO₃ and incubated in an anaerobic jar under a 100% CO₂ atmosphere. Acid-producing bacteria are recognized by the appearance of clear zones around colonies. They are purified by repeated isolation. The production of lactic acid is confirmed by HPLC (Yanagida et al., 1997).

For further cultivation, *Sporolactobacillus* strains grow well on GYP medium, which contains 2% glucose, 1% yeast extract, 1% peptone, 1% sodium acetate, and 0.5% (v/v) salt solution (pH 6.8). The salt solution contains 4% MgSO₄·7H₂O, 0.2% MnSO₄·4H₂O, 0.2% FeSO₄·7H₂O, and 0.2% NaCl. MRS medium at pH 5.5 is also useful for selective isolation and enrichment. The *Sporolactobacillus* strains isolated so far are mesophilic, with optimal growth temperatures of 30–35°C.

Maintenance procedures

Sporolactobacillus strains can be lyophilized or liquid-dried by using the same procedures as used for lactobacilli. They can also be preserved by freezing at –80°C or lower in the presence of 10% (v/v) skimmed milk broth or glycerol.

Differentiation of the genus *Sporolactobacillus* from the other genera

Phenotypic characteristics of the genus *Sporolactobacillus* and related spore-forming genera are summarized in Table 73. Some characteristics, e.g., endospore formation, the presence of iso- and anteiso-branched cellular fatty acids, MK-7 as the predominant menaquinone, and *meso*-DAP-containing peptidoglycan, are shared with the genera *Bacillus*, *Brevibacillus*, and *Paenibacillus*. Generally, members of these genera are strict aerobes and catalase positive, whereas *Sporolactobacillus* species are microaerophilic and catalase negative. *Bacillus coagulans* produces lactic acid anaerobically as an end product from glucose. Members of the genus *Amphibacillus* lack menaquinones, catalase and cytochromes, and major fermentation products from glucose are ethanol, acetic acid, and formic acid (Niimura et al., 1990).

Some non-sporulating Gram-positive bacteria show similar characteristics to those of members of the genus *Sporolactobacillus*. *Lactobacillus plantarum* strains produce lactic acid homofermentatively and possess *meso*-DAP-containing peptidoglycan, as observed in *Sporolactobacillus* species, but their cellular fatty acids are straight chain acids. Like members of the genus *Sporolactobacillus*, species of the genus *Marinococcus* are characterized by *meso*-DAP, MK-7, and iso- and anteiso-branched chain fatty acids (Li et al., 2005). However, strains of *Marinococcus* are strictly aerobic and do not form spores.

TABLE 73. Discriminative characteristics of some genera of aerobic, endospore-forming bacteria^a

Phylogenetically, the genus *Marinococcus* is the closest neighbor of the genus *Sporolactobacillus*, whereas the genus *Lactobacillus* is distantly related.

Taxonomic comments

The genus *Sporolactobacillus* was first established by Kitahara and Suzuki (1963) to accommodate the spore-forming lactic acid bacteria as a subgenus of the genus *Lactobacillus*. Later, the subgenus was elevated to the genus level in the Approved Lists of Bacterial Names (Skerman et al., 1980). Current phylogenetic analysis based on 16S rRNA gene sequences places the genus *Sporolactobacillus* in the family *Sporolactobacillaceae* of the order *Bacillales*, whereas *Lactobacillus* falls in the order *Lactobacillales*. A tree showing members of the family *Sporolactobacillaceae* and related genera is shown in Figure 69.

Sporolactobacillus inulinus was first isolated from chicken feed (Kitahara and Lai, 1967; Kitahara and Suzuki, 1963). Later, Nakayama and Yanoshi (1967a, 1967b) isolated a number of spore-forming lactic acid bacteria from soil of plant rhizospheres and proposed four species, namely “*Bacillus laevolacticus*”, “*Bacillus racemilacticus*”, “*Sporolactobacillus laevis*”, and “*Sporolactobacillus racemicus*” – none of these names was validly published. Yanagida et al. (1987b, 1987a) studied these spore-forming lactic acid bacteria by DNA–DNA hybridization as well as biochemical and physiological tests.

Andersch et al. (1994) proposed *Bacillus laevolacticus* for some catalase-positive strains. Based on the results of their previous studies, Yanagida et al. (1997) proposed four novel species and one novel subspecies in the genus *Sporolactobacillus*. Recently, *Bacillus laevolacticus* was transferred to the genus *Sporolactobacillus* as *Sporolactobacillus laevolacticus* (Hatayama et al., 2006), based on its phylogenetic position, as well as weak or non-existent catalase activity. The data for catalase activity differ in these studies. Catalase activity in *Sporolactobacillus laevolacticus* exists, but is extremely weak and quite different from the strong catalase activity observed in species of *Bacillus*. Strains of other species of the genus *Sporolactobacillus* do not possess catalase activity.

Differentiation of species of the genus *Sporolactobacillus*

The species of *Sporolactobacillus* have been established on the basis of DNA–DNA hybridization with consideration of phenotypic characteristics (Yanagida et al., 1987a, 1987b, 1997). The acid production profiles from various carbohydrates and the isomers of lactic acid produced are useful phenotypic criteria for species differentiation. Molecular techniques including 16S rRNA gene sequence analysis may provide useful information to classify and identify species of the genus.

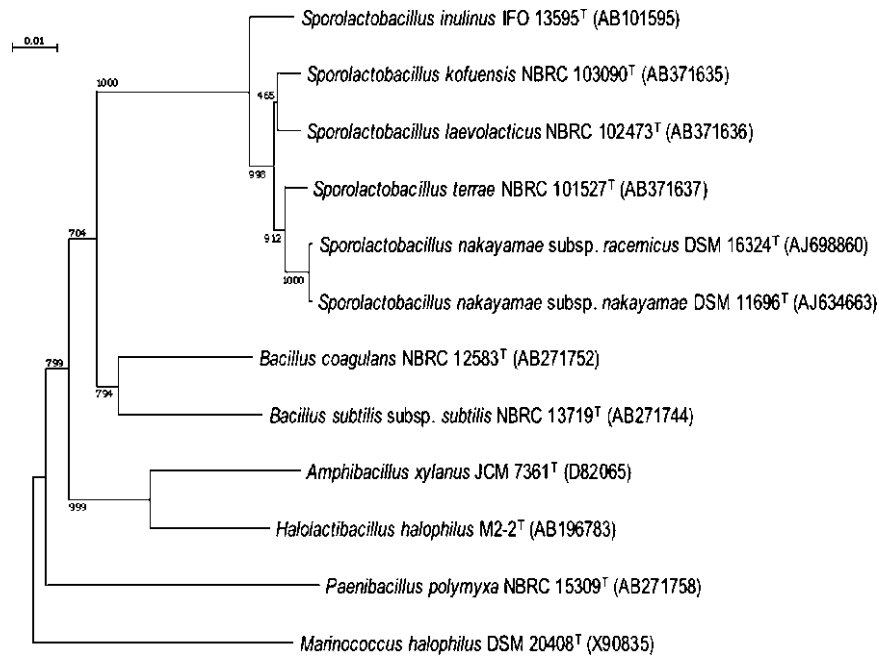

FIGURE 69. Phylogenetic tree of members of the genus *Sporolactobacillus* and related genera based on 16S rRNA gene sequences. Scale bar indicates the K_{nuc} values calculated from the nucleotide sequences. Numbers at branches indicate the confidence limits estimated by bootstrap analysis with 1000 resampling trials, which are shown only for the major clusters. (Tree and some sequences courtesy of M. Miyashita).

List of species of the genus *Sporolactobacillus*

- Sporolactobacillus inulinus*** (Kitahara and Suzuki 1963) Kitahara and Lai 1967, 197^{AL} (*Lactobacillus* (*Sporolactobacillus*) *inulinus* Kitahara and Suzuki 1963, 69*)
i.nu.li'nus. N.L. n. *inulum* inulin; N.L. adj. *inulinus* pertaining to inulin.

Cell morphology and chemotaxonomic characteristics are as described for the genus. Additional species characteristics are as follows. L-Lactic acid is produced. Acid is produced from raffinose, mannitol, starch, and methyl α -D-glucoside, but not from arabinose, ribose, xylose, galactose, rhamnose, cellobiose, lactose, melibiose, or salicin. The type strain produces acid from inulin.

Source: chicken feed and soil.
DNA G+C content (mol%): 47–50 (T_m); 47 for type strain.
Type strain: ATCC 15538, DSM 20348, JCM 6014, LMG 11481, NBRC 13595, NCIMB 9743.
GenBank accession number (16S rRNA gene): D16283, AB101595.
- Sporolactobacillus kofuensis*** Yanagida, Suzuki, Kozaki and Komagata 1997, 503^{VP}
ko.fu.en'sis. N.L. adj. *kofuensis* belonging to Kofu-city, Yamana-shi, Japan, the place of origin of the soil from which the organism was isolated.

Cell morphology and chemotaxonomic characteristics are as described for the genus. Additional species characteristics are as follows. L-Lactic acid is produced. Acid is produced from galactose, raffinose, mannitol, and inulin, but not from arabinose, ribose, xylose, rhamnose, cellobiose, lactose, melibiose, salicin, or sorbitol.

Source: soil.
DNA G+C content (mol%): 43 (T_m ; type strain).
Type strain: M-19, JCM 3419, LMG 18786 and NBRC 103090.
GenBank accession number (16S rRNA gene): AB371635.
- Sporolactobacillus lactosus*** Yanagida, Suzuki, Kozaki and Komagata 1997, 503^{VP}
lac.to'sus. N.L. adj. *lactosus* of lactose, pertaining to lactose.

Cell morphology and chemotaxonomic characteristics are as described for the genus. Additional species characteristics are as follows. Grows at 45°C and most strains grow at 15°C. L-Lactic acid is produced. Litmus milk is acidified and afterwards reduced by some strains. Acid is produced from galactose, lactose, melibiose, and raffinose.

* *Editorial note:* The original designation inadvertently reduced *Lactobacillus* to subgeneric rank and was presumably a *lapsus calami* for *Lactobacillus* (*Sporolactobacillus*) *inulinus*. In subsequent papers, Kitahara and co-workers referred to the organism as *Sporolactobacillus inulinus*, elevating *Sporolactobacillus* to generic rank. The Approved Lists of Bacterial Names cites Kitahara and Suzuki (1963) as the authors of the generic name and Kitahara and Lai (1967) as authors of the type species name, and we will follow that designation here.

Some strains produce acid from arabinose, ribose, xylose, rhamnose, cellobiose, salicin, sorbitol, starch, methyl α -D-glucoside, and inulin.

Source: soil in Japan and fermentation starters.

DNA G+C content (mol%): 43–46 (T_m); 46 for type strain.

Type strain: strain X1-1, JCM 9690 (the type strain does not seem to be available from any international culture collection and, therefore, this taxon may lose its standing in nomenclature).

4. ***Sporolactobacillus laevolacticus*** (Andersch, Pianka, Fritze and Claus 1994) Hatayama, Shoun, Ueda and Nakamura 2006, 2550^{VP} (*Bacillus laevolacticus* Andersch, Pianka, Fritze and Claus 1994, 663; "*Bacillus laevolacticus*" Nakayama and Yanoshi 1967a, 149)

lae.vo.lac'ticus. N.L. adj. *laevolacticus* referring to D(-)-lactic acid, the sole (levorotatory) isomer of lactic acid that is produced by the bacterium.

Cell morphology and chemotaxonomic characteristics are as described for the genus. Additional species characteristics are as follows. Litmus milk is acidified, reduced, and coagulated. DL-Lactic acid is produced. Acid is produced from galactose, lactose, melibiose, raffinose, mannitol, and inulin, but not from arabinose, ribose, xylose, rhamnose, cellobiose, salicin, or methyl α -D-glucoside. Some strains produce acid from sorbitol and starch.

Additional description by Andersch et al. (1994). No growth occurs in the presence of lysozyme or 5% NaCl. Starch and pullulan are hydrolyzed. Citrate and propionate are not utilized. Gelatin, DNA, tyrosine, and casein are not hydrolyzed. Indole is not produced. Nitrate is not reduced to nitrite. Negative for egg yolk lecithinase. No phenylalanine deaminase.

Additional description by Hatayama et al. (2006). Cell-wall peptidoglycan contains *meso*-DAP, alanine, glutamic acid, galactose, mannose, and rhamnose.

Source: soil in Japan and fermentation starters.

DNA G+C content (mol%): 43–45 (T_m); 45 for type strain.

Type strain: M-8, ATCC 23492, DSM 442, IAM 12321, JCM 2513, LMG 6329, NBRC 102473, NCIMB 10269.

GenBank accession number (16S rRNA gene): AB362642, AB371636.

5. ***Sporolactobacillus nakayamae*** Yanagida, Suzuki, Kozaki and Komagata 1997, 502^{VP}

na.ka.ya'mae. N.L. gen. n. *nakayamae* of Nakayama, named after Ooki Nakayama, a Japanese microbiologist who isolated a number of *Sporolactobacillus* strains.

Cell morphology and chemotaxonomic characteristics are as described for the genus. In addition, most strains grow at 15°C, but not at 45°C.

Source: soil.

DNA G+C content (mol%): 43–47 (T_m).

Type strain: M-114, ATCC 700379, DSM 11696, IAM 12388, JCM 3514, LMG 18787, NBRC 101526.

GenBank accession number (16S rRNA gene): AJ634663.

- a. ***Sporolactobacillus nakayamae* subsp. *nakayamae*** Yanagida, Suzuki, Kozaki and Komagata 1997, 502^{VP}

na.ka.ya'mae. N.L. gen. n. *nakayamae* of Nakayama, named after Ooki Nakayama, a Japanese microbiologist who isolated a number of *Sporolactobacillus* strains.

Cell morphology and chemotaxonomic characteristics are as described for the genus. In addition to the characteristics for the genus and the species, those for the subspecies are as follows. Does not acidify Litmus milk. L-Lactic acid is produced. Acid is produced from galactose, but not from arabinose, ribose, xylose, rhamnose, or lactose. Most strains produce acid from galactose, but not from cellobiose, melibiose, salicin, starch, or inulin.

Source: soil.

DNA G+C content (mol%): 43–47 (T_m); 45 for type strain.

Type strain: M-114, ATCC 700379, DSM 11696, IAM 12388, JCM 3514, LMG 18787, NBRC 101526.

GenBank accession number (16S rRNA gene): AJ634663.

- b. ***Sporolactobacillus nakayamae* subsp. *racemicus*** Yanagida, Suzuki, Kozaki and Komagata 1997, 503^{VP}

ra.ce.mi'cus. N.L. adj. *racelicus* racemic; DL-lactic acid is produced.

Cell morphology and chemotaxonomic characteristics are as described for the genus. In addition to the characteristics for the genus and the species, those for the subspecies are as follows. DL-Lactic acid is produced. Litmus milk is acidified. Acid is produced from galactose, melibiose, raffinose, and inulin, but not from arabinose, ribose, or xylose.

Source: soil.

DNA G+C content (mol%): 43–46 (T_m); 45 for type strain.

Type strain: M-17, ATCC 700381, DSM 16324, IAM 12396, JCM 3417, LMG 18785, NBRC 101524.

GenBank accession number (16S rRNA gene): AJ698860.

6. ***Sporolactobacillus terrae*** Yanagida, Suzuki, Kozaki and Komagata 1997, 503^{VP}

ter'rae. L. n. *terra* earth. L. gen. n. *terrae* of the earth.

Cell morphology and chemotaxonomic characteristics are as described for the genus. Additional species characteristics are as follows. Most strains grow at 15°C. Acid is produced from inulin, but not from ribose, xylose, rhamnose, lactose, or sorbitol. Most strains produce acid from galactose. Most strains do not produce acid from arabinose, melibiose, or starch.

Source: soil.

DNA G+C content (mol%): 43–46 (T_m); 44 for type strain.

Type strain: M-116, ATCC 700380, DSM 11697, IAM 14264, JCM 3516, LMG 18887, NBRC 101527.

GenBank accession number (16S rRNA gene): AJ634662, AB371637.

Family VIII. **Staphylococcaceae** fam. nov.

KARL-HEINZ SCHLEIFER AND JULIA A. BELL

Staph.y.lo.coc.ca'ce.ae. N.L. masc. n. *Staphylococcus* type genus of the family; -aceae ending to denote family; N.L. fem. pl. n. *Staphylococcaceae* the *Staphylococcus* family.

Circumscribed on the basis of 16S rDNA sequence analysis; contains the genera *Staphylococcus*, *Jeotgalicoccus*, *Macrococcus*, and *Salinicoccus*.

DNA G+C content (mol%): 30–51 (T_m , Bd).
Type genus: **Staphylococcus** Rosenbach 1884, 18.

Genus I. **Staphylococcus** Rosenbach 1884, 18^{AL} (Nom. Cons. Opin. 17 Jud. Comm. 1958, 153.)

KARL-HEINZ SCHLEIFER AND JULIA A. BELL

Staph.y.lo.coc'cus. Gr. n. *staphyle* bunch of grapes; Gr. n. *kokkos* a grain or berry; N.L. masc. n. *Staphylococcus* the grape-like coccus.

Cells spherical, 0.5–1.5 μm in diameter, occurring singly, in pairs, in tetrads, in short chains (3–4 cells), and characteristically dividing in more than one plane to form irregular grape-like clusters. **Gram-stain-positive**. Nonmotile. Resting stages not produced. **Cell wall contains peptidoglycan and teichoic acid. The diamino acid present in the peptidoglycan is L-lysine (peptidoglycan group A3)**. Usually unencapsulated or limited capsule formation.

Facultative anaerobes. With the exception of *Staphylococcus aureus* subsp. *anaerobius* and *Staphylococcus saccharolyticus*, growth is more rapid and abundant under aerobic conditions. **Usually catalase-positive and oxidase-negative**. Most strains grow in the presence of 10% NaCl and between 18 and 40°C.

Chemo-organotrophs; **metabolism respiratory and fermentative**. Some species are mainly respiratory or mainly fermentative. Unsaturated menaquinones and cytochromes *a* and *b* (and *c* in *Staphylococcus fleuretti*, *Staphylococcus lentus*, *Staphylococcus sciuri*, and *Staphylococcus vitulinus*) form the electron transport system. L- and/or D-lactic acid may be produced from glucose under anaerobic conditions. Lactose or D-galactose metabolized via the D-tagatose-6-phosphate or Leloir pathways, depending upon the particular species. Carbohydrates and/or amino acids utilized as carbon and energy sources. A variety of carbohydrates may be utilized aerobically with the production of acid. For most species, the main product of glucose fermentation is lactic acid; in the presence of air, the main products are acetic acid and CO₂.

Nutritional requirements are variable. Most species require an organic source of nitrogen, i.e., certain amino acids, and B group vitamins. Others can grow with (NH₄)₂SO₄ as a sole source of substrate nitrogen. Uracil and/or a fermentable carbon source may be required by certain species for anaerobic growth.

Susceptible to lysis by lysostaphin, but resistant to lysis by lysozyme. Species or strains which have significant amounts of L-serine or L-alanine replacing glycine in the interpeptide bridge of the peptidoglycan are generally less susceptible to lysostaphin than those with an interpeptide bridge consisting solely of glycine residues. Some species resistant to novobiocin. Generally susceptible to furazolidone and nitrofurantoin, and resistant to erythromycin and bacitracin at low levels. Usually susceptible to antibacterials such as phenols and their derivatives,

salicylanilides, carbanilides, and halogens (chlorine and iodine) and their derivatives.

Host for a variety of bacteriophages which may have a narrow or wide host range. Transfer of characters by transduction, transformation, and cell-to-cell contact has been demonstrated in some species.

Natural populations are mainly associated with skin, skin glands, and mucous membranes of warm-blooded animals. Host or niche range may be narrow or wide, depending upon the particular species or subspecies. Some organisms may be isolated from a variety of animal products (e.g., meat, milk, cheese) and environmental sources (e.g., fomites, soil, sand, dust, air, or natural waters). **Some species are opportunistic pathogens of humans and/or animals**. A list of staphylococcal species/subspecies together with some differential characteristics is summarized in Table 74.

DNA G+C content (mol%): 27–41 (T_m , Bd).

Type species: **Staphylococcus aureus** Rosenbach 1884, 18^{AL}.

Further descriptive information

Phylogeny. Based on comparative 16S rRNA sequence studies, the genus *Staphylococcus* belongs to the phylum *Firmicutes* [Gram-positive bacteria with a low (<50 mol%) DNA G+C content]. It is closely related to bacilli and other members of the phylum *Firmicutes* such as macrococci, enterococci, streptococci, lactobacilli, and listeria (Figure 70). It has been proposed to combine the genera *Staphylococcus*, *Gemella*, *Jeotgalicoccus*, *Macrococcus*, and *Salinicoccus* within the family *Staphylococcaceae* (Garrity and Holt, 2001); in the present volume, *Gemella* has been classified in Family X. *Incertae Sedis*.

The genus *Staphylococcus* is monophyletic (Figure 70) and well separated from other related genera with intergenera 16S rRNA sequence similarities of 93.4–95.3%. The intragenus similarities are significantly higher with at least 96.5% (Figure 71). Based on DNA–DNA hybridization studies, staphylococcal species can be placed in species groups (Kloos et al., 1992). The most important ones are the two coagulase-negative and novobiocin-susceptible species groups *Staphylococcus epidermidis* (e.g., *Staphylococcus capitis*, *Staphylococcus caprae*, *Staphylococcus epidermidis*, *Staphylococcus haemolyticus*, *Staphylococcus hominis*, *Staphylococcus saccharolyticus*, *Staphylococcus warneri*) and *Staphylococcus simulans* (e.g., *Staphylococcus carnosus*, *Staphylococcus*

simulans); the two coagulase-negative and novobiocin-resistant species groups *Staphylococcus saprophyticus* (e.g., *Staphylococcus cohnii*, *Staphylococcus saprophyticus*, *Staphylococcus xylosus*) and *Staphylococcus sciuri* (e.g., *Staphylococcus lentus*, *Staphylococcus sciuri*, *Staphylococcus vitulinus*), and the two coagulase-positive and novobiocin-susceptible species groups *Staphylococcus intermedius* (e.g., *Staphylococcus delphini*, *Staphylococcus intermedius*) and *Staphylococcus aureus* (e.g., *Staphylococcus aureus*, *Staphylococcus aureus* subsp. *anaerobius*).

The different species are genotypically well separated and demonstrate 60% or less DNA–DNA similarity under optimal hybridization conditions and less than 30% under restrictive conditions. The only exception is *Staphylococcus pulvereri*/*Staphylococcus vitulinus*. The two species appear identical on the basis of DNA similarity, pulse-field gel electrophoresis, ribotyping, and other taxonomic criteria (Kloos et al., 2001; Webster et al., 1994) *Staphylococcus pulvereri* is a later synonym of *Staphylococcus vitulinus*.

Species identity is also made on the basis of a variety of phenotypic characters such as cell-wall composition, colony morphology, activities and molecular properties of various enzymes, production of acid from various carbohydrates, resistance to certain antibiotics, nutritional and oxygen requirements, cytochrome composition, oxygen requirements, and fatty acid composition.

Cell-wall composition. The ultrastructure and chemical composition of the cell wall of staphylococci is similar to that of other Gram-positive bacteria. It consists of a thick (usually 60–80 nm), rather homogeneous, and not very electron-dense layer. It is made up of peptidoglycan, teichoic acid, and protein (Schleifer, 1984). A characteristic feature of the peptidoglycan of all staphylococci, with the exception *Staphylococcus succinus* subsp. *succinus*, is the occurrence of a peptidoglycan of group A 3 with L-lysine as the diamino acid in position 3 of the peptide subunit and a glycine-rich interpeptide bridge (Schleifer and Kandler, 1972). Penta- and hexaglycine interpeptide bridges are found in about half of the staphylococcal species (peptidoglycan type: Lys–Gly₅₋₆). In most of the other half, a minor part of the glycine residues can be replaced with L-serine (peptidoglycan type: Lys–Gly₄, Ser). *Staphylococcus sciuri*, *Staphylococcus lentus*, *Staphylococcus fleuretti*, and *Staphylococcus vitulinus* have an L-alanine instead of a glycine residue bound to lysine of the peptide subunit (peptidoglycan type: Lys–Ala–Gly₄). *Staphylococcus succinus* subsp. *succinus*, however, has been described with a completely different peptidoglycan type with meso-diaminopimelic acid in position 3 of the peptide subunit and a direct cross-linkage without an interpeptide bridge (Lambert et al., 1998). The occurrence of such a peptidoglycan type would be unique for staphylococci and is rather questionable because the closely related *Staphylococcus succinus* subsp. *casei* contains a typical staphylococcal peptidoglycan type (L-Lys–Gly₄, L-Ser; Place et al., 2002).

Additions to the peptidoglycan of *Staphylococcus aureus* also occur in the form of covalently linked wall teichoic acid. They are attached by phosphodiester linkages on C₆ of some of the muramic acid residues (Hay et al., 1965). Staphylococcal cell-wall teichoic acids are water-soluble polymers containing repeating phosphodiester groups that are covalently linked to peptidoglycan. They consist of polyols (glycerol or ribitol), sugars and/or N-acetylamino-sugars. Most staphylococci contain

glycerol or ribitol teichoic acids. The teichoic acids consist of polymerized polyol phosphates that are substituted with various combinations of sugars and/or N-acetylamino-sugar residues, and also ester-linked D-alanine residues. In some cases, N-acetylamino-sugar residues can also form an integral part of the polymer chain (Endl et al., 1983; Endl et al., 1984). The occurrence of the same major components does not always mean that the structure of teichoic acid is identical; for example, the teichoic acids of *Staphylococcus capitis* and *Staphylococcus hyicus* exhibit a similar composition, but their structures are quite different.

Pathogenicity. The coagulase-positive species *Staphylococcus aureus*, *Staphylococcus intermedius*, *Staphylococcus delphini*, and *Staphylococcus schleiferi* subsp. *coagulans* and the coagulase variable species *Staphylococcus hyicus* are regarded as potentially serious pathogens. *Staphylococcus aureus* is responsible for a variety of infections. In the late 1950s and early 1960s, *Staphylococcus aureus* caused considerable morbidity and mortality as a nosocomial pathogen of hospitalized patients. Among the major human infections caused by this species are furuncles, carbuncles, impetigo, toxic epidermal necrolysis (scalded skin syndrome), pneumonia, osteomyelitis, acute endocarditis, myocarditis, pericarditis, enterocolitis, mastitis, cystitis, prostatitis, cervicitis, cerebritis, meningitis, bacteremia, toxic shock syndrome, and abscesses of the muscle, skin, urogenital tract, central nervous system, and various intra-abdominal organs. In addition, staphylococcal enterotoxin is involved in food poisoning. Methicillin-resistant *Staphylococcus aureus* (MRSA) strains have emerged in the 1980s as a major clinical and epidemiological problem in hospitals. These strains are beginning to spread out of the hospitals and into communities.

Staphylococcus aureus is also capable of producing infections in a variety of other mammals and birds. The more common natural infections include mastitis, synovitis, arthritis, endometritis, furuncles, suppurative dermatitis, pyemia, and septicemia. Staphylococcal mastitis in either a clinical or subclinical form may have considerable economic consequences in the dairy industry. *Staphylococcus aureus* subsp. *anaerobius* is the etiologic agent of an abscess disease in sheep, symptomatically similar to caseous lymphadenitis (de la Fuente et al., 1985).

Staphylococcus intermedius is a serious opportunistic pathogen of dogs and may cause otitis externa, pyoderma, abscesses, reproductive tract infections, mastitis, and purulent wound infections. *Staphylococcus hyicus* has been implicated as the etiologic agent of infectious exudative epidermitis (greasy pig disease) and septic polyarthritis of pigs, skin lesions in cattle and horses, osteomyelitis in poultry and cattle, and occasionally has been associated with mastitis in cattle. *Staphylococcus delphini* has been implicated in purulent skin lesions of dolphins (Varaldo et al., 1988). *Staphylococcus schleiferi* subsp. *coagulans* is associated with the external auditory meatus of dogs suffering from external ear otitis (Igimi et al., 1990).

The coagulase-negative staphylococcal species constitute a major component of the normal microflora of the human; their role in causing nosocomial infections has been recognized and well documented over the last two decades. The increase in infections by these organisms has been correlated with the wide medical use of prosthetic and indwelling devices and the growing number of immunocompromised patients in hospitals. Within the coagulase-negative staphylococci, *Staphy-*

^mData from Hájek et al. (1996).

ⁿData from Kloos et al. (1997).

^oData from Lambert et al. (1998).

^pData from Place et al. (2003a).

^qData from Webster et al. (1994). *Staphylococcus vitulinus* is considered a senior heterotypic synonym of *Staphylococcus pulvereri* (Kloos et al., 2001; Petráš, 1998).

^rKloos et al. (1997) found that *Staphylococcus sciuri* subsp. *sciuri* and *Staphylococcus sciuri* subsp. *carnaticus* strains were negative when tested for Staph-A-Lex agglutination; all *Staphylococcus sciuri* subsp. *sciuri* strains were negative and some *Staphylococcus sciuri* subsp. *carnaticus* strains were positive when tested for Staph Latex agglutination. *Staphylococcus sciuri* subsp. *rodentium* was positive when tested with both systems.

FIGURE 70. 16S rRNA based tree reflecting the phylogenetic relationships of the genus *Staphylococcus* and selected representatives of the phylum *Firmicutes*. The tree topology was reconstructed by applying the ARB-parsimony tool (Ludwig et al., 2004) upon an ARB 16SrRNA database (<http://www.arb-home.de/>) comprising 28,980 almost complete sequences. The tree topology was corrected according to the data obtained by applying distance and maximum-likelihood methods. Only sequence positions which shared identical nucleotides in at least 50% of all compared sequences from representatives of the *Staphylococcaceae* were used to construct the tree. Length bar indicates 5% estimated sequence divergence.

lococcus epidermidis is the species that is associated most commonly with disease. It appears to have the greatest pathogenic potential and adaptive diversity. This species has been implicated in bacteremia, native and prosthetic valve endocarditis,

osteomyelitis, pyoarthritis, peritonitis during continuous ambulatory dialysis, mediastinitis, infections of permanent pacemakers, vascular grafts, cerebrospinal fluid shunts, prosthetic joints, and a variety of orthopedic devices, and urinary tract infections including urethritis and pyelonephritis. Recent reviews have been published on the nature of human infections caused by *Staphylococcus epidermidis* and other coagulase-negative species (Crossley and Archer, 1997; Kloos and Bannerman, 1994; Rupp and Archer, 1994). Nosocomial methicillin-resistant *Staphylococcus epidermidis* (MRSE) strains became a serious clinical problem in the 1980s, especially in patients with prosthetic heart valves or who have undergone other forms of cardiac surgery (Archer and Tenenbaum, 1980; Karchmer et al., 1983). *Staphylococcus epidermidis* has also occasionally been associated with mastitis in cattle (Baba et al., 1980; Devriese and De Keyser, 1980; Holmberg, 1986).

Certain other coagulase-negative species have been associated with infections in humans and animals. *Staphylococcus haemolyticus* is the second most frequently encountered species of this group found in human clinical infections. It has been implicated in native valve endocarditis, septicemia, peritonitis, and urinary tract infections, and is occasionally associated with wound, bone, and joint infections. *Staphylococcus haemolyticus* has occasionally been associated with mastitis in cattle (Baba et al., 1980). *Staphylococcus caprae*, which has previously been misidentified as *Staphylococcus haemolyticus*, *Staphylococcus hominis*, and *Staphylococcus warneri*, is widely distributed in human clinical specimens (Kawamura et al., 1998). *Staphylococcus caprae* has been implicated in cases of infective endocarditis, bacteremia, and urinary tract infections. *Staphylococcus lugdunensis* has been implicated in native and prosthetic valve endocarditis, septicemia, brain abscess, and chronic osteoarthritis and infections of soft tissues, bone, peritoneal fluid, and catheters, especially in patients with underlying diseases. *Staphylococcus schleiferi* has been implicated in human brain empyema, osteoarthritis, bacteremia, wound infections, and infections

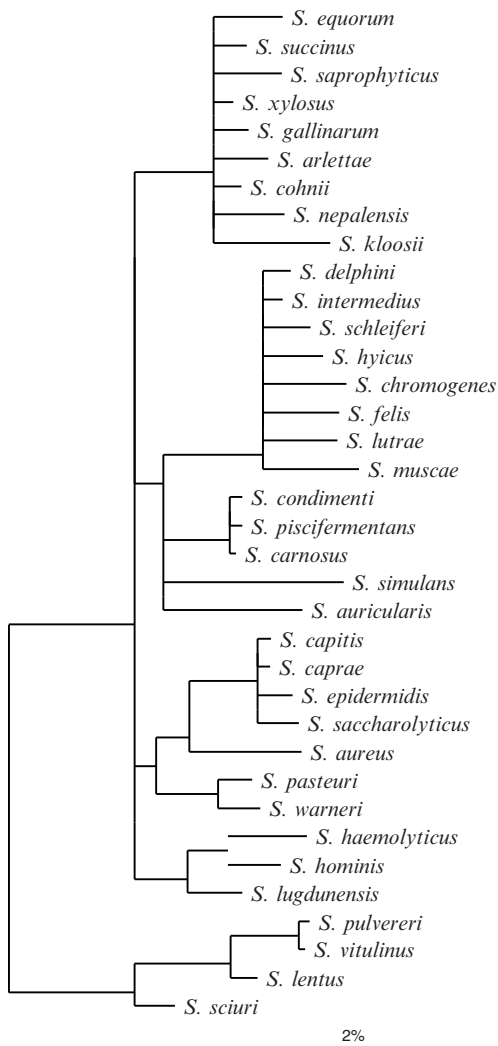

FIGURE 71. 16S rRNA based tree reflecting the relationships of the type strains of *Staphylococcus* species. The tree topology was reconstructed as described in the legend of Figure 70 in the *Staphylococcaceae* chapter. A relative branching order is shown if supported by all three treeing methods. Multifurcations indicate that a significant relative branching order could not be determined or not supported by all three treeing methods. The length bar indicates 2% estimated sequence divergence.

associated with a cranial drain and jugular catheter. However, this species occurs less frequently than *Staphylococcus lugdunensis* in the hospital environment and human infections. *Staphylococcus saprophyticus* is an important opportunistic pathogen in human urinary tract infections, especially in young, sexually active females. It is considered to be the second most common cause of urinary tract infections, such as acute cystitis or pyelonephritis, in these patients. This species has also occasionally been isolated from wound infections and septicemia (Fleurette et al., 1987; Marsik and Brake, 1982).

Staphylococcus warneri has been associated with mastitis in cattle (Devriese and De Keyser, 1980; Devriese and Derycke, 1979). *Staphylococcus simulans* has been isolated from patients with chronic osteomyelitis and from mastitis in cows. *Staphylococcus felis*, a relative of *Staphylococcus simulans*, has been associated

with skin infections of cats (Igimi et al., 1989). *Staphylococcus capitis* has been implicated in endocarditis, septicemia, and catheter infections. *Staphylococcus hominis* has been associated with human endocarditis, peritonitis, septicemia, and arthritis. *Staphylococcus cohnii* has been isolated from urinary tract infections and arthritis. *Staphylococcus chromogenes*, a close relative of *Staphylococcus hyicus*, is commonly present in the milk of cows suffering from mastitis, although its role as an etiologic agent is questionable (Devriese and De Keyser, 1980; Langlois et al., 1983; Watts et al., 1984). *Staphylococcus sciuri* subspecies have been isolated from wound, skin, and soft tissue infections (Marsou et al., 1999).

Genomes. The size range of staphylococcal genomes is about 2–3 Mbp (George and Kloos, 1994; Kloos et al., 1998b). Eight staphylococcal strains (seven *Staphylococcus aureus* and one *Staphylococcus epidermidis*) are completely sequenced. The genome size of the *Staphylococcus aureus* strains is 2.82–2.9 Mbp and that of *Staphylococcus epidermidis* 2.5 Mbp. Sequences of the genomes of *Staphylococcus epidermidis* RP62A, *Staphylococcus carnosus*, and *Staphylococcus haemolyticus* are due for completion but so far only the *Staphylococcus aureus* strains N315 and Mu50 (Kuroda et al., 2001) are annotated. Strain N315 is a methicillin-resistant *Staphylococcus aureus* and strain Mu50, in addition to being methicillin-resistant, is also vancomycin-resistant. Both strains contain one plasmid and three pathogenicity islands. The genome of *Staphylococcus aureus* N315, which causes acute infections, was compared with the genome of *Staphylococcus epidermidis* RP62A, which can cause chronic infections (Götz et al., 2003). Of the 125 selected virulence genes in *Staphylococcus aureus* N315, only 22 genes (18%) had homologous equivalents in *Staphylococcus epidermidis* RP62A. This clearly reflects the difference in the pathogenic potential of both species representatives and explains why *Staphylococcus aureus* is a rather aggressive pathogen and *Staphylococcus epidermidis* is not. Of the 40 toxin genes in *Staphylococcus aureus*, only three were identified in the *Staphylococcus epidermidis* genome. This finding is in agreement with the earlier observations of decreased toxin production of *Staphylococcus epidermidis* and corroborates well with the decreased severity of an *Staphylococcus epidermidis* infection. Compared to *Staphylococcus aureus*, *Staphylococcus epidermidis* also revealed a decreased number of other potential virulence factors such as exoenzymes and adhesins.

Enrichment and isolation procedures

Isolation of staphylococci from clinical specimens. Procedures used in the isolation and enumeration of staphylococci from clinical specimens including blood, pus, purulent fluids, sputum, urine, and feces can be found in the following texts: American Society for Microbiology (ASM) *Manual of Clinical Microbiology*, 7th edition (Murray et al., 1999), *A Guide to Specimen Management in Clinical Microbiology*, 2nd edition (Miller, 1998), and *Clinical Microbiology Procedures Handbook* (Isenberg, 1994).

Staphylococci from clinical specimens are usually isolated in primary culture on blood agar and in a fluid medium such as thioglycolate broth (Kloos and Bannerman, 1999; Murray et al., 1999). On blood agar, abundant growth of most staphylococcal species occurs within 18–24 h at 34–37°C. Colonies should be

allowed to grow for at least an additional 2–3 d before the primary isolation plate is confirmed for species or strain composition (Kloos and Schleifer, 1975a).

Several basic methods are available for isolating staphylococci and other aerobic bacteria from skin and the adjacent mucous membranes (reviewed by Noble and Sommerville, 1974). The medium most widely used for the isolation and culture of natural populations of staphylococci from the skin of humans and animals is P agar (Kloos et al., 1974).

Isolation of *Staphylococcus aureus* from food samples. A non-selective enrichment for the detection of *Staphylococcus aureus* in food samples has been described by Downes and Ito (2001). Black to dark gray colonies are selected for coagulase testing. When supplemented with egg yolk tellurite enrichment, Baird-Parker agar base can also be used for the detection and enumeration of coagulase-positive staphylococci in foods.

Selective enrichments. Selective enrichment is recommended for raw food ingredients and unprocessed foods expected to contain <100 *Staphylococcus aureus* cells/g and a large population of competing species. The recommended procedures for the selective enrichment of *Staphylococcus aureus* are the most probable number technique or the direct surface plating on Baird-Parker agar (Horowitz, 2000). Instead of Baird-Parker agar, the following media for the selective isolation and enumeration of staphylococci can be used: tellurite polymyxin egg yolk agar (Crisley et al., 1964), Kalium-Rhodanid (= potassium thiocyanate)-Actidione-Natriumazid (=sodium azide)-Egg yolk-Pyruvate (KRA-NEP) agar (Sinell and Baumgart, 1966), and Schleifer-Krämer (SK) agar (Harvey and Gilmour, 1988; Schleifer and Krämer, 1980).

Ecology

Human and animal sources. Staphylococci are a major group of bacteria inhabiting the skin, skin glands, and mucous membranes of humans, other mammals, and birds. They may be found on the skin as residents or transients (Kloos and Musselwhite, 1975; Noble and Somerville, 1974). Resident bacteria are indigenous to the host, maintain relatively stable populations, and increase in numbers mainly by multiplication of those already present. Transient bacteria are derived from exogenous sources, found primarily on exposed skin, and may easily be washed away.

Staphylococcus aureus is a major species of primates, though specific ecovars or biotypes can occasionally be found living on different domestic animals or birds (Kloos, 1980; Meyer, 1967). This species is found infrequently on nonprimate wild animals. In humans, *Staphylococcus aureus* has a niche preference for the anterior nares, especially in the adult. Nasal carrier rates range from less than 10% to more than 40% in normal adult human populations residing outside of the hospital (Noble and Somerville, 1974). *Staphylococcus epidermidis* (Schleifer and Kloos, 1975) is the most prevalent and persistent *Staphylococcus* species on human skin. It is found over much of the body surface and produces the largest populations where moisture content and nutrition are high, such as in the anterior nares, axillae, inguinal and perineal area, and toe webs. This species may be found occasionally on other hosts, such as domestic animals, but it is presumably transferred there from human sources. *Staphylococcus hominis* (Kloos and Schleifer, 1975a) is also prevalent

on human skin. Its population size is usually second or equal to *Staphylococcus epidermidis* on skin sites where apocrine glands are numerous (e.g., in the axillae and inguinal and perineal areas). It can also colonize the drier regions of skin (e.g., on the extremities) more successfully than other species. *Staphylococcus haemolyticus* (Schleifer and Kloos, 1975) shares many of the habitats of *Staphylococcus hominis*, but it is usually found in smaller populations. Some individuals may carry unusually large populations of *Staphylococcus haemolyticus*. *Staphylococcus warneri* (Kloos and Schleifer, 1975a) is found usually in small numbers on human skin, though a few individuals may carry unusually large populations. Occasionally, small transient populations of *Staphylococcus haemolyticus* or *Staphylococcus warneri* may be isolated from domestic animals. *Staphylococcus capitis* (Kloos and Schleifer, 1975a) produces large populations on the human scalp following puberty. It is also found on other regions of the adult head, e.g., forehead, face, eyebrows, and external auditory meatus in moderate-sized to large populations. *Staphylococcus auricularis* is one of the major species found living in the adult human external auditory meatus and demonstrates a strong preference for this niche (Kloos and Schleifer, 1983).

Staphylococcus caprae, originally isolated from the skin of domestic goats or in their milk (Devriese et al., 1983; Poutrel, 1984), has been isolated from human clinical specimens (Kawamura et al., 1998; Vandenesch et al., 1995). *Staphylococcus hominis* subsp. *novobiosepticus*, *Staphylococcus lugdunensis*, *Staphylococcus pasteurii*, and *Staphylococcus schleiferi* are other clinically significant species isolated from human specimens (Chesneau et al., 1993; Freney et al., 1988; Kloos et al., 1998b). Their original niche preference and prevalence is undetermined. The host range of *Staphylococcus saprophyticus* and similar species varies from humans to lower mammals and birds (Kloos, 1980) (Devriese, 1986). As a group, these staphylococci are most prevalent on lower primates and mammals. *Staphylococcus saprophyticus* is found usually in small, transient populations on the skin of humans or other primates. It may also be isolated from lower mammals and environmental sources. *Staphylococcus cohnii* (Schleifer and Kloos, 1975) is found as a temporary resident or transient on human skin. *Staphylococcus cohnii* subsp. *urealyticus* (Kloos and Wolfshohl, 1991) is sometimes found on human skin, but it is often one of the major species and subspecies of nonhuman primates, especially the lower primates. *Staphylococcus xylosus* (Schleifer and Kloos, 1975) is often found as a transient on the skin of lower primates and other mammals, and occasionally on birds (Akatov et al., 1985; Devriese et al., 1985; Kloos et al., 1976b). The related species *Staphylococcus kloosii* has been found living on a variety of lower mammals including wild marsupials, rodents, and carnivores, and less frequently on domestic animals (Kloos, 1980) (Schleifer et al., 1984). *Staphylococcus arlettae* has been isolated from poultry and goats, *Staphylococcus equorum* from horses, and *Staphylococcus gallinarum* from poultry (Devriese et al., 1983; Schleifer, 1984).

Staphylococcus intermedius is a major species of domestic dogs (Hajek and Marsalek, 1976). This species can be found in relatively large populations on canine skin and can on occasion be transferred to the skin of human handlers (Kloos et al., 1976b). *Staphylococcus intermedius* also appears to be indigenous to a variety of other carnivores including mink, foxes (Hajek, 1976), and raccoons (Kloos et al., 1976b). It has also been isolated

from horses and pigeons (Hajek, 1976). *Staphylococcus felis* is one of the major species of the domestic cat (Igimi et al., 1990). *Staphylococcus schleiferi* subsp. *coagulans* is a coagulase-positive species that has been isolated from the external auditory meatus of dogs with ear infections (Igimi et al., 1990). Other coagulase-positive species isolated from animals include *Staphylococcus delphini* (Varaldo et al., 1988) and *Staphylococcus lutrae* (Foster et al., 1997). *Staphylococcus sciuri*, *Staphylococcus sciuri* subsp. *carnaticus*, and *Staphylococcus sciuri* subsp. *rodentium* have been isolated from a variety of lower mammals and domestic animals (Kloos et al., 1997; Kloos et al., 1976a). In addition, the *Staphylococcus sciuri* subspecies may be isolated from human clinical specimens (Marsou et al., 1999). *Staphylococcus sciuri* appears to be a natural reservoir of methicillin resistance and staphylolytic enzyme genes (Kloos et al., 1997). Their role, if any, in the appearance of methicillin resistance in the more pathogenic species *Staphylococcus aureus* has not yet been determined. *Staphylococcus hyicus* and *Staphylococcus chromogenes* are found predominantly on domestic ungulates such as pigs, cattle, and horses (Devriese, 1986; Hajek et al., 1986). *Staphylococcus lentus* (Schleifer et al., 1983b) has been isolated in large populations from domestic sheep and goats (Kloos et al., 1976a; Kloos et al., 1976b) and occasionally from other domestic animals (Devriese et al., 1985); it is a major bacterium in saliva of rabbits (Kanda et al., 2001).

Flies of the genera *Musca*, *Fannia*, and *Stomoxys*, commonly found in human and animal habitations, can carry populations of staphylococci (e.g., *Staphylococcus muscae*; Hajek et al., 1992) and appear to be significant vectors of these organisms in an epizootiological chain (Hájek and Balusek, 1985).

Environmental sources and food. Staphylococci have been isolated sporadically from a wide variety of environmental sources such as soil, beach sand, sea water, fresh water, plant surfaces and products, feeds, meat and poultry, dairy products, and the surfaces of cooking ware, utensils, furniture, clothing, blankets, carpets, linens, paper currency, and dust and air in various inhabited areas.

Staphylococcus aureus has been confirmed to be a major causative agent of food poisoning. Other staphylococci may be involved in the production of certain fermented foods. The predominant bacterium in fermented meat is *Staphylococcus carnosus* which appears in the early literature as *Micrococcus* (Schleifer and Fischer, 1982). For more than 50 years, *Staphylococcus carnosus* has been used alone or in combination with lactobacilli or pediococci as a starter culture for the production of raw fermented sausages. During the ripening process of dry sausage, *Staphylococcus carnosus* exerts several desired functions (Götz, 1990; Liepe and Porobic, 1983). *Staphylococcus condimentii* was isolated from soy sauce mash (Probst et al., 1998), *Staphylococcus equorum* subsp. *linens* and *Staphylococcus succinus* subsp. *casei* from surface ripened cheeses (Place et al., 2002; Place et al., 2003b), *Staphylococcus fleuretii* from goats' milk cheese (Vernozy-Rozand et al., 2000), and *Staphylococcus piscifermentans* (Tanasupawat et al., 1992) from fermented shrimp and fish.

Staphylococcus sciuri and *Staphylococcus xylosus* can grow in habitats containing only an inorganic nitrogen source and thus might be more free-living than other staphylococci (Emmett and Kloos, 1979). These species have been isolated in small numbers from beach sand, natural waters, marsh grass (Kloos and Schleifer, 1981), and plant products (Pioch et al., 1988).

Identification

Conventional methods. Conventional methods for the determination of phenotypic characters were developed first and later staphylococci were examined through genotypic studies (reviewed by Kloos and Schleifer, 1986; Schleifer, 1986). A simplified system for the identification of human staphylococci has been described by Kloos and Schleifer (1975b). Key characteristics now used for species and subspecies identification include the following: colony morphology, oxygen requirements, coagulase, clumping factor, heat-stable nuclease (thermonuclease), hemolysins, catalase, oxidase, alkaline phosphatase, urease, ornithine decarboxylase, pyrrolidonyl arylamidase, β -galactosidase, acetoin production, nitrate reduction, esculin hydrolysis, aerobic acid production from a variety of carbohydrates including D-trehalose, D-mannitol, D-mannose, D-turanose, D-xylose, D-cellobiose, L-arabinose, maltose, lactose, sucrose, and raffinose, and intrinsic resistance to novobiocin and polymyxin B (reviewed by Kloos and Bannermann, 1999). Some conventional methods may require up to 3–5 d before a final result can be obtained, while others only require several hours for interpretation. Characteristic properties useful for the differentiation of the species and subspecies of the genus *Staphylococcus* are compiled in Table 74.

Rapid identification systems. Identification in the routine or clinical laboratory is carried out with rapid species identification kits or automated systems that require only a few hours to 1 d for the completion of tests. Identification of a number of the *Staphylococcus* species can be made with an accuracy of 70 to >90% using the commercial systems (Kloos et al., 1998a). *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Staphylococcus capitis*, *Staphylococcus haemolyticus*, *Staphylococcus saprophyticus*, *Staphylococcus simulans*, and *Staphylococcus intermedius* can be identified reliably by most of the commercial systems now available. Some identification systems now available include the following: RAPIDEC Staph (identification of *Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Staphylococcus saprophyticus*) and API STAPH (bioMérieux Vitek, Inc., Hazelwood, Mo.); VITEK, a fully automated microbiology system that uses a Gram-positive Identification (GPI) Card (bioMérieux Vitek); MicroScan Pos ID panel (read manually or on MicroScan instrumentation), MicroScan Rapid Pos ID panel (read by the WalkAway systems) (in addition, the ID panels are available with antimicrobial agents for susceptibility testing) (Dade MicroScan, Inc., West Sacramento, Calif.); Crystal Gram-positive Identification System, Crystal Rapid Gram-positive Identification System, Pasco MIC/ID Gram-positive Panel, and the Phoenix, an automated identification system (Becton Dickinson Microbiology Systems); GP MicroPlate test panel (read manually, using Biolog MicroLog system or read automatically with the Biolog MicroStation system) (Biolog, Haywood, Calif.); MIDI Sherlock Identification System Microbial Identification System (MIS) that automates microbial identification by combining cellular fatty acid analysis with computerized high-resolution gas chromatography (MIDI, Newark, Del.); and RiboPrinter Microbial Characterization System (Qualicon, Inc. Wilmington, Del.), based on ribotype pattern analysis.

Oligonucleotide probes directed against rRNA are also used for the rapid identification of the species *Staphylococcus aureus*, e.g., AccuProbe culture identification test for *Staphylococcus*

aureus (Gen-Probe, Inc., San Diego, Calif.). The oligonucleotide probe tests are usually very accurate (100% specificity). Additionally, PCR analysis of the 16S–23S rRNA intergenic spacer region has preliminarily shown successful results in discriminating among 31 *Staphylococcus* species (Mendoza et al., 1998). PCR analysis allows for the identification of pure culture.

Differentiation at the infrasubspecific level. For clinical, particularly epidemiological, studies it is important to distinguish bacteria at the infrasubspecific level. Therefore, many different methods were used for the typing of *Staphylococcus aureus* and *Staphylococcus epidermidis* strains. Besides conventional techniques including plasmid profiles and phage typing, molecular techniques are applied. The most powerful methods are pulsed-field gel electrophoresis (PFGE) and multilocus sequence typing (MLST). PFGE is based on direct comparison of DNA fragment patterns of the entire genome when restricted with a rare-cutting enzyme (Cookson et al., 1996; Tenover et al., 1995). This method has proved very useful for the investigation of nosocomial outbreaks and of the spread of multi-drug-resistant *Staphylococcus aureus* strains (Cox et al., 1995; de Sousa et al., 1998). A major disadvantage of PFGE is that it is rather time-consuming and subjective in interpretation (van Belkum et al., 1998). An alternative highly discriminative method is MLST. It is based on the comparison of sequence fragments of several house-keeping genes (Maiden et al., 1998). For each gene fragment, the different sequences are assigned as distinct alleles, and each isolate is defined by the alleles at

each of the house-keeping loci. Sequence data are readily compared between laboratories and easily cataloged. MLST has been used for the characterization of natural populations of *Staphylococcus aureus* (Enright et al., 2000; Grundmann et al., 2002; van Leeuwen et al., 2003) and of *Staphylococcus epidermidis* (Wang et al., 2003).

Taxonomic comments

The genus *Staphylococcus* has been considerably expanded since publication of Volume 2 of the first edition of *Bergey's Manual of Systematic Bacteriology* in which 19 species were listed. Currently, 37 species and several subspecies are recognized in the genus *Staphylococcus*. They form a coherent and well-defined group of related species that is widely divergent from those of the genus *Micrococcus*. A simple test system for the separation of staphylococci from micrococci has been described by Kloos and Schleifer (1975b). Staphylococci can be separated from macrococci on the basis of generally smaller cells, presence of cell-wall teichoic acids, a generally lower DNA G+C content (<40% mol%), 16S rRNA sequence, and unique ribotype patterns. The former *Staphylococcus caseolyticus* has been transferred to the genus *Macrococcus* as *Macrococcus caseolyticus* (Kloos et al., 1998a). Most members of the genus *Staphylococcus* are oxidase-negative whereas macrococci and salinicocci as well as jeotgalicocci are oxidase-positive. The DNA G+C content of salinicocci is significantly higher (46–51 mol%) than that of staphylococci.

List of species of the genus *Staphylococcus*

1. *Staphylococcus aureus* Rosenbach 1884, 18^{AL}

au're.us. L. masc. adj. *aureus* golden.

Nonmotile, nonspore-forming, Gram-stain-positive cocci; occur singly and form pairs and clusters. Facultatively anaerobic. Grows well in medium containing 10% NaCl, poorly in 15% NaCl. Positive reactions: alkaline phosphatase, catalase, coagulase, heat-stable nuclease, hemolysis, and hyaluronidase. Negative reactions: oxidase, β -galactosidase, β -glucuronidase. Produces acid aerobically from fructose, maltose, and sucrose. No acid produced from arabinose, cellobiose, melezitose, raffinose, salicin, xylitol, or xylose. Novobiocin-susceptible. Peptidoglycan type L-Lys-Gly₅₋₆. Teichoic acid contains ribitol and *N*-acetylglucosamine.

Additional characteristics of the subspecies are given below.

1a. *Staphylococcus aureus* subsp. *aureus* Rosenbach 1884, 18^{AL}

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.5–1.0 μ m in diameter; occur singly and form pairs and clusters. Colonies raised, smooth, glistening, translucent, with entire margins. Pigmentation varies from gray to yellow to orange. The pigments triterpenoid carotenoids or derivatives of them and are located in the cell membrane. Colony diameter >5 mm. Colonies are smooth, raised, glistening, circular, entire, and translucent. May produce capsules. Encapsulated strains usually produce smaller and more convex colonies. Capsular polysaccharides have been shown to contain *N*-acetyl-D-amino-galacturonic acid, *N*-acetyl-D-fucosamine, and taurine. Cell membranes contain the glycolipids, mono- and

diglycosyldiglyceride and the phospholipids, lysyl-phosphatidylglycerol, and cardiolipin.

Facultatively anaerobic. Growth is best under aerobic conditions. Temperature range for growth 10–45°C; optimum 30–37°C. Growth good in medium containing 10% NaCl; poor at 15% NaCl. Produces D- and L-lactate anaerobically from glucose. Addition of glucose to a growth medium suppresses the tricarboxylic acid cycle, resulting in the accumulation of acetate and carbon dioxide. D-Galactose and lactose are metabolized via the D-tagatose-6-phosphate pathway. Contain class I fructose-1,6-bisphosphate aldolase.

Protein A produced. Positive reactions: acetoin production, alkaline phosphatase, arginine dihydrolase, caseinase, catalase, clumping factor, coagulase, fibrinolysin, gelatinase, β -glucosidase, heat-stable nuclease (thermonuclease), hemolysin (at least four different ones), lipase, esterases, nitrate reduction, and urease. Negative reactions: amylase, ornithine decarboxylase, lysine decarboxylase and oxidase. Esculin and starch are not usually hydrolyzed.

Acid produced aerobically from fructose, galactose, glucose, glycerol, lactose, maltose, mannitol, mannose, ribose, sucrose, trehalose, and turanose. A few strains do not produce detectable acid from lactose, galactose, turanose, or mannitol. No acid produced from adonitol, arabinose, cellobiose, dextrin, dulcitol, erythritol, erythrose, fucose, gentiobiose, inositol, lyxose, melezitose, melibiose, raffinose, rhamnose, salicin, sorbitol, sorbose, xylitol, and xylose. Novobiocin-susceptible. Resistance to penicillin G and methicillin is quite common. Peptidoglycan type

L-Lys-Gly₅₋₆. Teichoic acid contains ribitol and *N*-acetylglucosamine. The major cellular fatty acids are C_{Bf-15}, C₂₀, C₁₈, and C_{Bf-17}. Unsaturated menaquinones (mainly MK-8; MK-7 and MK-9 as minor components) are present.

Some strains produce an epidermolytic toxin. Many strains produce enterotoxins. At least five different types of enterotoxins have been identified (A, B, C, D, and E). In addition, three different forms of enterotoxin C are known. Enterotoxin A is the most common one. An enterotoxin-like protein (enterotoxin F, pyrogenic exotoxin C) is produced by many of the strains associated with toxic shock syndrome.

Phage typing can be used for the differentiation of *Staphylococcus aureus* strains. Chromosomal and plasmid DNA may be transferred to appropriate recipient cells via transduction or transformation.

Isolated from nasal membranes (anterior nares, nasopharynx) and skin of warm-blooded animals. Can cause infection, food poisoning, and toxic shock syndrome.

DNA-DNA hybridization studies yielded relative DNA binding values >75% among *Staphylococcus aureus* subsp. *aureus* strains (Kloos and Wolfshohl, 1982; Meyer and Schleifer, 1978).

DNA G+C content (mol%): 32–36 (*T_m*, Bd).

Type strain: ATCC 12600, ATCC 12600-U, CCM 885, CCUG 1800, CIP 65.8, DSM 20231, HAMBI 66, NCAIM B.01065, NCCB 72047, NCTC 8532.

GenBank accession number (16S rRNA gene): D83357, L37597, X68417.

1b. ***Staphylococcus aureus* subsp. *anaerobius*** De La Fuente, Suarez and Schleifer 1985, 100^{VP}

an.ae.ro'bi.us. Gr. pref. an not; Gr. n. *aer* air; Gr. n. *bios* life; N.L. adj. *anaerobius* not living in air.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.8–1.0 µm in diameter; occur singly and form pairs and clusters. Grows microaerobically and anaerobically; weak aerobic growth can be obtained on subculturing. Produces L-lactate, acetate, and succinate anaerobically from glucose. Colonies on blood agar white, opaque, glistening, entire, smooth, and convex. Colony diameter 1–3 mm after incubation at 2 d on blood agar. Temperature range for optimal growth 30–40°C. No growth at 20 or 45°C. All strains tolerate 10% NaCl; most do not tolerate 15% NaCl. Positive reactions: acid and alkaline phosphatases, coagulase, hemolysis, caseinase, gelatinase, hyaluronidase, both heat-labile and heat-stable nucleases, and tellurite reduction. Negative reactions: acetoin production, benzidine test, catalase, oxidase, nitrate reduction, staphylokinase, and Tween 80 hydrolysis. Acid produced aerobically from fructose, glucose, maltose, and sucrose. No acid produced aerobically from amygdalin, arabinose, cellobiose, galactose, galactitol, gentiobiose, glycerol, inositol, inulin, lactose, mannitol, mannose, melibiose, melezitose, raffinose, rhamnose, ribose, salicin, sorbitol, trehalose, xylitol, or xylose. Lysozyme-resistant; lysostaphin-sensitive. Peptidoglycan type L-Lys-Gly₅₋₆. Ribitol-type teichoic acid containing *N*-acetylglucosamine. Class I fructose-1,6-bisphosphate aldolase. No production of enterotoxins A, B, C, D, or E or protein A.

Distinguished from *Staphylococcus aureus* subsp. *aureus* by lack of pigment and clumping factor and by the inability to

carry out anaerobic fermentation of mannitol, to grow at 45°C, to produce acetoin from glucose, to reduce nitrate, to produce β-glucosidase, and to produce acid from galactose, lactose, mannose, mannitol, ribose, and trehalose.

Found in abscesses of sheep; also pathogenic for goats. Not pathogenic for mice, rabbits, or guinea pigs. Primary isolation requires a medium supplemented with serum, egg yolk, or blood.

DNA-DNA hybridization studies yielded relative DNA binding values ≥80% between three strains of *Staphylococcus aureus* subsp. *anaerobius* and the type strain of *Staphylococcus aureus* subsp. *aureus* (de la Fuente et al., 1985).

DNA G+C content (mol%): 31.5–32.7 (*T_m*).

Type strain: MVF-7, ATCC 35844, CCUG 37246, CIP 103780, DSM 20714.

GenBank accession number (16S rRNA gene): D83355.

2. ***Staphylococcus arlettae*** Schleifer, Kilpper-Bälz and Devriese 1985, 224^{VP} (Effective publication: Schleifer, Kilpper-Bälz and Devriese 1984, 504..)

ar.let'tae. N.L. gen. n. *arlettae* of Arletta; named for Arlette van de Kerckhove, who has studied this and related species for many years.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.5–1.5 µm in diameter; occur singly and form pairs, clusters, and chains. Colonies beige or yellow, opaque, with entire margins. Colony diameter 6–8 mm after incubation for 2 d at 37°C on brain heart infusion agar. Aerobic. Positive reactions: catalase, esculin hydrolysis, and alkaline phosphatase. Produces very small amounts of lactate from glucose anaerobically. Weakly positive reactions: gelatinase and tributyrin hydrolysis. Negative reactions: coagulase, clumping factor, heat-stable nuclease, oxidase, hyaluronidase, staphylokinase, Tween 80 hydrolysis, fibrinolysin, hemolysis of sheep red blood cells, reduction of nitrate, urease, caseinase, and arginine hydrolysis. Acid produced aerobically from L-arabinose, arbutin, D-fructose, D-fucose (weak), β-gentiobiose, lactose, D-glucose, glycerol, maltose, D-mannitol, D-melezitose, raffinose, D-ribose, sucrose, trehalose, D-turanose, and D-xylose. No acid produced from amygdalin, cellobiose, L-rhamnose, D-sorbitol, or xylitol. Some strains produce acid from D-galactose, D-mannose, and D-melibiose. Peptidoglycan type Lys-Gly₅₋₆. Teichoic acids contain glucosamine, glycerol, and ribitol. Novobiocin-resistant.

Isolated from poultry (skin and nares) and goats (nares).

DNA-DNA hybridization studies yielded relative DNA binding values of 82–100% among *Staphylococcus arlettae* strains and 7–36% between *Staphylococcus arlettae* strains and nine other *Staphylococcus* species (Schleifer et al., 1984).

DNA G+C content (mol%): 31–32.6 (*T_m*).

Type strain: BP47, ATCC 43957, CCUG 32416, CIP 103501, DSM 20672, LMG 19114, NCTC 12413, NRRL B-14764

GenBank accession number (16S rRNA gene): AB009933.

3. ***Staphylococcus auricularis*** Kloos and Schleifer 1983, 9^{VP}

au.ri.cu.la'ris. L. adj. *auricularis* pertaining to the ear; named for the region of the body (external auditory meatus, external ear) where this species is commonly found.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.8–1.2 µm in diameter; form tetrads and pairs. Colonies white, convex, smooth, slightly glistening, opaque, and butyrous, with undulate margins that become crimped with age. Colony diameter 1.4–2.8 mm on P agar after incubation at 34–35°C for 3 d, then 25°C for 2 d. Facultatively anaerobic; anaerobic growth in thioglycolate medium slow and sparse. Grows best under aerobic conditions. Grows well in medium containing 10% NaCl, poorly in 15% NaCl. Temperature range for growth 20–45°C; optimum 30–40°C. Produces small amounts of L-lactate anaerobically from glucose. Positive reactions: catalase and lipase. Negative reactions: alkaline phosphatase, clumping factor, coagulase, heat-stable nuclease, hyaluronidase, oxidase, and urease. Acid produced aerobically from fructose, glucose, glycerol, maltose (delayed), and trehalose (delayed). No acid produced from arabinose, cellobiose, fucose, gentiobiose, inositol, mannitol, melezitose, raffinose, rhamnose, salicin, sorbitol, sorbose, xylitol, or xylose. Novobiocin-susceptible. Peptidoglycan type L-Lys-Gly_{4,3-4,8}, Ser_{0-0,6}. Teichoic acid contains N-acetylglucosamine 1-phosphate. Variable characteristics include acetoin production, arginine dihydrolase, β-galactosidase, hemolysis, and nitrate reduction.

Isolated from the external auditory meatus of primates, including humans.

DNA–DNA hybridization studies yielded relative DNA binding values of 90–99% between the type and other strains of *Staphylococcus auricularis* and 28–42% between the type strain of *Staphylococcus auricularis* and strains of 14 other *Staphylococcus* species (Kloos and Schleifer, 1983).

DNA G+C content (mol%): 38–39 (T_m).

Type strain: WK 811M, ATCC 33753, CCUG 15601, CCUG 36974, CIP 103587, DSM 20609, NCTC 12101, NRRL B-14762.

GenBank accession number (16S rRNA gene): D83358, L37598.

4. **Staphylococcus capitis** Kloos and Schleifer 1975a, 64^{AL}

ca'pi.tis. L. n. *caput* head; L. gen. n. *capitis* of the head; pertaining to that part of the human body where cutaneous populations of this species are usually the largest and most frequent.

Nonmotile, nonspore-forming, Gram-stain-positive cocci. Facultative anaerobes. Grows best under aerobic conditions. Positive reactions: catalase and aerobic production of acid from mannose, mannitol, and sucrose. Negative reactions: alkaline phosphatase, coagulase, clumping factor, β-galactosidase, β-glucosidase, β-glucuronidase, heat-stable nuclease, oxidase, and production of acid from arabinose, cellobiose, raffinose, trehalose, and xylose. Novobiocin-susceptible.

Additional characteristics of the subspecies are given below.

4a. **Staphylococcus capitis subsp. capitis** Kloos and Schleifer 1975a, 64^{AL}

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.8–1.2 µm in diameter; occur in pairs and tetrads. Colonies smooth, slightly convex, glistening, opaque, and white or grayish white; after storage in the cold (4–10°C), the colonies of some strains become yellowish or yellow-orange. Colony diameter 1–3 mm on P agar. Facultatively anaerobic.

Growth is best under aerobic conditions. Produces mainly L-lactate and lesser amounts of D-lactate anaerobically from glucose. Temperature range for growth 18–45°C; optimum 30–40°C. Growth good in medium containing 10% NaCl, poor or absent in 15% NaCl. Positive reactions: benzidine test, catalase, DNase (weak, not thermostable), lipases, and hemolysis of human blood. Negative reactions: alkaline phosphatase, coagulase, clumping factor, β-galactosidase, β-glucosidase, β-glucuronidase, heat-stable nuclease, proteases, urease, and oxidase. Acid produced aerobically from fructose, glucose, glycerol, mannose, mannitol, and sucrose (delayed). No acid produced from adonitol, arabinose, arabitol, cellobiose, erythritol, erythrose, fucose, galactose, gentiobiose, inositol, lyxose, maltose, melezitose, melibiose, raffinose, rhamnose, ribose, salicin, sorbitol, sorbose, tagatose, turanose, xylitol, or xylose. Lysozyme-resistant; moderate resistance to lysostaphin. Novobiocin-susceptible. Peptidoglycan type L-Lys-Gly_{3,5-4,3}, L-Ser_{0,8-1,2}. Teichoic acid contains glycerol and N-acetylglucosamine. Some strains may contain polymeric glutamic acid in their cell walls. Major fatty acids C_{18:1}, C_{18:2}, and C_{20:1}. Major menaquinone MK-7. Variable characteristics include growth on medium containing 15% NaCl, acetoin production, arginine dihydrolase, phosphatase, and nitrate reduction.

Isolated from the skin of the human head.

DNA–DNA hybridization studies yielded relative DNA binding values >90% among strains of *Staphylococcus capitis* (Kloos, 1980; Kloos and Wolfshohl, 1982).

DNA G+C content (mol%): 31–38.8 (T_m).

Type strain: LK499, ATCC 27840, CCM 2734, CCUG 7326, CIP 81.53, DSM 20326, JCM 2420, LMG 13353, NCTC 11045, NRRL B-14752.

GenBank accession number (16S rRNA gene): L37599.

4b. **Staphylococcus capitis subsp. urealyticus** Bannerman and Kloos 1991, 145^{VP}

ure.o.ly'ti.cus. N.L. n. *urea* urea; Gr. adj. *lutikos* dissolving; N.L. masc. adj. *ureolyticus* urea-dissolving.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.8–1.0 µm in diameter; occur singly and form pairs and clusters. Colonies raised, opaque, glistening; some strains develop yellow pigmentation late in incubation; colonies may be either smooth or rough and have either slightly irregular or entire edges. Colony diameter 4.3–7.1 mm. Facultatively anaerobic. Positive reactions: arginine utilization, catalase, nitrate reduction, and urease. Negative reactions: alkaline phosphatase, clumping factor, coagulase, esculin hydrolysis, β-galactosidase, β-glucosidase, β-glucuronidase, heat-stable nuclease, ornithine decarboxylase, and oxidase. Acid produced aerobically from D-mannose, D-mannitol, maltose, and sucrose. Acid not produced from N-acetylglucosamine, L-arabinose, D-cellobiose, raffinose, D-trehalose, or D-xylose. Novobiocin-susceptible. Peptidoglycan type L-Lys-Gly_{3,6}-Ser_{1,4}. Major fatty acids C_{15:0 iso}, C_{15:0 ante}, C_{18:0}, and C_{20:0}. Variable characteristics include colony pigmentation, hemolysis, acetoin production, nitrate reduction, and acid production from α-lactose and D-turanose.

Distinguished from *Staphylococcus capitis* subsp. *capitis* by production of urease, ability to produce acid from maltose, and fatty acid composition.

Isolated from humans, human clinical specimens, and animals.

DNA–DNA hybridization studies yielded relative DNA binding values of 81–100% among strains of *Staphylococcus capitis* subsp. *urealyticus*, of 80–100% between strains of *Staphylococcus capitis* subsp. *urealyticus* and strains of *Staphylococcus capitis* subsp. *capitis*, and 4–23% between the type strain of *Staphylococcus capitis* subsp. *urealyticus* and strains of 24 other *Staphylococcus* species (Bannerman and Kloos, 1991).

DNA G+C content (mol%): 38.8 (T_m).

Type strain: MAW 8436, ATCC 49326, CCUG 35142, CIP 104192, DSM 6717.

GenBank accession number (16S rRNA gene): AB009937.

5. ***Staphylococcus caprae*** Devriese, Poutrel, Kilpper-Bälz and Schleifer 1983, 483^{VP}

caprae. L. fem. n. *capra* goat; L. fem. gen. n. *caprae* of a goat.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.8–1.2 µm in diameter; occur singly and form pairs, chains, and clusters. Colonies nonpigmented, slightly convex, opaque, and glistening. Colony diameters differ; usually 5–8 mm. Facultatively anaerobic. Produces predominantly L-lactate anaerobically from glucose. FBP-aldolase is of class I type. Temperature range for growth 25–45°C, but growth is much slower at 25°C. Positive reactions: acetoin production, alkaline phosphatase, arginine dihydrolase, catalase, heat-labile DNase, hemolysis (delayed reaction), nitrate reduction, and urease. Negative reactions: caseinase, clumping factor, coagulase, esculin hydrolysis, heat-stable DNase, gelatinase, hyaluronidase, oxidase, staphylokinase, and Tween 80 hydrolysis. Acid produced aerobically from galactose, glucose, glycerol, lactose, mannose, and trehalose. No acid produced from amygdalin, arabinose, arbutin, cellobiose, fructose, fucose, β-gentiobiose, glucitol, mannitol, melezitose, melibiose, raffinose, rhamnose, ribose, salicin, sucrose, turanose, xylitol, or xylose. Novobiocin-susceptible. Lysozyme-resistant. Peptidoglycan type L-Lys–Gly₄₋₅, Ser_{0.8-1.2}. Teichoic acid contains glycerol, N-acetylglucosamine, and glucose. Variable characteristics include production of acid aerobically from maltose and mannitol.

Isolated from goats' milk.

DNA–DNA hybridization studies yielded relative DNA binding values of about 85% between the type strain and a second strain of *Staphylococcus caprae* and of 5–36% between the two *Staphylococcus caprae* strains and strains of 14 other *Staphylococcus* species (Devriese et al., 1983).

DNA G+C content (mol%): 35–37 (T_m).

Type strain: 143.22, ATCC 35538, CCM 3573, CCUG 15604, CIP 104000, DSM 20608, NCTC 12196, NRRL B-14757.

GenBank accession number (16S rRNA gene): AB009935, Y12593.

6. ***Staphylococcus carnosus*** Schleifer and Fischer 1982, 153^{VP}
car.no'sus. L. adj. *carnosus* pertaining to flesh.

Nonmotile, nonspore-forming, Gram-stain-positive cocci. Facultatively anaerobic. Grows best under aerobic conditions. Grows on medium containing 15% NaCl. Grows at 15°C. Positive reactions: arginine dihydrolase and nitrate reduction. Negative reactions: coagulase, β-glucuronidase,

and urease. Acid produced aerobically from fructose. No acid produced from arabinose, cellobiose, maltose, melezitose, sucrose, turanose, or xylose. Acid production from trehalose is variable. Novobiocin-susceptible.

Additional characteristics of the subspecies are given below.

6a. ***Staphylococcus carnosus* subsp. *carnosus*** Schleifer and Fischer 1982, 153^{VP}

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.5–1.5 µm in diameter; occur singly and form pairs. Colonies gray-white, slightly raised, smooth, and slightly glistening. May produce pigment during storage. Colony diameter 1–3 mm. Facultatively anaerobic. Produces D- and L-lactate anaerobically from glucose. Temperature range for growth 15–45°C; optimum 30–40°C. Grows in medium containing 15% NaCl. Positive reactions: acetoin production, alkaline phosphatase, arginine dihydrolase, catalase, nitrate reduction, β-galactosidase, and phosphatase. Negative reactions: coagulase, hemolysis, oxidase, and urease. Acid produced aerobically from fructose, glucose, glycerol, mannitol, and mannose. No acid produced from arabinose, fucose, maltose, melibiose, melezitose, raffinose, rhamnose, salicin, sucrose, turanose, xylitol, and xylose. Lysozyme-resistant. Novobiocin-susceptible. Peptidoglycan type L-Lys–Gly₃₋₆. Variable characteristics include production of heat-stable DNase, and acid production from galactose, lactose, and trehalose.

Isolated from dry sausage and is used as starter culture for the production of dry sausage.

DNA–DNA hybridization studies yielded relative DNA binding values of 100% between the type strain and three other strains of *Staphylococcus carnosus* and of 10–32% between the type strain of *Staphylococcus carnosus* and the type strains of eleven other *Staphylococcus* species (Schleifer and Fischer, 1982).

DNA G+C content (mol%): 34.8–36 (T_m).

Type strain: 361, ATCC 51365, CCUG 15605, CIP 103274, DSM 20501, NRRL B-14760.

GenBank accession number (16S rRNA gene): AB009934.

6b. ***Staphylococcus carnosus* subsp. *utilis*** Probst, Hertel, Richter, Wassill, Ludwig and Hammes 1998, 657^{VP}

ut.ti'lis. L. adj. *utilis* useful.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 1 µm in diameter; occur singly and form pairs and clusters. Colonies cream-colored, opaque, and entire. Colony diameter 0.5–1.5 mm after incubation at 2 d at 37°C on P agar. Temperature range for growth 15–42°C; no growth at 8°C. Tolerates 15% NaCl. Positive reactions: nitrate and nitrite reductases, catalase, and arginine dihydrolase. Negative reactions: phosphatase, β-galactosidase, β-glucuronidase, lecithinase, coagulase, and esculin hydrolysis. Acid produced aerobically from N-acetylglucosamine, fructose, and glucose, glycerol. No acid produced aerobically from cellobiose, galactose, lactose, maltose, mannitol, mannose, melezitose, raffinose, ribose, sorbitol, sucrose, or turanose. Lysozyme-resistant; lysostaphin-sensitive. Novobiocin-susceptible. Major menaquinone MK-7; minor menaquinones MK-6 and MK-8. Some strains produce acid from trehalose.

Distinguished from *Staphylococcus carnosus* subsp. *carnosus* by inability to grow at 45°C; lack of lipolytic activity,

alkaline phosphatase, and β -galactosidase; and lack of acid production from mannose and mannitol.

Found in fermented seafood sauces.

DNA G+C content (mol%): 34.8 (no method given).

Type strain: SK 11, LTH 3728, CIP 105758, DSM 11676, JCM 6067.

GenBank accession number (16S rRNA gene): AB233329.

7. **Staphylococcus chromogenes** (Devriese, Hájek, Oeding, Meyer and Schleifer 1978) Hájek, Devriese, Mordarski, Goodfellow, Pulverer and Varaldo 1987, 179^{VP} (Effective publication: Hájek, Devriese, Mordarski, Goodfellow, Pulverer and Varaldo 1986, 170.) (*Staphylococcus hyicus* subsp. *chromogenes* Devriese, Hájek, Oeding, Meyer and Schleifer 1978, 488.)

chro.mo'ge.nes. Gr. n. *chroma* color; Gr. v. *gennaio* to produce; N.L. adj. *chromogenes* producing color.

Nonmotile, nonspore-forming Gram-stain-positive cocci, 0.8–1.0 μm in diameter; form pairs, tetrads, and clusters as well as occurring singly. Colonies cream or orange, glistening, butyrous, with entire margins. Colony diameter 4–7 mm. Facultatively anaerobic. Produces L-lactate from glucose anaerobically. Optimum temperature range for growth 30–38°C. No growth at 45°C. Growth in medium containing 10% NaCl, but no growth or only weak growth at 15% NaCl. Positive reactions: arginine dihydrolase, benzidine test, caseinase, catalase, gelatinase, hippurate hydrolysis, nitrate reduction, phosphatase, and proteinase. Negative reactions: oxidase, acetoin production, clumping factor, coagulase, esculin hydrolysis, fibrinolysin, heat-stable nuclease, hemolysin, hyaluronidase, lecithinase, tellurite reduction, H₂S production, indole production, and Tween 80 hydrolysis. Produces acid aerobically from trehalose, sucrose, ribose, mannose, lactose, glycerol, glucose, galactose, and fructose. No acid produced from xylose, tagatose, salicin, raffinose, melezitose, melibiose, lyxose, β -gentiobiose, fucose, cellobiose, arabinose, xylitol, sorbitol, dulcitol, rhamnose, arabinol, amygdalin, or adonitol. Lysostaphin-sensitive; lysozyme-resistant. Novobiocin-susceptible. Peptidoglycan type L-Lys-Gly₄₋₅, Ser_{0-0.3}. Teichoic acid contains glycerol and α -N-acetylglucosamine. Major menaquinone MK-7. Variable characteristics include β -glucosidase, urease, and acid production from maltose, mannitol, and turanose.

Distinguished from *Staphylococcus hyicus* by pigmentation and lack of the following characteristics: heat-stable nuclease, hyaluronidase, Tween 80 hydrolysis, lecithinase, and pathogenicity for piglets.

Isolated from poultry, swine, and cattle.

Initial DNA–DNA hybridization studies yielded relative DNA binding values of 92–95% between two strains of *Staphylococcus chromogenes*, 30–55% between two strains of *Staphylococcus chromogenes* and three strains of *Staphylococcus hyicus*, and 9–19% between two strains of *Staphylococcus chromogenes* and three other *Staphylococcus* species (Devriese et al., 1978). Further DNA–DNA hybridization studies yielded relative DNA binding values of 84–100% between the type strain and nine other strains of *Staphylococcus chromogenes* and 43–65% between the type strain of *Staphylococcus chromogenes* and ten strains of *Staphylococcus hyicus* (Hájek et al., 1986).

DNA G+C content (mol%): 32–37 (T_m).

Type strain: A.C. Baird Parker 1462, ATCC 43764, CCM 3387, CIP 81.59, DSM 20454, NCTC 10530, NRRL B-14759.

GenBank accession number (16S rRNA gene): D83360.

Additional remarks: First described as *Staphylococcus hyicus* subsp. *chromogenes* (Devriese et al., 1978).

8. **Staphylococcus cohnii** Schleifer and Kloos 1975, 54^{AL} coh'ni.i. N.L. gen. n. *cohnii* of Cohn; named for Ferdinand Cohn, a German botanist and bacteriologist.

Nonmotile, nonspore-forming Gram-stain-positive cocci, 0.5–1.2 μm in diameter; form pairs as well as occurring singly. Facultatively anaerobic. Grows best under aerobic conditions. Produces small amounts of lactate (L and/or D) anaerobically from glucose. Growth good in medium containing up to 10% NaCl, poor at 15% NaCl. Grows at 15°C. Catalase-positive. Negative reactions: oxidase, nitrate reduction, coagulase, clumping factor, heat-stable nuclease, and β -glucosidase. Acid produced aerobically from fructose, glucose, glycerol, and trehalose. No acid produced from adonitol, arabinose, arabinol, cellobiose, dulcitol, erythritol, erythrose, fucose, gentiobiose, inositol, lyxose, melezitose, melibiose, raffinose, rhamnose, ribose, salicin, sorbitol, sorbose, sucrose, tagatose, turanose, or xylose. Novobiocin-resistant. Peptidoglycan type L-Lys-Gly₅₋₆. Teichoic acid contains glycerol, glucose, and N-acetylglucosamine, occasionally N-acetylgalactosamine or ribitol. Major menaquinone MK-7. Major fatty acids C_{B-15}, C₁₇, C₁₈, and C₂₀. Variable characteristics include growth at 45°C, acetoin production, caseinase, gelatinase, and production of acid from mannitol and xylitol.

Isolated from the skin of humans and other primates.

Additional characteristics of the subspecies are given below.

- 8a. **Staphylococcus cohnii** subsp. *cohnii* Schleifer and Kloos 1975, 54^{AL}

Nonmotile, nonspore-forming Gram-stain-positive cocci, 0.5–1.2 μm in diameter; form pairs as well as occurring singly. Colonies nonpigmented or yellowish, smooth, glistening, opaque, with entire margins. Colony diameters differ. Facultatively anaerobic. FBP-aldolase of class I type. Produces small amounts of L-lactate anaerobically from glucose. Catalase-positive. Negative reactions: alkaline phosphatase, arginine dihydrolase, clumping factor, coagulase, esculin hydrolysis, β -galactosidase, β -glucosidase, β -glucuronidase, heat-stable nuclease, nitrate reduction, ornithine decarboxylase, oxidase, and urease. Acid produced aerobically from β -D-fructose, D-glucose, glycerol, and D-trehalose. No acid produced from N-acetylglucosamine, L-arabinose, D-cellobiose, α -lactose, β -melezitose, L-rhamnose, ribose, sucrose, D-turanose, or D-xylose. Novobiocin-resistant. Peptidoglycan type L-Lys-Gly₅₋₆. Polyglycerolphosphate teichoic acids with N-acetylglucosamine. Major fatty acids C_{15:0 iso} and C_{15:0 ante}. Variable characteristics include growth at 45°C, tolerates 15% NaCl, hemolysis, acetoin production, and production of acid from maltose, D-mannitol, D-mannose, and xylitol.

Isolated from the skin of humans.

DNA–DNA hybridization studies yielded mean relative DNA binding values of 94 \pm 3% among eleven strains of *Staphylococcus cohnii* subsp. *cohnii*, 65 \pm 5% between strains of *Staphylococcus cohnii* subsp. *cohnii* and *Staphylococcus cohnii* subsp. *urealyticus*, and 8–19% between *Staphylococcus*

cohnii subsp. *cohnii* and ten other *Staphylococcus* species (Kloos and Wolfshohl, 1991).

DNA G+C content (mol%): 36–38 (T_m).

Type strain: GH137, ATCC 29974, CCUG 6463, CCUG 7322, CCUG 35144, CIP 81.54, DSM 20260, JCM 2417, NCTC 11041, NRRL B-14756.

GenBank accession number (16S rRNA gene): D83361.

8b. ***Staphylococcus cohnii* subsp. *urealyticus*** corrig. Kloos and Wolfshohl 1991, 287^{VP}

u.re.a.ly'ti.cus. N.L. fem. n. *urea* urea; Gr. adj. *lutikos* dissolving; N.L. masc. adj. *urealyticus* urea-dissolving.

Nonmotile, nonspore-forming Gram-stain-positive cocci, 0.5–1.2 µm in diameter; form pairs as well as occurring singly. Colonies raised to convex, smooth, glistening, translucent, with entire margins and gray or grayish white concentric rings. Colony diameter 5.5–8.0 mm on P agar. Human isolates nonpigmented; isolates from other primates pigmented and may have bands of alternating colors. Facultatively anaerobic. Produces equal small amounts of L- and D-lactate anaerobically from glucose. Positive reactions: alkaline phosphatase (expression may be delayed), catalase, β-galactosidase, β-glucuronidase, and urease. Negative reactions: clumping factor, coagulase, heat-stable nuclease, ornithine decarboxylase, and oxidase. Acid produced aerobically from β-D-fructose, D-glucose, glycerol, lactose, maltose (delayed), D-mannose, and D-trehalose. No acid produced from L-arabinose, D-cellobiose, β-gentiobiose, D-melezitose, β-melibiose, raffinose, L-rhamnose, D-ribose, salicin, sucrose, D-turanose, or D-xylose. Novobiocin-resistant. Peptidoglycan type L-Lys-Gly₅₋₆. Polyglycerolphosphate teichoic acids with N-acetylglucosamine and glucose. Major fatty acids C_{15:0 iso} and C_{15:0 ante}. Variable characteristics include growth at 45°C, tolerates 15% NaCl, hemolysis, nitrate reduction, acetoin production, β-glucosidase, arginine dihydrolase, esculin hydrolysis, and production of acid from galactose, mannitol, xylitol, and N-acetylglucosamine.

Distinguished from *Staphylococcus cohnii* subsp. *cohnii* by production of alkaline phosphatase, β-glucuronidase, β-galactosidase, and urease activity.

Isolated from the skin of humans and other primates.

DNA–DNA hybridization studies yielded mean relative DNA binding values of 92 ± 4% among 28 strains of *Staphylococcus cohnii* subsp. *urealyticus*, 68 ± 3% between strains of *Staphylococcus cohnii* subsp. *cohnii* and *Staphylococcus cohnii* subsp. *urealyticus*, and 7–15% between *Staphylococcus cohnii* subsp. *cohnii* and ten other *Staphylococcus* species (Kloos and Wolfshohl, 1991).

DNA G+C content (mol%): 37 (no method given).

Type strain: CK27, ATCC 49330, CCUG 35143, CIP 104024, DSM 6718.

GenBank accession number (16S rRNA gene): AB009936.

9. ***Staphylococcus condimentii*** Probst, Hertel, Richter, Wassill, Ludwig and Hammes 1998, 656^{VP}

con.di.men'ti. L. n. *condimentum* spice; L. gen. n. *condimenti* of the spice.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 1 µm in diameter; occur singly and form pairs, chains, and clusters. Colonies cream-colored, opaque, raised, and entire.

Colony diameter 1–2 mm after incubation at 2 d at 37°C on P agar. Temperature range for growth 15–42°C. Tolerates 15% NaCl. Positive reactions: alkaline phosphatase, arginine dihydrolase, catalase, β-galactosidase, lipase, nitrate and nitrite reductases, and urease. Negative reactions: coagulase, esculin hydrolysis, β-glucuronidase, and lecithinase. Acid produced aerobically from fructose, N-acetylglucosamine, galactose, glucose, glycerol, lactose, mannitol, mannose, sorbitol, sucrose (weak), and trehalose. No acid produced from arabinose, cellobiose, raffinose, ribose, or turanose. Lysozyme-resistant; lysostaphin-sensitive. Major menaquinone MK-7; minor menaquinones MK-6 and MK-8. Growth at 45°C is variable.

Found in soy sauce mash.

DNA–DNA hybridization studies yielded relative DNA binding values of 98% between the type strain and a second strain of *Staphylococcus condimentii*, 58% between the type strain of *Staphylococcus condimentii* and the type strain of *Staphylococcus carnosus* subsp. *carnosus*, and 51% between the type strain of *Staphylococcus condimentii* and the type strain of *Staphylococcus piscifermentans* (Probst et al., 1998).

DNA G+C content (mol%): 35.2–36 (no method given).

Type strain: F-2, LTH 3734, CCUG 39902, CIP 105760, DSM 11674, JCM 6074.

GenBank accession number (16S rRNA gene): Y15750.

10. ***Staphylococcus delphini*** Varaldo, Kilpper-Bälz, Biavasco, Satta and Schleifer 1988, 437^{VP}

del.phi'ni. L. gen. n. *delphini* of a dolphin.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.8–1.0 µm in diameter; occur singly and form clusters. Colonies nonpigmented, convex, smooth, glistening, and opaque. Colony diameter 5–7 mm. Facultatively anaerobic. Grows at 45°C; tolerate 15% NaCl. Positive reactions: arginine dihydrolase, caseinase, catalase, coagulase, hemolysis, nitrate reduction, phosphatase, and urease. Weak heat-labile DNase activity. Negative reactions: acetoin production, clumping factor, fibrinolysin, and gelatinase. Acid produced aerobically from fructose, glucose, lactose, mannitol, mannose, and sucrose. Acid not produced from arabinose, trehalose, xylitol, or xylose. Lysozyme-resistant; lysostaphin-sensitive. Novobiocin-susceptible. Peptidoglycan type Lys-Gly₅₋₆. Teichoic acid contains glycerol and N-acetylglucosamine.

Isolated from skin lesions of captive dolphins in an aquarium.

DNA–DNA similarity studies yielded relative DNA binding values of 99% between two strains of *Staphylococcus delphini* and 4–35% between the type strain of *Staphylococcus delphini* and the type strains of eleven other *Staphylococcus* species; the most closely related species was *Staphylococcus intermedius*.

DNA G+C content (mol%): 39 (T_m).

Type strain: Heidi, ATCC 49171, CCUG 30107, CIP 103732, DSM 20771, NCTC 12225, NRRL B-14767.

GenBank accession number (16S rRNA gene): AB009938.

11. ***Staphylococcus epidermidis*** (Winslow and Winslow 1908) Evans 1916, 449^{AL} emend. Schleifer and Kloos 1975, 52 (“*Albococcus epidermidis*” Winslow and Winslow 1908, 201.)

e.pi.der'mi.dis. Gr. n. *epiderma* the outer skin; N.L. gen. n. *epidermidis* of the epidermis.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.8–1.0 µm in diameter; occur in pairs and tetrads, occasionally single cells. Colonies usually nonpigmented (gray or grayish white), smooth, raised, glistening, with entire margins. May be mucoid or slimy; vary in translucency; may become sticky with age. Colony diameter 2.5–4.0 mm. Facultatively anaerobic, growth is best under aerobic conditions. Acetate and carbon dioxide are the major end products of aerobic glucose metabolism. Produces predominantly L-lactate anaerobically from glucose. D-Galactose and lactose are metabolized via the D-tagatose-6-phosphate pathway. FBP-aldolase belongs to the class I type. Growth is good at NaCl concentrations up to 7.5% and relatively poor at 10% NaCl. Temperature range for growth 15–45°C; optimum 30–37°C. Positive reactions: acetoin production, alkaline phosphatase, arginine dihydrolase, nitrate reduction, and urease. Negative reactions: clumping factor, coagulase, esculin hydrolysis, β-galactosidase, β-glucuronidase, ornithine decarboxylase, oxidase, starch hydrolysis, and growth in medium containing 15% NaCl. Acid produced aerobically from fructose, glucose, glycerol, maltose, mannose (delayed), and sucrose. No acid produced from arabinose, adonitol, arabitol, cellobiose, dulcitol, erythritol, erythrose, fucose, gentiobiose, inositol, lyxose, mannitol, melibiose, raffinose, rhamnose, salicin, sorbose, tagatose, trehalose, xylitol, or xylose. Novobiocin-susceptible. Lysozyme-resistant. Peptidoglycan type L-Lys-Gly₄₋₅, L-Ser_{0.7-1.5}. Teichoic acid contains glycerol, N-acetylglucosamine, and glucose. Major fatty acids C_{B₁₅}, C₁₈, and C₂₀. Major menaquinone MK-7. Variable characteristics include acid phosphatase, β-glucosidase, hyaluronidase, fibrinolysin; hemolysis (weak), DNase (weak), proteases, lipases, and production of acid from galactose, lactose, melizitose, ribose, and turanose.

Phage typing of *Staphylococcus epidermidis* has not been very successful. Chromosomal and plasmid DNA may be transferred to appropriate recipient cells via transduction.

Isolated from human skin where it is a resident; occasionally found on the skin of other mammals, particularly those living in close association with humans. Opportunistic pathogen, may colonize various indwelling medical devices, postoperative infections, urinary tract, and wound infections.

DNA–DNA hybridization studies yielded relative DNA binding values >85% among *Staphylococcus epidermidis* strains (Kloos and Wolfshohl, 1982).

DNA G+C content (mol%): 30–37 (T_m).

Type strain: Füssel, 2466, ATCC 14990, CCUG 18000 A, CCUG 39508, CIP 81.55, DSM 20044, LMG 10474, NCTC 11047.

GenBank accession number (16S rRNA gene): D83363, L37605.

12. ***Staphylococcus equorum*** Schleifer, Kilpper-Bälz and Devriese 1985, 224^{VP} (Effective publication: Schleifer, Kilpper-Bälz and Devriese 1984, 506.)

e.quor'rum. L. gen. n. *equus* of horses.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.5–1.8 µm in diameter; occur singly and form pairs,

clusters, and chains. Colonies white, opaque, with entire margins. Colony diameter 4–6 mm after incubation at 2 d at 37°C on brain heart infusion agar. Aerobic. Optimum growth temperature 30°C, no growth at 42°C. Positive reactions: catalase, β-glucuronidase, β-galactosidase, nitrate reduction, and urease. Weakly positive reactions: esculin and tributyrin hydrolysis. Negative reactions: oxidase, arginine hydrolysis, anaerobic growth. Acid produced aerobically from D-fructose, D-glucose, glycerol, D-mannose. Peptidoglycan type Lys-Gly₅₋₆. Teichoic acids contain glucosamine, glycerol, and small amounts of ribitol. Novobiocin-resistant. Variable characters include hemolysis, caseinase, and production of acid from lactose, and D-turanose.

Additional characteristics of the subspecies are given below.

- 12a. ***Staphylococcus equorum* subsp. *equorum*** Schleifer, Kilpper-Bälz and Devriese 1985, 224^{VP} (Effective publication: Schleifer, Kilpper-Bälz and Devriese 1984, 506.)

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.5–1.8 µm in diameter; occur singly and form pairs, clusters, and chains. Colonies white, opaque, with entire margins. Colony diameter 4–6 mm after incubation at 2 d at 37°C on brain heart infusion agar. Aerobic. Optimum growth temperature 30°C; no growth at 42°C. Positive reactions: catalase, β-glucuronidase, β-galactosidase, nitrate reduction, urease, and phosphatase. Weakly positive reactions: esculin and tributyrin hydrolysis. Negative reactions: coagulase, clumping factor, gelatinase, heat-stable nuclease, oxidase, hyaluronidase, staphylokinase, Tween 80 hydrolysis, fibrinolysin, acetoin production, and arginine hydrolysis. Acid produced aerobically from L-arabinose, D-fructose, D-galactose, D-glucose, glycerol, maltose, D-mannose, D-mannitol, D-melezitose, D-ribose, salicin, sorbitol, sucrose, trehalose, and D-xylose. No acid produced from amygdalin, D-fucose, β-gentiobiose, D-melibiose, raffinose, L-rhamnose, or xylitol. Peptidoglycan type Lys-Gly₅₋₆. Teichoic acids contain glucosamine, glycerol, and small amounts of ribitol. Novobiocin-resistant. Variable characters include hemolysis, caseinase, and production of acid from arbutin, cellobiose, lactose, and D-turanose.

Isolated from the skin of horses.

DNA–DNA hybridization studies yielded relative DNA binding values of 75–100% among *Staphylococcus equorum* strains and 15–33% between *Staphylococcus equorum* strains and *Staphylococcus kloosii*, *Staphylococcus arlettae*, *Staphylococcus saprophyticus*, *Staphylococcus cohnii*, *Staphylococcus gallinarum*, *Staphylococcus caprae*, *Staphylococcus epidermidis*, *Staphylococcus lentus*, and *Staphylococcus xylosum* (Schleifer, 1984).

DNA G+C content (mol%): 33.4–34.7 (T_m).

Type strain: PA231, ATCC 43958, CCUG 30109, CIP 103502, DSM 20674, NCTC 12414, NRRL B-14765.

GenBank accession number (16S rRNA gene): AB009939.

- 12b. ***Staphylococcus equorum* subsp. *linens*** Place, Hiestand, Gallmann and Teuber 2003b, 1219^{VP} (Effective publication: Place, Hiestand, Gallmann and Teuber 2003c, 36.)

lin'ens. L. pres. part. of *linere* smearing; named because the organism was isolated from the surface of a smeared red cheese.

Nonmotile, Gram-stain-positive cocci, 0.9–1.4 µm in diameter; occur singly and form pairs and chains. Colonies white, glossy, and opaque. Colony diameter 1–2 mm after 2 d on PC skim milk agar (Merck) at 32°C. Aerobic. Tolerates 15% NaCl in the medium, although growth is poor. Temperature range for growth 6–40°C; optimum 32°C. Positive reactions: nitrate reduction, and urease. Negative reactions: acetoin production, arginine dihydrolase, ornithine decarboxylase, β-glucuronidase, β-galactosidase, alkaline phosphatase, esculin hydrolysis, hemolysis, and oxidase. Acid produced aerobically from fructose, D-mannose, and turanose (weak). No acid produced from L-arabinose, cellobiose, D-galactose, α-D-lactose, maltose, mannitol, D-raffinose D-ribose, salicin, sucrose, D-trehalose, or D-xylose. Ferments D-glucose strongly and N-acetyl-D-glucosamine, 3-methyl-glucose, maltotriose, methyl-pyruvate, and pyruvic acid weakly. Does not ferment D-alanine, L-alanyl-glycine, arbutin, 2,3-butanediol, β-hydroxybutyric acid, or Tween 40. Novobiocin-susceptible. Peptidoglycan type L-Lys–Gly₅.

Distinguished from *Staphylococcus equorum* subsp. *equorum* by novobiocin susceptibility; lack of β-galactosidase; inability to produce acid from D-galactose, α-D-lactose, maltose, D-ribose, salicin, sucrose, and D-trehalose; and inability to ferment D-alanine, L-alanyl-glycine, D-mannitol, and D-raffinose.

DNA–DNA hybridization studies yielded relative DNA binding values of 68% between the type strains of *Staphylococcus equorum* subsp. *equorum* and *Staphylococcus equorum* subsp. *linens* and 68% between the type strains of *Staphylococcus equorum* subsp. *linens* and *Staphylococcus xylosus* (Place et al., 2003c).

Isolated from a surface-ripened Swiss cheese.

DNA G+C content (mol%): 35.1 (HPLC).

Type strain: RP29, CIP 107656, DSM 15097.

GenBank accession number (16S rRNA gene): AF527483.

13. ***Staphylococcus felis*** Igimi, Kawamura, Takahashi and Mitsuoka 1989, 374^{VP}

fe'lis. L. gen. n. *felis* of a cat.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.8–1.2 µm in diameter; occur singly and form pairs and clusters. Colonies low convex, nonpigmented, opaque, smooth, and glistening. Colony diameter 5–8 mm. Facultatively anaerobic. Grows in 10% NaCl in 24 h and in 15% NaCl in 72 h. Weak growth at 15 and 45°C. Weakly hemolytic; no α-, β-, or δ-hemolysin detected. Positive reactions: phosphatase, β-galactosidase, nitrate reduction, arginine dihydrolase, and urease. Negative reactions: coagulase, clumping factor, hyaluronidase, heat-stable nuclease (or very weak), acetoin production, and oxidase. Acid produced aerobically from fructose, glucose, glycerol, lactose, mannose, and trehalose. No acid produced aerobically from xylose, arabinose, cellobiose, raffinose, maltose, or xylitol. Acid production from sucrose, galactose, mannitol, and ribose varies between strains. Lysostaphin-sensitive. Novobiocin- and bacitracin-susceptible.

Isolated from various infections of cats.

DNA–DNA hybridization studies yielded relative DNA binding values of 84–93% between the type and four other

Staphylococcus felis strains and 1–9% between the type strain of *Staphylococcus felis* and the type strains of 28 other *Staphylococcus* species and subspecies (Igimi et al., 1989).

DNA G+C content (mol%): 35 (T_m).

Type strain: GD521, ATCC 49168, CCUG 32418, CCUG 38440, CIP 103366, DSM 7377, JCM 7469, NRRL B-14779.

GenBank accession number (16S rRNA gene): D83364.

14. ***Staphylococcus fleurettii*** Vernozy-Rozand, Mazuy, Meugnier, Bes, Lasne, Fiedler, Étienne and Freney 2000, 1523^{VP}

fleu.rett'i.i. N.L. gen. n. *fleurettii* of Fleurette in honor of the French microbiologist Jean Fleurette for his contribution to the taxonomy of staphylococci.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.8–1.4 µm in diameter; occur singly and form chains and clumps. Colonies opaque and usually nonpigmented (may be cream colored), with irregular centres and margins. Colony diameter <3 mm on P agar or 8–12 mm on tryptic soy agar at 37°C (incubation time not given). Facultatively anaerobic. Tolerates 10% NaCl. Positive reactions: catalase, nitrate reduction, and oxidase. Negative reactions: arginine dihydrolase, coagulase, clumping factor, β-galactosidase, β-glucuronidase, heat-stable nuclease, ornithine decarboxylase, staphylocoagulase, and urease. Acid produced aerobically from D-fructose, maltose, D-mannose, sucrose, D-trehalose, and turanose. No acid produced aerobically from cellobiose, L-fucose, D-galactose, α-lactose, D-melezitose, D-raffinose, salicin, or D-xylitol. Lysozyme-resistant; lysostaphin-sensitive. Novobiocin- and bacitracin-resistant. Peptidoglycan contains lysine, alanine, and glycine. Poly-(glycerolphosphate) teichoic acids contain glucose. Lipoteichoic acids present. No production of enterotoxins SEA, SEB, SEC₁, SEC₂, SEC₃, SED, and SEE. Variable characteristics include colony pigmentation, acetoin production, alkaline phosphatase, esculin hydrolysis, and acid production from L-arabinose and D-xylose.

Found in goats' milk cheese.

DNA–DNA hybridization studies yielded relative DNA binding values of 86–100% between the type strain and five other *Staphylococcus fleurettii* strains and 8–44% between the *Staphylococcus fleurettii* type strain and the type strains of 36 *Staphylococcus* species and subspecies (Vernozy-Rozand et al., 2000).

DNA G+C content (mol%): 31–32 (HPLC).

Type strain: 241, ATCC BAA-274, CCUG 43834, CIP 106114, DSM 13212.

GenBank accession number (16S rRNA gene): AB233330.

15. ***Staphylococcus gallinarum*** Devriese, Poutrel, Kilpper-Bälz and Schleifer 1983, 481^{VP}

gal.li.na'rum. L. fem. n. *gallina* hen; L. fem. gen. pl. n. *gallinarum* of hens.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.5–1.8 µm in diameter; occur singly and form pairs, short chains, and small groups. Colonies yellow, yellowish, or nonpigmented, flat, opaque, and dry, with lobate or crenate edges. Colony diameter 10–15 mm after 2 d on brain heart infusion agar and 5–10 mm after 2 d on tryptone soy agar. Small colony type smooth and glistening with entire

edges, 4–7 mm in diameter after 2 d on brain heart infusion agar. Facultatively anaerobic, growth is better under aerobic conditions. Produces L-lactate anaerobically from glucose. FBP-aldolase is of class I type. Temperature range for growth 25–42°C. Positive reactions: alkaline phosphatase, caseinase, catalase, esculin hydrolysis, nitrate reduction, and urease. Negative reactions: acetoin production, clumping factor, coagulase, heat-stable DNase, hyaluronidase, lipase, and oxidase. Acid produced aerobically from amygdalin, L-arabinose, arbutin, cellobiose, D-fructose, D-fucose (weak), D-galactose, β-gentiobiose, D-glucitol, glycerol, maltose, D-mannitol, D-mannose, melezitose, melibiose, D-ribose, salicin, sucrose, trehalose, turanose, and D-xylose. No acid produced from L-rhamnose. Novobiocin-resistant. Peptidoglycan type L-Lys–Gly_{4–5}, L-Ser_{0.7–1.0}. Teichoic acid contains glucose, glycerol, and N-acetylglucosamine (minor amounts). Variable characteristics include hemolysis (weak) and acid production from lactose and xylitol.

Isolated from the nares and skin of poultry.

DNA–DNA hybridization studies yielded relative DNA binding values of 72–100% among *Staphylococcus gallinarum* strains and 4–25% between the type strain of *Staphylococcus gallinarum* and 13 strains of other *Staphylococcus* species (Devriese et al., 1983).

DNA G+C content (mol%): 34–35 (T_m).

Type strain: VIII1, ATCC 35539, CCM 3572, CCUG 15600, CIP 103504, DSM 20610, LMG 19121, NCTC 12195, NRRL B-14763.

GenBank accession number (16S rRNA gene): D83366.

16. ***Staphylococcus haemolyticus*** Schleifer and Kloos 1975, 56^{AL} hae.mo.ly'ti.cus. N.L. adj. *haemolyticus* blood-dissolving.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.8–1.3 μm in diameter; form pairs and tetrads. Colonies nonpigmented or yellowish, smooth, glistening, opaque, with entire margins. Colony diameter 5–9 mm. Facultatively anaerobic. Growth is best under aerobic conditions. Produces only or predominantly D-lactate anaerobically from glucose. FBP-aldolase of class I type. Grows well in medium containing 10% NaCl; growth poor or absent at 15% NaCl. Temperature range for growth 18–45°C (optimum 30–40°C); growth poor or absent at 15°C. Positive reactions: acetoin production, arginine dihydrolase, benzidine test, catalase, hemolysis (sometimes weak), and lipase. Negative reactions: coagulase, DNase, ornithine decarboxylase, phosphatase, urease, and oxidase. Produces acid aerobically from glucose, glycerol, maltose, sucrose, and trehalose. No acid produced from adonitol, arabinose, arabitol, cellobiose, dulcitol, erythritol, erythrose, fucose, gentiobiose, inositol, lyxose, mannose, melezitose melibiose, raffinose, rhamnose, salicin, sorbitol, sorbose, tagatose, xylitol, or xylose. Lysostaphin-sensitive; lysozyme-resistant. Novobiocin-susceptible. Peptidoglycan type L-Lys–Gly_{3.3–4.0}, L-Ser_{0.9–1.5}. Teichoic acid contains glycerol and N-acetylglucosamine. Major fatty acids C_{B_r-15}, C_{B_r-17}, C₁₈, and C₂₀. The fatty acid profile is rather similar to that of *Staphylococcus hominis* and *Staphylococcus aureus*. Major menaquinone MK-7. Variable characteristics include acetoin production, β-glucosidase, β-glucuronidase, nitrate reduction, and acid production from fructose, galactose, lactose, mannitol, ribose, and turanose.

Isolated from humans and other primates; sometimes associated with infections.

DNA–DNA hybridization studies yielded relative DNA binding values ≥75% among *Staphylococcus hemolyticus* strains isolated from humans and among *Staphylococcus hemolyticus* strains isolated from nonhuman primates, however, relative DNA binding values between *Staphylococcus hemolyticus* strains from humans and from nonhuman primates were somewhat less: 65–77% under optimal hybridization conditions (Kloos and Wolfshol, 1979).

DNA G+C content (mol%): 34–36 (T_m).

Type strain: ATCC 29970, CCUG 7323, CIP 81.56, DSM 20263, JCM 2416, LMG 13349, NCTC 11042, NRRL B-14755.

GenBank accession number (16S rRNA gene): D83367, L37600.

17. ***Staphylococcus hominis*** Kloos and Schleifer 1975a, 68^{AL} emend. Kloos, George, Olgiate, Van Pelt, McKinnon, Zimmer, Muller, Weinstein and Mirrett 1998b, 807.

ho'mi.nis. L. gen. n. *hominis* of humans; named for the host on whose skin this species is commonly found.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 1.0–1.5 μm in diameter; occur singly and form tetrads and smaller numbers of pairs. Aerobic or facultatively anaerobic; anaerobic growth weak and delayed. Positive reactions: catalase and urease. Negative reactions: coagulase, clumping factor, alkaline phosphatase, β-galactosidase, β-glucosidase, β-glucuronidase, latex agglutination, ornithine decarboxylase, and oxidase. Acid produced aerobically from β-D-fructose, D-glucose, glycerol, maltose, and sucrose. No acid produced from L-arabinose, D-cellobiose, mannitol, D-mannose, D-raffinose, salicin, D-sorbitol, and D-xylose.

In conjunction with the description of *Staphylococcus hominis* subsp. *novobiosepticus* and the creation of *Staphylococcus hominis* subsp. *hominis*, Kloos et al. (1998b) emended the description of *Staphylococcus hominis* to include novobiocin-resistant strains as well as novobiocin-susceptible strains.

Additional characteristics of the subspecies are given below.

- 17a. ***Staphylococcus hominis* subsp. *hominis*** Kloos and Schleifer 1975a, 68^{AL} emend. Kloos, George, Olgiate, Van Pelt, McKinnon, Zimmer, Muller, Weinstein and Mirrett 1998b, 807.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 1.0–1.5 μm in diameter; occur singly and form tetrads and smaller numbers of pairs. Colonies may be nonpigmented or cream to yellow-orange. Colonies smooth, opaque, raised to umbonate, and butyrous, with entire margins. Colony diameter 3–5 mm. Aerobic or facultatively anaerobic; anaerobic growth weak and delayed. Growth is best under aerobic conditions. Nonhemolytic on sheep or bovine blood agar. Temperature range for growth 20–45°C; optimum 30–40°C. May produce only D-lactate or both L- and D-lactate from glucose anaerobically. Class I fructose-1,6-bisphosphate aldolase. Positive reactions: catalase, lipase, and urease. Negative reactions: alkaline phosphatase, caseinase, coagulase, DNase, β-galactosidase, β-glucosidase, β-glucuronidase, gelatinase, latex agglutination, ornithine decarboxylase, staphylocoagulase. capsular

polysaccharide/adhesion, and oxidase. Acid produced aerobically from β -D-fructose, D-glucose, glycerol, maltose, and sucrose. No acid produced from L-arabinose, D-cellobiose, D-mannose, D-raffinose, salicin, D-sorbitol, and D-xylose. Acid production from *N*-acetylglucosamine, galactose, α -lactose, D-mannitol, D-melezitose, D-trehalose, and turanose varies between strains. Novobiocin-susceptible. Peptidoglycan type L-Lys-Gly_{3.5-4.5}, L-Ser_{0.6-1.3}. Teichoic acid contains glycerol and *N*-acetylglucosamine. Major fatty acids are C_{B₁₅}, C₁₈, and C₂₀. Major quinone is MK-7. Variable characteristics: acetoin production, arginine utilization, and nitrate reduction.

Isolated from the skin of humans (one of the major staphylococcal species) and clinical specimens from human infections. Appears to be quite human-specific.

DNA-DNA hybridization studies yielded relative DNA binding values >85% between *Staphylococcus hominis* strains (Kloos, 1980; Kloos and Wolfshohl, 1982). A later study yielded relative DNA binding values of 84-94% between the type strain and four other strains of *Staphylococcus hominis* subsp. *hominis*, 62-76% between the type strain of *Staphylococcus hominis* subsp. *hominis* and eight strains of *Staphylococcus hominis* subsp. *novobiosepticus*, and 63-77% between the type strain of *Staphylococcus hominis* subsp. *novobiosepticus* and five strains of *Staphylococcus hominis* subsp. *hominis* (Kloos et al., 1998b).

DNA G+C content (mol%): 30-36 (T_m).

Type strain: ATCC 27844, CCUG 35516, CIP 102258, CIP 81.57, DM 122, DSM 20328, JCM 2419, LMG 13348, NCTC 11320, NRRL B-14737.

GenBank accession number (16S rRNA gene): L37601, X66101.

- 17b. ***Staphylococcus hominis* subsp. *novobiosepticus*** Kloos, George, Olgiate, Van Pelt, McKinnon, Zimmer, Muller, Weinstein and Mirrett 1998b, 809^{VP}
no.vo.bio.sep'ti.cus. N.L. n. *novobiocinum* novobiocini; L. adj. *septicus* septic; N.L. adj. *novobiosepticus* intended to mean resistant to novobiocin and growing in blood.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 1.0-1.5 μ m in diameter; occur singly and form tetrads and smaller numbers of pairs. Colonies grayish-white, convex to umbonate, butyrous, and opaque, with entire margins. Colony diameter 4-6 mm after incubation at 34-35°C for 3 d, then 25°C for 2 d on P, tryptic soy agar, or tryptic soy agar plus sheep blood agar. Aerobes or facultative anaerobes; anaerobic growth weak and delayed. Temperature optimum 35°C. Nonhemolytic. Positive reactions: catalase and urease. Negative reactions: oxidase, coagulase, alkaline phosphatase, β -glucosidase, β -galactosidase, β -glucuronidase, and capsular polysaccharide/adhesin. Acid produced aerobically from β -D-fructose, D-glucose, glycerol, maltose, and sucrose. No acid produced aerobically from *N*-acetyl-D-glucosamine, L-arabinose, D-cellobiose, D-mannitol, D-mannose, D-raffinose, salicin, D-sorbitol, D-trehalose, or D-xylose. Novobiocin-resistant. Strains differ in acid production from α -lactose and D-melezitose

and in production of acetoin. No production of ammonia from arginine.

Distinguished from *Staphylococcus hominis* subsp. *hominis* by novobiocin resistance, inability to utilize arginine, and inability to produce acid aerobically from D-trehalose and *N*-acetylglucosamine.

Isolated from human blood and clinical specimens from other body sites.

DNA-DNA hybridization studies yielded relative DNA binding values of 82-100% between the type strain and seven other strains of *Staphylococcus hominis* subsp. *novobiosepticus*, 63-77% between the type strain of *Staphylococcus hominis* subsp. *novobiosepticus* and five strains of *Staphylococcus hominis* subsp. *hominis*, and 62-76% between the type strain of *Staphylococcus hominis* subsp. *hominis* and five strains of *Staphylococcus hominis* subsp. *novobiosepticus* (Kloos et al., 1998b).

DNA G+C content (mol%): 35 (T_m).

Type strain: R22, ATCC 700236, CCUG 42399, CIP 105719.

GenBank accession number (16S rRNA gene): AB233326.

18. ***Staphylococcus hyicus*** (Sompolinsky 1953) Devriese, Hájek, Oeding, Meyer and Schleifer 1978, 488^{AL} ("Micrococcus hyicus" Sompolinsky 1953, 307; *Staphylococcus hyicus* subsp. *hyicus* Devriese et al., 1978, 488.)
hy'i.cus. Gr. n. *hyos* hog, pig; N.L. masc. adj. *hyicus* pertaining to a pig.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.6-1.3 μ m in diameter; form pairs, tetrads, and small clusters; occasionally occur as single cells. Colonies nonpigmented, slightly convex, glistening, and opaque, with entire margins. Colony diameter 4-7 mm. Growth poor or absent at 45°C and delayed at 22°C; optimum temperature range for growth 30-35°C. Facultatively anaerobic, growth is best under aerobic conditions. Produces L-lactate anaerobically from glucose. Galactose is metabolized via the D-tagatose-6-phosphate pathway. Strains tested possess both class I and II FBP-aldolases. Positive reactions: arginine dihydrolase, benzidine test, catalase, caseinase, gelatinase, heat-stable nuclease, hippurate hydrolysis, hyaluronidase, nitrate reduction, phosphatase, tributyrin hydrolysis, and Tween hydrolysis. Negative reactions: acetoin production, clumping factor, esculin hydrolysis, growth on medium containing 15% NaCl, hemolysin, H₂S production, indole production, and oxidase. Acid produced aerobically from fructose, glucose, galactose, glycerol, lactose, mannose, ribose, sucrose, and trehalose. No acid produced from adonitol, amygdalin, L(+)-arabinose, arabitol, cellobiose, dulcitol, L(-)-fucose, β -gentiobiose, lyxose, mannitol, melibiose, melezitose, raffinose, L(+)-rhamnose, salicin, sorbose, tagatose, xylitol, and xylose. Lysozyme-resistant, lysostaphin-sensitive. Novobiocin-susceptible. Peptidoglycan type L-Lys-Gly₄₋₅, Ser_{0-0.3}. Teichoic acid contains glycerol and *N*-acetylglucosamine.

Coagulase is produced by some strains (25-56%) although it is often weak in activity and may require 18-24 h for detection in the tube test with rabbit plasma. Other variable characters include fibrinolysin, β -glucosidase, β -glucuronidase, and urease. Variation in these characteristics is associated with differences in host of origin as well as geographic region of origin.

Isolated from skin of poultry, cattle, and swine. Pig strains pathogenic. Rarely isolated from cattle with mastitis.

Initial DNA–DNA hybridization studies yielded relative DNA binding values of 48–95% among three *Staphylococcus hyicus* strains, 30–55% between three strains of *Staphylococcus hyicus* and two strains of *Staphylococcus chromogenes*, and 10–19% between *Staphylococcus hyicus* and three other *Staphylococcus* species (Devriese et al., 1978). Further DNA–DNA hybridization studies yielded relative DNA binding values of 67–95% between the type strain and nine other strains of *Staphylococcus hyicus* and 38–52% between the type strain of *Staphylococcus hyicus* and ten strains of *Staphylococcus chromogenes* (Hajek et al., 1986).

DNA G+C content (mol%): 33–34 (T_m).

Type strain: D. Sompolinsky no. 1, ATCC 11249, CCM 2368, CIP 81.58, DSM 20459, JCM 2423, LMG 13352, NCTC 10350.

GenBank accession number (16S rRNA gene): D83368.

Additional remarks: Originally described as *Staphylococcus hyicus* subsp. *hyicus* (*Staphylococcus hyicus* Group A strains); became *Staphylococcus hyicus* when *Staphylococcus hyicus* subsp. *chromogenes* was elevated to species rank as *Staphylococcus chromogenes* (Hajek et al., 1986).

19. *Staphylococcus intermedius* Hájek 1976, 405^{AL}

in.ter.me'di.us. L. adj. *intermedius* in between, intermediate; intended to indicate that this species possesses some properties of *Staphylococcus aureus* and *Staphylococcus epidermidis*.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.5–1.5 μm in diameter; form pairs and clusters; also occur as single cells. Colonies nonpigmented, slightly convex, smooth, glistening, and butyrous, with entire margins. Colony diameter 5.0–6.5 mm. Facultatively anaerobic, growth is best under aerobic conditions. Produces L-lactate anaerobically from glucose. Contains FBP-dependent L-lactate dehydrogenase. Galactose and lactose are metabolized via the Leloir pathway and not via the D-tagatose-6-phosphate pathway as in the case of *Staphylococcus aureus*. Strains possess both class I and class II FBP-aldolases. Grows on agar medium containing up to 12.5% NaCl. Temperature range for growth 15–45°C; optimum 30–40°C. Positive reactions: acid and alkaline phosphatase, benzidine test, catalase, coagulase (rabbit and bovine plasma), gelatinase, heat-labile and heat-stable nucleases, methyl red test, nitrate reduction, and urease. Esterases are produced; their patterns are complex (polymorphic) and their electrophoretic migrations are slower than the major esterase of *Staphylococcus aureus*. Negative reactions: acetoin production, esculin hydrolysis, fibrinolysin, indole, H_2S , protein A, oxidase, and tellurite reduction. Acid produced aerobically from fructose, galactose, glucose, glycerol, maltose (weak), mannose, ribose, sucrose, and trehalose. No acid produced from arabinose, cellobiose, fucose, melezitose, raffinose, rhamnose, salicin, sorbitol, xylitol, or xylose. Lysozyme-resistant; lyso-staphin-sensitive. Novobiocin-susceptible. Peptidoglycan type L-Lys-Gly₄₋₅, L-Ser_{0.5-1.0}. Teichoic acid contains glycerol, N-acetylglucosamine, and/or glucose. Major menaquinone MK-7. Variable characteristics include arginine dihydrolase (pigeon strains usually negative), clumping factor, caseinase, coagulation of human plasma, hemolysin, β -D-galactosidase,

β -glucosidase, Tween hydrolysis, and acid production from lactose, mannitol, and turanose.

Isolated from dogs, horses, mink, and pigeons. Often predominant staphylococcal species inhabiting the nasal membranes and skin of carnivora (e.g., dogs, minks, raccoons, foxes). Associated with a variety of infections in dogs. Rarely isolated from humans or other primates.

DNA–DNA hybridization studies yielded relative DNA binding values of 75–95% among six strains of *Staphylococcus intermedius*, 33–55% between six strains of *Staphylococcus intermedius* and five strains of *Staphylococcus aureus*, and 40–45% between six strains of *Staphylococcus intermedius* and the type strain of *Staphylococcus epidermidis* (Meyer and Schleifer, 1978).

DNA G+C content (mol%): 31–36 (T_m).

Type strain: H 11/68, ATCC 29663, CCM 5739, CCUG 6520, CCUG 27191, CIP 81.60, CNCTC M16/75, DSM 20373, JCM 2422, LMG 13351, NCTC 11048, NRRL B-14754.

GenBank accession number (16S rRNA gene): D83369.

20. *Staphylococcus kloosii* Schleifer, Kilpper-Bälz and Devriese 1985, 224^{VP} (Effective publication: Schleifer, Kilpper-Bälz and Devriese 1984, 506.)

kloo'si.i. N.L. gen. n. *kloosii* of Kloos, named for Wesley E. Kloos, who made important contributions to the systematics of staphylococci.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.6–1.8 μm in diameter; occur singly and form pairs, clusters, and chains. Colonies opaque, glistening, with entire margins; yellowish or nonpigmented. Colony diameter 3–6 mm after incubation for 2 d at 37°C on brain heart infusion agar. Temperature range for growth 25–42°C. Aerobic. Positive reactions: catalase, phosphatase, and tributyrin hydrolysis. Negative reactions: coagulase, clumping factor, gelatinase, heat-stable nuclease, oxidase, hyaluronidase, staphylokinase, Tween 80 hydrolysis, fibrinolysin, and arginine hydrolysis. Acid produced aerobically from D-fructose, D-glucose, D-galactose, glycerol, maltose, D-mannitol, melizitose (weak), D-ribose, trehalose, and D-turanose (weak). No acid produced from amygdalin, arbutin, cellobiose, D-fucose, D-mannose, D-melibiose, L-rhamnose, sorbitol, sucrose or D-xylose. Peptidoglycan type Lys-Gly₅₋₆ or Lys-Gly₅, Ser_{0.3-0.8}. Teichoic acids contain glycerol, ribitol, and either glucosamine or galactosamine; glucose sometimes present. Novobiocin-resistant. Variable characters include hemolysis, urease, esculin hydrolysis, production of acetoin, and production of acid from L-arabinose, β -gentiobiose, lactose, D-melezitose (weak), raffinose (weak), and xylitol (weak).

Isolated from the skin of various animals, including squirrels, raccoons, opossums, swine, sheep, and horses.

DNA–DNA hybridization studies yielded relative DNA binding values of 51–100% among *Staphylococcus kloosii* strains and 20–38% between *Staphylococcus kloosii* strains and nine other *Staphylococcus* species (Schleifer et al., 1984).

DNA G+C content (mol%): 31–32.3 (T_m).

Type strain: SC210, ATCC 43959, CCUG 30110, CIP 103503, DSM 20676, NCTC 12415, NRRL B-14766.

GenBank accession number (16S rRNA gene): AB009940.

21. **Staphylococcus lentus** (Kloos, Schleifer and Smith 1976a) Schleifer, Geyer, Kilpper-Bälz and Devriese 1983a, 897^{VP} (Effective publication: Schleifer, Geyer, Kilpper-Bälz and Devriese 1983b, 385) (*Staphylococcus sciuri* subsp. *lentus* Kloos, Schleifer and Smith 1976a, 30.)

len'tus. L. adj. *lentus* slow; pertaining to slow growth.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.7–1.2 µm in diameter; occur singly and form pairs and tetrads. Colonies convex, small, glistening, smooth, with slightly undulate margins; pigmentation grayish white, white, or cream. Some strains mucoid. Colony diameter 0.5–5 mm on P agar or 2–7 mm on tryptic soy agar after incubation at 34–35°C for 3 d, then 25°C for 2 d. Facultatively anaerobes; anaerobic growth weak. Does not grow anaerobically in thioglycolate medium. Growth slow in medium containing 10% NaCl; growth poor in 15% NaCl. Produces L-lactate from glucose anaerobically. Temperature optimum 25–35°C; no growth at 15 or 45°C. Positive reactions: benzidine test, caseinase, catalase, esculin hydrolysis, gelatinase, β-glucosidase, nitrate reduction, nuclease, and oxidase (may be weak). Alkaline phosphatase activity weak or absent. Negative reactions: acetoin production, arginine dihydrolase, coagulase, elastase, β-galactosidase, β-glucuronidase, lipase, hemolysin, and urease. Acid produced aerobically from D(+)-cellobiose, β-D(-)-fructose, β-gentiobiose, D(+)-glucose, glycerol, D-mannitol, D(+)-mannose, raffinose, D(-)-ribose, sucrose, and D(+)-trehalose. No acid produced from adonitol, D-arabitol, dulcitol, *meso*-erythritol, D-erythrose, L(-)-fucose, *meso*-inositol, D-lyxose, D(+)-melezitose, L-sorbose, D(+)-tagatose, D(+)-turanose, or D(+)-xylose. Lysozyme-resistant. Resistant to 2–4 µg/ml novobiocin. Lysostaphin-sensitive. Peptidoglycan type L-Lys-L-Ala-Gly₄; serine sometimes present. Teichoic acids contain glycerol and glucosamine. Major menaquinone MK-6. Variable characteristics include production of staphylokinase and acid production from L(+)-arabinose, fucose, galactose, lactose, maltose, melibiose, rhamnose, salicin, sorbitol, and xylitol (weak).

Distinguished from *Staphylococcus sciuri* by production of acid from raffinose.

Isolated from udders of goats and sheep.

DNA–DNA hybridization studies yielded relative DNA binding values of 80–100% between the type strain and 14 other strains of *Staphylococcus lentus* and 35–41% between the type strain *Staphylococcus lentus* and four strains of *Staphylococcus sciuri* subsp. *sciuri*. The type strain of *Staphylococcus sciuri* subsp. *sciuri* was 36–43% similar to twelve strains of *Staphylococcus lentus* (Schleifer et al., 1983b).

DNA G+C content (mol%): 29.8–34.2 (T_m).

Type strain: Roguinsky K21, ATCC 29070, CCUG 15599, CIP 81.63, NCTC 12102, NRRL B-14758.

GenBank accession number (16S rRNA gene): D83370.

Additional remarks: Originally described as *Staphylococcus sciuri* subsp. *lentus*.

22. **Staphylococcus lugdunensis** Freney, Brun, Bes, Meugnier, Grimont, Grimont, Nervi and Fleurette 1988, 170^{VP} lug.dun.en'sis. L. adj. *lugdunensis* pertaining to Lugdunum, the Latin name of Lyon, a French city where the organism was first isolated.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.8–1.0 µm in diameter; occur singly and form pairs, clusters, and chains. Facultatively anaerobic. Colonies cream or pale yellow to golden, glistening, smooth, and entire. Colonial morphology somewhat variable. Colony diameter 1–4 mm after incubation for 72 h at 35°C on P agar. Temperature range for good growth 30–45°C; weak growth at 20°C. Tolerates 10% NaCl; delayed growth on 15% NaCl. Produces predominantly D-lactate anaerobically from glucose. Positive reactions: catalase, clumping factor, hemolysis (weak), nitrate reduction, ornithine decarboxylase, pyrrolidonyl aminopeptidase, *N*-acetylglucosaminidase, and acetoin production. Negative reactions: oxidase, coagulase, gelatinase, heat-stable nuclease, staphylokinase, alkaline phosphatase, β-glucuronidase, and β-galactosidase. Acid produced aerobically from D-fructose, D-glucose, α-methyl-D-glucoside, glycerol, lactose, maltose, D-mannose, sucrose, and trehalose. No acid produced aerobically from L-arabinose, cellobiose, D-mannitol, D-melibiose, D-raffinose, ribose, xylitol, or D-xylose. Lysostaphin-sensitive; lysozyme-resistant. Novobiocin-susceptible; bacitracin-resistant. Peptidoglycan type L-Lys-Gly₅₋₆. Teichoic acids contain glucosamine, glycerol, and glucose. Protein A not present. No production of TSST-1 toxin, exfoliative toxin, or enterotoxins A, B, or C. Variable characteristics include colony pigmentation, urease, and production of acid from turanose.

Isolated from clinical specimens from humans.

DNA–DNA hybridization studies yielded relative DNA binding values of 81–100% between the type and ten other strains of *Staphylococcus lugdunensis* and 1–8% between the type strain of *Staphylococcus lugdunensis* and type strains of 25 other species of *Staphylococcus* (Freney et al., 1988).

DNA G+C content (mol%): 32 (T_m).

Type strain: N860297, ATCC 43809, CCUG 25348, CIP 103642, DSM 4804, LMG 13346, NCTC 1221, NRRL B-14774.

GenBank accession number (16S rRNA gene): AB009941.

23. **Staphylococcus lutrae** Foster, Ross, Hutson and Collins 1997, 726^{VP}

lu'trae. L. fem. gen. n. *lutrae* of an otter.

Nonmotile, nonspore-forming, Gram-stain-positive cocci; occur singly and form pairs and clusters. Colonies convex, nonpigmented, opaque, glistening, and smooth, with entire margins. Colony diameter 3.5–4.5 mm after incubation for 3 d at 37°C on P agar. Facultatively anaerobic. Temperature range for growth 25–42°C. Positive reactions: growth in 10% NaCl, alkaline phosphatase, β-galactosidase, hemolysis (sheep blood), catalase, coagulase, DNase (weak), nitrate reduction, and urease. Negative reactions: growth in 15% NaCl, oxidase, clumping factor, hyaluronidase, arginine dihydrolase, and acetoin production. Acid produced aerobically from galactose, glucose, lactose, maltose, mannose, trehalose, xylose, adonitol, dulcitol, inositol, and sorbitol. Novobiocin-susceptible. Lysostaphin-sensitive. Acid production from mannitol varies between strains.

Isolated from dead otters.

16S rDNA sequence analysis showed that *Staphylococcus lutrae* was most closely related to *Staphylococcus felis*, *Staphylococcus schleiferi*, *Staphylococcus intermedius*,

Staphylococcus delphini, and *Staphylococcus muscae* (Foster et al., 1997).

DNA G+C content (mol%): 34 (no method given).

Type strain: M340/94/1, ATCC 700373, CCUG 38494, CIP 105399, DSM 10244.

GenBank accession number (16S rRNA gene): AB233333.

24. **Staphylococcus muscae** Hájek, Ludwig, Schleifer, Springer, Zitzelberger, Kroppenstedt and Kocur 1992, 99^{VP}

mus'cae. L. gen. n. *muscae* of a fly.

Nonmotile, nonspore-forming, Gram-stain-positive cocci (sometimes ovoid), 0.4–1.1 μm in diameter; occur singly and form clumps. Colonies gray-white, opaque, convex, low, with raised centres, smooth, somewhat glistening, and butyrous; margins entire. Colony diameter 5–6 mm after incubation for 5 d at 37°C on P agar. Facultatively anaerobic; better growth under aerobic conditions. No growth at 10 or 45°C. Positive reactions: growth on 10% NaCl, catalase, alkaline phosphatase, heat-labile nuclease, hemolysis on ovine blood agar, lecithinase, nitrate reduction, and degradation of Tweens 20, 40, and 80. Negative reactions: oxidase, coagulase, gelatinase, arginine dihydrolase, urease, β-galactosidase, α- or β-hemolysins, fibrinolysin, protease, protein A, clumping factor, acetoin production, degradation of starch and esculin, and growth on 15% NaCl. Acid produced aerobically from fructose, glucose, glycerol, sucrose, trehalose, turanose, and xylose. No acid produced aerobically from arabinose, cellobiose, fucose, galactose, lactose, maltose, mannose, melezitose, melibiose, raffinose, rhamnose, ribose, sorbose, tagatose, dulcitol, inositol, mannitol, arbutin, inulin, or salicin. Lysozyme-resistant. Bacitracin-resistant; novobiocin-susceptible. Peptidoglycan type Lys–Gly_{5–6} or Lys–Gly₄, Ser. Major fatty acids C_{15:0 iso} and C_{16:0}.

Isolated from flies associated with cattle but not thought to be a permanent part of the insects' microflora.

DNA–DNA hybridization studies yielded relative DNA binding values of 85–100% among four *Staphylococcus muscae* strains. 16S rDNA sequence analysis showed that the closest relative to *Staphylococcus muscae* was *Staphylococcus schleiferi* (Hájek et al., 1992).

DNA G+C content (mol%): 40–41 (*T_m*).

Type strain: MB4, ATCC 49910, CCUG 36972, CCM 4175, CIP 103641, DSM 7068.

GenBank accession number (16S rRNA gene): S83566.

25. **Staphylococcus nepalensis** Spergser, Wieser, Täubel, Rosselló-Mora, Rosengarten and Busse 2003, 2009^{VP}

ne.pa.len'sis. N.L. masc. adj. *nepalensis* pertaining to the kingdom of Nepal, where clinical samples for bacteriological examination were collected from local goats.

Nonmotile cocci; occur singly and form pairs and clusters. Colonies white, opaque, convex, low, glistening, and smooth. Colony diameter 2–6 mm after incubation for 2 d at 37°C on P agar. Facultatively anaerobic. No growth in 15% NaCl; growth variable at lower concentrations. Temperature range for growth 20–40°C; optimum 30°C. Positive reactions: catalase, urease, alkaline phosphatase, esculin and Tween 80 hydrolysis, pyrrolidonyl arylamidase, β-galactosidase, β-glucuronidase, and nitrate reduction. Negative reactions: acetoin production, arginine dihydrolase, oxidase,

clumping factor, coagulase, heat-labile and heat-stable nucleases, indole, H₂S, and hyaluronidase. Acid produced aerobically from *N*-acetylglucosamine, L-arabinose, arbutin, erythritol, D-fructose, galactose, D-glucose, glycerol, lactose, maltose, mannose, mannitol, salicin, sucrose, trehalose, and D-xylose. No acid production from adonitol, amygdalin, D-arabinose, L-arabitol, D-cellobiose, dulcitol, D-fucose, L-fucose, gentiobiose, gluconate, glycogen, inositol, inulin, D-lyxose, 2-ketogluconate, 5-ketogluconate, melibiose, melezitose, methyl-α-D-glucoside, methyl-α-D-mannoside, methyl-β-D-xyloside, D-raffinose, rhamnose, ribose, L-sorbose, starch, D-tagatose, or L-xylose. Variable characteristics include aerobic production of acid from D-arabitol, sorbitol, turanose, and xylitol. Major quinone MK-7, minor quinones MK-6 and MK-8. Major fatty acids C_{15:0 ante}, C_{15:0 iso}, and C_{17:0 ante}. Major polar lipids diphosphatidylglycerol, phosphatidylglycerol, and an unidentified lipid. Novobiocin- and bacitracin-resistant. Lysozyme-resistant; lysostaphin-sensitive.

Isolated from goats with respiratory disease.

DNA–DNA hybridization studies yielded relative DNA binding values of 42–68% between the type strain of *Staphylococcus nepalensis* and eleven other *Staphylococcus* species and subspecies. 16S rDNA sequence analysis yielded similarity values of 98.1–99% between *Staphylococcus nepalensis* and seven other *Staphylococcus* species and subspecies (Spergser et al., 2003).

DNA G+C content (mol%): 33 (HPLC).

Type strain: CW1, CCM 7045, DSM 15150.

GenBank accession number (16S rRNA gene): AJ517414.

26. **Staphylococcus pasteurii** Chesneau, Morvan, Grimont, Labischinski and El Solh 1993, 241^{VP}

pas'teur.i. L. gen. n. *pasteurii* of Pasteur, honoring the French microbiologist Louis Pasteur for his contribution in 1878 to the recognition of staphylococci as pathogenic agents and also referring to the research institute, Institute Pasteur, Paris, France, where the new species was characterized.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.5–1.5 μm in diameter; occur singly and form pairs, tetrads, and clusters. Colonies usually yellow, raised, glistening, and smooth. Colony diameter 4–7 mm. Facultatively anaerobic. Temperature range for growth 15–45°C. Grows in 5–15% NaCl. Produces L- and D-lactate from glucose anaerobically. Positive reactions: catalase, β-glucosidase, β-glucuronidase, urease, and hemolysis. Negative reactions: oxidase, coagulase, clumping factor, β-galactosidase, fibrinolysin, DNase, ornithine decarboxylase, esculin hydrolysis, and alkaline phosphatase. Acid produced aerobically from β-D-fructose, D-glucose, sucrose, and trehalose. No acid produced aerobically from L-arabinose, D-cellobiose, D-mannose, α-D-melibiose, D-raffinose, D-ribose, D-xylose, or xylitol. Variable characteristics include acetoin production, nitrate reduction, and aerobic production of acid from maltose and mannitol. Lysostaphin-resistant. Novobiocin-susceptible; bacitracin-resistant. Peptidoglycan type L-Lys–Gly₄, Ser. Teichoic acid contains glycerol but not ribitol. Produces β-toxin.

Isolated from humans, animals, and food.

DNA–DNA hybridization studies yielded relative DNA binding values of 93–98% between the type strain and three

other *Staphylococcus pasteurii* strains and 2–13% between the type strain of *Staphylococcus pasteurii* and the type strains of 27 other *Staphylococcus* species (Chesneau et al., 1993).

DNA G+C content (mol%): 35 (T_m).

Type strain: BM9357, ATCC 51129, CCUG 32420, CIP 103540, DSM 10656.

GenBank accession number (16S rRNA gene): AB009944, AF041361.

27. ***Staphylococcus piscifermentans*** Tanasupawat, Hashimoto, Ezaki, Kozaki and Komagata 1992, 578^{VP}

pis.ci.fer.men'tans. L. n. *piscis* fish; L. part. adj. *fermentans* fermenting; N.L. part. adj. *piscifermentans* fish fermenting.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 1.0 µm in diameter; occur singly and form pairs, tetrads, and clusters. Colonies low, convex, white and opaque with a yellow-orange tint and entire margins. Colony diameters not reported. Facultatively anaerobic. Produces D- and L-lactate anaerobically from glucose. Temperature range for growth 18–42°C. Positive reactions: arginine hydrolysis, benzidine test, catalase, β-glucosidase, growth in 10% NaCl, nitrate reduction, and urease. Negative reactions: oxidase, coagulase, hemolysis, acetoin production, alkaline phosphatase, gelatinase, citrate utilization, β-glucuronidase, and β-galactosidase. Acid produced aerobically from D-fructose, D-glucose, and D-trehalose. No acid produced aerobically from D-arabinose, D-cellobiose, L-fucose, gluconate, D-mannose, raffinose, D-turanose, D-xylose, gluconate, or xylitol. Resistant to lysozyme; sensitive to lysostaphin; susceptible to novobiocin. Major menaquinone MK-7; minor menaquinones MK-6 and MK-8. Peptidoglycan type L-Lys-Gly₄₋₅. Major fatty acids C_{15:0 ante'}, C_{18:0}, and C_{20:0}. Variable characteristics: growth in 15% NaCl, esculin hydrolysis, Tween 80 hydrolysis, and production of acid from D-galactose, glycerol, lactose, maltose, D-mannitol, D-melezitose, D-ribose, salicin, sucrose, and D-sorbitol.

Isolated from fermented shrimp and fish.

DNA–DNA hybridization studies yielded relative DNA binding values of 65–100% among strains of *Staphylococcus piscifermentans* and 2–32% relative DNA binding between *Staphylococcus piscifermentans* strain Ph79L and 19 other species and subspecies of *Staphylococcus* (Tanasupawat et al., 1992).

DNA G+C content (mol%): 36–37 (T_m).

Type strain: SK03, ATCC 51136, CCUG 35133, CIP 103958, DSM 7373, JCM 6057, NRIC 1817, TISTR 824.

GenBank accession number (16S rRNA gene): AB009943, Y15754.

28. ***Staphylococcus pulvereri*** Zakrzewska-Czerwinska, Gaszewska-Mastalarz, Lis, Gamian and Mordarski 1995, 171^{VP}

pul'ver.er.i. N.L. gen. n. *pulvereri* of Pulver, in honor of the German microbiologist Gerhard Pulverer for contributions to the study of staphylococcal infections in clinical microbiology.

Nonmotile, nonspore-forming, Gram-stain-positive cocci. Colonies nonpigmented or yellowish, smooth, with entire margins. Colony diameter 4–8 mm. Facultatively anaerobic; anaerobic growth weak; no anaerobic growth in thioglycolate medium. Grows on medium containing 15% NaCl and at 10°C. No growth at 45°C. Positive reactions: catalase. Negative

reactions: clumping factor and staphylocoagulase. Acid produced aerobically from D-fructose, D-glucose, maltose, and sucrose. No acid produced aerobically from D-arabinose, D-cellobiose, raffinose, D-ribose, or D-turanose. Resistant to lysozyme and novobiocin; susceptible to lysostaphin. Major fatty acids include both iso and anteiso forms of C₁₅, C₁₇, and C₁₉ fatty acids. Peptidoglycan type L-Lys-Ala-Gly₄₋₅. Teichoic acids contain polyglycerol phosphate, ribose, and N-acetylglucosamine. Variable characteristics: acetoin production, alkaline phosphatase, arginine dihydrolase, β-galactosidase, β-glucuronidase, urease, and acid production from lactose, D-mannitol, D-mannose, N-acetylglucosamine, and D-trehalose.

Isolated from humans and animals.

DNA–DNA hybridization studies yielded relative DNA binding values of 85–100% between the type strain and four other *Staphylococcus pulvereri* strains and 3–36% between the *Staphylococcus pulvereri* type strain and 30 other species of *Staphylococcus* (Vernozy-Rozand et al., 2000). The most closely related species was *Staphylococcus vitulinus*. On the basis of DNA–DNA hybridization studies, pulse field electrophoresis, ribotyping and other taxonomic criteria, *Staphylococcus pulvereri* is identical with *Staphylococcus vitulinus* (Kloos et al., 2001).

DNA G+C content (mol%): 27–30 (T_m).

Type strain: B92/87, NT215, ATCC 51698, CCM 4481, CCUG 33938, CIP 104364, DSM 9930, PCM 2443.

GenBank accession number (16S rRNA gene): AB009942.

Additional remarks: *Staphylococcus pulvereri* is considered a junior heterotypic synonym of *Staphylococcus vitulinus* (Kloos et al., 2001; Petráš, 1998).

29. ***Staphylococcus saccharolyticus*** (Foubert and Douglas 1948) Kilpper-Bälz and Schleifer 1984, 91^{VP} (Effective publication: Kilpper-Bälz and Schleifer 1981, 329.) (“*Micrococcus saccharolyticus*” Foubert and Douglas 1948, 31; *Peptococcus saccharolyticus* (Foubert and Douglas 1948) Douglas 1957, 478.)

sac.cha.ro.ly'ti.cus. Gr. n. *sacchar* sugar; Gr. adj. *lyticus* able to loose; M.L. adj. *saccharolyticus* sugar-digesting.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.6–1.0 µm in diameter; occur singly and form pairs, tetrads, and clusters. Colonies nonpigmented (faintly yellow on agar containing hemin), slightly convex, glistening, and opaque, with entire margins. Colony diameter 0.5–2.0 mm. Anaerobic, no growth or poor growth under aerobic conditions. Optimum temperature range for growth 30–37°C. Produces CO₂, ethanol, acetate, small amounts of formate, and lactate anaerobically from glucose. FBP-aldolase is of the class I type. Positive reactions: arginine dihydrolase, benzidine test, catalase (weak unless medium contains hemin), and nitrate reduction. Negative reactions: amylase, coagulase, esculin hydrolysis, gelatinase, hemolysis, H₂S, indole, and oxidase. Acid produced from fructose, glucose, glycerol, and mannose. No acid produced from adonitol, amygdalin, arabinose, cellobiose, galactose, inulin, lactose, maltose, mannitol, melezitose, raffinose, ribose, rhamnose, salicin, sorbitol, sucrose, trehalose, xylitol, or xylose. Lysozyme-resistant; lysostaphin-sensitive. Novobiocin-susceptible. Peptidoglycan type L-Lys-Gly₄, Ser_{0.7-1.2}. Teichoic acid contains glycerol and N-acetylglucosamine. Acetoin production is variable.

Isolated from human skin; occasionally found in clinical specimens.

DNA–DNA hybridization studies yielded relative DNA binding values of 93–100% between the type strain and nine other strains of *Staphylococcus saccharolyticus* (*Pep-tococcus saccharolyticus*) (Crosa et al., 1979), 22–24% between two *Staphylococcus saccharolyticus* strains and the type strain of *Staphylococcus aureus*, and 10–39% between two strains of *Staphylococcus saccharolyticus* and *Staphylo-coccus* species (Kilpper et al., 1980).

DNA G+C content (mol %): 33–34 (T_m).

Type strain: ATCC 14953, CCUG 9989, CCUG 24040, CIP 103275, DSM 20359, NCTC 11807, NRRL B-14778.

GenBank accession number (16S rRNA gene): L37602.

30. **Staphylococcus saprophyticus** (Fairbrother 1940) Shaw, Stitt and Cowan 1951, 1021^{AL} emend. Schleifer and Kloos 1975, 53 (Fairbrother 1940, 87.)

sa.pro.phy'tic.us. Gr. adj. *sapros* putrid; Gr. n. *phyton* plant; N.L. adj. *saprophyticus* saprophytic, growing on dead tissues.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.6–1.2 μ m in diameter; occur singly and form pairs. Colonies nonpigmented or slightly yellow, raised, smooth, glistening, and opaque, with entire margins. Facultatively anaerobic. Grows best under aerobic conditions. Many strains only ferment glucose weakly and would be misclassified as micrococci on the basis of the O/F-test. Produces mainly L-lactate (small amounts) anaerobically from glucose. FBP-aldolase is of the class I type. Grows in medium containing 15% NaCl. Temperature range for growth 10–40°C; optimum 28–35°C. Positive reactions: benzidine test, catalase, and urease. Negative reactions: coagulase, clumping factor, and oxidase. Acid produced aerobically from fructose, glucose, glycerol, maltose, and trehalose. No acid produced from adonitol, arabinose, cellobiose, dulcitol, erythritol, erythrose, fucose, gentiobiose, inositol, lyxose, melibiose, melezitose, raffinose, rhamnose, sorbitol, sorbose, tagatose, or xylose. Lysozyme-resistant; lysostaphin-sensitive. Novobiocin-resistant. Peptidoglycan type L-Lys–Gly_{4–5}, Ser_{0.6–0.8}. Teichoic acid contains ribitol, small amounts of glycerol, and N-acetylglucosamine. Major fatty acids C_{B_r-15}, C₁₆, C₁₈, and C₂₀. Major menaquinone MK-7. Variable characteristics: arginine dihydrolase (weak), β -galactosidase, growth at 45°C, caseinase, gelatinase, and production of acid from fructose, lactose, trehalose, turanose, and xylitol.

Isolated from skin of humans and animals. Associated with human urinary tract infections.

Additional characteristics of the subspecies are given below.

- 30a. **Staphylococcus saprophyticus subsp. saprophyticus** (Fairbrother 1940) Shaw, Stitt and Cowan 1951, 1021^{AL} emend. Schleifer and Kloos 1975, 53 (Fairbrother 1940, 87.)

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.6–1.2 μ m in diameter; occur singly and form pairs. Colonies nonpigmented or slightly yellow, raised, smooth, glistening, and opaque, with entire margins. Colony diameter 4.0–9.0 mm. Facultatively anaerobic. Produces mainly L-lactate (small amounts) anaerobically from glucose.

Grows in medium containing 10% NaCl. Temperature range for growth 10–40°C; optimum 28–35°C. Lactose is metabolized via the Leloir pathway (Schleifer et al., 1978). Positive reactions: acetoin production, benzidine test, catalase, and urease. Negative reactions: coagulase, DNase, esculin hydrolysis, hemolysin, nitrate reduction, ornithine decarboxylase, and phosphatase. Acid produced aerobically from fructose, glucose, glycerol, maltose, sucrose, trehalose, and turanose. No acid produced from adonitol, arabinose, arabinose, cellobiose, dulcitol, erythritol, erythrose, fucose, galactose, gentiobiose, inositol, lyxose, mannose, melibiose, melezitose, raffinose, rhamnose, ribose, salicin, sorbitol, sorbose, tagatose, or xylose. Lysozyme-resistant; lysostaphin-sensitive. Novobiocin-resistant. Peptidoglycan type L-Lys–Gly_{4–5}, Ser_{0.6–0.8}. Teichoic acid contains ribitol, small amounts of glycerol, and N-acetylglucosamine. Major fatty acids C_{B_r-15}, C₁₆, C₁₈, and C₂₀. Major menaquinone MK-7. Variable characteristics: arginine dihydrolase (weak), β -galactosidase, β -galactosidase, growth at 45°C, growth in media containing 15% NaCl, caseinase, gelatinase, and production of acid from lactose, mannitol, and xylitol.

Isolated from skin of humans and animals. Associated with human urinary tract infections. *Staphylococcus saprophyticus* and *Staphylococcus epidermidis* are the predominant coagulase-negative staphylococcal species isolated from human urinary infections.

DNA–DNA hybridization studies yielded relative DNA binding values of >85% among strains of *Staphylococcus saprophyticus* (Kloos and Wolfshohl, 1982).

DNA G+C content (mol %): 31–36 (T_m).

Type strain: S-41, ATCC 15305, CCUG 3706, BCRC 10786, CIP 76.125, DSM 20229, IAM 12452, JCM 2427, LMG 13350, NCAIM B.01067, NCCB 73011, NCTC 7292, NRRL B-14751.

GenBank accession number (16S rRNA gene): D83371, L37596.

- 30b. **Staphylococcus saprophyticus subsp. bovis** Hájek, Meugnier, Bes, Brun, Fiedler, Chmela, Lasne, Fleurette and Freney 1996, 793^{VP}

bo'vis. L. n. *bos* a cow; L. gen. n. *bovis* of a cow.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.7–1.4 μ m in diameter; occur singly and form pairs, chains, and clumps. Colonies low, convex, glistening, butyrous, with entire margins; presence and color of pigmentation varies between strains. Colony diameter 4 mm after incubation for 3 d at 35°C on P agar. Facultatively anaerobic. Grows weakly at 10°C; does not grow at 45°C. Grows in medium containing 10% but not 15% NaCl. Positive reactions: benzidine test, catalase, hippurate hydrolysis, nitrate reduction, and urease. Negative reactions: acetoin production, arginine dihydrolase, clumping factor, coagulase, elastase, fibrinolysin, heat-labile and heat-stable nucleases, hyaluronidase, hemolysin, ornithine decarboxylase, esculin hydrolysis, starch hydrolysis, utilization of citrate, and production of H₂S. Acid produced aerobically from N-acetylglucosamine, fructose, glucose, maltose, ribose, trehalose, glycerol, and mannitol. No acid produced aerobically from cellobiose, raffinose, rhamnose, xylose,

adonitol, or dulcitol. Sensitive to lysostaphin; resistant to lysozyme. Resistant to novobiocin and bacitracin. Peptidoglycan type Lys-Gly_{3,4-1,0}⁺ Ser_{0,2-0,7}⁻. Major fatty acids C_{15:0 ante} and C_{17:0 ante}. Teichoic acids of most strains contain ribitol and *N*-acetylglucosamine. Variable characteristics: colony pigmentation; gelatinase; caseinase; β -galactosidase; β -glucuronidase; lecithinase; hydrolysis of Tween 20, 40, and 80; alkaline phosphatase; ability to produce acetoin; and production of acid from arabinose, galactose, lactose, mannose, sucrose, and turanose.

Distinguished from *Staphylococcus saprophyticus* subsp. *saprophyticus* by smaller colony size, ability to reduce nitrate, and fermentation of ribose.

Isolated from the nostrils of healthy cattle.

DNA-DNA hybridization studies yielded relative DNA binding values of 94–99% between the type and four other *Staphylococcus saprophyticus* subsp. *bovis* strains, 71% between the type strain of *Staphylococcus saprophyticus* subsp. *bovis* and the type strain of *Staphylococcus saprophyticus* subsp. *saprophyticus*, and 2–32% between the type strain of *Staphylococcus saprophyticus* subsp. *bovis* and 19 other *Staphylococcus* species (Hajek et al., 1996).

DNA G+C content (mol %): 31 (HPLC).

Type strain: KV 12, CCUG 36975, CCM 4410, CCUG 38042, CIP 105260.

GenBank accession number (16S rRNA gene): AB233327.

31. ***Staphylococcus schleiferi*** Freney, Brun, Bes, Meugnier, Grimont, Grimont, Nervi and Fleurette 1988, 171^{VP}

schleiferi. N.L. gen. n. *schleiferi* of Schleifer, in honor of Karl-Heinz Schleifer, German microbiologist, for his many contributions to the taxonomy of Gram-positive organisms.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.8–1.0 μ m in diameter; occur singly and form pairs, clusters, and chains. Colonies nonpigmented, low convex, smooth, glistening, with entire margins. Facultatively anaerobic. Tolerates 10% NaCl. Temperature range for growth 20–45°C. Hemolytic. Produces mostly L-lactic acid in thioglycolate medium. Positive reactions: arginine dihydrolase, alkaline phosphatase, heat-stable nuclease, catalase, nitrate reduction, and acetoin production. Negative reactions: oxidase and staphylokinase. Acid produced aerobically from D-glucose, glycerol, and D-mannose. No acid produced from L-arabinose, D-cellobiose, α -methyl-D-glucoside, lactose, maltose, D-mannitol, D-melibiose, D-raffinose, xylitol, or D-xylose. Novobiocin-susceptible; bacitracin-resistant. Lysostaphin-sensitive; lysozyme-resistant. Peptidoglycan type L-Lys-Gly₅₋₆⁻ Ser_{0,2-0,3}⁻. Teichoic acids contain glucosamine, glucose, and glycerol. No production of protein A, TSST-1 toxin, exfoliative toxin, or enterotoxins A, B, or C. Variable characteristics include gelatinase and acid production from trehalose and D-fructose.

Isolated from human clinical specimens.

DNA-DNA hybridization studies yielded relative DNA binding values of 73–100% between the type and eleven other strains of *Staphylococcus schleiferi* and 2–9% between the type strain of *Staphylococcus schleiferi* and the type strains of 25 other species of *Staphylococcus* (Freney et al., 1988).

Additional characteristics of the subspecies are given below.

31a. ***Staphylococcus schleiferi* subsp. *schleiferi*** Freney, Brun, Bes, Meugnier, Grimont, Grimont, Nervi and Fleurette 1988, 171^{VP}

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.8–1.0 μ m in diameter; occur singly and form pairs, clusters, and chains. Colonies nonpigmented, low convex, smooth, glistening, with entire margins. Colony diameter 3–5 mm after 4 d on P agar. Facultatively anaerobic. Tolerates 10% NaCl; growth on 15% NaCl delayed. Temperature range for growth 20–45°C. Weakly hemolytic. Produces mostly L-lactic acid in thioglycolate medium. Positive reactions: arginine dihydrolase, alkaline phosphatase, heat-stable nuclease, catalase, clumping factor, nitrate reduction, and acetoin production. Negative reactions: oxidase, coagulase, staphylokinase, ornithine decarboxylase, and urease. Acid produced aerobically from D-glucose, glycerol, and D-mannose. No acid produced from L-arabinose, D-cellobiose, α -methyl-D-glucoside, lactose, maltose, D-mannitol, D-melibiose, D-raffinose, ribose, sucrose, turanose, xylitol, or D-xylose. Novobiocin-susceptible; bacitracin-resistant. Lysostaphin-sensitive; lysozyme-resistant. Peptidoglycan type L-Lys-Gly₅₋₆⁻ Ser_{0,2-0,3}⁻. Teichoic acids contain glucosamine, glucose, and glycerol. No Protein A. No production of TSST-1 toxin, exfoliative toxin, or enterotoxins A, B, or C. Variable characteristics include gelatinase and acid production from trehalose and D-fructose.

Isolated from human clinical specimens.

DNA-DNA hybridization studies yielded relative DNA binding values of 73–100% between the type strain and eleven other strains of *Staphylococcus schleiferi* and 2–9% between the type strain of *Staphylococcus schleiferi* and the type strains of 25 other species of *Staphylococcus* (Freney et al., 1988).

DNA G+C content (mol %): 37 (T_m).

Type strain: N850274, ATCC 43808, CCUG 25351, CIP 103643, DSM 4807, LMG 13347, NCTC 12218, NRRL B-14775.

GenBank accession number (16S rRNA gene): S83568.

31b. ***Staphylococcus schleiferi* subsp. *coagulans*** Igimi, Takahashi and Mitsuoka 1990, 410^{VP}

co.a'gu.lans. L. adj. *coagulans* curdling, coagulating.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.8–1.2 μ m in diameter; occur singly and form pairs and clusters. Colonies nonpigmented, low convex, opaque, and glistening. Colony diameter 1.5–2.0 mm after 24 h on blood agar at 37°C. Facultatively anaerobic. Positive reactions: acetoin production, arginine hydrolysis, coagulase, heat-stable nuclease, hemolysis, nitrate reduction, phosphatase, and urease. Produces β -hemolysin. Negative reactions: clumping factor, hyaluronidase, and oxidase. Acid produced aerobically from fructose, galactose, glucose, glycerol, mannose, and ribose. No acid produced from adonitol, arabinose, cellobiose, dulcitol, erythritol, glycogen, inositol, maltose, melibiose, melezitose, raffinose, rhamnose, sorbitol, trehalose, xylitol, or xylose. Acid production from lactose, mannitol, and sucrose varies between strains.

Distinguished from *Staphylococcus schleiferi* subsp. *schleiferi* by production of coagulase, urease, lack of clumping factor, and the production of acid from D-ribose.

Isolated from external ear infections of dogs.

DNA–DNA hybridization studies yielded relative DNA binding values of 67–99% among *Staphylococcus schleiferi* subsp. *coagulans* strains, 55–73% between *Staphylococcus schleiferi* subsp. *coagulans* strains and the type strain of *Staphylococcus schleiferi* subsp. *schleiferi*, and 5–27% between *Staphylococcus schleiferi* subsp. *coagulans* strains and *Staphylococcus aureus* subsp. *aureus*, *Staphylococcus aureus* subsp. *anaerobius*, *Staphylococcus intermedius*, and *Staphylococcus hyicus* (Igimi et al., 1990).

DNA G+C content (mol%): 35–37 (T_m).

Type strain: GA211, ATCC 49545, CCUG 37248, CIP 104370, DSM 6628, JCM 7470.

GenBank accession number (16S rRNA gene): AB009945.

32. **Staphylococcus sciuri** Kloos, Schleifer and Smith 1976a, 23^{AL} emend. Kloos, Ballard, Webster, Hubner, Tomasz, Couto, Sloan, Dehart, Fiedler, Schubert, de Lencastre, Santos Sanchez, Heath, Leblanc and Ljungh 1997, 320.

sci'uri. L. masc. n. *Sciurus* a squirrel and also the genus name of a squirrel on whose skin this species is commonly found in large populations; L. gen. n. *sciuri* of the squirrel.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.7–1.2 μ m in diameter; occur singly and form pairs and tetrads. Most isolates facultatively anaerobic; some do not grow in anaerobic zone of thioglycolate medium. Grows much better under aerobic conditions. Many strains only ferment glucose weakly and would be misclassified as micrococci on the basis of the O/F-test. Possesses cytochromes *aa₃* and *c* and therefore oxidase-positive. No growth or poor growth at 45°C. Positive reactions: benzidine test, catalase, β -glucosidase, nitrate reduction, and oxidase. Negative reactions: arginine dihydrolase, coagulase, elastase, β -galactosidase, β -glucuronidase, lipase, urease, and heat-stable nuclease. Acid produced aerobically from β -D(-)-fructose, D(+)-glucose, glycerol, D-mannitol, D(-)-ribose, and sucrose. No acid produced from *N*-acetylglucosamine, D-arabitol, dulcitol, *meso*-erythritol, D-erythrose, L(-)-fucose, D-lyxose, L-sorbose, tagatose, or xylitol. Lysozyme-resistant. Novobiocin-resistant. Peptidoglycan type L-Lys-L-Ala-Gly₄. Teichoic acids usually contain glycerol and glucosamine, sometimes ribitol or glucose. Major menaquinone MK-6.

Isolated from a variety of animals and animal products. Also found in soil, sand, and water.

Additional characteristics of the subspecies are given below.

- 32a. **Staphylococcus sciuri subsp. sciuri** Kloos, Schleifer and Smith 1976a, 23^{AL} emend. Kloos, Ballard, Webster, Hubner, Tomasz, Couto, Sloan, Dehart, Fiedler, Schubert, de Lencastre, Santos Sanchez, Heath, Leblanc and Ljungh 1997, 320.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.7–1.2 μ m in diameter; occur singly and form pairs and tetrads. Most isolates facultatively anaerobic; anaerobic growth poor or absent. Colonies large, raised, smooth, glistening, and opaque. Colony edges often undulating; center elevated in aged colonies; pigmentation gray-white to cream or yellowish. Colony diameter 7 ± 2 mm on P agar and 10 ± 2 mm on tryptic soy agar after incubation at

34–35°C for 3 d, then 25°C for 2 d. Produces small amount of L-lactate from glucose anaerobically. FBP-aldolase is of class I type. Tolerates 10% NaCl; growth poor in 15% NaCl. Optimal temperature for growth 35–40°C on tryptic soy agar and 35°C on P agar. Positive reactions: catalase, nitridine test, caseinase, gelatinase, hemolysis (weak), nitrate reduction, oxidase, and DNase. Negative reactions: acetoin production (or very weak), clumping factor, coagulase, elastase, and lipase. Protein A not produced. Acid produced aerobically from D(+)-cellobiose (sometimes weak), β -D(-)-fructose, D(+)-fucose, D(+)-galactose, β -gentiobiose, D(+)-glucose, glycerol, D-mannitol, D(-)-ribose, D-sorbitol, sucrose, and D(+)-trehalose (sometimes weak). No acid produced from adonitol, D-arabitol, dulcitol, *meso*-erythritol, D-erythrose, L(-)-fucose, *meso*-inositol, D-lyxose, D-melibiose, raffinose, L-sorbose, tagatose, D-turanose, or xylitol. Lysozyme-resistant. Novobiocin-resistant. Peptidoglycan type L-Lys-L-Ala-Gly₄. Major menaquinone MK-6. Variable characteristics include anaerobic growth, alkaline phosphatase, and production of acid from L-arabinose, α -lactose, maltose, D-mannose, D-melezitose, α -L-rhamnose, salicin, D-sorbitol, and D-xylose.

All strains of *Staphylococcus sciuri* subsp. *sciuri*, 58% of *Staphylococcus sciuri* subsp. *carnaticus* strains, and 67% of *Staphylococcus sciuri* subsp. *rodentium* strains produce acid aerobically from cellobiose. All strains of *Staphylococcus sciuri* subsp. *sciuri*, 29% of *Staphylococcus sciuri* subsp. *carnaticus* strains, and 67% of *Staphylococcus sciuri* subsp. *rodentium* strains possess alkaline phosphatase. No strains of *Staphylococcus sciuri* subsp. *sciuri* or *Staphylococcus sciuri* subsp. *carnaticus* strains, but approximately 95% of *Staphylococcus sciuri* subsp. *rodentium* strains were positive when tested for Staph-A-Lex agglutination; no strains of *Staphylococcus sciuri* subsp. *sciuri*, 36% of *Staphylococcus sciuri* subsp. *carnaticus* strains, and 94% of *Staphylococcus sciuri* subsp. *rodentium* strains were positive when tested for Staph Latex agglutination (Kloos et al., 1997).

Isolated from squirrels, mice, a prairie vole, opossums, a red kangaroo, horses, bottle-nosed dolphins, a pilot whale, a dog, a squirrel monkey, cattle and meat from cattle, and marsh grass.

DNA–DNA hybridization studies yielded relative DNA binding values of 81–100% among *Staphylococcus sciuri* subsp. *sciuri* strains, 61–73% between *Staphylococcus sciuri* subsp. *sciuri* strains and *Staphylococcus sciuri* subsp. *carnaticus* strains, and 49–68% between *Staphylococcus sciuri* subsp. *sciuri* strains and *Staphylococcus sciuri* subsp. *rodentium* strains (Kloos et al., 1997).

DNA G+C content (mol%): 35–36 (T_m).

Type strain: SC 116, DD 4277, ATCC 29062, CCUG 15598, CIP 81.62, DSM 20345, JCM 2425, NCTC 12103, NRRL B-14777.

GenBank accession number (16S rRNA gene): AJ421446, S83569.

- 32b. **Staphylococcus sciuri subsp. carnaticus** Kloos, Ballard, Webster, Hubner, Tomasz, Couto, Sloan, Dehart, Fiedler, Schubert, de Lencastre, Santos Sanchez, Heath, Leblanc and Ljungh 1997, 320^{VP} car.na'ti.cus. N.L. adj. *carnaticus* pertaining to meat.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.7–1.2 µm in diameter; occur singly and form pairs and tetrads. Colonies of type strain smooth and glistening with undulate, raised margins; translucent to opaque; may have nonpigmented and cream-colored pigmented sectors. Colony diameter 5 ± 2 mm on P agar and 9 ± 1 mm on tryptic soy agar after incubation at 34–35°C for 3 d, then 25°C for 2 d. Facultatively anaerobic; anaerobic growth delayed and weak. Temperature range for growth 15–40°C; optimum 35–40°C on tryptic soy agar and 35°C on P agar; no growth or poor growth at 45°C. Tolerate 10% NaCl; growth poor in 15% NaCl. Positive reactions: benzidine test, caseinase, catalase, esculin hydrolysis, gelatinase, β-glucosidase, hemolysis (weak), nitrate reduction, DNase, and oxidase. Negative reactions: acetoin production, arginine dihydrolase, coagulase, heat-stable nuclease, elastase, β-galactosidase, β-glucuronidase, lipase, urease. Acid produced aerobically from β-D(-)-fructose D-fucose, galactose, D(+)-glucose, maltose (delayed), D-mannitol, D(-)-ribose, sucrose, D-trehalose, and D-xylose. No acid production from D-arabitol, dulcitol, meso-erythritol, D-erythrose, L(-)-fucose, D-lyxose, D-melezitose, α-L-rhamnose, L-sorbose, tagatose or xylitol. Lysozyme-resistant. Novobiocin-resistant. Peptidoglycan type L-Lys-L-Ala-Gly₄. Teichoic acids usually contain glycerol and glucosamine, sometimes ribitol or glucose. Major menaquinone MK-6. Variable characteristics: alkaline phosphatase, clumping factor, and production of acid from L-arabinose, cellobiose, α-lactose, mannose, salicin, and sorbitol.

All *Staphylococcus sciuri* subsp. *carnaticus* strains, 12% of *Staphylococcus sciuri* subsp. *sciuri* strains, and 17% of *Staphylococcus sciuri* subsp. *rodentium* strains produce acid aerobically from D-xylose. All *Staphylococcus sciuri* subsp. *carnaticus* strains, 50% of *Staphylococcus sciuri* subsp. *sciuri* strains, and 89% of *Staphylococcus sciuri* subsp. *rodentium* strains produce acid aerobically from maltose at least weakly. All *Staphylococcus sciuri* subsp. *carnaticus* strains, 38% of *Staphylococcus sciuri* subsp. *sciuri* strains, and 56% of *Staphylococcus sciuri* subsp. *rodentium* strains are unable to produce acid aerobically from melezitose. Seven percentage of *Staphylococcus sciuri* subsp. *carnaticus* strains, 65% of *Staphylococcus sciuri* subsp. *sciuri* strains, and 33% of *Staphylococcus sciuri* subsp. *rodentium* strains produce colonies with diameters ≥7 mm on P agar (Kloos et al., 1997). No strains of *Staphylococcus sciuri* subsp. *sciuri* or *Staphylococcus sciuri* subsp. *carnaticus* strains, but approximately 95% of *Staphylococcus sciuri* subsp. *rodentium* strains were positive when tested for Staph-A-Lex agglutination; no strains of *Staphylococcus sciuri* subsp. *sciuri*, 36% of *Staphylococcus sciuri* subsp. *carnaticus* strains, and 94% of *Staphylococcus sciuri* subsp. *rodentium* strains were positive when tested for Staph Latex agglutination (Kloos et al., 1997).

Isolated from a cavy, a bottle-nosed dolphin, cattle, and meat from cattle.

DNA–DNA hybridization studies yielded relative DNA binding values of 81–98% among *Staphylococcus sciuri* subsp. *carnaticus* strains, 61–73% between *Staphylococcus sciuri* subsp. *carnaticus* strains and *Staphylococcus sciuri* subsp. *sciuri* strains, and 53–65% between *Staphylococcus*

sciuri subsp. *carnaticus* strains and *Staphylococcus sciuri* subsp. *rodentium* strains (Kloos et al., 1997).

DNA G+C content (mol%): 36 (T_m).

Type strain: DD 791, ATCC 700058, CCUG 39509, CIP 105826.

GenBank accession number (16S rRNA gene): AB233331.

- 32c. **Staphylococcus sciuri subsp. rodentium** Kloos, Ballard, Webster, Hubner, Tomasz, Couto, Sloan, Dehart, Fiedler, Schubert, de Lencastre, Santos Sanchez, Heath, Leblanc and Ljungh 1997, 321^{VP}

ro.den'ti.um. L. pl. gen. n. *rodentium* of rodents.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.7–1.2 µm in diameter; occur singly and form pairs and tetrads. Colonies of type strain smooth and glistening with undulate, raised margins; translucent, yellow-gray. Colony diameter 6 ± 2 mm on P agar and 10 ± 1 mm on tryptic soy agar after incubation at 34–35°C for 3 d, then 25°C for 2 d. Most isolates facultatively anaerobic; some do not grow in anaerobic zone of thioglycolate medium; growth of others weak and delayed. Growth temperature optimum 35–40°C on tryptic soy agar and 35°C on P agar; no growth or poor growth at 45°C. Positive reactions: benzidine test, caseinase, catalase, clumping factor, esculin hydrolysis, gelatinase, β-glucosidase, nitrate reduction, nuclease, and oxidase. Negative reactions: acetoin production, arginine dihydrolase, coagulase, elastase, β-galactosidase, β-glucuronidase, lipase, ornithine decarboxylase, urease, and heat-stable nuclease. Acid produced aerobically from β-D(-)-fructose, fucose, galactose, D(+)-glucose, glycerol, maltose, D-mannose, D-mannitol, D(-)-ribose, sucrose, and D-trehalose. No acid produced from N-acetylglucosamine, D-arabitol, dulcitol, meso-erythritol, D-erythrose, α-lactose, D-lyxose, L-sorbose, tagatose, or xylitol. Lysozyme-resistant. Novobiocin-resistant. Peptidoglycan type L-Lys-L-Ala-Gly₄. Teichoic acids usually contain glycerol and glucosamine, sometimes ribitol or glucose. Major menaquinone MK-6. Variable characteristics include alkaline phosphatase, hemolysis, staphylolysin, and production of acid from L-arabinose, D-cellobiose, D-melezitose, α-L-rhamnose, salicin, D-sorbitol, and D-xylose.

No strains of *Staphylococcus sciuri* subsp. *sciuri* or *Staphylococcus sciuri* subsp. *carnaticus* strains, but approximately 95% of *Staphylococcus sciuri* subsp. *rodentium* strains were positive when tested for Staph-A-Lex agglutination; no strains of *Staphylococcus sciuri* subsp. *sciuri*, 36% of *Staphylococcus sciuri* subsp. *carnaticus* strains, and 94% of *Staphylococcus sciuri* subsp. *rodentium* strains were positive when tested for Staph Latex agglutination (Kloos et al., 1997). *Staphylococcus sciuri* subsp. *rodentium* strains were also more likely to exhibit at least intermediate levels of resistance to cefazolin, methicillin, and oxacillin (Kloos et al., 1997).

Isolated from squirrels, rats, a pilot whale, and humans.

DNA–DNA hybridization studies yielded relative DNA binding values of 80–88% between the type strain and three other strains of *Staphylococcus sciuri* subsp. *rodentium* strains, 49–68% between the type strain of *Staphylococcus sciuri* subsp. *rodentium* strain and eight *Staphylococcus sciuri* subsp. *sciuri* strains, and 53–65% between the type

strain of *Staphylococcus sciuri* subsp. *rodentium* strains and seven *Staphylococcus sciuri* subsp. *carnaticus* strains (Kloos et al., 1997).

DNA G+C content (mol%): 35 (T_m).

Type strain: DD 4761, R1-33, ATCC 700061, CCUG 37923, CIP 105829.

GenBank accession number (16S rRNA gene): AB233332.

33. **Staphylococcus simulans** Kloos and Schleifer 1975a, 69^{AL}

sim'u.lans. L. part. adj. *simulans* imitating; named for having similarities to certain coagulase-positive staphylococci, including *Staphylococcus aureus*.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.8–1.5 μm in diameter; form pairs and tetrads; occasionally occur as single cells. Colonies nonpigmented (gray-white), slightly raised, smooth, glistening, translucent, with entire margins. Colony diameter 5–7.5 mm. Facultatively anaerobic. Grows better under aerobic conditions. Strains may produce either L-lactate alone or both D- and L-lactate anaerobically from glucose. Grows in medium containing 10% NaCl; growth poor or absent at 15% NaCl. FBP-aldolase of class I type. Temperature range for growth 15–45°C; optimum 25–40°C. Positive reactions: arginine dihydrolase, benzidine test, catalase (may be weak), DNase, β -galactosidase, heat-stable nuclease (some strains), lipase, nitrate reduction, and urease. Negative reactions: caseinase, coagulase, clumping factor, gelatinase, β -glucosidase, and oxidase. Acid produced aerobically from fructose, glucose, glycerol, lactose, mannitol, and sucrose. No acid production from adonitol, arabinose, arabitol, cellobiose, dulcitol, erythritol, erythrose, fucose, gentiobiose, inositol, lyxose, melezitose, melibiose, raffinose, rhamnose, salicin, sorbitol, sorbose, tagatose, turanose, xylitol, or xylose. Lysozyme-resistant; lysostaphin-sensitive. Novobiocin-susceptible. Peptidoglycan type L-Lys-L-Gly₅₋₆. The lysostaphin-producing strain (NRRL B-22628) designated *Staphylococcus simulans* biovar *staphylolyticus* (Sloan et al., 1982) has a peptidoglycan of the type L-Lys-Gly_{2,3}, L-Ser_{1,3}. The high serine content in the interpeptide bridge of the peptidoglycan contributes to the lysostaphin resistance of this strain. Teichoic acid contains glycerol, N-acetylgalactosamine, and N-acetylglucosamine. Major fatty acids C_{B-15}, C₁₈, and C₂₀. Major menaquinone MK-7. Variable characteristics include acetoin production (weak), phosphatase (weak), β -glucuronidase, growth in medium containing 15% NaCl, hemolysis (may be weak), and acid production from galactose, maltose, mannose, ribose, and trehalose.

Staphylococcus simulans is found occasionally on the skin of humans and other primates; may be associated with infection.

DNA–DNA hybridization studies yielded relative DNA-binding values >80% among *Staphylococcus simulans* strains (Kloos and Wolfshohl, 1982). The *Staphylococcus simulans* biovar *staphylolyticus* demonstrated 100% DNA–DNA similarity with the type strain of *Staphylococcus simulans* (Sloan et al., 1982). *Staphylococcus simulans* is more closely related to *Staphylococcus carnosus* than to other species.

DNA G+C content (mol%): 34–38 (T_m).

Type strain: MK 148, ATCC 27848, CCUG 7327, CIP 81.64, DSM 20322, HAMBI 2058, JCM 2424, NCTC 11046, NRRL B-14753.

GenBank accession number (16S rRNA gene): D83373.

34. **Staphylococcus succinus** Lambert, Cox, Mitchell, Rosselló-Mora, Del Cueto, Dodge, Orkland and Cano 1998, 516^{VP}
suc.cin'us. L. masc. adj. *succinum* of amber.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.6–1.9 μm in diameter. Occur in rosettes of 3–6 cells. Colonies may be either opaque, white, crenated, rough, and umbonate, or opaque, grayish white, glistening, smooth, entire, and raised. Temperature range for growth 25–40°C; optimum 28°C. No growth at 45°C. Aerobic. No growth in anaerobic zone of thioglycolate medium. Can grow in 15% NaCl. Positive reactions: β -galactosidase, β -glucuronidase, and urease. Acid produced aerobically from fructose, lactose, maltose, mannitol, salicin, sucrose, and trehalose. Negative reactions: acetoin production, oxidase, reduction of nitrate to nitrite, and hydrolysis of arginine. Novobiocin- and bacitracin-resistant. Additional characteristics of the subspecies are given below.

34a. **Staphylococcus succinus subsp. succinus** Lambert, Cox, Mitchell, Rosselló-Mora, Del Cueto, Dodge, Orkland and Cano 1998, 516^{VP}

Gram-stain-positive cocci, 0.6–1.9 μm in diameter. Occur in rosettes of 3–6 cells. Colonies may be either opaque, white, crenated, rough, and umbonate or opaque, grayish white, glistening, smooth, entire, and raised. Colony diameter 4–6 mm after incubation for 2 d at 25°C on tryptic soy agar. Temperature range for growth 25–40°C; optimum 28°C. No growth in anaerobic zone of thioglycolate medium. Grows in presence of 40% bile and at pH 4.9. Acid produced aerobically from fructose, galactose (weak), lactose, maltose (weak), mannitol, salicin, sucrose, and trehalose. Does not ferment arabinose, fucose, mannose, melizitose, raffinose, turanose, xylitol, or xylose. Produces catalase, β -D-glucuronidase, β -D-galactopyranosidase, phosphatase, and urease. Hydrolyzes indoxyl phosphate. Does not produce oxidase, reduce nitrate to nitrite, or hydrolyze arginine. No acetoin production. Novobiocin- and bacitracin-resistant. DAP-type peptidoglycan (has to be confirmed). Major fatty acids are iso and anteiso forms of C_{13:0}, C_{15:0}, and C_{17:0}; also contains C_{20:0} and tuberculostearic acid.

Found in Dominican amber.

In DNA–DNA hybridization studies, the DNA of the type strain of *Staphylococcus succinus* gave a relative binding value of 95% to the DNA of a second strain of *Staphylococcus succinus*, 6% to *Staphylococcus saprophyticus*, 23% to *Staphylococcus xylosus*, and 38% to *Staphylococcus equorum*.

DNA G+C content (mol%): 34.4–35 (HPLC).

Type strain: AMG-D1, ATCC 700337, CCUG 43571, DSM 14617.

GenBank accession number (16S rRNA gene): AF004220.

34b. **Staphylococcus succinus subsp. casei** Place, Hiestand, Burri and Teuber 2003b, 1^{VP} (Effective publication: Place, Hiestand, Burri and Teuber 2002, 359.)

ca'se.i. L. gen. n. *casei* of cheese, named because the organism was isolated from cheese.

Nonmotile cocci, 1.1–2.0 μm in diameter that form pairs and clumps as well as occurring singly. Does not form

rosettes. Nonmotile. Colonies opaque, white, crenated, rough, and umbonate. Colony diameter 4–6 mm after incubation for 2 d at 32°C on PC skim milk agar. Temperature range for growth 6–41°C; optimum 32°C. Does not grow anaerobically. Tolerant to 15% NaCl. No growth at pH 4.9. Positive reactions: nitrate reduction to nitrite, urease, β -galactosidase, β -glucuronidase, and esculin hydrolysis. Negative reactions: acetoin production, arginine dihydrolase, ornithine decarboxylase, oxidase, and hemolysis. Weak production of alkaline phosphatase. Acid produced aerobically from fructose, D-galactose, α -D-lactose, maltose, mannitol, D-mannose, D-melezitose, D-ribose, salicin, sucrose, and D-trehalose. Weak acid production from turanose and xylose. No acid produced from L-arabinose, cellobiose, L-fucose, raffinose, or xylitol. Ferments adenosine, 2' deoxyadenosine, 2,3-butanediol, gentiobiose, inosine, α -ketovaleric acid, D-melibiose, D-sorbitol, and thymidine-5' monophosphate. Does not ferment D-alanine. Novobiocin-resistant. Peptidoglycan type L-Lys-Gly₄, Ser. Major fatty acids are iso and anteiso forms of C_{15:0} and C_{17:0}. Also contains tuberculostearic acid.

Distinguished from *Staphylococcus succinus* subsp. *succinus* by ability to reduce nitrate, production of acid aerobically from D-mannose and D-melizitose, and inability to grow at pH 4.9; fermentation patterns of the two subspecies also differ, although some reactions are weak (Place et al., 2002).

Found in surface ripened cheese.

DNA–DNA hybridization studies yielded a relative DNA binding value of 72.3% between the type strain of *Staphylococcus succinus* subsp. *casei* and the type strain of *Staphylococcus succinus* subsp. *succinus* and 42–51.2% between the type strain of *Staphylococcus succinus* subsp. *casei* and the type strains of *Staphylococcus equorum*, *Staphylococcus xylosus*, and *Staphylococcus gallinarum*. 16S rDNA sequence analysis showed that the *Staphylococcus* species most closely related to *Staphylococcus succinus* subsp. *succinus* and *Staphylococcus succinus* subsp. *casei* were *Staphylococcus saprophyticus*, *Staphylococcus xylosus*, *Staphylococcus equorum*, *Staphylococcus arlettae*, and *Staphylococcus gallinarum* (Place et al., 2002).

DNA G+C content (mol%): 34.4 (HPLC).

Type strain: SB72, DSM 15096, CIP 107658.

GenBank accession number (16S rRNA gene): AJ320272.

35. ***Staphylococcus vitulinus*** corrig. Webster, Bannerman, Hubner, Ballard, Cole, Bruce, Fiedler, Schubert and Kloos 1994, 458^{VP}

vit'u.lin.us. L. masc. adj. *vitulinus* pertaining to veal.

Nonmotile, nonspore-forming, Gram-stain-positive cocci; occur singly and form pairs, tetrads, and clusters. Colonies usually pigmented, opaque, raised, with irregular edges; may be sectored. Colony diameter <3 mm on P agar and 8–12 mm on tryptic soy agar after incubation at 35°C. No growth at 45°C or anaerobically in thioglycolate medium. Weak growth on sheep blood agar or tryptic soy agar in anaerobic jars. Positive reactions: catalase, oxidase, and nitrate reduction. Negative reactions: acetoin production, alkaline phosphatase, arginine utilization, β -galactosidase, β -glucuronidase, ornithine decarboxylase, staphylocoagulase,

thermonuclease, and urease. Acid produced aerobically from fructose, glycerol, mannitol, and sucrose. No acid produced from N-acetyl-D-glucosamine, L-arabinose, galactose, lactose, maltose, D-mannose, melezitose, raffinose, rhamnose, D-turanose, and xylitol. Peptidoglycan type L-Lys-L-Ala-Gly_{3-3.4}. Glycerol teichoic acids contain N-acetylglucosamine, N-acetylglucosamine 1-phosphate, or N-acetylglucosamine. Novobiocin-resistant. Variable characteristics include β -glucosidase, esculin hydrolysis, clumping factor, and aerobic production of acid from D-cellobiose, D-ribose, salicin, D-trehalose, and D-xylose.

Isolated from various animals (horse, pine vole, pilot whale) and meats (veal, beef, chicken, lamb).

DNA–DNA hybridization studies yielded relative DNA binding values of 74–97% at 55°C and 75–93% at 70°C among strains of *Staphylococcus vitulinus*. Relative DNA binding values of two strains of *Staphylococcus vitulinus* to the type strains of nine other *Staphylococcus* species were 13–53% at 55°C and 5–15% at 70°C; the most closely related species were *Staphylococcus sciuri* and *Staphylococcus lentus* (Webster et al., 1994).

DNA G+C content (mol%): 34 (T_m).

Type strain: DD 756, ATCC 51145, CCM 4511, CCUG 33636, CIP 104850.

GenBank accession number (16S rRNA gene): AB009946.

Additional remarks: *Staphylococcus vitulinus* is considered a senior heterotypic synonym of *Staphylococcus pulvereri* (Kloos et al., 2001; Petráš, 1998).

36. ***Staphylococcus warneri*** Kloos and Schleifer 1975a, 63^{AL}

war.ner'i. N.L. gen. n. *warneri* of Warner; named for Arthur Warner, from whom this organism was originally isolated.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.5–1.2 μ m in diameter; occur singly and form pairs, occasionally tetrads. Colonies sticky, raised, smooth, glistening, and opaque, with entire margins. Pigmentation varies from nonpigmented to yellow-orange; colonies may have a yellow-orange rim or a yellowish center. Colony diameters 3–6 mm. Facultatively anaerobic. Growth is best under aerobic conditions. Produces both D- and L-lactate anaerobically from glucose. FBP-aldolase is of the class I type. Grows in medium containing 10% NaCl. Temperature range for growth 15–45°C (optimum 30–40°C). Positive reactions: acetoin production, benzidine test, catalase, β -glucosidase, lipase, and urease. Negative reactions: caseinase, coagulase, clumping factor, gelatinase, ornithine decarboxylase, oxidase, and phosphatase. Acid produced aerobically from fructose, glucose, glycerol, maltose (delayed), sucrose, and trehalose. No acid produced from adonitol, arabinose, arabitol, cellobiose, dulcitol, erythritol, erythrose, fucose, gentiobiose, inositol, lyxose, mannose, melibiose, raffinose, rhamnose, salicin, sorbitol, sorbose, tagatose, xylitol, or xylose. Novobiocin-susceptible. Lysozyme-resistant; slightly lysostaphin-resistant. Peptidoglycan type L-Lys-Gly_{3.3-4.5}, Ser_{0.6-1.4}. Teichoic acid contains glycerol, glucose, and N-acetylglucosamine. Major fatty acids C_{B_F-15}, C₁₈, and C₂₀; C₂₂ also produced. Major menaquinone MK-7. Variable characteristics include arginine dihydrolase, β -glucuronidase, growth at 15°C, growth in medium containing 15% NaCl, heat-labile DNase (may be weak), hemolysis (may be weak),

nitrate reduction (weak), and acid production from galactose, lactose, mannitol, melezitose, ribose, and turanose.

Isolated from skin of humans and nonhuman primates. One of the major *Staphylococcus* species found living on the skin and nasal membranes of various monkeys and prosimians. Sometimes associated with infections.

DNA–DNA hybridization studies yielded relative DNA binding values of >80% both among *Staphylococcus warneri* strains from humans and among *Staphylococcus warneri* strains from nonhuman primates, but only 50–67% between human and primate strains under optimal conditions (Kloos and Wolfshol, 1979).

DNA G+C content (mol%): 34–35 (T_m).

Type strain: AW25, ATCC 27836, CCUG 7325, CIP 81.65, DSM 20316, JCM 2415, LMG 13354, NCTC 11044, NRRL B-14736.

GenBank accession number (16S rRNA gene): L37603.

37. ***Staphylococcus xylosus*** Schleifer and Kloos 1975, 57^{AL}
xy.lo'sus. N.L. adj. *xylosus* belonging to xylose.

Nonmotile, nonspore-forming, Gram-stain-positive cocci, 0.8–1.2 µm in diameter; occur singly and form pairs, occasionally tetrads. Colony characteristics variable: may be raised to slightly convex, rough or smooth, dull to glistening, usually opaque, with entire, undulate, or crenate margins. Pigmentation ranges from white to yellowish to yellow-orange. Colony diameter 5–10 mm. Facultatively anaerobic. Grows best under aerobic conditions. Some strains ferment glucose weakly and would be misclassified as micrococci on the basis of the O/F-test. Produces

small amounts of L-lactate anaerobically from glucose. FBP-aldolase is of the class type I. Galactose is metabolized via the Leloir pathway (Schleifer et al., 1978). Temperature range for growth 10–40°C; optimum 25–35°C. Grows in medium containing 10% NaCl. Positive reactions: benzidine test, catalase, β-galactosidase, β-glucosidase, and urease. Negative reactions: arginine dihydrolase, coagulase, clumping factor, and hemolysis. Acid produced aerobically from arabinose, fructose, glucose, glycerol, maltose, mannose, sucrose, trehalose, and xylose. No acid produced from adonitol, arabitol, cellobiose, dulcitol, erythritol, erythrose, fucose, lyxose, melezitose, melibiose, raffinose, sorbose, or tagatose. Lysostaphin-sensitive; lysozyme-resistant. Novobiocin-resistant. Peptidoglycan type L-Lys–Gly_{5–6}. Teichoic acid contains glycerol, ribitol, and glucosamine. Major fatty acids C_{B-15}, C_{B-17}, C₁₈, and C₂₀. Major menaquinone MK-7. Variable characteristics include acetoin production, β-glucuronidase, DNase (weak), growth at 45°C, growth in medium containing 15% NaCl, lipase, alkaline phosphatase, nitrate reduction, and acid production from arabinose, galactose, gentiobiose, inositol, lactose, mannitol, rhamnose, ribose, salicin, sorbitol, turanose, and xylitol (weak).

Isolated from mammals, including humans and other primates, and the environment. Rarely associated with human or animal infections.

DNA–DNA hybridization studies yielded relative DNA binding values >70% among strains of *Staphylococcus xylosus*, except for one group of strains from New World monkeys. Relative DNA binding values between these strains and the other staphylococci examined were 38–39% (Kloos and Wolfshohl, 1982; Schleifer et al., 1979).

DNA G+C content (mol%): 30–36 (T_m).

Type strain: KL162, ATCC 29971, CCUG 7324, CIP 81.66, DSM 20266, HAMB1 2057, JCM 2418, LMG 20217, NCTC 11043, NRRL B-14776.

GenBank accession number (16S rRNA gene): D83374.

Addendum

Staphylococcus pseudintermedius Devriese, Vancanneyt; Baele, Vanechoutte, de Grafe, Snauwaert, Cleenwerck, Dawyndt, Swings, Decostere and Haesebrouck 2005, 1571

pseu.do.in.ter.me'di.us. Gr. adj. *pseudēs* or *pseudos* false; L. masc. adj. *intermedius* intermediate, and also a specific epithet; N.L. masc. adj. *pseudintermedius* a false (*Staphylococcus*) *intermedius*, because of the high phenotypic similarity to *Staphylococcus intermedius*.

Nonmotile, non-spore-forming Gram-stain-positive cocci predominantly in groups. Colonies on Columbia sheep blood agar unpigmented and surrounded by double zone hemolysis. Outer band incompletely hemolytic, turns into complete hemolysis after being put at 4°C (hot–cold hemolysis), typical of staphylococcal β-hemolysin (a sphingomyelinase). Catalase-positive, coagulate rabbit plasma, clumping-factor-negative. Produce strong DNase. Positive reactions for acetoin, β-glucosidase, arginine dihydrolase, urease, nitrate reduction, pyrrolidonyl arylamidase and ONPG (β-galactosidase). Negative reaction: β-glucuronidase. Susceptible to 8 µg acriflavine ml⁻¹ and to novobiocin. Resistant to deferroxamine. Acid produced from glycerol (weakly and delayed), ribose, galactose, D-glucose, D-fructose, D-mannose, mannitol (weakly and delayed), N-acetylglucosamine, maltose, lactose, sucrose, trehalose and D-turanose (weakly and delayed). No acid produced from erythritol, D-arabinose, L-arabinose, D-xylose, L-xylose, adonitol, methyl β-D-xyloside, L-sorbose, rhamnose, dulcitol, inositol, sorbitol, methyl α-D-glucoside, methyl α-D-xyloside, amygdalin, arbutin, esculin, salicin, cellobiose, melibiose, inulin, melezitose, D-raffinose, starch, glycogen, xylitol, D-lyxose, D-tagatose, D-fucose, L-fucose, L-arabitol, gluconate, 2-ketogluconate or 5-ketogluconate.

Isolated from lesions in different animal host species, but the habitat and pathogenic activity are unknown.

DNA G+C content (mol%): 38 (HPLC).

Type strain: LMG 22219^T (=ON 86^T=CCUG 49543^T).

GenBank accession number (16S rRNA gene): AJ780976.

***Staphylococcus simiae* sp. nov.** Pantucek., Sedlacek, Petras, Koukalova, Svec, Stetina, Vancanneyt, Chrasttinova, Vokurkova, Ruzickova, Doskar, Swings, and Hajek 2005, 1957

si'mi.ae. L. gen. fem. n. *simiae* of/from a monkey.

Nonmotile, non-spore-forming Gram-stain-positive cocci; 0.7–0.8 µm in diameter; singly in pairs and in irregular clusters. Colonies 1–1.5 mm in diameter on glucose/yeast extract/peptone agar after 24 h at 36.5°C; circular, smooth, flat with low-convex centres, glistening, white with continuous margins. Strains grow anaerobically in thioglycolate medium. Grow at 15 and 45°C and in 12 % NaCl. All strains susceptible to lysostaphin, novobiocin and nitrofurantoin and resistant to bacitracin and polymyxin B. Catalase-positive, oxidase-negative, coagulase-negative and clumping-factor-negative. Produce alkaline phosphatase, acid phosphatase, urease, leucine arylamidase, esterase and esterase-lipase and reduce nitrate to nitrite. Weak δ-hemolysis activity. No production of acetoin, heat-stable or heat-labile nuclease, arginine arylamidase, ornithine decarboxylase, valine arylamidase, cystine arylamidase,

pyrrolidonyl arylamidase, lipase, *N*-acetyl- β -glucosaminidase, α -fucosidase, α -galactosidase, α -glucosidase, α -mannosidase or β -glucuronidase. β -galactosidase weakly positive when ONPG is used as a substrate and variable when 2-naphthyl β -D-galactopyranoside is used; the type strain is β -galactosidase-negative. Similarly, cells are β -glucosidase-positive when 2-nitrophenyl β -D-glucopyranoside is used as a substrate and negative when 6-bromo-2-naphthyl β -D-glucopyranoside is used. Acid produced aerobically from D-fructose, D-glucose, galactose, lactose, D-maltose, D-mannitol, sucrose, D-trehalose and D-turanose. Delayed positive test result (2 d) obtained for acidification of melezitose and *N*-acetylglucosamine. No aerobic production of acid from D-cellobiose, D-raffinose, D-mannose, D-melibiose, D-ribose, xylitol, methyl α -D-glu-

coside and for anaerobic fermentation of D-mannitol. Variable reactions obtained for acid production from L-arabinose (3/8 positive, type strain negative), sorbitol (3/8 positive, type strain negative) and D-xylose (3/8 positive, type strain negative), for production of arginine dihydrolase (5/8 positive, type strain positive) and lecithinase (4/8 positive, type strain weakly positive) and for hydrolysis of casein (6/8 positive, type strain weakly positive), gelatin (6/8 positive, type strain positive) and Tween 80 (5/8 positive, type strain positive). No hydrolysis of elastin, esculin, starch and tyrosine.

Isolated from the feces of a squirrel monkey.

DNA G+C content (mol%): 33.8 (HPLC).

Type strain: CCM 7213^T (=LMG 22723^T).

GenBank accession number (16S rRNA gene): AY727530.

Genus II. *Jeotgalicoccus* Yoon, Lee, Weiss, Kang and Park 2003, 600^{VP}

THE EDITORIAL BOARD

Je.ot.ga.li.coc'cus. N.L. n. *jeotgalum* (Korean n. *jeotgal*) jeotgal, traditional Korean seafood; Gr. masc. n. *kokkos* a grain or berry; N.L. masc. n. *Jeotgalicoccus* coccus from jeotgal.

Nonsporeforming cocci (0.6–1.1 μ m). **Gram-positive**. Nonmotile. **Facultatively anaerobic**. Optimal pH for growth is 7.0–8.0 and no growth occurs at 5.5. **Catalase- and oxidase-positive**. Urease negative. Nitrate is not reduced to nitrite. Cell-wall peptidoglycan contains L-lysine at position 3 of the peptide subunit. **Peptidoglycan type is A3 α** based on L-Lys–Gly₃₋₄–L-Ala(Gly). **The principal menaquinone is MK-7**. **Major fatty acids are C_{15:0 ante} and C_{15:0 iso}**.

DNA G+C content (mol%): 38–42.

Type species: *Jeotgalicoccus halotolerans* Yoon, Lee, Weiss, Kang and Park 2003, 600^{VP}.

Further descriptive information

Strains grow optimally in the presence of 2–5% (w/v) NaCl. On marine agar, colonies are smooth, glistening, low convex, circular to slightly irregular, and light yellow in color. They have the peptidoglycan type A3 α , based on the structure L-Lys–Gly₃₋₄–L-Ala(Gly). Analysis of dihydrophenylated cell walls indicated the N-terminal glycine residue of the interpeptide bridge is mostly replaced by an alanine residue. MK-7 represents 80–86% of the menaquinone. The main cellular fatty acids are C_{15:0 ante} and C_{15:0 iso}. The polar fatty acids include phosphatidylglycerol, diphosphatidylglycerol, and unidentified phospholipids. No glycolipids are detected.

Differential characteristics for the species of the genus are given in Table 75.

Differentiation from closely related taxa

Jeotgalicoccus is distinguished from *Salinicoccus* by the type of menaquinone (MK-7 vs. MK-6, respectively), type of cell-wall peptidoglycan (L-Lys–Gly₃₋₄–L-Ala(Gly) vs. L-Lys–Gly₅) and colony color (light yellow vs. reddish orange). It can also be distinguished from *Nesterenkonia* on the basis predominant menaquinones and cell-wall peptidoglycan (MK-8 and MK-9; L-Lys–Gly–Glu) as well as mol% G + C of the DNA (42 vs. 72), from *Staphylococcus* on the basis of predominant menaquinones (MK-6, 7, 8), from *Macrococcus* on the basis of peptidoglycan type (L-Lys–Gly₃₋₄, L-Ser), from *Marinococcus* on the basis of peptidoglycan type (*meso*-diaminopimelic acid at position 3), and from *Tetragenococcus* on the basis of peptidoglycan type (L-Lys–D-Asp [A4 α]), fatty acid profile (abundant C_{18:1} and C_{16:0}), and some physiological properties (no catalase or oxidase activity, and lactic acid production in some species).

Taxonomic comments

On the basis of its 16S rRNA gene, *Jeotgalicoccus* is assigned to the family *Staphylococcaceae*. Its closest relatives within that family are *Salinicoccus roseus* DSM 5351^T and *Salinicoccus hispanicus* DSM 5352^T (with 92.6–93.5% sequence similarity).

List of species of the genus *Jeotgalicoccus*

1. *Jeotgalicoccus halotolerans* Yoon, Lee, Weiss, Kang and Park 2003, 600^{VP}

ha.lo.to'le.rans. Gr. n. *hals* salt; L. pres. part. *tolerans* tolerating, enduring; N.L. part. adj. *halotolerans* salt-tolerating.

Characteristics are the same as described for the genus except as follows. Growth occurs at 4 and 42°C, but not at 43°C, and at pH 5.5, and is optimal at 30–35°C and at pH 7.0–8.0. Growth occurs in the presence of 0–20%, but not 21%, NaCl and is optimal in 2–5% NaCl. Grows anaerobi-

cally on marine agar. Acid is produced from L-arabinose, D-mannose, D-ribose, and D-mannitol but not from D-cellobiose, D-fructose, D-galactose, D-glucose, lactose, maltose, D-melezitose, melibiose, D-raffinose, L-rhamnose, stachyose, sucrose, D-trehalose, D-xylose, adonitol, myoinositol, or D-sorbitol.

Source: traditional Korean fermented seafood.

DNA G + C content (mol%): 42 (HPLC).

Type strain: YKJ-101, JCM 11198, KCCM 41448.

GenBank accession number (16S rRNA gene): AY028925.

TABLE 75. Characteristics differentiating the species of the genus *Jeotgalicoccus*^a

2. ***Jeotgalicoccus pinnipedialis*** Hoyles, Collins, Foster, Falsen and Schumann 2004, 747^{VP}
pin.ni.ped.i.a'lis. N.L. masc. adj. *pinnipedialis* pertaining to pinnipeds.

The description of this species is identical to that of the genus except as follows. Cells appear as grape-like bunches, in pairs, or in tetrads. They are non-acid-fast. Nonhemolytic, buff or fawn, round, convex colonies (2 mm in diameter) form on blood agar after aerobic incubation for 24 h. Colonies have a similar appearance on nutrient agar. Increasing the CO₂ concentration does not enhance growth. Grows at 25 and 42°C, but not at 4°C. Grows in 2% and 6% NaCl, but not in 0% and 14%. Using API systems, acid is not produced from arabinose, cellobiose, glucose, glycogen, fructose, lactose, mannose, mannitol, maltose, melibiose, α-methyl D-glucoside (methyl α-D-glucopyranoside), raffinose, ribose, sucrose, trehalose, turanose, xylitol, or D-xylose. Gelatin, but not esculin or hippurate, is hydrolyzed. Acid phosphatase, phosphoamidase, pyrazinaminidase, and pyrrolidonyl arylamidase activities are detectable, but ester lipase C8 activity is weakly detectable or absent. No activity for the following is present: alkaline phosphatase, arginine dihydrolase, arginine arylamidase, chymotrypsin, cystine arylamidase, esterase C4, α-fucosidase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, β-glucuronidase, leucine arylamidase, lipase C14, α-mannosidase, ornithine decarboxylase,

N-acetylglucosaminidase, trypsin, valine arylamidase, or urease. Acetoin is not produced. An additional polar lipid (phosphatidylinositol) was detected in addition to those included in the genus description. Its habitat is unknown.

Source: mouth swab of a Southern elephant seal.

DNA G + C content (mol%): 38.6 (HPLC).

Type strain: A/G14/99/10, CCUG 42722, CIP 107946.

GenBank accession number (16S rRNA gene): AJ251530.

3. ***Jeotgalicoccus psychrophilus*** Yoon, Lee, Weiss, Kang and Park 2003, 601^{VP}
psy.chro'phil.us. Gr. adj. *psychros* cold; Gr. adj. *philos* liking, loving; N.L. adj. *psychrophilus* cold-loving.

The description of this species is identical to that of the genus except as follows. Growth occurs at 4 and 34°C, but not above 35°C, and at pH 5.5, and is optimal at 20–25°C and at pH 7.0–8.0. Growth occurs in the presence of 14%, but not at 0% or 15%, NaCl and is optimal in 2–5% NaCl. Acid is not produced from L-arabinose, D-cellobiose, D-fructose, D-galactose, D-glucose, lactose, maltose, D-mannose, D-melezitose, melibiose, D-raffinose, L-rhamnose, D-ribose, stachyose, D-trehalose, D-xylose, adonitol, D-mannitol, myoinositol, or D-sorbitol.

Source: a traditional Korean fermented seafood.

DNA G + C content (mol%): 42 (HPLC).

Type strain: YKJ-115, JCM 11199, KCCM 41449.

GenBank accession number (16S rRNA gene): AY028926.

Genus III. *Macrococcus* Kloos, Ballard, George, Webster, Hubner, Ludwig, Schleifer, Fiedler and Schubert 1998a, 871^{VP}

KARL-HEINZ SCHLEIFER

Ma.cro.coc'cus. Gr. adj. *macrus* large; Gr. masc. n. *kokkos* a grain or berry; N.L. masc. n. *Macrococcus* a large coccus.

Cells are **spherical** or **cocoid**, 0.74–2.5 μm in diameter, occurring mostly in pairs and tetrads or in irregular clusters. Nonmotile. Do not form endospores. Gram-stain-positive. Metabolism is mainly respiratory; growth is chemo-organotrophic and only marginally facultatively anaerobic. **Catalase-** and **oxidase-positive**. Resistant to bacitracin and lysozyme and susceptible to furazolidone. Do not produce acid from D-cellobiose.

Habitat: skin of animals, milk of cattle.

DNA G+C content (mol%): 38–45.

Type species: Macrococcus equipercicus Kloos, Ballard, George, Webster, Hubner, Ludwig, Schleifer, Fiedler and Schubert 1998a, 873^{VP}.

Further descriptive information

Macrococci are similar to oxidase-positive, novobiocin-resistant staphylococci (*Staphylococcus sciuri*, *Staphylococcus lentus*, and *Staphylococcus vitulinus*) but differ in their somewhat higher G+C content of DNA and generally larger cells. Strains of *Macrococcus lamae*, however, are novobiocin-sensitive. Most macrococci do not grow in the anaerobic portion of a thio-glycolate semisolid medium. They are negative for coagulase, ornithine decarboxylase, β-glucuronidase, and β-galactosidase. Do not utilize arginine. No acid production from D-cellobiose, D-melezitose, D-xylose, L-arabinose, D-turanose, D-sorbitol,

xylitol, salicin, and D-raffinose. Macrococci can contain *a*-, *b*-, and/or *c*-type cytochromes. The genome size is in the range of 1500–1800 kb (Kloos et al., 1998a).

Enrichment and isolation procedures

Isolation of macrococci does not require a special medium. Good growth occurs on nutrient or brain heart infusion agar at 30–35°C.

Taxonomic comments

The genus *Macrococcus* has been described on the basis of comparative 16S rRNA analysis, DNA–DNA hybridization studies, ribotype patterns, cell-wall composition, and phenotypic characteristics (Kloos et al., 1998a; Mannerova et al., 2003). Macrococci can be separated from staphylococci on the basis of a generally higher DNA G+C content (38–45 mol%), unique ribotype patterns, and usually larger cells. Members of the genus *Macrococcus* are oxidase-positive, whereas most staphylococci are oxidase-negative. The DNA G+C content of *Macrococcus caseolyticus* is 38–39 mol% (Schleifer et al., 1982) which is similar to that of several staphylococcal species.

The peptidoglycan type of the cell wall of four macrococcal species has been determined (Kloos et al., 1998a). *Macrococcus caseolyticus*, *Macrococcus equiperficus*, and *Macrococcus carouselicus* contain the Lys–Gly_{3–4}, L-Ser-type and *Macrococcus bovicus* contains the Lys–Gly₃, L-Ser-type. Small amounts of an atypical cell-wall teichoic acid (poly(*N*-acetylglucosaminylphosphate) or poly(*N*-acetylgalactosaminylphosphate)) were found in *Macrococcus caseolyticus* (Kloos et al., 1998a; Schleifer et al., 1982). A similar cell-wall teichoic acid occurs in *Staphylococcus auricularis* (Endl et al., 1983). In contrast to staphylococci, none of the other macrococcal species tested contain a cell-wall teichoic acid (Kloos et al., 1998a; Schleifer, 1986).

Based on comparative 16S rRNA gene sequence studies, the genus *Macrococcus* belongs to the phylum *Firmicutes*. They are closely related to staphylococci and members of the *Firmicutes* such as bacilli, enterococci, streptococci, lactobacilli, and listeria (Figure 72). It has been proposed to combine the genera *Staphylococcus*, *Gemella*, *Macrococcus*, and *Salinicoccus* within the family *Staphylococcaceae* (Garrity and Holt, 2001); in the present volume, *Gemella* has been classified in Family X. *Incertae Sedis*.

The genera *Staphylococcus* and *Macrococcus* are monophyletic and well separated from each other with intergeneric 16S rRNA sequence similarities of 93.4–95.3%. The intrageneric similarities are significantly higher with at least 96.5% for staphylococci and 97.7% for macrococci. A phylogenetic tree based on comparative sequence analysis of the 16S rRNA genes of the type strains of the seven macrococcal species is depicted in Figure 73.

The phylogenetic relationships of staphylococci and four of the seven macrococcal species were also inferred from comparative sequence analysis of the highly conserved gene encoding the heat-shock protein (Hsp60) (Kwok and Chow, 2003). The four macrococcal species (*Macrococcus bovicus*, *Macrococcus carouselicus*, *Macrococcus caseolyticus*, and *Macrococcus equiperficus*) are clearly separated from the staphylococcal species, but are closely related (especially *Macrococcus caseolyticus*) to the *Staphylococcus sciuri* species group, the only staphylococci

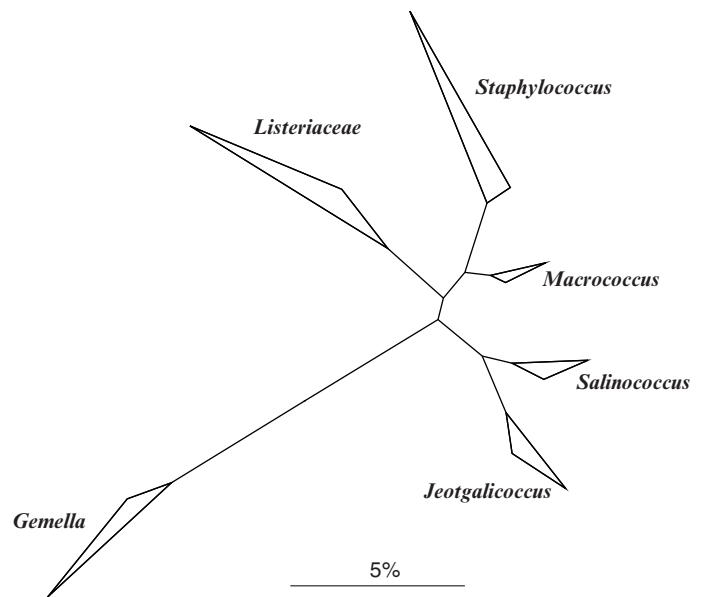

FIGURE 72. 16S rRNA tree reflecting the phylogenetic relationships of the genus *Macrococcus* and selected representatives of the phylum *Firmicutes*. The tree topology was reconstructed by applying the ARB-parsimony tool (Ludwig et al., 2004) upon an ARB 16SrRNA database (<http://www.arb-home.de>) comprising 28,980 almost complete sequences. The tree topology was corrected according to the data obtained by applying distance and maximum-likelihood methods. Only sequence positions which shared identical nucleotides in at least 50% of all compared sequences from representatives of the *Staphylococcaceae* were used to construct the tree. Length bar indicates 5% estimated sequence divergence.

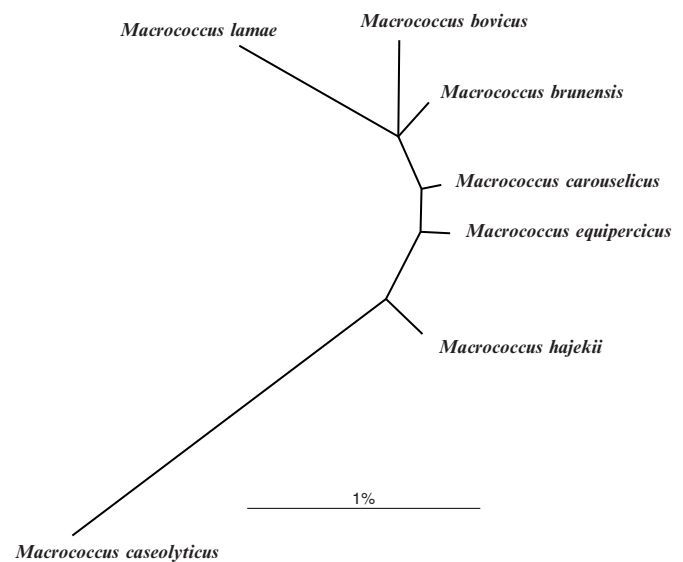

FIGURE 73. 16S rRNA based tree reflecting the relationships of the type strains of the *Macrococcus* species. The tree topology was reconstructed as described in the legend of Figure 72. The length bar indicates 1% estimated sequence divergence.

that are oxidase-positive. Pairwise sequence identity scores based on partial *hsp60* gene sequences among the four macrococcal species ranged from 82–87%, while those among the 40 staphylococcal species and subspecies ranged from 74–98% (Kwok and Chow, 2003). Thus, *hsp60* sequences appear to be more discriminatory than 16S rRNA gene sequences for differentiating macrococcal and staphylococcal species.

Based on DNA–DNA hybridization studies, the species *Macrococcus equiperficus*, *Macrococcus bovicus*, and *Macrococcus carouzelicus* are more closely related to one another than to *Macrococcus caseolyticus* (Kloos et al., 1998a). Both DNA–DNA hybridization studies and 16S rRNA sequence analysis indicate a closer relationship of the genus *Macrococcus* to the *Staphylococcus sciuri* species group than to other staphylococcal species.

In particular, *Macrococcus caseolyticus* is more closely related to staphylococci than the other macrococci. This agrees well with the significantly lower DNA G+C content (38–39 mol%) of *Macrococcus caseolyticus* that is shared by several of the staphylococcal species.

Acknowledgements

I thank Wolfgang Ludwig for reconstructing the 16S rDNA tree.

Differentiation of the species of the genus *Macrococcus*

Differential characteristics of the species of the genus *Macrococcus* are compiled in Table 76. Identification of macrococci at the species level on the basis of phenotypic tests alone is unreliable; molecular methods have to be applied.

List of species of the genus *Macrococcus*

1. ***Macrococcus equiperficus*** Kloos, Ballard, George, Webster, Hubner, Ludwig, Schleifer, Fiedler and Schubert 1998a, 873^{VP}

e. qui. per'ci. cus. L. gen. n. *equi* of horse; N.L. adj. *equiperficus* pertaining to a horse named Percy, from which this species was first isolated.

Surface colonies about 6 mm in diameter. Convex, entire, butyrous, dull to slightly glistening, and opaque. Light to medium orange. No or only weak anaerobic growth. Optimum growth temperature is 35°C. No hemolysis. No production of acetylmethylcarbinol (acetoin). Acid produced from D-fructose and, with the exception of one strain out of 22 strains, from D-mannitol. No acid produc-

tion from lactose and, with the exception of one strain, from D-ribose.

DNA G+C content (mol%): 45 (T_m).

Type strain: DD 9350, Kloos H8h3, ATCC 51831, CCUG 38363, CIP 105716.

EMBL accession number (16S rRNA gene): Y15712.

Additional remarks: Type strain was isolated from the skin of an Irish thoroughbred horse. This species has a preference for horses and ponies and is commonly found as large populations on the skin of these mammals.

2. ***Macrococcus bovicus*** Kloos, Ballard, George, Webster, Hubner, Ludwig, Schleifer, Fiedler and Schubert 1998a, 874^{VP}

bovic'us. Gr. n. *bou* cow; L. gen. n. *bovis* of a cow; N.L. adj. *bovicus* pertaining to a bovine or cow, from which organism was first isolated.

Surface colonies about 4 mm in diameter. Slightly convex, entire, butyrous, glistening, and opaque. Pale yellow to medium orange. No anaerobic growth. Optimum growth temperature is 35°C. No cell-wall teichoic acid. Partial hemolysis (greening) of horse and bovine blood. No production of acetoin. Acid produced from glycerol, D-mannitol, and D-fructose. No acid production from lactose.

DNA G+C content (mol%): 42–44 (T_m).

Type strain: Kloos C2F4, DD 4516, ATCC 51825, CCUG 38365, CIP 105714.

EMBL accession number (16S rRNA gene): Y15714.

Additional remarks: Type strain was isolated from the skin of a Holstein cow. This species appears to have a preference for cattle, horses, and ponies.

3. **Macrocooccus brunensis** Mannerová, Pantú ek, Doška, Švec, Snauwaert, Vancanneyt, Swings and Sedlá ek 2003, 1652^{VP} bru.nen'sis. L. adj. *brunensis* from *Bruna*, the Roman name of the city of Brno, Czech Republic, where the type strain was isolated.

Surface colonies 2–4 mm in diameter. Circular, smooth, and glossy. No pigment produced. Facultatively anaerobic growth. Growth in 4% NaCl. No growth at 4 or 42°C. Hydrolysis of casein and gelatin, but not Tween 80, starch, lecithin, esculin, or tyrosine. No production of acetoin. No hemolysis. No activities of urease, hemolysis, arginine dihydrolase, arginine arylamidase, esterase, lipase, naphthol-AS-BI-phosphohydrolase, valine arylamidase, cystine arylamidase, α -galactosidase, *N*-acetyl- β -glucosaminidase, α -mannosidase, and α -fucosidase. Acid produced from maltose, D-mannitol, D-fructose, D-trehalose, and D-glucose. No acid production from sucrose, D-galactose, lactose, D-ribose, D-melibiose, or *N*-acetylglucosamine.

DNA G+C content (mol%): 41–42 (HPLC).

Type strain: CCM 4811, LMG 21712.

GenBank accession number (16S rRNA gene): AY119686.

Additional remarks: Type strain was isolated from llama skin.

4. **Macrocooccus carouselicus** Kloos, Ballard, George, Webster, Hubner, Ludwig, Schleifer, Fiedler and Schubert 1998a, 874^{VP} car.ou.sel'i.cus. N.L. adj. *carouselicus* pertaining to carousel or merry-go-round, which has carousel horses.

Surface colonies 5–7 mm in diameter. Slightly convex, entire, butyrous, glistening, and opaque. Cream to light orange pigmentation. No anaerobic growth. Optimum growth at 35°C. No hemolysis and no cell-wall teichoic acid. No acetoin production. All strains are susceptible to lyso-staphin and oxacillin. Weak acid production from D-fructose. No acid production from maltose, D-ribose, or lactose.

DNA G+C content (mol%): 41 (T_m).

Type strain: DD 9348, Kloos H8b16, ATCC 51828, CCUG 38360, CIP 105711.

EMBL accession number (16S rRNA gene): Y15713.

Additional remarks: Type strain was isolated from the skin of an Irish thoroughbred horse. This species has a prefer-

ence for horses and is commonly found as large populations on the skin of these mammals.

5. **Macrocooccus caseolyticus** Kloos, Ballard, George, Webster, Hubner, Ludwig, Schleifer, Fiedler and Schubert 1998a, 871^{VP}

ca.se.o.ly'ti.cus. L. n. *caseus* cheese; Gr. adj. *lutikos* able to loose; N.L. adj. *caseolyticus* casein-dissolving.

Surface colonies 3–7 mm. Slightly convex, entire, butyrous, glistening, and opaque. Unpigmented or pale yellow. No or weak anaerobic growth. Growth in 10% NaCl. Optimum growth at 35°C. Low amounts of atypical cell-wall teichoic acid: poly(*N*-acetylglucosaminylphosphate) or poly(*N*-acetylgalactosaminylphosphate). Most strains, except the type strain, produced partial hemolysis (greening) of horse blood. Produce acetoin. No urease and β -glucosidase activities. Acid production from maltose, D-fructose, D-trehalose, and D-glucose. No acid production from D-mannitol.

DNA G+C content (mol%): 38–39 (T_m).

Type strain: DD 4508, ATCC 13548, CCUG 15606, CIP 100755, DSM 20597.

EMBL accession number (16S rRNA gene): Y15711.

Additional remarks: Type strain was isolated from cow's milk, which was previously designated the type strain of *Staphylococcus caseolyticus* (Schleifer et al., 1982). This relatively uncommon species appears to have a preference for cattle, sheep, goats, and whales and may be found in their milk and meat products.

6. **Macrocooccus hajekii** Mannerová, Pantú ek, Doška, Švec, Snauwaert, Vancanneyt, Swings and Sedlá ek 2003, 1653^{VP} ha.je'ki.i. N.L. gen. n. *hajekii* of Hajek, named after Vaclav Hajek, a Czech microbial taxonomist.

Surface colonies 2–3 mm in diameter. Circular, smooth, and glossy, without pigment. No growth at 4 or 42°C or in 4% NaCl. Hydrolysis of casein and gelatin. No hydrolysis of Tween 80, starch, lecithin, esculin, and tyrosine. No acetoin production. No activities of urease, hemolysis, arginine dihydrolase, arginine arylamidase, esterase, lipase, naphthol-AS-BI-phosphohydrolase, valine arylamidase, cystine arylamidase, α -galactosidase, *N*-acetyl- β -glucosaminidase, α -mannosidase, α -fucosidase, or acid phosphatase. Acid production from sucrose, maltose, D-mannitol, D-fructose, D-trehalose, and D-glucose. No acid production from xylitol, D-galactose, lactose, D-ribose, D-melibiose, *N*-acetylglucosamine, or methyl α -D-glucoside.

DNA G+C content (mol%): 40 (HPLC).

Type strain: CCM 4809, LMG 21711.

GenBank accession number (16S rRNA gene): AY119685.

Additional remarks: Type strain was isolated from llama skin.

7. **Macrocooccus lamae** Mannerová, Pantú ek, Doška, Švec, Snauwaert, Vancanneyt, Swings and Sedlá ek 2003, 1653^{VP} la'mae. N.L. fem. gen. n. *lamae* of *Lama*, the zoological genus name of llama.

Surface colonies 2–5 mm in diameter. Circular, smooth, and glossy. Orange pigment. No growth at 4 and 42°C and in 4% NaCl. Hydrolysis of casein and gelatin, but not Tween 80, starch, lecithin, esculin, or tyrosine.

No acetoin production. No activities of urease, hemolysis, arginine dihydrolase, arginine arylamidase, esterase, lipase, naphthol-AS-BI-phosphohydrolase, valine arylamidase, cystine arylamidase, α -galactosidase, *N*-acetyl- β -glucosaminidase, α -mannosidase, or α -fucosidase. Acid production from sucrose, maltose, *D*-mannitol, *D*-fructose, *D*-trehalose, and *D*-glucose. No acid production

from xylitol, *D*-galactose, lactose, ribose, *D*-melibiose, *N*-acetylglucosamine, or methyl α -*D*-glucoside. Susceptible to novobiocin.

DNA G+C content (mol %): 41–42 (HPLC).

Type strain: CCM 4815, LMG 21713.

GenBank accession number (16S rRNA gene): AY119687.

Additional remarks: Type strain was isolated from llama skin.

Genus IV. **Salinicoccus** Ventosa, Márquez, Ruiz-Berraquero and Kocur 1990b, 320^{VP}
(Effective publication: Ventosa, Márquez, Ruiz-Berraquero and Kocur 1990a, 32.)

ANTONIO VENTOSA

Sa.li.ni.coc'cus. L. adj. *salinus* saline; Gr. n. *kokkos* a grain or berry; N.L. masc. n. *Salinicoccus* saline coccus.

Gram-stain-positive spherical cells, 0.5–2.5 μm in diameter, occurring singly, in pairs, tetrads, or clumps. **Nonmotile, non-spore-forming.** Colonies are round, smooth, and form **pink-red or orange, nondiffusible pigments. Strictly aerobic.** Catalase- and oxidase-positive. **Moderately halophilic.** Optimal NaCl concentration for growth is 4–10%; growth occurs in media with 0–25% NaCl. Temperature range for growth is 4–49°C; optimal temperature is 30–37°C. pH range for growth is 6–11.5; optimal pH is 7–9.5. **The predominant lipoquinone is MK-6. The cell wall contains murein of the L-Lys–Gly₅ type,** which corresponds to the A3 α type according to Schleifer and Kandler (1972).

DNA G+C content (mol %): 45.6–51.2.

Type species: **Salinicoccus roseus** Ventosa, Márquez, Ruiz-Berraquero and Kocur 1990b, 320^{VP} (Effective publication: Ventosa, Márquez, Ruiz-Berraquero and Kocur 1990a, 32.).

Further descriptive information

The polar lipids of *Salinicoccus* are phosphatidylglycerol, diphosphatidylglycerol, and a glycolipid of unknown structure (Ventosa et al., 1990a; Ventosa et al., 1993). Sprott et al. (2006) reported that a major lipid in *Salinicoccus hispanicus* is the sulfonolipid sulfoquinovosyl diacylglycerol. They observed that the ratio of sulfonolipid to phospholipid is dependent on the salinity of the growth media, when grown in media with low phosphate content. The fatty acid composition of species of *Salinicoccus* includes the presence of predominantly straight and branched-chain fatty acids (Aslam et al., 2007; Ventosa et al., 1990a; Ventosa et al., 1993; Zhang et al., 2002; Zhang et al., 2007).

In order to grow over a wide range of salt concentrations, moderately halophilic micro-organisms accumulate organic osmotic solutes (Ventosa et al., 1998). In *Salinicoccus roseus* and *Salinicoccus hispanicus* the main organic osmotic solute is proline (Ventosa et al., 1998). When grown in complex media, they accumulate glycine betaine from the medium (Ventosa et al., 1998).

The susceptibility pattern of *Salinicoccus roseus* to 16 antimicrobial compounds has been reported and shows a remarkable resistance to ampicillin, cephalotin, erythromycin, gentamicin, novobiocin, and penicillin G (Nieto et al., 1993). It must be considered that the salt concentration may influence the susceptibility of moderately halophilic bacteria to antimicrobial compounds (Coronado et al., 1995).

In general, the species of the genus *Salinicoccus* do not produce extracellular hydrolytic enzymes. In a screening focused

on the isolation from several hypersaline environments of moderately halophilic strains with hydrolytic activities, two *Salinicoccus* strains able to produce a protease and a lipase, respectively, have been reported (Sanchez-Porro et al., 2003).

Enrichment and isolation procedures

Organisms of the genus *Salinicoccus* have been isolated from water of salterns and saline soils, from soda lakes, and from salted materials. Specific enrichment or isolation media have not been described. They grow well in complex culture media supplemented with a mixture of salts. For the species that grow at neutral pH values the medium described by Ventosa et al. (1983) can be used. The alkaliphilic species requires a pH of 9.0–9.5 and can be grown by using the medium described by Zhang et al. (2002). They can be grown aerobically at 32–37°C. Typically, colonies of strains of *Salinicoccus* can be differentiated in these media by their pink to red or orange pigmentation, since most moderately halophilic species are cream, white, yellow, or nonpigmented.

Maintenance procedures

Strains belonging to *Salinicoccus* can be maintained by the standard procedures such as freeze-drying, storage at –80°C or under liquid nitrogen. Slant cultures can be conserved for several months at room temperature using a medium with 10% salts, at pH 7.5 or 9.0 (for the alkaliphilic species). Nutrient agar plus a mixture of salts can be used. For species that grow at neutral pH the MH medium has been described. The composition of this medium is (in g/l): MgCl_2 , 81.0; MgSO_4 , 9.6; CaCl_2 , 0.36; KCl , 2.0; NaHCO_3 , 0.06; NaBr , 0.026; proteose-peptone no. 3 (Difco), 5.0; yeast extract (Difco), 10.0; glucose, 1.0; Bacto-agar (Difco), 20.0 (Ventosa et al., 1982; Ventosa et al., 1983). For haloalkaliphilic species the following medium can be used (in g/l): NaCl , 100; Na_2CO_3 , 10; K_2HPO_4 , 1; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.2; glucose, 10; polypeptide, 5; yeast extract, 5; agar, 20 (Zhang et al., 2002).

Differentiation of the genus *Salinicoccus* from other genera

The genus *Salinicoccus* can be differentiated from other Gram-stain-positive cocci by comparative analysis of the 16S rRNA sequence as well as by several phenotypic and chemotaxonomic features. In contrast to the members of the genus *Marinococcus* that are also moderately halophilic, the species of *Salinicoccus* are nonmotile. *Salinicoccus* has MK-6 as the characteristic predominant menaquinone system in contrast to other Gram-

stain-positive cocci such as *Marinococcus* (Hao et al., 1984) and *Jeotgalicoccus* (Yoon et al., 2003) that have MK-7, and *Nesterenkonia* that has MK-6, MK-7, and MK-8 (Stackebrandt et al., 1995). Another differential and characteristic feature of the species of *Salinicoccus* is that their cell walls contain murein of the L-Lys-Gly₅ type in contrast to that found in *Marinococcus*, showing peptidoglycan of the meso-diaminopimelic acid type (Hao et al., 1984), in *Nesterenkonia*, that has murein of L-Lys-Gly-L-Glu type (Mota et al., 1997; Stackebrandt et al., 1995), and the peptidoglycan of *Jeotgalicoccus*, based on L-Lys-Gly₃₋₄-L-Ala(Gly) (Yoon et al., 2003). Finally, another differential feature is the DNA base composition. The G + C range for *Salinicoccus* is 45.6–51.2 mol%, while for *Marinococcus* it is 44.9–46.4 mol% (Hao et al., 1984), for *Nesterenkonia* it is 70.0–72.0 mol% (Mota et al., 1997; Stackebrandt et al., 1995), and for *Jeotgalicoccus* it is 42 mol% (Yoon et al., 2003).

Taxonomic comments

The genus *Salinicoccus* was proposed on the basis of a single Gram-stain-positive, moderately halophilic, non-

motile coccus, that was proposed as the new species *Salinicoccus roseus* (Ventosa et al., 1990a). Lately, two culture collection strains, CCM 168 and CCM 1405, previously assigned to the genus *Micrococcus* were also shown to be members of this species (Ventosa et al., 1993). In a study based on chemotaxonomic features, Ventosa et al. (1992) showed that the moderately halophilic bacterium *Marinococcus hispanicus* was also a species of the genus *Salinicoccus*, *Salinicoccus hispanicus*. Laterly, Zhang et al. (2002) described a new species of the genus *Salinicoccus*, *Salinicoccus alkaliphilus*, an alkaliphilic and moderately halophilic coccus isolated from a soda lake. More recently, three new species have been proposed and several new isolates will probably represent new species of this genus. Phylogenetically, members of the genus *Salinicoccus* constitute a monophyletic branch within the *Firmicutes*.

Differentiation of the species of the genus *Salinicoccus*

Some differential features of the species of the genus *Salinicoccus* are given in Table 77.

List of species of the genus *Salinicoccus*

- 1. *Salinicoccus roseus*** Ventosa, Márquez, Ruiz-Berraquero and Kocur 1990b, 320^{VP} (Effective publication: Ventosa, Márquez, Ruiz-Berraquero and Kocur 1990a, 32.)

ro'se.us. L. adj. *roseus* rose-colored.

See the generic description for many features.

Spherical cells, 1.0–2.5 µm in diameter, occurring singly, in pairs, tetrads, or clumps. Nonmotile, nonspore-forming. Colonies are round, smooth, and form a pink-red, nondiffusible pigment. In liquid medium the cultures are slightly turbid and form a viscous sediment.

Moderately halophilic. Growth occurs in media containing 0.9–25 % NaCl. Optimal growth at 10% NaCl. No growth in the absence of NaCl. Growth at 15–40°C and pH 6–9; optimal growth at 37°C and pH 8.0.

Acid is not produced from arabinose, fructose, D-galactose, D-glucose, glycerol, lactose, maltose, D-mannitol, sucrose, D-trehalose, and D-xylose. Nitrate is reduced to nitrite. Esculin is not hydrolyzed. Benzidine test is positive. The following tests are negative: urease, Simmons' citrate, arginine, lysine, ornithine decarboxylases, methyl red, Voges-Proskauer, indole, egg-yolk, β-galactosidase, H₂S production, and phenylalanine deaminase.

The following compounds are utilized as sole carbon and energy sources: D-gluconolactone, D-glucosamine, D-melibiose, sucrose, D-trahalose, erythritol, ethanol, *m*-inositol, propanol, D-sorbitol, *N*-acetylglucosamine, aconitate, α-aminobutyrate, benzoate, butyrate, citrate, fumarate, DL-glycerate, D-gluconate, hippurate, DL-malate, propionate, quinate, and D-tartrate. The following compounds are not utilized as sole carbon and energy sources: starch, D-amygdalin, L-arabinose, D-cellobiose, esculin, D-fructose, D-fucose, D-galactose, D-glucose, inulin, lactose, maltose, D-mannose, L-raffinose, L-rhamnose, ribose, salicin, D-xylose, adonitol, dulcitol, DL-glycerol, D-mannitol, acetate, caprylate, glucuronate, *p*-hydroxybenzoate, malonate, oxalate, pyruvate, saccharate, salicylate, suberate, succinate, L-aspartic acid, betaine, creatine, and ethionine.

The following compounds are utilized as sole carbon, nitrogen, and energy sources: L-alanine, allantoin, DL-arginine, L-asparagine, phenylalanine, glycine, L-glutamine, L-histidine, L-isoleucine, L-leucine, and L-proline. The following compounds are not utilized as sole carbon, nitrogen, and energy sources: L-glutamic acid, L-lysine, methionine, L-ornithine, L-serine, threonine, L-tryptophan, and L-valine.

Isolated from a marine saltern in Spain, salted meat, and salted horse hide.

DNA G+C content (mol%): 51.2 (*T_m*).

Type strain: 9, ATCC 49258, CCM 3516, CIP 104761, DSM 5351.

GenBank accession number (16S rRNA gene): X94559.

- 2. *Salinicoccus alkaliphilus*** Zhang, Xue, Ma, Zhou, Ventosa and Grant 2002, 792^{VP}

al.ka.li'phi.us. N.L. n. *alkali* alkali; Gr. adj. *philos* loving; N.L. masc. adj. *alkaliphilus* liking alkaline media.

See the generic description for many features.

Cells are cocci, 0.5–0.8 µm in diameter, occurring singly, in pairs, tetrads, or clumps. Nonmotile, nonspore-forming. Colonies are round, smooth, and slightly convex with pinkish color and nondiffusible pigment.

Alkaliphilic and moderately halophilic. Growth occurs at pH 6.5–11.5; optimal growth at pH 9.5. Growth occurs in media containing 0–25 % NaCl. Optimal growth at 10 % NaCl. Growth at 10–49°C; optimal growth at 32°C.

Acid is produced from D-glucose but not from maltose, galactose, fructose, sucrose, D-arabinose, glycerol, or D-xylose. Nitrate is reduced. Urease-positive. Esculin is hydrolyzed, but casein, starch, gelatin, and Tween 80, 60 and 20 are not. The following tests are negative: methyl red, Voges-Proskauer, indole, and H₂S production.

The following compounds are utilized as sole carbon and energy sources: D-arabinose, D-melibiose, creatinine, esculin, lactose, D-xylose, D-fructose, amylose, sorbose, D-α-melzitose,

erythritol, inulin, *meso*-erythritol, trehalose, D-mannose, D-sorbitol, stachyose, ribose, mannitol, D-galactose, adonitol, D-cellobiose, glycogen, dulcitol, and α-L-rhamnose.

The following compounds are utilized as sole nitrogen and energy sources: polypeptone, yeast extract, DL-tryptophan, bacto-peptone, casitone, urea, L-proline, L-methionine, L-serine, L-arginine, L-alanine, L-threonine, L-histidine, sodium L-glutamate, L-ornithine, L-leucine, L-glycine, L-glutamic acid, and DL-lysine. The following compounds are not utilized as sole nitrogen and energy sources: L-asparagine, L-tyrosine, L-isoleucine, and L-cysteine.

Isolated from Baer Soda Lake in Inner Mongolia Autonomous Region, China.

DNA G+C content (mol%): 49.6 (T_m).

Type strain: T8, AS 1.2691, JCM 11311.

GenBank accession number (16S rRNA gene): AF275710.

3. *Salinicoccus hispanicus* (Márquez, Ventosa and Ruiz-Berraquero 1990) Ventosa, Márquez, Weiss and Tindall 1993, 398^{vp} (Effective publication: Ventosa, Márquez, Weiss and Tindall 1992, 533) (*Marinococcus hispanicus* Márquez, Ventosa and Ruiz-Berraquero 1990, 167.)

his.pa'ni.cus. L. adj. *hispanicus* Spanish.

See the generic description for many features.

Spherical cells, 1.0–2.0 µm in diameter, occurring singly, in pairs, tetrads, or clumps. Nonmotile, nonspore-forming. Colonies are round and smooth and form a reddish orange, nondiffusible pigment. Broth cultures are uniformly turbid.

Moderately halophilic. Growth occurs in media containing 0.5–25 % NaCl. Optimal growth at 10% NaCl. No growth in the absence of NaCl. Growth at 15–37°C and pH 5–9; optimal growth at 37°C and pH 7.5.

Acid is produced from fructose, galactose, glycerol, D-glucose, and D-mannitol, but not from arabinose, lactose, D-trehalose, and xylose. Nitrate is reduced to nitrite. Gelatin, esculin, and DNA are hydrolyzed. Casein, starch, Tween 80, and tyrosine are not hydrolyzed. Methyl red test positive. The following tests are negative: Simmons' citrate, arginine, lysine and ornithine decarboxylase, Voges–Proskauer, indole, H₂S production, and phenylalanine deaminase.

The following compounds are utilized as sole carbon and energy sources: D-glucose, D-mannose, L-raffinose, L-rham-

nose, ribose, salicin, and sucrose. The following compounds are not utilized as sole carbon and energy sources: amygdalin, D-cellobiose, D-fructose, D-fucose, D-galactose, D-galactosamine, lactose, maltose, D-trehalose, D-xylose, adonitol, dulcitol, erythritol, ethanol, propanol, D-sorbitol, *N*-acetylglucosamine, DL- α -aminobutyrate, δ -aminovalerate, benzoate, butyrate, caprylate, lactate, DL-malate, oxalate, propionate, quinate, D-saccharate, succinate, and D-tartrate.

L-Glutamine is utilized as sole source of carbon, nitrogen, and energy. The following compounds are not utilized as sole carbon, nitrogen, and energy sources: L-allantoin, DL-arginine, L-asparagine, aspartic acid, betaine, creatine, ethionine, phenylalanine, glycine, glutamic acid, L-histidine, L-leucine, DL-lysine, L-ornithine, putrescine, sarcosine, L-serine, L-threonine, and L-valine.

Isolated from salterns and saline soils.

DNA G+C content (mol%): 45.7 (T_m).

Type strain: J-82, ATCC 49259, CCG 43288, CIP 104760, CCM 4148, DSM 5352.

GenBank accession number (16S rRNA gene): AY028927.

Additional Remarks: Mol% G + C ranges from 45.6 to 49.3 (T_m) for various strains.

4. **Salinicoccus luteus** Zhang, Yu, Liu, Zhang, Xu and Li 2007, 1903^{VP}

lu.te'us. L. masc. adj. *luteus* orange-colored.

See the generic description for many features.

Cells are nonmotile, nonspore-forming cocci, 0.9 μ m in diameter. Colonies are circular, opaque and approximately 1.0 mm in diameter after 48 h at 30°C, with orange pigmentation.

Moderately halophilic. Growth occurs at pH 7.0–11.0; optimal growth at pH 8.0–9.0. Growth occurs in media containing 1–25 % NaCl. Optimal growth at 10 % NaCl. Growth at 4–45°C; optimal growth at 30°C.

Acid is produced from D-glucose, maltose, sucrose, malonate and *N*-acetylglucosamine. Nitrate is reduced. Ornithine and arginine decarboxylases, arginine dihydrolase and β -glucosidase-positive. Tween 20 is hydrolyzed, but casein, starch, gelatin, and Tween 80 are not. The following tests are negative: methyl red, Voges–Proskauer, H₂S and melanin production, *N*-acetylglucosaminidase, β -glucuronidase, β -galactosidase and α -galactosidase.

The following compounds are utilized as sole carbon and energy sources: maltose, mannitol, glucose, adonitol, arabinose, arabinol, mannose, inositol, sorbitol, fructose, cellobiose, salicin, acetamide, galactose, xylose and dextrin. Rhamnose and starch are not utilized.

Isolated from a desert soil sample from Egypt.

DNA G+C content (mol%): 49.7 (HPLC).

Type strain: YIM 70202, CGMCC 1.6511, KCTC 3941.

GenBank accession number (16S rRNA gene): DQ352839.

5. **Salinicoccus jeotgali** Aslam, Lim, Im, Yasir, Chung and Lee 2007, 637^{VP}

je.ot.ga'li. N.L. gen. n. *jeotgali* of jeotgal, a traditional Korean fermented seafood, from which the type strain was isolated.

See the generic description for many features.

Cells are nonmotile, nonspore-forming cocci, 1.0–2.0 μ m in diameter. Colonies are smooth, circular, orange-colored with transparent edges and 1–2 mm in diameter.

Moderately halophilic. Growth occurs at pH 6.5–11.0; optimal growth at pH 7.0. Growth occurs in media containing 0.5–15 % NaCl. Optimal growth at 5 % NaCl. Growth at 20–30°C; optimal growth at 30°C.

Acid is produced from D-glucose, D-fructose, D-maltose, D-trehalose, *N*-acetyl-D-glucosamine and glycerol but not from D-mannitol, sucrose, D-arabinose, L-arabinose, D-ribose, D-xylose, L-xylose, D-adonitol, D-galactose, D-mannose, L-sorbose, L-rhamnose, D-sorbitol, D-cellobiose, D-lactose, D-melibiose, D-melezitose, D-raffinose, D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, erythritol, methyl β -D-xylopyranoside, dulcitol, inositol, methyl α -D-mannopyranoside, methyl α -D-glucopyranoside, amygdalin, arbutin, salicin, inulin, starch, glycogen, xylitol, gentiobiose, potassium gluconate, potassium 2-ketogluconate or potassium 5-ketogluconate. Nitrate is reduced to nitrite, but not to nitrogen gas. Indole and H₂S are produced. Esculin is hydrolyzed, but casein, gelatin, and DNA are not. The following tests are negative: urease, Voges–Proskauer, arginine dihydrolase, lysine and ornithine decarboxylase, and β -glucosidase.

The following compounds are utilized as sole carbon and energy sources: salicin, L-arabinose, D-glucose, citrate, histidine, L-rhamnose, *N*-acetyl-D-glucosamine, D-maltose, D-lactate, L-alanine and 5-ketogluconate. The following compounds are not utilized as sole carbon and energy sources: mannitol, D-melibiose, L-fucose, D-sorbitol, propionate, caprylate, valerate, 2-ketogluconate, 3-hydroxybutyrate, L-proline, D-ribose, inositol, D-sucrose, itaconate, suberate, malonate, acetate, glycogen, 3-hydroxybenzoate, 4-hydroxybenzoate and L-serine.

Isolated from jeotgal, a traditional Korean fermented seafood.

DNA G+C content (mol%): 47.0 (HPLC).

Type strain: S2R53-5, KCTC 13030, LMG 23640.

GenBank accession number (16S rRNA gene): DQ471329.

6. **Salinicoccus salsiraiiae** França, Rainey, Nobre and da Costa 2007, 433^{VP} (Effective publication: França, Rainey, Nobre and da Costa 2006, 535.)

sal.si.ra'i.a.e. L. adj. *salsus* salted; L. n. *raia* a ray; N.L. gen. n. *salsiraiiae* of a salted ray.

See the generic description for many features.

Spherical cells, 1.0–2.5 μ m in diameter, occurring singly, in pairs, tetrads, or clumps. Nonmotile, nonspore-forming. Colonies form a pink-red pigment.

Moderately halophilic. Growth occurs in media containing 0–22 % NaCl. Optimal growth at 4% NaCl. Growth at 20–45°C and pH 6.5–9.5; optimal growth at 37°C and pH 8.0.

Acid is produced from D-ribose, glycerol, D-glucose, D-fructose, *N*-acetylglucosamine, D-maltose, D-trehalose, 2-ketogluconate, and 5-ketogluconate. Nitrate is reduced to nitrite. Gelatin, casein, arbutin, hippurate, hide powder azure and DNA are hydrolyzed. Starch, elastin, fibrin, and esculin are not hydrolyzed. Methyl red, Voges–Proskauer and indole production are negative.

Isolated from a salted ray (skate).

DNA G+C content (mol%): 46.2 (HPLC).

Type strain: RH1, LMG 22840, CIP 108576.

GenBank accession number (16S rRNA gene): DQ333949.

Family IX. **Thermoactinomycetaceae** Matsuo, Katsuta, Matsuda, Shizuri,
Yokota and Kasai 2006, 2840^{VP}

MICHAEL GOODFELLOW AND AMANDA L. JONES

Ther'mo.ac.ti.no.my.ce.ta'ce.ae. N.L. masc. n. *Thermoactinomyces* type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Thermoactinomycetaceae* the *Thermoactinomyces* family.

Aerobic, Gram-stain-positive, chemo-organotroph. **Substrate mycelium well-developed, branched, and septate.** Usually forms an abundant white or yellow aerial mycelium. **Spores formed singly on aerial and substrate hyphae, sessile or on simple or branched sporophores with the structure and properties of bacterial endospores. Mesophilic or thermophilic. Wall peptidoglycan contains meso-diaminopimelic acid but no characteristic sugars.** Major menaquinones unsaturated with seven or nine isoprene units. Rich in straight-chain and iso- and anteiso-fatty acids. Members of the family have been isolated from air, humidifier and air conditioning units, soils, muds, marine sediments, moldy and decaying plant materials, and composts, often with spontaneous heating.

DNA G+C content (mol%): 40.0–60.3.

Type genus: **Thermoactinomyces** Tsiklinsky 1899, 501 emend. Yoon, Kim, Shin and Park 2005, 398.

Further descriptive information

Phylogeny. The classification of thermoactinomycetes has undergone significant changes since the First Edition of *Bergey's Manual of Systematic Bacteriology* where they were assigned to the genus *Thermoactinomyces* (Lacey and Cross, 1989), a taxon which mainly encompassed thermophilic organisms. The genus *Thermoactinomyces* and its type species, *Thermoactinomyces vulgaris*, were described by Tsiklinsky in 1899. Subsequently, additional *Thermoactinomyces* species were proposed, including *Thermoactinomyces peptonophilus* Nonomura and Ohara 1971, *Thermoactinomyces sacchari* Lacey (1971a), *Thermoactinomyces candidus* Kurup et al. 1975, *Thermoactinomyces intermedius* Kurup et al. 1980, *Thermoactinomyces thalpophilus* Unsworth and Cross (1980), and *Thermoactinomyces putidus* Lacey and Cross 1989. In addition, *Thermoactinomyces dichotomicus* was proposed by Cross and Goodfellow (1973) for organisms previously classified as “*Actinobifida dichotomica*” by Krasil'nikov and Agre (1964). It was recognized that members of the species were closely related though the standing of some of the species was questioned (Lacey and Cross, 1989).

More recently, *Thermoactinomyces candidus* and *Thermoactinomyces thalpophilus* were reclassified as synonyms of *Thermoactinomyces vulgaris* and *Thermoactinomyces sacchari*, respectively, based on DNA–DNA relatedness and 16S rRNA gene sequence data (Yoon et al., 2000). Additional comparative studies on representatives of validly published *Thermoactinomyces* species showed that they belong to four phyletic lines, the taxonomic standings of which were supported by chemotaxonomic and phenotypic data (Yoon et al., 2005). Three new genera were proposed on the basis of these data. *Thermoactinomyces putidus* and *Thermoactinomyces sacchari* were assigned to the genus *Laceyella* as *Laceyella putida* and *Laceyella sacchari*, *Thermoactinomyces peptonophilus* to the genus *Seinonella* as *Seinonella peptonophila*, and *Thermoactinomyces dichotomicus* to the genus *Thermoactinomyces* as *Thermoactinomyces dichotomicus*. The revised genus *Thermoactinomyces* was left as a home for *Thermoactinomyces intermedius* and *Thermoactinomyces vulgaris*.

Similar studies on additional thermoactinomycetes led to proposals for the recognition of three additional taxa, the genera *Mechercharimycetes* Matsuo et al. 2006, *Planifilum* Hatayama et al. 2005b, and *Shimazuella* Park et al. 2007. The genus *Mechercharimycetes* contains two species, *Mechercharimycetes mesophilus*, the type species, and *Mechercharimycetes asporophorigenens*. The genus *Planifilum* also contains two species, *Planifilum fimeticola*, the type species, and *Planifilum fulgidum*. The genus *Shimazuella* contains a single species, *Shimazuella kribbensis*. Members of the genera *Mechercharimycetes* and *Shimazuella* are mesophiles whereas those assigned to the genus *Planifilum* are thermophiles.

The family *Thermoactinomycetaceae* was proposed by Matsuo et al. (2006) to accommodate the genera *Laceyella*, *Mechercharimycetes*, *Planifilum*, *Seinonella*, *Thermoactinomyces*, and *Thermoactinomyces*. This taxon is one of the families that constitute the order *Bacillales*. The relationships between the constituent genera of the family *Thermoactinomyces* and between them and the type strains of the type species of some of the genera classified in the order *Bacillales* are shown in Figure 74.

General comments. The following sections provide further descriptive information on the properties of species assigned to the genus *Thermoactinomyces sensu lato*, along the lines described in the previous edition of the *Systematics* (Lacey and Cross, 1989). In contrast, nothing is known about the properties of the species classified in the genera *Mechercharimycetes* and *Planifilum* beyond the details published in the original species descriptions. In addition to this unavoidable limitation, the details of the better-known species of the genus *Thermoactinomyces sensu lato* are given under names of the taxa used in the earlier literature though the names in the Figures have been updated. It has been shown that *Thermoactinomyces putidus*, *Thermoactinomyces sacchari*, and *Thermoactinomyces vulgaris* strains share little DNA hybridization with each other (Hirst et al., 1991).

Cell morphology. The substrate mycelium consists of stable, branched, septate hyphae from which aerial hyphae arise. They first arise vertically but, in most species, then form a loose network of almost straight hyphae over the substrate (Locci, 1972). Intercalary growth of the primary substrate mycelium has been reported for *Thermoactinomyces thalpophilus* (Kretschmer, 1984c). Aerial hyphae of *Thermoactinomyces vulgaris* are hydrophobic and may be found within 6.5 h of spore germination (Kretschmer, 1984a). The aerial hyphae may autolyze (within 2–4 d in *Thermoactinomyces vulgaris* or more rapidly in *Thermoactinomyces sacchari*) depositing spores on the agar surface (Küster and Locci, 1963; Lacey, 1971a). Spores are formed singly on both substrate (Figure 75) and aerial mycelium and may be either sessile or on hyphae called sporophores (Figure 76, Figure 77, Figure 78, Figure 79, and Figure 80). In *Thermoactinomyces dichotomicus*, both sporophores and mycelium may be dichotomously branched (Figure 80). The spores are spheroidal, 0.5–1.5 µm in diameter, with a ridged surface that gives an angular appearance by

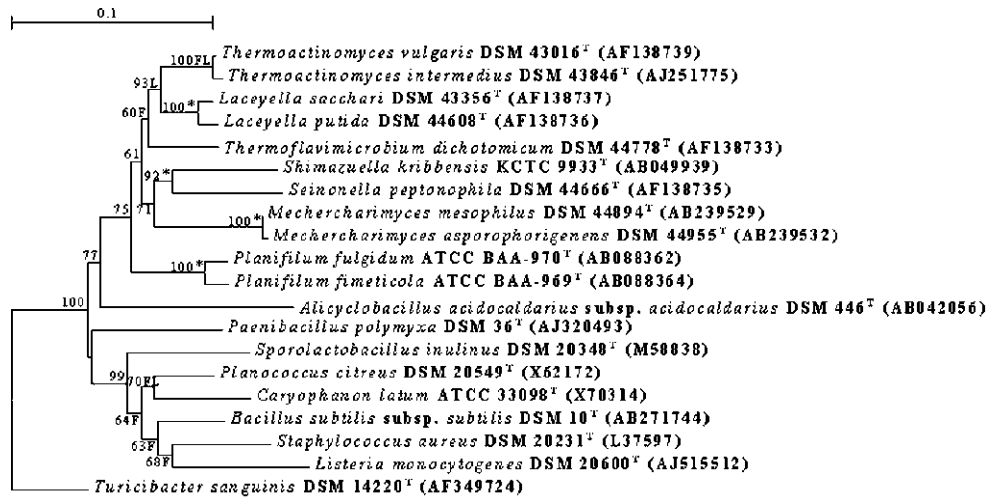

FIGURE 74. Neighbor-joining tree showing the positions of genera and species of the family *Thermoactinomycetaceae* and their relationship to phylogenetically close organisms classified in the order *Bacillales*. The asterisks indicate phyletic lines that were also recovered using the least-squares, maximum-likelihood, and maximum-parsimony tree-making algorithms. When lineages were not recovered in all three algorithms, F, L, and P indicate branches that were recovered using the least-squares, maximum-likelihood and maximum-parsimony methods, respectively. The numbers at the nodes are percentage bootstrap values based on a neighbor-joining analysis of 1000 resampled datasets; only values above 50% are given. The scale bar indicates 0.01 substitutions per nucleotide position.

FIGURE 82. Scanning electron micrograph of spores of *Thermoactinomyces* (*Thermoactinomyces*) *dichotomicus*. Bar = 0.5 µm.

transmission electron microscopy. By scanning electron microscopy, the ridges can be seen to form pentagonal and hexagonal areas on the spore surface. Most species resemble that studied by McVittie et al. (1972) in having approximately 12 pentagonal and 12 hexagonal faces (Figure 81), although *Thermoactinomyces dichotomicus* has only approximately 12 faces in total (Figure 82). The spores are refractile and phase-bright by light microscopy, staining only with endospore stains.

Cell-wall composition. The wall peptidoglycan contains meso-A₂ pm but no diagnostic sugars (wall chemotype III; Becker et al., 1965). Menaquinones are unsaturated, with seven (*Thermoactinomyces dichotomicus*, *Thermoactinomyces sacchari*, and *Thermoactinomyces vulgaris*) or nine (*Thermoactinomyces putidus* and *Thermoactinomyces thalpopophilus*) isoprene units in major amounts (Collins et al., 1982). Organisms contain straight-chain and iso- and anteiso-branched fatty acids, but phospholipids of diagnostic value have not been studied (Goodfellow and Cross, 1984). As with bacterial endospores, spores of *Thermoactinomyces* species contain dipicolinic acid (6.5–7% (w/w) in *Thermoactinomyces vul-*

FIGURE 83. Thin-section of *Laceyella* (*Thermoactinomyces*) *sacchari* endospore. Bar = 0.1 µm. C, core; CO, cortex; IC, inner spore coat; IM, inner forespore membrane; OC, outer spore coat; E, possible exosporium.

garis and *Thermoactinomyces sacchari*, 3.6% in *Thermoactinomyces dichotomicus*, but only 0.6% in *Thermoactinomyces peptonophilus*) (Attwell, 1978; Cross, 1968; Lacey, 1971a). They also contain large amounts of calcium and magnesium ions (Kalakoutsii and Agre, 1973, 1976; Kalakoutsii et al., 1969). The DNA base composition of *Thermoactinomyces* species is similar to that of other endospore-forming bacteria. Values of mol% G+C (T_m) of 52.0 (Fritzsche, 1967), 53.4–54.8 (Craveri and Manachini, 1966), 54.1–54.8 (Craveri et al., 1966b), and 48.7–52.2 (Hirst et al., 1991) have been reported.

Fine structure. In thin section, hyphae of *Thermoactinomyces* species are 0.3–0.6 μm in diameter and bounded by a wall about 22 nm thick, similar to that of other Gram-stain-positive bacteria. The cytoplasm is bounded by a plasma membrane; a typical unit membrane about 10 nm thick that bears tubular vesicular mesosomes 0.1–0.3 μm in diameter. Septa are formed by a single ingrowth of plasma membrane and hyphal wall, often bearing mesosomes (type I; Williams et al., 1973). Nuclear material occurs as an axial filament, and ribosomes, about 12 nm in diameter, are usually present. Such structures have been observed in *Thermoactinomyces peptonophilus*, *Thermoactinomyces sacchari*, and *Thermoactinomyces thalpopophilus* (Attwell, 1978; Cross et al., 1968b; Dorokhova et al., 1968, 1970b, a; Lacey and Vince, 1971), but in *Thermoactinomyces sacchari*, although the cytoplasm is uniformly dense in young cells, it soon becomes coarsely granular and less dense and is then released by lysis of the cells (Lacey and Vince, 1971).

Spore formation follows the same stages of development as with *Bacillus* endospores. The first stage is the formation of a double membrane across the cell forming a spore septum about 18 h after inoculation. The septum lengthens as the area of attachment to the plasma membrane progressively decreases, engulfing cytoplasm and nuclear material from the mother cell. Mesosomes are closely associated with this process. Eventually this membrane closes and breaks away from the plasma membrane to form a forespore, one to a cell, which moves to the hyphal wall and out into a lateral sporangium that is sessile in *Thermoactinomyces thalpopophilus* and terminal on a short sporophore in *Thermoactinomyces sacchari* (Figure 83). A cortex is formed up to 0.17 μm thick, with a dense inner layer, a thick, pale middle layer, and a dark, granular outer layer. The inner spore coat is multilayered, with 6–10 alternating light and dark layers about 27 nm thick forming first in discrete zones. The two-layer outer spore coat consists of an inner, ridged layer 25–70 nm thick surrounded by a dense layer 8 nm thick (Figure 84). After maturity, often no sporangium is recognizable (probably due to lysis), but a thin, dark membrane may surround the spore, perhaps the remains of the sporangium or of an exosporium (Figure 84). The outer coat of the mature spore consists of parallel rows of fibrils, each measuring about 5 nm. Nuclear material is often poorly differentiated from the cytoplasm but may appear irregular, U-shaped, or as separate areas at opposite poles of the spore. Ribosome granules up to 15 nm in diameter are frequent in the cytoplasm, and the middle cortex may show radial striations (Lacey and Vince, 1971; McVittie et al., 1972). Spore development in *Thermoactinomyces dichotomicus* and *Thermoactinomyces peptonophilus* is essentially the same, differing chiefly in the degree of sporophore development and in the possible presence of an exosporium in *Thermoactinomyces dichotomicus* (Attwell, 1978; Cross et al., 1968b; Dorokhova et al., 1970b).

FIGURE 84. Thin-section of *Laceyella* (*Thermoactinomyces*) *dichotomicum* endospore. Bar = 0.4 μm . C, core; CO, cortex; IC, inner spore coat; IM, inner forespore membrane; OC, outer spore coat; E, possible exosporium, SP, sporangial wall.

Spore germination may occur within 3 h of incubation but frequently takes longer. Enhanced CO_2 levels (Kretschmer and Jacob, 1983) and a pH greater than 7.0 are reported to be essential to germination. Optimum pH is 8.0–10.0 (Foerster, 1975). Activation and germination may be stimulated by calcium dipicolinate, L-alanine, L-leucine, L- α -aminobutyric acid, inosine, and adenosine; by heating briefly to 100°C; or by cooling to 20°C. However, heating may also deactivate spores (Agre et al., 1972a, b; Attwell et al., 1972; Foerster, 1975; Kalakoutsii and Agre, 1976; Kirillova et al., 1974). Agre et al. (1972a, 1972b) observed variation in the ability of spores to germinate, identifying in aqueous spore suspensions three types consisting of those germinating without previous activation, those requiring mild activation treatment, and those needing severe activation treatment. Activated spores either had germinated, were activated, or could be deactivated by heating at 80°C. Ability to germinate was decreased by drying. Kokina and Agre (1977b, 1977a) found that cultures degenerated with repeated subculture, resulting in less sporulation and poor spore germination.

On germination, the cortex disappears, the core swells to fill the space, and U-shaped fibrillar areas of nuclear material arise. The core swells to about 2 μm diameter with destruction of the spore coats, although the outermost layer may remain more or less intact. Finally, a germ tube is formed with an axial nuclear area of coarsely granular material and the spore contents then senesce (Dorokhova et al., 1968; Lacey and Vince, 1971).

Cultural characteristics. Colonies are usually fast-growing at 55°C on nutrient or Czapek-yeast-casein (CYC)* agars, flat or lightly ridged, usually with white aerial mycelium. However, in *Thermoactinomyces sacchari* aerial mycelia are often transient, and colonies may appear “bacterial”. In contrast, in *Thermoactinomyces dichotomicus* the aerial mycelium is yellow. In *Thermoactinomyces putidus* and *Thermoactinomyces sacchari*, lysis may deposit spores on the

*CYC agar: Czapek-Dox agar powder (Oxoid CM 97), 33.4 g; yeast extract, 2.0 g; vitamin-free Casamino acids, 6.0 g; pH 7.2. Novobiocin (Albamylin, Upjohn; 25 $\mu\text{g}/\text{ml}$) and cycloheximide (Acti-dione, Koch-Light; 50 $\mu\text{g}/\text{ml}$) added after autoclaving.

agar surface (Lacey, 1971a; Unsworth, 1978). *Thermoactinomyces peptonophilus* is exceptional in being mesophilic and requiring peptone and B vitamins for growth. Aerial mycelium production is favored by 0.02% (w/v) glycerol or glucose as supplements in glycerol-asparagine, oatmeal, yeast-starch, and peptone-yeast extract (PY)^{*} agars (Nonomura and Ohara, 1971). Soluble pigments are produced by some species, and *Thermoactinomyces intermedius*, *Thermoactinomyces putidus*, and *Thermoactinomyces thalpophilus* produce brown, water-soluble melanin pigments with 0.5% L-tyrosine in CYC agar (Kurup et al., 1980; Lacey, 1971a; Unsworth, 1978).

Life cycles. Alternative life cycles for a *Thermoactinomyces* species, *Thermoactinomyces thalpophilus*, have been suggested (Kretschmer, 1984a). The primary mycelium formed on germination, with septa about every 10 µm, continues to grow without producing endospores, until growth conditions become limiting. At that time, two types of secondary mycelium, substrate or aerial, may form depending on the composition of the substrate, while older hyphae may lyse. Hydrophobic aerial mycelium may develop as soon as nutrients become limiting, while secondary substrate mycelium develops after a lag phase. Coincidentally, the intervals between septa decreases to 0.75–0.8 µm and endospores form. Whether secondary substrate or aerial mycelia are formed depends on the nature of the limitation and differs between different agar media. The low phosphate in corn steep liquor (CSL) agar[†] favors secondary aerial mycelium production, whereas the low nitrogen in Czapek-Dox (CD) agar[‡] favors the production of secondary substrate mycelium. Changes in gene expression occur during the lag period before the secondary substrate mycelium is formed, resulting in the production of extracellular proteases. Since spore formation starts as soon as the aerial mycelium is produced, mature spores are produced by this route approximately 5 h earlier than by the secondary substrate mycelium route. Intercalary extension of cells may sometimes be observed giving a zig-zag appearance, but separation of cells (as in *Nocardia*) never occurs (Kretschmer, 1984b).

Nutrition and growth conditions. Nutritional requirements of *Thermoactinomyces* species are incompletely known. All the thermophilic species tested degrade casein and, except for some strains of *Thermoactinomyces sacchari*, gelatin, but none degrades hypoxanthine or xanthine. *Thermoactinomyces peptonophilus* degrades neither gelatin nor casein. *Thermoactinomyces vulgaris* isolates differ greatly in their ability to utilize individual carbon sources. Few isolates of any species reduce nitrate to nitrite. Water-soluble melanin pigments are produced by *Thermoactinomyces intermedius*, *Thermoactinomyces putidus*, and *Thermoactinomyces thalpophilus* on media containing tyrosine provided that these do not contain inhibitory peptones (Unsworth, 1978). Biotin and methionine are reported to be essential for growth of at least some *Thermoactinomyces* isolates, and no aerial growth is obtained in the absence of methionine (Webley, 1958).

^{*}PY agar: peptone, 20 g; yeast extract, 20 g; glycerol, 2 g; MgSO₄ · 7H₂O, 0.3 g; agar, 20 g; water 1 l; pH 7.6.

[†]CSL agar: corn steep liquor (50% dry matter), 5 g; vitamin-free Casamino acids (Difco), 3 g; sucrose, 15 g; corn starch, 5 g; NaNO₃, 1 g; NaCl, 2.5 g; KCl, 0.025 g; CaCl₂, 0.25 g; FeSO₄ · 7H₂O, 0.005 g; magnesium glycerophosphate, 0.25 g; agar, 20 g; distilled water, 1 l; pH 7.2.

[‡]CD agar: sucrose, 10 g; vitamin-free Casamino acids (Difco), 1.5 g; casein peptone (Serval), 1.5 g; NaCl, 1.0 g; K₂HPO₄, 1.2 g; Na₂HPO₄, 1.2 g; Na₂HPO₄ · 2H₂O, 2.8 g; CaCO₃, 0.005 g; FeSO₄ · 7H₂O, 0.01 g; MgSO₄, 0.5 g; agar, 20 g; water, 1 l; pH 6.3.

Most *Thermoactinomyces putidus* isolates produce acid from sucrose, and up to 30% of *Thermoactinomyces thalpophilus* strains produce acid from fructose, glycerol, mannitol, mannose, ribose, sucrose, and trehalose. A few isolates of *Thermoactinomyces vulgaris* produce acid from these sugars, whereas only 20% of *Thermoactinomyces sacchari* produce acid from glycerol but no other sugar. Acid production by other species has not been tested (Unsworth, 1978). *Thermoactinomyces dichotomicus*, *Thermoactinomyces intermedius*, *Thermoactinomyces sacchari*, *Thermoactinomyces thalpophilus*, and *Thermoactinomyces vulgaris* are all resistant to lysozyme, but the resistance of other species is not known (Goodfellow and Pirouz, 1982; Kurup et al., 1980).

Thermophilic *Thermoactinomyces* species all grow between 35° and 58°C, but *Thermoactinomyces putidus* and *Thermoactinomyces thalpophilus* grow down to 29°C, *Thermoactinomyces sacchari* grows up to 60°C, and *Thermoactinomyces dichotomicus* and *Thermoactinomyces vulgaris* up to 62°C. *Thermoactinomyces peptonophilus* grows poorly at 25°C and optimally at 35°C, and fails to grow at 45°C (Lacey, 1971a; Nonomura and Ohara, 1971; Unsworth, 1978).

Production of aerial mycelium may be inhibited when air is replaced by pure oxygen, perhaps through the inactivation of essential -SH groups in thiol enzymes (Webley, 1954). Respiration is greatest in 1–2-d-old cultures bearing aerial mycelium. Vegetative mycelium more than 1 d old and spores respire little (Erikson and Webley, 1953), perhaps a consequence of low cytochrome α content (Tapykova et al., 1969).

Enzyme production. Because of their activity at high temperatures, enzymes of *Thermoactinomyces* species, especially their amylases, lipases, and proteases, have attracted much interest. Thermitase is an extracellular endopeptidase that is reportedly well-suited for use in the food industry. It is the principal component of proteases produced in culture medium; temperature of optimal activity against peptide esters is 60°C, against peptide *p*-nitroanilides is 65–75°C, and against casein is 90°C, although it is rapidly inactivated at this temperature (Behnke et al., 1982). Optimum production of thermitase is at 50–52°C with a pH of 6.6–7.3 (Leuchtenberger and Ruttloff, 1983). The crystal structure of thermitase from *Thermoactinomyces vulgaris* has been determined (Teplyakov et al., 1989).

Protease production begins at the transition from exponential to linear growth phases after about 5 h of incubation. During linear growth, up to 45% of the hyphae are lysed. After 22 h of fermentation, the enzyme comprises three components forming 33%, 64%, and 3% of the total, differing in their retention in Sephadex gel and also in the protein bands on polyacrylamide gel electrophoresis. Enzyme production ceases after 10 h of growth when easily utilizable carbohydrates are exhausted, leading to decreased respiration (Kretschmer et al., 1982; Taufel et al., 1979). Enzyme synthesis is promoted by adding rape oil to the medium as an antifoam agent because lysis of the mycelium is decreased (Leuchtenberger and Ruttloff, 1983). Autolysis is closely associated with heat inactivation of the enzyme thermitase.

Serine proteases reported by Roberts et al. (1977) from both *Thermoactinomyces thalpophilus* and *Thermoactinomyces vulgaris* were similar, but *Thermoactinomyces sacchari* shows no proteolytic activity. However, zymograms of the first two species differ, with *Thermoactinomyces vulgaris* showing two intense proteolytic bands at rA 0.3 and 1.4 and *Thermoactinomyces thalpophilus* 3–4 bands between rA 0.1 and 0.4. Proteolytic enzymes with molecular weights of 27,500 and 23,800 are produced optimally by some

Thermoactinomyces isolates at 60–70°C and pH 9.0 and cause lysis of heat-inactivated cells of fungi, mycobacteria, and *Firmicutes* and especially, *Proteobacteria* (Desai and Dhala, 1966; Desai and Dhala, 1967; Desai and Dhala, 1969; Golovina et al., 1973). Strong lipolytic activity may be found in *Thermoactinomyces thalophilus* (Elwan et al., 1978a; Elwan et al., 1978b). Lipase is produced optimally at 55°C and pH 6.8 in shake culture in a Czapek medium containing corn oil and 0.2% (w/v) yeast extract, incubated for 24–36 h. Activity of the isolated enzyme is greatest at 55°C and pH 8.0. Inactivation occurs in 45 min at 80°C and in 5 min at 90°C and 100°C.

Kuo and Hartman (1966) first reported α -amylase activity by a *Thermoactinomyces* species, probably *Thermoactinomyces thalophilus*, and subsequently this was confirmed by others (Allam et al., 1975; Obi and Odibo, 1984; Shimizu et al., 1978). Although the organism used by Allam et al. (1975) was described as *Thermomonospora vulgaris*, illustrations of it in Hussein et al. (1975) are consistent with *Thermoactinomyces thalophilus*. However, more than one enzyme may be involved. Kuo and Hartman (1966, 1967) found a neutral α -amylase with optimum activity at 60°C and pH 5.9–7.0, whereas other α -amylases with different temperature and pH optima of 70°C and pH 5.0 and 80°C and pH 7.0, respectively, were found in other studies (Obi and Odibo, 1984; Shimizu et al., 1978). The amylase of Shimizu et al. (1978) also had pullulan-hydrolyzing ability, giving panose as the main product, unlike other pullulanases. Cellulolytic activity has been reported in a *Thermoactinomyces* isolate by Hägerdal et al. (1978) but not by Fergus (1969), nor has cellulose utilization ever been found in taxonomic tests. It is possible that the isolate used by Hägerdal et al. (1978) was in fact a species of *Thermomonospora*, a genus in which cellulolytic activity is well known (McCarthy and Cross, 1984a).

Enzymic profiles of double-dialysis antigens (Edwards, 1972) on API ZYM strips (APL Systems) show similarities between *Thermoactinomyces sacchari* and *Thermoactinomyces vulgaris* in that both possess alkaline phosphatase, C_4 esterase, and C_8 esterase-lipase, all of which were absent from *Thermoactinomyces thalophilus* antigens. P. Boiron (personal communication) has additionally found C_{14} lipase, leucine arylamidase, acid phosphatase, and naphthol AS-BI phosphohydrolase in *Thermoactinomyces sacchari* preparations. However, *Thermoactinomyces thalophilus* is the only species to possess α -glucosidase. Weak acid phosphatase activity is present in *Thermoactinomyces vulgaris* and phosphoamidase activity in *Thermoactinomyces thalophilus*. C_4 esterase, leucine aminopeptidase, and chymotrypsin activity are present in *Thermoactinomyces thalophilus* when whole cells are used (Hollick, 1982).

Antimicrobial activity. Antimicrobial activity has been reported in cultures of *Thermoactinomyces dichotomicus* and *Thermoactinomyces thalophilus* (Craveri et al., 1964; Cross and Unsworth, 1976; Krasil'nikov and Agre, 1964). Both these species can inhibit growth of *Thermoactinomyces vulgaris*, which accounts for the so-called autoinhibition phenomenon (Locci, 1963) observed between isolates when *Thermoactinomyces vulgaris* was considered to be a single variable species. *Thermomonospora chromogena* (Krasil'nikov and Agre 1965) McCarthy and Cross 1984b is also inhibited by *Thermoactinomyces dichotomicus*, whereas thermorubin (Moppett et al., 1972) isolated from cultures of *Thermoactinomyces thalophilus* (then named *Thermoactinomyces antibioticus*) is more inhibitory to Gram-stain-positive

than to Gram-stain-negative bacteria, but it is also highly toxic to mammals (Kosmachev, 1962; Terao et al., 1965).

Genetics. Recombination, with substitution of small fragments of homologous segments of genetic material, has been observed with mutants obtained from a *Thermoactinomyces thalophilus* isolate (Hopwood and Ferguson, 1970). It was also shown that *Thermoactinomyces thalophilus*, like other prokaryotes, has partially diploid zygotes. Most recombinants differed from one or another parent strain by only a single marker, irrespective of the coupling of the markers. The process was characterized as transformation that occurred when agar containing a constant amount of DNA was tested with $>10^5$ spores leading to confluent mycelial growth (Hopwood and Wright, 1972). The transformation frequency has been estimated at 1×10^{-3} to 1×10^{-4} (Kretschmer and Sarfert, 1980). This high transformation frequency in *Thermoactinomyces thalophilus* implies that there is little extracellular DNase activity. Transformation was inhibited if DNase was added during the first 6–8 h of incubation but not if it was added after 7–9 h of growth. Competence develops at the time when aerial mycelium first appears (Hopwood and Wright, 1972).

Phages. Phages to *Thermoactinomyces* species have been reported frequently (Agre, 1961; Kretschmer, 1982; Kretschmer and Sarfert, 1980; Kurup and Heinzen, 1978; Patel, 1969; Prauser and Momirova, 1970; Sarfert et al., 1979; Treuhaft, 1977), mostly from *Thermoactinomyces thalophilus* but also from *Thermoactinomyces sacchari* and *Thermoactinomyces vulgaris*. The size and structure of phages from various sources differ, having heads 60–72 \times 62–84 nm and tails 5–20 \times 90–120 nm (Agre, 1961; Kurup and Heinzen, 1978). Some of the tails had a helical structure with about 29 turns (Patel, 1969); in two others, the DNA content was 28.8×10^6 and 37×10^6 daltons per phage (Kretschmer, 1982). Infectivity was lost after 10 min at 70°C and pH 3.6 or when treated with H_2O_2 (Kurup and Heinzen, 1978).

Phages differed in their species specificity. Those from *Thermoactinomyces sacchari* were species specific, but some from *Thermoactinomyces thalophilus* and *Thermoactinomyces vulgaris* could infect the other species (Kurup and Heinzen, 1978; Treuhaft, 1977). None infected other genera. Plaque morphology differed among hosts. When *Thermoactinomyces thalophilus* phage infected *Thermoactinomyces thalophilus*, confluent lysis was characteristic, but, when infecting *Thermoactinomyces vulgaris*, only small plaques were formed (Treuhaft, 1977). Seven host range/plaque type groups were distinguished using two isolates of *Thermoactinomyces thalophilus* and *Thermoactinomyces vulgaris* (Treuhaft, 1977) and three types of interaction between phage and host were found in *Thermoactinomyces thalophilus* (Kretschmer, 1982). Multiplication of phages occurred only in the primary mycelium, and they decreased in number in secondary mycelium and during sporulation. The phage genome was incorporated into spores early in their formation in a heat-stable state and only multiplied on germination. Growing secondary substrate mycelium was competent to take up exogenous DNA, but transfection did not occur (Kretschmer, 1980).

Antigenicity. Species of *Thermoactinomyces* differ antigenically, although there are common components that give some cross-reactivity. *Thermoactinomyces dichotomicus*, *Thermoactinomyces putidus*, *Thermoactinomyces sacchari*, and *Thermoactinomyces vulgaris* are serologically homogeneous, whereas *Thermoactinomyces thalophilus* isolates are heterogeneous (Arden-Jones and

Cross, 1980). *Thermoactinomyces intermedius* and *Thermoactinomyces sacchari* both cross-react with *Thermoactinomyces thalophilus* and *Thermoactinomyces vulgaris* but not with one another (Kurup et al., 1980; Kurup et al., 1976b; Lacey, 1971a). Distinctive protein bands are found on polyacrylamide gel electrophoresis of double-dialysis antigens (Edwards, 1972). *Thermoactinomyces vulgaris* gives 10–16 bands, five of which are glycoprotein. There are major bands at rA 0.42, 0.66, and 1.32 that differ from a more diffuse band at rA 0.54 and a prominent solitary band at rA 0.97 in *Thermoactinomyces thalophilus*. *Thermoactinomyces sacchari* combined the features of both preceding species but two bands are distinctive (Hollick et al., 1979; Roberts et al., 1977). Pyridine extracts revealed only 8–11 protein bands, three of which were glycoprotein. Crossed immunoelectrophoresis of *Thermoactinomyces vulgaris* antigen revealed 15 immunogens when tested against homologous antiserum and 19 bands with isoelectric points between 3.5 and 5.7 during flat bed isoelectric focusing. Most were heat labile and unaffected by Pronase (Hollick and Larsh, 1979). Most components of *Thermoactinomyces sacchari* antigen are heat labile and partially sensitive to Pronase (Lehrer and Salvaggio, 1978), perhaps because this species lacks serine protease (Roberts et al., 1977).

Antibiotic sensitivity. There is little information on antibiotic sensitivity of *Thermoactinomyces* species. However, all of the thermophilic species, but not the mesophilic *Thermoactinomyces peptonophilus*, are tolerant to nalidixic acid and up to 200 µg novobiocin/ml (Cross, 1968; Cross and Attwell, 1975). Most isolates are sensitive to ampicillin, benzylpenicillin, cephaloridine, chloramphenicol, colistin sulfate, demethylchlortetracycline, erythromycin, gentamicin, kanamycin, neomycin, nitrofurantoin, oleandomycin, penicillin, streptomycin, and tetracycline; *Thermoactinomyces dichotomicus* isolates are also sensitive to lincomycin and vancomycin and *Thermoactinomyces vulgaris* is sensitive to chloramphenicol. Isolates of some species differ in their sensitivity (Goodfellow and Pirouz, 1982).

Pathogenicity. *Thermoactinomyces* species have often been implicated as causes of extrinsic allergic alveolitis (hypersensitivity pneumonitis). *Thermoactinomyces dichotomicus*, *Thermoactinomyces thalophilus*, and *Thermoactinomyces vulgaris* have all been implicated in farmers' lung disease, although *Faenia rectivirgula* (Cross et al., 1968a) is the major source of the antigen. *Thermoactinomyces putidus* has been identified from a lung biopsy of a patient (Cross and Unsworth, 1976; Molina, 1974; Pepys et al., 1963; Pether and Greatorex, 1976; Terho and Lacey, 1979; Unsworth, 1978; Wenzel et al., 1967; Wenzel et al., 1974). *Thermoactinomyces sacchari* is a principal source of bagassosis antigen (Lacey, 1971a), and *Thermoactinomyces vulgaris* is reported to cause humidifier fever (Banaszak et al., 1970; Sweet et al., 1971). Often the role of individual species has not been clear because *Thermoactinomyces thalophilus* and *Thermoactinomyces vulgaris* have not been differentiated. More farmers have been found with precipitins to *Thermoactinomyces vulgaris* than to *Thermoactinomyces thalophilus* (Greatorex and Pether, 1975; Terho and Lacey, 1979), but most screening has been done with antigens prepared from *Thermoactinomyces thalophilus*. Although *Thermoactinomyces vulgaris* is much more abundant than *Thermoactinomyces thalophilus* in hay (Terho and Lacey, 1979), isolates of *Thermoactinomyces thalophilus* were chosen for antigen production because they were regarded, at the time,

as more vigorously growing variants of *Thermoactinomyces vulgaris*, following the species concept of Küster and Locci (1964). Commercial antigens labeled "*Thermoactinomyces vulgaris*" have represented both species and it is necessary that these be identified and the role of *Thermoactinomyces* species in farmer's lung be re-evaluated (Lacey, 1981). *Thermoactinomyces thalophilus* and *Thermoactinomyces vulgaris*, at least, should be present in panels of antigens used for screening (Terho and Lacey, 1979). A 16S rRNA primer set is now available for the identification of *Thermoactinomyces sensu lato* strains associated with allergic alveolitis and pneumonitis (Xu et al., 2002).

Ecology. *Thermoactinomyces* species are most abundant in moldy fodders and other vegetable matter including straw cereal grains, cotton, composts, hay, and manures (Craveri et al., 1966a; Desai and Dhala, 1966; Fergus, 1964; Forsyth and Webley, 1948; Gregory and Lacey, 1963; Gregory et al., 1963; Henssen, 1957; Lacey, 1973; Lacey, 1978; Lacey and Lacey, 1987). They are favored by spontaneous heating to temperatures up to 70°C, often resulting in production of more than 10⁷ spores/g dry weight. The spores easily become airborne when the substrate is disturbed. However, growth may be limited where aeration is restricted. Growth in agar cultures was halved by decreasing the oxygen concentrations in air to 1% (v/v). Although some growth occurred with 0.1% oxygen, little or no sporulation occurred with less than 1% (Deploey and Fergus, 1975). *Thermoactinomyces vulgaris* is usually the most abundant species, but *Thermoactinomyces thalophilus* is also common (Terho and Lacey, 1979), and *Thermoactinomyces dichotomicus* has been isolated from mushroom composts. *Thermoactinomyces sacchari* is most abundant in heated sugar cane bagasse where it occupies a niche similar to that of *Thermoactinomyces thalophilus* and *Thermoactinomyces vulgaris* in moldy hay. All three species have also been isolated from soil and peat, although usually in small numbers seldom exceeding 10⁴/g dry weight of soil (Goodfellow and Cross, 1974; Küster and Locci, 1963). Many originate from manure, sewage, or dung added to the soil (Cross, 1968; Diab, 1978), but deposition of airborne spores from moldy hay on farms is also possible. Some growth may also occur on vegetation heated by the sun. Even in temperate regions, solar heating may raise the temperature of soil and litter to more than 30°C (Eggs et al., 1972).

Erosion of soil may result in the accumulation of spores in lake muds and marine sediments, giving counts of 10⁴–10⁶ spores/g dry weight (Cross and Johnston, 1971). The presence of thermoactinomycetes in marine environments is a reliable and established indicator of terrestrial wash-in as spore germination and growth do not occur at low *in situ* temperatures (Attwell and Colwell, 1984; Goodfellow and Haynes, 1984; Pathom-aree et al., 2006). The occurrence of *Thermoactinomyces* species in deep mud cores and in archaeological excavations suggests that spores may remain viable for thousands of years and hence may be useful as palaeoindicators in studies on the agricultural history of soils (Cross and Attwell, 1974; Jackson et al., 1997; Nilsson and Renberg, 1990; Seaward et al., 1976; Unsworth et al., 1977). *Thermoactinomyces peptonophilus* and *Thermoactinomyces putidus* have also been isolated from soil (Nonomura and Ohara, 1971), but *Thermoactinomyces intermedius* has been found only in air conditioners, humidifiers, house dust, and grass compost (Kurup et al., 1980) where it occurs with other *Thermoactinomyces* species (Kurup et al., 1976a).

Miscellaneous. Spores of *Thermoactinomyces* species are characteristically heat resistant, surviving up to 4h at 100°C in sucrose solution or 15h of dry heat at this temperature (Fergus, 1967). Survival curves and $D_{100^\circ\text{C}}$ values have been calculated for *Thermoactinomyces dichotomicus* (77 min), *Thermoactinomyces sacchari* (59 min), and *Thermoactinomyces thallopophilus* (11 min) (Cross et al., 1968b; Lacey, 1971a). A report that heat resistance may be lost in 24h at 4°C (Kirillova et al., 1973) was not confirmed by Foerster (1978). Heat shock at 100°C or low-temperature storage may also sometimes decrease germination or kill spores (Attwell and Cross, 1973; Ensign, 1978; Foerster, 1978; Kirillova et al., 1973).

Enrichment and isolation procedures

Isolation of most thermophilic *Thermoactinomyces* species may be achieved on agar media containing 25 µg novobiocin/ml and 50 µg cycloheximide/ml incubated at 50–55°C. SuiTable media include CYC agar and half-strength nutrient or tryptone soya-casein agars (Lacey and Dutkiewicz, 1976b). Samples may be suspended in an aqueous diluent containing gelatin (0.5 g/l) or agar (0.2 g/l) and suiTable dilutions spread on agar in pre-poured plates. Alternatively, spores may be suspended in the air of a small wind tunnel or sedimentation chamber and plated using an Andersen sampler (Gregory and Lacey, 1963; Lacey and Dutkiewicz, 1976a).

Maintenance procedures

Thermophilic species may be maintained on the same media as used for isolation, incubating for 2–3 d at 50–55°C. Incubation may be continued for up to 1 week if plates are enclosed in polyethylene bags or in sealed containers with some water. Transfer

of *Thermoactinomyces sacchari* is aided by transfer of agar bearing the culture and by sealing the Petri dish with a broad rubber band (Lacey, 1971a). Cultures can be maintained on agar slopes in screw-capped bottles at room temperature or 40°C, but for long-term preservation lyophilization is preferred with spores suspended in double-strength skim milk or other media.

Differentiation of *Thermoactinomyces sensu lato* from other genera

Some *Thermomonospora* species often appear similar to *Thermoactinomyces* species on isolation plates, growing well at 55°C, producing white aerial mycelium, and having a chemotype III wall (Becker et al., 1965). However, the sporophores of the latter show differing degrees of dichotomous branching, causing the spores to appear clustered, although they are formed singly, which gives the colony a granular appearance. Also, *Thermomonospora* spores are usually ovoid with a smooth or spiny surface, they are not endospores, and they are killed at 70°C (Cross and Lacey, 1970; McCarthy and Cross, 1984a). *Thermomonospora* species will not grow in the presence of 25 µg novobiocin/ml. *Saccharomonospora viridis* (Schuurmans et al., 1956) Nonomura and Ohara, 1971 also produces single oval spores that are not endospores and are heat sensitive. Colonies of this taxon are characteristically blue-green but may remain white when grown at suboptimal temperatures. This genus has a chemotype IV wall (Becker et al., 1965).

Differentiation of the genera of the family *Thermoactinomycetaceae*

Phenotypic characteristics that differentiate the genera are shown in Table 78.

TABLE 78. Phenotypic characteristics differentiating member genera of the family *Thermoactinomycetaceae*^{a,b}

Characteristic	<i>Thermoactinomyces</i>	<i>Laceyella</i>	<i>Mechercharomyces</i>	<i>Planiflum</i>	<i>Seimonella</i>	<i>Shimazella</i>	<i>Thermoflaccimicrobium</i>

Taxonomic comments

Until recently, the genus *Thermoactinomyces* was considered to be an actinomycete, mainly because of its ability to form aerial mycelium when cultured on solid media. However, a wealth of taxonomic data, including the ability to produce dipicolinic acid-containing endospores (Cross et al., 1968b; Lacey and Vince, 1971), low G+C content of DNA (Lacey and Cross, 1989), menaquinone composition (Collins et al., 1982; Tseng et al., 1990), 5S rRNA (Park et al., 1993) and 16S rRNA gene sequences (Stackebrandt and Woese, 1981; Yoon and Park, 2000), and comparative ribosomal AT-L30 protein analyses (Ochi, 1994) showed that thermoactinomycetes were closely related to other endospore-forming bacteria. Consequently, it is now accepted that the genus is a member of the order *Bacillales*. Nevertheless, because of their morphological properties, thermoactinomycetes were considered with the actinomycetes in the last edition of the *Systematics* (Lacey and Cross, 1989).

The Eighth Edition of the *Determinative* (Küster, 1974) listed only two species of *Thermoactinomyces* (*Thermoactinomyces sacchari* and *Thermoactinomyces vulgaris*), the Approved Lists of Bacterial Names (Skerman et al., 1980) included five species, and the last edition of the *Systematics* seven (Lacey and Cross, 1989). Changes since the Eighth Edition include the transfer of *Thermoactinomyces dichotomicus* from the genus *Actinobifida* on the basis of endospore formation, the description of *Thermoactinomyces candidus*, *Thermoactinomyces intermedius*, *Thermoactinomyces peptonophilus*, and *Thermoactinomyces putidus* as new species, and the revival of *Thermoactinomyces thalpopophilus*. Numerical studies have shown the genus *Thermoactinomyces* to be defined at the 70% similarity (S_{SM} coefficient) level, although *Thermoactinomyces intermedius* and *Thermoactinomyces peptonophilus* were not included (Unsworth, 1978). Individual species were defined at the 79% similarity (S_{SM}) level or greater, while in another study, *Thermoactinomyces sacchari*, *Thermoactinomyces thalpopophilus*, and *Thermoactinomyces vulgaris* formed an aggregate cluster at the 85% S_{SM} level of similarity (Goodfellow and Pirouz, 1982).

The status of *Thermoactinomyces candidus*, *Thermoactinomyces thalpopophilus*, and *Thermoactinomyces vulgaris* has been a source of confusion; indeed the epithet *vulgaris* has been used in the literature in three senses: synonymous with *Thermoactinomyces candidus*, synonymous with *Thermoactinomyces thalpopophilus*, and for an aggregate species comprising all the thermophilic taxa except *Thermoactinomyces dichotomicus* and *Thermoactinomyces sacchari*. The confusion arose because of changing concepts of *Thermoactinomyces* species. Prior to 1964, six species had been described. Of these, three including "*Thermoactinomyces glaucus*" Henssen 1957, "*Thermoactinomyces thermophilus*" (Berestnev) Waksman 1961, and "*Thermoactinomyces monosporus*" (Lehmann and Schutze) Waksman 1953 (in Waksman and Corke, 1953), are *nomina dubia*; one, "*Thermoactinomyces viridis*" Schuurmans et al., 1956, is now placed in the genus *Saccharomonospora* Nonomura and Ohara 1971; and the remaining two, *Thermoactinomyces thalpopophilus* and *Thermoactinomyces vulgaris*, were placed in synonymy by Küster and Locci 1964. *Thermoactinomyces vulgaris* was considered to be

a variable species, a conclusion supported by Flockton and Cross (1975), but it was concluded that the variation was insufficient to justify creation of additional taxa. As a consequence, *Thermoactinomyces vulgaris* acquired characters that were not present in the original concept of Tsiklinsky 1899. A prime example is the ability to utilize starch. Tsiklinsky (1899) stated clearly "il ne donne pas d'amylase", but later Kuo and Hartman (1966) described isolates that produced amylase, and this character is found in the description of *Thermoactinomyces vulgaris* in the Eighth Edition of the *Determinative*. Kurup et al. (1975) placed isolates producing amylase or not into two species, supported also by differences in their ability to utilize arbutin, esculin, hypoxanthine, and tyrosine. They named isolates lacking amylase as *Thermoactinomyces candidus* and those producing amylase as *Thermoactinomyces vulgaris* and also noted that isolates of *Thermoactinomyces candidus* produced spores on short sporophores while those of *Thermoactinomyces vulgaris* were mostly sessile. Sporophores are also described by Tsiklinsky 1899 in her description of *Thermoactinomyces vulgaris*. It is therefore appropriate that such isolates should remain the type species of *Thermoactinomyces* rather than those considered by Kurup et al. 1975 to be *Thermoactinomyces vulgaris*.

Type cultures of *Thermoactinomyces vulgaris* are not extant and the neotype proposed for the genus *Thermoactinomyces* and for *Thermoactinomyces vulgaris* is the oldest strain. This was isolated by Erikson 1953 as "*Micromonospora vulgaris*" strain D, and is listed in the Approved Lists of Bacterial Names as KCC A-0162. This corresponds to Tsiklinsky's original concept of *Thermoactinomyces vulgaris*, as does also *Thermoactinomyces candidus*. The two species should therefore be regarded as synonymous and, in accordance with the Code of Bacteriological Nomenclature, the oldest legitimate epithet retained. Thus *Thermoactinomyces vulgaris* remains the legitimate name for this taxon. Isolates that Kurup et al. (1975) named as *Thermoactinomyces vulgaris* are thus left without a name, but correspond to the aggregate cluster for which Unsworth and Cross (1980) proposed reviving the name *Thermoactinomyces thalpopophilus* Waksman and Corke 1953. The original strains of Waksman and Corke are not extant, but a strain isolated by Henssen 1957, which she considered identical with strains from Waksman, has been designated the neotype. However, this occurs at the margin of the *Thermoactinomyces thalpopophilus* phenon of Unsworth and Cross (1980), and additional reference strains have been specified. Isolations from hay, cotton, and other substrates suggest that isolates unable to produce amylase and with the characters of *Thermoactinomyces vulgaris sensu* Unsworth and Cross (1980) are more abundant than those producing amylase and therefore most likely to be the type isolated by Tsiklinsky (1899) (Cross and Unsworth, 1981; Lacey and Lacey, 1987; Terho and Lacey, 1979). "*Thermoactinomyces antibioticus*" Craveri, Coronelli, Pagani and Sensi 1964 is a synonym of *Thermoactinomyces thalpopophilus* and "*Thermoactinomyces albus*" Orłowska (1969) of *Thermoactinomyces vulgaris*. In contrast, there is evidence that additional species of *Thermoactinomyces sensu lato* remain to be described (Goodfellow and Pirouz, 1982; Song et al., 2001).

Genus I. *Thermoactinomyces* Tsiklinsky 1899, 501^{AL} emend. Yoon, Kim, Shin and Park 2005, 398^{VP}

MICHAEL GOODFELLOW AND AMANDA L. JONES

Ther.mo.ac.ti.no.my'ces. Gr. adj. *thermos* hot; Gr. n. *actis, actinos* a ray; Gr. n. *myces* fungus; N.L. masc. n. *Thermoactinomyces* heat (loving) ray fungus.

Aerobic, Gram-stain-positive, non-acid-fast chemo-organotroph. **Aerial mycelium is abundant and white.** Well-developed, branched and septate substrate mycelium is formed. **Endospores are sessile and produced singly on aerial and substrate hyphae or on unbranched short sporophores. Thermophilic.** Growth occurs at 55°C, but not at 30°C. Wall peptidoglycan contains *meso*-diaminopimelic acid but no characteristic sugars. **The predominant menaquinone is MK-7. The major fatty acid is C_{15:0 iso}; significant amounts of C_{17:0 iso} are present.** The phylogenetically nearest neighbor is the genus *Laceyella*.

DNA G+C content (mol%): 48.

Type species: *Thermoactinomyces vulgaris* Tsiklinsky 1899, 501^{AL}. (*Thermoactinomyces albus* Orłowska 1969, 25; *Thermoactinomyces candidus* Kurup, Barboriak, Fink and Lechevalier 1975, 152.)

Further descriptive information

Thermoactinomyces strains degrade arbutin and esculin, but not chitin (Lacey and Cross, 1989). Additional shared phenotypic features are given in Table 78. Ohshima et al. (1994) purified, characterized, cloned, and sequenced a gene expressing a thermostable leucine dehydrogenase from *Thermoactinomyces intermedius*. *Thermoactinomyces vulgaris* strains degrade elastin, DNA, RNA, and Tweens 20, 40, 60, and 80, but not adenine, cellulose, guanine, keratin, testosterone, or xylan, use D-glucose as a sole carbon source but not starch, grow in the presence of lysozyme and at 1% (w/v) sodium chloride but not in the presence of demethylchlortetracycline (500), gentamicin (50), kanamycin (100), neomycin (50), or vancomycin (50); the Figures in parentheses indicate the concentrations of antimicrobial compounds (µg/ml) used to soak filter paper discs (Goodfellow and Pirouz, 1982; Lacey and Cross, 1989). *Thermoactinomyces vulgaris* strain R-47 produces α-amylases that hydrolyze cyclodextrins, pullulan, and starch (Abe et al., 2005; Ohtaki et al., 2006). Additional phenotypic properties of *Thermoactinomyces vulgaris* strains can be found in the corresponding

section under the family *Thermoactinomycetaceae*. An isolate of *Thermoactinomyces vulgaris* recovered from compost was shown to be pathogenic for mice (Unaogu and Gughani, 1999).

Enrichment and isolation procedures

Isolation of members of the genus can be achieved using CYC, half-strength nutrient, and tryptic soy agars supplemented with 25 µg novobiocin/ml and 50 µg cycloheximide/ml, and incubating for 2–3 d at 50–55°C (Lacey and Dutkiewicz, 1976c).

Maintenance procedures

Cultures can be maintained on the same media used for selective isolation, incubating at 50–55°C for up to 3 d. Long-term storage can be accomplished by freezing at –80°C or in liquid nitrogen or by lyophilization with spores suspended in double strength skim milk.

Differentiation of the genus *Thermoactinomyces* from other genera

The genus *Thermoactinomyces* is phylogenetically distinct from neighboring genera based on 16S rRNA gene sequences (Figure 74). The type strains of the two constituent species share a 16S rRNA gene similarity of 99.4%, a value that corresponds to 9 nucleotide differences at 1437 locations. Members of the two species can be distinguished from those in other genera classified in the family *Thermoactinomycetaceae* using a range of phenotypic properties (Table 78).

Differentiation of the species of the genus *Thermoactinomyces*

Few phenotypic characteristics have been highlighted for the differentiation of *Thermoactinomyces intermedius* and *Thermoactinomyces vulgaris*. However, unlike *Thermoactinomyces intermedius*, *Thermoactinomyces vulgaris* strains are unable to degrade tyrosine or produce melanin pigments on CYC agar supplemented with 0.5% (w/v) tyrosine (Lacey and Cross, 1989).

List of species of the genus *Thermoactinomyces*

1. *Thermoactinomyces vulgaris* Tsiklinsky 1899, 501^{AL} (*Thermoactinomyces albus* Orłowska 1969, 25; *Thermoactinomyces candidus* Kurup, Barboriak, Fink and Lechevalier 1975, 152.)

vul.ga'ris. L. adj. *vulgaris* common.

Colonies fast-growing, flat on nutrient and CYC agars at 55°C, with a moderate covering of white mycelium and often, a feathery margin on CYC agar. Endospores are produced on short, unbranched sporophores (Figure 75 and Figure 76). The colony reverse is white or cream, never pink or brown. Soluble pigments are not formed. Does not produce amylase or degrade L-tyrosine. Grows on CYC agar + 5% (w/v) NaCl.

Frequently isolated from soils and muds, vegetable composts, hay, straw, cereal grains, sugar cane bagasse, cotton, mushroom compost, humidifiers and air conditioning units, and from air.

A probable cause of extrinsic allergic alveolitis (hypersensitivity pneumonitis), but its importance has probably been underestimated because isolates used in testing patients'

antisera have often been *Laceyella sacchari* (previously *Thermoactinomyces thalophilus*).

DNA G+C content (mol%): 48.0 (HPLC).

Type strain: ATCC 43649, CBS 505.77, DSM 43016, JCM 3162, KCC A-0162, KCTC 9076, NBRC 13606, VKM Ac-1195.

GenBank accession number (16S rRNA gene): AF138739.

2. *Thermoactinomyces intermedius* Kurup, Hollick and Pagan, 1981, 216^{VP} (Effective publication: Kurup, Hollick and Pagan 1980, 107.)

in.ter.me'di.us. L. masc. adj. *intermedius* intercalated, intermediate.

Colonies have white aerial mycelium and yellowish to yellowish-brown substrate mycelium. Brown, water-soluble melanin pigments produced on CYC agar + 0.5% (w/v) L-tyrosine. Degrades L-tyrosine. Endospores are sessile or produced on short sporophores. Growth is good at 50–55°C

but poor at 37°C. The maximum temperature for growth has not been determined. Few nutritional and physiological characters have been determined. Isolated from air conditioner filters.

DNA G+C content (mol%): unknown.

Type strain: T-323, ATCC 33205, DSM 43846, DSM 44011, JCM 3312, KCTC 9646, NBRC 14230, NRRL B-16979, VKM Ac-1427.

GenBank accession number (16S rRNA gene): AF138734, AJ251775.

Genus II. *Laceyella* Yoon, Kim, Shin and Park 2005, 398^{VP}

MICHAEL GOODFELLOW AND AMANDA L. JONES

La.cey.el'la. N.L. dim. fem. n. *Laceyella* named to honor John Lacey, an English microbiologist, for his contributions to the taxonomy of the genus *Thermoactinomyces* and actinomycetes.

Aerobic, Gram-stain-positive, non-acid-fast chemo-organotroph. Aerial and substrate mycelia are formed. **Aerial mycelium is white.** Yellow-brown or grayish-yellow soluble pigment may be produced. **Endospores produced on short or long sporophores.** **Thermophilic.** Wall peptidoglycan contains *meso*-diaminopimelic acid but no characteristic sugars. **The predominant menaquinone is MK-9. The major fatty acids are C_{15:0 iso} and C_{15:0 ante}.** The phylogenetic nearest neighbor is the genus *Thermoactinomyces*.

DNA G+C content (mol%): 48–49.

Type species: *Laceyella sacchari* (Waksman and Cork 1953) Yoon, Kim, Shin and Park 2005, 398^{VP} (*Thermoactinomyces thalpopophilus* Waksman and Corke 1953, 378; *Thermoactinomyces sacchari* Lacey 1971a, 327; *Thermoactinomyces thalpopophilus* Lacey and Cross 1989, 2582.)

Further descriptive information

Laceyella strains use D-glucose but not D-mannose as sole carbon sources, produce alkaline phosphatase, C₄ esterase, and C₈ lipase but not α - or β -glucosidase or β -glucuronidase (API ZYM tests) and are sensitive to ampicillin (25), chloramphenicol (50), colistin sulfate (10), erythromycin (10), nitrofurantoin (200), oleandomycin (5), streptomycin (100), and sulfafurazole (500) but not to nalidixic acid (30) or sulfafurazole (100); the Figures in parentheses indicate the concentration of antimicrobial agent ($\mu\text{g}/\text{ml}$) used to soak filter paper discs (Goodfellow and Pirouz, 1982; Lacey and Cross, 1989). They are also sensitive to penicillin (10 IU). Additional shared phenotypic features are given in Table 78 and in the corresponding section under the family *Thermoactinomycetaceae*. *Laceyella sacchari* strains degrade elastin, DNA, RNA, and Tweens 20, 40, 60, and 80 but not adenine, cellulose, chitin, or guanine, use L-arabinose but not *meso*-inositol, D-mannose, L-rhamnose, or D-xylose as sole carbon sources, and are sensitive to filter paper discs soaked in cephaloridine (100), demethylchlortetracycline (500), gentamicin (50), kanamycin (100), neomycin (50), and vancomycin (50); as

outlined above (Goodfellow and Pirouz, 1982; Lacey and Cross, 1989).

Enrichment and isolation procedures

Isolation of *Laceyella* species may be achieved on CYC agar supplemented with 25 μg novobiocin/ml and 50 μg cycloheximide/ml incubated at 50–55°C for up to 3 d (Lacey and Cross, 1989). Isolation of *Laceyella sacchari* is best achieved on yeast-malt agar (Shirling and Gottlieb, 1966) supplemented 25 μg novobiocin and 50 μg cycloheximide/ml and incubated at 55°C (Lacey, 1971b).

Maintenance procedures

Cultures can be maintained on the same media used for selective isolation with plates incubated at 50–55°C for up to 3 d. Long-term storage can be accomplished by freezing at –80°C, or in liquid nitrogen, or by lyophilization with spores suspended in double strength skim milk.

Differentiation of the genus *Laceyella* from other genera

The genus *Laceyella* is phylogenetically distinct from neighboring genera based on 16S rRNA gene sequences (Figure 74). The type strains of the two constituent species share a 16S rRNA gene similarity of 98.3%, a value that corresponds to 25 nucleotide differences at 1458 locations. Members of the two species can be distinguished from those classified in the family *Thermoactinomycetaceae* using a range of phenotypic properties (Table 78).

Differentiation of the species of the genus *Laceyella*

Members of the *Laceyella* species can be distinguished using a range of phenotypic characters (Lacey and Cross, 1989). Only the *Laceyella putida* strains degrade L-tyrosine, produce acid phosphatase, chymotrypsin, and leucine arylamidase, use D-sucrose as a sole carbon source, and form melanin pigments on CYC agar supplemented with 0.5% w/v tyrosine. In contrast, only *Laceyella sacchari* strains degrade DNA and use D-fructose and D-mannose as sole carbon sources.

List of species of the genus *Laceyella*

1. *Laceyella sacchari* (Waksman and Cork 1953) Yoon, Kim, Shin and Park 2005, 398^{VP} (*Thermoactinomyces thalpopophilus* Waksman and Corke 1953, 378; *Thermoactinomyces sacchari* Lacey 1971a, 327; *Thermoactinomyces thalpopophilus* Lacey and Cross 1989, 2582.)
sac'cha.ri. N.L. n. *saccharum* generic name of sugar cane; N.L. gen. n. *sacchari* of sugar cane.

Produces olive-buff, lightly ridged colonies which are “bacterial-like” in appearance. A sparse, transient, tufted aerial mycelium rapidly autolyzes depositing endospores in a thick layer on the surface of yeast malt or nutrient agar supplemented with 1% (w/v) glucose. Growth on nutrient agar is poor, restricted and thin with no aerial mycelium and few spores. Endospores are produced on sporophores up to

3 µm long (Figure 78). Yellow-brown soluble pigments may be formed. Grows at 55°C but growth is variable at 30°C. Water-soluble melanin may be produced on CYC agar supplemented with 0.5% (w/v) L-tyrosine. Elastin, DNA, RNA, and Tween 20, 40, 60, and 80 are degraded but not adenine, cellulose, guanine, or keratin. Degradation of esculin, arbutin, chitin and tyrosine is variable. D-fructose, D-glucose, and D-mannitol are used as carbon sources but not cellulose, meso-inositol, D-raffinose, L-rhamnose, or D-xylose. Does not grow in the presence of 5% (w/v) NaCl; growth variable in the presence of 1% (w/v) NaCl. Isolated from sugar cane, self-heated sugar cane bagasse, filter press muds, sugar mills, and soil.

DNA G+C content (mol%): 48 (HPLC).

Type strain: ATCC 27375, CCUG 7967, DSM 43356, JCM 3137, JCM 3214, KCTC 9790, NBRC 13920, NCIMB 10486, NCTC 10721, NRRL B-16981, VKM Ac-1360.

GenBank accession number (16S rRNA gene): AF138737, AJ251779.

2. *Laceyella putida* (Lacey and Cross 1989) Yoon, Kim, Shin and Park 2005, 399^{VP} (*Thermoactinomyces putidus* Lacey and Cross 1989, 2582.)

pu'ti.da. L. fem. adj. *putida* stinking, fetid.

Colonies are usually highly wrinkled and puckered with endospores formed on short and unbranched sporophores (Figure 79). Aerial mycelium is white, but may appear cream, pale yellow or yellowish-brown due to a yellowish-brown substrate mycelium. During sporulation, hyphae lyse quickly, leaving spores on the surface of agar. A grayish-yellow soluble pigment may be produced; a brown, water-soluble melanin pigment is formed on CYC agar supplemented with 0.5% (w/v) L-tyrosine. Grows between 36°C and 58°C, optimally at 48°C. Sensitive to 1% (w/v) NaCl. Cultures characteristically produce a distinctive, unpleasant smell. Tyrosine is degraded, but not DNA. D-glucose and D-sucrose are used as sole carbon sources, but not D-fructose, glycerol, D-mannitol, D-mannose, D-ribose, or D-trehalose. Isolated from deep mud cores, soil, and a lung biopsy of a patient with farmer's lung.

DNA G+C content (mol%): 49 (HPLC).

Type strain: ATCC 49853, DSM 44608, KCTC 3666, JCM 8091, NCIMB 12324.

GenBank accession number (16S rRNA gene): AF138736, AJ251776.

Genus III. *Mechercharimyces* Matsuo, Katsuta, Matsuda, Shizuri, Yokota and Kasai 2006, 2840^{VP}

MICHAEL GOODFELLOW AND AMANDA L. JONES

Me.cher.cha.ri'my.ces. N.L. n. *Mecherchar* a marine lake located on Mechechar Island in the Republic of Palau, where the organisms were isolated; Gr. masc. n. *mukes* fungus; N.L. masc. n. *Mechercharimyces* a fungus of Mecherchar.

Aerobic, Gram-stain-positive, chemo-organotroph. Aerial and substrate mycelia are formed. **Aerial mycelium is abundant and white.** Well-developed, branched and septate substrate mycelium is formed on marine agar 2216. Soluble pigments are not produced. **Endospores formed singly on short, unbranched sporophores. Mesophilic.** Cell-wall peptidoglycan contains meso-diaminopimelic acid, alanine, and glutamic acid but no characteristic sugars. **The predominant menaquinone is MK-9. The major fatty acid is C_{15:0 iso}.** The phylogenetically nearest neighbor is the genus *Seimonella*.

DNA G+C content (mol%): 45.

Type species: *Mechercharimyces mesophilus* Matsuo, Katsuta, Matsuda, Shizuri, Yokota and Kasai 2006, 2840^{VP}.

Further descriptive information

The chemotaxonomic characteristics of the type strains of *Mechercharimyces mesophilus* (YM3-251^T) and *Mechercharimyces asporophorigenens* (YM11-542^T) were determined by using biomass cultured in marine broth 2216 at the exponential phase of growth. The cell-wall peptidoglycan contained meso-diaminopimelic acid, glutamic acid, and alanine in the ratio 1.1:1:2.7 for strain YM3-251^T and 1.2:1:2.9 for strain YM11-542^T, but no characteristic sugars. MK-8 and MK-9 were observed in strains YM3-251^T (21.7% and 73.0%, respectively) and YM11-542^T (23.9% and 76.1%, respectively). This profile is similar to those of members of the genus *Laceyella* Yoon et al. 2005.

In API ZYM tests, alkaline phosphatase activity was observed in the two type strains and in the additional strains of *Mechercharimyces mesophilus* (YM-653 and YM-671). Degradation of substrates was determined using marine agar 2216 supplemented with 0.1% esculin, 0.15% chitin, 1% gelatin, 0.5% hypoxanthine, 0.5% tyrosine, and 0.5% xanthine. All four strains degraded casein

and gelatin, but not the remaining substrates. They also formed a dark brown pigment on the L-tyrosine-containing marine agar. Reproducible results were not obtained using GP2 Microplates (Biolog) because of the weak growth of the strains. The type strain of *Mechercharimyces mesophilus* produces two cytotoxic substances, namely mechercharmycins A and B (Kanoh et al., 2005).

Enrichment and isolation procedures

Mechercharimyces mesophilus strains YM3-251^T, YM3-653 and YM3-671 were isolated from sediment samples collected from a marine lake on Mecherchar Island, Republic of Palau, by using, respectively 1/10 MYGS-AF medium*, skim milk medium†, 1/10 PYGS-AF medium‡ (Matsuo et al., 2006). The *Mechercharimyces*

* 1/10 MYGS-AF medium: Malt extract 1g, yeast extract 500mg, glucose 500mg, seawater 1 l, agar 20g; pH 7.8–8.0; cycloheximide 100mg, nystatin 50mg, griseofulvin 20mg.

† Skim milk medium: skim milk (Difco) 5g, distilled water 200ml, yeast extract 500mg, seawater 800ml, agar 20g, pH 7.8–8.0.

‡ 1/10 PYGS-AF medium: Metals mix X¹ 250ml, distilled water 750ml, agar 20g, bacto peptone 1g, yeast extract 0.5g, C Soln² 5ml, cycloheximide 50mg, griseofulvin 25mg, nalidixic acid 20mg, aztreonam 40mg.

¹ Metal mix X: NaCl 500g, MgSO₄ · 7H₂O 180g, CaCl₂ · 2H₂O 2.8g, KCl 14g, Na₂HPO₄ · 12H₂O 5g, FeSO₄ · 7H₂O 200mg, PII metals³ 600ml, S2 metals⁴ 100ml, distilled water, 4300ml, pH 7.6.

² C soln: sodium pyruvate 25g, mannitol 50g, glucose 50g, distilled water 500ml pH7.5, sterilized by filtration.

³ PII metals: Na₂-EDTA 1g, H₃BO₃ 1.13g, Fe soln 1ml (FeCl₃ · 6H₂O [2.42g/50ml]), Mn soln 1ml (MnCl₂ · 4H₂O [7.2g/50ml]), Zn soln 1ml (ZnCl₂ [0.52g/50ml (+HCl)]), Co soln 1ml (CoCl₂ · 6H₂O [0.2g/50ml]), distilled water 996ml, pH 7.5.

⁴ S2 metals: NaBr 1.28g, Mo soln 10ml (Na₂MoO₄ · 2H₂O [0.63g/50ml]), Sr soln 10ml (SrCl₂ · 6H₂O [3.04g/50ml]), Rb soln 10ml (RbCl [141.5mg/50ml]), Li soln 10ml (LiCl [0.61g/50ml]), I soln 10ml (KI [6.55mg/50ml]), V soln 10ml (V₂O₅ [1.785mg/50ml (+ NaOH)]), distilled water 940ml, pH 7.5.

phorigenens strain was isolated from a marine lake in the northern part of Urukthapel Island, Republic of Palau, by using 1/10 PYGS-AF medium. For the isolation of strain YM3-251^T, the sediment sample was heated at 52°C for 2 h prior to inoculating the medium. Strain YM3-653 was isolated from a sediment sample that had been dried on filter paper for 24 h and then on silica gel for a month. The two remaining strains were isolated from sediment samples without preheating.

Maintenance procedures

Specific information on suitable procedures for the maintenance of *Mechercharimyces* species is not available. It can be assumed that the procedures satisfactory for other members of the family *Thermoactinomycetaceae* will be suitable for the maintenance of *Mechercharimyces* isolates.

Differentiation of the genus *Mechercharimyces* from other genera

The genus *Mechercharimyces* is phylogenetically distinct from neighboring genera based on 16S rRNA gene sequences

(Figure 74). The four constituent members of the clade have highly conserved sequences as they share 16S rRNA similarities within the range 99.4–99.9%, values that correspond to 2–9 nucleotide differences at 1428 locations. The organisms can also be readily distinguished from representatives of the genera *Laceyella*, *Seinonella*, *Thermoactinomyces*, and *Thermoflavimicrobium* in phylogenetic and molecular evolutionary analyzes based on *gyrB* sequences. They share an optimal growth temperature that distinguishes them from members of these taxa (Table 78). Together with *Laceyella* strains they are characterized by having MK-9 as the predominant isoprenologue.

Differentiation of the species of the genus *Mechercharimyces*

Members of the two *Mechercharimyces* species can be distinguished on the basis of 16S rRNA and *gyrB* gene sequence similarities, the level of DNA–DNA relatedness, and the presence of endospores.

List of species of the genus *Mechercharimyces*

1. ***Mechercharimyces mesophilus*** Matsuo, Katsuta, Matsuda, Shizuri, Yokota and Kasai 2006, 2840^{VP}
 me.so.phi'lus. Gr. adj. *mesos* middle; Gr. adj. *philos* loving; N.L. masc. adj. *mesophilus* middle (temperature) -loving, mesophilic.
 Colonies are fast-growing, lightly ridged, with a moderate covering of white aerial hyphae and a feathery margin on marine agar 2216 at 27°C. Endospores are formed singly on short, unbranched sporophores. Produces a dark-brown pigment on marine agar supplemented with L-tyrosine. Growth occurs at 15–37°C, optimally at 30°C. Shows trypsin activity in API ZYM tests. Casein and gelatin are degraded, but not hypoxanthine, starch, L-tyrosine, or xanthine. Growth occurs in the presence of 25 µg novobiocin/ml. Major cellular fatty acids are C_{15:0 iso}, C_{16:0 iso}, C_{17:1 iso ω11c}, and C_{17:0 iso}. Isolated from sediment samples collected from a marine lake in Mecherchar Island, Republic of Palau.
DNA G+C content (mol%): 45.1 (HPLC).
Type strain: YM3-251, DSM 44894, MBIC06230.
GenBank accession number (16S rRNA gene): AB239529.
2. ***Mechercharimyces asporophorigenens*** Matsuo, Katsuta, Matsuda, Shizuri, Yokota and Kasai 2006, 2840^{VP}
 a.spo'ro.pho.ri.gen.ens. Gr. prep. *a* not; Gr. n. *sporophora* sporophore; L. part. adj. *genens* producing; N.L. part. adj. *asporophorigenens* sporophore nonproducing.
 Colonies are fast-growing, lightly ridged, with a moderate covering of white aerial hyphae and a feathery margin on marine agar 2216 at 27°C. Oval shaped endospores are borne on aerial and substrate hyphae. Produces a dark-brown pigment on marine agar supplemented with L-tyrosine. Growth occurs at 20–37°C, optimally at 30°C. Does not show trypsin activity in API ZYM tests. Casein and gelatin are degraded but not hypoxanthine, starch, L-tyrosine or xanthine. Growth occurs in the presence of 25 µg/ml novobiocin. Major cellular fatty acids are C_{15:0 iso}, C_{16:0 iso}, C_{17:1 iso ω11c}, and C_{17:0 iso}. Isolated from a sediment sample collected from a marine lake in the northern part of Urukthapel Island, Republic of Palau.
DNA G+C content (mol%): 45.2 (HPLC).
Type strain: YM11-542, DSM 44955, MBIC06487.
GenBank accession number (16S rRNA gene): AB239532.

Genus IV. *Planifilum* Hatayama, Shoun, Ueda and Nakamura 2005b, 2104^{VP}

MICHAEL GOODFELLOW AND AMANDA L. JONES

Pla.ni.fi'lum. L. adj. *planus* flat; L.neut. n. *filum* a thread; N.L. neut. n. *Planifilum* a flat thread.

Aerobic, Gram-stain-positive organism which forms a substrate mycelium, but not an aerial mycelium on CYC, LB, and SY agars. Single endospores are borne on substrate hyphae. Thermophilic. Casein and starch are degraded but not hypoxanthine or xanthine. The cell-wall peptidoglycan contains meso-diaminopimelic acid, alanine, and glutamic acid but no diagnostic sugars.

The predominant menaquinone is MK-7. The major fatty acids are C_{17:0 iso}, C_{17:0 ante}, and either C_{15:0 iso} or C_{16:0 iso}. The phylogenetic nearest neighbor is the genus *Thermoactinomyces*.

DNA G+C content (mol%): 58.7–60.3.

Type species: ***Planifilum fimeticola*** Hatayama, Shoun, Ueda and Nakamura 2005b, 2104^{VP}.

Further descriptive information

Does not degrade 1% avicel, 1% carboxymethylcellulose, or 1% xylan. Utilization of sugars by the methods of Shirling and Gottlieb (1966) and Fotina et al. (2001) did not yield reproducible results due to weak growth of the strains.

Enrichment and isolation procedures

The two species were isolated from samples taken from a hyperthermal composting process (Hatayama et al., 2005a) by cultivation on Luria–Bertani agar plates at 65°C.

Maintenance procedures

Specific information on suitable procedures for the maintenance of *Planifilum* species is not available. It can be assumed that the procedures satisfactory for other members of the family

Thermoactinomycetaceae will also be suitable for the maintenance of *Planifilum* isolates.

Differentiation of the genus *Planifilum* from other genera

Planifilum isolates can be distinguished from members of the other genera classified in the family *Thermoactinomycetaceae* based on the absence of aerial mycelia, growth temperatures, DNA G+C content, and cellular fatty acid and menaquinone composition (Table 78). Phylogenetic analyzes show that *Planifilum* isolates form a distinct branch in the *Thermoactinomycetaceae* 16S rRNA gene tree (Figure 74).

Differentiation of the species of the genus *Planifilum*

Members of the two *Planifilum* species can be distinguished on the basis of 16S rRNA gene sequence similarities, levels of DNA–DNA relatedness, differences in cellular fatty acid profiles, and on the ability to degrade L-tyrosine (Hatayama et al., 2005b).

List of species of the genus *Planifilum*

1. ***Planifilum fimeticola*** Hatayama, Shoun, Ueda and Nakamura 2005b, 2104^{VP}

fi.me.ti.co'la. L. n. *fimetum* a dung-hill and, by extension, compost; L. masc. suffix *-cola* inhabitant; N.L. masc. n. *fimeticola* inhabitant of compost, referring to the habitat of the type strain.

Colonies are lustrous, cream-yellow with radial wrinkles. Growth occurs at 50–65°C, optimally at 55–63°C. L-Tyrosine is degraded. The major cellular fatty acids are C_{16:0 iso}, C_{17:0 iso} and C_{17:0 ante}. Isolated from a hyperthermal composting process plant in Okinawa Prefecture, Japan.

DNA G+C content (mol%): 60.3% (HPLC).

Type strain: H0165, ATCC BAA-969, JCM 12507.

GenBank accession number (16S rRNA gene): AB088364.

2. ***Planifilum fulgidum*** Hatayama, Shoun, Ueda and Nakamura 2005b, 2104^{VP}

ful'gi.dum. L. neut. adj. *fulgidum* lustrous, referring to the colony character.

Colonies are lustrous, cream-yellow with radial wrinkles. Growth occurs at 50–67°C, optimally at 60–65°C. L-tyrosine is not degraded. The major cellular fatty acids are C_{17:0 iso}, C_{17:0 ante} and C_{15:0 iso}. Isolated from a hyperthermal composting process plant in Okinawa Prefecture, Japan.

DNA G+C content (mol%): 58.7–60 (HPLC).

Type strain: 500275, ATCC BAA-970, JCM 12508.

GenBank accession number (16S rRNA gene): AB088362.

Genus V. *Seinonella* Yoon, Kim, Shin and Park 2005, 399^{VP}

MICHAEL GOODFELLOW AND AMANDA L. JONES

Sei.no.nel'la. N.L. dim. fem. n. *Seinonella* named to honor Akio Seino, a Japanese microbiologist, for his contributions to the genus *Thermoactinomyces* and actinomycetes.

Aerobic, Gram-stain-positive, non-acid-fast chemo-organotroph. The substrate mycelium is white to yellowish-brown and the aerial mycelium white. **Sessile endospores are produced on the substrate mycelium and on filamentous branches of the aerial mycelium. Growth at 25–45°C, and optimally at 35°C.** The wall peptidoglycan contains meso-diaminopimelic acid. **The predominant menaquinone is MK-7**, significant amounts of MK-8, MK-9, and MK 10 are also present. **The major fatty acids are C_{14:0 iso} and C_{15:0 ante}.** The phylogenetic nearest neighbor is the genus *Merchercharimyces*.

DNA G+C content (mol%): 40.

Type species: ***Seinonella peptonophila*** (Nonomura and Ohara 1971) Yoon, Kim, Shin and Park 2005, 400^{VP} (*Thermoactinomyces peptonophilus* Nonomura and Ohara 1971, 902.)

Further descriptive information

Endospores are less heat-resistant ($D_{90^\circ\text{C}} = 45\text{min}$) than those of other thermoactinomycetes (Attwell, 1978). Does not grow below pH 5.0.

Enrichment and isolation procedures

Seinonella peptonophila has been isolated from dry heat treated (100°C) soil samples using MGA-SE agar*. However, growth on this medium occurred only in the presence of actinomycete colonies because of the restricted nutritional requirements of the organism (Nonomura and Ohara, 1971).

* MGA-SE agar: glucose 2.0g, L-asparagine 1.0g, K₂HPO₄ 0.5g, MgSO₄·7H₂O 0.5g, soil extract 200ml; penicillin 1mg, polymixin β 5mg, cycloheximide 50mg, nystatin 50mg, agar 20g, water 800ml, pH 8.0. Soil extract: 1000g soil autoclaved with 11 water for 30 mins, decanted, and filtered.

Maintenance procedures

Seinonella peptonophila must be grown on glycerol-asparagine agar (Shirling and Gottlieb, 1966) supplemented with 10g yeast extract or on PY agar with incubation at 35°C (Nonomura and Ohara, 1971). Long-term storage can be achieved by freezing at -80°C or in liquid nitrogen or by lyophilization with spores suspended in double strength skim milk.

Differentiation of the genus *Seinonella* from other genera

The genus *Seinonella* is phylogenetically distinct from neighboring genera based on 16S rRNA gene sequences (Figure 74). The organism can be distinguished from those classified in the family *Thermoactinomycetaceae* using a combination of phenotypic properties (Table 78), notably by its low optimal temperature for growth.

List of species of the genus *Seinonella*

1. ***Seinonella peptonophila*** (Nonomura and Ohara 1971) Yoon, Kim, Shin and Park 2005, 400^{VP} (*Thermoactinomyces peptonophilus* Nonomura and Ohara 1971, 902.)

pep.to.no'phi.la. Gr. adj. *peptos* cooked; Gr. adv. *philos* loving; N.L. adj. *peptonophila* peptone loving (Note: Rule 61 of the *Bacteriological Code* prevents the correction of the epithet to *peptoniphila*).

B vitamins and high concentrations of peptone (3%, w/v) are essential for growth. Aerial mycelium production is favored

by glycerol or glucose (0.2%, w/v) and is best on supplemented glycerol-asparagine, oatmeal, yeast-starch, and PY agars at 35°C. Grows poorly at 25°C and not at all at 45°C. Optimum pH for growth is 7.0–8.0; no growth at pH 5.0. Nitrate reduction is negative. Tyrosine is not degraded. Isolated from soil.

DNA G+C content (mol%): 40 (HPLC).

Type strain: ATCC 27302, DSM 44666, JCM 10113, KCTC 9740.

GenBank accession number (16S rRNA gene): AF 138735.

Genus VI. ***Shimazuella*** Park, Dastagar, Lee, Yeo, Yoon and Kim 2007, 2663^{VP}

MICHAEL GOODFELLOW AND AMANDA L. JONES

Shi.maz ue'lla. N.L. fem. dim. n. *Shimazuella* of Shimazu, named after Akira Shimazu of Tokyo University for his contributions to prokaryotic taxonomy.

Aerobic, Gram-stain-positive, mesophilic, chemorganotroph. Aerial and substrate mycelia are formed. Aerial mycelium is abundant and white. Well developed, branched and septate mycelium is formed on Bennett's and yeast extract-malt extract agars. Soluble pigments are not produced. **Single endospores formed on both aerial and substrate mycelium with sizes ranging from 1.0–1.4 to 0.7–0.9 µm. Extensively branched sporophores are formed on aerial hyphae with sizes ranging from 0.3–0.6 µm in length. Spore surface spiny.** Grows at 20–50°C and optimally at 32°C. Cell-wall peptidoglycan contains *meso*-diaminopimelic acid, alanine, and glutamic acid but no characteristic sugars. Predominant menaquinone is MK-9. Major fatty acid is C_{15:0 iso}. The phylogenetically nearest neighbor is the genus *Laceyella*.

DNA G+C content (mol%): 39.4.

Type species: ***Shimazuella kribbensis*** Park, Dastagar, Lee, Yeo, Yoon and Kim 2007, 2663^{VP}.

Further descriptive information

Has chemotaxonomic and morphological features consistent with its classification in the family *Thermoactinomycetaceae*. Grows on glycerol-asparagine, inorganic salts-starch, oatmeal, tyrosine, and yeast extract-malt extracts agar (Shirling and

Gottlieb, 1966). Phosphatidylethanolamine is the diagnostic phospholipid. Contains MK-9 and MK-10 in the ratio of 7:3.

Isolation procedures

Strain A 9500^T was isolated from a soil sample collected from Mount Sobaek, Republic of Korea, by plating soil suspensions onto Bennett's agar (Atlas, 1993) and incubating at 30°C for 2 weeks.

Maintenance procedures

The organism can be maintained on Bennett's agar plates but additional information on suitable procedures for the maintenance of *Shimazuella* strains is not available. It can be assumed that the procedures satisfactory for other members of the family *Thermoactinomycetaceae* will be suitable for the maintenance of *Shimazuella* isolates.

Differentiation of the genus *Shimazuella* from other genera

The genus *Shimazuella* is phylogenetically distinct from neighboring genera based on 16S rRNA gene sequences (Figure 74). Members of the taxon can be distinguished from genera classified in the family *Thermoactinomycetaceae* using a range of phenotypic properties (Table 78), notably by its menaquinone profile.

List of species of the genus *Shimazuella*

1. ***Shimazuella kribbensis*** Park, Dastagar, Lee, Yeo, Yoon and Kim 2007, 2663^{VP}

krib.ben'sis. N.L. fem. adj. *kribbensis* pertaining to KRIBB, an arbitrary adjective formed from the acronym of the Korea Research

Institute of Bioscience and Biotechnology (KRIBB), where the taxonomic studies on the organism were undertaken.

Fast-growing, lightly ridged colonies with a pale yellow substrate mycelium, a feathery margin, and an abundant white aerial

mycelium are formed on Bennett's agar. Casein and starch are degraded, but not gelatin, hypoxanthine, L-tyrosine, or xanthine. Growth occurs in the presence of 25 µg novobiocin/ml. The fatty acid profile consists of C_{15:0 ante} (43.4%), C_{16: iso} (14.2), C_{16:0} (7.9%), C_{15:0 iso} (7.4%), C_{17:0 ante} (7.2%), C_{14:0 iso} (6.1%), C_{14:0}

(6.1%), C_{15:0} (4.0%), and C_{16:0 ante} (3.8%). Isolated from a soil sample collected from Mount Sobaek, Republic of Korea.

DNA G+C content (mol%): 39.4 (HPLC).

Type strain: A9500, KCTC 9933, KCCM 41585.

GenBank accession number (16S rRNA gene): AB049939.

Genus VII. *Thermoflavimicrobium* Yoon, Kim, Shin and Park 2005, 399^{VP}

MICHAEL GOODFELLOW AND AMANDA L. JONES

Ther'mo.fl.a.vi.mi.cro'bi.um. Gr. adj. *thermos* hot; L. adj. *flavus* yellow; Gr. adj. *mikros* small; Gr. n. *bios* life; N.L. neut. n. *Thermoflavimicrobium* a thermophilic yellow-colored microbe.

Aerobic, Gram-stain-positive, non-acid-fast chemo-organotroph. Aerial and substrate mycelia are formed. **Aerial mycelium is abundant and yellow. Sessile endospores are produced on dichotomously branched sporophores. Thermophilic.** Growth occurs at 55°C but not at 30°C. The wall peptidoglycan contains *meso*-diaminopimelic acid but no characteristic sugars. **Predominant menaquinone is MK-7. Major fatty acids are C_{15:0 iso}, C_{15:0 ante}, and C_{16:0 iso}.** The phylogenetically nearest neighbor is the genus *Planofilum*.

DNA G+C content (mol%): 43.

Type species: *Thermoflavimicrobium dichotomicum* (Krasil'nikov and Agre, 1964) Yoon, Kim, Shin and Park 2005, 399^{VP} (*Actinobifida dichotomica* Krasil'nikov and Agre 1964, 939; *Thermoactinomyces dichotomicus* corrig. Cross and Goodfellow 1973, 77.).

Further descriptive information

Thermoflavimicrobium strains grow up to 62°C, produce alkaline phosphatase, C₄ esterase, and C₈ lipase but not chymotrypsin, α- or β- glucosidase, β-glucuronidase, or leucine arylamidase (API ZYM tests) and are sensitive to cephaloridine (100), demethylchlortetracycline (500), gentamicin (100), kanamycin (100), lincomycin (100), neomycin (100), streptomycin (100), tobramycin (100), and vancomycin (100) but not to novobiocin (50); the Figures in parentheses indicate the concentrations of antimicrobial compounds (µg/ml) used to soak filter paper discs (Goodfellow and Pirouz, 1982; Lacey and Cross, 1989).

The organism is also sensitive to penicillin (10 IU) and NaCl (0.5%, w/v).

Enrichment and isolation procedures

Isolation may be achieved on half-strength nutrient agar supplemented with 25 µg novobiocin/ml and 50 µg cycloheximide/ml following incubation for up to 3 d at 50–55°C (Lacey and Cross, 1989). Colonies on isolation plates are recognized by their bright yellow color.

Maintenance procedures

Agre (1964) recommended a maize-starch medium*. Cultures can be maintained on agar slopes in screw-capped bottles at room temperature or at 4°C. Long-term storage can be accomplished by freezing at –80°C or in liquid nitrogen or by lyophilization with spores suspended in double strength skim milk.

Differentiation of the genus *Thermoflavimicrobium* from other genera

The genus *Thermoflavimicrobium* is phylogenetically distinct from neighboring genera based on 16S rRNA gene sequences (Figure 74). Members of the genus can be distinguished from those classified in the family *Thermoactinomycetaceae* using a range of phenotypic properties (Table 78), notably by their ability to produce single spores on dichotomously branched sporophores (Figure 80) and yellow pigmented colonies.

List of species of the genus *Thermoflavimicrobium*

1. ***Thermoflavimicrobium dichotomicum*** (Krasil'nikov and Agre 1964) Yoon, Kim, Shin and Park 2005, 399^{VP} (*Actinobifida dichotomica* Krasil'nikov and Agre 1964, 939; *Thermoactinomyces dichotomicus* corrig. Cross and Goodfellow 1973, 77.)

di.chot'o.mi.cus. Gr. adj. *dichotomos* cut in two parts, forked; L. suff. *-icus* suffix used with several meanings; N.L. neut. adj. *dichotomicus* dichotomous.

Distinctive, fast-growing yellow to orange colonies with dichotomously branched mycelium and sporophores are produced on nutrient and CYC agars at 55°C; margins are entire on CYC agar. The presence of an exosporium surrounding the spore has been suggested. Elastin, DNA, guanine, RNA, and Tween 20, 40, 60, and 80 are degraded, but not esculin, adenine, arbutin, cellulose, hippurate, keratin, or tyrosine. Growth occurs in the presence of 0.5% (w/v) NaCl,

but not in the presence of 1.0% (w/v) NaCl. L-arabinose, D-galactose, D-glucose, glycerol, D-lactose, D-maltose, D-mannitol, *meso*-inositol, D-raffinose, L-rhamnose, D-sorbitol, starch, sucrose, and D-xylose are used as sole carbon sources. Isolated from soil and mushroom compost.

DNA G+C content (mol%): 43 (HPLC).

Type strain: ATCC 49854, DSM 44778, JCM 9688, KCTC 3667, NCIMB 10211, VKM Ac-1435.

GenBank accession number (16S rRNA gene): AF138733, L16902.

*Maize-starch medium: split maize 50g, boiled in 1l water for 30min, then filtered before adding starch 10g, NaCl 5g, CaCl₂ 0.5g, peptone (Oxoid) 5g, agar 20g, pH 7.2.

Family X. Incertae Sedis

Previously assigned to the “*Paenibacillaceae*” by Garrity et al. (2005), subsequent analyses suggest that the genus *Thermicanus* represents a very deep group that is only distantly related to any

of the previously described families within the *Bacillales*. In view of its ambiguous status, it has been assigned to its own family *incertae sedis*.

Genus I. **Thermicanus** Gössner, Devereux, Ohnemüller, Acker, Stackebrandt and Drake 2000, 423^{VP} (Effective publication: Gössner, Devereux, Ohnemüller, Acker, Stackebrandt and Drake 1999, 5131.)

HAROLD L. DRAKE

Therm.i.ca'nus. Gr. adj. *thermos* hot; Gr. adj. *hikanos*; N.L. masc. adj. *icanus* capable; N.L. masc. n. *Thermicanus* the capable thermophile.

Thermophilic, chemotrophic, and facultative microaerophile. Cells are **weakly Gram-stain-positive** and **rod-shaped** (Figure 85).

DNA G+C content (mol%): 50.3.

Type species: Thermicanus aegyptius Gössner, Devereux, Ohnemüller, Acker, Stackebrandt and Drake 2000, 423^{VP} (Effective publication: Gössner, Devereux, Ohnemüller, Acker, Stackebrandt and Drake 1999, 5131.).

Further descriptive information

Members of the genus *Thermicanus* are currently represented by a single species, i.e., the type species *Thermicanus aegyptius*. *Thermicanus aegyptius* is phylogenetically distantly related to the genera *Paenibacillus*, *Oxalophagus*, *Bacillus*, and *Thermoactinomyces*. Sequence similarity of the 16S rRNA gene of *Thermicanus aegyptius* to that of its closest relative approximates 88% (Gössner et al., 1999).

Enrichment and isolation procedures

The type species, *Thermicanus aegyptius*, was isolated from soil obtained from Egypt (Gössner et al., 1999). A near pH neutral medium designed for the enrichment of acetogens was inoculated with soil and incubated at 55°C. An isolated colony obtained from an anoxic streak plate prepared from an acetogenic enrichment contained two organisms designated ET-5a (a new strain of the acetogen *Moorella thermoacetica*, DSM 12797) and ET-5b (*Thermicanus aegyptius*). *Thermicanus aegyptius* was subsequently enriched and isolated from the co-culture by selective cultivation on cellobiose under oxic conditions. The type species was derived from an isolated colony.

Maintenance procedures

The type species is easily maintained in the carbonate-buffered, yeast extract medium described by Gössner et al. (1999). Stability under long-term storage conditions has not been determined.

FIGURE 85. Transmission electron micrographs of *Thermicanus aegyptius* (DSM 12793). (top) The arrow indicates fibrillar structures in the capular domain. The large filaments are flagella. Bar = 0.3 μ m. (bottom) Hexagonal subunits of the S-layer. Bar = 0.1 μ m. (Reproduced with permission from Gössner et al.; Applied and Environmental Microbiology 65: 5124–5133, 1999, ©American Society for Microbiology.)

List of species of the genus *Thermicanus*

1. **Thermicanus aegyptius** Gössner, Devereux, Ohnemüller, Acker, Stackebrandt and Drake 2000, 423^{VP} (Effective publication: Gössner, Devereux, Ohnemüller, Acker, Stackebrandt and Drake 1999, 5131.)

ae.gyp'ti.us. L. adj. *aegyptius* Egyptian or from Egypt (to indicate the origin of the type species).

Cells are approximately 2.5 \times 0.5 μ m with an S-layer and outer and cytoplasmic membranes; nonspore-forming. Cells are flagellated and motile. Colonies on solidified media are beige. Growth is optimal at 55–60°C and

pH 6.5–7; doubling times approximate 1.5–2 h. Prefers anoxic or microaerophilic conditions. Substrates include stachyose, raffinose, maltose, sucrose, cellobiose, lactose, galactose, glucose, fructose, mannose, and xylose. Acetate, formate, and succinate are only utilized under oxic conditions. Fermentation products are acetate, succinate, ethanol, formate, lactate, and H₂; fermentation products are also formed under oxic conditions. Nitrate, sulfate, and thiosulfate are not dissimilated; Fe³⁺ is reduced to Fe²⁺ as a side reaction. Particulate and soluble fractions

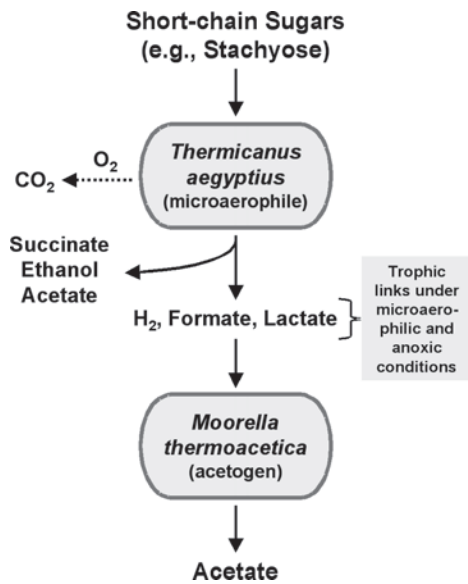

FIGURE 86. Scheme illustrating the trophic interaction of *Thermicanus aegyptius* and *Moorella thermoacetica*. (Reproduced with permission from Gössner et al.; Applied and Environmental Microbiology 65:5124–5133, 1999, ©American Society for Microbiology.)

have *b*-type cytochromes. The thermophilic acetogen *Moorella thermoacetica* ET-5a (DSM 12797) grows by symbiotic interaction with *Thermicanus aegyptius* on oligosaccharides via the commensal transfer of H₂, formate, and lactate (Figure 86).

DNA G+C content (mol%): 50.3 (HPLC).

Type strain: ET-5b, ATCC 700890, DSM 12793.

GenBank accession number (16S rRNA gene): AJ242495.

Family XI. Incertae Sedis

Previously assigned to the “*Staphylococcaceae*” by Garrity et al. (2005), subsequent analyses suggest that the genus *Gemella* is outside the radiation of this family. Moreover, *Gemella* is distinguished from the *Staphylococcaceae stricto sensu* because it is

catalase- and oxidase-negative and possesses predominantly straight-chained saturated and monounsaturated rather than branched-chain fatty acids. In view of its ambiguous status, it has been assigned to its own family *incertae sedis*.

Genus I. *Gemella* Berger, 1960, 253^{AL}

MATTHEW D. COLLINS AND ENEVOLD FALSEN

Ge.mel'la. L. n. *gemellus* a twin; N.L. fem. n. *Gemella* a little twin.

Ovoid in shape and arranged in pairs, tetrads, small clusters, and sometimes in short chains. Cells stain Gram-positive, but some strains may decolorize readily and appear Gram-negative. Nonmotile and nonsporeforming. **No growth at 10 or 45°C or in broth containing 6.5% NaCl.** Negative bile-sculin reaction. **Facultatively anaerobic. Catalase- and oxidase-negative. Gas is not produced in MRS broth. Glucose and some other carbohydrates are fermented.** Esculin, gelatin, and hippurate are not hydrolyzed. **Pyrrolidonyl arylamidase is produced by most strains.** Leucine aminopeptidase may or may not be produced. Nitrate is not reduced. **Vancomycin-sensitive.**

DNA G + C content (mol%): 30–34.

Type species: *Gemella haemolysans* (Thjøtta and Bøe, 1938) Berger, 1960, 253^{AL} (*Neisseria haemolysans* Thjøtta and Bøe 1938, 531.).

Further descriptive information

The cell walls of gemellae are of a Gram-positive type. They generally stain Gram-positive, but some decolorize easily and

give Gram-variable or Gram-negative reactions. The walls of gemellae are relatively thin (10–20 nm; Mills et al., 1984; Reyn et al., 1970) which probably accounts for their Gram-variable character. Gemellae divide in two planes, generally at right angles to each other. Cells are cocci arranged in pairs often with adjacent sides flattened, or arranged in tetrads, clusters, or short chains. Pleomorphism may be observed; elongate and rod-shaped forms occur. Morphology varies with strain and cultural conditions (Berger, 1992). Size of the cells may vary considerably; diameter varies from about 0.5 μm to more than 1 μm and “giant cells” have been observed (Berger, 1992). In *Gemella morbillorum* pleomorphism may be very pronounced; coccal forms are frequently elongate, and cells may be of unequal size. Elongate cells are generally 0.5 by 1.2 μm (Holdeman and Moore, 1974), but longer cells (up to 2–3 μm) have been reported (Berger, 1992; Prévot, 1933).

Growth of *Gemella* species is slow. Colonies are small, circular, entire, low convex, translucent to opaque, non-pigmented, smooth, and occasionally mucoid. On blood

agar media, some strains of gemellae are hemolytic (Berger, 1992). On trypticase soy sheep blood agar, most strains are α - or non-hemolytic. The expression of hemolysis can depend on the type of blood and agar base used. Wide zone (β) hemolysis may be observed with some strains, especially *Gemella haemolysans*, on blood agar bases containing rabbit blood. Examination for β -hemolysis is best performed on Mueller–Hinton agar supplemented with rabbit blood (Berger, 1992).

Gemellae are facultatively anaerobic. Some strains may require anaerobic conditions on primary isolation but become more aerotolerant after transfer to suitable media. While incubation in elevated CO₂ concentrations may stimulate growth, *Gemella haemolysans* grows better in the presence of free O₂. Strains of *Gemella morbillorum* prefer an anaerobic atmosphere. *Gemella* species are cytochrome oxidase, catalase and peroxidase-negative. The optimum growth temperature of gemellae is 35 to 37°C; all species grow over a wide range of temperatures, but none grow at 10 or 45°C. Gemellae are fermentative; acid is produced from some carbohydrates. Acid formation in carbohydrate broth, using conventional tests, can be somewhat varied with some substrates. There is sometimes poor correlation between commercially available miniaturized tests (e.g., API systems) and conventional tube methods. Glucose is degraded fermentatively by *Gemella* species. Major end products of anaerobic glucose metabolism by *Gemella haemolysans* and *Gemella morbillorum* are L-lactic and acetic acids (Brooks et al., 1971; Holdeman and Moore, 1974). Acid is produced from mannitol and sorbitol by some *Gemella* strains, but these can be variable characteristics depending on the test method. Using the API rapid ID 32Strep system, *Gemella sanguinis*, *Gemella cuniculi*, and most strains of *Gemella morbillorum* ferment these substrates whereas *Gemella haemolysans* and *Gemella palaticanis* do not. Some strains of *Gemella bergeri* produce acid from mannitol but fail to ferment sorbitol. *Gemella haemolysans*, *Gemella morbillorum*, *Gemella palaticanis*, and *Gemella sanguinis* produce acid from maltose and sucrose whereas *Gemella bergeri* and *Gemella cuniculi* do not. *Gemella palaticanis* produces acid from lactose whereas other gemellae do not. Using the same test system, none of the *Gemella* species produces acid from D-arabitol, L-arabinose, cyclodextrin, glycerol, melibiose, melezitose, methyl- β -D-glucopyranoside, pullulan, raffinose, ribose, or tagatose. Gemellae do not hydrolyze esculin, gelatin, or hippurate. They are urease-negative and do not reduce nitrate. Some species produce acid and alkaline phosphatases. Activities for both of these enzymes are detected in *Gemella cuniculi*, *Gemella hemolyticus*, and *Gemella sanguinis* using the API rapid ID 32Strep and API ZYM systems but not in the other species. All gemellae are arginine dihydrolase, α -galactosidase, β -galactosidase, β -glucuronidase, α -mannosidase, α -fucosidase, lipase C14, trypsin, N-acetyl- β -glucosaminidase, and valine arylamidase-negative.

The reported DNA G+C contents of *Gemella haemolysans*, *Gemella bergeri*, *Gemella morbillorum*, *Gemella palaticanis*, and *Gemella sanguinis* are 33.5 \pm 1.6 (Bd), 32.5 (T_m), 30 (T_m), 32 (T_m), and 31 (T_m) mol%, respectively (Collins et al., 1998a, 1998b, 1999b; Kilpper-Bälz and Schleifer, 1988). The cell-

wall murein of *Gemella morbillorum* is of the L-Lysine-Ala₁₋₃ type (Kilpper-Bälz and Schleifer, 1988).

Information on the antimicrobial susceptibilities of gemellae is somewhat fragmentary (Berger, 1992; Buu-Hoi et al., 1982). *Gemella haemolysans* and *Gemella morbillorum* are susceptible to penicillins, cephalosporins, tetracyclines, chloramphenicol, and lincomycins. *Gemella haemolysans* is also strongly inhibited by macrolide antibiotics (erythromycin, spiramycin, oleandomycin), vancomycin, ristocetin, novobiocin, and tyrothricin. Some strains are, however, resistant to erythromycin and tetracycline. *Gemella haemolysans* is resistant to sulfonamides and trimethoprim and also displays low-level resistance to aminoglycosides (streptomycin, kanamycin, gentamicin, tobramycin, amikacin, and neomycin). Synergy between penicillin G and either gentamicin or streptomycin, and between vancomycin and the aforementioned aminoglycosides is also observed (Buu-Hoi et al., 1982). The antimicrobial susceptibilities of gemellae resemble those of viridans streptococci.

Gemellae are residents of the mucous membranes of humans and some other animals (Berger, 1992). In healthy people, *Gemella haemolysans* has been found in the oral cavity and upper respiratory tract whereas *Gemella morbillorum* is, in addition, found as a component of the normal human intestinal flora (Berger, 1985, 1992; Facklam and Elliott, 1995; Holdeman and Moore, 1974). *Gemella haemolysans* and *Gemella morbillorum*, like many other commensal bacteria of the human microbiota, are opportunistic pathogens causing severe localized and generalized infection, particularly in immunocompromised patients (Durak et al., 1983; Eggelmeijer et al., 1992; Etienne et al., 1984; Mitchell and Teddy, 1985; Petit et al., 1993; Pradeep et al., 1997). *Gemella haemolysans* has been isolated from blood cultures of patients with endocarditis (Brack et al., 1991; Fressard et al., 1993; Kaufhold et al., 1989; Morea et al., 1991) and from cerebrospinal fluid (CSF) cultures of patients with meningitis (Aspevall et al., 1991; May et al., 1993; Mitchell and Teddy, 1985; Petit et al., 1993). *Gemella morbillorum* has been recovered from blood cultures of patients with endocarditis (Maxwell, 1989; Omran and Wood, 1993), from cultures of synovial fluid from septic arthritis (von Essen et al., 1993) and from CSF cultures of patients with meningitis (Debast et al., 1993). Little is known about the distribution of the more recently described *Gemella* species. Both *Gemella bergeri* and *Gemella sanguinis* have been isolated from blood cultures of persons with subacute bacterial endocarditis (Collins et al., 1998a, 1998b; Shukla et al., 2002). *Gemella palaticanis* was originally isolated from the oral cavity of a dog (Collins et al., 1999b) whereas the only known strain of *Gemella cuniculi* was recovered, in mixed culture, from a submandibular abscess of a rabbit (Hoyle et al., 2000).

Isolation procedures

Gemella species can be grown on blood agar at 37°C in air (with or without additional CO₂, 5–10%), with the exception of *Gemella morbillorum*, for which oxygen has to be excluded (Berger and Pervanidis, 1986). While incubation in elevated CO₂ concentrations stimulates the growth of gemellae, the aerotolerant *Gemella morbillorum* prefers an anaerobic atmosphere.

For recovering *Gemella haemolysans* from oropharyngeal swabs, organisms should be streaked onto blood agar, where they form smooth, nonhemolytic or α -hemolytic colonies that resemble viridans streptococci. The expression of hemolysis, an important characteristic for the presumptive identification of *Gemella haemolysans*, depends on the nature of the growth medium (choice of blood and agar base). β -Hemolysis is only consistent on Mueller–Hinton agar supplemented with 5% rabbit blood. This is the best-suited medium for the isolation of colonies suspected of being *Gemella haemolysans*. For isolating *Gemella haemolysans* from septicemic infections, freshly drawn blood can be transferred to commercially available blood culture media and incubated aerobically or anaerobically. The liquid medium generally becomes slightly turbid after 3 d of incubation after which culture fluid can be streaked onto blood (rabbit, sheep, or horse) agar plates incubated aerobically or under increased CO₂ levels. The isolation of *Gemella haemolysans* from cerebrospinal fluid (CSF) can be achieved by streaking out a small amount of CSF deposit onto blood agar (Mitchell and Teddy, 1985). *Gemella haemolysans* has also been recovered from dental plaque (see De Jong and van der Hoeven (1987) for a description of the method).

Gemella morbillorum has been isolated from a wider range of clinical sources than *Gemella haemolysans*. From swabs and pus, *Gemella morbillorum* can be isolated by plating onto blood (usually 5% defibrinated sheep blood) agar plates. Minute colonies of *Gemella morbillorum* are generally either nonhemolytic or are surrounded by a zone of α -hemolysis (greening) (Facklam, 1977; Holdeman and Moore, 1974). In *Gemella morbillorum*, hemolysis is not a constant character. Hemolysis may or may not be influenced by blood source (Berger and Pervanidis, 1986; Facklam and Wilkinson, 1981). Hemolysis may also be influenced by the strain, presence/absence of oxygen, and CO₂ levels. *Gemella morbillorum* can be recovered from dental plaque. Samples taken with a sterile curette are immediately transferred to thioglycolate broth (Difco) containing 20% beef infusion, and dilutions streaked onto Columbia blood agar incubated in an atmosphere containing H₂, CO₂, and N₂ (1:1:8; Kolenbrander and Williams, 1983). *Gemella morbillorum* has been isolated from the human intestinal tract using rumen-fluid-glucose-cellobiose agar (RGCA) used for culturing anaerobes (Holdeman et al., 1976; Holdeman and Moore, 1974). The composition of RGCA is given in the VPI Anaerobic Laboratory Manual (Holdeman and Moore, 1975).

Maintenance procedures

Gemellae grow poorly on media without serum or blood. They can be routinely maintained on a variety of agar media, such as heart infusion agar, Mueller–Hinton agar, trypticase soy agar, and Columbia agar, supplemented with blood (5–7% v/v), serum (5–10% v/v) or ascitic fluid (10% v/v). Plates can be incubated aerobically (with or without additional CO₂). Fresh isolates of *Gemella morbillorum*, which are not adapted to these conditions, should be cultured anaerobically. Heart infusion broth, brain heart infusion broth, and trypticase soy broth enriched with serum (10%

v/v) serve as suitable liquid media. *Gemella morbillorum* has been preserved in chopped meat-glucose broth at room temperature (Kannangara et al., 1981). For long-term preservation, strains can be stored on cryogenic beads at –70°C, or lyophilized.

Taxonomic comments

Thjøtta and Bøe (1938) originally isolated the bacterium, which is now referred to as *Gemella haemolysans*, from the sputum of a patient with chronic bronchitis and assigned it to the genus *Neisseria*, as *Neisseria haemolysans*. The species differed markedly from other members of the *Neisseria* genus, and Berger (1960) therefore created the monospecific genus *Gemella* to accommodate the species. Berger (1960, 1961) originally proposed *Gemella* as an aerobic, oxidase-negative, catalase-negative genus within the family *Neisseriaceae*, but later studies by Reyn et al. (1970, 1966) showed *Gemella haemolysans* possessed a Gram-positive type cell wall, and it is now known that phylogenetically the species belongs to the order *Bacillales* of the *Firmicutes* (Collins et al., 1998a, 1998b, 1999b; Ludwig et al., 1988; Reyn et al., 1970; Whitney and O'Connor, 1993). A second species, *Gemella morbillorum*, was added to the genus *Gemella* by Kilpper-Bälz and Schleifer (1988). *Gemella morbillorum* has had a checkered taxonomic history. The species was first isolated by Tunncliffe in 1917 and named "*Diplococcus rubeolae*" (Tunncliffe, 1933) but this name was withdrawn (Tunncliffe, 1936) and Prévot's epithet for the same organism, *Diplococcus morbillorum*, was adopted until the species was transferred to the genus *Peptostreptococcus*, as *Peptostreptococcus morbillorum* by Smith (1957). Holdeman and Moore (1974) considered the species to be an anaerobic to aerotolerant streptococcus, and reclassified the species as *Streptococcus morbillorum*. The species was finally transferred to the genus *Gemella* on the basis of physiological and phylogenetic evidence (Kilpper-Bälz and Schleifer, 1988), a placement confirmed by comparative 16S rRNA sequencing (Collins et al., 1998a, 1998b, 1999b; Whitney and O'Connor, 1993). In the past few years, four other new species have been assigned to the *Gemella* genus including *Gemella bergeri* and *Gemella sanguinis* from human clinical sources (Collins et al., 1998a, 1998b), *Gemella palaticanis* from the oral cavity of a dog (Collins et al., 1999b) and *Gemella cuniculi* from a rabbit (Hoyles et al., 2000). All six *Gemella* species form a robust rRNA cluster within the *Bacillales* and do not display a particularly close phylogenetic affinity with any described Gram-positive, catalase-negative genus (Collins et al., 1999b; Hoyles et al., 2000; Whitney and O'Connor, 1993).

Differentiation of the genus *Gemella* from other genera

The identification of *Gemella* species in the routine laboratory can be problematic. Gemellae grow poorly on blood agar and often take 48 h to grow. On commonly used blood agar media, gemellae form small, nonhemolytic or α -hemolytic colonies that resemble viridans streptococci. β -Hemolysis (some strains) is only evident on Mueller–Hinton agar supplemented with rabbit blood. Cellular morphology may be helpful in differentiating gemellae from streptococci. Cells of *Gemella* species may appear

TABLE 79. Characteristics distinguishing species of the genus *Gemella*^{a,b}

Characteristic	1. <i>G. haemolysans</i>	2. <i>G. bergeri</i>	3. <i>G. cuniculi</i>	4. <i>G. morbillorum</i>	5. <i>G. palaticanis</i>	6. <i>G. sanguinis</i>

^aSymbols: +, >85% positive; d, different strains give different reactions (16–84% positive); -, 0–15% positive.

^bTests performed using API Rapid ID32 Strep system except for production of PAC which is performed using API ZYM kit. Abbreviations: PAC, acid phosphatase; PAL, alkaline phosphatase; APPA, alanyl phenylalanine proline arylamidase; GTA, glycyl tryptophan arylamidase.

Gram-variable. They divide in two planes, generally at right angles to each other. Cocci are often arranged in pairs with adjacent sides flattened, or are arranged in tetrads, small clusters or short chains. Gemellae isolates fail to grow in broth containing 6.5% NaCl, fail to give a positive bile-esculin reaction, and do not grow at 10 or 45°C. Most *Gemella* strains are pyrolydonyl-arylamidase-positive, but the only known isolate of *Gemella cuniculi* is pyrolydonyl-arylamidase-negative.

Differentiation of the species of the genus *Gemella*

Numerous biochemical tests have been proposed to differentiate the various *Gemella* species, but some of these are controversial and dependent on the test method. There is sometimes poor correlation between results obtained by conventional methods and those obtained by miniaturized test systems (such as API kits). *Gemella haemolysans* can, however, usually be distinguished from *Gemella morbillorum* by producing alkaline phosphatase and by failing to produce acid from mannitol and sorbitol. Most strains of *Gemella morbillorum* are alkaline-phosphatase-negative and most pro-

duce acid from mannitol and sorbitol (Berger, 1961; Berger and Pervanidis, 1986). The reduction of nitrite is also a typical characteristic of *Gemella haemolysans* but is negative for *Gemella morbillorum* (Berger and Pervanidis, 1986). *Gemella sanguinis* and *Gemella bergeri*, also associated with human clinical sources, can be readily distinguished biochemically from each other and the aforementioned species by using the API rapid ID 32Strep system. *Gemella sanguinis* is similar to *Gemella morbillorum* in forming acid from mannitol and sorbitol but differs from the latter species in producing alkaline phosphatase. Similarly, *Gemella bergeri* differs from *Gemella haemolysans*, *Gemella morbillorum*, and *Gemella sanguinis* by failing to produce acid from maltose and sucrose (Collins et al., 1998b). It further differs from *Gemella haemolysans* and *Gemella sanguinis* by being alkaline-phosphatase-negative (Collins et al., 1998a). Biochemical tests using the commercially available API rapid ID 32Strep system, which are useful in distinguishing between the various *Gemella* species, are shown in Table 79.

All six *Gemella* species possess characteristic 16S rRNA gene sequences. 16S rRNA gene sequencing is probably the quickest and most reliable tool for identifying *Gemella* isolates to the species level.

List of species of the genus *Gemella*

- Gemella haemolysans*** (Thjøtta and Bøe 1938) Berger 1960, 253 (*Neisseria haemolysans* Thjøtta and Bøe 1938, 531.) hae.mo.ly'sans. Gr. n. *haema* blood; Gr. v. *lyo* dissolve, break up; N.L. part. adj. *haemolysans* dissolving blood.
Type strain: ATCC 10379, CCUG 37985, CIP 101126, LMG 18984, NCTC 12968.
GenBank accession number (16S rRNA gene): L14326, M58799.
- Gemella bergeri*** Collins, Hutson, Falsen, Sjøden and Facklam 1998c, 631^{VP} (Effective publication: 1998b, 1292.) ber.geri. N.L. gen. n. *bergeri* of Berger, named after Ulrich Berger in recognition of his contributions to the microbiology of gemellae.
Type strain: 617-93, ATCC 700627, CCUG 37817, CIP 105584, LMG 18983.
GenBank accession number (16S rRNA gene): Y13365.
- Gemella cuniculi*** Hoyles, Foster, Falsen and Collins 2000, 2039^{VP} cu.ni'cu.li. L. gen. masc. n. *cuniculi* of the rabbit.
Type strain: M60449/99/1, ATCC BAA-287, CCUG 42726, CIP 106481.
GenBank accession number (16S rRNA gene): AJ251987.
- Gemella morbillorum*** (Prévot 1933) Kilpper-Bälz and Schleifer 1988, 442^{VP} (*Diplococcus morbillorum* Prévot 1933, 148; *Streptococcus morbillorum* Holdeman and Moore 1974, 269.)

mor.bil'lor.um. N.L. gen. n. *morbilloorum* of measles; once considered to be associated with measles.

Type strain: Prévot 2917B, ATCC 27824, CCUG 15561, CCUG 18164, CIP 81.10, DSM 20572, LMG 18985, NCTC 11323, VPI 5424.

GenBank accession number (16S rRNA gene): L14327.

5. ***Gemella palaticanis*** Collins, Rodriguez Jovita, Foster, Sjöden and Falsen 1999b, 1525^{VP}
pa.la.ti.ca'nis. L. neut. n. *palatum* gum; L. masc. n. *canis* dog; N.L. gen. masc. n. *palaticanis* of the gum of a dog.

Type strain: M663-98-1, ATCC BAA-58, CCUG 39489, CIP 106318.

GenBank accession number (16S rRNA gene): Y17280.

6. ***Gemella sanguinis*** Collins, Hutson, Falsen, Sjöden and Facklam 1999a, 1^{VP} (Effective publication: 1998a, 3092.)
san'gui.nis. L. gen. n. *sanguinis* of the blood.
Type strain: 2045-94, ATCC 700632, CCUG 37820, CIP 105929, LMG 18986.
GenBank accession number (16S rRNA gene): Y13364.

Family XII. Incertae Sedis

Previously assigned to the *Bacillaceae* by Garrity et al. (2005), subsequent analyses suggest that the genus *Exiguobacterium* is only distantly related to this and any of the previously described

families within the *Bacillales*. Its inability to form endospores, which is a common property within the *Bacillaceae*, further supports its assignment to its own family *incertae sedis*.

Genus I. **Exiguobacterium** Collins, Lund, Farrow and Schleifer 1984, 91^{VP} (Effective publication: Collins, Lund, Farrow and Schleifer 1983, 2039.)

MATTHEW D. COLLINS

Ex.ig.uo.bac.te'ri.um. L. adj. *exiguus* short, small; L. n. *bacillus* rod; N.L. neut. n. *Exiguobacterium* small rod

Cells may be ovoid or short rods occurring singly, in pairs, or chains. Gram-stain-positive and not acid-fast. Nonspore-forming. Motile. Facultatively anaerobic and catalase-positive. No growth at 10 or 45°C. Gas is not produced. Acid is produced from D-glucose and some other sugars. The cell-wall murein is based on L-lysine. Menaquinones are the sole respiratory quinones, with menaquinone-7 predominating. Mycolic acids are not present. The long-chain cellular fatty acids consist of a mixture of straight-chain saturated, anteiso- and iso-methyl branched, and monounsaturated types. The polar lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylserine and phosphatidylethanolamine; phosphatidylinositol and unidentified phospholipids may be present. The G+C content of the DNA is 46.6–55.8 mol% (T_m).

Type species: Exiguobacterium aurantiacum Collins, Lund, Farrow and Schleifer 1984, 91^{VP} (Effective publication: Collins, Lund, Farrow and Schleifer 1983, 2040).

Further descriptive information

Cells vary in shape from short rods to coccoid forms; cells may occur singly, in pairs or in chains. Cells vary in length from about 1–4 µm; long distorted rods may be observed during exponential growth of *Exiguobacterium aurantiacum* at pH >10. Exiguobacteria are motile by means of peritrichous flagella. In cellular morphology they may somewhat resemble some coryneforms. Colonies of *Exiguobacterium aurantiacum* on PPYG agar (Gee et al., 1980) are 2–3 mm in diameter after 3 d at 25°C, and are low convex, orange, opaque, butyrous and easily emulsified. Colonies on heart infusion agar are normally flatter and fainter orange. The orange pigment does not diffuse into the medium; pigment production does not occur anaerobically. Colonies of *Exiguobacterium acetylicum* on PYE agar are flat with irregular edge and are yellow-orange in color; the pigment does not diffuse into the medium. Surface colonies of *Exiguobacte-*

rium antarcticum and *Exiguobacterium undae* on tryptone soy agar are 2–3 mm in diameter, orange in color, convex, entire, and shiny after 2 d at 25°C. The optimum growth temperature of *Exiguobacterium acetylicum* is between 25 and 30°C and for *Exiguobacterium aurantiacum* it is approximately 37°C; growth occurs at 10 and 40°C. The temperature range for growth of *Exiguobacterium aurantiacum* is from 7 to 43°C. *Exiguobacterium acetylicum* grows slowly at 5°C but not at 45°C. Neither *Exiguobacterium undae* nor *Exiguobacterium antarcticum* grow at 45°C. *Exiguobacterium aurantiacum* is alkalophilic whereas *Exiguobacterium acetylicum* is not. The pH range for growth of *Exiguobacterium aurantiacum* at 25°C is approximately 6.5–11.5, with two maxima, at pH 8.5 and 9.5 (Gee et al., 1980).

Exiguobacteria grow under aerobic and anaerobic conditions. All species are catalase-negative. *Exiguobacterium aurantiacum* is oxidase-negative whereas *Exiguobacterium acetylicum*, *Exiguobacterium antarcticum* and *Exiguobacterium undae* are oxidase-positive. All species produce acid from glucose, fructose, glycogen, β -gentiobiose, maltose, salicin, sucrose and trehalose but not from adonitol, D-arabitol, L-arabitol, D-arabinose, L-arabinose, dulcitol, erythritol, D-fucose, inositol, inulin, 2-keto-gluconate, 5-keto-gluconate, lactose, D-lyxose, melezitose, rhamnose, sorbitol, L-sorbose, D-xylose, L-xylose, D-turbinose or xylitol. All species hydrolyze casein, DNA, esculin and starch; *Exiguobacterium acetylicum*, *Exiguobacterium undae* and *Exiguobacterium antarcticum* also hydrolyzes gelatin but *Exiguobacterium aurantiacum* may or may not. None of the species hydrolyzes cellulose or Tweens 40 and 80. *Exiguobacterium aurantiacum* does not attack dextran, tributyrin, or pectin. Reports vary on the ability of *Exiguobacterium aurantiacum* to reduce nitrate (Collins et al., 1983; Fritze et al., 1990) but *Exiguobacterium acetylicum*, *Exiguobacterium undae*, and *Exiguobacterium antarcticum* do not reduce nitrate. Using API systems, both *Exiguobacterium acetylicum* and *Exiguobacterium aurantiacum* produce α -glucosidase, esterase C-4, ester lipase C8, and pyrazinamidase. Alkaline phosphatase is produced by *Exiguobacterium acetylicum* but may or may not be produced by *Exiguobacterium aurantiacum*. β -Galactosidase is detected in *Exiguobacterium acetylicum* but not in *Exiguobacterium aurantiacum*. Neither species produces acid phosphatase, chymotrypsin, trypsin, α -fucosidase, α -galactosidase, β -glucosidase, β -glucuronidase, lipase C14, leucine arylamidase, α -mannosidase, N-acetyl- β -glucosaminidase, pyrrolydonyl arylamidase, valine arylamidase, or urease.

The cell-wall murein of *Exiguobacterium aurantiacum*, *Exiguobacterium undae*, and *Exiguobacterium antarcticum* is type L-lysine-glycine (Collins et al., 1983; Fruhling et al., 2002) whereas that of *Exiguobacterium acetylicum* is reported to be type L-lysine-D-aspartic acid (Schleifer and Kandler, 1972). The major polar lipids of exiguobacteria are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylserine, and phosphatidylethanolamine; phosphatidylinositol and other unidentified phospholipids may be produced but glycolipids are not present (Fruhling et al., 2002; Yamada and Komagata, 1970). It is not known how much the phospholipid composition of exiguobacteria is influenced with growth conditions such as media and pH. The fatty acids of exiguobacteria are

characterized by mixtures of straight-chain saturated, anteiso- and iso-methyl-branched chain, and monounsaturated types. Species of exiguobacteria display differences in their fatty acid profiles but there are also some quantitative differences between different reports in the literature (Collins and Kroppenstedt, 1983; Fruhling et al., 2002). The G+C content of DNA of *Exiguobacterium aurantiacum* is within the range 53.2–55.8 mol% (T_m) whereas that of the type strain of *Exiguobacterium acetylicum*, ATCC 953, is reported to be 46.6 mol% (T_m) (Yamada and Komagata, 1970). There are no data on the G+C contents of *Exiguobacterium antarcticum* or *Exiguobacterium undae*.

There is little information on susceptibilities of exiguobacteria to antimicrobial agents. The growth of *Exiguobacterium aurantiacum* is inhibited by chloramphenicol (10 μ g per disc), erythromycin (10 μ g per disc), novobiocin (5 μ g per disc), oleandomycin (5 μ g per disc), penicillin (1 μ g per disc) and tetracycline (10 μ g per disc) but not by sulfafurazole (100 μ g per disc) (Gee et al., 1980).

Exiguobacterium aurantiacum was isolated from potato-processing effluent (Gee et al., 1980) whereas the type strain of *Exiguobacterium acetylicum*, ATCC 953, was recovered from creamery waste (Levine and Soppeland, 1926). *Exiguobacterium undae* has been isolated from garden pond water in Germany whereas *Exiguobacterium antarcticum* has been recovered from a microbial mat from Lake Fryxell, Antarctica (Fruhling et al., 2002).

Isolation procedures

Exiguobacterium aurantiacum has been recovered from potato-processing effluent by enrichment in PPYG medium (composition g/l: peptone (Difco), 5; yeast extract (Difco), 1.5; glucose, 5; $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$, 1.5; NaCl, 1.5; $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ 0.1; Na_2CO_3 , 5.03. Solutions of glucose and Na_2CO_3 are sterilized separately by autoclaving; final pH of medium 10.5–11.0) at 20°C followed by plating on PPYG agar (Gee et al., 1980) (Gee et al., 1980). *Exiguobacterium undae* has been isolated from water by streaking onto GS medium (composition g/l: glucose, 0.15; yeast extract, 1.0; $(\text{NH}_4)_2\text{SO}_4$, 0.5; CaCO_3 , 0.1; $\text{Ca}(\text{NO}_3)_2$, 0.1; KCl, 0.05; K_2PO_4 , 0.05; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.05; $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$, 0.2; 10 ml of vitamin cocktail; GS medium no. 851 DSMZ, 1998) (DSMZ, 1998). Isolated colonies developing after 2 days at room temperature were purified on tryptone soy agar (Difco) (Fruhling et al., 2002). *Exiguobacterium antarcticum* has been retrieved from anaerobic enrichments from a microbial mat from an Antarctic Lake (see Brambilla et al., (2001) for details of the methods used).

Maintenance procedures

Exiguobacteria grow well on ordinary laboratory growth media such as nutrient agar, tryptone soy agar, or heart infusion agar at 30–37°C. The pH of the medium should be adjusted to about 8.5 for *Exiguobacterium aurantiacum* as this species prefers alkaline conditions. For long-term preservation, strains can be stored on cryogenic beads at –70°C or lyophilized.

Taxonomic comments

The genus *Exiguobacterium* was created in 1983 (Collins et al., 1983) to accommodate an alkalophilic bacterium originally isolated from potato-processing effluent by (Gee et al., 1980). The genus originally contained a single species, *Exiguobacterium aurantiacum*. This species showed some morphological similarities with some coryneform bacteria but chemotaxonomic investigations, most notably G+C, murein and menaquinone determinations, indicated a closer affinity to some low-G+C-content taxa, such as *Bacillus pasteurii*, *Bacillus sphaericus*, and *Kurthia* (Collins et al., 1983). *Exiguobacterium acetylicum* was assigned to the genus *Exiguobacterium* by Farrow et al. (1994). This species was originally isolated by Levine and Soppeland (1926) from skimmed milk and designated "*Flavobacterium acetylicum*". The species was subsequently classified in the genus *Brevibacterium* by Breed (1957). Chemotaxonomic studies by Collins and Kroppenstedt (1983) however revealed that the type strain of the species was incompatible with the genus *Brevibacterium*, and a very close chemical similarity with *Exiguobacterium* became apparent. The affinity between *Brevibacterium acetylicum* and *Exiguobacterium aurantiacum* was unequivocally demonstrated by comparative 16S rRNA sequencing (Farrow et al., 1994), with the two species forming a distinct phylogenetic group within the overall radiation of genera associated with *Bacillus* (including genera such as *Kurthia* and *Planococcus*). Although *Exiguobacterium aurantiacum* differed markedly from *Exiguobacterium acetylicum* in being alkalophilic, the two species display only about 5.5% 16S rRNA sequence divergence, and treeing analysis shows their association is statistically significant (Farrow et al., 1994). Recently two further species, *Exiguobacterium undae* and *Exiguobacterium antarcticum*, were assigned to the genus by (Fruhling et al., 2002). Phylogenetically *Exiguobacterium*

undae and *Exiguobacterium antarcticum* are more closely related to each other than to *Exiguobacterium acetylicum* or *Exiguobacterium aurantiacum*. The former two species show about 2.1–2.8% 16S rRNA gene sequence divergence to *Exiguobacterium acetylicum* and about 6.2–6.7% divergence to *Exiguobacterium aurantiacum*.

Differentiation of the genus *Exiguobacterium* from other genera

Traits which are useful in differentiating exiguobacteria from closely related genera include their rod-shaped morphology, motility, peritrichous flagellation, absence of endospores, facultatively anaerobic nature, and catalase- and oxidase-positive reactions. Useful chemical characteristics include presence of a cell-wall murein based on L-Lysine, MK-7 as the major respiratory quinone, long-chain fatty acids of the straight-chain saturated, iso- and anteiso- methyl-branched and monounsaturated types, phospholipids comprising diphosphatidylglycerol, phosphatidylglycerol, phosphatidylserine, and phosphatidylethanolamine (also phosphatidylinositol and other unidentified phospholipids may be produced) and a G+C range of approximately 46–56 mol%.

Differentiation of the species of the genus *Exiguobacterium*

Available comparative biochemical data on the different *Exiguobacterium* species is currently based on the analysis of relatively few strains (in some cases single strains). Although there are numerous tests which "potentially" serve to distinguish between species, until a larger number of strains of each species are examined, it is difficult to assess how reliable, if at all, these reported differential tests are. Tests

which appear to be useful in distinguishing *Exiguobacterium* species in the literature, using the API 50CHE system, are shown in Table 80. *Exiguobacterium* species are also pur-

ported to be distinguished from each other by using the Biolog GP Microplate system (see Table 81 and Frühling et al., 2002).

List of species of the genus *Exiguobacterium*

1. ***Exiguobacterium aurantiacum*** Collins, Lund, Farrow and Schleifer 1984, 91^{VP} (Effective publication: Collins, Lund, Farrow and Schleifer 1984, 2040.)
au.ran.ti'ac.um. L. neut. n. *aurum* gold; N.L. neut. n. *aurantiacum* generic name of the orange; N.L. neut. adj. *aurantiacum* orange-colored.
DNA G+C content (mol%): 53.2–55.8 (T_m).
Type strain: ATCC 35652, BL 77/1, CIP 103353, NCIMB 11798, DSM 6208, CCUG 44910, NBRC 14763, NCDO 2321, 1005, IMET 11072.
GenBank accession number (16S rRNA gene): X70316.
2. ***Exiguobacterium acetylicum*** (Levine and Soppeland 1926) Farrow, Wallbanks and Collins 1994, 81^{VP} (Levine and Soppeland 1926, 46.)
a.ce.ty'li.cum. L. neut. n. *acetum* vinegar; N.L. neut. n. *acetylum* the organic radical acetyl; N.L. adj. *acetylicus* pertaining to acetyl.
DNA G+C content (mol%): 46.6 (T_m).
Type strain: ATCC 953, CCUG 32630, DSM 20416, NCIMB 9889, CIP 82.109, HAMBI 2009, NBRC 12146, JCM 1968.
GenBank accession number (16S rRNA gene) for strain C/C-aer/b: X70313.
3. ***Exiguobacterium antarcticum*** Frühling, Schumann, Hippe, Sträubler and Stackebrandt 2002, 1175^{VP}
ant.arc'ti.cum. N.L. gen. n. *antarcticum* of Antarctica.
DNA G+C content (mol%): not reported.
Type strain: H2, CIP 107163, DSM 14480.
GenBank accession number (16S rRNA gene): AJ297437.
4. ***Exiguobacterium undae*** Frühling, Schumann, Hippe, Sträubler and Stackebrandt 2002, 1173^{VP}
un'dae. L. fem. n. *unda* water; L. gen. n. *undae* of the water.
DNA G+C content (mol%): not reported.
Type strain: L2, CIP 107162, DSM 14481.
GenBank accession number (16S rRNA gene): AJ344151.
Editorial note: Since this chapter was accepted for publication, eight more species have been described. They are:

Exiguobacterium aestuarii (Kim et al., 2005), *Exiguobacterium artemiae* (Lopez-Cortes et al., 2006), *Exiguobacterium indicum* (Chaturvedi and Shivaji, 2006), *Exiguobacterium marinum* (Kim et al., 2005), *Exiguobacterium mexicanum* (Lopez-Cortes et al., 2006), *Exiguobacterium oxidotolerans* (Yumoto

et al., 2004), *Exiguobacterium profundum* (Crapart et al., 2007), and *Exiguobacterium sibiricum* (Rodrigues et al., 2006).

Order II. **Lactobacillales** ord. nov.

WOLFGANG LUDWIG, KARL-HEINZ SCHLEIFER AND WILLIAM B. WHITMAN

Lac.to.ba.cil.la'les. N.L. masc. n. *Lactobacillus* type genus of the order; suff. -ales ending to denote an order; N.L. fem. pl. n. *Lactobacillales* the *Lactobacillus* order.

The order *Lactobacillales* is circumscribed for this volume on the basis of the phylogenetic analyses of the 16S rRNA sequences and includes the family *Lactobacillaceae* and its close relatives “*Aerococcaceae*”, “*Carnobacteriaceae*”, “*Enterococcaceae*”, “*Leuconos-*

tocaceae”, and *Streptococcaceae*. It is composed of Gram-stain-positive rods and cocci. Endospores are not formed. Usually facultatively anaerobic and catalase-negative.

Type genus: **Lactobacillus** Beijerinck 1901, 212^{AL}.

Lac.to.ba.cil.la'ce.ae. N.L. masc. n. *Lactobacillus* type genus of the family; suff. -aceae ending denoting family; N.L. fem. pl. n. *Lactobacillaceae* the *Lactobacillus* family.

The family *Lactobacillaceae* is circumscribed on the basis of phylogenetic analyses of the 16S rRNA gene sequences and includes the genera *Lactobacillus*, *Paralactobacillus* and *Pediococcus*.

Cells vary from long and slender, sometimes bent rods to short coryneform coccobacilli or spherical cells. Chain formation common; with the exception of pediococci which form pairs or tetrads. Nonsporeforming, Gram-positive, fermentative metabolism, obligately saccharo-clastic. At least half of

the end product carbon is lactate. Additional products may be acetate, ethanol, CO₂, formate, or succinate. Oxidase- and cytochrome-negative. Catalase usually negative, although some strains may produce pseudocatalase. Complex nutritional requirements for amino acids, peptides, nucleic acid derivatives, vitamins, salts, fatty acids or fatty acid esters, and fermentable carbohydrates.

Type genus: Lactobacillus Beijerinck 1901, 212^{AL}.

Genus I. **Lactobacillus** Beijerinck 1901, 212^{AL}

WALTER P. HAMMES AND CHRISTIAN HERTEL

Lac.to.ba.cil'lus. L. n. *lac*, *lactis* milk; L. n. *bacillus* a rod; N.L. masc. n. *Lactobacillus* milk rodlet.

Cells vary from **long and slender, sometimes bent rods to short, often coryneform coccobacilli**; chain formation common. **Motility** uncommon; when present, by peritrichous flagella. **Nonspore-forming. Gram-stain-positive.** Some strains exhibit bipolar bodies, internal granulations, or a barred appearance with the Gram-reaction or methylene blue stain.

Fermentative metabolism; obligately saccharoclastic. At least half of **end product** carbon is **lactate**. Lactate is usually not fermented. Additional products may be acetate, ethanol, CO₂, formate, or succinate.

Facultatively anaerobic; surface growth on solid media generally enhanced by anaerobiosis or reduced oxygen pressure and 5–10% CO₂. Strictly aerobic conditions are commonly growth inhibitory; some are anaerobes on isolation.

Nitrate reduction unusual; if present, only when terminal pH is poised above 6.0 and/or heme is added to the growth medium. **Gelatin not liquefied.** Casein not digested, but small amounts of soluble nitrogen produced by most strains. Indole and H₂S not produced.

Catalase and cytochrome negative (porphyrins absent), however, a few strains in several species decompose peroxide by a pseudocatalase or by true catalase when heme is present. Benzidine reaction negative.

Pigment production rare; if present, yellow or orange to rust or brick red.

Complex nutritional requirements for amino acids, peptides, nucleic acid derivatives, vitamins, salts, fatty acids or fatty acid esters, and fermentable carbohydrates. Nutritional requirements are generally characteristic for each species, often particular strains only.

Growth temperature range 2–53°C, optimum generally 30–40°C.

Aciduric, optimal pH usually 5.5–6.2; growth generally occurs at pH 5.0 or less; the growth rate is often reduced in neutral or initially alkaline conditions.

Found in dairy products, grain products, meat and fish products, beer, wine, fruits and fruit juices, pickled vegetables, mash, sauerkraut, silage, sourdough, water, soil, and sewage; they are a part of the normal flora in the mouth, intestinal tract, and vagina of humans and many animals. Pathogenicity is absent or, in rare cases, restricted to persons with an underlying disease.

DNA G+C content (mol%): 32–55 (Bd, T_m).

Type species: Lactobacillus delbrueckii (Leichmann 1896b) Beijerinck 1901, 229^{AL} (*Bacillus Delbrücki* (*sic*) Leichmann 1896b, 284.

Further descriptive information

Introductory remarks. In the previous edition of *Bergey's Manual* (Sneath et al., 1986), only 44 *Lactobacillus* species were listed. Subsequently, the genus *Weissella* was created from a group of heterofermentative species (Collins et al., 1993) and three species were no longer included in the genus *Lactobacillus* (*Lactobacillus vitulinus*, *Lactobacillus maltaromicus*, *Lactobacillus bavaricus*). At a rate of six species *per annum*, the number of new *Lactobacillus* species grew up during the last 10 years to the present number of 96 species and 16 subspecies. The character of the species description has changed in so far as morphological, physiological, and biochemical properties became reduced, and more genotypic data, especially sequences of the 16S rRNA genes, have been used to support the species rank of new isolates. Therefore, genotypic characteristics will increasingly be needed to allot an isolate to one of the newly described (and often not known for long) species. In addition, in several cases only a single isolate was obtained and simple properties have only a limited value for correct identification. To facilitate access to the species of the genus, the *Lactobacillus* species are listed in Table 82. Each species is classified as belonging to one of three fermentation-type groups (A, B, or C, see below), the habitat or origin of the isolates is indicated, and the phylogenetic group is given.

^aAbbreviations: A, obligately homofermentative; B, facultatively heterofermentative; C, obligately heterofermentative.

^bD, food associated, usually involved in spoilage; F, involved in fermentation of food and feed; I, associated with humans and/or animals, e.g., oral cavity, intestines, vagina; S, sewage; (P), recovered from diseased parrot, safe status not known.

^cDetermined by C. Hertel, unpublished results. de, *Lactobacillus delbrueckii* group; re, *Lactobacillus reuteri* group; sl, *Lactobacillus salivarius* group; u, unique. To relate species to phylogenetic groups, sequences of species have been considered for which at least 90% of the complete 16S rDNA sequences have been published. These species were considered for construction of the phylogenetic trees (Figure 90, Figure 91, and Figure 92).

Cell morphology. The variability of lactobacilli from long, straight, or slightly crescent rods to coryneform coccobacilli is depicted in Figure 87. The length of the rods and the degree of curvature depends on the age of the culture, the composition of the medium (e.g., availability of oleic acid esters) (Jacques et al., 1980), and the oxygen tension. However, the main morphological differences between the species usually remain clearly recognizable. Some species of the gas-producing lactobacilli

(e.g., *Lactobacillus fermentum*, *Lactobacillus brevis*) always exhibit a mixture of long and short rods (Figure 87E).

Cell division occurs only in one plane. The tendency toward chain formation varies between species and even strains. It depends on the growth phase and the pH of the medium (Rhee and Pack, 1980). The asymmetrical development of cells during cell division in coryneform lactobacilli (Figure 88) leads to wrinkled chains or even ring formation. Irregular involution forms

FIGURE 87. Phase contrast (A–E) and electron (F) micrographs showing different cell morphology of lactobacilli: A, *Lactobacillus gasseri*; B, *Lactobacillus agilis*; C, *Lactobacillus curvartus*; D, *Lactobacillus minor*; E, *Lactobacillus fermentum*; and F, involuption form of lactobacilli in a thin section of a kefir grain.

FIGURE 88. Electron micrograph of a dividing cell of *Lactobacillus coryniformis* showing asymmetric growth (m, mesosome; n, nucleoid).

may be observed under symbiotic growth, e.g., in kefir grains (Figure 87F) or under the influence of high concentrations of glycine, D-amino acids, or cell wall-active antibiotics (Hammes et al., 1973; Schleifer et al., 1976). Motility by peritrichous flagellation is observed in only a few species. It is highly dependent on the medium and the age of the culture and is sometimes observed only during isolation, but lost after several transfers on artificial media.

All lactobacilli stain clearly Gram-stain-positive. Dying cells may give variable results. Internal granulation is often revealed by Gram or methylene blue stain especially in the homofermentative long rods. The large bipolar bodies probably contain polyphosphate and appear very electron-dense in electron microscopy.

Cell wall and fine structure. Electron micrographs of thin sections reveal a typical Gram-stain-positive cell wall profile (Figure 88 and Figure 89). The cell wall contains peptidoglycan (murein) of various chemotypes of the cross-linkage group A. The Lys-D-Asp type is the most widespread peptidoglycan type (Schleifer and Kandler, 1972) (some species have the Orn-D-Asp type), followed by the *meso*-Dpm-direct type. The species *Lactobacillus sanfranciscensis* and *Lactobacillus rossiae* are unique as they possess the Lys-Ala and Lys-Ser-Ala₂ types, respectively. The cell wall also contains polysaccharides attached to peptidoglycan by phosphodiester bonds (Knox and Hall, 1964). Membrane-bound teichoic acid is present in all species (Archibald and Baddiley, 1966); cell wall-bound teichoic acid is present only in some of the species (Coyette and Ghuyssen, 1970; Knox and Wicken, 1973).

S-Layers that have been detected in the group of lactic acid bacteria were found exclusively in several species of the genus *Lactobacillus*. In these species, the proteinaceous S-layers are characterized by small size (40–60 kDa) and high predicted pI value (pH >9) (Avall-Jaaskelainen and Palva, 2005).

Extracellular polysaccharides (EPS) are formed by strains of numerous *Lactobacillus* species and can be divided into two classes of compounds: (i) extracellularly synthesized homopolysaccharides (mainly dextran, glucan, and levan) and (ii) heteropolysaccharides with and without regularly repeating units that are synthesized from nucleotide-activated precursors. Homosaccharides are mainly produced by heterofermentative

FIGURE 89. Electron micrograph of *Lactobacillus acidophilus* showing a mesosome connected with the cytoplasmic membrane.

species, especially those occurring in cereal environments, e.g., *Lactobacillus pontis*, *Lactobacillus frumenti*, *Lactobacillus sanfranciscensis*, and *Lactobacillus reuteri* (Tieking et al., 2003). The production is greatly enhanced by addition of sucrose to the medium. Heteropolysaccharides (mw 4×10^4 – 6×10^6) are produced in small amounts, usually 0.1–1.5 g/l by homofermentative and facultatively heterofermentative species (e.g., *Lactobacillus kefiranofaciens*, *Lactobacillus delbrueckii* subsp. *bulgaricus*, *Lactobacillus paracasei*, *Lactobacillus rhamnosus*, *Lactobacillus helveticus*, and *Lactobacillus sakei*) that, for example, are isolated from dairy or meat environments (De Vuyst and Degeest, 1999).

EPS-producing strains of *Lactobacillus delbrueckii* subsp. *bulgaricus* are utilized for production of dairy products such as yogurt as they positively affect the rheological properties with regard to texture, shear stability of the gel, decreased syneresis, and viscosity. The polysaccharide from *Lactobacillus kefiranofaciens* appears to constitute a matrix, so named kefir grains, acting as an ecological niche (Cheirsilp et al., 2003) for the microbial associations containing yeasts and lactobacilli. These grains are harvested and serve as inocula for kefir production. In meat products, the slime-forming potential is seen in spoiled refrigerated material.

In addition to nucleoids and ribosomes typical of all prokaryotes, electron micrographs of thin sections frequently show large mesosomes (Figure 89). They are formed by invaginations of the cytoplasmic membrane and are filled with tubuli, probably derived from secondary membrane invaginations (Schötz et al., 1965).

Colony and cultural characteristics. Colonies on agar media are usually small (2–5 mm) with entire margins, convex, smooth, glistening, and commonly opaque without pigment. In rare cases they are yellowish or reddish. A triterpeneoid carotenoid 4,4'-diaponeurosporene was identified as pigment in *Lactobacillus plantarum* (Breithaupt et al., 2001). Some species form rough colonies. Clearing zones caused by exoenzymes are usually not observed when grown on agar media containing dispersed protein or fat. However, most strains exhibit slight proteolytic activity due to cell-wall-bound or cell-wall-released proteases and peptidases (Kunji et al., 1996) and a weak lipolytic activity due to predominantly intracellular lipases. Distinct starch degradation leading to clearing zones on starch plates is only observed in a few species (e.g., *Lactobacillus amylophilus*, *Lactobacillus amylovorans*, and *Lactobacillus fermentum*). Growth in liquid media generally occurs throughout the liquid, but the

cells settle soon after growth ceases. The sediment is smooth and homogeneous, rarely granular or slimy. Aggregation of cells in culture can be mediated by factors of proteinaceous nature (Schachtsiek et al., 2004). Clumping of cells of the same strain is called autoaggregation, whereas in coaggregation, aggregates form with genetically distinct cells. Both types occur in lactobacilli, e.g., in *Lactobacillus crispatus*, *Lactobacillus gasseri*, *Lactobacillus reuteri*, and *Lactobacillus coryniformis*. Aggregation plays a role in colonization of the oral cavity and the urogenital tract as well as in genetic exchange via conjugation.

Lactobacilli do not develop characteristic odors when grown in common media. When growing in food, they produce numerous volatile compounds that contribute either to food spoilage or to the desired, pleasant aroma of fermented food. Diacetyl, acetic acid, and acetaldehyde are examples of compounds derived from carbohydrate metabolism, and H₂S, amines, carbonyl compounds, cresol, skatol, benzaldehyde, and methanethiol are derived from amino acid catabolism (Margalith, 1981; Tanous et al., 2002). Their concentration is strongly affected by the potential of the strain, the microbial coassociation, and the environmental factors such as pH, water activity, temperature, and presence of electron acceptors (e.g., oxygen, fructose).

Nutrition and growth conditions. Lactobacilli are extremely fastidious organisms, adapted to complex organic substrates. They not only require carbohydrates as energy and carbon sources, but also require nucleotides (Elli et al., 2000), amino acids, and vitamins. Although pantothenic acid and nicotinic acid are, with the exception of a few strains, required by all species, thiamine is only necessary for the growth of the heterofermentative lactobacilli. The requirements for folic acid, riboflavin, pyridoxal phosphate, and *p*-aminobenzoic acid are scattered among the various species with riboflavin being the most frequently required compound. Biotin and vitamin B₁₂ are required by only a few strains. Although the pattern of vitamin auxotrophy is considered to be characteristic of particular species (Rogosa et al., 1961), deviating strains are common (Abo-Elnaga and Kandler, 1965a; Ledesma et al., 1977). Vitamin-dependent strains are commonly used for bioassays of vitamins and are listed in the catalogues of most culture collections. The pattern of amino acid requirements also differs among species and even strains. By sequential mutagenesis, quintuple mutants of *Lactobacillus casei* were obtained which had lost their requirement for 5 amino acids (Morishita et al., 1974). However, the mutants grew significantly slower and reverted frequently to their amino-acid-dependent state when transferred back to the complete medium. Corresponding results were also obtained with four other species (Morishita et al., 1981).

These studies show that many of the nutritional requirements of lactobacilli can be the result of numerous minor defects within the genome and that much of the information encoding the various biosynthetic pathways is still present in the chromosome. On the other hand, the comparison of the complete genomes of *Lactobacillus plantarum* and *Lactobacillus johnsonii* revealed remarkable differences in the genetic endowments of these two species which are adapted to a great variety of environments and to the intestinal tract, respectively (Boekhorst et al., 2004). Although the *Lactobacillus plantarum* genome encodes 90 proteins predicted to be involved in transport and metabolism of vitamins and cofactors, the *Lactobacillus johnsonii* genome encodes only 30. In addition, 268 proteins are pre-

dicted to be involved in metabolism and transport of amino acids in *Lactobacillus plantarum*, whereas only 125 are encoded in the *Lactobacillus johnsonii* genome. *Lactobacillus plantarum* encodes the enzymes required for biosynthesis of all amino acids with the exception of leucine, isoleucine, and valine, whereas *Lactobacillus johnsonii* is predicted to be incapable of synthesizing most, if not all, of the 20 standard amino acids. A similar reduction of the genetic endowment was also found for proteins predicted to be involved in fatty acid biosynthesis and carbohydrate transport and metabolism.

The various requirements for essential nutrients are normally met when the media contain fermentable carbohydrate, peptone, and meat and yeast extracts. Supplementations with tomato juice, manganese, acetate and oleic acid esters, and especially Tween 80, are stimulatory or even essential for most species. Therefore, these compounds are included in the widely used MRS medium (De Man et al., 1960). Lactobacilli that are adapted to very particular substrates may require special growth factors. For instance, D-mevalonic acid is necessary for rice wine (sake) spoilage organisms (Tamura, 1956), and a small peptide isolated from freshly prepared yeast extract was found to be required for luxurious growth of *Lactobacillus sanfranciscensis* (Berg et al., 1981), a sourdough organism. To meet the requirement of a still unknown growth factor, some of the original substrate must be added.

Lactobacilli grow best in slightly acidic media with an initial pH of 6.4–5.4. Growth ceases commonly when pH 3.6–4.0 is reached, depending on the species and strain. Exceptions are found in isolates from fruit meshes, e.g., *Lactobacillus subcicus* grows even at pH 2.8 (Kleynmans et al., 1989). A similar pH tolerance is also found in strains of *Lactobacillus casei* and *Lactobacillus plantarum*. Lactobacilli can adapt to growth at an initial pH of 10.0 by gradually increasing the starting pH during subsequent enrichment test runs (Suhaimi et al., 1987). Although most strains are fairly aerotolerant, optimal growth is achieved under microaerophilic or anaerobic conditions. Increased CO₂ concentration (~5%) may stimulate growth.

Most lactobacilli grow best at mesophilic temperatures with an upper limit of around 40°C. Some also grow below 15°C and some strains even below 5°C. The thermophilic lactobacilli may have an upper limit of 55°C and do not grow below 15°C. Extremely thermophilic lactobacilli growing above 55°C are as yet unknown.

Metabolism. Metabolically, lactobacilli are at the threshold of anaerobic-to-aerobic life. They possess efficient carbohydrate fermentation pathways coupled with substrate level phosphorylation. A second substrate level phosphorylation site is the conversion of carbamyl phosphate to CO₂ and NH₃ the final step of arginine fermentation. However, only some of the species forming NH₃ from arginine are able to grow on arginine as the only energy source. In addition to substrate level phosphorylation, energy is generated by secondary transport systems including uniporters, proton-solute symporters, and antiporters (Konings, 2002), all contributing to the generation of a proton motive force (PMF). These systems are of special importance for cell survival under stress conditions, for example, as they occur after consumption of the carbohydrate substrate, accumulation of lactic acid, and corresponding decrease of pH. Lactobacilli, except *Lactobacillus mali* and *Lactobacillus rhamnosus*, contain no isoprenoid quinones (Collins and Jones, 1981) and

no cytochrome systems to perform oxidative phosphorylation. However, they possess flavine-containing oxidases and peroxidases to carry out the oxidation of NADH_2 with O_2 as the final electron acceptor. When nitrite is used as an electron acceptor for lactate oxidation (Wolf et al., 1990), ammonia is formed in a reaction catalyzed by a heme-dependent nitrite reductase present in *Lactobacillus plantarum* and *Lactobacillus pentosus*. In strains of *Lactobacillus delbrueckii* subsp. *lactis*, *Lactobacillus sakei*, *Lactobacillus farciminis*, *Lactobacillus brevis*, *Lactobacillus buchneri*, and *Lactobacillus suebicus*, a heme-independent enzyme is active and forms NO and N_2O as end products. Lactobacilli are also able to perform a manganese-catalyzed scavenging of superoxide (Archibald and Fridovich, 1981; Götz et al., 1980), although they are generally devoid of superoxide dismutase and usually catalase. However, superoxide dismutase activity has been described for an oxygen tolerant strain of *Lactobacillus sakei* (Amanatidou et al., 2001).

The main fermentation pathways for hexoses are the Embden-Meyerhof pathway converting 1 mol of hexose to 2 mol of lactic acid (homolactic fermentation) and the 6-phosphogluconate pathway, resulting in 1 mol CO_2 , 1 mol ethanol (or acetic acid), and 1 mol lactic acid (heterolactic fermentation). Under aerobic conditions, most strains are able to reoxidize NADH_2 with oxygen serving as the final electron acceptor, thus acetyl-CoA is not, or at least not completely, reduced to ethanol. Consequently, additional ATP is formed by substrate level phosphorylation and varying ratios of acetic acid and ethanol are found, depending on the oxygen supply.

Pyruvate, intermediately formed in both pathways, may partly undergo several alternative conversions yielding either the well-known aroma compound diacetyl and its derivatives or acetic acid (ethanol); with hexose limitation, the latter pathway may become dominant and the homolactic fermentation may be changed to a heterofermentation with acetic acid, ethanol, and formic acids as the main products (de Vries et al., 1970; Thomas et al., 1979). Even lactate may be partially oxidized and broken down to acetic acid and formate or CO_2 by various little known mechanisms (Kandler et al., 1983). The conversion of glycerol to 1,3-propanediol with glucose serving as electron donor is observed in *Lactobacillus brevis* (Schütz and Radler, 1984), *Lactobacillus buchneri*, and *Lactobacillus reuteri*. In this pathway, glycerol serves as electron acceptor and is converted to 3-hydroxypropionaldehyde. The reaction is catalyzed by a vitamin B_{12} -dependent glycerol dehydratase. Remarkably, strains of *Lactobacillus reuteri* can synthesize cobalamine and are thus vitamin B_{12} -independent (Taranto et al., 2003). *Lactobacillus reuteri* can accumulate and excrete 3-hydroxypropionaldehyde (Talarico and Dobrogosz, 1989), which has an antimicrobial potential and has become known as reuterin. Strains of *Lactobacillus buchneri* and *Lactobacillus parabuchneri* can produce 1,2-propanediol from lactate in a sequence of reactions presumably catalyzed by lactaldehyde dehydrogenase and an NAD-linked 1,2-propanediol-dependent oxidoreductase (Krooneman et al., 2002). Remarkably, *Lactobacillus diolivorans* can utilize 1,2-propanediol converting it (still hypothetically) to propionic aldehyde that becomes disproportioned to 1-propanol and propionic acid (Oude Elferink et al., 2001). The antimycotic potential of propionic acid is well established and can contribute to the stability of silage.

At the enzyme level, homo- and heterofermentative lactobacilli differ with respect to the presence or absence of FDP

aldolase or phosphoketolase. Whereas the heterofermentative lactobacilli possess phosphoketolase but no aldolase, the obligately homofermentative ones possess FDP aldolase but no phosphoketolase. They are thus unable to ferment any of the pentoses which are broken down by the heterofermenters via phosphoketolase yielding equimolar amounts of lactic acid and acetic acid. This basic rule no longer appears to be absolutely valid, as homofermentation with fructose and a fructose-inducible FDP aldolase were detected in a strain of *Lactobacillus brevis* (Saier et al., 1996). Correspondingly, fructose phosphoketolase was found in a ribose-fermenting strain of *Lactobacillus acidophilus* (Biddle and Warner, 1993). These findings have strong implications for the traditional grouping of the lactobacilli (see below). Homofermentative lactobacilli, traditionally named "Streptobacteria" (Orla-Jensen, 1919), possess an inducible phosphoketolase with pentoses acting as inducers. They are thus able to ferment pentoses upon adaption to lactic acid and acetic acid, whereas hexoses are homofermentatively metabolized. Therefore, these lactobacilli must be called facultative heterofermenters (group B; see below). The ability to ferment pentoses does not necessarily mean that the organism can grow on these carbohydrates. Because hexoses are required for biosynthesis of peptidoglycan and other building blocks, these sugars have to be synthesized from the C_5 compounds. It was shown (Westby et al., 1993) that an arabinose, xylose, and ribose fermenting strain of *Lactobacillus plantarum* does not grow on the pentoses and is devoid of fructose-1,6-diphosphatase which plays a key role in gluconeogenesis. A homolactic fermentation of pentoses was detected in an unidentified thermophilic *Lactobacillus* (Barre, 1969) and is also found in *Lactobacillus murinus* (D. Hemme, personal communication). In these organisms an as yet unknown pathway appears to exist which does not involve phosphoketolase. Such fermentations may involve the transformation of pentoses to hexoses via transaldolase and transketolase reactions followed by glycolysis (Kandler, 1983) with lactic acid being the only fermentation product.

Carbohydrates may also contribute to other reactions. Sucrose is not only a substrate for fermentation, but also for the formation of dextrans and levans (slime) catalyzed by dextran and levan sucrases, respectively (see *Cell wall and fin structure*, above). Fructose serves not only as a substrate for fermentation, but also as an electron acceptor and becomes reduced to mannitol by most heterofermentative lactobacilli. Correspondingly, glycerol is formed from triosephosphate and excreted into the medium by some heterofermentative strains and even erythritol is formed in an unspecific reaction by *Lactobacillus pontis* (Hammes et al., 1996).

Solutes such as amino acids and mono- and oligosaccharides are taken up by lactic acid bacteria by the different transport systems common to bacteria. As described by Poolman (1993, 2002), the energy-providing principles used in the translocation processes are: (i) secondary transport (e.g., PMF-driven), (ii) primary transport (e.g., ATP-driven), and (iii) group translocation (chemical modification with concomitant transport), by means of the phosphoenolpyruvate:sugar phosphotransferase system (sugar PTS). Most information on these transport systems in lactic acid bacteria have been obtained from studies with *Lactococcus lactis*, and rather little is known about these systems in lactobacilli. Oligosaccharides are split inside the cell by the respective glycosidases prior to the phosphorylation of

the resulting monosaccharides. However, at least lactose and galactose are taken up by some lactobacilli via the phosphoenolpyruvate-dependent phosphotransferase system (Chassy and Thompson, 1983). The lactose phosphate formed is split to glucose and D-galactose-6-phosphate. The latter is then metabolized via the D-tagatose-6-phosphate pathway (Kandler, 1983). The hierarchical utilization of available carbohydrates is governed by a transcriptional control mechanism that has evolved in low-G+C Gram-stain-positive bacteria including lactobacilli (Poolman, 2002; Titgemeyer and Hillen, 2002). The gene expression is regulated by the pleiotropic control protein CcpA that binds the seryl-phosphorylated form of the phosphotransferase HPr (HPr-ser-P). Operons and genes under control of this mechanism have been characterized in *Lactobacillus delbrueckii* subsp. *lactis*, *Lactobacillus casei*, *Lactobacillus plantarum*, and *Lactobacillus pentosus*. HPr-ser-P can also inhibit carbohydrate permeases and thus trigger inducer exclusion and mediate inducer expulsion. In this mechanism of carbon catabolite repression, the histidyl-phosphorylated HPr that is generally involved in transport of many carbon sources via the phosphotransferase system controls further regulatory reactions and catabolic enzymes.

Organic acids such as citric, tartaric, succinic, and malic acids, are degraded by lactobacilli. These compounds are constituents of raw plant materials used for the fermentative production of, for example, wine and cider. Citric acid is also contained in milk. The conversion of these compounds has profound effects on sensory properties. The degradation proceeds commonly via oxaloacetic acid and pyruvate to CO₂ and lactic or acetic acid (Radler, 1986; Radler and Brohl, 1984). The reactions result in a change of charges that can be used to generate metabolic energy (Konings, 2002). Malate is converted by lactobacilli to CO₂ and lactate. Detailed studies on the catalytic and regulatory properties of the DNA-dependent malic enzymes of lactic acid bacteria were performed by London et al. (1971). Alternatively, malic acid is split to CO₂ and L(+)-lactic acid in many lactobacilli by a multifunctional malolactic enzyme with all intermediates remaining tightly bound to the enzyme complex (Radler, 1975). *Lactobacillus fermentum* possesses neither the malic nor the malolactic enzyme and converts malate via fumarate to succinate (Whiting, 1975).

Several amino acids, e.g., lysine, ornithine, histidine, phenylalanine, and tyrosine, are decarboxylated and excreted by lactobacilli (Straub et al., 1995). The resulting biogenic amines are of hygienic concern, and strains used in starter cultures should lack the potential of their formation. The reaction can again be used by the lactobacilli to generate metabolic energy.

Phenolic compounds are converted in several reactions. Chlorogenic acid and *p*-coumarylquinic acid are metabolized after malic acid fermentation is completed. They are hydrolyzed and the resulting (-)-quinic acid is reduced to (-)-dehydroshikimic acid by heterofermentative lactobacilli. It is further reduced to dihydroxycyclohexane-*c*-1-carboxylic acid by homofermenters. Shikimic acid may be reduced to catechol by *Lactobacillus plantarum* which also converts *p*-coumaric acid to *p*-ethylphenol. The electron source of these reactions is lactate which becomes oxidized to CO₂ and acetic acid (Whiting, 1975). Lactobacilli isolated from whisky fermentations decarboxylate *p*-coumaric acid and/or ferulic acid with the production of 4-vinylphenol and/or 4-vinylguaiacol, respectively (van Beek and Priest, 2002). Isolates from food and from human and animal intestines possess

tannase (tannin acylhydrolase). Hydrolyzable tannins such as gallotannin and ellagitannin are widely distributed in plants and are considered effective antinutritive compounds. The activity was described for *Lactobacillus plantarum*, *Lactobacillus paraplantarum*, *Lactobacillus pentosus*, *Lactobacillus murinus*, and *Lactobacillus animalis* (Nishitani et al., 2004; Sasaki et al., 2005).

The lactic acid formed by the various fermentation pathways possesses either the L- or the D-configuration depending on the stereospecificity of the lactated dehydrogenase present in the cells. Racemate may be formed when both L- and D-lactate dehydrogenase are present in the same cell or, in rare cases, by the action of an inducible lactate racemase in combination with a constitutive L-lactate dehydrogenase (Stetter and Kandler, 1973). Lactate dehydrogenases of the various species often differ from each other considerably, e.g., with respect to their electrophoretic mobility and their kinetic properties. Most enzymes are nonallosteric, but some species contain allosteric L-lactate dehydrogenases with FDP and Mn²⁺ acting as effectors (Garvie, 1980; Hensel et al., 1977).

Phages. *Lactobacillus* phages can interfere with the performance of their hosts in fermentation processes and have been studied under this practical aspect (Hammes and Hertel, 2003). Phages inhibiting processes in the dairy field are of greatest importance and, therefore, most knowledge is available for dairy *Lactobacillus* phages, including those added to the process to achieve probiotic effects (Brussow, 2001). All *Lactobacillus* phages belong to the families *Myoviridae* and *Siphoviridae*, have double stranded DNA, and are *cos*-site or *pae*-site phages. The genome size ranges between 40 kbp (*Lactobacillus casei* phage pL1) and 133 kbp (*Lactobacillus plantarum* phage fri). Complete sequences are available for *Lactobacillus delbrueckii* subsp. *lactis*, *Lactobacillus casei*, *Lactobacillus johnsonii*, and *Lactobacillus plantarum* (Desiere et al., 2002). No sequence similarities were detected between phages infecting distinct *Lactobacillus* species. The incidence of lysogeny is very high and DNA/DNA hybridization revealed a close relatedness between the virulent and temperate phages of a species (Lahbib-Mansais et al., 1988; Mata and Ritzenthaler, 1988).

Antagonistic compounds. Lactobacilli share with other lactic acid bacteria the potential to inhibit the growth of competing micro-organisms and, thus, to prevent food spoilage and the growth of undesired micro-organisms in association with humans and animals. The primary effect of pH reduction is of major importance, but this effect is supported by formation of numerous compounds that may be produced depending on environmental factors and on the genetic endowment of a species or strain (Hammes and Tichaczek, 1994; Ouwehand, 1998). At low pH, lactic acid and acetic acid act as weakly dissociated compounds which are inhibitory per se as is the gaseous fermentation product CO₂. H₂O₂ is formed in reactions catalyzed by flavoproteins. In substrates such as milk, lactoperoxidase catalyzes a reaction that uses H₂O₂ and thiocyanate and forms hypothionite (OSCN⁻) which inhibits membrane functions (Kamau et al., 1990) and several reactions of glycolysis (Condon, 1987). The effect of H₂O₂ on Gram-stain-positive organisms is bacteriostatic, whereas it is bacteriocidal against Gram-stain-negative bacteria. Many low molecular mass compounds with antimicrobial properties are produced by lactobacilli. Reuterin, already introduced as 3-hydroxypropanal (see above), is excreted by

Lactobacillus reuteri, *Lactobacillus buchneri*, *Lactobacillus brevis*, *Lactobacillus collinoides*, and *Lactobacillus coryniformis* (Schnürer and Magnusson, 2005). It inhibits thiol enzymes and has a broad antimicrobial spectrum including fungi, protozoa, and bacteria. Pyroglutamic acid (2-pyrrolidone-5 carboxylic acid) with activity against *Bacillus subtilis*, *Panathoea agglomerans*, and *Pseudomonas* species is produced by strains of *Lactobacillus casei* (Chen and Russell, 1989; Huttunen et al., 1995), *Lactobacillus helveticus*, *Lactobacillus delbrueckii* subsp. *bulgaricus*, and *Lactobacillus delbrueckii* subsp. *lactis* (Mucchetti et al., 2002). Strains of *Lactobacillus plantarum* produce benzoic acid, methylhydantoin, mevalonolactone, and cyclo (glycyl-L-leucyl). The producer strain inhibits *Panathoea agglomerans* and *Fusarium avenaceum*, and the single compounds each exhibit a fraction of the total effect. *Lactobacillus plantarum* MiLAB 393 produces cyclo (L-Phe-L-Pro), cyclo (L-Phe-trans-4-OH-L-Pro) and phenyl lactic acid exhibiting activity especially against molds and yeasts. The latter compound as well as 4-hydroxyphenyllactic acid appears to be a rather common product in food-fermenting lactobacilli (Valerio et al., 2004) and is especially active against molds causing spoilage of baked goods (Lavermicocca et al., 2003). *Lactobacillus reuteri* produces a tetramic acid derivative named reutericyclin (Ganzle et al., 2000). The compound is also formed in sourdough (Ganzle and Vogel, 2003) and inhibits Gram-stain-positive bacteria. Bacteriocins are proteinaceous compounds that have been divided into four classes (Klaenhammer, 1993). Class I includes lantibiotics; Class II includes small (<10 kDa), moderate (100°C) to high (121°C) heat-stable non-lanthionine-containing membrane-active peptides. Subgroups have been defined within this class: IIa are *Listeria*-active peptides with a -Y-G-IV-G-V-X-C-sequence near the amino terminus. IIb are two-peptide bacteriocins, and IIc are thiol-activated peptides. Class III are large (>30 kDa) heat-labile proteins, and Class IV contains complex bacteriocins, e.g., proteins with lipid and/or carbohydrate. Groups I and II are by far most studied for their biosynthesis, genetics regulation, and mode of action (Nes et al., 1996; Twomey et al., 2002). Lactobacilli are most often cited for production of bacteriocins and produce all four classes of bacteriocins (Klaenhammer, 1993). In general, their inhibitory spectrum is narrow and includes closely related species. Depending on environmental conditions (Ganzle et al., 1999) and type of compound, the spectrum may also include rather unrelated organisms including *Proteobacteria* and even *Archaea* (Hammes et al., 1979). Bacteriocinogenic strains have been found among homo- and heterofermentative species. Class I bacteriocins are ribosomally synthesized polypeptides that are characterized by containing ring structures introduced post-translationally by lanthionine or methylanthionine bridges. Further modifications may include presence of D-alanine, dehydroalanine, dehydroaminobutyrate, and N-terminal bound pyruvate (lactocin S) or lactate. The compounds partially interfere with membrane function by pore formation and partially inhibit cell wall synthesis by complexing with lipid II (Reisinger et al., 1980). Well studied examples of lantibiotics (Twomey et al., 2002) are plantaricin C (Turner et al., 1999), plantaricin W (Holo et al., 2001), and lactocin S (Mortvedt et al., 1991). Each compound belongs to one specific lantibiotic subgroup. Plantaricin W is a two-component bacteriocin characterized by an inherent activity of each component. Plw α and Plw β group with the mersacidin and ltnAZ compounds, respectively. Lactocin S

is produced by *Lactobacillus sakei* L 45 and constitutes a separate group. Plantaricin C is included in the lactocin 481 group.

Resistance to chemotherapeutics. Initially studies on the sensitivity or resistance pattern of lactobacilli toward antibiotics originated mainly from problems created by the presence of antibiotics in milk resulting from mastitis therapy (Sozzi and Smiley, 1980). The general increase of antibiotic resistance in pathogenic bacteria and the recognition that some *Lactobacillus* species had been involved in cases of bacteremia led to new and special interest in the sensitivity of lactobacilli to chemotherapeutics. Sensitivity testing of lactobacilli is still problematic as several species require complex media with compounds and pH conditions that interfere with the test substance. To determine antibiotic concentrations needed in plasma levels, the differentiation between minimal inhibitory concentration (MIC) and minimal bactericidal concentration (MBC) is essential. In a study (Bayer et al., 1978) of the effects of penicillin, ampicillin, clindamycin, cephalotin, cefoxitin, and metronidazol on 40 lactobacilli belonging to seven species, it was observed that the MBC:MIC ratios are high, ranging from 30:1 for cephalotin to 266:1 for ampicillin. For cefoxitin and metronidazol an achievable MIC and/or MBC were observed with 87.5–100% of the strains. In a study of 15 antibiotics with major use in veterinary practice and with 43 lactobacilli from nine species mainly of food and partially of clinical origin it has been observed (Klein, 1992) that intrinsic antibiotic resistance exists against colistin sulfate and sulfonamide. In this study, MRS medium had been used in agar diffusion and suspension tests. Thirty-one strains of *Lactobacillus delbrueckii* subsp. *bulgaricus* used in yogurt cultures had an intrinsic resistance toward mycostatin, nalidixic acid, neomycin, polymyxin B, trimethoprim, colimycin, sulfomethoxazol, and sulfonamides (Sozzi and Smiley, 1980). Intrinsic resistance exists, furthermore, for most lactobacilli against vancomycin because of the presence of D-alanine:D-alanine ligase related enzymes (Elisha and Courvalin, 1995). The acquisition of antibiotic resistance by horizontal gene transfer has become of great concern (Teuber et al., 1999). Resistance genes were located on conjugative or mobilizable plasmids and transposons in isolates from humans or animals and in food-associated lactobacilli. The evolution of antibiotic resistance is enhanced by these genetic elements, by possession of integrons and insertion elements, and by lytic and temperate phages. All elements occur in lactobacilli. Lactobacilli associated with food may become part of the intestinal association. These bacteria together with the resident lactobacilli may acquire and exchange resistance genes and contribute to their spread in human-associated bacteria. For that reason, it is necessary not to use lactobacilli that carry acquired antibiotic resistance genes in starter cultures.

Pathogenicity. Based on their numbers in human food, lactobacilli are the most important group of living micro-organisms ingested. From long-term experience, it can be concluded that lactobacilli are safe organisms. However, an increasing number of reports of cases of lactobacillemia led to some doubts on the validity of that general statement. Infections caused by lactobacilli are very rare and have been estimated to represent 0.05–0.48% of all cases of infective endocarditis and bacteremia (Gasser, 1994; Husni et al., 1997; Saxelin et al., 1996). In the vast majority of these cases an underlying disease indicated a

predisposition of the patients (Hammes and Hertel, 2003). Lactobacilli were involved in endocarditis, bloodstream infection, and local infection (Aguirre and Collins, 1993; Gasser, 1994). The most frequently isolated species were *Lactobacillus rhamnosus*, *Lactobacillus paracasei*, and *Lactobacillus plantarum*, and with lower incidence *Lactobacillus brevis*, *Lactobacillus delbrueckii*, *Lactobacillus gasseri*, *Lactobacillus jensenii*, *Lactobacillus johnsonii*, *Lactobacillus salivarius*, *Lactobacillus acidophilus*, *Lactobacillus casei*, and *Lactobacillus fermentum* were found. The correct identification of the latter three species may be questioned (see below) because of the insufficient identification methods available at the time of the early reports and, in the case of *Lactobacillus casei*, changes in nomenclature at the time of the description of *Lactobacillus paracasei* and *Lactobacillus rhamnosus* (Collins et al., 1989). All species are part of the human intestinal association. With the exception of *Lactobacillus gasseri*, *Lactobacillus jensenii*, and *Lactobacillus salivarius* they also occur in food association and are partially used in starter cultures in food fermentation or as probiotics. Thus, the clinical isolates may have originated from the indigenous body association (mouth, vagina, intestines) or from ingested food. Pathogenicity factors are unknown for lactobacilli. Their application in food should exclude any avoidable negative effect on human health. Clearly, transferable antibiotic resistance should be absent. Additional undesired properties (Hammes and Hertel, 2003) are formation of biogenic amines in food and, for short-bowl patients, the formation of D-lactic acid is a disadvantageous property, as the lactobacilli (e.g., in probiotics) may overgrow commensal bacteria and cause D-lactate acidosis (Bongaerts et al., 1997; Coronado et al., 1995). Binding to extracellular matrices (e.g., collagen) or serum proteins (e.g., fibrinogen and fibronectin) as well as aggregation of human platelets were also considered as critical properties (Anonymous, 2000). Isolates from infective endocarditis (IE) patients (five strains each of the species *Lactobacillus paracasei* and *Lactobacillus rhamnosus*) were investigated for these properties by (Harty et al., 1994). Ten control strains of the same species and various oral isolates were used as comparators. Platelets aggregated with *Lactobacillus rhamnosus* IE-isolates and half of the control strains. A positive reaction with *Lactobacillus paracasei* was observed for two out of five IE-isolates and two out of nine control strains. Platelet aggregation was also observed with oral strains of *Lactobacillus acidophilus* (1/1), *Lactobacillus salivarius* (2/3), *Lactobacillus plantarum* (3/5), and *Lactobacillus fermentum* (2/3). These results show that platelet aggregation is dispersed among lactobacilli and not a characteristic of clinical isolates. Virtually the same result was obtained in the study of the potential of the strains to bind to fibrinogen, fibronectin, and collagen. A similarly dispersed distribution was observed in preceding studies (Harty et al., 1993) in which just a significant tendency of the IE-isolates to show higher hydrophobicity, hydroxyapatite adhesion, and salivary aggregation values was observed. These results are consistent with the conclusion that a specific pathogenicity related property cannot be found in isolates from diseased persons.

Ecology, habitats, and biotechnology. Lactobacilli grow under anaerobic conditions or at least under reduced oxygen tension in all habitats providing ample carbohydrates, breakdown products of protein and nucleic acids, and vitamins. A mesophilic to slightly thermophilic temperature range is favorable. However, strains of some species (e.g., *Lactobacillus*

sakei, *Lactobacillus curvatus*, *Lactobacillus fuchuensis*, *Lactobacillus algidus*, *Lactobacillus plantarum*) grow, albeit slowly, even at temperatures close to freezing point, e.g., in refrigerated meat (Kato et al., 2000; Kitchell and Shaw, 1975; Sakala et al., 2002) and fish (Ringo and Gatesoupe, 1998; Schröder et al., 1980). Lactobacilli are, in general, aciduric or acidophilic, and decrease the pH of their substrates to below 4.0 by lactic acid formation, thus preventing, or at least severely delaying, growth of virtually all competitors except other lactic acid bacteria and yeasts. These properties make lactobacilli valuable inhabitants of the intestinal tract of humans and animals and important contributors to food technology. However, they are also potent spoilage organisms as they may affect the sensory properties through flavor, texture, color, slime, cloudiness, and formation of biogenic amines.

Several individual species have adapted to specific ecological niches and generally are not found outside their specialized habitats. The relative ease with which such species can be reisolated from their respective sources since their first discovery, sometimes almost 100 years ago, indicates that these niches are, in fact, their natural habitats, although sometimes man-made.

Plant sources. Lactobacilli occur in nature in low numbers on all plant surfaces (Keddie, 1959; Mundt and Hammer, 1968), and together with other lactic acid bacteria grow luxuriously in all decaying plant material, especially decaying fruits. Hence, lactobacilli are important for the production as well as the spoilage of fermented vegetable feed and food (e.g., silage, sauerkraut, kimchi, olives, mixed pickles) and beverages (e.g., beer, wine, juices). The chiefly isolated species include *Lactobacillus plantarum*, *Lactobacillus brevis*, *Lactobacillus coryniformis*, *Lactobacillus paracasei*, *Lactobacillus curvatus*, *Lactobacillus sakei*, and *Lactobacillus fermentum* (Carr et al., 1975; Hammes and Hertel, 2003; Kandler, 1984; Sharpe, 1981).

Fermented products from plants can be grouped according to the nature of the fermentation substrates. Starchy substrates are cereals (Hammes et al., 2005), potatoes, and cassava; products of their fermentation are, e.g., sourdough, beer, spirits, cassava sour starch, and fufu. Roughly 30 *Lactobacillus* species have been isolated from sourdough, including highly adapted species described recently, *Lactobacillus sanfranciscensis*, *Lactobacillus pontis*, *Lactobacillus panis*, *Lactobacillus mindensis*, *Lactobacillus hammesii*, *Lactobacillus acidifarinae*, *Lactobacillus spicheri*, *Lactobacillus paralimentarius*, and *Lactobacillus frumenti* (De Vuyst and Neysens, 2005; Ehrmann and Vogel, 2005). In addition, species also common in other substrates occur, e.g., *Lactobacillus plantarum*, *Lactobacillus reuteri*, *Lactobacillus fermentum*, *Lactobacillus delbrueckii*, *Lactobacillus fructivorans*, *Lactobacillus alimentarius*, *Lactobacillus parabuchneri*, *Lactobacillus faeciminis*, *Lactobacillus brevis*, *Lactobacillus reuteri*, *Lactobacillus homohiochii*, *Lactobacillus hilgardii*, and *Lactobacillus amylovorus*, and, remarkably, species that are known as inhabitants of the human and/or animal tract, such as *Lactobacillus gasseri*, *Lactobacillus amylovorus*, *Lactobacillus pontis*, *Lactobacillus sakei*, *Lactobacillus delbrueckii* subsp. *lactis*, *Lactobacillus murinus*, *Lactobacillus acidophilus*, *Lactobacillus reuteri*, *Lactobacillus johnsonii*, and *Lactobacillus mucosae*. These lactobacilli often occur together with *Weissella* species, pediococci, leuconostocs, and yeasts (Hammes et al., 2005). The composition of the association is governed by the technology of dough preparation (Ganzle et al., 1998). Traditionally propagated doughs contain mainly 2–3 obligately heterofermentative species (*Lactobacillus sanfranciscensis*, *Lactobacillus pontis*, and *Lactobacillus mindensis*).

In beer, lactobacilli are the most important agents of spoilage. Adapted species tolerate ethanol (commonly 4–5%), pH values of 3.8–4.7, high CO₂ concentration, and bitter hops compounds (Sakamoto and Konings, 2003). The following species have been identified in spoiled beer: *Lactobacillus brevis*, *Lactobacillus buchneri*, *Lactobacillus paracasei*, *Lactobacillus coryniformis*, *Lactobacillus curvatus*, *Lactobacillus lindneri*, *Lactobacillus malefermentans*, *Lactobacillus parabuchneri*, *Lactobacillus plantarum*, *Lactobacillus paraplantarum*, *Lactobacillus paracollinoides*, and *Lactobacillus collinoides*. The common hop sensitivity of Gram-stain-positive bacteria is overcome by lactobacilli, e.g., *Lactobacillus brevis*, by active extrusion of the drug mediated by a (multi) drug resistance pump located in the cytoplasmic membrane (Sakamoto et al., 2001). This mechanism is supported by the ability of the resistant strains to maintain a larger Δ pH (Simpson and Fernandez, 1994) and to create an ATP pool that is larger than in hop-sensitive strains. In lactic-acid containing beer, such as the Belgian Rodenbach or Gueuze beer, the Berliner Weisse beer, the Russian kwass (Verachtert and Iserentant, 1995), and maheu (bantu beer), less hops are commonly used and lactobacilli contribute to the acid taste of the alcoholic drinks. In the case of maheu, the thermophilic *Lactobacillus delbrueckii* subsp. *delbrueckii*, which was first isolated from potato and grain mashes fermented at 40–55°C, is used (Henneberg, 1903). The organism is also used for production of lactic acid (Buchta, 1983).

In whisky production, the wort is not boiled before yeasts start the alcoholic fermentation and therefore, lactobacilli can grow and are considered to contribute favorably to the flavor (Pedersen et al., 2004; van Beek and Priest, 2002). The following species have been found in the fermenting whisky wort: *Lactobacillus plantarum*, *Lactobacillus fermentum*, *Lactobacillus brevis*, *Lactobacillus paracasei*, *Lactobacillus mucosae*, *Lactobacillus ferintoshensis*, *Lactobacillus sanfranciscensis*-like bacteria, and *Lactobacillus suntoreus* (Cachat and Priest, 2005).

In the seed mash of sake fermentation (moto), *Lactobacillus sakei* and *Lactobacillus plantarum* have been described as acidifying lactobacilli (Kitahara et al., 1957), and *Lactobacillus homohiochii*, *Lactobacillus fermentum*, *Lactobacillus plantarum*, and *Lactobacillus fructivorans* were found in spoiled sake (hiochi) (Katagiri et al., 1934). *Lactobacillus satsumensis* was found in the mash of shochu, a traditional distilled Japanese spirit (Endo and Okada, 2005).

The second group of fermented plant products is raw material containing soluble carbohydrates such as vegetables and fruits for food fermentation, and grass, clover, maize, etc. for silage production. The fermentation processes are commonly not controlled by starter cultures and are characterized by successions in the microbial associations involved. An example is the fermentation of cabbage to produce sauerkraut (Hammes and Hertel, 2003; Pedersen, 1979; Splittstoesser et al., 1975; Stamer, 1975). In an initial phase, for 5 d *Leuconostoc mesenteroides* represents approximately 90% of the lactic acid bacteria involved and *Lactobacillus sakei*, *Lactobacillus curvatus*, *Lactobacillus plantarum* and *Lactobacillus brevis* are found within the remaining 10%. Thereafter “betabacteria” evolve (mainly *Lactobacillus brevis* and *Lactobacillus buchneri*), and finally homofermenters dominate (mainly *Lactobacillus plantarum*, *Lactobacillus curvatus*, and *Lactobacillus sakei*). Similar successions occur in the Korean kimchi, made from Chinese cabbage, radish, cucumber, onion, garlic,

pepper, etc. *Lactobacillus kimchii* was isolated from fermenting kimchi (Yoon et al., 2000).

Successions occur also in fermenting silage (Hammes and Hertel, 2003). In silage made from grass and red clover, pediococci, *Lactobacillus plantarum*, and *Lactobacillus graminis* became dominant after an initial phase characterized by the presence of leuconostocs and “*Lactobacillus coprophilus*” (Beck et al., 1987).

In wine, lactobacilli have to tolerate high levels of alcohol (e.g., up to 15–22% in desert wines), low pH (3.0–4.0), and the presence of SO₂. In addition to *Oenococcus oeni*, pediococci, and leuconostocs, the following lactobacilli have been isolated from wine at the various production stages: *Lactobacillus brevis*, *Lactobacillus hilgardii*, *Lactobacillus plantarum*, *Lactobacillus fermentum*, *Lactobacillus buchneri*, *Lactobacillus fructivorans*, *Lactobacillus mali*, *Lactobacillus jensenii*, *Lactobacillus kunkeei*, and *Lactobacillus nagelii* (Edwards et al., 2000). The latter two species have been shown to slow down alcoholic fermentation of grape musts and to be responsible for sluggish or stuck alcohol fermentation which is a well-known problem in wine making (Edwards et al., 2000; Edwards et al., 1998). The presence of the lactobacilli is undesirable because they may affect the flavor and cause cloudiness. *Lactobacillus fructivorans* and *Lactobacillus hilgardii* can even spoil fortified wines (Lonvaud-Funel, 1999). They may also form biogenic amines as shown for *Lactobacillus hilgardii* (Farias et al., 1993) and *Lactobacillus buchneri* (Liu et al., 1994). Heterofermentative lactobacilli, e.g., *Lactobacillus buchneri*, may also produce the ethylcarbamate precursor (carbamyolphosphate) from arginine. The lactobacilli association in wine is characterized by population successions and preferential growth at the end of malolactic fermentation which is desirably performed by *Oenococcus oeni*.

Lactobacillus hilgardii and *Lactobacillus fructivorans* (Fornachon et al., 1949) are typical organisms of acidic and alcoholic beverages; *Lactobacillus collinoides* (Carr and Davies, 1972) and *Lactobacillus mali* (Carr and Davies, 1970; Carr et al., 1977) are found in cider and other fruit juices. Fruit mashes for production of fruit brandy may be acidified with sulfuric acid to achieve pH values <3.0. Highly acid-resistant lactobacilli were isolated from mashes that had sometimes been stored for a year (Heinzl and Hammes, 1986). Strains of *Lactobacillus plantarum* and *Lactobacillus suebicus* grow at pH 2.5 in the presence of 12 and 14% ethanol, respectively. *Lactobacillus brevis* and *Lactobacillus hilgardii* are additional species that are found in numbers of >10⁶ c.f.u./ml.

Milk and dairy products. Milk contains no lactobacilli when it leaves the udder, but is very easily contaminated with lactobacilli by dust, dairy utensils, etc. Because streptococci grow faster, the number of lactobacilli usually remains fairly low even in spontaneously soured milk. Only after prolonged incubation do lactobacilli take over because of their higher acid tolerance. In sour whey, the most acid-tolerant and thus typical species is *Lactobacillus helveticus* which produces as much as 3% lactic acid. It is traditionally used in starters for the production of Swiss cheese and other types of hard cheeses, e.g., Grana, Gorgonzola, and Parmesan (Bottazzi et al., 1973). Nowadays, *Lactobacillus delbrueckii* subsp. *bulgaricus* and subsp. *lactis* are also used (Auclair and Accolas, 1983; Biede et al., 1976; Teuber, 2000). Artisanal starter cultures are still in use, in Italy and Switzerland, for example. In addition to enterococci, these contain, *Streptococcus thermophilus*, lactococci, *Lactobacillus fermentum*,

Lactobacillus salivarius, *Lactobacillus helveticus*, and *Lactobacillus delbrueckii* subsp. *lactis*. In all types of cheese with ripening periods longer than about 14 d, several mesophilic lactobacilli (*Lactobacillus plantarum*, *Lactobacillus brevis*, *Lactobacillus casei*, etc.) originating from the milk or the dairy environment reach levels as high as 10^6 – 10^8 c.f.u./g cheese (Abo-Elnaga and Kandler, 1965b; Sharpe, 1962; Van Kerken and Kandler, 1966). *Lactobacillus cypricasei* has been isolated from Halloumi cheese, a semi-hard cheese of Cyprus (Lawson et al., 2001a).

Lactobacilli that are very specifically adapted for the production of sour milks include *Lactobacillus delbrueckii* subsp. *bulgaricus* and subsp. *indicus* which are components present in the yogurt and Indian dahi flora, respectively (Davis, 1975; Dellaglio et al., 2005) and also *Lactobacillus kefir* and *Lactobacillus parakefir* (Kandler and Kunath, 1983; Takizawa et al., 1994) as well as *Lactobacillus kefiranoferens* subsp. *kefiranoferens* and subsp. *kefirgranum* (Fujisawa et al., 1988; Vancanneyt et al., 2004) which are the heterofermentative and homofermentative components, respectively, of the Caucasian sour milk kefir. These two sour milks are the only known habitats of these lactobacilli.

Several species of lactobacilli may contribute to spoilage of dairy products by slime or gas production. The formation of biogenic amines by *Lactobacillus buchneri*, for example, is of hygienic concern, and *Lactobacillus bifementans* has been found to cause the blowing of Edam cheese (Pette and van Beynum, 1943).

Meat and meat products. Lactobacilli play an important role in fermented sausages. The most common naturally occurring species found in ripening raw sausages are *Lactobacillus sakei*, *Lactobacillus curvatus*, and with minor incidence, *Lactobacillus versmoldensis*, *Lactobacillus plantarum*, *Lactobacillus brevis*, *Lactobacillus farciminis*, *Lactobacillus alimentarius*, *Weissella* species, pediococci, and leuconostocs (Hammes et al., 1990; Krockel et al., 2003). Because meat does not contain appreciable amounts of fermentable carbohydrates, glucose, and/or sucrose is added to the meat mixture together with spices and curing salt. The pH drops during fermentation to values ranging between 4.8 and 5.4, depending on the sausage type. Starters added to the meat mix usually contain, in addition to micrococci/staphylococci, *Lactobacillus sakei*, *Lactobacillus curvatus*, *Lactobacillus plantarum*, or pediococci (Hammes and Hertel, 1998; Lücke, 2000). Various species of lactobacilli multiply during cold storage of meat and meat products such as sausage and cooked ham, especially when packaged air tight. They may delay spoilage by proteolytic bacteria, but may also lead to spoilage by producing off-flavor, acid taste, gas, slime, or greening (Egan, 1983). In addition to leuconostocs, *Weissella* species, and carnobacteria, *Lactobacillus sakei*, *Lactobacillus curvatus*, *Lactobacillus algidus*, *Lactobacillus fucuiensis*, *Lactobacillus plantarum*, and *Lactobacillus brevis* have been isolated frequently. In meat packed in oxygen-impermeable bags and stored refrigerated for 16 weeks, a strain of *Lactobacillus delbrueckii* grew to dominant numbers in the lactic acid bacterial association (Jones, 2004).

Fish and marinated fish. Lactobacilli have been found to occur in the intestines of fish (Ringo and Gatesoupe, 1998), however, they do not belong to the dominant lactic acid bacteria association. For example, they represent only 0.44% in wild brown trout (Gonzalez et al., 2000). *Lactobacillus plantarum*-like strains have been identified. In Asian regions numerous types of food are produced by fermentation of fish and shellfish.

Lactobacilli and species of all other lactic acid bacteria except carnobacteria are involved in that process (Paludan-Muller et al., 1999; Tanasupawat et al., 1998). *Lactobacillus acidipiscis* had been isolated from pla-ra and pla-chom in Thailand (Tanasupawat et al., 2000). Homo- and heterofermentative lactobacilli play an important role in the spoilage of marinated fish (Blood, 1975). In these and similar types of food, acetic acid, sometimes in combination with lactic acid, is used as an acidulans. Acetic acid is a weak acid (pK 4.75) and a traditional food preservative. It is suggested that the acetic acid added to herring provides the necessary acid environment for the action of proteinases present in the fish muscle (Meyer, 1962). The free amino acids thus liberated then provide the energy source for acetic-acid-tolerant and salt-tolerant lactobacilli which are able to decarboxylate amino acids and form biogenic amines. The CO₂ formed is the first indication of spoilage. In carbohydrate-containing marinades, the carbohydrates may be the source of CO₂ liberated by heterofermentative lactobacilli. Meyer (1956) distinguished between a “carbohydrate swell” and a “protein swell”. Lactobacilli isolated from marinated herring were mainly allotted to *Lactobacillus plantarum*, *Lactobacillus brevis*, and *Lactobacillus buchneri*. However, reinvestigation of such isolates by employing modern biochemical and genomic characteristics is necessary to elucidate their true taxonomic positions. *Lactobacillus plantarum* and *Lactobacillus casei* have been identified as causatives of ropy appearance in cooked marinades (Priebe, 1970).

Mayonnaise, dressings, and salads are further examples of food preserved mainly by acetic acid. They are sensitive to spoilage by yeasts and lactic acid bacteria. *Lactobacillus plantarum*, *Lactobacillus buchneri*, *Lactobacillus brevis*, *Lactobacillus delbrueckii*, *Lactobacillus casei*, and *Lactobacillus fructivorans* were isolated from spoiled food of these types (Baumgart et al., 1983). The highest resistance to acetic acid was found for *Lactobacillus acetotolerans* (Entani et al., 1986). The organism grows even in fermenting rice vinegar broth and tolerates 4–5 % acetic acid at pH 3.5.

Humans and animals. Humans and warm-blooded animals harbor lactobacilli in the oral cavity, the intestines, and the vagina (Hammes and Hertel, 2003).

Oral cavity. Lactobacilli constitute <0.1% of cheek and tongue bacteria, <0.005% of the intragingival plaque, and <1% of the saliva and gingival crevice bacteria (Marsh and Martin, 1984). In saliva specimens of 130 school children, *Lactobacillus casei* and *Lactobacillus fermentum* were identified in 59 and 45% of samples, respectively (Rogosa et al., 1953). With lower incidence, *Lactobacillus acidophilus* (22%), *Lactobacillus brevis* (17%) and *Lactobacillus buchneri*, *Lactobacillus salivarius*, and *Lactobacillus plantarum* were found. *Lactobacillus oris* was isolated from human saliva and described as new species by (Farrow and Collins, 1988). *Lactobacillus rhamnosus* was dominant in softened and hard dentin of molars (Kneist et al., 1988).

The comparison of the saliva-*Lactobacillus* association between 12 individuals with open caries (group A) and 12 no-caries individuals (group B) revealed that of 153 isolates obtained, 82% (group A) and 90% (group B) were identified as homofermentative species (Botha et al., 1998). With decreasing incidence, *Lactobacillus paracasei* (A, 39%; B, 30%) and *Lactobacillus rhamnosus* (A, 31%; B, 41%) were identified. The heterofermentative species identified were *Lactobacillus fermentum* (A, 68%; B, 100%) and *Weissella* species.

Similar studies were performed with the direct dental carious lesions and use of culture-dependent as well as independent identification methods. In the predominant association, *Lactobacillus rhamnosus* constituted 8%, whereas in the teeth with caries, *Lactobacillus gasseri*/*Lactobacillus johnsonii* and *Lactobacillus rhamnosus* represented 14 and 8%, respectively, of the total association. Lactobacilli are commonly recovered from dental lesions but do not appear to be involved in the progression of dental caries (Hammes and Hertel, 2003). According to the "dental plaque hypothesis" (Marsh, 1994), carbohydrates cause the selective growth of lactic acid bacteria and especially lactobacilli at the expense of less acid-tolerant species. The low pH in carious cavities is initially the result of streptococcal metabolism which is followed in a succession by the more acid-resistant lactobacilli growing to high numbers in the cavity.

Intestinal tract of humans and animals. The anatomical differences that exist between the intestines of humans and animals strongly affect the numbers and composition of the microorganisms, especially lactobacilli. The stomach is lined with a glandular mucosa in humans, whereas in pigs, mice, and rats it is partly lined with a nonglandular, stratified squamous epithelium (Tannock, 1992). This type of epithelium is also present in the crop of birds and in the stomach of horses. Lactobacilli adhere directly to these epithelia named *pars oesophagea* in pigs and forestomach in mice and rats, and form a cell layer. Correspondingly, they colonize these epithelia in birds and horses. From these places, the lactobacilli continuously inoculate the digesta resulting in large numbers in the proximal part of the digestive tract. The *Lactobacillus* association in ruminants, especially of the rumen of adult animals, has not been investigated in depth. Lactic acid bacteria constitute a minor fraction in adult sheep and cattle (Stewart, 1992). They dominate, however, in young animals and animals fed with a high grain starch diet (Hespell et al., 1997). In these animals, lactobacilli and *Streptococcus bovis* grow up to $>10^9$ c.f.u./ml and decrease the pH to 4.5. These conditions can cause acidosis in the animals.

In the human stomach, the numbers of lactobacilli are low ($<10^3$ c.f.u./ml) and only species adapted to the acidic environment (pH 2.2–4.2) can use this ecological niche. Two obligately heterofermentative species (*Lactobacillus gastricus* and *Lactobacillus antri*) and two obligately homofermentative species (*Lactobacillus kalixensis* and *Lactobacillus ultunensis*) were isolated from biopsies of healthy volunteers (Roos et al., 2005). The numbers of bacteria increase from $>10^4$ c.f.u./ml in the digesta of the duodenum to 10^8 – 10^9 in the ileum. Lactobacilli together with enterococci dominate in the duodenum and in the jejunum. In the ileum, the composition of the microbial association approaches that of the large intestines. Most knowledge of the latter has been obtained from analysis of feces. Lactobacilli can be found in feces in numbers ranging from 0 to $<10^9$ c.f.u./g. They constitute only a minor fraction within the $>10^{11}$ bacteria/g feces which make up approximately 55% of the total mass. In animals, e.g., pigs, dogs, chicken, mice, rats, and hamsters, lactobacilli represent a greater fraction of the population (Mitsuoka, 1992). Species detected in the intestinal tract of humans and animals are compiled in Table 83 which also includes also species that have been detected by culture-independent methods (Leser et al., 2002; Vaughan et al., 2002). It is assumed that numerous species are not yet culturable (Vaughan et al., 2002) and that specifically adjusted conditions are needed for

the detection of others by culturing. For example, *Lactobacillus sakei* does not grow on the commonly used acetate-rich media but requires an acetate-free medium, incubation at 30°C, and an atmosphere with 2% (Dal Bello and Hertel, 2006). Changes in taxonomy and the use of genotypic identification methods indicate that the conclusions with regard to dominant species drawn from studies between 1960 and 1980 need certain modifications. *Lactobacillus acidophilus* isolates have to be allotted mainly to *Lactobacillus gasseri* and *Lactobacillus crispatus*. *Lactobacillus fermentum* strains belong to *Lactobacillus reuteri* and the *Catenabacterium catenaforme* isolates were identified as *Lactobacillus ruminis* (Mitsuoka, 1992; Reuter, 2001). The definition of autochthonous human *Lactobacillus* species is still a matter of controversial discussion (Hammes and Hertel, 2003). As *Lactobacillus salivarius* and *Lactobacillus ruminis* strains were recovered from some individuals for at least 18 months, these species may be autochthonous (Tannock et al., 2000). However, they are not present in all individuals and, in fact, this is true for all *Lactobacillus* species. Furthermore, lactobacilli cannot be recovered at all from some individuals. Moreover, ecological studies indicate that most *Lactobacillus* species found in the human gastrointestinal tract are likely to be transient, originating from either the oral cavity (Dal Bello and Hertel, 2006) or food (Dal Bello et al., 2003; Heilig et al., 2002; Walter et al., 2001).

In accordance with the probiotic concept (Guarner and Schaafsma, 1998), lactic acid bacteria (mainly lactobacilli and bifidobacteria) are used in food, preferentially in fermented milk products and as feed additives, to achieve an improvement of health (Klaenhammer, 2001). Species used in food and having research documentation for defined strains include the following lactobacilli: *Lactobacillus acidophilus*, *Lactobacillus casei*, *Lactobacillus delbrueckii* subsp. *bulgaricus*, *Lactobacillus fermentum*, *Lactobacillus johnsonii*, *Lactobacillus paracasei*, *Lactobacillus plantarum*, *Lactobacillus reuteri*, *Lactobacillus rhamnosus*, and *Lactobacillus salivarius* (Sanders and Huis in't Veld, 1999). Cultures for farm animals contain *Lactobacillus acidophilus*, *Lactobacillus brevis*, *Lactobacillus casei*, *Lactobacillus delbrueckii* subsp. *bulgaricus*, *Lactobacillus fermentum*, *Lactobacillus helveticus*, *Lactobacillus plantarum*, *Lactobacillus reuteri*, and *Lactobacillus rhamnosus* (Fuller, 1999). These lactobacilli usually persist during the intestinal transit but do not colonize for an extended time.

Vertebrates acquire their intestinal association at or after birth. Lactobacilli can be cultured from human feces 1–3 d after birth. The numbers detected in the following periods increase (Conway, 1997) (from weeks 1–19 to approximately 10^7 c.f.u./g feces) depending on individual factors and on the diet (Mitsuoka, 1992). The food may contain lactobacilli that persist on the intestinal transit and might be recovered from feces. This may at least partially explain the fluctuation of the *Lactobacillus* association observed in individuals of all ages.

Vaginal lactobacilli. Similar to intestinal lactobacilli, the presence of lactobacilli in the vagina is subject to great variation with regard to the numbers as well as species and strains. Healthy subjects may contain none or virtually 100% lactobacilli in their vaginal association (Hyman et al., 2005). Lactobacilli are believed to maintain low pH at values ranging throughout the menstrual cycle between 3.5 and 4.5, and to exert a protective effect against colonization of undesired microorganisms (Hill et al., 1985). This concept may be modified because certain subjects do not harbor lactobacilli and because the vaginal

References include Mitsuoka, 1992; Tannock, 1992; Walter et al., (2001), Tannock et al., 2000; Roos et al., 2000; Gusils et al., 1999; Rubio et al., 1998; Marounek et al., 1988; Stewart, 1992; Serra et al., (1992), Walter et al., 2001; Yuki et al., 2000; Morotomi et al., 2002; Liu and Dong, 2002; Vaughan et al., 2002; Leser et al., 2002; Dal Bello et al., 2003; Mukai et al., 2003; Niamsup et al., 2003; Roos et al., (2005).

^cThe species composition has not been studied so far.

secretion is already acidic at birth, when the vagina is still sterile (Hammes and Hertel, 2003; Redondo-Lopez et al., 1990). Early descriptions of vaginal lactobacilli suffer from the inaccuracy of the identification methods of their time (Döderlein, 1894; Lenzner, 1966; Rogosa and Sharpe, 1960; Wylie and Henderson, 1969). At later times, species were isolated from the female urogenital tract that can be considered to be adapted to this environment. *Lactobacillus jensenii* was isolated from vaginal discharge (Gasser et al., 1970) and belongs together with *Lactobacillus gasseri* and *Lactobacillus crispatus* to the most often detected lactobacilli. *Lactobacillus gasseri* is a predominantly detected organism which is also part of the intestinal association in humans and animals, and occurs also in fermented food (Lauer and Kandler, 1980b). Similarly, *Lactobacillus crispatus* (Cato et al.,

1983) is commonly associated with humans, animals (Table 83), and fermented food.

Adaption comparable to *Lactobacillus jensenii* can be attributed to *Lactobacillus vaginalis* which was originally isolated from patients suffering from trichomoniasis (Embley et al., 1989), *Lactobacillus fornicalis* isolated from the posterior fornix of a healthy woman attending pre- and postnatal clinics (Dicks et al., 2000), *Lactobacillus iners* isolated from the urine and vaginal discharge of adult women (Falsen et al., 1999), and *Lactobacillus coleohominis*, isolated from the vaginas of young women (Nikolaitchouk et al., 2001). Extensive studies of vaginal lactobacilli have been performed using phenotypic as well as genotypic methods (Antonio et al., 1999; Hyman et al., 2005; Vasquez et al., 2002; Zhou et al., 2004), showing or confirming that

Lactobacillus crispatus, *Lactobacillus gasseri*, *Lactobacillus jensenii*, and *Lactobacillus iners* are the most commonly occurring species. Numerous additional species were recovered from the human body association (*Lactobacillus reuteri*, *Lactobacillus ruminis*, *Lactobacillus oris*, *Lactobacillus vaginalis*) (Antonio et al., 1999; Burton et al., 2003) and mainly from food association (*Lactobacillus rhamnosus*, *Lactobacillus paracasei*, *Lactobacillus fermentum* and *Lactobacillus plantarum*). Solely using gene-targeted methods, rather unexpected, tightly food-associated bacteria have been identified, such as *Lactobacillus kefiranoferens*, *Lactobacillus delbrueckii* subsp. *delbrueckii*, subsp. *lactis*, and subsp. *bulgaricus*. Remarkably, in one subject 20 contigs allotted to *Lactobacillus crispatus* were identified showing that they are far from clonal. Lactobacilli with defined properties have been used therapeutically in the treatment of bacterial vaginosis (McLean and Rosenstein, 2000; Reid and Heinemann, 1999) with the aim of restoring the normal *Lactobacillus* association.

Sewage and manure. Sewage and manure are secondary habitats of all lactobacilli found in the intestine or other primary habitats in more or less direct contact. *Lactobacillus coryniformis* and *Lactobacillus curvatus* are frequently found in manure (Abo-Elnaga and Kandler, 1965b). *Lactobacillus vaccinoferens* has only been found in cow dung (Okada et al., 1979).

In municipal sewage, levels of 10^4 – 10^5 lactobacilli/ml have been found (Weiss et al., 1981). The heterofermentative strains (approx. 25% of the isolates) have been classified as *Lactobacillus fermentum*, *Lactobacillus reuteri*, and *Lactobacillus brevis* and, to a lesser extent, as *Lactobacillus confusus*. The homofermentative strains (approx. 75% of the isolates) belonged to a great number of species. However, about 10% of the strains could not be allotted to any of the known species. They have been described as representatives of the two new species *Lactobacillus sharpeae* and *Lactobacillus agilis*.

Enrichment and isolation procedures

Procedures for the isolation of lactobacilli must take into account their aciduric or acidophilic nature, their complex nutritional requirements, and their preference for microaerophilic conditions. When lactobacilli are the predominant flora in the source material, the rather nonselective MRS agar (De Man et al., 1960) or the somewhat similar APT agar (Evans and Niven, 1951) may be used for isolation. APT agar and sorbic acid agar (Reuter, 1968) are commonly used for isolating lactobacilli from meat products. When lactobacilli occur as part of a complex population, selective media are required. Most lactobacilli from many different sources have been successfully isolated on the widely used acetate medium (SL) of Rogosa et al., (1951). SL medium is not completely selective for lactobacilli as other lactic acid bacteria, e.g., leuconostocs, pediococci, enterococci, *Weissella* species, bifidobacteria, and yeasts may also grow. Thus, colonies may have to be further examined. Yeasts can be eliminated by the addition of cycloheximide at a concentration of 100 mg/l. Intestinal lactobacilli are commonly isolated on MRS, SL, or LAMVAP agar (Hartemink et al., 1997). For the isolation of anaerobic lactobacilli from intestinal sources, 0.05% (w/v) cysteine should be added, and it may be necessary to pre-reduce poured, dried plates by overnight incubation in an anaerobic jar.

Lactobacillus iners (Falsen et al., 1999), which was isolated from the human vagina, does not grow on MRS or SL agar but

needs to be cultured on blood agar. Depending on the source of isolation, other lactobacilli, mainly from quite specialized environments, require minor modifications of SL medium such as supplementing with more or less specific growth factors, e.g., meat extract, tomato juice, fresh yeast extract, malt extract, ethanol, mevalonic acid, or even some of the natural substrate (beer, fruit juices, cheese whey). Replacement of glucose, either completely or partially, by other carbohydrates such as maltose, fructose, sucrose, or arabinose is recommended in some cases, especially where heterofermentative lactobacilli play an important role. An example is Homohiochii Medium (Kleynmans et al., 1989). For the detection of beer-spoiling bacteria including nutritionally fastidious lactobacilli, a special medium (NBB medium) has been described by Back (1980). Several other media are also in use, which have been reviewed by Sakamoto and Konings (2003). An extensive literature survey of the use of culture media for lactic acid bacteria, including lactobacilli, was given by Carr et al. (2002).

Because most lactobacilli generally grow better either anaerobically or in the presence of increased CO₂ tension, agar plates should be incubated in jars that have been evacuated and filled with 90% N₂ or H₂ + 10% CO₂ or in anaerobic jars (BBL, Oxoid) using H₂ + CO₂ generating kits.

Maintenance procedures

For short-term preservation, cultures are preferably inoculated into MRS or optimal medium agar slabs, incubated until growth becomes visible, stored at 4–7°C, and transferred monthly. Some species or strains, however, die out quite rapidly within a series of transfers. Alternatively, cultures grown to the early stationary growth phase may be deep frozen in the growth medium and stored at –20°C for several months. The cultures can be kept for years by adding 20% glycerol and storing at –80°C in screw caps.

The method of choice for long-term preservation is lyophilization. Cells grown to the late exponential growth phase are collected by centrifugation, resuspended in sterile skim milk or horse serum containing 7.5% (w/v) glucose, and lyophilized. Ampules are sealed under vacuum and stored at 5–8°C. Most strains preserved by this method are still viable after 10–20 years, although some require more frequent re-lyophilization. Strains may also be kept for long periods (over 30 years) in liquid nitrogen.

Procedures for testing special characters

The development and increasingly common use of genotypic identification methods (see below) has led progressively to a reduction of the physiological and biochemical characterization of newly described species. An example is *Lactobacillus suntuoreyus* whose description included the basic properties, i.e., morphology, culture conditions, motility, spore formation potential, and was furthermore limited by the carbohydrate fermentation pattern, sequencing of the 16S rDNA, and DNA/DNA hybridization. Formerly included properties (Kandler and Weiss, 1986; Vandamme et al., 1996) such as configuration of lactate, G+C content, cell wall composition (peptidoglycan type, teichoic acids), electrophoretic pattern of lactate dehydrogenases, and cellular fatty acids are thus no longer known. The peptidoglycan type is a especially reliable criterion for the identification of certain species, e.g., *Lactobacillus sanfranciscensis* (Lys–Ala) and *Lactobacillus rossiae* (Lys–Ser–Ala₂). It is also of great value when

obligately heterofermentative lactobacilli that can be confused with weissellas have to be identified. The interpeptide bridge of the latter genus is (Lys– mono-amino mono-carboxylic acids).

Carbohydrate fermentation. MRS broth without meat extract and glucose and with 0.05% (w/v) chlorphenol red is generally used as basal medium. Filter-sterilized solutions of the test carbohydrates are added to a final concentration of 1%. Tests are incubated at the optimum growth temperature and results recorded up to 7 d. In a few cases, e.g., for some strains of *Lactobacillus delbrueckii*, the addition of 0.2% meat extract broadens the pattern of fermented carbohydrates somewhat, and the fermentation of glucose is distinctly improved. For strains that will not grow reasonably in MRS broth, the optimal growth medium should be used as basal medium. The use of this procedure delivers clear results with regard to the growth and fermentation potential, i.e., whether or not the fermented carbohydrate supports the growth of the strain. However, as it is a time and labor consuming procedure, the use of the API system is presently the standard. As discussed previously, the results obtained are not always consistent with growth of the organisms on the fermentable carbohydrate.

Lactic acid configuration. The amount of the isomers of lactic acid produced is best determined enzymically using D-lactate (Gawehn and Bergmeyer, 1974) and L-lactate dehydrogenase (Gutmann and Wahlefeld, 1974). Corrections must be made for the lactic acid content of the medium before inoculation. Care must be taken to analyze cultures after they have reached the stationary growth phase, since some DL-lactate-formers produce predominantly L(+)-lactic acid or, in a few cases, D(–)-lactic acid during the early growth phase.

Differentiation from closely related taxa

Lactobacilli are metabolically very similar to the other genera of lactic acid bacteria. Only their rod shape readily distinguishes them from the coccid genera. Strains of *Lactococcus* that form atypically elongated cells may also be confused with coccoid rods of lactobacilli. Here, differentiation may require genotypic identification as in the case of *Lactobacillus xylosus* and "*Lactobacillus hordniae*", both of which have been shown to belong to the genus *Lactococcus* (Garvie et al., 1981; Kilpper-Bälz et al., 1982).

The rod-shaped bifidobacteria, which until the eighth edition of *Bergey's Manual* had long been included in the genus *Lactobacillus* as "*Lactobacillus bifidus*", may be differentiated from lactobacilli on the basis of their characteristic hexose fermentation pathway which yields lactic acid and acetic acid at a molar ratio of 2:3, but no CO₂, instead of lactic acid, acetic acid (or ethanol), and CO₂ at a molar ratio of 1:1:1 which is the pattern of fermentation products typical of obligately heterofermentative lactobacilli. Carnobacteria can be differentiated from lactobacilli by their reduced acid tolerance and their potential to grow at pH values up to 9.5. The differentiation of lactobacilli from weissellas is problematic, but possible by determination of the peptidoglycan type (see above). The differentiation from *Paralactobacillus* is best made by using genotypic identification methods.

Genotypic identification methods. For identification of lactobacilli, genotypic methods are increasingly applied and the polyphasic approach is considered to provide the most reliable identification results. The classical genotypic methods are based on the determination of DNA base composition (mol% G+C)

and DNA–DNA similarity. The whole genome DNA–DNA similarity study is still an important criterion in the current species concept (Rosselló-Mora and Amann, 2001). Its usefulness for delineation of *Lactobacillus* species is reviewed by Vandamme et al. (1996). However, this approach was mainly employed to identify new species or to clarify relationships among existing species. It plays only a minor role in rapid identification of unknown isolates. For this purpose, comparative analysis of 16S and/or 23S rRNA gene sequences can be used, but it should be taken into account that several *Lactobacillus* species show very high 16S rRNA sequence similarity, e.g., *Lactobacillus plantarum*, *Lactobacillus pentosus*, and *Lactobacillus paraplantarum* (99.7–99.9%), *Lactobacillus kimchii* and *Lactobacillus paralimentarius* (99.9%), *Lactobacillus mindensis* and *Lactobacillus farcininis* (99.9%), and *Lactobacillus animalis* and *Lactobacillus murinus* (99.7%). In such cases multilocus sequence analysis (MLSA) of conserved protein-coding loci may help to overcome this limitation. Recently, the applicability of this technique to identifying species of lactic acid bacteria was demonstrated for the genus *Enterococcus* (Naser et al., 2005). Nevertheless, the analysis of 16S rRNA sequences (especially of the first 900 bases) is still a fast tool that can be used to gain insight into the taxonomic position of an unknown *Lactobacillus* isolate.

Comparative analysis of rRNA sequences reveals evolutionarily less conserved regions that are diagnostic for species, genus, or groups of phylogenetically related organisms (Amann et al., 1995; Schleifer et al., 1993). These regions serve as target sites for specific probes and primers (Amann and Ludwig, 2000; Coeuret et al., 2003; Satokari et al., 2003) which can be used in combination with a variety of hybridization and PCR techniques, e.g., *in situ* colony hybridization (Brockmann et al., 1996; Hertel et al., 1992), reverse dot blot hybridization (Ehrmann et al., 1994), fluorescent *in situ* hybridization (Blasco et al., 2003; Lick et al., 2000; Matte-Tailliez et al., 2001), species-specific PCR (Bunte et al., 2000; Dickson et al., 2005), and multiplex PCR (Muller et al., 2000; Settanni et al., 2005; Song et al., 2000; Yost and Nattress, 2000). In addition, the DNA spacer sequences between the rRNA genes of lactobacilli are highly variable but sufficiently conserved to construct species-specific PCR primers (Berthier and Ehrlich, 1998; Chen et al., 2000; Tannock et al., 1999; Tilsala-Timisjarvi and Alatossava, 1997). It was shown that 16S–23S rRNA gene intergenic spacer region sequence comparison can especially be useful in identifying closely related species, e.g., *Lactobacillus curvatus*, *Lactobacillus sakei*, and *Lactobacillus graminis* as well as *Lactobacillus paraplantarum*, *Lactobacillus plantarum*, and *Lactobacillus pentosus* (Berthier and Ehrlich, 1998). The amplified rDNA restriction analysis (ARDRA), which is mostly based on the restriction length polymorphism of 16S rRNA gene fragments amplified by PCR, is also a useful tool for species identification (Bouton et al., 2002; Giraffa et al., 1998; Moschetti et al., 1997; Roy et al., 2000; Ventura et al., 2000).

Methods have been developed for culture-independent analysis of the diversity of complex microbial communities. Denaturing gradient gel electrophoresis (DGGE) of 16S rDNA amplicons has been demonstrated to be a suitable tool to identify *Lactobacillus* species in and to monitor the diversity and dynamics of a microbiota in which lactobacilli belong to the dominating organisms (ben Omar and Ampe, 2000; Cocolin et al., 2001; Ercolini et al., 2001; Meroth et al., 2004; Meroth et al.,

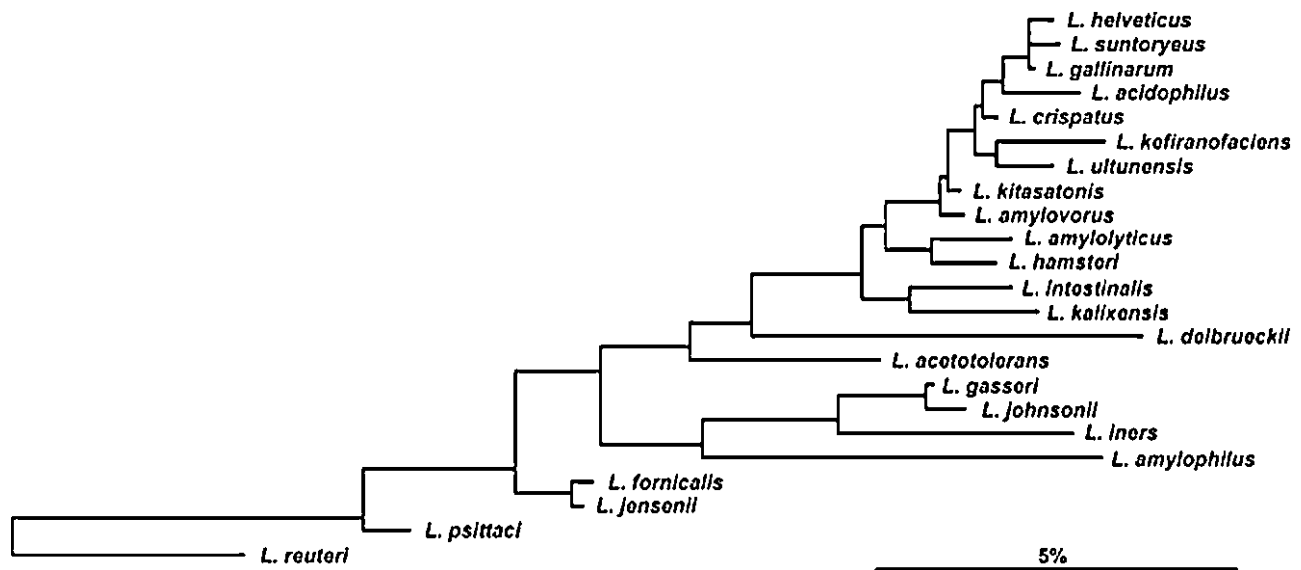

FIGURE 90. Maximum likelihood tree reflecting the relationship among members of the *Lactobacillus delbrueckii* group. The tree is based on analyses of all available at least 90% complete 16S rRNA sequences of *Lactobacillaceae*. Alignment positions that share identical residues in at least 50% of all sequences of the genera *Lactobacillus* and *Pediococcus* were considered. The bars indicate 5% estimated sequence divergence.

2003; Randazzo et al., 2002). For detection of *Lactobacillus* species in a microbiota in which they represent only a minor part of the population (e.g., the intestinal microbiota), the DGGE has to be combined with a *Lactobacillus* group-specific PCR (Heilig et al., 2002; Walter et al., 2001). The usefulness of PCR-DGGE was demonstrated by the identification of *Lactobacillus iners* as the most common *Lactobacillus* species in the vaginal bacterial microbiota (Burton et al., 2003). The important role was difficult to detect because this species does not grow on the common selective media used for isolation of lactobacilli (Falsen et al., 1999).

Taxonomic comments

The species of the genera *Lactobacillus* belong together with the genera *Paralactobacillus* and *Pediococcus* to the family *Lactobacillaceae* which is a member of the order “*Lactobacillales*”, one of the major phylogenetic groups of the *Firmicutes*. Although the pediococci are highly related to the lactobacilli, they are treated in separate chapters. Using 16S rRNA gene sequence analysis, the phylogeny of lactic acid bacteria has been studied extensively in the past (reviewed by Hammes and Hertel, 2003). It has become evident that only little correlation exists between the traditional classification and the phylogenetic relatedness of lactic acid bacteria. As a result of these studies, it has been proposed (Hammes and Hertel, 2003) to subdivide the genus *Lactobacillus* into seven phylogenetic groups (*Lactobacillus buchneri* group, *Lactobacillus casei* group, *Lactobacillus delbrueckii* group, *Lactobacillus plantarum* group, *Lactobacillus reuteri* group, *Lactobacillus sakei* group, and *Lactobacillus salivarius* group). Following this concept of grouping, the phylogenetic relatedness of lactobacilli was reinvestigated by using all available 16S rRNA gene sequences deposited in public databases (C. Hertel, unpublished results). Various datasets differing with respect to the selection of sequences and sequence positions were used for phylogenetic analyzes applying three methods, namely, distance matrix, maximum-parsimony, and maximum-likelihood

(Ludwig and Klenk, 2001). The analyzes revealed that just three distinct phylogenetic groups can be defined. These are depicted in Figure 90, Figure 91, and Figure 92 as *Lactobacillus delbrueckii* group, *Lactobacillus reuteri* group, and *Lactobacillus salivarius* group, respectively. The definition of further groups of lactobacilli was no longer possible as the discriminatory power of the 16S rRNA gene sequences is limited, and the large increase of new 16S rRNA gene sequences in recent years abolished formerly recognized phylogenetic lines of relationship. The newly described *Lactobacillus* species branch deeply within the previously defined seven phylogenetic groups. For example, in the case of *Lactobacillus algidus*, the positioning varies with the sequence positions selected and the methods used for tree construction. In just a few cases of tree construction, the species could be allotted to the *Lactobacillus salivarius* group as shown in Figure 92. Thus, a more reliable insight into the evolutionary relationships of the numerous *Lactobacillus* species must still be obtained by applying novel approaches that are based on comparative analysis of conserved macromolecules or even whole-genome sequences (Coenye et al., 2005).

The *Lactobacillus delbrueckii* group (Figure 90) is consistent with the formerly described *Lactobacillus delbrueckii* group (Collins et al., 1991; Hammes and Hertel, 2003; Schleifer and Ludwig, 1995a, b). As *Lactobacillus delbrueckii* is the type species of the genus *Lactobacillus*, we use the designation *Lactobacillus delbrueckii* group instead of *Lactobacillus acidophilus* group used by Schleifer and Ludwig (1995b). It contains mainly obligate homofermenters but also some facultative heterofermenters. The G+C content within this group ranges rather widely from 34 up to 51 mol% which may be explained by changes in the codon usages originating from the degeneracy of the genetic code (Schleifer and Ludwig, 1995b). The peptidoglycan type of all species in this group is of the Lys-D-Asp type (Schleifer and Kandler, 1972). *Lactobacillus delbrueckii* contains four subspecies and *Lactobacillus kefiranoformans* two subspecies that cannot be reliably differentiated by rRNA sequence analysis.

FIGURE 91. Maximum likelihood tree reflecting the relationship among members of the *Lactobacillus reuteri* group. The tree is based on analyses of all available at least 90% complete 16S rRNA sequences of *Lactobacillaceae*. Alignment positions that share identical residues in at least 50% of all sequences of the genera *Lactobacillus* and *Pediococcus* were considered. The bars indicate 5% estimated sequence divergence.

The *Lactobacillus reuteri* group (Figure 91) exclusively contains obligate heterofermenters, and its members show again a wide range in the G+C content of their DNA (38–54 mol%). In contrast to the previously defined *Lactobacillus reuteri* group (Hammes and Hertel, 2003), the species *Lactobacillus durianis*, *Lactobacillus rossiae*, *Lactobacillus suebicus*, and *Lactobacillus vaccinofermentus* could no longer be allotted to the *Lactobacillus reuteri* group. The split into two evolutionary lines containing as prominent species *Lactobacillus reuteri* and *Lactobacillus fermentum*, respectively, was evident in most of the phylogenetic analyzes. The peptidoglycan types in this group are Lys–D-Asp, Orn–D-Asp.

The *Lactobacillus salivarius* group (Figure 92) contains obligate homofermenters and facultative heterofermenters, and again the G+C content ranges widely within the species (32–44%). The peptidoglycan types occurring in this group are Lys–D-Asp and meso-Dpm-direct. Certain species show high 16S rRNA sequence similarities, e.g., *Lactobacillus animalis* and *Lactobacillus murinus* (99.7%), *Lactobacillus cypricasei* and *Lactobacillus acidipiscis* (99.7%). A similar situation can also be found among other species of the genus *Lactobacillus*, e.g., in *Lactobacillus*

plantarum, *Lactobacillus pentosus*, and *Lactobacillus paraplantarum* (99.7–99.9%). The species *Lactobacillus aviarius* and *Lactobacillus salivarius* each contain two subspecies which cannot be differentiated by rRNA sequence analysis.

The history of the genus *Lactobacillus* starts with the proposal of a new genus by Beijerinck (1901). In the following years, new species were described which increased to the present number of 96 recognized species. Their taxonomic treatment was and still is a challenge for taxonomists, and their task is by far not finished. The taxonomic tools and the availability of genomes of lactic acid bacteria (reviewed by Klaenhammer et al., 2005) will provide a basis for a more conclusive classification. Several scientists contributed to the present status of *Lactobacillus* taxonomy (Kandler and Weiss, 1986; Orla-Jensen, 1919, 1942, 1943; Rogosa, 1970, 1974; Sharpe, 1979). Their bases for grouping the large number of species were and still are the characteristics of morphology, fermentation of carbohydrates, nutritional requirements, growth dependence on temperature, agglutination properties, and the potential for performing homo- or heterofermentation. Kandler and Weiss

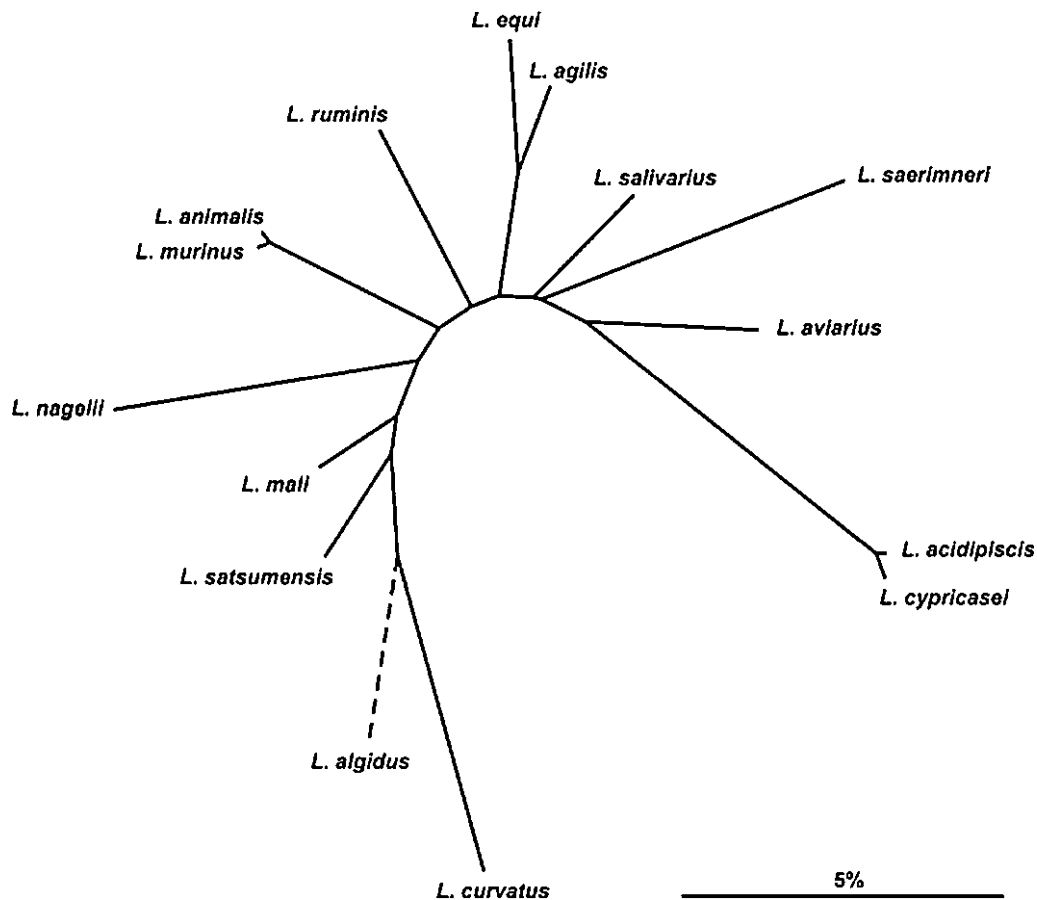

FIGURE 92. Maximum likelihood tree reflecting the relationship among members of the *Lactobacillus salivarius* group. The tree is based on analyses of all available at least 90% complete 16S rRNA sequences of *Lactobacillaceae*. Alignment positions that share identical residues in at least 50% of all sequences of the genera *Lactobacillus* and *Pediococcus* were considered. The positioning of *Lactobacillus acidipiscis* is based on partial sequence data and may be subject to changes. *Lactobacillus algidus* is included into this tree, although its positioning depends on the method applied for tree reconstruction. The bars indicate 5% estimated sequence divergence.

(1986) have already recognized that their scheme of allotting the species to groups (I-III) is not supported by phylogenetic data. We follow their way of grouping, which no longer includes the formerly used criteria of morphology and the range of growth temperature, but rests solely on the fermentation types. It was recognized that a substantial number of species allotted by Kandler and Weiss (1986) to the obligately homofermentative group (I) bacteria had to be transferred to the new group of facultatively heterofermentative species (B). This change is remarkable as it especially concerns species of the *Lactobacillus delbrueckii* and the *Lactobacillus salivarius* groups, which are now found in two groups (A and B). The allotment of the species to groups named A, B, and C is indicated in Table 82, and the differentiation characteristics for *Lactobacillus* species shown Table 84, Table 85, and Table 86 mainly rest on that grouping. The groups are defined as follows:

Group A, obligately homofermentative lactobacilli: Hexoses are fermented almost exclusively to lactic acid by the Embden-Meyerhof pathway; pentoses or gluconate are not fermented.

It can be assumed that for certain strains of group A species, the formation of acid from pentoses will be discovered, as occurred recently. In the hands of Kandler and Weiss (1986), a number of species, which are now placed in group B, did not

grow on pentoses, despite a reported potential to ferment pentoses. As has been discussed previously in the metabolism section (see above), the formation of acid from a carbohydrate does not necessarily mean that the organism can grow on it. Thus, there is clearly a need for further studies of the metabolic potential of these organisms.

Group B, facultatively heterofermentative lactobacilli: Hexoses are fermented almost exclusively to lactic acid by the Embden-Meyerhof pathway or, at least by some species, to lactic acid, acetic acid, ethanol, and formic acid under glucose limitation; pentoses are fermented to lactic acid and acetic acid via an inducible phosphoketolase.

Group C, obligately heterofermentative lactobacilli: Hexoses are fermented to lactic acid, acetic acid (ethanol), and CO₂ via the phosphogluconate pathway. Pentoses are fermented to lactic acid and acetic acid by the related pentose phosphate pathway.

In general, these pathways involve phosphoketolase. *Lactobacillus bifermens* probably possesses other pathways for carbohydrate breakdown leading to production of gas from hexoses and has therefore tentatively also been included in group C. *Lactobacillus bifermens* ferments glucose homofermentatively to DL-lactic acid, but, depending on pH, the lactic acid formed

Differentiation and characteristics of the species of the genus *Lactobacillus*

The key characteristics for differentiation of the species of the genus *Lactobacillus* are compiled in Table 84, Table 85, and Table 86.

List of species of the genus *Lactobacillus**

1. ***Lactobacillus delbrueckii*** (Leichmann 1896b) Beijerinck 1901, 229^{AL} (*Bacillus Delbrückii* (*sic*) Leichmann 1896b, 284.) del.bruec'ki.i. N.L. gen. n. *delbrueckii* of Delbrück; named for M. Delbrück, a German bacteriologist.

Cells are nonmotile rods with rounded ends (0.5–0.8 × ~2–9 μm) occurring singly and in short chains. Often containing internal granulation demonstrable with methylene blue stain. Surface growth is greatly enhanced by reduced O₂-tension or anaerobiosis. Obligately homofermentative. Good growth at 45°C or even at 48–52°C. Indole is not formed. Growth factor requirements: pantothenic acid and niacin generally essential; riboflavin, folic acid, vitamin B₁₂, and thymidine are essential for particular strains; thiamine, pyridoxin, biotin, and *p*-aminobenzoic acid are not required. The species contains four subspecies.

Phylogenetic position: *Lactobacillus delbrueckii* group.

DNA G+C content (mol%): 49–51 (Bd, T_m).

Additional remarks: Because of the high phenotypic and genomic similarities between *Lactobacillus delbrueckii*, *Lactobacillus leichmannii*, *Lactobacillus lactis*, and *Lactobacillus bulgaricus*, only *Lactobacillus delbrueckii* is retained here as a separate species. Both *Lactobacillus lactis* and *Lactobacillus leichmannii* are treated as *Lactobacillus delbrueckii* subsp. *lactis* and *Lactobacillus bulgaricus* as *Lactobacillus delbrueckii* subsp. *bulgaricus* (see Weiss et al., 1983b, 1984).

1a. ***Lactobacillus delbrueckii* subsp. *delbrueckii*** (Leichmann 1896a) Weiss, Schillinger and Kandler 1984, 270^{VP} (Effective publication: Weiss, Schillinger and Kandler 1983b, 556.) (*Bacillus Delbrückii* (*sic*) Leichmann 1896b, 284.)

Arginine hydrolysis is strain dependent. Distinguishing physiological and biochemical properties are compiled in Table 84.

Isolated mainly from plant material fermented at high temperatures (40–53°C).

Type strain: ATCC 9649, CCUG 34222, CIP 57.8, DSM 20074, NBRC 3202, JCM 1012, LMG 6412, NCIMB 8130, NRRL B-763, VKM B-1596.

DNA G+C content (mol%): 49–51 (Bd, T_m)

GenBank accession number (16S rRNA gene): AY050172, M58814, X52654.

1b. ***Lactobacillus delbrueckii* subsp. *bulgaricus*** (Orla-Jensen 1919) Weiss, Schillinger and Kandler 1984, 270^{VP} (Effective publication: Weiss, Schillinger and Kandler 1983b, 556.) (*Thermobacterium bulgaricum* Orla-Jensen 1919, 164; *Lactobacillus bulgaricus* Rogosa and Hansen 1971, 181.)

bul.ga'ri.cus. N.L. adj. *bulgaricus* Bulgarian.

Arginine hydrolysis negative.

Ferments only a few carbohydrates. The distinguishing physiological and biochemical properties are compiled in Table 84.

Isolated from yogurt and cheese.

Type strain: ATCC 11842, CCUG 41390, CIP 101027, DSM 20081, NBRC 13953, JCM 1002, LMG 6901, LMG 13551, NCTC 12712, VKM B-1923.

DNA G+C content (mol%): 49–51 (Bd, T_m).

GenBank accession number (16S rRNA gene): AY050171.

1c. ***Lactobacillus delbrueckii* subsp. *lactis*** (Orla-Jensen 1919) Weiss, Schillinger and Kandler 1984, 270^{VP} (Effective publication: Weiss, Schillinger and Kandler 1983b, 556.) (*Thermobacterium lactis* Orla-Jensen 1919, 164; *Lactobacillus leichmannii* (Henneberg) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 249.)

lac'tis. L. n. *lac* milk; L. gen. n. *lactis* of milk.

Arginine hydrolysis is strain dependent. The distinguishing physiological and biochemical properties are compiled in Table 84.

Isolated from milk, cheese, compressed yeast, and grain mash.

Type strain: ATCC 12315, CCUG 31454, CIP 101028, DSM 20072, JCM 1248, LMG 7942, NRRL B-4525.

DNA G+C content (mol%): 49–51 (Bd, T_m).

GenBank accession number (16S rRNA gene): AY050173, M58823.

* *Editorial note*: Since this chapter was accepted for publication, 24 new species have been validly published. They are: *Lactobacillus apodemi* Osawa et al. (2006), *Lactobacillus camelliae* Tanasupawat et al. (2007), *Lactobacillus ceti* Vela et al. (2008), *Lactobacillus composti* Endo and Okada (2007a), *Lactobacillus concavus* Tong and Dong (2005b), *Lactobacillus crustorum* Scheirlinck et al. (2007b), *Lactobacillus cypriacasi* Lawson et al. (2001a), *Lactobacillus durianis* Leisner et al. (2002), *Lactobacillus equigenersi* Endo et al. (2008), *Lactobacillus farraginis* Endo and Okada (2007b), *Lactobacillus ghanensis* Nielsen et al. (2007), *Lactobacillus harbinensis* Miyamoto et al. (2006), *Lactobacillus hayakitensis* Morita et al. (2007), *Lactobacillus namurensis* Scheirlinck et al. (2007a), *Lactobacillus nantensis* Valcheva et al. (2006), *Lactobacillus parabrevis* Vancanneyt et al. (2006), *Lactobacillus parafarraginis* Endo and Okada (2007b), *Lactobacillus vennini* Chenoll et al. (2006), *Lactobacillus secaliphilus* Ehrmann et al. (2007), *Lactobacillus senmaizukei* Hiraga et al. (2008), *Lactobacillus siliginis* Aslam et al. (2006), *Lactobacillus sobrius* Konstantinov et al. (2006), *Lactobacillus thailandensis* Tanasupawat et al. (2007), and *Lactobacillus vini* Rodas et al. (2006).

- 1d. **Lactobacillus delbrueckii subsp. indicus** Dellaglio, Felis, Castioni, Torriani and Germond 2005, 403^{VP}
in 'di.cus. L. masc. adj. *indicus* from India, referring to the geographical origin of the strains.

Growth is observed in MRS plus 2.5% (w/v) NaCl, except for strain NCC780; none of the strains grows in MRS plus 5% (w/v) NaCl. All the strains grow in MRS at pH 3, 4, and 5, but not at pH 7.8. Ferments only a few carbohydrates. Distinguishing physiological and biochemical properties are compiled in Table 84.

Genotypic analysis showed that the subspecies represents a coherent cluster differentiating it from all other subspecies.

Isolated from a traditional Indian dairy fermented (type Dahi) product.

Type strain: NCC725, DSM 15996, LMG 22083.

DNA G+C content (mol%): 49–51 (Bd, T_m).

GenBank accession number (16S rRNA gene): AY421720.

2. **Lactobacillus acetotolerans** Entani, Masai and Suzuki 1986, 547^{VP}

a.ce.to.tole.rans. L. n. *acetum* vinegar; L. pres. part. *tolerans* tolerating, enduring; M.L. part. adj. *acetotolerans* vinegar tolerating.

Cells are nonmotile rods (0.4–0.5 × 1.1–3.4 μm) occurring singly, in pairs, or occasionally in short chains. The colonies are 0.3–1.5 mm in diameter, circular to irregular, convex, opaque, yellowish white, rough, and undulate when grown at 30°C for 14 d on Briggs agar (pH 5.0). Growth is generally observed at pH 3.3–6.6 and at 23–40°C. Resistant to 4–5% and 9–11% acetic acid at pH 3.5 and 5.0, respectively. Facultatively heterofermentative (some strains utilize ribose). No gas is produced from D-glucose or D-gluconate. Arginine and starch not hydrolyzed. Additional physiological and biochemical characteristics are presented in Table 85. Milk is not curdled. Riboflavin, pantothenic acid, folic acid, uracil, and Tween 80 are required for growth, but thiamine, *p*-aminobenzoic acid, biotin, adenine, guanine, xanthine, mevalonic acid, acetic acid, and ethanol are not required. Some strains require pyridoxal, nicotinic acid, vitamin B₁₂, and peptides.

Isolated from fermented vinegar broth.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: ATCC 43578, CCUG 32229, CIP 103180, DSM 20749, JCM 3825, LMG 10751, NBI 3014.

DNA G+C content (mol%): 35.3–36.5 (T_m).

GenBank accession number (16S rRNA gene): e.g., M58801.

Additional remarks: Two biovars were described. Strains of biovar I produce acid from D-mannitol but not from cellobiose, whereas strains of biovar II produce acid from cellobiose but not from D-mannitol. Strains of biovar II are more fastidious than those of biovar I. Only the strains of biovar II require nicotinic acid, vitamin B₁₂, and peptides in addition to common growth factors.

3. **Lactobacillus acidifarinae** Vancanneyt Neysens, De Wachter, Engelbeen, Snauwaert, Cleenwerck, Van der Meulen, Hoste, Tsakalidou, De Vuyst and Swings 2005, 619^{VP}
a.ci.di.fa'ri.nae. L. adj. *acidus* sour; N.L. n. *farina* flour; N.L. gen. n. *acidifarinae* of a sour flour.

Cells are nonmotile rods (1.0 × 2–20 μm) occurring singly, in pairs, or in chains. After 24 h, colonies are beige, circular with a rough and wrinkled surface, and approximately 1 mm in diam-

eter. Growth occurs at 5% NaCl. Obligately heterofermentative. Gas is produced from glucose and gluconate. Additional physiological and biochemical characteristics are presented in Table 86.

Isolated from a Belgian artisan wheat sourdough.

Phylogenetic position: unique.

Type strain: R-19065, CCM 7240, LMG 22200.

DNA G+C content (mol%): 51 (HPLC).

GenBank accession number (16S rRNA gene): AJ632158.

4. **Lactobacillus acidipiscis** Tanasupawat, Shida, Okada and Komagata 2000, 1481^{VP}

a.ci.di'pis.cis. L. adj. *acidus* sour; L. n. *piscis* fish; N.L. gen. n. *acidipiscis* of a sour fish, an isolation source of strains of this species.

Cells are nonmotile rods (0.4–0.6 × 1.2–5.0 μm) occurring singly, in pairs, and in chains. Colonies on MRSH agar plate are circular, slightly convex with an entire margin, and non-pigmented. Does not produce gas from glucose. Arginine is not hydrolyzed; no formation of slime from sucrose. Most strains show no reaction in litmus milk. Grows at 25–37°C but not at 15 or 42°C. Does not grow at pH 4.0 or pH 8.5. Grows in 10% NaCl. Some strains grow in the presence of 12% NaCl. Facultatively heterofermentative. Additional physiological and biochemical characteristics are presented in Table 85. Requires niacin and calcium pantothenate for growth. Major cellular fatty acids are straight-chained C_{16:0} and C_{18:0}.

Isolated from fermented fish (pla-ra and pla-chom) in Thailand.

Phylogenetic position: *Lactobacillus salivarius* group.

Type strain: FS60–1, CIP 106750, HSCC 1411, JCM 10692, NRIC 0300, PCU 207, TISTR 1386.

DNA G+C content (mol%): 38.6–41.5 (HPLC).

GenBank accession number (16S rRNA gene): AB023836.

5. **Lactobacillus acidophilus** (Moro 1900) Hansen and Møquot 1970, 326^{AL} (*Bacillus acidophilus* Moro 1900, 115.)

a.ci.do'phi.lus. N.L. n. *acidum* acid; Gr. adj. *philos* loving; N.L. adj. *acidophilus* acid-loving.

Cells are nonmotile rods with rounded ends (0.6–0.9 × 1.5–6 μm) occurring singly, in pairs, and in short chains. The colonies on trypticase-glucose-agar are rough, showing fuzzy outlines. Starch is fermented by most strains. Obligately homofermentative. Additional physiological and biochemical characteristics are presented in Table 84. Nutritional requirements: calcium pantothenate, folic acid, niacin, and riboflavin are essential; pyridoxal, thiamine, thymidine, and vitamin B₁₂ are not required.

Isolated from the intestinal tract of humans and animals, human mouth, vagina, sourdough, and wine.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: ATCC 4356, CCUG 5917, CIP 76.13, DSM 20079, NBRC 13951, JCM 1132, LMG 9433, LMG 13550, NCTC 12980, NRRL B-4495, VKM B-1660.

DNA G+C content (mol%): 34–37 (Bd, T_m).

GenBank accession number (16S rRNA gene): M58802, X61138.

Additional remarks: *Lactobacillus acidophilus* cannot be differentiated reliably from *Lactobacillus gasseri*, *Lactobacillus crispatus*, and *Lactobacillus amylovorus* by any simple phenotypic test; electrophoretic analysis of soluble cellular proteins or lactate

dehydrogenases, detailed cell wall studies or, preferentially, genotypical identification methods are necessary. Synonymous with *Lactobacillus acidophilus* group A-1 of Johnson et al. (1980).

6. ***Lactobacillus agilis*** Weiss, Schillinger, Laternser and Kandler 1982, 266^{VP} (Effective publication: Weiss, Schillinger, Laternser and Kandler 1981, 252.)

a'gi.lis. L. adj. *agilis* agile, motile.

Cells are rods with rounded ends (0.7–1.0 × 3–6 μm) occurring singly, in pairs, and in short chains. Motile with peritrichous flagella; motility normally easy to demonstrate in MRS broth. Arginine not hydrolyzed. Facultatively heterofermentative. Additional physiological and biochemical characteristics are presented in Table 85.

Habitat is the crop of pigeons (Baele et al., 2001b); isolated from municipal sewage.

Phylogenetic position: *Lactobacillus salivarius* group.

Type strain: CIP 101264, CCUG 31450, DSM 20509, JCM 1187, LMG 9186, NRRL B-14856.

DNA G+C content (mol%): 43–44 (T_m).

GenBank accession number (16S rRNA gene): M58803.

Additional remarks: "*Lactobacillus plantarum* var. *mobilis*" isolated from feces of turkey (Harrison and Hansen, 1950) was only tentatively named and therefore omitted from the Approved Lists of Bacterial Names (Skerman et al., 1980). According to the original description and later investigations (Sharpe et al., 1973) this organism may belong to *Lactobacillus agilis*.

7. ***Lactobacillus algidus*** Kato, Sakala, Hayashidani, Kiuchi, Kaneuchi and Ogawa 2000, 1148^{VP}

al'gi.dus. L. adj. *algidus* cold, referring to the ability to grow at low temperature.

The cellular morphology depends on growth medium: coccobacilli or short rods in MRS broth and rods (0.3–0.7 × 1.1–1.9 μm) on MRS agar. Nonmotile. Colonies are circular, convex, smooth, cream-white, and 1.0–1.5 mm in diameter after 48 h incubation at 20°C on MRS agar. Facultatively heterofermentative. Growth occurs at 0–25°C. No growth at 30°C. No dextran is produced from sucrose. Additional physiological and biochemical characteristics are presented in Table 85.

The major cellular fatty acids produced by strain M6A9^T are the straight-chain mono-unsaturated oleic acid (C_{18:1 ω9}) and straight-chain saturated palmitic acid (C_{16:0}).

Isolated from vacuum-packaged refrigerated beef, stored at low temperature.

Phylogenetic position: *Lactobacillus salivarius* group.

Type strain: M6A9, CIP 106688, JCM 10491.

DNA G+C content (mol%): 36.8 ± 3 (HPLC).

GenBank accession number (16S rRNA gene): AB033209.

8. ***Lactobacillus alimentarius*** Reuter 1983a, 672^{VP} (Effective publication: Reuter 1983b, 278.)

a.li.men.ta'ri.us. L. adj. *alimentarius* pertaining to food.

Cells are nonmotile, short, slender rods (0.6–0.8 × 1.5–2.5 μm). Growth in the presence of 10% NaCl. Acetoin is produced from glucose. Facultatively heterofermentative. Additional physiological and biochemical characteristics are presented in Table 85.

Isolated from marinated fish products, meat products (fermented sausages, sliced prepacked sausages), and sour-dough.

Phylogenetic position: unique.

Type strain: ATCC 29643, CCUG 30672, CIP 102986, DSM 20249, JCM 1095, LMG 9187.

DNA G+C content (mol%): 36–37 (T_m).

GenBank accession number (16S rRNA gene): M58804.

9. ***Lactobacillus amylolyticus*** Bohak, Back, Richter, Ehrmann, Ludwig and Schleifer 1999, 1^{VP} (Effective publication: Bohak, Back, Richter, Ehrmann, Ludwig and Schleifer 1998, 363.)

a.my.lo.ly'ti.cus. Gr. n. *amyllum* starch, Gr. adj. *lyticus* able to loosen; N.L. adj. *amylolyticus* starch-digesting.

Cells are nonmotile rods with rounded ends (0.7–0.9 μm × 5–20 μm) occurring singly, in pairs, or in short chains. Colonies on MRS flat, rough, dull surface, beige to dirty-white color; diameter 2–3 mm. Growth in agar stabs occurs throughout the stab but not up to the surface. Can grow up to 52°C; optimum at 45°C–48°C; no growth at 20°C. Optimum at pH 5–5.5; no growth below pH 3.5 or above pH 6. Obligately homofermentative. Esculin is hydrolyzed in some cases; arginine is not hydrolyzed. Urease is not produced. Additional physiological and biochemical characteristics are presented in Table 84. Cell walls contain teichoic acid.

Isolated from brewery, unhoped wort, malt-mash, and malt.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: LA 5, CCUG 39901, DSM 11664, JCM 12529, LMG 18796.

DNA G+C content (mol%): 39 (T_m).

GenBank accession number (16S rRNA gene): Y17361.

10. ***Lactobacillus amylophilus*** Nakamura and Crowell 1981, 216^{VP} (Effective publication: Nakamura and Crowell 1979, 539.)

a.my.lo'phi.us. Gr. n. *amyllum* starch; Gr. adj. *philos* loving; N.L. adj. *amylophilus* starch-loving.

Cells are nonmotile thin rods (0.5–0.7 × 2–3 μm) occurring singly and in short chains. Actively ferments starch and displays extracellular amylolytic enzyme activity. Obligately homofermentative. Additional physiological and biochemical characteristics are presented in Table 84. Growth factor requirements: riboflavin, pyridoxal, pantothenic acid, niacin, and folic acid are essential; thiamine is not required.

Isolated from swine waste-corn fermentation.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: ATCC 49845, CCUG 30137, CIP 102988, DSM 20533, NBRC 15881, JCM 1125, LMG 6900, NCAIM B.01457, NRRL B-4437, NRRL B-4476.

DNA G+C content (mol%): 44–46 (Bd).

GenBank accession number (16S rRNA gene): M58806.

11. ***Lactobacillus amylovorus*** Nakamura 1981, 61^{VP}

a.my.lo.vo'rus. Gr. n. *amyllum* starch; L. v. *vorare* to devour; N.L. adj. *amylovorus* starch-devouring.

Cells are nonmotile rods (1 × 3–5 μm) occurring singly and in short chains. Good growth at 45°C. Actively ferments starch and displays extracellular amylolytic enzyme activity. Obligately homofermentative. Additional physiological and biochemical characteristics are presented in Table 84.

Growth factor requirements: niacin, pantothenic acid, folic acid, and riboflavin are essential; thiamine is not required.

Isolated from cattle waste-corn fermentation.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: ATCC 33620, CCUG 27201, CIP 102989, DSM 20531, JCM 1126, LMG 9496, NCAIM B.01458, NRRL B-4540.

DNA G+C content (mol%): 40.3 ± 0.1 (Bd).

GenBank accession number (16S rRNA gene): AY944408, M58805.

Additional remarks: Synonymous with *Lactobacillus acidophilus* group A 3 of Johnson et al. (1980). See comments on *Lactobacillus acidophilus*.

12. ***Lactobacillus animalis*** Dent and Williams 1983, 439^{VP} (Effective publication: Dent and Williams 1982, 384.) a.ni.ma'lis. L. n. *animal* animal; L. gen. n. *animalis* of an animal.

Cells are nonmotile rods (1.0–1.2 × 3–6 µm) with rounded ends; exponential growth phase cells in MRS broth occur singly or in pairs. Good growth at 45°C. Arginine not hydrolyzed. Facultatively heterofermentative. Additional physiological and biochemical characteristics are presented in Table 85.

Isolated from dental plaques and intestines of animals.

Phylogenetic position: *Lactobacillus salivarius* group.

Type strain: 1535, ATCC 35046, CCUG 33906, CIP 103152, DSM 20602, NBRC 15882, JCM 5670, LMG 9843, NCIMB 13278, NRRL B-14176.

DNA G+C content (mol%): 41–44 (T_m).

GenBank accession number (16S rRNA gene): M58807, X61133.

Additional remarks: Some of the strains on which the description of *Lactobacillus animalis* was based ferment arabinose and ribose weakly thus resembling *Lactobacillus murinus*. The comparison of the sequences of >1400 bp of the 16S rRNA reveals 99.7% identity. DNA/DNA similarity studies should be directed towards establishing the genomic relationship of the different strains of *Lactobacillus animalis* among each other and with *Lactobacillus murinus*.

13. ***Lactobacillus antri*** Roos, Engstrand and Jonsson 2005, 80^{VP} an'tri. L. gen. n. *antri* of a cave (the antrum region of the stomach).

Cells are nonmotile rods (1 × 1.2–2 µm) occurring singly or in pairs. After anaerobic growth at 37°C for 48 h, colonies on MRS agar are 2–3.5 mm in diameter; they are white, smooth, and slightly convex. Growth on MRS agar under aerobic conditions is very weak. In MRS broth, growth occurs at 25 and 45°C, but not at 20°C. Obligately heterofermentative. Gas is produced from glucose. Additional physiological and biochemical characteristics are presented in Table 86.

Isolated from a biopsy of the healthy human gastric mucosa.

Phylogenetic position: *Lactobacillus reuteri* group.

Type strain: Kx146A4, CCUG 48456, DSM 16041, LMG 22111.

DNA G+C content (mol%): 44 (HPLC).

GenBank accession number (16S rRNA gene): AY253659.

14. ***Lactobacillus aviarius*** Fujisawa, Shirasaka, Watabe and Mitsuoka 1985, 223^{VP} (Effective publication: Fujisawa, Shirasaka, Watabe and Mitsuoka 1984, 419.)

a.vi.a'ri.us. L. adj. *aviarius* pertaining to birds.

Cells nonmotile, short to coccoid rods (0.5–1.0 × 0.5–1.6 µm) with rounded ends, occurring singly or in short chains. Surface colonies on BL agar after 2 d of anaerobic incubation are 0.3–1.2 µm in diameter, round, globular, yellowish-white to reddish-brown, with a smooth surface and entire edge. Strictly anaerobic. No gas from glucose. The final pH of glucose broth is 3.9–4.0. Obligately homofermentative. Two subspecies are currently recognized.

Phylogenetic position: *Lactobacillus salivarius* group.

DNA G+C content (mol%): 39–43 (T_m).

Additional remarks: On Validation List no. 17, the type strain, strain 75 (DSM 20655) was incorrectly cited.

- 14a. ***Lactobacillus aviarius* subsp. *aviarius*** Fujisawa, Shirasaka, Watabe and Mitsuoka 1985, 223^{VP} (Effective publication: Fujisawa, Shirasaka, Watabe and Mitsuoka 1984, 419.)

Distinguishing physiological and biochemical properties are compiled in Table 84.

Isolated from chicken and duck alimentary tract and feces.

Type strain: 75, ATCC 43234, DSM 20655, CCUG 32230, CIP 103144, JCM 5666, LMG 10753.

DNA G+C content (mol%): 39–43.

GenBank accession number (16S rRNA gene): M58808.

- 14b. ***Lactobacillus aviarius* subsp. *araffinosus*** Fujisawa, Shirasaka, Watabe and Mitsuoka 1985, 223^{VP} (Effective publication: Fujisawa, Shirasaka, Watabe and Mitsuoka 1984, 419.)

a.raffi.no'sus. Gr. pref. *a* not; N.L. adj. *raffinosus* of raffinose; N.L. adj. *araffinosus* not fermenting raffinose.

Distinguishing physiological and biochemical properties are compiled in Table 84.

Isolated from chicken duodenum.

Type strain: DSM 20653.

DNA G+C content (mol%): 41.3.

GenBank accession number (16S rRNA gene): unavailable.

Additional remarks: The effective date of validation for this subspecies is that of Validation List no. 17 from which it was accidentally omitted (see Fujisawa et al., 1986, and Validation List no. 20, footnote d.)

15. ***Lactobacillus bifermantans*** Kandler, Schillinger and Weiss 1983, 896^{VP} (Effective publication: Kandler, Schillinger and Weiss 1983, 409.)

bi.fer.men'tans. L. pref. *bis* twice; L. part. *fermantans* leavening; N.L. part. adj. *bifermantans* doubly fermenting.

Cells are nonmotile irregular rods with rounded or often tapered ends (0.5–1.0 × 1.5–2.0 µm) occurring singly, in pairs, or irregular short chains, often forming clumps. No growth at 42°C. Homofermentative production of DL-lactic acid in media containing more than 1% fermentable hexoses. Lactic acid is fermented to acetic acid, ethanol, traces of propionic acid, CO₂, and H₂ at pH >4.0. Arginine not hydrolyzed. Additional physiological and biochemical characteristics are presented in Table 85. In contrast to all other lactobacilli, *Lactobacillus bifermantans* ferments lactate

and produces free H₂ and was therefore put on the list of species *incertae sedis* in the eighth edition of the *Manual*.

Isolated from spoiled Edam and Gouda cheeses where it forms undesired small cracks ("Boekelscheuren", Pette and van Beynum (1943).

Phylogenetic position: unique.

Type strain: ATCC 35409, CCUG 32234, CIP 102811, DSM 20003, JCM 1094, LMG 9845.

DNA G+C content (mol%): 45 (*T_m*).

GenBank accession number (16S rRNA gene): M58809.

16. **Lactobacillus brevis** (Orla-Jensen 1919) Bergey, Breed, Hammer, Huntoon, Murray and Harrison 1934, 312^{AL} (*Betabacterium breve* Orla-Jensen 1919, 175.) *bre'vis*. L. adj. *brevis* short.

Cells are rods with rounded ends, generally 0.7–1.0 × 2–4 μm, occurring singly and in short chains. Growth factor requirements: calcium pantothenate, niacin, thiamine, and folic acid are essential; riboflavin, pyridoxal, and vitamin B₁₂ not required. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86.

Isolated from milk, cheese, sauerkraut, sourdough, silage, cow manure, feces, mouth, and intestinal tract of humans and rats.

Phylogenetic position: unique.

Type strain: ATCC 14869, CCUG 30670, CIP 102806, DSM 20054, JCM 1059, LMG 6906, LMG 7944, NRRL B-4527.

DNA G+C content (mol%): 44–47 (Bd, *T_m*).

GenBank accession number (16S rRNA gene): M58810, X61134.

Additional remarks: *Lactobacillus brevis* is often difficult to distinguish clearly from *Lactobacillus buchneri*, *Lactobacillus hilgardii*, *Lactobacillus collinoides*, *Lactobacillus kefir*, *Lactobacillus spicheri*, or *Lactobacillus acidifarnae* by simple physiological tests, especially carbohydrate fermentation reactions. Identification by using genotypical methods is most suitable (see *Lactobacillus acidophilus*).

17. **Lactobacillus buchneri** (Henneberg 1903) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 251^{AL} (*Bacillus Buchneri* (*sic*) Henneberg 1903, 163.)

buch'ne.ri. N.L. gen. n. *buchneri* of Buchner; named for E. Buchner, a German bacteriologist.

Cells are nonmotile rods with rounded ends (0.7–1.0 × 2–4 μm) occurring singly and in short chains. *Lactobacillus buchneri* is identical in almost all characteristics with *Lactobacillus brevis*. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86.

Isolated from pressed yeast, milk, cheese, fermenting plant material, and human mouth.

Phylogenetic position: unique.

Type strain: ATCC 4005, CCUG 21532, CIP 103023, DSM 20057, JCM 1115, LMG 6892, NCAIM B.01145, NRRL B-1837, VKM B-1599.

DNA G+C content (mol%): 44–46 (Bd, *T_m*).

GenBank accession number (16S rRNA gene): AB205055, M58811, X61139.

18. **Lactobacillus casei** (Orla-Jensen 1916) Hansen and Lessel 1971, 71^{AL} (*Streptobacterium casei* Orla-Jensen 1919, 166.) *ca'se.i*. L. n. *caseus* cheese; L. gen. n. *casei* of cheese.

Cells are nonmotile rods (0.7–1.1 × 2.0–4.0 μm) often with square ends and tending to form chains. Facultatively heterofermentative. L-LDH is activated by FDP and Mn²⁺. Growth factor requirements: riboflavin, folic acid, calcium pantothenate, and niacin are essential; pyridoxal or pyridoxamine is essential or stimulatory; thiamine, vitamin B₁₂, and thymidine are not required. Additional physiological and biochemical characteristics are presented in Table 85.

Isolated from milk, cheese, and intestinal tract.

Phylogenetic position: unique.

Type strain: ATCC 393, BCRC 10697, CCUG 21451, CECT 475, CIP 103137, DSM 20011, IAM 12473, NBRC 15883, JCM 1134, KCTC 3109, LMG 6904, NCIMB 11970, NCIMB 11970, NRRL B-1922.

DNA G+C content (mol%): 45–47 (Bd).

GenBank accession number (16S rRNA gene): AF469172, AY773945, D16551, M23928, X61135.

Additional remarks: The taxonomic status of *Lactobacillus casei* is characterized by certain inconsistencies (Dellaglio et al., 2002; Dicks et al., 1996). The type strain ATCC 393 is closely related to *Lactobacillus zeae* and does not appear to represent the majority of strains isolated from multitude of habitats as they are described in the previous edition of *Bergey's Manual*. Instead only few strains are known to which the type strain ATCC 393 is genetically closely related. When *Lactobacillus paracasei* had been described by Collins et al. (1989), the 16S rRNA sequences of crucial strains were not included in their investigation. Thus, *Lactobacillus paracasei* reflects the ecological distribution that was formerly attributed to *Lactobacillus casei*. Based on numerous arguments, Dellaglio et al. (2002) have presented a Request for an Opinion to the Judicial Commission asking to abolish the species *Lactobacillus paracasei* and to transfer the present type strain of *Lactobacillus casei* to *Lactobacillus zeae*.

19. **Lactobacillus coleohominis** Nikolaitchouk, Wachter, Falsen, Andersch, Collins and Lawson 2001, 2084^{VP}

co.le.o.ho'mi.nis. Gr. n. *koleos* vagina; L. gen. n. *hominis* of humans; N.L. gen. n. *coleohominis* of the vagina of humans.

Cells are rods. On Columbia horse-blood agar, its colonies are small, entire, non-pigmented, and do not produce an odor. In the original description it was stated that glucose was fermented without gas formation. In our laboratory (Hammes and Hertel, unpublished results), the type strain produced gas from glucose. Ammonia is not produced from arginine. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86. Activity is detected for acid phosphatase (weak reaction), β-galactosidase, β-glucuronidase, and phosphoamidase (weak reaction). Activity is not detected for alanine phenylalanine proline arylamidase, alkaline phosphatase, cystine arylamidase, N-acetyl-β-glucosaminidase, chymotrypsin, ester lipase C8, lipase C14, -fucosidase, glycytryptophan arylamidase, α-mannosidase, β-mannosidase, pyroglutamic acid arylamidase, valine arylamidase, trypsin, or urease. The reactions are variable for arginine dihydrolyase, esterase C-4, α-glucosidase, β-glucosidase, and leucine

arylamidase. Hippurate are hydrolyzed. Voges–Proskauer-negative.

Isolated from human vagina and urinary tract.

Phylogenetic position: *Lactobacillus reuteri* group.

Type strain: CCUG 44007, CIP 106820, DSM 14060, JCM 11550.

DNA G+C content (mol%): not determined.

GenBank accession number (16S rRNA gene): AJ293530, AM113776.

20. ***Lactobacillus collinoides*** Carr and Davies 1972, 470^{AL} col.li.no.i'des. L. adj. *collinus* hilly; Gr. suff. *eides* resembling, similar; N.L. adj. *collinoides* hill-shaped, pertaining to colony form.

Cells are rods with rounded ends (0.6–0.8 × 3–5 μm); tendency to form long filaments, occurring singly, in palisades, and irregular clumps. Growth in MRS broth is distinctly improved by the addition of 20% tomato juice and by replacement of glucose by maltose. Mannitol formed from fructose. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86.

Isolated from cider.

Phylogenetic position: unique.

Type strain: ATCC 27612, CCUG 32259, CIP 103008, DSM 20515, JCM 1123, LMG 9194.

DNA G+C content (mol%): 46 (T_m).

GenBank accession number (16S rRNA gene): AB005893.

21. ***Lactobacillus coryniformis*** Abo-Elnaga and Kandler 1965c, 18^{AL}

co.ry'ni.for'mis. Gr. n. *coryne* a club; L. adj. *formis* shaped; N.L. adj. *coryniformis* club-shaped.

Cells are short, often coccoid rods; frequently somewhat pear-shaped (0.8–1.1 × 1–3 μm) occurring singly, in pairs, or in short chains. Facultatively heterofermentative. Additional physiological and biochemical characteristics are presented in Table 85. Growth factor requirements: pantothenic acid, niacin, riboflavin, biotin, and *p*-aminobenzoic acid are essential for all or the majority of the strains tested; folic acid, pyridoxin, thiamine, and vitamin B₁₂ are not required.

Isolated from silage, cow dung, dairy barn air, and sewage. Two subspecies are recognized within *Lactobacillus coryniformis*.

Phylogenetic position: unique.

DNA G+C content (mol%): 45 (T_m).

- 21a. ***Lactobacillus coryniformis* subsp. *coryniformis*** Abo-Elnaga and Kandler 1965c, 18^{AL}

The lactic acid produced from glucose contains substantial amounts of the L-isomer (15–20% of total lactic acid).

Type strain: ATCC 25602, CIP 103133, DSM 20001, CCUG 30666, JCM 1164, LMG 9196, NRRL B-4391.

DNA G+C content (mol%): 45 (T_m).

GenBank accession number (16S rRNA gene): M58813.

- 21b. ***Lactobacillus coryniformis* subsp. *torquens*** Abo-Elnaga and Kandler 1965c, 19^{AL}

tor'quens. L. pres. part. *torquens* twisting.

Exclusively D(–)lactic acid is produced.

Type strain: ATCC 25600, CCUG 30667, CIP 103134, DSM 20004, JCM 1166, LMG 9197, NRRL B-4390.

DNA G+C content (mol%): 45 (T_m).

GenBank accession number (16S rRNA gene): not available.

22. ***Lactobacillus crispatus*** (Brygoo and Aladame 1953) Moore and Holdeman (1970), 15^{AL} emend. Cato, Moore and Johnson 1983, 15^{AL} (*Eubacterium crispatum* Brygoo and Aladame 1953, 641.)

cris.pa'tus. L. part. adj. *crispatus* curled, crisped, referring to morphology observed originally in broth media.

Cells are straight to slightly curved rods with rounded ends (0.8–1.6 × 2.3–11 μm) occurring singly and in short chains. Esculin and starch hydrolyzed. Arginine not hydrolyzed. Obligately homofermentative. Additional physiological and biochemical characteristics are presented in Table 84.

Isolated from human feces, vagina, and buccal cavities, crops and ceca of chicken; also found in patients with purulent pleurisy, leucorrhoea, and urinary tract infection.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: ATCC 33820, CCUG 30722, CIP 102990, CIPP II, DSM 20584, JCM 1185, LMG 9479, VPI 3199.

DNA G+C content (mol%): 35–38 (T_m).

GenBank accession number (16S rRNA gene): AF257097, Y17362.

Additional remarks: See comments on *Lactobacillus acidophilus*. Synonymous with *Lactobacillus acidophilus* group A2 of Johnson et al. (1980).

23. ***Lactobacillus curvatus*** (Troili-Petersson 1903) Abo-Elnaga and Kandler 1965c, 19^{AL} (*Bacterium curvatum* Troili-Petersson 1903, 137.)

cur.va'tus. L. v. *curvare* to curve; L. past. part. *curvatus* curved.

Cells are curved, bean-shaped rods with rounded ends (0.7–0.9 × 1–2 μm) occurring in pairs and short chains; closed rings of usually four cells or horseshoe forms frequently observed. Some strains at first motile; motility lost on subculture. Some strains tested grow even at 2–4°C. L-LDH is activated by FDP and Mn²⁺. Possesses lactic acid racemase whose biosynthesis is induced by L(+)-lactic acid. Racemase induction generally not repressed by acetate. Arginine not hydrolyzed. Formation of catalase in the presence of heme is strain dependent. Facultatively heterofermentative. Additional physiological and biochemical characteristics are presented in Table 85.

Isolated from cow dung, milk, silage, sauerkraut, prepacked finished dough, sourdough, pressed yeast, and meat products.

Phylogenetic position: unique.

Type strain: ATCC 25601, CCUG 30669, CIP 102992, DSM 20019, NBRC 15884, JCM 1096, LMG 9198, LMG 13553, NRRL B-4562.

DNA G+C content (mol%): 42–44 (T_m).

GenBank accession number (16S rRNA gene): AJ621550, AM113777.

Additional remarks: Two subspecies were validly published by Torriani et al. (1996). Based on molecular studies, it was shown by Koort et al. (2004) that the type strain of subspecies *melibiosus* was synonymous with *Lactobacillus sakei* subsp. *carnosus*.

24. **Lactobacillus cypricasei** Lawson, Papademas, Wacher, Falsen, Robinson and Collins 2001a, 48^{VP}
cy.pri.ca'se.i. N.L. masc. gen. n. *cypricasei* of cheese from Cyprus, referring to the original isolation source.
 Cells are rods with rounded ends occurring as single cells, in pairs, or in short chains (0.6–0.8 × 3–5 µm). When grown on MRS agar, colonies are small, entire, and cream colored. No growth is observed at 15 or 45°C in MRS broth after 48 h incubation. The optimum pH range is 5.5–7.5. Facultatively heterofermentative. No gas is produced from glucose metabolism. Additional physiological and biochemical characteristics are presented in Table 85. Positive reactions are obtained for arginine dihydrolase, β-galactosidase, β-galacturonidase, α-glucosidase, β-glucosidase, leucine arylamidase, pyroglutamic acid arylamidase (weak reaction), and valine arylamidase. Negative reactions are obtained for alanine phenylalanine proline arylamidase, alkaline phosphatase, chymotrypsin, esterase C-4, ester lipase C8, α-fucosidase, β-glucuronidase, glycine-tryptophan arylamidase, lipase C14, β-mannosidase, trypsin, and urease. Variable reactions are obtained for acid phosphatase, N-acetyl-β-glucosaminidase, cystine arylamidase, α-galactosidase, α-mannosidase, and phosphoamidase. Hippurate is not hydrolyzed. Acetoin is produced.
 Isolated from Halloumi cheese, a cheese prevalent in Cyprus.
Phylogenetic position: *Lactobacillus salivarius* group.
Type strain: LMK3, ATCC BAA-288, CCUG 42961, CIP 106393, DSM 15353, JCM 11551.
DNA G+C content (mol%): not determined.
GenBank accession number (16S rRNA gene): AJ251560.
25. **Lactobacillus diolivorans** Krooneman, Alderkamp, Oude Elferink, Driehuis, Cleenwerck, Swings, Gottschal and Vancanneyt 2002, 645^{VP}
di.o.li.vo'rans. N.L. *diol* from 1,2-propanediol; L. v. *vorare* to devour; N.L. adj. *diolivorans* devouring diols.
 Cells are nonmotile rods that occur as single cells, in pairs, or occasionally in short chains. On MRS-MOD medium with 1,2-propanediol as substrate, cells are 1 µm × 2 µm whereas, on glucose, the cells are longer, up to 10 µm. Colonies are off-white on MRS medium. Obligately heterofermentative. Fermentative growth on 1,2-propanediol under anoxic conditions, producing propanol and propionic acid. Optimal temperature and pH for growth on 1,2-propanediol are 30–32°C and pH 5.7. No growth is obtained at 12 or 42°C. Growth at NaCl concentrations of 2% (w/v) at 30°C; no growth at 4%. Additional physiological and biochemical characteristics are presented in Table 86.
 Isolated from maize silage in the Netherlands.
Phylogenetic position: unique.
Type strain: JKD6, DSM 14421, JCM 12183, LMG 19667.
DNA G+C content (mol%): 40 (HPLC).
GenBank accession number (16S rRNA gene): AF264701.
26. **Lactobacillus durianis** Leisner, Vancanneyt, Lefebvre, Vandemeulebroecke, Hoste, Euras Vilalta, Rusul and Swings 2002, 929^{VP}
du.ri.an'is. N.L. gen. n. *durianis* of the durian fruit.
 Cells are nonmotile rods occurring singly, as pairs, or in chains (fewer than five cells) in APT broth supplemented with glucose, D-xylose, or both components. Surface colonies on APT agar with D-xylose or glucose after 3 d of microaerophilic incubation at 30°C are 1 mm or less in diameter, round, and with smooth surfaces. The colonies are smaller with glucose than with D-xylose (growth is enhanced by replacing glucose with D-xylose). Obligately heterofermentative. Gas is produced from gluconic acid but not from glucose. None of the three strains reduces tetrazolium on SBM agar, nor do they grow in Clark & Lubbs broth used in the Voges–Proskauer test. Able to grow on acetate agar but unable to acidify La-broth below pH 4.15. No growth in the presence of 6.5 or 8% NaCl. Resistant towards 30 µg vancomycin/g. Additional physiological and biochemical characteristics are presented in Table 86.
 Isolated from a Malaysian acid-fermented condiment, tempoyak, made from the durian fruit.
Phylogenetic position: unique.
Type strain: CCUG 45405, JCM 12184, LMG 19193.
DNA G+C content (mol%): 43.2–43.3 (HPLC).
GenBank accession number (16S rRNA gene): AJ315640.
27. **Lactobacillus equi** Morotomi, Yuki, Kado, Kushiro, Shimazaki, Watanabe and Yuyama 2002, 214^{VP}
e'qui. L. n. *equus* horse; L. gen. n. *equi* of the horse.
 Cells are nonmotile rods (0.6–0.8 × 1.3–3.5 µm) occurring singly and in pairs. Colonies on MRS agar are white, smooth, convex, and approximately 2 mm in diameter. Some strains contain filamentous cells. Catalase-negative. Facultatively heterofermentative, as several pentoses are fermented. Additional physiological and biochemical characteristics are presented in Table 85. Acid is not produced from glycerol. Reactions of esculin hydrolysis and acid production from rhamnose, sorbitol, N-acetylglucosamine, ribose, mannose, and D-turanose are variable.
 Isolated from feces of horses.
Phylogenetic position: *Lactobacillus salivarius* group.
Type strain: YIT 0455, ATCC BAA-261, JCM 10991.
DNA G+C content (mol%): 38.9 ± 0.8 (HPLC).
GenBank accession number (16S rRNA gene): AB048833.
28. **Lactobacillus farciminis** Reuter 1983a, 672^{VP} (Effective publication: Reuter 1983b, 278.)
far.ci'mi.nis. L. n. *farcimen* sausage; L. gen. n. *farciminis* of sausage.
 Cells are nonmotile, slender rods (0.6–0.8 × 2–6 µm) occurring singly and in short chains. Grows in the presence of 10% NaCl and occasionally 12% NaCl. Arginine is hydrolyzed. Obligately homofermentative. Additional physiological and biochemical characteristics are presented in Table 84.
 Isolated from meat products (fermented sausages) and sourdough.
Phylogenetic position: unique.
Type strain: ATCC 29644, DSM 20184, CCUG 30671, CIP 103136, JCM 1097, LMG 9200, NRRL B-4566.
DNA G+C content (mol%): 34–36 (T_m).
GenBank accession number (16S rRNA gene): M58817.
29. **Lactobacillus ferintoshensis** Simpson, Pettersson and Priest 2002a, 1075^{VP} (Effective publication: Simpson, Pettersson and Priest 2001, 1015.)
fe.rin.to.shen'sis. N.L. adj. *ferintoshensis* from Ferintosh, a Scottish estate famous for its whisky.

Cells are nonmotile rods (3–4 µm × 1 µm) occurring singly, in pairs, or in short chains. After 48 h incubation on modified MRS agar (MRS agar supplemented with vitamins), colonies are 2–5 mm in diameter, circular, shiny, and creamy white in color. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86.

Isolated from malt whisky fermentations.

Phylogenetic position: unique

Type strain: R7-84, CIP 106749, JCM 12511.

DNA G+C content (mol%): not determined.

GenBank accession number (16S rRNA gene): AF275311.

30. **Lactobacillus fermentum** Beijerinck 1901, 233^{AL}

fer.men'tum. L. n. *fermentum* ferment, yeast.

Cells are nonmotile rods (0.5–0.9 µm thick and highly variable in length), occurring singly or in pairs. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86. Growth factor requirements: calcium pantothenate, niacin, and thiamine are essential; riboflavin, pyridoxal, and folic acid not required.

Isolated from yeast, milk products, sourdough, fermenting plant material, manure, sewage, and mouth and feces of humans.

Phylogenetic position: *Lactobacillus reuteri* group.

Type strain: ATCC 14931, CCUG 30138, CIP 102980, DSM 20052, NBRC 15885, JCM 1173, LMG 6902, NCCB 46038, NCIMB 11840, NRRL B-4524.

DNA G+C content (mol%): 52–54 (Bd, T_m).

GenBank accession number (16S rRNA gene): M58819, X61142.

Additional remarks: *Lactobacillus fermentum* cannot be definitely distinguished from *Lactobacillus reuteri* by simple physiological tests. The genotypic methods used provide clear results (Dellaglio et al., 2004). *Lactobacillus cellobiosus* Rogosa et al. 1953, 693^{AL} has been reclassified as a later synonym of *Lactobacillus fermentum* Beijerinck (1901) by Dellaglio et al. (2004).

31. **Lactobacillus fornicalis** Dicks, Silvester, Lawson and Collins 2000, 1258^{VP}

for.nic.a'lis. N.L. adj. *fornicalis* pertaining to the posterior fornix.

Cells are nonmotile rods. Colonies on MRS agar are round, smooth, white, and approximately 1 mm in diameter. Grows well on the surface of MRS agar when not incubated under microaerophilic conditions. Facultatively heterofermentative, with no gas production from glucose or gluconate, but ribose is fermented. Voges–Proskauer-negative. Indole is not formed. Polysaccharides are not produced from sucrose. Additional physiological and biochemical characteristics are presented in Table 85.

Isolated from the posterior fornix fluid of the human vagina.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: TV 1018, ATCC 700934, CCUG 43621, CIP 106679, DSM 13171, JCM 12512.

DNA G+C content (mol%): 37 (T_m).

GenBank accession number (16S rRNA gene): Y18654.

32. **Lactobacillus fructivorans** Charlton, Nelson And Werkman 1934, 1^{AL}

fruc.ti.vo'rans. L. n. *fructus* fruit; L. v. *vorare* to eat; N.L. pres. part. *fructivorans* fruit-eating, intended to mean fructose-devouring.

Cells are nonmotile rods (0.5–0.8 × 1.5–4 µm) with rounded ends, occurring singly, in pairs, and in chains; very long, more or less curved or coiled filaments often observed. Acidophilic; favorable pH is 5.0–5.5; no growth at an initial pH higher than 6.0. Nutritionally very exacting, at least on primary isolation. Depending on the source of isolation, mevalonic acid, tomato juice, and/or ethanol are required for growth. Some strains, especially those isolated from non-alcohol-containing sources, often become less fastidious during laboratory transfers and grow well in MRS broth. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86.

Isolated from spoiled mayonnaise, salad dressings, vinegar preserves, spoiled sake, dessert wines, and aperitifs.

Phylogenetic position: unique.

Type strain: ATCC 8288, CCUG 32260, CIP 103042, DSM 20203, NBRC 13954, JCM 1117, LMG 9201, NRRL B-1841.

DNA G+C content (mol%): 38–40 (T_m).

GenBank accession number (16S rRNA gene): M58818, X76330.

Additional remarks: *Lactobacillus trichodes* Fornachon et al. 1949, 129^{AL} and *Lactobacillus heterohiochii* Kitahara et al. 1957, 117^{AL} have been reclassified as later synonyms of *Lactobacillus fructivorans* by Weiss et al. (1983a).

33. **Lactobacillus frumenti** Müller, Ehrmann and Vogel 2000b, 2132^{VP}

fru.men'ti. L. gen. n. *frumenti* from cereal.

Cells are nonmotile rods occurring singly or in pairs (seldom in chains). Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86.

Isolated from sourdough.

Phylogenetic position: *Lactobacillus reuteri* group.

Type strain: TMW 1.666, CIP 106922, DSM 13145, JCM 11122, LMG 19473.

DNA G+C content (mol%): 43–45 (HPLC).

GenBank accession number (16S rRNA gene): AJ250074.

34. **Lactobacillus fuchuensis** Sakala, Kato, Hayashidani, Murakami, Kaneuchi and Ogawa 2002, 1153^{VP}

fu.chu.en'sis. N.L. adj. *fuchuensis* of Fuchu, the city in which the bacterium was originally isolated.

Cells are nonmotile, straight, and curved rods (0.5–0.75 µm × 2–6 µm) occurring singly, in pairs, or short chains. Colonies on MRS agar plates after 48 h are small, about 1.0–2.0 mm in diameter, smooth, entire, convex, and cream colored. No growth is observed at 37°C in MRS broth after 48 h incubation or on acetate agar (pH 5.4). No gas is produced from glucose or gluconate. Facultatively heterofermentative. Additional physiological and biochemical characteristics are presented in Table 85. Alanine-phenylalanine-proline arylamidase, arginine dehydrolase, α-glucosidase, N-acetyl-β-glucosaminidase, glycyl-tryptophan arylamidase, and β-mannosidase activities are detected. No activity for β-galactosidase, β-glucuronidase,

α -galactosidase, alkaline phosphatase, or pyrrolidonyl arylamidase is detected. Hippurate is not hydrolyzed. Acetoin is produced weakly. Urease is not produced. *m*-Dmp is not detected in the cell wall.

Isolated from vacuum-packaged refrigerated beef. Habitat is not known.

Phylogenetic position: unique.

Type strain: B5M10, DSM 14340, JCM 11249.

DNA G+C content (mol%): 41–41.7 (HPLC).

GenBank accession number (16S rRNA gene): AB063479.

35. ***Lactobacillus gallinarum*** Fujisawa, Benno, Yaeshima and Mitsuoka 1992, 489^{VP}

gallinarum. L.n. *gallina* the hen. L. gen. pl. *gallinarum* of hens.

Cells from BL agar plate cultures are short to long rods (0.5–1.5 × 1.5–10 µm) occurring singly, in pairs, and sometimes in short chains. Colonies on BL agar are 0.5–2.0 mm in diameter, circular to slightly irregular, entire, grayish brown to reddish brown, and rough. Obligately homofermentative. Additional physiological and biochemical characteristics are presented in Table 84. Strains are tolerant to 4.0% NaCl. (This property differentiates the species from *Lactobacillus acidophilus*, *Lactobacillus amylovorus*, and *Lactobacillus crispatus*).

Isolated from chicken intestine.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: ATCC 33199, CCUG 30724, CIP 103611, DSM 10532, JCM 2011, LMG 9435, VPI 1294.

DNA G+C content (mol%): 35.9–37.2 (T_m).

GenBank accession number (16S rRNA gene): AJ242968, AJ417737.

Additional remarks: Synonymous with *Lactobacillus acidophilus* group A4 of Johnson et al. (1980).

36. ***Lactobacillus gasseri*** Lauer and Kandler 1980a, 60^{VP} (Effective publication: Lauer and Kandler 1980b, 77.)

gasseri. N.L. gen. n. *gasseri* of Gasser, named for F. Gasser, a French bacteriologist.

Cells are rods with rounded ends (0.6–0.8 × 3.0–5.0 µm) occurring singly and in chains. Formation of mini-cells and snakes is frequently observed. Starch is fermented by most strains. Unlike all other lactobacilli, the d-alanyl-d-alanine termini of peptide subunits of peptidoglycan not involved in cross-linkage are preserved because of the lack of D,D-carboxypeptidase action. Arginine is not hydrolyzed. Obligately homofermentative. Additional physiological and biochemical characteristics are presented in Table 84.

Isolated from the human mouth and vagina and from the intestinal tract of man and animals; also found in wounds, urine, blood, and pus of patients suffering from septic infections.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: 63 AM of Gasser, ATCC 33323, CCUG 31451, CIP 102991, DSM 20243, JCM 1131, LMG 9203, NRRL B-14168, NRRL B-4240.

DNA G+C content (mol%): 33–35 (T_m).

GenBank accession number (16S rRNA gene): AF519171, M58820, X61137.

Additional remarks: Synonymous with *Lactobacillus acidophilus* group B-1 of Johnson et al. (1980). See comments on *Lactobacillus acidophilus*.

37. ***Lactobacillus gastricus*** Roos, Engstrand and Jonsson 2005, 80^{VP}

gastricus. N.L. masc. adj. *gastricus* from Gr. adj. *gastrikos* of the stomach.

Cells are nonmotile rods (0.9 × 1.2 µm) occurring as single cells or in pairs. After anaerobic growth at 37°C for 48 h, colonies on MRS agar are 2 mm in diameter; they are white, smooth, and convex. Growth on MRS agar under aerobic conditions is very weak. In MRS broth, growth occurs at 25 and 42°C, but not at 20 or 45°C. Gas is produced from glucose. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86.

Isolated from a biopsy of the healthy human gastric mucosa.

Phylogenetic position: *Lactobacillus reuteri* group.

Type strain: Kx156A7, DSM 16045, CCUG 48454, LMG 22113.

DNA G+C content (mol%): 41.3 (HPLC)

GenBank accession number (16S rRNA gene): AY253658.

38. ***Lactobacillus graminis*** Beck, Weiss and Winter 1989, 93^{VP} (Effective publication: Beck, Weiss and Winter 1988, 282.)

graminis. L. n. *gramen* grass, N.L. gen. *graminis* of grass.

Cells are nonmotile, slightly curved rods with rounded ends (0.7–1 × 1.5–2 µm) occurring singly, in pairs, or in short chains, slightly curved. Colonies smooth, round, non-pigmented. Flocculant sediment after 3 d of growth in MRS broth. Facultatively heterofermentative. Additional physiological and biochemical characteristics are presented in Table 85. Cell wall teichoic acid not detectable.

Habitat: grass silage.

Phylogenetic position: unique.

Type strain: G90 (1), ATCC 51150, CCUG 32238, CIP 105164, DSM 20719, JCM 9503, LMG 9825, NRRL B-14857.

DNA G+C content (mol%): 41–43 (T_m).

GenBank accession number (16S rRNA gene): AJ621551, AM113778.

39. ***Lactobacillus hammesii*** Valcheva, Korakli, Onno, Prévoost, Ivanova, Ehrmann, Dousset, Gänzle and Vogel 2005, 766^{VP}

hammesii. N.L. gen. n. *hammesii* of Hammes, named for Walter P. Hammes, a German microbiologist who contributed to the microbiological and technological development of wheat and rye sourdough research.

Cells are nonmotile straight rods (0.5 × 2–4 µm) occurring as single in pairs or occasionally in short chains. Colonies on MRS agar appeared white circular with a smooth surface and edges (1–1.5 mm after 2 d of growth). Good growth in liquid or solid MRS in aerobiosis. The optimal initial pH ranges from 4.7 to 7.2. In MRS4 at pH 6.2 and at 30°C the specific growth rate of strain LP38 is 0.42 ± 0.01/h. Strain LP38 grows well up to a NaCl content of 2%, and at a salt content of 6.6% the specific growth rate was 26% (100% without NaCl). Obligately heterofermentative.

Additional physiological and biochemical characteristics are presented in Table 86. Fructose is either used as an energy source or as an electron acceptor and is reduced to mannitol. Strain LP38 grows better in media containing electron acceptors such as fructose in addition to a carbon source (maltose or glucose). Strain LP38 produces lactic acid and ethanol from glucose or maltose and in the presence of fructose produces lactic and acetic acid.

Isolated from sourdough.

Phylogenetic position: unique.

Type strain: LP38, CIP 108387, DSM 16381, TMW 1.1236.

DNA G+C content (mol%): 52.6 (HPLC).

GenBank accession number (16S rRNA gene): AJ632219.

40. **Lactobacillus hamsteri**. Mitsuoka and Fujisawa, 1988, 220^{VP} (Effective publication: Mitsuoka and Fujisawa, 1987, 272.)

hams'te.ri. N.L. gen. n. *hamsteri* of the hamster from which the isolate was derived.

Cells are nonmotile, long stout rods (1.0–1.3 µm × 5.0–10.0 µm) occurring singly, in pairs, and in short chains. Surface colonies on BL agar (2 d anaerobic incubation) are 0.7–3.0 mm in diameter, round, umbonate, brown in color, with a rough surface and erose edge. Strictly anaerobic. Final pH of glucose broth is 3.7. Facultatively heterofermentative. Additional physiological and biochemical characteristics are presented in Table 85.

Habitat: hamster intestine and feces. Isolated from hamster feces.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: Ha5F1, ATCC 43851, CCUG 30726, CIP 103365, DSM 5661, JCM 6256, LMG 10754.

DNA G+C content (mol%): 33.1–35.1 (T_m).

GenBank accession number (16S rRNA gene): AJ306298.

41. **Lactobacillus helveticus** (Orla-Jensen 1919) Bergey, Harrison, Breed, Hammer and Huntoon 1925, 184^{AL} (*Thermobacterium helveticum* Orla-Jensen 1919, 164.)

hel.ve'ti.cus. L. adj. *helveticus* Swiss.

Cells are nonmotile rods (0.7–0.9 to 6.0 µm) occurring singly and in chains. Lactose agar colonies are small, grayish, and viscid. Maximum growth temperature 50–52°C. Arginine is not hydrolyzed. Obligately homofermentative. Additional physiological and biochemical characteristics are presented in Table 84. Growth factor requirements: calcium pantothenate, niacin, riboflavin, pyridoxal, or pyridoxamine is essential; thiamine, folic acid, vitamin B₁₂, and thymidine are not required.

Isolated from sour milk, cheese starter cultures, and cheese, particularly Emmental and Gruyère cheese.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: ATCC 15009, CCUG 30139, CIP 103146, DSM 20075, NBRC 15019, JCM 1120, LMG 6413, LMG 13555, NRRL B-4526.

DNA G+C content (mol%): 37–40 (Bd, T_m).

GenBank accession number (16S rRNA gene): AM113779, X61141.

42. **Lactobacillus hilgardii** Douglas and Cruess 1936, 115^{AL}

hil.gar'di.i. N.L. gen. n. *hilgardii* of Hilgard, named for Eugene W. Hilgard, a German-American scientist.

Cells are nonmotile rods with rounded ends (0.5–0.8 × 2–4 µm) occurring singly, in short chains, and frequently in long filaments. Growth on solid media is poor, colonies are punctiform, white, glistening, translucent, with edges entire. Optimal initial pH for growth and carbohydrate fermentation reactions is in the range of 4.5–5.5. Grows in the presence of 15–18% ethanol. End products from fructose are lactic acid, acetic acid, and CO₂. Mannitol is not formed. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86.

Isolated from California table wines; widely distributed in wines of different origin.

Phylogenetic position: unique.

Type strain: ATCC 8290, CCUG 30140, CIP 103007, DSM 20176, NBRC 15886, JCM 1155, LMG 6895, NRRL B-1843.

DNA G+C content (mol%): 39–41 (T_m).

GenBank accession number (16S rRNA gene): M58821.

43. **Lactobacillus homohiochii** Kitahara, Kaneko and Goto 1957, 118^{AL}

ho'mo.hi.o'chi.i. Gr. adj. *homos* like, equal; Japanese n. *hiochi* spoiled sake; N.L. gen. n. *homohiochii* probably intended to mean homofermentative lactobacillus of hiochi.

Cells are rods with rounded ends (0.7–0.8 × 2–4 µm or, occasionally, 6 µm) Does not grow in MRS broth. In Rogosa SL broth supplemented with DL-mevalonic acid (30 mg/liter) and ethanol (40 mg/liter), copious growth is obtained at 30°C after a marked lag phase of 4–7 d. No growth at 45°C and at an initial pH higher than 5.5. Resistant to 13–16% ethanol. Facultatively heterofermentative. Additional physiological and biochemical characteristics are presented in Table 85. Growth factor requirements: D-mevalonic acid is essential or highly stimulatory; ethanol is promotive.

Isolated from spoiled sake.

Phylogenetic position: unique.

Type strain: ATCC 15434, CCUG 32247, CIP 103141, DSM 20571, NBRC 15887, JCM 1199, JCM 7793, LMG 9478, NRRL B-4559.

DNA G+C content (mol%): 35–38 (T_m).

GenBank accession number (16S rRNA gene): AJ621552, AM113780.

44. **Lactobacillus iners** Falsen, Pascual, Sjöden, Ohlén and Collins 1999, 220^{VP}

L. adj. *iners* inert, lazy.

Cells are nonmotile rods and occur singly, in pairs, or in short chains. After 24 h incubation on blood agar under anaerobic conditions, colonies are small (<1 mm diameter), smooth, circular, translucent, and nonpigmented. Old cultures display a "fried egg" appearance. Grows on blood agar but not MRS agar or Rogosa agar. Grows in the presence of 1.5% NaCl, but not 3% NaCl. Obligately homofermentative. Additional physiological and biochemical characteristics are presented in Table 84. Positive for alanine-phenylalanine-proline arylamidase, esterase C4, α-glucosidase, leucine arylamidase, and phosphoamidase. Negative for alkaline phosphatase, arginine dihydrolase, chymotrypsin, α-fucosidase, α-galactosidase, β-galactosidase,

β -galacturonidase, β -glucosidase, β -glucuronidase, glycylotryptophan arylamidase, α -mannosidase, β -mannosidase, lipase C14, trypsin, and urease. Acid phosphatase, ester lipase C8, and pyroglutamic acid arylamidase activity is detected in some strains. Hippurate is hydrolyzed. Voges-Proskauer-negative.

Isolated from human clinical specimens (urine, vagina) and medical care products.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: CCUG 28746, CIP 105923, DSM 13335, JCM 12513, LMG 18914.

DNA G+C content (mol%): 34.4 (T_m).

GenBank accession number (16S rRNA gene): Y16329.

45. ***Lactobacillus ingluviei*** Baele, Vancanneyt, Devriese, Lefebvre, Swings and Haesebrouck 2003, 135^{VP}

in.glu'vi.ei. L. n. *ingluviei* crop sac; L. gen. n. *ingluviei* of a crop sac.

Cells are nonmotile, very short, plump rods, rapidly decolorizing in the Gram-stain procedure. Cells mostly occur singly or in pairs, and some appear to be slightly longer than others. Colonies are white and smooth or crumbly and dry. Growth is enhanced under anaerobic conditions and also slightly in the presence of 5% CO₂, compared with aerobic growth. Better growth is obtained at 42°C than at 37°C. No growth occurs at 25°C and growth is poor at 30°C. The strains grow as nonhemolytic streptococcus-like colonies on Columbia blood agar with diameters of up to 0.5 mm. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86. The characteristic tDNA-PCR fingerprint is composed of fragments with lengths of 162.5, 176.5, 185.5, and 255.2 bp, as determined by fluorescent capillary electrophoresis.

Habitat is pigeon crop and intestines.

Phylogenetic position: *Lactobacillus reuteri* group.

Type strain: KR3, CCUG 45722, JCM 12531, LMG 20380.

DNA G+C content (mol%): 49 (HPLC).

GenBank accession number (16S rRNA gene): AF333975.

46. ***Lactobacillus intestinalis*** (ex Hemme 1974) Fujisawa, Itoh, Benno and Mitsuoka 1990, 303^{VP}

in.tes.tin.al'is. N.L. adj. *intestinalis* pertaining to the intestine.

Cells are nonmotile rods (0.6–0.8 × 2.0–6.0 μm) occurring singly, in pairs, or occasionally in short chains. Surface colonies on glucose-blood-liver agar after 2 d of anaerobic incubation at 37°C are 0.7–2.5 mm in diameter, round, flat, and light brown with rough surfaces and erose edges. No gas from glucose and ribose is fermented. Facultatively heterofermentative. The final pH of glucose broth is 3.7. Additional physiological and biochemical characteristics are presented in Table 85.

The habitat of the species is the intestines of mice and rats.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: Th4, ATCC 49335, CCUG 30727, CIP 104793, DSM 6629, JCM 7548, LMG 14196.

DNA G+C content (mol%): 32.5–35.4 (T_m).

GenBank accession number (16S rRNA gene): AJ306299.

Additional remarks: First described as *Thermobacterium* Group Th4 by Raibaud et al. (1973) and as *Lactobacillus intestinalis* (Hemme, 1974) but not validly published.

47. ***Lactobacillus jensenii*** Gasser, Mandel and Rogosa 1970, 221^{AL}

jen.se'ni.i. N.L. gen. n. *jensenii* of Jensen; named for S. Orla-Jensen, a Danish microbiologist.

Cells are rods with rounded ends (0.6–0.8 × 2.0–4.0 μm) occurring singly and in short chains. Arginine is hydrolyzed. Facultatively heterofermentative. Additional physiological and biochemical characteristics are presented in Table 85. Folic acid, vitamin B₁₂, nicotinic acid, and calcium pantothenate required for growth.

Isolated from human vaginal discharge and blood clot.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: ATCC 25258, CCUG 21961, CCUG 35572, CIP 69.17, DSM 20557, JCM 1146, LMG 6414, NRRL B-4550.

DNA G+C content (mol%): 35–37 (Bd).

GenBank accession number (16S rRNA gene): AF243176.

Additional remarks: *Lactobacillus jensenii* is indistinguishable from *Lactobacillus delbrueckii* by simple physiological tests.

48. ***Lactobacillus johnsonii*** Fujisawa, Benno, Yaeshima and Mitsuoka 1992, 489^{VP}

john.so'ni.i. M.L. gen. n. *johnsonii* of Johnson; named for J.L. Johnson, an American microbiologist.

Cells from BL agar plate cultures are short to long rods (0.5–1.5 × 1.5–10 μm) occurring singly, in pairs, and sometimes in short chains. Colonies on BL agar are 0.5–2.0 mm in diameter, circular to slightly irregular, entire, grayish brown to reddish brown, and rough. Obligately homofermentative. Tolerant to 4% NaCl. Additional physiological and biochemical characteristics are presented in Table 84.

Isolated from human blood and feces of chicken, mice, calf, and pig.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: ATCC 33200, CCUG 30725, CIP 103620, DSM 10533, JCM 2012, VPI 7960.

DNA G+C content (mol%): 32.7–34.8 (T_m).

GenBank accession number (16S rRNA gene): AJ002515.

Additional remarks: Synonymous with *Lactobacillus acidophilus* group B2 of Johnson et al. (1980). See comments on *Lactobacillus acidophilus*.

49. ***Lactobacillus kalixensis*** Roos, Engstrand and Jonsson 2005, 81^{VP}

ka.lix.en'sis. N.L. masc. adj. *kalixensis* pertaining to Kalix, a town in northern Sweden where the gastric biopsies were sampled.

Cells are nonmotile rods (1 × 1.5–10 μm) occurring as singly, in pairs, or in chains. After anaerobic growth at 37°C for 48 h, colonies on MRS agar are 2 mm in diameter; they are white, smooth, and convex. Growth on MRS agar under aerobic conditions is weak. In MRS broth, growth occurs at 25 and 45°C, but not at 20°C. Gas is not produced from glucose. Obligately homofermentative. Additional physiological and biochemical characteristics are presented in Table 84.

Isolated from a biopsy of the healthy human gastric mucosa.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: Kx127A2, CCUG 48459, DSM 16043, LMG 22115.

DNA G+C content (mol%): 35.5 (HPLC).

GenBank accession number (16S rRNA gene): AY253657.

50. ***Lactobacillus kefiranofaciens*** Fujisawa, Adachi, Toba, Arihara and Mitsuoka 1988, 13^{VP} emend. Vancanneyt, Mengaud, Cleenwerck, Vanhonacker, Hoste, Dawyndt, Degivry, Ringuet, Janssens and Swings 2004, 555.

ke.fi.ra.no.fa'ci.ens. N.L. n. *kefiran* a polysaccharide of kefir grain, kefiran; L. v. *facio* produce; N.L. part. adj. *kefiranofaciens* kefiran-producing.

Cells are nonmotile rods (0.5–1.2 × 3.0–20 μm) occurring singly, in pairs, or occasionally in short chains. Colony morphology is subspecies-dependent (see below). Obligately homofermentative. Habitat of the species is kefir grains. The species contains two subspecies.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: WT-2B, ATCC 43761, CCUG 32248, CIP 103307, DSM 5016, JCM 6985, LMG 19149.

DNA G+C content (mol%): 37.3–38.2 (HPLC) or 34.3–38.6 (T_m).

- 50a. ***Lactobacillus kefiranofaciens* subsp. *kefiranofaciens*** (Fujisawa, Adachi, Toba, Arihara and Mitsuoka 1988) Vancanneyt, Mengaud, Cleenwerck, Vanhonacker, Hoste, Dawyndt, Degivry, Ringuet, Janssens and Swings 2004, 555^{VP} (Fujisawa, Adachi, Toba, Arihara and Mitsuoka 1988)

The description is as that for the species, with the following additional characteristics. Cells are capsulated. On modified KPL agar (pH 5.5) at 30°C after 10 d, colonies are circular or irregular, 0.5–3.0 mm in diameter, convex, transparent to translucent, white, smooth to rough, and rosy. On MLR medium under anaerobic conditions after 7–14 d incubation at 25 or 30°C, colonies are transparent, glossy, convex, and extremely slimy. Large amounts of polysaccharides are produced. Hydrolysis of esculin is negative. Additional physiological and biochemical characteristics are presented in Table 84.

Habitat of the species is kefir grains.

Type strain: WT-2B, ATCC 43761, CCUG 32248, CIP 103307, DSM 5016, JCM 6985, LMG 19149.

DNA G+C content (mol%): 37.3–38.2 (HPLC) or 34.3–38.6 (T_m).

GenBank accession number (16S rRNA gene): AJ575279, AM113781.

- 50b. ***Lactobacillus kefiranofaciens* subsp. *kefirgranum*** (Takizawa, Kojima, Tamura, Fujinaga, Benno and Nakase 1994) Vancanneyt, Mengaud, Cleenwerck, Vanhonacker, Hoste, Dawyndt, Degivry, Ringuet, Janssens and Swings 2004, 555^{VP} (*Lactobacillus kefirgranum* Takizawa, Kojima, Tamura, Fujinaga, Benno and Nakase 1994, 438.)

ke.fir.gra'num. Turkish n. *kefir* Caucasian sour milk; L. n. *granum* grain; N.L. adj. *kefirgranum* kefir grain.

The description is as for the species, with the following additional characteristics. On R-CW agar (Kojima et al.,

1993) at 30°C for 5 d, colonies are 0.5–3.0 mm in diameter, circular to irregular, convex, opaque, white, and smooth to rough. On MLR medium under anaerobic conditions after 7–14 d incubation at 25 or 30°C, colonies are white, dry, compact, dull, and bulging. Flocculus or powdery sediment is formed in broth. Weak growth occurs at 15°C. Hydrolysis of esculin is positive. Additional physiological and biochemical characteristics are presented in Table 84.

Habitat of the species is kefir grains.

Type strain: GCL 1701, ATCC 51647, CCUG 39467, CIP 104241, DSM 10550, JCM 8572, LMG 15132.

DNA G+C content (mol%): 37.3–38.2 (HPLC) or 34.3–38.6 (T_m).

GenBank accession number (16S rRNA gene): AJ575742, AJ575261, AM113782.

51. ***Lactobacillus kefir*** corrig. Kandler and Kunath 1983, 672^{VP} (Effective publication: Kandler and Kunath 1983, 292.)

ke'fir.i. Latinized Turkish n. *kefirum* kefir, a Caucasian sour milk (Trüper and de Clari, 1997). N.L. gen. n. *kefir* of kefir.

Cells are nonmotile rods with rounded ends (0.6–0.8 × 3.0–15 μm) with tendency to form chains of short rods or long filaments, often containing polyphosphate granules usually terminal. Colonies on MRS agar are grayish, smooth and flat, 2–4 mm in diameter. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86.

Isolated from kefir grains and drink kefir.

Phylogenetic position: unique.

Type strain: A/K, ATCC 35411, CCUG 30673, CIP 103006, DSM 20587, NBRC 15888, JCM 5818, LMG 9480.

DNA G+C content (mol%): 41–42 (T_m).

GenBank accession number (16S rRNA gene): AB024300, AJ621553, AY579584.

52. ***Lactobacillus kimchii*** Yoon, Kang, Mheen, Ahn, Lee, Kim, Park, Kho, Kang and Park 2000, 1794^{VP}

kim'chi.i. N.L. gen. n. *kimchii* of kimchi, a Korean fermented-vegetable food.

Cells are short, slender, nonmotile rods (0.6–0.8 × 1.5–3.0 μm) occurring singly, in pairs, or occasionally in short chains. After 3 d incubation on MRS agar, colonies are white, circular to slightly irregular, convex, smooth, opaque, and approximately 0.8–1.5 mm in diameter. Catalase-negative. Casein is hydrolyzed but starch and urea are not. Arginine is not hydrolyzed. Indole is not produced. Facultatively heterofermentative. Optimal temperature and pH for growth are approximately 30°C and 6.0–7.0. Grows in the presence of 8% NaCl but not in the presence of 10% NaCl. Additional physiological and biochemical characteristics are presented in Table 85. The major fatty acid is the unsaturated fatty acid C_{18:1}^{09c}.

Isolated from kimchi, a Korean fermented vegetable food.

Phylogenetic position: unique.

Type strain: MT-1077, ATCC BAA-131, CIP 107019, DSM 13961, JCM 10707, KCTC 8903P.

DNA G+C content (mol%): 35 (HPLC).

GenBank accession number (16S rRNA gene): AF183558.

53. **Lactobacillus kitasatonis** Mukai, Arihara, Ikeda, Nomura, Suuki and Ohori 2003, 2057^{VP}
 ki.ta.sa.to'nis. L. gen. n. *kitasatonis* referring to Shibasaburo Kitasato, the founder of Kitasato Institute, the father of Japanese bacteriology.
 Cells are nonmotile rods (0.6–1.0 × 2.0–20.0 μm) occurring singly, in pairs, or occasionally in short chains. When the organism is grown on MRS agar at 37°C for 2 d, colonies are 1.2–2.1 mm in diameter, circular to slightly irregular, convex, opaque, rough, and white. Obligately homofermentative. Milk is not curdled. Additional physiological and biochemical characteristics are presented in Table 84.
 Habitat is the intestine of chickens.
Phylogenetic position: *Lactobacillus delbrueckii* group.
Type strain: JCM 1039, KCTC 3155.
DNA G+C content (mol%): 37–40 (HPLC).
GenBank accession number (16S rRNA gene): AB107638.
54. **Lactobacillus kunkeei** Edwards, Haag, Collins, Hutson and Huang 1998, 1083^{VP} (Effective publication: Edwards, Haag, Collins, Hutson and Huang 1998, 700.)
 kun'ke.ei L. gen. n. *kunkeei* of Kunkee. Named after Ralph E. Kunkee, University of California, Davis, CA, USA, for his contributions to the microbiology of wines.
 Cells are rods (0.5 × 1–1.5 μm). Colonies on MR agar appear opaque, concave, and approximately 1–2 mm in diameter after 3 d of growth at 25°C. Catalase-positive (weakly). Obligately heterofermentative. Acid and gas are produced from glucose. Additional physiological and biochemical characteristics are presented in Table 86. Citrate or malate is utilized in the presence of glucose. Growth in MR media at pH 3.7, 4.5, or 8.0 (25°C). Weak growth in 5% NaCl.
 Isolated from partially fermented grape juice.
Phylogenetic position: unique.
Type strain: YH-15, ATCC 700308, DSM 12361.
DNA G+C content (mol%): not determined.
GenBank accession number (16S rRNA gene): Y11374.
55. **Lactobacillus lindneri** (ex Henneberg 1901) Back, Bohak, Ehrmann, Ludwig and Schleifer 1997, 601^{VP} (Effective publication: Back, Bohak, Ehrmann, Ludwig and Schleifer 1996, 324.)
 lind'neri. L. gen. n. *lindneri* of Lindner, referring to P. Lindner, a German bacteriologist.
 Cells are nonmotile rods (0.9–5 μm), occurring singly, in pairs, or in chains. Depending on the medium, some strains show a strong tendency to alter their cell length and chain length. Colonies are usually small (2 mm), smooth, low convex, flat, and white on NBB-agar. Obligately heterofermentative. Growth occurs at 15–30°C but not above, optimum at 22–25°C; growth occurs at initial pH value of 5.8, some strains at 5.4; optimum at pH 4.6–5.2; no growth at or above pH 6.5. Acid and gas are produced from glucose. Additional physiological and biochemical characteristics are presented in Table 86. Urease is not produced. Cell wall does not contain teichoic acid.
 Isolated from spoiled beer.
Phylogenetic position: unique.
Type strain: KPA, CIP 102983, DSM 20690, JCM 11027, LMG 14528.
DNA G+C content (mol%): 35 (T_m).
GenBank accession number (16S rRNA gene): X95421.
56. **Lactobacillus malefermentans** (ex Russell and Walker 1953) Farrow, Phillips and Collins 1989, 371^{VP} (Effective publication: Farrow, Phillips and Collins 1988, 165.)
 ma.le.fer.men'tans. L. adj. *malus* bad. L. part. adj. *fermentans* fermenting; N.L. adj. *malefermentans* badly fermenting, referring to spoiled beer.
 Cells are nonmotile rods (0.8–1.0 × 1.5–2.5 μm) occurring singly, in pairs, or in chains. Gas is produced from glucose. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86. Urease is not produced. Voges–Proskauer-negative.
 Isolated from beer.
Phylogenetic position: unique.
Type strain: D2 MF1, ATCC 49373, CCUG 32206, CIP 103367, DSM 5705, NBRC 15905, JCM 12497, LMG 11455, NCIMB 701410.
DNA G+C content (mol%): 41–42 (T_m).
GenBank accession number (16S rRNA gene): AJ575743, AM113783.
57. **Lactobacillus mali** Carr and Davies, 1970, 769^{AL} emend. Kameuchi, Seki and Komagata 1988, 272.
 ma'li. L. n. *malus* apple; L. gen. n. *mali* of the apple.
 Cells are rods (0.5–0.8 × 1.2–1.3 μm) occurring singly, in pairs, and in short chains. Nonmotile or weakly motile with a few peritrichous flagella. Colonies are white, smooth, and glistening after a few days. Liquid cultures are turbid after few days, with subsequent clearing and sediment. Obligately homofermentative (see below). Additional physiological and biochemical characteristics are presented in Table 84. No change in litmus milk. Dextran is produced from sucrose. Mannitol is not produced from fructose. Arginine is not hydrolyzed. Esculin is hydrolyzed. Acetoin is produced. H₂S, indol, lecithinase, lipase, and urease not formed. Malic acid is decomposed to lactic acid and CO₂. Most strains exhibit pseudocatalase activity when grown on MRS agar containing 0.1% (w/v) glucose. The following characteristics are negative: gas production from citrate; growth in ethanol (15 and 30%), 4% taurocholate, and sodium lauryl sulfate (0.005%); The following characteristics are variable: growth in 6% NaCl and at 45°C, catalase production.
 The type strains of *Lactobacillus mali*, and *Lactobacillus yamanashiensis* are negative for the latter two reactions, indicating a heterofermentative potential in the species.
 Isolated from wine must, fermenting cider, and fermented molasses.
Phylogenetic position: *Lactobacillus salivarius* group.
Type strain: ATCC 27053, CCUG 30141, CCUG 32228, CIP 103142, DSM 20444, JCM 1116, LMG 6899, NCIMB 10560, NRRL B-4563, VKM B-1600.
DNA G+C content (mol%): 32.5 (T_m).
GenBank accession number (16S rRNA gene): M58824.
58. **Lactobacillus manihotivorans** Morlon-Guyot, Guyot, Pot, Jacobe de Haut and Raimbault 1998, 1107^{VP}
 ma.ni.ho.ti.vo'rans. L. n. *manihot* cassava; L. v. *vorare* to devour; N.L. adj. *manihotivorans* cassava-devouring.

Cells are nonmotile rods that occur in short chains or occasionally as single cells. Optimal temperature, 30°C; optimal pH for growth, 6.0. Grows at NaCl concentrations of 20–65 g/l and does not grow at 100 g/l NaCl. Obligately homofermentative. Starch is utilized. Strain OND 32^T has an extracellular amylase activity and strain YAM 1 shows cell-linked amylase activity. Additional physiological and biochemical characteristics are presented in Table 84.

Isolated from sour cassava starch fermentation.

Phylogenetic position: unique.

Type strain: OND 32, CCUG 42894, CIP 105851, DSM 13343, JCM 12514, LMG 18010.

DNA G+C content (mol%): 48.4 ± 0.2 (T_m).

GenBank accession number (16S rRNA gene): AF000162.

59. **Lactobacillus mindensis** Ehrmann, Müller and Vogel 2003, 11^{VP}

min.den'sis. N.L. adj. *mindensis* pertaining to the city of Minden, Germany, from where the first strain of this species was isolated.

Cells are nonmotile rods (0.9–5 µm), occurring singly, in pairs, or in chains. Colonies are usually small (2 mm), smooth, low convex, flat, and white on MRS agar. Obligately homofermentative. Growth occurs at 15–30°C but not above. Growth optimum is at pH 4.6–5.2; no growth at or above pH 6.5. Additional physiological and biochemical characteristics are presented in Table 84. Arginine is not hydrolyzed. Urease is not produced. The cell wall does not contain teichoic acid.

Isolated from commercial sourdough starter preparations and from bakeries' sourdough after continuous propagations for long periods.

Phylogenetic position: unique.

Type strain: TMW 1.80, DSM 14500, JCM 12532, LMG 21508.

DNA G+C content (mol%): 37.5 (T_m).

GenBank accession number (16S rRNA gene): AJ313530.

60. **Lactobacillus mucosae** Roos, Karner, Axelsson and Jonsson 2000, 256^{VP}

mu'co.sae. N.L. gen. n. *mucosae* of mucosa.

Cells are nonmotile rods (1 × 2–4 µm) occurring singly, in pairs, or as short chains. After anaerobic growth at 37°C for 2 d, colonies on MRS agar are 1.2 mm in diameter. They are white, smooth, and convex. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86.

Isolated from the small intestines of pigs and from sourdough.

All strains of this species so far isolated have a homolog to the mucus-binding protein, Mub, and bind mucus *in vitro*.

Phylogenetic position: *Lactobacillus reuteri* group.

Type strain: S32, CCUG 43179, CIP 106485, DSM 13345, JCM 12515.

DNA G+C content (mol%): 46.5 ± 0.2 (HPLC).

GenBank accession number (16S rRNA gene): AF126738.

61. **Lactobacillus murinus** Hemme, Raibaud, Ducluzeau, Galpin, Sicard and Van Heijenoort 1982, 384^{VP} (Effective publication: Hemme, Raibaud, Ducluzeau, Galpin, Sicard and

Van Heijenoort 1980, 306.)

mu.ri'nus. L. adj. *murinus* of mice.

Cells are nonmotile rods with rounded ends (0.8–1.0 × 2.0–4.0 µm), frequently in chains. Ribose and arabinose slowly fermented. L-LDH is activated by FDP and Mn²⁺. Facultatively heterofermentative. Grows in the presence of 6% (w/v) NaCl. Urea and hippurate not hydrolyzed; malate is decarboxylated. Additional physiological and biochemical characteristics are presented in Table 85. Growth factor requirement: riboflavin is essential; thiamine, and vitamin B₁₂ not required.

Isolated from the intestinal tract of mice and rats and from sourdough.

Phylogenetic position: *Lactobacillus salvarius* group.

Type strain: 313, ATCC 35020, CCUG 33904, CIP 104818, CNRZ 220, DSM 20452, NBRC 14221, JCM 1717, LMG 14189.

DNA G+C content (mol%): 43.4–44.3 (T_m).

GenBank accession number (16S rRNA gene): AJ621554, M58826.

Additional remarks: See *Lactobacillus animalis*.

62. **Lactobacillus nagelii** Edwards, Collins, Lawson and Rodriguez 2000, 700^{VP}

na'gel.i.i. N.L. gen. n. *nagelii* of Nagel, after Charles W. Nagel, Washington State University, WA, USA, for his contributions to the science of wines.

Cells are rods (0.5 × 1–1.5 µm). Colonies on MR agar appear opaque with smooth edges and are approximately 2 mm diameter after 4–5 d growth at 25°C. Glucose fermented without gas formation. Mannitol is not formed from fructose. Both citrate and malate are utilized in the presence of glucose. Arginine is not hydrolyzed. Dextran is formed from sucrose. Obligately homofermentative. Additional physiological and biochemical characteristics are presented in Table 84.

Growth in MR broth containing 5% (w/v) NaCl (pH 4.5) and at pH 3.7, 4.5, and 8.0 (25°C). Weak growth at 5°C (pH 4.5).

Isolated from partially fermented grape juice.

Phylogenetic position: *Lactobacillus salvarius* group.

Type strain: LuE₁₀, ATCC 700692, CCUG 43575, DSM 13675, JCM 12492.

DNA G+C content (mol%): not determined.

GenBank accession number (16S rRNA gene): AB162131, Y17500.

63. **Lactobacillus oris** Farrow and Collins 1988, 116^{VP}

or'is. L. gen. n. *oris* of the mouth.

Cells are nonmotile rods (0.8–1.0 × 2–4 µm) occurring singly, in pairs, or short chains. Colonies are small, raised, semirough, or rough. Grows at 30 and 40°C but not at 22 or 48°C; some strains grow at 45°C. Obligately heterofermentative. Gas is produced from glucose. Additional physiological and biochemical characteristics are presented in Table 86. Some strains hydrolyze hippurate. Some strains produce urease. Grows in 4% NaCl.

Isolated from human saliva.

Phylogenetic position: *Lactobacillus reuteri* group.

- Type strain*: 5A1 of Hayward, ATCC 49062, CCUG 37396, CIP 103255, CIP 105162, DSM 4864, JCM 7507, JCM 11028, LMG 9848, NCIMB 8831.
DNA G+C content (mol%): 49.3–50.7 (T_m).
GenBank accession number (16S rRNA gene): X61131, X94229.
64. **Lactobacillus panis** Wiese, Strohmair, Rainey and Diekmann 1996, 452^{VP}
 pa'nis. L. masc. gen. n. *panis* of bread.
 Cells are nonmotile rods shaped (0.7–0.9 × 2.5–6 mm) occurring in chains or clusters. Colonies are white to gray, convex, smooth, and up to 2 mm in diameter. Anaerobic. Arginine is not hydrolyzed. Oligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86.
 Isolated from long-fermented rye sourdough.
Phylogenetic position: *Lactobacillus reuteri* group.
Type strain: CCUG 37482, DSM 6035, JCM 11053.
DNA G+C content (mol%): 48.0–48.3 (HPLC).
GenBank accession number (16S rRNA gene): X94230.
65. **Lactobacillus pantheris** Liu and Dong 2002, 1747^{VP}
 pan'ther.is. L. gen. n. *pantheris* of the panther, referring to the isolation of the strains from jaguar feces.
 Cells are nonmotile rods (0.5 × 1.5–2.5 μm) after 24 h incubation in TPYG liquid medium.
 Colonies are convex, opaque, and rough with irregular edges and less than 1 mm in diameter after 24 h cultivation on TPYG plates. No gas is produced from glucose fermentation. Obligately homofermentative. The optimum pH for growth is 6.0–6.4 and growth can occur at pH 4.5, but not at pH values above 7.5. Arginine is hydrolyzed and esculin is hydrolyzed. Additional physiological and biochemical characteristics are presented in Table 84.
 Isolated from the feces of a jaguar in Beijing Zoo.
Phylogenetic position: unique.
Type strain: A24-2-1, AS 1.2826, JCM 12539, LMG 21017.
DNA G+C content (mol%): 52.7 (T_m).
GenBank accession number (16S rRNA gene): AF413523.
66. **Lactobacillus parabuchneri** Farrow, Phillips and Collins 1989, 371^{VP} (Effective publication: Farrow, Phillips and Collins 1988, 165.)
 pa.ra.buch.ne'ri. Gr. prep. *para* resembling; N.L. gen. n. *buchneri* specific epithet; N.L. gen. n. *parabuchneri* resembling *Lactobacillus buchneri*.
 Cells are nonmotile rods (0.8–1.0 × 2–4 μm) occurring singly, in pairs, or short chains. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86. Urease is not produced. Voges–Proskauer-negative.
 Isolated from human saliva, cheese, and contaminated brewery yeasts.
Phylogenetic position: unique.
Type strain: ATCC 49374, CCUG 32261, CIP 103368, DSM 5707, JCM 12493, LMG 11457, NCIMB 8838.
DNA G+C content (mol%): 44 (T_m).
GenBank accession number (16S rRNA gene): AB205056, AJ970317, AY026751.
67. **Lactobacillus paracasei** Collins, Phillips and Zanoni 1989, 107^{VP}
 pa.ra.ca'se.i. Gr. prep. *para* resembling; N.L. gen. n. *casei* a specific epithet; N.L. gen. n. *paracasei* resembling *Lactobacillus casei*.
 Cells are rods (0.8–1.0 × 2.0–4.0 μm), often with square ends, occurring singly or in chains. Growth at 10 and 40 °C. Some strains grow at 5 and 45 °C. Facultatively heterofermentative. Two subspecies are validly published.
Phylogenetic position: unique.
DNA G+C content (mol%): 45–47 (Bd).
Further comments: see *Lactobacillus casei*.
- 67a. **Lactobacillus paracasei subsp. paracasei** Collins, Phillips and Zanoni 1989, 107^{VP}
 Cells are nonmotile rods (0.8–1.0 × 2.0–4.0 μm), often with square ends, occurring singly or in chains. L(+)-Lactic acid is produced; a few strains formerly described as "*Lactobacillus pseudopiantarum*" produce inactive lactic acid due to the activity of L-lactic acid racemase. Additional physiological and biochemical characteristics are presented in Table 85. Ammonia is not produced from arginine. Urease-negative.
 Isolated from dairy products, sewage, silage, humans, and clinical sources.
Type strain: ATCC 25302, CCUG 32212, CIP 103918, DSM 5622, NBRC 15889, JCM 8130, LMG 13087, NCIMB 700151.
DNA G+C content (mol%): 45–47 (Bd).
GenBank accession number (16S rRNA gene): D79212.
- 67b. **Lactobacillus paracasei subsp. tolerans** (Abo-Elnaga and Kandler 1965c) Collins, Phillips and Zanoni 1989, 108^{VP} (*Lactobacillus casei* subsp. *tolerans* Abo-Elnaga and Kandler 1965c, 26.)
 to.le'rans. L. pres. part. *tolerans* tolerating, enduring; means survival during the pasteurization of milk.
 Cells are nonmotile rods (0.8–1.0 × 2.0–4.0 μm), often with square ends, occurring singly or in chains. Grows at 10 and 37 °C; no growth at 40 °C. Survives heating at 72 °C for 40 s. Arginine is not hydrolyzed. Urease-negative. Additional physiological and biochemical characteristics are presented in Table 85.
 Isolated from dairy products.
Type strain: ATCC 25599, CCUG 34829, CIP 102994, CIP 103024, DSM 20258, NBRC 15906, JCM 1171, LMG 9191, NCIMB 9709.
DNA G+C content (mol%): 45–47 (Bd).
GenBank accession number (16S rRNA gene): AB181950, D16550.
Additional remarks: *Lactobacillus paracasei* subsp. *tolerans* does not ferment ribose and gluconate and therefore does not fit the definition of group B, however, the high DNA/DNA similarity with *Lactobacillus paracasei* subsp. *paracasei* indicates that the lack of these characteristics is caused by minor genomic differences.
68. **Lactobacillus paracollinoides** Suzuki, Funahashi, Koyanagi and Yamashita 2004, 116^{VP}
 pa.ra.col.li.noi'des. Gr. pref. *para* beside; N.L. masc. adj. *collinoides* hill-shaped, referring to the colony form of *Lac-*

tobacillus collinoides; N.L. masc. adj. *paracollinoides* beside *collinoides*, referring to the close relationship to *Lactobacillus collinoides*.

Cells are nonmotile rods, occurring singly or in short chains. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86.

Isolated from brewery environments.

Phylogenetic position: unique.

Type strain: LA2, DSM 15502, JCM 11969.

DNA G+C content (mol%): 44.8 (T_m).

GenBank accession number (16S rRNA gene): AJ786665.

Additional remarks: "*Lactobacillus pastorianus*" (Van Laer, 1892) was not validly published and was identified as *Lactobacillus paracollinoides* (Ehrmann and Vogel, 2005).

69. **Lactobacillus parakefiri** corrig. Takizawa, Kojima, Tamura, Fujinaga, Benno and Nakase 1994, 439^{VP}

pa.ra.ke'fir.i. Gr. prep. *para* resembling; N.L. n. *kefiri* the specific epithet of *Lactobacillus kefiri*; N.L. gen. n. *parakefiri*, resembling *Lactobacillus kefiri*.

Cells are nonmotile rods (0.5–1.2 × 1.0–3.5 μm) occurring singly, in pairs, or occasionally in short chains. When the organism is grown on R-CW agar at 30°C for 5 d, colonies are 0.5–2.0 mm in diameter, circular to irregular, flat, opaque, white, and rough. Obligately heterofermentative. Gas is produced from glucose, but not from gluconate. Milk is curdled. Additional physiological and biochemical characteristics are presented in Table 86.

Isolated from kefir grains.

Phylogenetic position: unique.

Type strain: GCL 1731, ATCC 51648, CCUG 39468, CIP 104242, DSM 10551, NBRC 15890, JCM 8573, LMG 15133.

DNA G+C content (mol%): 41.4–42.0 (T_m).

GenBank accession number (16S rRNA gene): AY026750.

70. **Lactobacillus paralimentarius** Cai, Okada, Mori, Benno and Nakase 1999b, 1455^{VP}

pa.ra.li.men.ta'ri. us. Gr. pref. *para* beside; N.L. adj. *alimentaryarius* a specific epithet; N.L. adj. *paralimentaryarius* beside [*Lactobacillus*] *alimentarius*.

Cells are nonmotile rods (0.7–1.0 × 4.0–7.0 μm). Growth occurs at pH 4.5, 40°C, and 6.5% NaCl, but not above 45°C. Grows well anaerobically on MRS agar at 37°C. Facultatively heterofermentative. Additional physiological and biochemical characteristics are presented in Table 85.

Isolated from sourdough.

Phylogenetic position: unique.

Type strain: TB 1, CCUG 43349, CIP 106794, DSM 13238, JCM 10415, LMG 19152.

DNA G+C content (mol%): 37.2–38.0 (HPLC).

GenBank accession number (16S rRNA gene): AB018528, AJ417500.

72. **Lactobacillus paraplantarum** Curk, Hubert and Bringel 1996, 598^{VP}

pa.ra.plan.tar'um. Gr. prep. *para* resembling; N.L. gen. n. *plantarum* specific epithet of *Lactobacillus plantarum*; N.L. gen. pl. n. *paraplantarum* resembling *Lactobacillus plantarum*.

Cells are nonmotile rods occurring singly, in pairs, and sometimes in short chains. Colonies grown on MRS agar are round, smooth, dome shaped, and creamy colored. Grows in MRS medium at pH 5 and 7, but not at pH 4 and tolerates NaCl up to a concentration of 8%. Facultatively heterofermentative. Arginine is not hydrolyzed. Additional physiological and biochemical characteristics are presented in Table 85.

Isolated from beer and human feces in France.

Phylogenetic position: unique

Type strain: ATCC 700211, CCUG 35983, CIP 104668, CNRZ 1885, CST 10961, DSM 10667, JCM 12533, LMG 16673, NRRL B-23115.

DNA G+C content (mol%): 44–45 (E_{280} , pH 3).

GenBank accession number (16S rRNA gene): AJ306297.

72. **Lactobacillus pentosus** (ex Fred, Peterson and Anderson 1921) Zanoni, Farrow, Phillips and Collins 1987, 339^{VP}

pen.to'sus. N.L. adj. *pentosus* of pentose, pertaining to pentoses.

Cells are nonmotile rods (1–1.2 μm × 2–5 μm) with rounded ends, straight, and may occur singly, in pairs, or in short chains. Facultatively heterofermentative. Arginine is not hydrolyzed. Voges–Proskauer-positive. Acid and clot produced in litmus milk. Acid is produced from glycerol. Additional physiological and biochemical characteristics are presented in Table 85.

Isolated from corn silage, fermenting olives, and sewage.

Phylogenetic position: unique.

Type strain: ATCC 8041, CCUG 33455, CIP 103156, DSM 20314, JCM 1558, LMG 10755, NCAIM B.01727, NCCB 32014, NCIMB 8026, NRRL B-227, NRRL B-473.

DNA G+C content (mol%): 46.1–47.2 (T_m).

GenBank accession number (16S rRNA gene): D79211.

73. **Lactobacillus perolens** Back, Bohak, Ehrmann, Ludwig, Pot, Kersters and Schleifer 2000, 3^{VP} (Effective publication: Back, Bohak, Ehrmann, Ludwig, Pot, Kersters and Schleifer 1999, 358.)

per.o'lens. L. pref. *per* through, penetrating; L. part. adj. *olens* having an odor; N.L. part. adj. *perolens* offensive-smelling.

Cells are nonmotile rods with rounded ends (0.7–2.5 μm) occurring singly, in pairs, or in short chains. Colonies on MRS flat or little convex, wavy, or dentated with rough, dull surface, beige to dirty-white; mean diameter 2.5 mm. Can grow up to 42°C with an optimum at 28–32°C, no growth below 15°C. Optimum growth at pH 5.5–6.5, no growth below pH 3.7. Facultatively heterofermentative. Arginine is not hydrolyzed. Urease not produced.

Additional physiological and biochemical characteristics are presented in Table 85.

Isolated from spoiled soft drinks and from brewery environment.

Phylogenetic position: unique.

Type strain: L 532, DSM 12744, JCM 12534, LMG 18936.

DNA G+C content (mol%): 49–53 (T_m).

GenBank accession number (16S rRNA gene): Y19167.

74. **Lactobacillus plantarum** (Orla-Jensen 1919) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 250^{AL}. (*Streptobacterium plantarum* Orla-Jensen 1919, 174.)

plan.ta'rum. L. fem. n. *planta* a plant; N.L. gen. pl. n. *plantarum* of plants.

Cells are nonmotile rods with rounded ends, straight (0.9–1.2 µm × 3–8 µm) occurring singly, in pairs, or in short chains. Some strains reduce nitrate provided the concentration of glucose in the medium is limited and the pH poised at 6.0 or higher. Some strains exhibit pseudocatalase activity, especially if grown under glucose limitation, or true catalase when heme is present. Cell walls contain either ribitol or glycerol teichoic acid. Facultatively heterofermentative. Growth factor requirements: calcium pantothenate and niacin required; thiamine, pyridoxal or pyridoxamine, folic acid, vitamin B₁₂, thymidine, or deoxyribosides not required; riboflavin generally not required.

Phylogenetic position: unique. The species contains two subspecies.

DNA G+C content (mol%): 44–46 (Bd, T_m).

- 74a. **Lactobacillus plantarum subsp. plantarum** (Bergey, Harrison, Breed, Hammer and Huntoon 1923) Bringel, Castioni, Olukoya, Felis, Torriani and Dellaglio 2005, 1633^{VP} (*Lactobacillus plantarum* Bergey, Harrison, Breed, Hammer and Huntoon 1923, 250.)

The description is that of the species. Additional physiological and biochemical characteristics are presented in Table 85.

Isolated from dairy products and environments, silage, sauerkraut, pickled vegetables, sourdough, cow dung, and the human mouth, intestinal tract and stools, and from sewage.

Type strain: ATCC 14917, CCUG 30503, CIP 103151, DSM 20174, NBRC 15891, JCM 1149, LMG 6907, NCIMB 11974, NRRL B-4496.

DNA G+C content (mol%): 44–46 (Bd, T_m).

GenBank accession number (16S rRNA gene): D79210.

Additional remarks: The differentiation from the related species *Lactobacillus paraplantarum*, *Lactobacillus pentosus*, and *Lactobacillus plantarum* subsp. *argentoratensis* is problematic when using physiological and biochemical characteristics. The use of genotypic methods provides clear identification results (Bringel et al., 2005).

- 74b. **Lactobacillus plantarum subsp. argentoratensis** Bringel, Castioni, Olukoya, Felis, Torriani and Dellaglio 2005, 1633^{VP}

ar.gen.to.ra.ten'sis. L. masc. adj. *argentoratensis* of or pertaining to Argentoratus, the Roman name of the City of Strasbourg in Alsace, France.

The description is that of the species. Additional physiological and biochemical characteristics are presented in Table 85. The only difference from the other subspecies is the absence of melizitose fermentation in 14 strains of subsp. *argentoratensis*.

Isolated from starchy food and fermenting food of plant origin.

Type strain: DKO 22, CIP 108320, DSM 16365.

DNA G+C content (mol%): 44–46 (Bd, T_m).

GenBank accession number (16S rRNA gene): AJ640078.

Additional remarks: For further information, see subsp. *plantarum*.

75. **Lactobacillus pontis** Vogel, Böcker, Stolz, Ehrmann, Fanta, Ludwig, Pot, Kersters, Schleifer and Hammes 1994, 228^{VP}

pon'tis L. gen. n. *pontis* of the bridge, referring to BRIDGE, which is the abbreviation for the Commission of the European Communities Research Programme entitled Biotechnology Research, for Innovation Development and Growth in Europe. During this program, the organism was isolated and characterized by the joined efforts of three laboratories.

Cells are nonmotile slender rods (0.3–0.6 × 4–6 µm) occurring singly, in pairs, and in chains. Some strains have a strong tendency to form chains of long bent rods or even resembling a vine tendril. Colonies on sanfrancisco agar are 1–2 mm in diameter, rough circular plateaus with irregular borders and smooth convex centers, translucent, and grayish after 2–5 d of anaerobic incubation at 30°C. The terminal pH in sanfrancisco-medium ranges from 3.9 to 4.2. The main fermentation products from maltose or fructose are lactate, acetate, ethanol, glycerol, and CO₂. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86.

Isolated from rye sourdough.

Phylogenetic position: *Lactobacillus reuteri* group.

Type strain: LTH 2587, ATCC 51518, CCUG 33456, CIP 104232, DSM 8475, JCM 11051, LMG 14187.

DNA G+C content (mol%): 53–55 (HPLC).

GenBank accession number (16S rRNA gene): AJ422032, X76329.

76. **Lactobacillus psittaci** Lawson, Wachter, Hansson, Falsen and Collins 2001b, 969^{VP}

psit.ta'ci. L. gen. masc. n. *psittaci* of the parrot, from which the organism was first isolated.

Cells are coccibacilli to rod-shaped, occurring singly or in pairs. After 24 h incubation on Columbia horse blood agar, colonies are 1–2 mm in diameter, colorless, and do not produce an odor. α-Hemolytic. Gas is produced from glucose (Gibson's semisolid medium). Growth is observed on acetate agar (pH 5.4). Optimum pH range is 5.5–7.5. Grows in 2% NaCl, but not in 6% NaCl. Obligately homofermentative (see below). Additional physiological and biochemical characteristics are presented in Table 84. Positive reactions are obtained for acid phosphatase, alanine-phenylalanine-proline arylamidase, alkaline phosphatase, cystine arylamidase, α-galactosidase, α-glucosidase, β-glucosidase, leucine arylamidase, phosphoamidase, and valine arylamidase (weak reaction). Negative reactions are observed for N-acetyl-β-glucosaminidase, arginine dihydrolyase, chymotrypsin, esterase C-4, ester lipase C8, lipase C14, -fucosidase, β-galactosidase, β-glucuronidase, glycyl-tryptophan arylamidase, α-mannosidase, β-mannosidase, methyl β-D-glucopyranosidase, pyrazinamidase, pyroglutamic acid arylamidase, pyrrolidonyl arylamidase, trypsin, and urease. Esculin is hydrolyzed, but hippurate is not. Voges–Proskauer test is negative.

Isolated from the lungs of a dead hyacinth macaw (*Anodorhynchus hyacinthinus*). Habitat is not known.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: CCUG 42378, CIP 106492, DSM 15354, JCM 11552.

DNA G+C content (mol%): not determined.

GenBank accession number (16S rRNA gene): AJ272391.

Additional remarks: The formation of gas from glucose on Gibson's semisolid medium would place *Lactobacillus psittaci* to the group of obligately heterofermentative species. The phylogenetic data are not consistent with that biochemical characteristic.

77. **Lactobacillus reuteri** Kandler, Stetter and Köhl 1982, 266^{VP} (Effective publication: Kandler, Stetter and Köhl 1980, 267.) (*Lactobacillus fermentum* Type II Lerche and Reuter 1962, 462.)

reu'te.ri. N.L. gen. n. *reuteri* of Reuter; named for G. Reuter, a German bacteriologist.

Cells are nonmotile, slightly irregular, bent rods with rounded ends (0.7–1.0 × 2.0–5.0 μm), occurring singly, in pairs, and in small clusters. In the original description, it was mistakenly stated that ammonia is not produced from arginine. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86.

Isolated from human and animal feces, sourdough, and meat products.

Phylogenetic position: *Lactobacillus reuteri* group.

Type strain: ATCC 23272, CCUG 33624, CIP 101887, DSM 20016, NBRC 15892, JCM 1112, LMG 9213, LMG 13557, NRRL B-14171.

DNA G+C content (mol%): 40–42.3 (Bd, T_m).

GenBank accession number (16S rRNA gene): L23507, X76328.

Additional remarks: Synonymous with *Lactobacillus fermentum* Type II Lerche and Reuter 1962, 462. (Lerche and Reuter, 1962). *Lactobacillus reuteri* cannot be definitely distinguished from *Lactobacillus fermentum* by simple physiological tests. Determination of diamino acid of peptidoglycan or, preferentially, genotypical methods clearly separate the two species.

78. **Lactobacillus rhamnosus** (Hansen 1968) Collins, Phillips and Zanoni 1989, 108^{VP} (*Lactobacillus casei* subsp. *rhamnosus* Hansen 1968, 76.)

rham.no'sus. N.L. adj. *rhamnosus* pertaining to rhamnose.

Cells are nonmotile rods (0.8–1.0 × 2.0–4.0 μm) often with square ends, occurring singly or in chains. Facultatively heterofermentative. Additional physiological and biochemical characteristics are presented in Table 85. Arginine is not hydrolyzed. Urease-negative.

Isolated from dairy products, sewage, humans, and clinical source.

Phylogenetic position in the genus: unique.

Type strain: ATCC 7469, CCUG 21452, CIP A157, DSM 20021, NBRC 3425, JCM 1136, LMG 6400, NCAIM B.01147, NCCB 46033, NCIMB 6375, NCTC 12953, NRRL B-442, VKM B-574.

DNA G+C content (mol%): 45–47 (Bd).

GenBank accession number (16S rRNA gene): D16552.

79. **Lactobacillus rossiae** corrig. Corsetti, Settanni, Sinderen, Felis, Dellaglio and Gobbetti 2005, 39^{VP}

ros.si'ae. N.L. gen. n. *rossiae* of Rossi, to honor Jone Rossi, University of Perugia, Perugia, Italy, for her major contribution to dairy and sourdough microbiology.

Cells are nonmotile rods (0.5 × 1–1.5 μm), occurring singly, in pairs, and in short chains. After growth for 3 d at 30°C on MRS agar plates, colonies are 1–1.5 mm in diameter, white, smooth, and circular or convex. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86. Peptidoglycan structure is A3α (L-Lys-L-Ser-L-Ala₂) type.

Isolated from wheat sourdough.

Phylogenetic position: unique.

Type strain: CS1, ATCC BAA-822, DSM 15814.

DNA G+C content (mol%): 44.6 (HPLC).

GenBank accession number (16S rRNA gene): AJ564009.

80. **Lactobacillus ruminis** Sharpe, Latham, Garvie, Zirngibl and Kandler 1973, 47^{AL}

ru'mi.nis. L n. *rumen* rumen; N.L. gen. n. *ruminis* of rumen.

Cells are rods (0.6–0.8 × 3–5 μm), occurring singly, in pairs, and in short chains. Motile by peritrichous flagella; motility not always easy to demonstrate and often sluggish, best demonstrated as stab cultures in semisolid media containing low concentrations of glucose. Anaerobic. Surface growth is obtained only under reduced oxygen pressure; growth in liquid media is improved by the addition of cysteine-HCl. Unlike the strains isolated from the rumen, many strains from sewage were nonmotile and failed to grow at 45°C. Arginine is not hydrolyzed. Obligately homofermentative. Additional physiological and biochemical characteristics are presented in Table 84.

Isolated from rumen of cow and from sewage.

Phylogenetic position: *Lactobacillus salivarius* group.

Type strain: ATCC 27780, CCUG 39465, CIP 103153, DSM 20403, JCM 1152, LMG 10756, NRRL B-14853.

DNA G+C content (mol%): 44–47 (T_m).

GenBank accession number (16S rRNA gene): M58828.

81. **Lactobacillus saerimneri** Pedersen and Roos 2004, 1367^{VP}

sae.rim'ne.ri. N.L. gen. masc. n. *saerimneri* of Saerimner, a pig occurring in Nordic mythology, because the organism was isolated from pigs.

Cells are nonmotile rods (1 × 1.5–4 μm) occurring singly or in pairs. After anaerobic growth at 37°C for 48 h, colonies on MRS agar are 2–3 mm in diameter; they are white with an opaque border, smooth, and convex. Growth on MRS agar also occurs under aerobic conditions, but at a considerably lower rate. Gas is not produced from glucose. Obligately homofermentative. Additional physiological and biochemical characteristics are presented in Table 84. Esculin is not hydrolyzed.

Isolated from pig feces. Habitat is intestines of pigs.

Phylogenetic position: *Lactobacillus salivarius* group.

Type strain: GDA154, CCUG 48462, DSM 16049, LMG 22087.

DNA G+C content (mol%): 42.9 (HPLC).

GenBank accession number (16S rRNA gene): AY255802.

82. **Lactobacillus sakei** corrig. Katagiri, Kitahara and Fukami 1934, 157^{AL}

sa'ke.i. Latinized Japanese n. *sakeum* sake, a Japanese rice wine, N.L. gen. n. *sakei* of sake.

Cells are nonmotile rods (0.6–0.8 × 2–3 μm) with rounded ends, occurring singly and in short chains; frequently slightly curved and irregular, especially during stationary growth phase. Many of the strains tested grow even at 2–4°C. L-LDH is activated by FDP and Mn²⁺. Possesses lactic acid racemase; induction of racemase in most strains is repressed by acetate. Therefore, the majority of strains produce L(+)-lactic acid in MRS broth, whereas DL-lactic acid is produced in cabbage press juice. A few strains, whose identity with *Lactobacillus sakei* is confirmed by DNA/DNA similarity, however, produce inactive lactic acid also in MRS broth. Facultatively heterofermentative.

Originally isolated from sake starter; regularly found in sauerkraut and other fermented plant material, meat products, prepacked finished dough, and human feces.

Phylogenetic position: unique.

Type strain: ATCC 15521, CCUG 30501, CIP 103139, DSM 20017, NBRC 15893, JCM 1157, LMG 9468, LMG 13558.

DNA G+C content (mol%): 42–44 (*T_m*).

Additional remarks: Because of the difficulty in differentiating between strains of the species *Lactobacillus curvatus* and *Lactobacillus sakei*, an extraordinarily great number of strains has been subjected to detailed taxonomic studies (Berthier and Ehrlich, 1999; Torriani et al., 1996). Based on numerical analysis of total soluble cell protein patterns, biochemical test data, and RAPD-PCR, profiles of two subspecies were defined for each species. This grouping had to be withdrawn for the *Lactobacillus curvatus* subspecies because Koort et al. (2004) showed that the type strain of *Lactobacillus curvatus* subspecies *melibiosus* was actually a strain of *Lactobacillus sakei*. More clear-cut grouping of data for both species was provided by Berthier and Ehrlich (1999). Strains of *Lactobacillus sakei* were allotted to four phenotypic groups (4, 5, 6, 7) within two RAPD groups. All *Lactobacillus sakei* strains hydrolyze arginine (all *Lactobacillus curvatus* strains do not). Further key properties in phylogenetic grouping of the *Lactobacillus sakei* strains are melibiose fermentation (restricted to *Lactobacillus sakei*), formation of catalase in the presence of heme (found in 3 of 4 phenotypes), and production of D-lactate. Both *Lactobacillus sakei* and *Lactobacillus curvatus* contain strains that are negative in that property which had been formerly allotted to the invalid species "*Lactobacillus bavariensis*" (Kagermeier-Callaway and Lauer, 1995). In addition, PCR-primers were derived that permitted the identification of strains of each subgroup.

- 82a. ***Lactobacillus sakei* subsp. *sakei*** (corrig. Katagiri, Kitahara and Fukami 1934) Torriani, Van Reenen, Klein, Reuter, Dellaglio and Dicks 1996, 1162^{VP} (corrig. Katagiri, Kitahara and Fukami 1934, 157.)

The key characteristics of facultatively heterofermentative species, shown in Table 85, do not permit differentiation of the two subspecies. Ammonia is always produced from arginine. Most strains grow in the presence of 10% NaCl and produce acetoin from glucose.

Isolated from sake starter. Regularly found in fermented meat products, vacuum-packaged meat, sauerkraut and other fermented plant material, and human feces.

Type strain: ATCC 15521, CCUG 30501, CIP 103139, DSM 20017, NBRC 15893, JCM 1157, LMG 9468, LMG 13558.

DNA G+C content (mol%): 42–44 (*T_m*).

GenBank accession number (16S rRNA gene): AM113784, AY204893, M58829.

- 82b. ***Lactobacillus sakei* subsp. *carneus*** Torriani, Van Reenen, Klein, Reuter, Dellaglio and Dicks 1996, 1162^{VP}

car.no'sus. L. adj. *carneus* pertaining to meat.

The physiological and biochemical characteristics are presented in Table 85. They do not permit the differentiation of the two subspecies.

Isolated from fermented meat products. Regularly found in vacuum-packaged meat, sauerkraut, and other fermented plant material.

Type strain: R 14b/a, CCUG 31331, CIP 105422, JCM 11031, LMG 17302.

DNA G+C content (mol%): 42–44 (*T_m*).

GenBank accession number (16S rRNA gene): AY204892.

83. ***Lactobacillus salivarius*** Rogosa, Wiseman, Mitchell and Disraely 1953, 691^{AL}

sa.li.va'ri.us. L. adj. *salivarius* salivary.

Cells are rods with rounded ends (0.6–0.9 × 1.5–5 μm) occurring singly and in chains of varying length. Arginine is not hydrolyzed. Obligately homofermentative.

Isolated from the mouth and intestinal tract of humans, hamsters, and chickens. Two subspecies are recognized.

Phylogenetic position: *Lactobacillus salivarius* group.

DNA G+C content (mol%): 34–36 (Bd).

- 83a. ***Lactobacillus salivarius* subsp. *salivarius*** Rogosa, Wiseman, Mitchell and Disraely 1953, 691^{AL}

Description as for the species. Ferments rhamnose but not salicin and esculin. Additional physiological and biochemical characteristics are presented in Table 84.

Type strain: ATCC 11741, CCUG 31453, CIP 103140, DSM 20555, JCM 1231, LMG 9477, NRRL B-1949.

DNA G+C content (mol%): 34–36 (Bd).

GenBank accession number (16S rRNA gene): AF089108.

- 83b. ***Lactobacillus salivarius* subsp. *salicinii*** Rogosa, Wiseman, Mitchell and Disraely 1953, 691^{AL}

sa.li.ci'ni.us. N.L. adj. *salicinii* pertaining to salicin, a glycoside.

Description as for the species. Ferments salicin and esculin but not rhamnose. Additional physiological and biochemical characteristics are presented in Table 84.

Type strain: ATCC 11742, CCUG 39464, CIP 103155, DSM 20554, JCM 1150, LMG 9476, NRRL B-1950.

DNA G+C content (mol%): 34–36 (Bd).

GenBank accession number (16S rRNA gene): M59054.

84. ***Lactobacillus sanfranciscensis*** corrig. Weiss and Schilling 1984a, 503^{VP} (Effective publication: Weiss and Schilling 1984b, 231.)

san.fran.cis.cen'sis. N.L. adj. *sanfranciscensis* from San Francisco, named after the city where the sourdough from which the organism was first isolated had been propagated for more than 100 years.

Cells are rods with rounded ends ($0.6\text{--}0.8 \times 2\text{--}4\ \mu\text{m}$) occurring singly and in pairs. On primary isolation some strains do not grow reasonably in MRS broth unless freshly prepared yeast extract is added and the initial pH is lowered to 5.6. A small peptide isolated from yeast extract was found responsible for the growth-promoting effect (Berg et al., 1981). In our laboratory, all strains grew well on MRS5 (Meroth et al., 2003). Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86. The peptidoglycan is of the Lys-Ala-type.

Isolated from sourdough.

Phylogenetic position: unique.

Type strain: L-12, ATCC 27651, CCUG 30143, CIP 103252, DSM 20451, JCM 5668, LMG 16002, NRRL B-3934.

DNA G+C content (mol%): 36–38 (T_m).

GenBank accession number (16S rRNA gene): AY459586, M58830, X61132, X76327.

Additional remarks: Kline and Sugihara (1971) proposed the name *Lactobacillus sanfrancisco* with reservation as to results of pending DNA/DNA similarity studies. Later on they briefly confirmed the proposal and designated a type strain (Sugihara and Kline, 1975). The name, however, was omitted from the Approved Lists of Bacterial Names and consequently has no standing in bacteriological nomenclature and has been revived (Weiss and Schillinger, 1984b).

85. ***Lactobacillus satsumensis*** Endo and Okada 2005, 85^{VP} sat.su.men'sis. N.L. masc. adj. satsumensis, pertaining to Satsuma (old name for the southern part of Kyushu in Japan), from where the type strain was isolated.

Cells are rods ($0.6\text{--}0.8 \times 1.0\text{--}1.5\ \mu\text{m}$) occurring singly or in pairs. Motile with peritrichous flagella. Colonies on MRS agar are white, smooth, and approximately 2 mm in diameter after incubation for 2 d. Obligately homofermentative. Additional physiological and biochemical characteristics are presented in Table 84. Dextran is formed from sucrose. Growth is observed in MRS broth containing 5% (w/v) NaCl and at pH 3.5 in MRS broth. No growth is observed in MRS broth containing 10% (v/v) ethanol.

Isolated from shochu mashes collected at a shochu distillery in the South Kyushu district of Japan.

Phylogenetic position: *Lactobacillus salvarius* group.

Type strain: DSM 16230, JCM 12392, NRIC 0604.

DNA G+C content (mol%): 39–41 (HPLC).

GenBank accession number (16S rRNA gene): AB154519.

86. ***Lactobacillus sharpeae*** Weiss, Schillinger, Laternser and Kandler 1982, 266^{VP} (Effective publication: Weiss, Schillinger, Laternser and Kandler 1981, 251.) shar'pe.ae. M.L. gen. n. *sharpeae* of Sharpe; named for M. Elisabeth Sharpe, an English bacteriologist.

Cells are nonmotile rods with rounded ends ($0.6\text{--}0.8 \times 3\text{--}8\ \mu\text{m}$) with a pronounced tendency to form "snakes" and, after prolonged incubation, long characteristically wrinkled chains. In broth cultures, a flocculent sediment is observed. Colonies are grayish and flat. Obligately homofermentative. Additional physiological and biochemical characteristics are presented in Table 84. Indole, lipase, and urease are not produced. Arginine is not hydrolyzed.

Habitat unknown; isolated from municipal sewage.

Phylogenetic position: unique.

Type strain: ATCC 49974, CIP 101266, DSM 20505, JCM 1186, LMG 9214, NRRL B-14855.

DNA G+C content (mol%): 53 (T_m).

GenBank accession number (16S rRNA gene): M58831.

87. ***Lactobacillus spicheri*** Meroth, Hammes and Hertel 2004, 631^{VP} (Effective publication: Meroth, Hammes and Hertel 2004, 157.)

spi'cher.i. N.L. gen. n. *spicheri* of Spicher, honoring Gottfried Spicher, a German researcher who contributed to the chemical, microbial, and technological characterization of wheat and rye sourdoughs.

Cells are nonmotile rods ($1.5 \times 3\text{--}5\ \mu\text{m}$) occurring singly or in pairs and seldom in short chains. Catalase-negative. After 3 d of incubation on MRS5 agar, colonies are white, circular with a smooth surface and border, and approximately 0.5–1 mm in diameter. Grows well in MRS5 medium up to pH 5.0 or 5.5% NaCl but not with 7.0% NaCl. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86. Fermentation of glucose is weak, but it is strong in combination with fructose. Fructose is reduced to mannitol.

Isolated from an industrial processed rice sourdough.

Phylogenetic position: unique.

Type strain: LTH 5753, DSM 15429, LMG 21871.

DNA G+C content (mol%): 55 (T_m).

GenBank accession number (16S rRNA gene): AJ534844.

88. ***Lactobacillus suebicus*** Heinzl and Hammes 1989, 495^{VP} (Effective publication: Kleynmans, Heinzl and Hammes 1989, 270.)

suè.bi.cus. L. n. *suebia* Swabia a region in southern Germany; N.L. adj. *suebicus* pertaining to Swabia.

Cells are nonmotile rods ($0.6\text{--}0.8 \times 2\text{--}3\ \mu\text{m}$) with rounded ends, occurring singly or pairs, seldom in short chains. Colonies are white, round, convex, smooth, slimy, and 2 mm in diameter on Homohiochi agar after incubation for 4 d at 30°C in an atmosphere 95% N₂ and 5% CO₂. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 82. No reaction in litmus milk; no slime production from sucrose. The lowest limits for growth are 10°C and pH 2.8. The upper limit for growth is 14% ethanol at pH 3.3.

Habitats are stored apple and pear mashes.

Phylogenetic position: unique.

Type strain: I, ATCC 49375, CCUG 32233, CIP 103411, DSM 5007, JCM 9504, LMG 11408.

DNA G+C content (mol%): 40.4 ± 0.4 (T_m).

GenBank accession number (16S rRNA gene): AJ306403, AJ575744, AM113785.

89. ***Lactobacillus suntoryeus*** Cachat and Priest 2005, 33^{VP} sun.to.ry.e'us. N.L. masc. adj. *suntoryeus* occurring in Suntory malt whisky fermentations.

Cells are nonmotile rods varying in length from 2 μm to long filaments. After 48 h incubation on MRS agar (supplemented with maltose and brain heart infusion broth), colonies are circular, shiny, creamy white in color, and 2–5 mm in diameter. Growth is poor in unsupplemented

MRS medium. Obligately homofermentative. Additional physiological and biochemical characteristics are presented in Table 84.

Isolated from whisky fermentations.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: SA, LMG 22464, NCIMB 14005.

DNA G+C content (mol%): not determined.

GenBank accession number (16S rRNA gene): AY445815.

90. ***Lactobacillus thermotolerans*** Niamsup, Sujaya, Tanaka, Sone, Hanada, Kamagata, Lumyong, Assavanig, Asano, Tomita and Yokota 2003, 267^{VP}
therm.o.toler'ans. Gr. n. *thermos* heat; L. pres. part. *tolerans* tolerating; N.L. part. adj. *thermotolerans* heat-tolerating.

Cells are nonmotile rods ($1 \times 2\text{--}3\ \mu\text{m}$) occurring singly, in pairs, or in short chains. After anaerobic growth at 42°C for 2 d, colonies on MRS agar are 1–1.5 mm in diameter, white, circular, convex, smooth, and opaque. Anaerobic. Obligately heterofermentative. Grows up to 50°C, but not at 15°C; optimum temperature for growth is 42°C. No dextran is produced from sucrose. Additional physiological and biochemical characteristics are presented in Table 86.

Major cellular fatty acid is a straight-chain, unsaturated acid, C_{18:1}.

Isolated from the feces of chickens in Thailand.

Phylogenetic position: *Lactobacillus reuteri* group.

Type strain: G 35, DSM 14792, JCM 11425.

DNA G+C content (mol%): 50.5 (HPLC).

GenBank accession number (16S rRNA gene): AF317702.

91. ***Lactobacillus ultunensis*** Roos, Engstrand and Jonsson 2005, 81^{VP}
ul.tun.en'sis. N.L. masc. adj. *ultunensis* pertaining to Ultuna, the site of Swedish University of Agricultural Sciences in Uppsala, Sweden.

Cells are nonmotile rods ($1 \times 2\text{--}30\ \mu\text{m}$) occurring as single cells, pairs, or filaments. After anaerobic growth at 37°C for 48 h, colonies on MRS agar are 2–3 mm in diameter; they are white, irregular, and have a dry appearance. Growth on MRS agar under aerobic conditions is very weak. Anaerobic. In MRS broth, growth occurs at 25 and 42°C, but not at 20 or 45°C. Gas is not produced from glucose. Obligately homofermentative. Esculin is hydrolyzed. Additional physiological and biochemical characteristics are presented in Table 84.

Isolated from a biopsy of the healthy human gastric mucosa.

Phylogenetic position: *Lactobacillus delbrueckii* group.

Type strain: Kx146C1, CCUG 48460, DSM 16047, LMG 22117.

DNA G+C content (mol%): 35.7 (HPLC).

GenBank accession number (16S rRNA gene): AY253660.

92. ***Lactobacillus vaccinostercus*** Okada, Suzuki and Kozaki 1983, 439^{VP} (Effective publication: Okada, Suzuki and Kozaki 1979, 217.)
vac.ci.no.ster'cus. L. adj. *vaccinus* from cows; L. n. *stercus* dung; N.L. adj. *vaccinostercus* from cow dung.

Cells grown in xylose-YP broth are nonmotile rods ($0.9\text{--}1.0 \times 1.5\text{--}2.5\ \mu\text{m}$) with rounded ends, occurring mostly in

pairs. Colonies on xylose-YP agar for 48 h at 30°C are 2 mm in diameter. Obligately heterofermentative. Litmus milk is not changed. Grows in the range from 20–40°C. Additional physiological and biochemical characteristics are presented in Table 86. Growth factor requirements: thiamine, pantothenic acid, niacin, and biotin are essential; pyridoxal, *p*-aminobenzoic acid, and folic acid not required.

Isolated from cow dung.

Phylogenetic position: unique.

Type strain: X-94, ATCC 33310, CCUG 30723, CIP 102807, DSM 20634, JCM 1716, LMG 9215, TUA 055B.

DNA G+C content (mol%): 36 (T_m).

GenBank accession number (16S rRNA gene): AB212087, AJ621556, AM113786.

93. ***Lactobacillus vaginalis*** Embley, Faquir, Bossart and Collins 1989, 368^{VP}
va.gi.na'lis. N.L. adj. *vaginalis* of the vagina.

Cells are nonmotile rods ($0.5\text{--}0.8 \times 1.5\text{--}25\ \mu\text{m}$) occurring singly, in pairs, or in short chains. Colonies are white to gray, 1–5 mm in diameter, and semirough, often with raised areas. Grows at 30 and 45°C but not at 22 or 48°C. Obligately heterofermentative. Additional physiological and biochemical characteristics are presented in Table 86. Produces straight-chain and monounsaturated long-chain fatty acids of the vaccenic series and *cis*-11,12-methylene-octadecenoic (lactobacillic) acid.

Isolated from the vagina of patients suffering from trichomoniasis.

Phylogenetic position: *Lactobacillus reuteri* group.

Type strain: ATCC 49540, CCUG 31452, CIP 105932, DSM 5837, JCM 9505, LMG 12891, NCTC 12197.

DNA G+C content (mol%): 38–41 (T_m).

GenBank accession number (16S rRNA gene): AF243177, X61136.

94. ***Lactobacillus versmoldensis*** Kröckel, Schillinger, Franz, Bantleon and Ludwig 2003, 516^{VP}
vers.mold.en'sis. N.L. masc. adj. *versmoldensis* pertaining to Versmold, the town in Germany where the strains were isolated.

Cells are nonmotile rods with rounded ends, ($0.9 \times 1.6\text{--}6.0\ \mu\text{m}$) occurring singly, in pairs, and in chains of generally four cells. Cells aggregate during growth in MRS broth. Colonies on MRS agar after 3 d incubation at 30°C are small (up to 1 mm in diameter), circular, convex with entire edges, and grayish-white. Facultatively heterofermentative. Gas is not produced from glucose. Arginine is not hydrolyzed. Maximum NaCl tolerance for growth in MRS broth is in the range 8–14%. Additional physiological and biochemical characteristics are presented in Table 85.

Isolated from poultry salami.

Phylogenetic position: unique.

Type strain: KU-3, ATCC BAA-478, DSM 14857, NCCB 100034.

DNA G+C content (mol%): 40.5 (T_m).

GenBank accession number (16S rRNA gene): AJ496791.

95. ***Lactobacillus zeae*** (Kuznetsov 1959) Dicks, Du Plessis, Delaglio and Lauer 1996, 340^{VP} (*Lactobacterium zeae* Kuznetsov 1959, 368.)

ze.ae. L. gen. n. *zeae* pertaining to *Zea mays*, corn.

Cells are nonmotile rods (0.5–0.6 × 1.2–2.4 μm) occurring singly or in chains, depending on growth conditions. Surface colonies on MRS agar are smooth, glistening, white, and 1–2 mm in diameter. Grows at 10 and 45°C. Arginine is not hydrolyzed. Facultatively heterofermentative. Additional physiological and biochemical characteristics are presented in Table 85. Strain ATCC 15820^T ferments rhamnose, whereas strain ATCC 393^T does not. Gas is produced from gluconate. Benzidine, urease, and indole tests are negative.

Isolated from corn steep liquor.

Phylogenetic position: unique.

Type strain: ATCC 15820, CCUG 35515, DSM 20178, JCM 11302, LMG 17315, NCIMB 9537.

DNA G+C content (mol%): 48–49.

GenBank accession number (16S rRNA gene): D86516.

Additional remarks: See *Lactobacillus casei*.

96. **Lactobacillus zymae** Vancanneyt, Neysens, De Wachter, Engelbeen, Snauwaert, Cleenwerck, Van der Meulen, Hoste, Tsakalidou, De Vuyst and Swings 2005, 619^{VP}

zymae. N.L. n. *zyma* (from Gr. n. *zume*), leaven, sourdough; N.L. gen. n. *zymae* of sourdough.

Cells are nonmotile rods (1.0 × 2–20 μm) occurring singly, in pairs, and in chains. After 24 h, colonies are beige, circular with a rough and wrinkled surface, and approximately 1 mm in diameter. Growth occurs at 7% NaCl. Obligately heterofermentative. Gas is produced from gluconate and gluconate. Additional physiological and biochemical characteristics are presented in Table 86.

Isolated from a Belgian artisan wheat sourdough.

Phylogenetic position: unique.

Type strain: R-18615, CCM 7241, LMG 22198.

DNA G+C content (mol%): 53–54 (HPLC).

GenBank accession number (16S rRNA gene): AJ632157.

Genus II. **Paralactobacillus** Leisner, Vancanneyt, Goris, Christensen and Rusul 2000, 22^{VP}

JØRGEN J. LEISNER AND MARC VANCANNEYT

Pa.ra.lac.to.ba.cill'us. Gr. prep. *para* resembling; N.L. n. *Lactobacillus* a bacterial genus; N.L. masc. n. *Paralactobacillus* resembling the genus *Lactobacillus*.

Cells straight slender **rods**. **Nonmotile**. **Do not form spores**. **Gram-positive**. Aerobic and facultatively anaerobic. Grows slowly at 15°C but not at 45°C. Able to grow on acetate agar. **Catalase-negative**, oxidase-negative. **Homofermentative**. **D- and L-lactic acid produced from glucose**. Nitrate not reduced. **Ammonia not produced from arginine**. Esculin is hydrolyzed.

DNA G+C content (mol%): 46 (HPLC).

Type species: **Paralactobacillus selangorensis** Leisner, Vancanneyt, Goris, Christensen and Rusul 2000, 23.

Further descriptive information

Based upon 16S rDNA analysis, *Paralactobacillus* forms a separate branch of lactic acid bacteria and is most related to the genera *Lactobacillus* and *Pediococcus*. Highest sequence similarities are found with the *Lactobacillus casei*/*Pediococcus* cluster ranging from 90.1 to 91.7% (Leisner et al., 2000) and up to 93.1% with *Lactobacillus pantheris* (Liu and Dong, 2002). GenBank accession numbers are AF049745 and AF049742 for strains LMG 17710^T and LMG 17714, respectively.

Cells are nonspore-forming, straight, slender rods 2.5–6.5 μm long and <1.0 μm wide, usually occurring singly or as pairs but sometimes in older cultures as short chains. Colonies < 1–1.5 mm in diameter, round, and with a gray color after growth on All Purpose Tween (APT) agar incubated at 30°C for 5 d. Visible growth at 15°C was observed only after 5–10 d incubation. Variable growth at 37°C. No growth above 37°C or below 15°C. Growth at 30°C is slow in sterilized chili bo and in Man Rogosa Sharpe (MRS) broth at initial pH 4.0–5.0 compared with strains of *Lactobacillus plantarum* or *Pediococcus acidilactici* (unpublished results). No growth in the presence of 6.5% NaCl. No growth on cattle blood agar after 5 d incubation at 30°C (unpublished results). No growth on SBM agar*, supplemented with 0.01% tetrazolium (unpublished results). Able to lower pH to < 4.15 in La-broth[†].

Homofermentative with no gas production from glucose. No growth with gluconic acid as substrate. Catabolism of glucose

results in production of D- and L-lactic acid in the approximate ratio 1.6–2:1 (D:L) for static cultures in MRS broth. Only trace amounts of acetic acid and ethanol are produced. Acid is produced from D-glucose, D-fructose, D-mannose, N-acetylglucosamine, salicin, and maltose after 4 d of incubation at 30°C. No acid is produced from ribose, D-xylose, mannitol, lactose, inulin, D-raffinose, or starch. The cellular fatty acid composition is similar to that for the genus *Lactobacillus*, consisting mostly of straight-chain saturated and monounsaturated types. DNA–DNA hybridization values within the single described species of the genus range between 99% and 104% among the five isolates tested.

None of 22 strains examined show antagonistic activity towards *Lactobacillus plantarum* ATCC 14917 or *Lactobacillus pentosus* LMG 17682. Twenty-one of 22 strains examined by the spot-on-lawn method were resistant towards nisin produced by *Lactococcus lactis* ATCC 11454. LMG 17710^T exhibits sensitivity towards nisin produced by *Lactococcus lactis* ATCC 11454 when examined by the deferred inhibition test (Moreno et al., 2002). Resistant towards 30 μg vancomycin/g MRS agar.

Genus was isolated from a Malaysian food ingredient, chili bo. The primary source of these bacteria is not known.

Enrichment and isolation procedures

Paralactobacillus may be isolated on media traditionally employed for isolation of species of *Lactobacillus*. These may include APT agar, MRS agar or acetate agar. There is no selective medium available that allows exclusive growth of *Paralactobacillus* or any indicative medium that allows ready identification of this genus in mixed cultures. Therefore, additional tests are necessary in order to obtain a proper identification. *Paralactobacillus* usually exhibits slow growth during

* SBM agar, g/l: peptone, 15; yeast extract, 1; Tween 80 1; K₂HPO₄, 2; MgSO₄·7H₂O, 0.2; MnSO₄·4H₂O, 0.05; agar 10; pH 7.0.

† La-broth: MRS broth without phosphate buffer and with 0.3% (w/v) sodium citrate replacing ammonium citrate and adjusted to an initial pH of 6.8.

microaerophilic incubation at 30°C. It is therefore necessary to incubate the agar plates for at least 3 d in order to secure growth of visible colonies.

Maintenance procedures

Storage in frozen medium at -80°C or as a lyophilized culture is effective for long-term maintenance.

Differentiation of the genus *Paralactobacillus* from other genera

Differentiation of the genus from other related rod-shaped taxa is indicated in Table 87. Within the family of *Lactobacillaceae*, *Paralactobacillus* is distinguished from obligatory heterofermentative *Lactobacillus* species other than *Lactobacillus rogosae* by its inability to produce gas from glucose. *Lactobacillus rogosae* is differentiated by production of acetic acid from fructose and little or no fermentation of other carbohydrates.

Paralactobacillus is distinguished from facultative heterofermentative *Lactobacillus* species, except for some strains of *Lactobacillus acetotolerans*, *Lactobacillus coleohominis*, *Lactobacillus cypricasei*, *Lactobacillus equi*, and *Lactobacillus homohiochii*, by lack of production of gas from gluconic acid and lack of production of acid from ribose or xylose. *Lactobacillus acetotolerans*, *Lactobacillus coleohominis*, and *Lactobacillus cypricasei* are distinguished from *Paralactobacillus* by no growth at 15°C; *Lactobacillus equi*

is distinguished by no growth at 15°C and production of acid from raffinose and lactose, and *Lactobacillus homohiochii* is distinguished by lack of growth in MRS broth.

The differentiation of *Paralactobacillus* from homofermentative *Lactobacillus* species is more problematic and requires the use of a combination of characters. *Paralactobacillus* is distinguished from homofermentative *Lactobacillus* species by a minimum requirement of the following combination of characteristics: nonmotile, growth at 15°C but not 45°C, able to grow under aerobic conditions, no acid from L-arabinose, raffinose, D-ribose or lactose, and production of both D- (more than 25% of total amount) and L-isomers of lactic acid.

Paralactobacillus is readily distinguished from the third genus of *Lactobacillaceae*, *Pediococcus*, by possessing a rod-shaped cell morphology.

Paralactobacillus is distinguished from other genera of lactic acid bacteria as follows: from obligatory heterofermentative *Weissella*, *Oenococcus*, and *Leuconostoc* by no production of gas from glucose; from rod-shaped *Allofustis*, *Atopostipes*, *Carnobacterium*, *Desemzia*, *Isobaculum*, *Marinilactibacillus* and *Pilibacter* by the criteria listed in Table 87; from rod-shaped *Alkalibacterium* by the criteria listed in Table 87 and by no growth with 6.5% NaCl; from the pleiomorphic *Melissococcus* by no growth at 45°C; and from *Aerococcus*, *Abiotrophia*, *Agiticoccus*, *Alloiococcus*, *Atopobacter*, *Atopococcus*, *Catelliococcus*, *Dolosiococcus*, *Dolosigranulum*,

^bAdditional information is listed in the text.

^cInclude facultatively and obligatory heterofermentative species. Additional information is listed in the text.

^dDifferentiation of *Paralactobacillus* from homofermentative *Lactobacillus* requires the use of a combination of characteristics as listed in the text.

^eCell morphology ranges from irregular rods to short coccoid rods or cocci.

^fInformation is given for the type species which constitutes the only species of the genus.

Enterococcus, *Eremococcus*, *Facklamia*, *Globicatella*, *Granulicatella*, *Ignavigranum*, *Lactococcus*, *Lactovum*, *Streptococcus*, *Tetragenococcus*, *Trichococcus*, and *Vagococcus* by possessing a distinctive rod-shaped cell morphology.

Taxonomic comments

The genus *Paralactobacillus* was described to accommodate a Gram-positive rod originating from the Malaysian food ingredi-

ent chili bo. The genus is phylogenetically related to the genera *Lactobacillus* and *Pediococcus*.

The genera *Lactobacillus* and *Pediococcus* are phylogenetically complex and there is extensive intermixing of species of the two genera. The genus *Paralactobacillus* forms a distinct clade related to the *Lactobacillus/Pediococcus* group. The branching point between *Paralactobacillus* and this group has moderate support as demonstrated by a bootstrap value of 48%.

List of species of the genus *Paralactobacillus*

1. ***Paralactobacillus selangorensis*** Leisner, Vancanneyt, Goris, Christensen and Rusul 2000, 23^{VP}
sel.an.gor'en.sis. N.L. adj. *selangorensis* belonging to the province of Selangor, Malaysia.

The characteristics are as described for genus with the following additional information. Some strains produce acid from galactose, rhamnose, α -methyl-D-glucoside, amygdalin, arbutin, cellobiose, sucrose, trehalose, β -gentiobiose, D-turanose, and D-tagatose after 4 d or more (up to 2 weeks) incubation at 30°C.

No acid is produced from glycerol, erythritol, D-arabinose, L-arabinose, L-xylose, adonitol, β -methyl-xyloside, L-sorbose, dulcitol, inositol, sorbitol, α -methyl-D-mannoside, melibiose, melizitose, glycogen, xylitol, D-lyxose, D-fucose, L-fucose, D-arabitol, L-arabitol, gluconate, 2-ketogluconate, or 5-ketogluconate.

DNA G+C content (mol%): 46 (HPLC).

Type strain: ATCC BAA-66, CCUG 43347, CIP 106482, DSM 13344, LMG 17710.

GenBank accession number (16S rRNA gene): AF049745.

Genus III. *Pediococcus* Claussen 1903, 68^{AL}

WILHELM. H. HOLZAPFEL, CHARLES M.A.P. FRANZ, WOLFGANG LUDWIG AND LEON M.T. DICKS

Pe.di.o.coc'cus. Gr. n. *pedium* a plane surface; Gr. n. *kokkos* a grain or berry; N.L. masc. n. *Pediococcus* coccus growing in one plane.

Nine species are recognized within this genus, including *Pediococcus acidilactici* (Lindner, 1887; Skerman et al., 1980), *Pediococcus claussenii* (Dobson et al., 2002), *Pediococcus cellicola* (Zhang et al., 2005), *Pediococcus damnosus* (Balcke, 1884; Claussen, 1903; Skerman et al., 1980), *Pediococcus dextrinicus* (Back, 1978a; Coster and White, 1964; Skerman et al., 1980), *Pediococcus inopinatus* (Back, 1978a, 1988), *Pediococcus parvulus* (Günther and White, 1961; Skerman et al., 1980), *Pediococcus pentosaceus* (Mees, 1934; Skerman et al., 1980) with the subspecies *Pediococcus pentosaceus* subsp. *pentosaceus* and *Pediococcus pentosaceus* subsp. *intermedius*, and *Pediococcus stilesii* (Franz et al., 2006). The *Pediococcus* type species is *Pediococcus damnosus*

(Claussen, 1903). Judicial Opinion 52 states that this generic name is conserved over *Pediococcus* (Balcke, 1884) and all earlier objective synonyms. Erroneously, the genus name *Pediococcus* (Balcke, 1884) has been cited in the Approved Lists of Bacterial Names (Skerman et al., 1980) and in the Amended Edition of the Approved Lists of Bacterial Names (Euzéby, 1998; Skerman et al., 1989). These species can clearly be distinguished on the basis of DNA–DNA similarity (Table 88).

The species *Pediococcus dextrinicus* is considered atypical for the genus *Pediococcus*; it produces L(+)-lactic acid from glucose via a fructose-1,6-diphosphate FDP inducible L-lactate dehydrogenase (L-LDH; Back, 1978b) and may represent a new genus

^bFrom Weiss (1992), Simpson and Taguchi (1995), and Dobson et al. (2002).

(Ludwig and Back, personal communication) (Table 89). A new *Lactobacillus* species (*Lactobacillus concavus* sp. nov.) is closely related to *Pediococcus dextrinicus* JCM 5887^T, with 97.9% similarity (Tong and Dong, 2005a). The former *Pediococcus halophilus* was renamed to *Tetragenococcus halophilus* by Collins et al. (1990) and is synonymous to "*Pediococcus soyae*" (Weiss, 1992). The genus *Tetragenococcus* exhibits a low 16S rRNA sequence similarity ($\leq 90\%$) with the true pediococci (see chapter by Dicks et al. on *Tetragenococcus*, below). The taxonomic status of *Pediococcus urinaeequi* was described by Felis et al. (2005), who proposed the transfer of this species to the genus *Aerococcus* with the name *Aerococcus urinaeequi* comb. nov. on the basis of comparative analysis of the 16S rRNA gene sequence and DNA-DNA hybridization data.

The cells of typical representatives are nonmotile, spherical, occasionally ovoid, and divide to form pairs or divide alternately in two perpendicular directions to form tetrads (Axelsson, 1998) but never chains. Cells may occur singly and in pairs, especially during early or mid-exponential growth. Individual cells measure 0.5–1.0 μm . The cells are Gram-positive, asporogenic, and oxidase-negative. Cytochromes are absent, and catalase is not produced, although some strains of *Pediococcus pentosaceus* have been reported to produce catalase or pseudocatalase (Simpson and Taguchi, 1995). More than 50% of the *Pediococcus pentosaceus* strains isolated from goat milk, Feta cheese, and Kaseri cheese were reported to have a weak catalase activity (Tzanetakis and Litopoulou-Tzanetaki, 1989). Arginine hydrolysis is rare but has been recorded for *Pediococcus acidilactici* and *Pediococcus pentosaceus* (Simpson and Taguchi, 1995). Homofermentative, producing lactic acid but no CO_2 from glucose. Chemo-organotrophic. Facultatively anaerobic. Growth at pH 5 but not at pH 9, except for *Pediococcus stilesii*. Optimum growth temperature is 25–35°C, but is species dependent. All species except *Pediococcus clausenii* produce DL-lactic acid from glucose. Nitrate not reduced. *Peptidoglycan type*: Lys-D-Asp (Holzapfel et al., 2005).

DNA G+C content (mol%): 35–44 (T_m).

Type species: ***Pediococcus damnosus*** Claussen 1903, 68^{AL}.

Further descriptive information

The cell morphology of the *Pediococcus* species is similar to that of *Tetragenococcus* species, and members of these two genera are the only lactic acid bacteria (LAB) dividing in two perpendicular directions resulting in the formation of pairs and tetrads, but

never of typical chains. The coccoid cells are perfectly round and rarely ovoid, in contrast to other coccus-shaped lactic acid bacteria such as *Leuconostoc*, *Lactococcus*, and *Enterococcus* species. The cell size may vary from 0.6–1.0 μm diameter, depending on the strain and species, but remains uniform within a culture.

The genus *Pediococcus* forms part of the *Clostridium* branch of descent with a low DNA base composition of less than 50 mol% G + C, whereas on the basis of 16S rDNA similarity, Collins et al. (1991) grouped this genus in the *Lactobacillus* branch of LAB. This could be confirmed by comparative analysis of the currently available sequence dataset comprising 950 almost complete 16S rRNA primary structures from representatives of the *Lactobacillales*. Overall, 16S rRNA sequence similarities for pediococci and closely related *Lactobacillus* species range from 85–94%. The corresponding values for other genera of the *Lactobacillales*, i.e., *Leuconostoc/Oenococcus*, *Enterococcus*, *Lactococcus*, *Vagococcus*, *Tetragenococcus*, and *Carnobacterium* are 80–90%, 84–91%, 84–87%, 88–90%, 88–91%, and 85–87%, respectively. Small-subunit rRNA-based phylogenetic analyses support a monophyletic group comprising eight *Pediococcus* species (*Pediococcus acidilactici*, *Pediococcus cellicola*, *Pediococcus damnosus*, *Pediococcus dextrinicus*, *Pediococcus inopinatus*, *Pediococcus parvulus*, *Pediococcus pentosaceus*, and *Pediococcus stilesii*) to the exclusion of only distantly related *Pediococcus dextrinicus* (Figure 93). The close relationship within the *Pediococcus* cluster is reflected by overall 16S rRNA sequence similarities greater than 94%, whereas the remote position of *Pediococcus dextrinicus* is documented by lower values (90.2–92.4% 16S rRNA sequence similarity for *Pediococcus dextrinicus* and other members of the cluster).

The *Pediococcus* species exhibit a low 16S rRNA sequence similarity with the genus *Tetragenococcus*. Similarity values to *Tetragenococcus halophilus* were determined for *Pediococcus acidilactici* (89.7%), *Pediococcus pentosaceus* (88.3%), *Pediococcus damnosus* (88.7%), *Pediococcus parvulus* (87.4%), and *Pediococcus dextrinicus* (88.6%) (Collins et al., 1990). The phylogenetic relatedness of *Aerococcus*, *Enterococcus*, *Vagococcus*, *Carnobacterium*, *Pediococcus*, *Tetragenococcus*, and *Lactococcus* is indicated in Figure 114 and Figure 115 in the chapter on *Tetragenococcus* by Dicks et al. in this edition.

Identification at species level within the genus *Pediococcus* may be achieved by 16S rRNA gene sequencing (Barney et al., 2001; Collins et al., 1990; Kurzak et al., 1998; Omar et al., 2000),

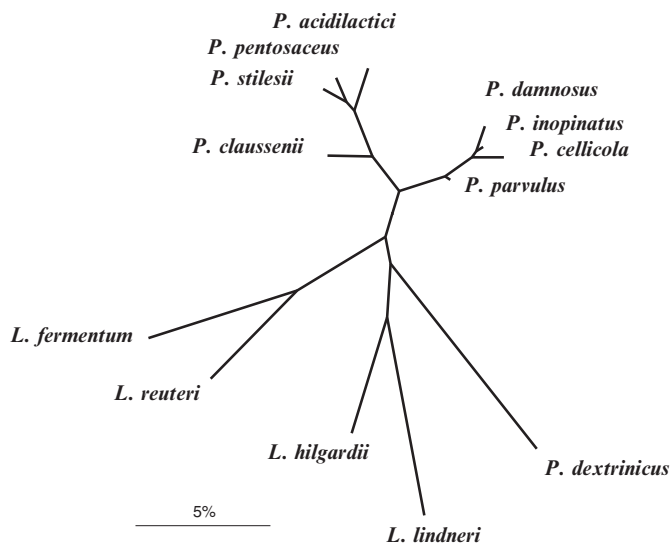

FIGURE 93. 16S rRNA-based phylogeny of the validly published *Pediococcus* and selected *Lactobacillus* reference species. The tree is based upon a maximum-parsimony analysis of 41,230 almost complete small-subunit rRNA primary structures using the ARB databases and software (Ludwig et al., 2004). The tree topology was evaluated by applying alternative treeing approaches (maximum-likelihood and distance matrix) as well as various positional filters based on conservation profiles (Ludwig and Klenk, 2001).

by the use of specific DNA target probes (Lonvaud-Funel et al., 1993, 2000a; Mora et al., 1997, 1998; Rodrigues et al., 1997), ribotyping (Barney et al., 2001; Jager and Harlander, 1992; Santos et al., 2005; Satokari et al., 2000), randomly amplified polymorphic DNA (RAPD) PCR (Fujii et al., 2005; Kurzak et al., 1998; Mora et al., 2000b; Nigatu et al., 1998; Simpson et al., 2002b; Tamang et al., 2005), and pulsed-field gel electrophoresis (PFGE) (Barros et al., 2001; Dellaglio et al., 1981; Luchansky et al., 1992). A rapid PFGE protocol was developed by Simpson et al. (2006) for species and strain-level verification of pediococci within less than 3 d. A solution phase hybridization PCR-ELISA was used for the detection and quantification of *Enterococcus faecalis* and *Pediococcus pentosaceus* in Nurmi-type cultures (Waters et al., 2005). Total genomic DNA–DNA hybridization remains the most reliable method of differentiating among species (Back and Stackebrandt, 1978; Dellaglio et al., 1981; Franz et al., 2006) and is considered the gold standard for genotypic delineation (Mehlen et al., 2004). Real-time PCR is increasingly being used for quantitative detection of *Pediococcus* species among other lactic acid bacteria (Delaherche et al., 2004; Lan et al., 2004; Stevenson et al., 2005).

Glucose is metabolized homofermentatively to lactic acid, probably by the Embden–Meyerhof pathway. For typical *Pediococcus* species, it appears that CO₂ is not produced from gluconate. *Pediococcus dextrinicus* is an exception but is also considered an atypical species (see taxonomic comments). Strains of *Pediococcus* species possess varying degrees of β- and α-D-glucopyranosidase activities which are influenced differently by ethanol, sugars, temperature, and pH. Strains with these characteristics may influence the glycoside composition of wine (Grimaldi et al., 2005).

Graham and McKay (1985) were the first to describe plasmids for the genus *Pediococcus*. Many genes regulating the fermentation of sugars are plasmid encoded, e.g., the fermentation of raffinose, melibiose, and sucrose by *Pediococcus pentosaceus* (Gonzalez and Kunka, 1986; Hoover et al., 1988), and the fermentation of sucrose for some strains of *Pediococcus acidilactici* (Hoover et al., 1988). Besides sugar fermentation, genes encoding antibiotic resistance may also be plasmid encoded. For example, an erythromycin resistance is encoded on a 40-MDa plasmid in *Pediococcus acidilactici* (Torriani et al., 1987). According to Gonzalez and Kunka (1983) plasmids are frequently transferred between *Pediococcus* and *Enterococcus*, *Streptococcus*, and *Lactococcus* species.

Limited information is available on bacteriophages of pediococci. The bacteriophages of *Pediococcus acidilactici* were studied by Caldwell et al. (1999), and were temperate, but could be induced with mitomycin C and were classified into two genetic groups (Caldwell et al., 1999).

Most of the genetic studies conducted on *Pediococcus* species revolve around the genes encoding different bacteriocins. Most bacteriocins (pediocins) produced by pediococci are grouped into Class IIa, i.e., small (less than 10 kDa), non-lanthionine-containing and *Listeria*-active peptides with a YGNGV (tyrosine-glycine-asparagine-glycine-valine) -consensus sequence in the N terminus (Nes et al., 1996). Pediocins are membrane active and resistant to temperatures of up to 100°C; a few pediocins withstand autoclaving (15 min at 121°C). Among all pediocins and other bacteriocins within Class IIa, pediocin PA-1 is the best characterized (Gonzalez and Kunka, 1987; Rodrigues et al., 2002). Pediocins share many sequence similarities with bacteriocins produced by *Lactobacillus* species, e.g., curvacin A, sakacin P, bavaricin A, and bavaricin MN; *Leuconostoc* species, e.g., leukocin A and mesentericin Y105; *Streptococcus* species, e.g., mundticin; *Enterococcus* species, e.g., enterocin A; and *Carnobacterium* species, e.g., carnobacteriocin B2 and piscicolin 126 (Holzapfel et al., 2005).

Some strains of pediococci have been associated with infections in humans and may be considered opportunistic pathogens (Barros et al., 2001; Barton et al., 2001; Colman and Efstratiou, 1987; Golledge et al., 1990; Green et al., 1991; Mastro et al., 1990; Riebel and Washington, 1990; Sarma and Mohanty, 1998). They may cause infections in individuals debilitated as a result of trauma or underlying disease (Barton et al., 2001; Facklam and Elliott, 1995; Mastro et al., 1990; Sarma and Mohanty, 1998). Some strains are resistant to vancomycin and teicoplanin (Swenson et al., 1990; Tankovic et al., 1993) which may provide them with a competitive advantage in medical care environments (Colman and Efstratiou, 1987; Golledge et al., 1990; Green et al., 1991; Mastro et al., 1990; Ruoff et al., 1988; Swenson et al., 1990). Some pediococci are also resistant to quinolone antibiotics and tetracycline (Sarma and Mohanty, 1998; Tankovic et al., 1993), but they are generally sensitive to antibiotics such as penicillin, ampicillin, and aminoglycosides (especially gentamicin and netilmicin) and moderately sensitive towards chloramphenicol (Barton et al., 2001; Mastro et al., 1990; Swenson et al., 1990; Tankovic et al., 1993).

Enrichment and isolation procedures

Members of the genus *Pediococcus* share several physiological properties with the genera *Lactobacillus*, *Leuconostoc*, and

Weissella. Together they may be called the LLPW physiological group, and they generally respond in the same way to conditions or compounds inhibitory to nonlactics (Schillinger and Holzapfel, 2003). This is because they often share the same habitat and show relatively similar growth requirements (Holzapfel, 1992). Therefore, most culture media developed for the detection of *Pediococcus* species are not completely selective for this genus. Examples of semiselective media include Selective SL Medium for Isolating *Pediococci* (Rogosa et al., 1951) and Acetate Agar for Isolation of *Leuconostoc* and *Pediococcus* (Whittenbury, 1965). Simpson et al. (2006) evaluated a *Pediococcus* Selective Medium (PSM) for the enumeration of *Pediococcus acidilactici* and *Pediococcus pentosaceus* from probiotic animal feed and silage inoculants. This medium is based on MRS supplemented with cysteine hydrochloride, novobiocin, vancomycin, and nystatin. Inoculation in the latter medium and incubation at 37°C under anaerobic conditions for 24 h stimulates the growth of pediococci in samples that also contain bacilli, bifidobacteria, enterococci, lactobacilli, lactococci, propionibacteria, streptococci, and yeasts. Growth of *Lactobacillus plantarum* and *Lactobacillus casei* is inhibited by the addition of ampicillin (PSM+A).

Several growth media have been developed to detect spoilage strains of *Pediococcus damnosus* and *Pediococcus clausenii* in beer. One such medium is MRS agar adjusted to pH 5.5. Back (1978a) used a combination of MRS broth and beer (1:1 v/v) and incubated at 22°C in the presence of 90% N₂ + 10% CO₂. Taguchi et al. (1990) used a complex Kirin-Ohkochi-Taguchi (KOT) medium, consisting of beer, malt extract, liver concentrate, maltose, L-malic acid, cytidine, thymidine, actidione, and sodium azide, in addition to other typical LAB growth medium components. Beer is frequently used as a major component of media (Back, 1978a; Nakagawa, 1964), thereby selectively promoting the growth of pediococci that are adapted to beer and hops. Apart from hops, selective agents commonly added to media may include cycloheximide, actidione, or sorbic acid. Gram-negative bacteria are usually inhibited by polymyxin B, acetic acid (together with reduced pH), and thallos acetate (Schillinger and Holzapfel, 2003). The European Brewery Convention has recommended three media for the simultaneous detection of lactobacilli and pediococci in beer, namely, MRS agar, supplemented with cycloheximide to prevent growth of aerobes such as yeasts and molds; Raka-Ray medium, supplemented with cycloheximide; and VLB (Versuchs- und Lehranstalt für Brauerei, Berlin, Germany) (Holzapfel et al., 2005). NBB may be one of the most successful and most appropriate media for detection and cultivation of beer pediococci. The most rapid and intensive growth rate was recorded on this medium (Dachs, 1981), whereas the high beer-specific selectivity results in the inhibition of yeasts and Gram-negative bacteria (Back, 1994, 2000).

Maintenance procedures

For short-term storage, cultures may be kept as stabs in appropriate growth media supplemented with 0.3% CaCl₂ as pH neutralizer, at 4°C, with monthly transfers to freshly prepared

medium. For long-term storage, exponential-phase cultures may be mixed with an equal volume of 80% (v/v) sterile glycerol and stored in cryotubes at -20 or -80°C. Lyophilization with sterile skim milk or storage in liquid nitrogen is recommended for longer-term storage. Vancomycin may be added (Björkroth and Holzapfel, 2003). Strains are maintained as described in the chapter for *Leuconostoc*. For more information, see Schillinger and Holzapfel (2003).

Differentiation from closely related taxa

The true pediococci may be distinguished from closely related or morphologically similar genera and groups by a number of phenotypic characteristics, as is shown in Table 89. In general, they are characterized by their nonhalophilic but aciduric nature and facultative aerobic growth (Holzapfel et al., 2005; Weiss, 1992), which distinguishes them from *Tetragenococcus*, *Aerococcus*, and *Pediococcus dextrinicus*. The latter, in addition, is able to produce CO₂ from gluconate and to hydrolyze starch, in contrast to the true pediococci and tetragenococci.

Habitat

Pediococcus species share common habitats with other LAB, and especially with *Lactobacillus*, *Leuconostoc*, and *Weissella* species. *Pediococcus acidilactici*, *Pediococcus parvulus*, *Pediococcus inopinatus*, *Pediococcus stilesii*, and *Pediococcus pentosaceus* may be naturally associated with plants and fruits (Back, 1978a; Dellaglio et al., 1981; Mundt et al., 1969; Wilderdyke et al., 2004) and also with the fermentation of plant materials, such as silage, maize, cucumbers, olives, or cereal gruels. Some strains also contribute to meat fermentations. *Pediococcus damnosus*, *Pediococcus dextrinicus*, *Pediococcus inopinatus*, and *Pediococcus cellicola* are often associated with the brewery environment or environments in which alcoholic beverages are produced (Back, 1978a; Simpson and Taguchi, 1995; Zhang et al., 2005). Pediococci may also be important constituents of the nonstarter lactic acid bacteria involved in ripening of cheese (Olson, 1990). Some reports suggest the association of pediococcal strains with human and animal hosts, e.g., with human saliva (Sims, 1986) and with the digestive tract of humans and animals and in human feces (Heilig et al., 2002; Ruoff et al., 1988; Walter et al., 2001). *Pediococcus acidilactici* and *Pediococcus pentosaceus* were also detected in the gastrointestinal (GI) tracts of poultry (Juvén et al., 1991) and ducks (Kurzak et al., 1998) and in freshwater prawns (*Macrobrachium rosenbergii*) in Thailand (Cai et al., 1999a). *Pediococcus pentosaceus* was reported to form part of the Gram-positive tonsillar and nasal microbial population of piglets (Baele et al., 2001a; Martel et al., 2003).

The association of pediococci with the clinical environment has been discussed (see above). The genomic diversity within the genus *Pediococcus* has been investigated by Simpson et al. (2002b) using RAPD-PCR and PFGE. These techniques proved useful for the rapid classification of *Pediococcus* strains isolated from sources such as food, feed, silage, beer, and human clinical samples. Comparative information may be found in the chapter on *Tetragenococcus* by Dicks et al.

List of species of the genus *Pediococcus*

Table 90 gives some conditions under which the different species will grow and phenotypic features for a preliminary discrimination at species level.

1. *Pediococcus damnosus* Claussen 1903, 68^{AL} dam.no'sus. L. adj. *damnosus* destructive.

Morphology as general description. Growth is often slow and 2–3 d incubation at 22°C may be required for good growth. Broth cultures will develop without anaerobic conditions, but cysteine added to the medium improves growth. On an agar surface, colony development is poor unless cultures are incubated anaerobically. The final pH in broth is about 4.0. Optimum pH for growth is 5.5; cells do not grow at pH 8.5. Growth occurs in the range of 8–30°C. No growth occurs at 35°C; some strains grow in the presence of 4% NaCl. Although some strains grow in the presence of 5% (w/v) NaCl (Table 90), none grow in the presence of 5.5% NaCl (Simpson and Taguchi, 1995). Acetoin or diacetyl are readily produced and cause sarcina (buttery) odor in spoiled beer. Slime-forming strains are reported (Carr, 1970; Shimwell, 1948). The exopolysaccharide produced by a ropy strain of *Pediococcus damnosus* was shown to be a 2-substituted (1–3)-β-D-glucan (Duenas-Chasco et al., 1997). Hops humulone may cause the formation of giant cells of 5–15 μm (Nakagawa and Kitahara, 1962). *Pediococcus damnosus* strain NCFB1832 produces the bacteriocin pedio-

cin PD-1 with activity against various food spoilage and food pathogenic bacteria (Bauer et al., 2005; Green et al., 1997). Fatty acid analysis using pyrolysis mass spectrometry showed that the major FAME profiles for *Pediococcus damnosus* were palmitic acid methyl ester (C_{16:0} FAME), oleic acid methyl ester (C_{18:1} FAME), and cyclopropyl nonadecanoic acid methyl ester (C_{19:0} FAME_{cyclo}).

Phenotypically, the inability to hydrolyze arginine separates *Pediococcus damnosus* from *Pediococcus acidilactici* and *Pediococcus pentosaceus*. Furthermore, *Pediococcus damnosus* has low genomic relatedness to *Pediococcus acidilactici* and *Pediococcus pentosaceus* (Dellaglio et al., 1981; Simpson and Taguchi, 1995). In contrast, *Pediococcus damnosus* shows a high degree of genomic relatedness to *Pediococcus inopinatus* and *Pediococcus parvulus* (34–36%) in DNA–DNA hybridization experiments (Table 88). Such a close relationship is also reflected in the phylogenetic relatedness based on 16S rDNA sequences (Dobson et al., 2002). Cells are readily destroyed by heat, i.e., 60°C for 10 min.

The type strain was isolated from lager beer yeast.

DNA G+C content (mol%): 37–42 (*T_m*) (Kocur et al., 1971).

Type strain: Be.1, ATCC 29358, CCUG 32251, CIP 102264, DSM 20331, JCM 5886, LMG 11484, NCIMB 12010, VKM B-1602.

GenBank accession number (16S rRNA gene): AJ318414, D87678.

2. ***Pediococcus acidilactici*** Lindner 1887, 440^{AL}
a.ci.di.lac.ti'ci. N.L. gen. n. *acidilactici* of lactic acid.

Morphological, cultural, and physiological properties do not readily separate *Pediococcus acidilactici* from *Pediococcus pentosaceus*. Growth occurs at pH 4.2 and 8.0 and sometimes at pH 8.5. Final pH in MRS broth is between 3.5 and 3.8. Optimum temperature of growth is 40°C, while the maximum growth temperature is 50–53°C. All strains grow at 50°C. Cells grow in the presence of 9–10% (w/v) NaCl (Simpson and Taguchi, 1995) (Table 90). Cells are heat tolerant, but are killed after 10 min at 70°C. Some strains may be even more heat tolerant, particularly when newly isolated. *Pediococcus acidilactici* and *Pediococcus pentosaceus* are difficult to separate using physiological tests, suggesting a high degree of relatedness. These two species also show a higher relatedness to each other than to other pediococci when considering their phylogenetic relationship based on 16S rDNA analysis (Holzapfel et al., 2005). However, on the genome level they actually share low DNA–DNA relatedness (5–35% similarity, Table 88) (Dellaglio and Torriani, 1986). At the phenotypic level, the inability of *Pediococcus acidilactici* to ferment maltose and its ability to grow at 50°C differentiates it from *Pediococcus pentosaceus*. Some strains of *Pediococcus acidilactici* produce the bacteriocin pediocin PA-1/AcH (Marugg et al., 1992; Mora et al., 2000a).

The type strain was isolated from barley.

DNA G+C content (mol%): 38–44 (T_m) (Simpson and Taguchi, 1995).

Type strain: Back S213C, B213c, CCUG 32235, CIP 103408, DSM 20284, LMG 11384, NCIMB 12174.

GenBank accession number (16S rRNA gene): AJ305320, M58833.

3. ***Pediococcus cellicola*** Zhang, Tong and Dong 2005, 2169^{VP}
cel.li.co'la. L. n. *cella* a storeroom for wine and food; L. suff. *cola* from L. n. *incola* an inhabitant, dweller; N.L. n. *cellicola* an inhabitant of a storeroom, indicating that the strain was isolated from a distilled-spirit-fermenting cellar.

Morphology as general description. Strains are facultatively anaerobic and produce DL-lactate. Growth at 13–44°C with an optimum at 30–37°C. Optimum pH for growth is pH 6.0–6.8. No growth at pH 3.8 and pH 8.2. No growth in 10% NaCl (Table 90). Utilizes rhamnose, ribose, D-xylose, and L-xylose as sole carbon energy source which can be used to differentiate *Pediococcus cellicola* from the closely related species *Pediococcus damnosus*, *Pediococcus inopinatus*, and *Pediococcus parvulus* that cannot ferment these sugars. Tolerant to 10% (v/v) ethanol. A phylogenetic study based on 16S rDNA sequence analysis indicated a close relationship with *Pediococcus damnosus*, *Pediococcus inopinatus*, and *Pediococcus parvulus* (Zhang et al., 2005).

The type strain was isolated from a cellar for spirit fermentation.

DNA G+C content (mol%): 37–39 (T_m) (Zhang et al., 2005).

Type strain: Z-8, AS 1.3787, LMG 22956.

GenBank accession number (16S rRNA gene): AY956788.

4. ***Pediococcus clausenii*** Dobson, Deneer, Lee, Hemmingsen, Glaze and Ziola 2002, 2009^{VP}

claus'sen.i.i. N.L. gen. n. *Claussenii* of clausen, in honor of N.H. Clausen.

Morphology as general description. Some strains form slime. Unlike other pediococci (with the exception of *Pediococcus dextrinicus*) *Pediococcus clausenii* produces L(+)-lactate (Table 90). However, so far only the type strain of *Pediococcus clausenii* was tested (Holzapfel et al., 2005) for this trait. Should this remain a reliable phenotypic characterization trait, it may serve as a distinguishing feature for this species, as well as for the other L(+)-lactate-producing *Pediococcus* species, *Pediococcus dextrinicus*. However, *Pediococcus dextrinicus* is quite different from other pediococci at the 16S rDNA level and, as mentioned above, will probably be reclassified as a new genus in the future. Dobson et al. (2002) used three different comparative phylogenetic sequence analyses, comprising the 16S rDNA, 16S–23S internally transcribed spacer region, and the heat-shock protein HSP60 gene for investigating the phylogenetic relationships among pediococci and showed that *Pediococcus clausenii* could be well separated from other *Pediococcus* species. (As mentioned above, these investigations also confirmed other observations that *Pediococcus pentosaceus* and *Pediococcus acidilactici* are closely related.) The type strain was isolated from beer.

DNA G+C content (mol%): 40.0–41.7 (T_m) (Dobson et al., 2002).

Type strain: P06, ATCC BAA-344, DSM 14800, KCTC 3811, LMG 21948.

GenBank accession number (16S rRNA gene): AJ621555.

5. ***Pediococcus dextrinicus*** (Coster and White 1964) Back 1978b, 523^{AL} (*Pediococcus cerevisiae* subsp. *dextrinicus* Coster and White 1964, 29.)
dex.trin'i.cus. N.L. n. *dextrinum* dextrin; N.L. masc. adj. *dextrinicus* relating to dextrin.

Morphology as general description. Less anaerobic than previously described species. Colonies develop on agar aerobically, but growth is improved in an atmosphere of H₂ + 10%CO₂. In MRS broth, the final pH is about 4.4. Growth does not occur at pH 4.2, but does at pH 8.0. Optimum pH for growth is 6.5. Optimum temperature 30–35°C. Cells grow in the presence of 6% (w/v) NaCl. In contrast to all other pediococci, *Pediococcus dextrinicus* utilizes starch and produces acid and gas from gluconate. *Pediococcus dextrinicus* produces L(+)-lactate from glucose (Table 89 and Table 90). 16S RNA sequencing has shown that the species is not closely related to other pediococci (Collins et al., 1991; Dobson et al., 2002). Thus, although this species is still classified as belonging to the genus *Pediococcus* (Euzéby, 1998; updated March 01, 2005: <http://www.bacterio.cict.fr/almr.html>), genetic and phenotypic data (see above) support its allocation to a new genus. Growth requirements have not been studied. Growth occurs in weakly hopped beer; its habitat is fermenting vegetables and beer.

The type strain was isolated from silage.

DNA G+C content (mol%): 40–41 (T_m) (Simpson and Taguchi, 1995).

Type strain: ATCC 33087, CCUG 18834, CIP 103407, DSM 20335, JCM 5887, LMG 11485, NCIMB 701561, VKM B-1603.

GenBank accession number (16S rRNA gene): D87679.

6. ***Pediococcus inopinatus*** Back 1988, 221^{VP} (Effective publication: Back 1978a, 245.)
in.o.pin.a'tus. L. adj. *inopinatus* unexpected.

Morphology as general description. On agar, growth is slow and colonies may take 3–5 d to develop. The final pH in MRS broth is about 4.0. There is a close similarity between *Pediococcus inopinatus* and *Pediococcus parvulus* which both occur in the same habitat. The maximum pH value for growth is 7.5, while the maximum temperature for growth is 37–40°C. The optimum growth temperature lies between 30 and 32°C. Cells grow in the presence of 6–8% (w/v) NaCl (Table 90). *Pediococcus inopinatus* can be differentiated from *Pediococcus pentosaceus* and *Pediococcus acidilactici* by its inability to utilize pentoses and hydrolyze arginine (Table 90). It differs from *Pediococcus dextrinicus* in being unable to grow on starch or produce acid and gas from gluconate. Some strains form slime (Simpson and Taguchi, 1995). Habitat: fermenting vegetables and beverages such as beer and wine. The mol% G+C of the DNA is close to that of the other *Pediococcus* species (Table 90). Separation of *Pediococcus parvulus* and *Pediococcus inopinatus* was initially obtained by the electrophoresis of the L-(+)- and D-(-)-LDHs (Back, 1978b) and later confirmed by DNA–DNA hybridization and comparison of 16S rDNA sequences (Simpson and Taguchi, 1995).

The type strain was isolated from brewery yeast.

DNA G+C content (mol%): 39–40 (T_m) (Simpson and Taguchi, 1995).

Type strain: ATCC 49902, CCUG 38496, CIP 102406, DSM 20285, JCM 12518, LMG 11409, NCIMB 12564.

GenBank accession number (16S rRNA gene): AJ271383.

7. ***Pediococcus parvulus*** Günther and White 1961, 195^{AL}
par'vu.lus. L. dim. adj. *parvulus* very small.

Morphology as general description. Colonies on tomato juice agar were originally reported to be very small, but improved growth can be obtained particularly when anaerobic incubation is used. Larger colonies usually develop after 48 h at 30°C. Broth cultures are improved by the addition of cysteine and Tween 80, but 48 h incubation may be needed (Garvie and Gregory, 1961). Some strains require asparagine (Garvie et al., 1961) but not folic acid. The final pH in broth is about 4.0 for well-grown strains. The optimal growth pH is 6.5 with the upper limit for growth between pH 7.0 and 7.5. The optimum growth temperature is 30°C. Maximum temperature for growth is 37–39°C. Growth occurs in the presence of 5.5–8% (w/v) NaCl (Simpson and Taguchi, 1995). Maximum temperature is 37–39°C. The inability of *Pediococcus parvulus* to utilize pentoses (Table 90) separates it from *Pediococcus pentosaceus* and *Pediococcus acidilactici* (Simpson and Taguchi, 1995). Some strains form slime and some are reported to produce high levels of histamine during wine fermentation (Landete et al., 2005). *Pediococcus damnosus* strain ATO77 produces the bacteriocin pediocin PA-1 (Bennik et al., 1997). Habitat: fermenting vegetables and wine fermentations.

The type strain was isolated from silage. Tolerance to hop antiseptic is unknown.

DNA G+C content (mol%): 40.5–41.6 (T_m) (Simpson and Taguchi, 1995).

Type strain: ATCC 19371, CCUG 28439, CIP 102262, DSM 20332, JCM 5889, LMG 11486, NBRC 100673, NCIMB 9447, VKM B-1604.

GenBank accession number (16S rRNA gene): D88528.

8. ***Pediococcus pentosaceus*** Mees 1934, 96^{AL}
pen.to.sa'ce.us. N.L. neut. n. *pentosum* a pentose sugar; N.L. adj. *pentosaceus* relating to a pentose.

Morphology as general description. Anaerobic incubation is not necessary, and colonies should be visible on agar after aerobic incubation for 24 h at 30°C. Litmus milk reactions are variable and may be related to growth requirements. The requirement for folic acid varies between strains. A limited study of the aldolases found in pediococci has shown that *Pediococcus pentosaceus* and *Pediococcus acidilactici* are closely related species which are separate from *Pediococcus parvulus*. There is some evidence that not all strains of *Pediococcus pentosaceus* have the same aldolase (London and Chace, 1976).

In broth, growth can be very rapid and the final pH in MRS broth is usually below 4.0. Optimal growth pH is between 6.0 and 6.5, but growth may occur at pH 8.0 (Simpson and Taguchi, 1995) (Table 90). Optimal growth temperature is between 28 and 32°C and not above 39–45°C. Cells grow in the presence of 9–10% (w/v) NaCl (Simpson and Taguchi, 1995). *Pediococcus pentosaceus* is less heat resistant than *Pediococcus acidilactici* and is killed after 8 min. at 65°C. The sugar fermentation reactions of *Pediococcus pentosaceus* resemble those of *Pediococcus acidilactici*. However, the ability to ferment maltose and a lower growth temperature differentiates *Pediococcus pentosaceus* from *Pediococcus acidilactici* (although not invariably). *Pediococcus pentosaceus* could also be confused with micrococci as it can form small colonies on sugar-free agar and can grow at pH 9.0. *Pediococcus pentosaceus* can also be weakly catalase-positive when grown in medium with low glucose content (Whittenbury, 1965). The rapid growth, low final pH, and absence of cytochromes distinguish *Pediococcus pentosaceus* from micrococci.

Various strains of *Pediococcus pentosaceus* have been reported to produce bacteriocins such as pediocin PA-1 (Miller et al., 2005), pediocin ST18 (Todorov and Dicks, 2005), pediocin – A (Piva and Headon, 1994), and pediocin ACCEL (Wu et al., 2004). The type strain was isolated from dried American beer yeast.

DNA G+C content (mol%): 35–39 (T_m) (Simpson and Taguchi, 1995).

Type strain: ATCC 33316, CCUG 32205, CIP 102260, DSM 20336, JCM 5890, LMG 11488, NCIMB 12012, NCTC 12956.

GenBank accession number (16S rRNA gene): AJ305321, M58834.

9. ***Pediococcus stilesii*** Franz, Vancanneyt, Vandemeulebroecke, De Wachter, Cleenwerck, Hoste, Schillinger, Holzappel and Swings 2006, 332^{VP}
stiles.i.i. N.L. gen. n. *stilesii* of Stiles, in honor of M.E. Stiles, a microbiologist.

Morphology as general description. Currently only one strain known. Produces DL-lactate. Acid produced from ribose, galactose, fructose, maltose, and mannose. Unlike most other pediococci, *Pediococcus stilesii* can grow at high

pH, even pH 9.6. Grows at 35–45°C, no growth at 48°C. Cells grow in the presence of 8% NaCl (Table 90). Using 16S rDNA sequencing for phylogenetic comparison, *Pediococcus pentosaceus*, *Pediococcus acidilactici*, *Pediococcus stilesii*, and *Pediococcus clausenii* were each shown to occupy a distinct branch, yet were also more closely related with each other than with other *Pediococcus* species (Franz et al., 2006). However, using DNA–DNA hybridization, only low similarity was observed with DNA from *Pediococcus acidilactici* (14.5%) and *Pediococcus pentosaceus* (21%). Pheno-

typically, *Pediococcus stilesii* is distinguished from *Pediococcus pentosaceus* by its inability to ferment arabinose and lactose, from *Pediococcus acidilactici* by its inability to ferment xylose, and from *Pediococcus clausenii* by its ability to produce acid from galactose and DL-lactate from glucose. The type strain was isolated from steeped maize grains.

DNA G+C content (mol%): 38 (T_m) (Franz et al., 2006).

Type strain: LMG 23082, BFE 1652, CCUG 51290, FAIR-E 180.

GenBank accession number (16S rRNA gene): AJ973157.

Family II. *Aerococcaceae* fam. nov.

WOLFGANG LUDWIG, KARL-HEINZ SCHLEIFER AND WILLIAM B. WHITMAN

A.e.ro.coc.ca'ce.ae. N.L. masc. n. *Aerococcus* type genus of the family; suff. *-aceae* ending denoting family; N.L. fem. pl. n. *Aerococcaceae* the *Aerococcus* family.

The family *Aerococcaceae* is circumscribed for this volume on the basis of phylogenetic analyses of the 16S rRNA gene sequences and includes the genus *Aerococcus* and its close relatives. It is composed of nonmotile, Gram-positive ovoid cocci or coccobacilli. When it has been measured, cell walls have been found to

contain the diamino acid lysine. Endospores are not formed. Facultatively anaerobic and catalase-negative. May grow in media containing 6.5 % NaCl.

Type genus: Aerococcus Williams, Hirsch and Cowan 1953, 475^{AL}.

Genus I. *Aerococcus* Williams, Hirsch and Cowan 1953, 475^{AL}

MATTHEW D. COLLINS AND ENEVOLD FALSSEN

A.ë.ro.coc'cus. Gr. masc. n. *aër* air, gas; Gr. n. *kokkos* a berry; N.L. masc. n. *Aerococcus* air coccus.

Cells are ovoid in shape (1–2 µm in diameter) and divide on two planes at right angles, giving rise to tetrad and cluster arrangements; some pairs and single cells may also be observed. **α-Hemolytic.** Gram-positive and nonmotile. Non-sporeforming. **Facultatively anaerobic. Catalase-negative. Oxidase-negative. Grows in 6.5% NaCl. Gas is not produced in MRS broth. Acid is produced from glucose and some other carbohydrates.** Hippurate is hydrolyzed by most strains. Leucine aminopeptidase and β-glucuronidase may or may not be produced. Arginine is not deaminated by most strains and urease is not produced. **Voges–Proskauer-negative. Vancomycin-sensitive.**

DNA G+C content (mol%): 35–44 (T_m).

Type species: Aerococcus viridans Williams, Hirsch and Cowan 1953, 477.

Further descriptive information

Aerococci produce an α-hemolytic reaction on blood agar and form small (generally 1 mm or less), nonpigmented colonies (with the occasional exception of yellow pigment production by *Aerococcus viridans* strains) after 24 h incubation at 37°C. Aerococci generally consist of Gram-positive cocci arranged in clusters and tetrads except for *Aerococcus christensenii* which exhibits short chains. They are facultatively anaerobic; *Aerococcus christensenii* prefers anaerobic conditions. Aerococci are catalase-negative, but some strains may display a weak non-heme pseudocatalase activity. Cytochrome enzymes are absent. Aerococci are nutritionally fastidious. Pantothenic acid, nicotinic acid, and biotin are either required or stimulatory for the growth of *Aerococcus viridans*; guanine or another purine base is also required. Amino acids are needed for the growth of *Aerococcus viridans*, but the requirement is not specific or sharply defined (Miller and Evans, 1970). All aerococci grow in 6.5% NaCl, and *Aerococcus viridans* grows in 10% NaCl. Strains differ in their growth temperature characteristics. Most strains of *Aerococcus urinae* grow at 45°C whereas most strains of *Aerococcus viridans* do not. *Aerococcus urinae* and *Aerococcus viridans* do not grow at 10°C (Facklam and Elliott, 1995), although there are reports of the latter species (Evans, 1986) growing at this temperature. Most *Aerococcus viridans* strains and *Aerococcus sanguinicola* give a positive bile-esculin reaction, whereas *Aerococcus urinae* is bile-esculin negative. Aerococci are chemo-organotrophic; acid, but

no gas, is produced from glucose and other sugars. Acid production from carbohydrates differs between species and also between the test systems employed (conventional tests or API kits). *Aerococcus urinae*, *Aerococcus urinaehominis*, *Aerococcus sanguinicola*, and a minority of strains of *Aerococcus viridans* produce β-glucuronidase. *Aerococcus urinae* produces leucine aminopeptidase but not pyrrolidonyl aminopeptidase, whereas *Aerococcus viridans* displays the opposite reactions (Christensen et al., 1997). By contrast, *Aerococcus sanguinicola* is positive for both leucine aminopeptidase and pyrrolidonyl aminopeptidase. None of the currently described *Aerococcus* species displays activity for alanyl-phenylalanine-proline arylamidase, glycyl-tryptophan arylamidase, β-mannosidase, N-acetyl-β-glucosaminidase, or urease. Aerococci do not hydrolyze gelatin and do not reduce nitrate to nitrite.

The cell-wall murein of *Aerococcus viridans* and *Aerococcus christensenii* are based on L-lysine (directly cross-linked, type A1α) (Collins et al., 1999d). Polyamines are not detected in *Aerococcus viridans* (Hamana, 1994). Aerococci lack respiratory menaquinones. The predominant long chain fatty acids of *Aerococcus viridans* are C_{16:0}, C_{16:1 09c}, C_{18:0}, C_{18:1 09c}, and C_{20:0 09c}, together with smaller amounts of C_{14:0}, C_{16:1 09t}, and C_{18:1 07c} (Bosley et al., 1990). The major cellular fatty acids of *Aerococcus urinae* have been reported to be C_{16:0}, C_{18:1 09c}, and C_{18:0}; C_{18:1 07t} has also been reported in this species (Zbinden et al., 1999). The reported G+C content of DNA of *Aerococcus viridans*, *Aerococcus urinae*, and *Aerococcus christensenii* is 35–40, 44.4 and 38.5 mol%, respectively. *Aerococcus viridans* is reported to have a relatively small genome ranging from 0.57 × 10⁹ to 1 × 10⁹ Da (Wiik et al., 1986).

Aerococcus urinae is susceptible to a wide range of antimicrobials including β-lactams but is resistant to sulfonamides and aminoglycosides. Christensen et al. (1996) found *Aerococcus urinae* was susceptible to penicillin, ampicillin, cephalosporins, tetracycline, doxycycline, chloramphenicol, furazolidone, erythromycin, clindamycin, vancomycin, teicoplanin, daptomycin, rifampin, clavulanate, and mupirocin but resistant to aminoglycosides, sulfonamides, trimethoprim, nalidixic acid, colistin, aztreonam, sulbactam, and bacitracin. *Aerococcus viridans* was not susceptible to bacitracin, clavulanate, colistin, furazolidone, penicillin, and tobramycin (Christensen et al., 1996). Penicillin resistance among strains

of *Aerococcus viridans* has been reported, although there are reports describing isolates that are susceptible to penicillin (Kern and Vanek, 1987). Kern and Vanek (1987) reported that some strains of *Aerococcus viridans* were resistant to sulfamethoxazole-trimethoprim-methoxazole and ofloxacin. Buu-Hoi et al. (1989) reported several strains of *Aerococcus viridans* that had acquired the *ermB* gene of *Enterococcus faecalis*. Other strains acquired the *tetM* gene to confirm tetracycline resistance. *Aerococcus viridans* is reported to produce a bacteriocin, designated viridicin (Ballester et al., 1980).

Aerococci have been recovered from a wide range of environments. *Aerococcus viridans* is generally saprophytic and is found in air, dust, vegetation, meat-curing brines, soil, and marine sources. The species can also be found in small numbers as part of the indigenous flora in the upper respiratory tract and on the skin of normal persons. *Aerococcus viridans* is a common airborne organism in hospital environments (Kerbaugh and Evans, 1968) and is associated, albeit infrequently, with human infections (Facklam and Elliott, 1995) such as endocarditis (Bru et al., 1986; Janosek et al., 1980; Untereker and Hanna, 1976), urinary tract infections (Colman, 1967), septic arthritis (Taylor and Trueblood, 1985), and acute childhood meningitis (Nathavitharana et al., 1983). *Aerococcus viridans* has been isolated from subclinical intramammary infections in dairy cows (Devriese et al., 1999) and is responsible for a fatal disease (gaffkemia) of lobsters (Fisher et al., 1978; Hitchner and Snieszko, 1947). *Aerococcus urinae* can cause infections in humans. This organism was originally characterized by Christensen et al. (1991, 1989) from urine samples of elderly persons with urinary tract infections. *Aerococcus urinae* infections are usually mild, but serious infections such as endocarditis, septicemia, urosepsis, and soft tissue infections have been reported (Christensen et al., 1991, 1995; Gritsch et al., 1999; Kristensen and Nielsen, 1995; Schuur et al., 1999; Zbinden et al., 1999). The three recently described species, *Aerococcus christensenii*, *Aerococcus sanguinicola*, and *Aerococcus urinaehominis*, have all been isolated from human sources including vagina, blood, and urine respectively (Collins et al., 1999d; Lawson et al., 2001a, 2001b).

Isolation procedures

Aerococci can be isolated on a variety of rich agar-containing media, such as heart infusion agar supplemented with 5% (v/v) sheep or horse blood at 37°C.

Maintenance procedures

Aerococci can be maintained on a variety of rich media generally used for other Gram-positive cocci, such as heart infusion or tryptic soy agar with or without animal blood (5% v/v). Strains can be maintained on cryogenic beads at -70°C or lyophilized for long-term preservation.

Taxonomic comments

The genus *Aerococcus* was created by Williams et al. (1953) to accommodate some Gram-positive, microaerophilic, catalase-negative, coccoid-shaped organisms that differed from streptococci primarily by their characteristic tetrad cellular arrangement. Until recently, the genus contained only a single species, *Aerococcus viridans*, and historically, because

of its cellular morphology, this species was thought to resemble pediococci more than streptococci. Similarities were also apparent between *Aerococcus viridans* and the lobster pathogen "*Gaffkya homari*" (Deibel and Niven, 1960), and it is now evident that these represent a single species (Evans, 1986; Kelly and Evans, 1974; Wiik et al., 1986). *Pediococcus urinaeequi* has also been known for a long time to resemble *Aerococcus viridans* closely. These two species are biochemically and culturally indistinguishable, display similar antibiograms, possess almost identical 16S rRNA sequences (Christensen et al., 1996, 1997; Collins et al., 1990), and are considered to be the same species. DNA pairing investigations by Bosley et al. (1990) indicate that while most strains of *Aerococcus viridans* form a genetically highly related group, there is evidence of a second genomic species (designated genospecies 2) which is very closely related to *Aerococcus viridans*. During the past decade, four other *Aerococcus* species, *Aerococcus urinae*, *Aerococcus christensenii*, *Aerococcus urinaehominis*, and *Aerococcus sanguinicola*, have been described from human sources (Aguirre and Collins, 1992a; Collins et al., 1999d; Lawson et al., 2001a, 2001b). Comparative 16S rRNA gene sequencing studies have shown that this expanded *Aerococcus* genus forms a robust group among the catalase-negative, Gram-positive cocci (Collins et al., 1999d; Lawson et al., 2001a, 2001b) and is phylogenetically distinct from other genera such as *Streptococcus* and *Pediococcus* with which it has been historically associated. A tree depicting the phylogenetic interrelationships of aerococci and its close relatives is shown in Figure 94.

Differentiation of the genus *Aerococcus* from other genera

Although the genus *Aerococcus* is phylogenetically distinct, there are few phenotypic traits which serve to distinguish the genus from related genera. For example, when the genus was restricted to *Aerococcus viridans*, tests such as cellular arrangements, arginine dehydrolase (ADH), pyrrolidonyl arylamidase (PYRA), leucine aminopeptidase (LAP), vancomycin sensitivity, and growth at 45°C were useful aids in distinguishing aerococci from related genera (Bosley et al., 1990; Facklam and Elliott, 1995). However, with the possible exception of tetrad/cluster cellular arrangements (although *Aerococcus christensenii* displays short chains) and susceptibility to vancomycin, the newly defined *Aerococcus* species, in many instances, differ from *Aerococcus viridans* or from each other with respect to these and other traits, making simple identification of the genus somewhat difficult. For example, *Aerococcus urinae* produces LAP, is PYRA negative and grows at 45°C, whereas *Aerococcus viridans* displays the opposite results. The formation of tetrad/cluster cellular arrangements serves to distinguish aerococci from most other catalase-negative, Gram-positive cocci. Aerococci can be distinguished from other non-chain forming, Gram-positive cocci, such as *Pediococcus*, *Alloiooccus*, and *Gemella*, using conventional tests (Facklam and Elliott, 1995). For example, aerococci differ from pediococci in being sensitive to vancomycin. By contrast, pediococci are resistant to this antibiotic. Alloioocci differ from aerococci in not growing anaerobically (except for a few exceptional strains) and by failing to grow on a variety of commonly used media such as on sheep blood agar or in thioglycollate broth. Similarly, gemellae differ from most aerococcal species by failing to grow in 6.5% NaCl.

FIGURE 94. Neighbor-joining tree based on 16S rRNA sequences depicting the phylogenetic relationships of aerococci.

Differentiation of the species of the genus *Aerococcus*

In contrast to identification at the rank of genus, the phenotypic identification of aerococci at the species level is not problematic. All currently defined species can be easily recognized using conventional and miniaturized API test systems. Tests

which are useful in distinguishing the various *Aerococcus* species from each other using conventional methods and the API Rapid ID32 Strep system are shown in Table 91 and Table 92, respectively.

List of species of the genus *Aerococcus**

1. ***Aerococcus viridans*** Williams, Hirsch and Cowan 1953, 477^{AL}. vi.ri'dans. L. part. adj. *viridans* producing a green color.
DNA G+C content (mol%): not reported.
Type strain: ATCC 11563, CCM 1914, CCUG 4311, CIP 54.145, DSM 20340, HAMBI 1583, LMG 17931, NBRC 12219, NCAIM B.01070, NCTC 8251.
GenBank accession number (16S rRNA gene): M58797.
2. ***Aerococcus christensenii*** Collins, Rodriguez Jovita, Hutson, Ohlén and Falsen 1999d, 1128^{VP}. christ.en.sen'i.i. N.L. gen. n. *christensenii* named after the Danish microbiologist Jens J. Christensen.
DNA G+C content (mol%): 38.5 (T_m).
Type strain: UW06, CCUG 28831, CIP 106115.
GenBank accession number (16S rRNA gene): Y17005.
3. ***Aerococcus sanguinicola*** corrig. Lawson, Falsen, Truberg-Jensen and Collins 2001b, 478^{VP}. san.guin'i.co.la. L. n. *sanguis* blood; L. sulf-*cola* dweller; N.L. n. *sanguinicola* blood-dweller.
DNA G+C content (mol%): not reported.
Type strain: CCUG 43001, CIP 106533, JCM 11549.
GenBank accession number (16S rRNA gene): AJ276512.
4. ***Aerococcus urinae*** Aguirre and Collins 1992b, 511^{VP} (Effective publication: Aguirre and Collins 1992a, 403.) u.ri'nae. L. fem. n. *urinae* pertaining to urine.
Two biotypes of *Aerococcus urinae* are recognized depending on their ability to hydrolyze esculin (Christensen et al., 1997).
DNA G+C content (mol%): not known.
Type strain: E2, ATCC 51268, CCUG 29291, CCUG 29564, CCUG 34223, CCUG 36881, CIP 104688, DSM 7446, NBRC 15544, NCFB 2893, NCIMB 702893, NCTC 12142.
GenBank accession number (16S rRNA gene): M77819.
5. ***Aerococcus urinaehominis*** Lawson, Falsen, Ohlén and Coillins 2001a, 685^{VP}

* Editorial note. Since this chapter was accepted for publication, two more *Aerococcus* species have been described, *Aerococcus suis* (Vela et al., 2007) and *Aerococcus urinaeequi* (Felis et al., 2005).

DNA G+C content (mol%): not reported.

Type strain: CCUG 42038B, CIP 106675.

GenBank accession number (16S rRNA gene): AJ278341.

Genus II. **Abiotrophia** (Bouvet, Grimonet and Grimont 1989) Kawamura, Hou, Sultana, Liu, Yamamoto and Ezaki 1995, 802^{VP}

TAKAYUKI EZAKI AND YOSHIKI KAWAMURA

A.bi.o.tro'phi.a. Gr. pref. a-, negative (un-); Gr. n. *bios* life; Gr. n. *trophe* nutrition; N.L. fem. n. *Abiotrophia* life-nutrition-deficiency.

Cells are mainly cocci, but pleomorphic ovoid cells, coccobacilli, and rod-shaped cells may occur. Pyridoxal hydrochloride (0.001%) or L-cysteine (0.01%) required for growth on blood agar. Nonsporeforming. Nonmotile. Gram-positive. Facultative anaerobes. Catalase- and oxidase-negative. Lactic acid is the major end product of glucose fermentation. Gas is not produced from glucose. Growth does not occur at 10 and 45°C or in the presence of 6.5% NaCl. Alpha-hemolytic on supplemented sheep blood agar. Pyrrolidonyl arylamidase and leucine arylamidase are positive. Hippurate is not hydrolyzed. Argin-

ine dihydrolase is negative. Resistant to optochin and susceptible to vancomycin. The organisms have been isolated from human clinical specimens, such as blood with sepsis (Bouvet et al., 1989; Carey et al., 1975) and endocarditis (Bouvet, 1995; Bouvet et al., 1980, 1981).

DNA G+C content (mol%): 46.0–46.6.

Type species: **Abiotrophia defectiva** (Bouvet, Grimonet and Grimont 1989) Kawamura, Hou, Sultana, Liu, Yamamoto and Ezaki 1995, 802 (*Streptococcus defectives* Bouvet, Grimonet and Grimont 1989, 290.)

Further descriptive information

The phylogenetic position of the genus within the family *Aerococcaceae* is given in Figure 95. Only one species, *Abiotrophia defectiva*, is currently included in the genus.

Lysine is the diamino acid at position 3 in the cell-wall peptidoglycan, and the peptide bridge consists of alanine or alanyl-alanine.

Abiotrophia is nutritionally fastidious: no growth or only slight growth occurs on a blood agar plate without supplements. Thiol compounds (0.01% L-cysteine is usually used) or vitamin B6 (0.001% pyridoxal hydrochloride is usually used) is required for growth. Growth occurs as satellite colonies adjacent to *Staphylococcus epidermidis* on blood agar.

Differentiation of the genus *Abiotrophia* from other genera

Characteristics differentiating *Abiotrophia defectiva* from other catalase-negative, Gram-positive cocci are listed in Table 93. *Abiotrophia defectiva* does not hydrolyze hippurate, and arginine dihydrolase-negative, whereas species in the genus *Granulicatella* (Collins and Lawson, 2000) are variable in these tests. *Abiotrophia defectiva* produces strong α -galactosidase and produces

acid from sucrose, whereas species in the genus *Granulicatella* are variable in these biochemical tests. The mol% DNA G+C content of the genus *Granulicatella* is 36.6–37.4 mol%, which is lower than that for the genus *Abiotrophia* (46.0–46.6 mol%).

Taxonomic comments

Members of this genus were originally described as the nutritionally variant streptococci *Streptococcus defectiva* and *Streptococcus adiacens*, and the two species were transferred to different phylogenetic groups (family *Aerococcaceae* and family “*Carnobacteriaceae*”). They were then transferred to a new genus, *Abiotrophia*, by Kawamura et al. (1995). Later, *Abiotrophia adiacens* was moved to a new genus, *Granulicatella* (Collins and Lawson, 2000) in the family “*Carnobacteriaceae*”. The phylogenetic relationship between the two genera is shown in Figure 95.

Differentiation of the species of the genus *Abiotrophia*

Characteristics to differentiate *Abiotrophia defectiva* from closely related species of the genus *Granulicatella*, which also requires cysteine or pyridoxal hydrochloride to grow on a blood agar plate, are given in Table 94.

Genus III. **Dolosicoccus** Collins, Rodriguez Jovita, Hutson, Falsen, Sjöden and Facklam 1999c, 1441^{VP}

MATTHEW D. COLLINS

Do.lo'si.coc.cus. L. adj. *dolosus* crafty, deceptive; Gr. n. *kokkos* a grain; N.L. masc. n. *dolosicoccus* a deceptive coccus

Cells are ovoid, occurring singly, in pairs, or in or short chains. Gram-stain-positive and nonmotile. Nonspore-forming. Facultatively anaerobic and catalase and oxidase-negative. No growth

at 10 or 45°C or in broth containing 6.5% NaCl. Weak acid production but no gas produced from glucose. Starch, esculin, gelatin, and urea are not hydrolyzed. Negative bile-esculin

reaction. Pyroglutamic acid arylamidase is produced but not leucine aminopeptidase. Voges–Proskauer-negative. Nitrate is not reduced to nitrite. **Vancomycin-sensitive.**

DNA G+C content (mol%): 40.5 (T_m).

Type species: Dolosicoccus paucivorans Collins, Rodriguez Jovita, Hutson, Falsen, Sjöden and Facklam 1999c, 1442^{VP}.

Further descriptive information

The genus contains only one species, *Dolosicoccus paucivorans*, and therefore the characteristics described refer to this species. Grows on 5% (v/v) horse or sheep blood agar producing a weak α -hemolytic reaction. Cells are nonpigmented. Pyruvate is not utilized and 0.04% tellurite is not tolerated. No dextrans or levans are formed on 5% sucrose. No acid or clot is formed in litmus milk. Using conventional heart infusion base medium, acid is produced from lactose (weak), maltose (weak), D-raffinose, ribose, and sucrose. Acid is not produced from L-arabinose, glycerol, melibiose, inulin, sorbitol, L-sorbose, or trehalose. Esculin is not hydrolyzed. Using conventional tests (Facklam and Elliott, 1995), pyroglutamic acid arylamidase is produced but leucine aminopeptidase is not. Using the API Rapid ID32 Strep system, acid may or may not be produced from lactose, maltose, mannitol, ribose, and sucrose. Acid is not produced from L-arabinose, D-arabitol, cyclodextrin, glycogen, melezitose, melibiose, methyl- β -D-glucopyranoside, pullulan, raffinose, sorbitol, tagatose, or trehalose. Alanine phenylalanine proline arylamidase, arginine dihydrolase, and pyroglutamic acid arylamidase may or may not be detected. Alkaline phosphatase, α -galactosidase, β -galactosidase, β -glucosidase, β -glucuronidase, glycyL tryptophan arylamidase, N-acetyl- β -glucosaminidase, β -mannosidase, and urease are not detected. Hippurate may or may not be hydrolyzed. Using the API ZYM system, esterase C4 (weak), ester lipase C8 (weak), and leucine arylamidase (weak) are detected. Alkaline phosphatase and acid phosphatase may or may not be detected. No activity is detected for cystine arylamidase, chymotrypsin, α -fucosidase, α -galactosidase, β -galactosidase, α -glucosidase, β -glucosidase, β -glucuronidase, N-acetyl- β -glucosaminidase, lipase C14, α -mannosidase, phosphoamidase, valine arylamidase, or trypsin.

Dolosicoccus paucivorans has been recovered from human blood (Collins et al., 1999c). Its habitat is not known.

Isolation procedures

Dolosicoccus paucivorans may be isolated at 37°C on rich agar-containing media containing 5% (v/v) animal blood. It can be

cultivated under aerobic or anaerobic conditions. There is no information on selective media for this species.

Maintenance procedures

Strains grow well on blood-based agars and in rich broths such as brain heart infusion or Todd–Hewitt at 37°C. For long-term preservation, strains can be stored on cryogenic beads at –70°C or lyophilized.

Taxonomic comments

The genus *Dolosicoccus* was proposed in 1999 for some Gram-stain-positive, catalase-negative, chain-forming, coccus-shaped organisms recovered from a human blood specimen (Collins et al., 1999c). Phylogenetically, the genus *Dolosicoccus* belongs to the order *Lactobacillales* and family *Aerococcaceae* of the phylum *Firmicutes*. Comparative 16S rRNA gene sequencing shows the genus *Dolosicoccus* represents a distinct subline among the Gram-stain-positive, catalase-negative cocci, with *Eremococcus coleocola*, *Globicatella sanguinis*, *Abiotrophia defectiva*, *Ignavigranum ruoffiae*, and *Facklamia* species as its nearest phylogenetic relatives (Collins et al., 1999c).

Differentiation of the genus *Dolosicoccus* from other genera

Using conventional phenotypic tests (Facklam and Elliott, 1995), the genus *Dolosicoccus* somewhat resembles *Dolosigranulum pigrum*, *Ignavigranum ruoffiae*, and *Facklamia* species in forming chains of cocci, being nonmotile, pyrrolidonyl- β -naphthylamide-positive, and catalase-negative, not growing at 10 or 45°C, having a negative bile-esculin reaction, and being susceptible to vancomycin. *Dolosicoccus paucivorans* differs from these taxa, however, in failing to produce leucine aminopeptidase and by not growing in 6.5% NaCl. *Dolosicoccus paucivorans* resembles *Globicatella sanguinis* in being leucine aminopeptidase-negative, but differs from this species by growing in 6.5% NaCl. In addition, *Globicatella sanguinis* differs markedly from *Dolosicoccus paucivorans* in fermenting a wide range of sugars (Collins et al., 1992). Classical phenotypic tests that are useful in distinguishing *Dolosicoccus paucivorans* from related Gram-stain-positive cocci are outlined in Table 95. *Dolosicoccus paucivorans* can also be readily identified using the commercially available API Rapid ID32 Strep system. Tests based on the API Rapid ID32 Strep system, which are useful in distinguishing *Dolosicoccus paucivorans* from related organisms, are shown in Table 96.

List of species of the genus *Dolosicoccus*

1. ***Dolosicoccus paucivorans*** Collins, Rodriguez Jovita, Hutson, Falsen, Sjöden and Facklam 1995, 1442^{VP}
pau.ci'vo.rans. N.L. adj. *paucivorans* eating little, relating to the observation that the organism utilizes few carbohydrates.

DNA G+C content (mol%): 40.5 (T_m).
Type strain: 2992-95, ATCC BAA-56, CCUG 39307, CIP 106314.
GenBank accession number (16S rRNA gene): AJ012666.

Genus IV. ***Eremococcus*** Collins, Rodriguez Jovita, Lawson, Falsen and Foster 1999f, 1383^{VP}

MATTHEW D. COLLINS AND PAUL A. LAWSON

E.re.mo.coc'cus. Gr. adj. *eremos* lonely; Gr. n. *kokkos* a grain or berry; N.L. masc. n. *Eremococcus* a lonely or isolated coccus, referring to its distinct phylogenetic position.

Cells are cocci, some of which may elongated, and occur singly, in pairs, and in short chains. Gram-stain-positive and nonmotile. Nonsporeforming. **Facultatively anaerobic and catalase-negative. No growth at 10°C or in 10% NaCl. Gas is not produced. Acid is produced from D-glucose. Arginine dihydrolase and pyroglutamic acid arylamidase are produced. Hippurate is hydrolyzed but starch and gelatin are not hydrolyzed.** Nitrate is not reduced. Voges–Proskauer-negative. **The cell-wall murein is type L-lysine direct (A1α).**

DNA G+C content (mol%): 40 (T_m).

Type species: ***Eremococcus coleocola*** Collins, Rodriguez Jovita, Lawson, Falsen and Foster 1999f, 1383.

Further descriptive information

The genus contains only one species, *Eremococcus coleocola*, and therefore the characteristics provided below refer to this species. Grows on 5% (v/v) horse or sheep blood agar producing

an α-hemolytic reaction. Cells are nonpigmented, nonmotile cocci which most commonly are arranged in short chains or pairs. Colonies are pinpoint, shiny, entire, circular, convex, and noncorroding on blood agar after 24 hours. Growth occurs at 42°C but not at 10°C; grows weakly in 6.5% NaCl but not in 10% NaCl. Acid is produced from glucose but from few other sugars. Acid may be produced from maltose and sometimes weakly from mannitol. Acid is not formed from L-arabinose, D-arabitol, cyclodextrin, glycogen, lactose, melibiose, melezitose, methyl-β-D-glucopyranoside, pullulan, raffinose, ribose, sorbitol, sucrose, tagatose, trehalose, or D-xylose. Activity is displayed for arginine dihydrolase, esterase C4, ester lipase C8, leucine arylamidase, N-acetyl-β-glucosaminidase, pyroglutamic acid arylamidase, and pyrrolydonyl arylamidase. Activity for alkaline phosphatase, acid phosphatase, urease, and valine arylamidase may or may not be detected. No activity is detected for alanine phenylalanine proline arylamidase, chymotrypsin,

α -fucosidase, α -galactosidase, β -galactosidase, α -glucosidase, β -glucosidase, β -glucuronidase, glycine tryptophan arylamidase, α -mannosidase, β -mannosidase, lipase C14, pyrazinamidase, or trypsin. Hippurate is hydrolyzed, but esculin, starch, and gelatin are not hydrolyzed. Nitrate is not reduced and acetoin is not produced. The only known sources from which *Eremococcus coleocola* has been isolated are equine vaginal discharge and equine clitoral fossa (Collins et al., 1999f).

Isolation procedures

Eremococcus coleocola has been isolated from a vaginal discharge specimen and a clitoral fossa swab of horses using sheep blood agar at 37°C in air plus 5% CO₂. There is no information on enrichment or selective media for this species.

Maintenance procedures

Strains grow well on blood-based agar and in brain heart infusion and Todd–Hewitt broth at 37°C. For long-term preservation, strains can be maintained in media containing 15–20% glycerol at –70°C, or lyophilized.

Taxonomic comments

The genus *Eremococcus* was created in 1999 to accommodate a phylogenetically distinct catalase-negative, Gram-stain-positive, coccus-shaped bacterium originating from the reproductive tract of horses (Collins et al., 1999f). 16S rRNA gene sequencing shows that the genus belongs to the *Clostridium* subphylum of the *Firmicutes*. According to the revised roadmap for Volume 3 (Ludwig et al., this volume) *Eremococcus* has been placed in the new family *Aerococcaceae*, which includes *Aerococcus*, *Abiotrophia*, *Dolosicoccus*, *Facklamia*, *Ignavigranum*, and *Globicatella*. *Eremococcus coleocola* forms a distinct subline within this grouping and does not display a particularly close affinity with any of the aforementioned taxa.

Differentiation of the genus *Eremococcus* from other genera

Eremococcus coleocola can be readily distinguished from its nearest phylogenetic relatives using a combination of phenotypic tests.

Eremococcus coleocola can be readily distinguished from *Globicatella* species by its inability to ferment a broad range of sugars (Collins et al., 1999f). By contrast, globicatellae are relatively saccharolytic (Collins et al., 1992; Vandamme et al., 2001). In addition, globicatellae hydrolyze starch and are arginine dihydrolase-negative, whereas *Eremococcus coleocola* gives the opposite reactions. In terms of its restricted ability to ferment carbohydrates, *Eremococcus coleocola* more closely resembles some *Facklamia* species and *Ignavigranum ruoffiae*. However, *Eremococcus coleocola* can easily be distinguished from *Facklamia hominis* by failing to produce alanyl phenylalanine arylamidase and leucine arylamidase, whereas *Facklamia hominis* produces these enzymes. Similarly, *Facklamia ignava* differs from *Eremococcus coleocola* by producing alanyl phenylalanine arylamidase and being arginine dihydrolase-negative. In addition, unlike *Facklamia hominis* and *Facklamia ignava* which possess a type L-lysine-D-aspartic acid (variation A4 α , for nomenclature see Schleifer and Kandler, 1972) cell-wall murein, *Eremococcus coleocola* contains an L-lysine-direct (variation A1 α) type wall (Collins et al., 1997, 1998a). *Eremococcus coleocola* can be distinguished from *Facklamia languida* by hydrolyzing hippurate, producing arginine dihydrolase and failing to produce leucine arylamidase. *Facklamia languida* does not hydrolyze hippurate, is arginine dihydrolase-negative, and is leucine arylamidase-positive (Lawson et al., 1999a). *Facklamia sourekkii* can be distinguished from *Eremococcus coleocola* by producing acid from a broader range of carbohydrates and by its positive leucine arylamidase and negative arginine dihydrolase reactions.

Eremococcus coleocola can be readily identified using API commercial kits. In particular, the API Rapid ID32 Strep code of 1, 0, 0, 0, 0, 3, 1, 0/1, 0, 0, 0/6 and the API Coryne code of 4, 1, 2, 0, 1, 3, 0 serve to distinguish *Eremococcus coleocola* from related species. Tests which are useful in distinguishing *Eremococcus coleocola* from its nearest phylogenetic relatives using the API Rapid ID32 Strep system are given in Table 96.

Type strain: M1832/95/2, ATCC BAA-57, CCUG 38207, CIP 106310.
GenBank accession number (16S rRNA gene): Y17780.

Genus V. ***Facklamia*** Collins, Falsen, Lemosy, Åkervall, Sjöden and Lawson 1997, 882^{VP}

MATTHEW D. COLLINS AND PAUL A. LAWSON

Fack.lam'i.a. N.L. fem. n. *Facklamia* named after Richard R. Facklam, an American microbiologist.

Cells are ovoid, occurring in pairs, groups, or chains. Gram-stain-positive and nonmotile. Nonsporeforming. **Facultatively anaerobic and catalase-negative. No growth at 10 or 45°C. Gas is not produced. Acid is produced from D-glucose and some other sugars. Pyrrolidonylarylamidase and leucine aminopeptidase are produced.** Vancomycin-sensitive.

DNA G+C content (mol%): 40–42 (T_m).

Type species: ***Facklamia hominis*** Collins, Falsen, Lemosy, Åkervall, Sjöden and Lawson 1997, 882^{VP}.

Further descriptive information

Grows on 5% (v/v) horse or sheep blood agar producing a γ - or occasionally weak α -hemolytic reaction. Cells are nonpigmented, nonmotile cocci that most commonly are arranged in

short chains or pairs; unlike other *Facklamia* species, cells of *Facklamia languida* are usually observed in clusters with little chaining. Acid is produced from glucose and other sugars, but reactions differ among species. *Facklamia sourekii* ferments a far greater range of sugars than the other species. None of the species produces acid from L-arabinose, cyclodextrin, glycogen, lactose, melibiose, melezitose, methyl- β -D-glucopyranoside, pullulan, raffinose, ribose, or tagatose. None of the species displays activity for alkaline phosphatase, β -glucosidase, β -glucuronidase, or β -mannosidase. Three species (*Facklamia hominis*, *Facklamia ignava*, and *Facklamia sourekii*) hydrolyze hippurate whereas the others do not. None of the *Facklamia* species hydrolyzes esculin or gelatin and none reduces nitrate to nitrite.

The cell-wall murein of *Facklamia hominis* and *Facklamia ignava* contains L-lysine as the dibasic amino acid, type L-lysine-D-aspartic acid (A4 α , see Schleifer and Kandler, (1972) for nomenclature) (Collins et al., 1997, 1998a).

Facklamia species have been recovered from a variety of sources. Four of the six recognized species of the genus *Facklamia* have been isolated from human clinical sources (abscess, bone, cerebrospinal fluid, gall bladder, and vagina) (Collins et al., 1997, 1999b, 1998a; LaClaire and Facklam, 2000a; Lawson et al., 1999a). *Facklamia tabacinasalis* was originally isolated as a contaminant of powdered tobacco (snuff) (Collins et al., 1999a) and has also been isolated from sheep (Fernandez-Garazabal, Lawson, and Collins, unpublished). The only known strain of *Facklamia miroungae* was recovered from the nasal cavity of a juvenile southern elephant seal (*Mirounga leonina*). The habitats of *Facklamia* species are not known, but it has been speculated that the female genitourinary tract may be the natural habitat of human *Facklamia* species (LaClaire and Facklam, 2000a).

The antimicrobial susceptibilities of 18 strains of *Facklamia* species (*Facklamia hominis*, *Facklamia languida*, *Facklamia ignava*, *Facklamia sourekii*, and *Facklamia tabacinasalis*) were examined by LaClaire and Facklam (2000a). Seventeen per cent of strains were intermediate in resistance to penicillin, 44% were resistant to cefotaxime, and 33% presumptively resistant to cefuroxime. Twenty-two per cent were resistant to erythromycin and 33% to clindamycin. Twenty-eight per cent were presumptively resistant to trimethoprim-sulfamethoxazole and 17% to rifampin. There are appreciable differences in susceptibilities to antimicrobials among the various *Facklamia* species (LaClaire and Facklam, 2000a). Two out of five *Facklamia ignava* strains and one out of four *Facklamia hominis* strains were intermediate in resistance to penicillin, whereas all *Facklamia languida* and *Facklamia sourekii* strains were susceptible. One out of five *Facklamia ignava* strains, one out of three *Facklamia sourekii* strains, and all six *Facklamia languida* strains tested were resistant to cefotaxime whereas one out of four *Facklamia hominis* and five out of six *Facklamia languida* strains were presumptively resistant to cefuroxime. Some strains of *Facklamia ignava* (three out of five) and *Facklamia languida* (two out of six) were resistant to erythromycin whereas strains of *Facklamia hominis* (four strains) and *Facklamia sourekii* (three strains) were susceptible. Three out of four strains of *Facklamia hominis* were resistant to rifampin, but strains of *Facklamia ignava*, *Facklamia languida*, and *Facklamia sourekii* were susceptible.

Isolation procedures

Strains can be isolated on a variety of rich agar-containing media (such as heart infusion agar) supplemented with 5% (v/v) ani-

mal blood (sheep or horse). Strains grow at 37°C in ambient atmospheres or under anaerobic conditions.

Maintenance procedures

Strains can be maintained on agar media (such as heart infusion or Columbia agar) supplemented with blood (5% v/v). Strains grow in brain heart infusion broth. For long-term preservation, strains can either be stored at -70°C on cryogenic beads or lyophilized.

Taxonomic comments

The genus *Facklamia* was created in 1997 to accommodate a phylogenetically distinct group of catalase-negative, chain-forming, coccus-shaped organisms encountered in human clinical specimens. The genus was originally monospecific, containing the species *Facklamia hominis* (Collins et al., 1997). Subsequently, five other species have been assigned to the genus including *Facklamia ignava* (Collins et al., 1998a), *Facklamia languida* (Lawson et al., 1999a), and *Facklamia sourekii* (Collins et al., 1999b) from human clinical sources, *Facklamia miroungae* (Hoyles et al., 2001) from elephant seal, and *Facklamia tabacinasalis* (Collins et al., 1999a) from tobacco. According to the revised roadmap for Volume 3 (Ludwig et al., this volume) *Facklamia* has been placed in the new family *Aerococcaceae* in the order *Lactobacillales* of the phylum *Firmicutes*. 16S rRNA gene sequencing shows that the nearest relative of *Facklamia* is *Ignavigranum ruoffiae*. Treeing analysis has shown that sometimes *Ignavigranum ruoffiae* branches close to the periphery of the genus *Facklamia*, whereas in other cases it phylogenetically intermingles with *Facklamia* species (Figure 96). *Facklamia languida* and *Facklamia miroungae* are phylogenetically closely related to the type species, *Facklamia*

FIGURE 96. Neighbor-joining tree based on 16S rRNA sequences depicting the phylogenetic relationships of *Facklamia* species and close relatives. Bootstrap values determined from 500 replications.

hominis, and these three species form a robust phylogenetic cluster (Hoyles et al., 2001). It seems likely that in the future the genus *Facklamia* will be restricted to *Facklamia hominis* and its nearest relatives, with other *Facklamia* species possibly forming the nuclei of different genera/taxa.

Differentiation of the genus *Facklamia* from other genera

Identification of the genus *Facklamia* is not easy but can be aided using a combination of traditional tests (LaClaire and Facklam, 2000b). *Facklamia* species give positive pyrrolidonyl- β -naphthylamide (PYR) and leucine aminopeptidase reactions (LAP), grow in 6.5% NaCl broth, are susceptible to vancomycin, do not produce gas, give a negative bile-esculin reaction, are weak α - or γ -hemolytic on 5% (v/v) sheep blood agar, and fail to grow at 10°C and 45°C. This combination of reactions together with their cellular morphology is not, however, unique to the genus *Facklamia*. *Alloiococcus otitis*, *Dolosigranulum pigrum*, and *Ignavigranum ruoffiae* also share these characteristics (LaClaire

and Facklam, 2000b). *A. otitis* can be differentiated from the genus *Facklamia* by not growing anaerobically. *Facklamia* species can be differentiated from each other and from *Dolosigranulum pigrum* and *Ignavigranum ruoffiae* using additional traditional tests (Facklam and Elliott, 1995) including deamination of arginine, hydrolysis of hippurate and esculin, and acid production from sorbitol and sucrose broths (LaClaire and Facklam, 2000b) (see Table 97).

Differentiation of the species of the genus *Facklamia*

Species of the genus *Facklamia* can be distinguished from each other using the conventional biochemical tests listed in Table 97. *Facklamia* species can also be distinguished readily from each other using the commercially available API Rapid ID32 Strep system (Collins et al., 1999b, 1999a; Hoyles et al., 2001; Lawson et al., 1999a). A summary of the most useful tests for identifying *Facklamia* species using the API Rapid ID32 Strep system is shown in Table 98.

^aSymbols: +, >85% positive; d, different strains give different reactions (16–84% positive); -, 0–15% positive. Abbreviations: ADH, arginine dihydrolase; APP, alanine phenylalanine proline arylamidase; α -Gal, α -galactosidase; β -Gal, β -galactosidase; GTA, glycine tryptophan arylamidase; NAG, N-acetyl β -glucosaminidase; PYRA, pyroglutamic acid arylamidase; all species fail to produce acid from L-arabinose, cyclodextrin, glycogen, lactose, melibiose, melezitose, methyl- β -D-glucopyranoside, pullulan, raffinose, ribose, and tagatose. None display activity for alkaline phosphatase, β -glucosidase, β -glucuronidase, or β -mannosidase.

List of species of the genus *Facklamia*

1. ***Facklamia hominis*** Collins, Falsen, Lemosy, Åkervall, Sjö-dén and Lawson 1997, 882^{VP}
ho'mi.nis. L. gen. n. *hominis* of humans, from which the organisms were first isolated.
DNA G+C content (mol%): 41.0.
Type strain: ATCC 700628, CCUG 36813, CIP 105962, LMG 18980.
GenBank accession number (16S rRNA gene): Y10772.
2. ***Facklamia ignava*** Collins, Lawson, Monasterio, Falsen, Sjö-dén and Facklam 1998a, 1083^{VP} (Effective publication: Collins, Lawson, Monasterio, Falsen, Sjö-dén and Facklam 1998b, 2148.)
ig.na.va. L. fem. adj. *ignava* lazy, unreactive.
DNA G+C content (mol%): 42.0.
Type strain: 164-97, ATCC 700631, CCUG 37419, CIP 105583, LMG 18981.
GenBank accession number (16S rRNA gene): Y15716.
3. ***Facklamia languida*** Lawson, Collins, Falsen, Sjö-dén and Facklam 1999b, 935^{VP} (Effective publication: Lawson, Collins, Falsen, Sjö-dén and Facklam 1999a, 1164.)
lan.guida. L. adj. *languidus* languid; L. fem. adj. *languida* pertaining to the lack of activity of the organisms in biochemical tests.
DNA G+C content (mol%): not reported.
Type strain: 1144-97, CCUG 37842, CIP 105964.
4. ***Facklamia miroungae*** Hoyles, Foster, Falsen, Thomson and Collins 2001, 1403^{VP}
mi.roung'ae. N.L. gen. n. *miroungae* of *Mirounga*, named because the species was first isolated from the southern elephant seal, *Mirounga leonina*.
DNA G+C content (mol%): not reported.
Type strain: A/G13/99/2, CCUG 42728, CIP 106764.
GenBank accession number (16S rRNA gene): AJ277381.
5. ***Facklamia sourekii*** Collins, Hutson, Falsen and Sjö-dén 1999b, 637^{VP}
schou.rek.i.i. (Czech pronunciation) N.L. gen. n. *sourekii* of Šourek, named after the Czech microbiologist Jiří Šourek.
DNA G+C content (mol%): 41.5.
Type strain: SS 1019, ATCC 700629, de Moor M13582, CCUG 28783 A, CDC1, CIP 105940, CNCTC 2/84, LMG 18982.
GenBank accession number (16S rRNA gene): Y17312.
6. ***Facklamia tabacinasalis*** Collins, Hutson, Falsen and Sjö-dén 1999a, 1249^{VP}
ta.ba.ci.na'sa.lis. N.L. n. *tabacum* tobacco; L. adj. *nasalis* pertaining to the nose; N.L. gen. fem. adj. *tabacinasalis* of snuff.
DNA G+C content (mol%): 40.0 (T_m).
Type strain: ATCC 700838, CCUG 30090, CIP 106117.
GenBank accession number (16S rRNA gene): Y17820.

Genus VI. ***Globicatella*** Collins, Aguirre, Facklam, Shallcross and Williams 1995, 418^{VP} (Effective publication: Collins, Aguirre, Facklam, Shallcross and Williams 1992, 436.)

MATTHEW D. COLLINS

Glo.bi.ca.tel'la L. n. *globus* round body, sphere; L. fem. n. *catella* small chain; N.L. fem. n. *Globicatella* a short chain made up of spheres.

Cells are ovoid, occurring singly, in pairs or short chains. Gram-positive, but sometimes cells stain Gram-negative. Nonmotile and nonsporeforming. **Facultatively anaerobic and catalase-negative.** Grows in broth containing 6.5% NaCl. No growth at 10 or 45°C. Gas is not produced. Acid is produced from D-glucose and some other sugars. Pyroglutamic acid arylamidase is produced. Pyrrolidonyl arylamidase and leucine aminopeptidase may or may not be produced. Arginine dihydrolase and urease are not produced. Pyruvate is not utilized. **Voges-Proskauer-negative.** Vancomycin-sensitive. Cell-wall murein is based on L-Lysine (type Lys-direct).

DNA G+C content (mol%): 35.7–37 (T_m).

Type species: ***Globicatella sanguinis*** corrig. Collins, Aguirre, Facklam, Shallcross and Williams 1995, 418^{VP} (Effective publication: Collins, Aguirre, Facklam, Shallcross and Williams 1992, 436.).

Further descriptive information

The genus currently contains two species, *Globicatella sanguinis* and *Globicatella sulfidifaciens*. *Globicatella* grow on 5% (v/v) horse or sheep blood agar forming small viridans streptococcus-like colonies and producing a weak α -hemolytic reaction. *Globicatella sanguinis* does not tolerate tellurite (0.04%) or tetrazolium (0.25%). *Globicatella* do not grow at 10°C and most do not grow at 45°C. Most strains grow in 6.5% NaCl, but

occasional strains do not. Bile-esculin reaction for *Globicatella sanguinis* is variable (Facklam and Elliott, 1995). *Globicatella sulfidifaciens* does not grow on bile-esculin agar (Vandamme et al., 2001). Both *Globicatella* species produce acid from glucose, glycogen, maltose, melibiose (most strains), raffinose, trehalose, and sucrose. Most strains of *Globicatella sanguinis* form acid from mannitol and ribose whereas strains of *Globicatella sulfidifaciens* fail to produce acid from these substrates. *Globicatella sanguinis* is reported to form acid from maltotriose and methyl β -glucoside, whereas *Globicatella sulfidifaciens* does not (Vandamme et al., 2001). *Globicatella sulfidifaciens* ferments inulin, but *Globicatella sanguinis* does not (Vandamme et al., 2001). Acid production from lactose, methyl β -D-glucopyranoside and sorbitol is variable in *Globicatella sanguinis* but negative in *Globicatella sulfidifaciens*. Neither species produces acid from D-arabitol, cyclodextrin, melezitose, or D-tagatose. Starch and esculin are hydrolyzed by both species. *Globicatella sanguinis* hydrolyzes hippurate, but *Globicatella sulfidifaciens* gives variable results. Both *Globicatella* species produce alanine phenylalanine proline arylamidase, α -galactosidase, β -glucosidase, and pyroglutamic acid arylamidase. Activity for β -galactosidase and pyrrolidonyl arylamidase may or may not be detected. *Globicatella sulfidifaciens* displays activity for β -glucuronidase whereas most strains of *Globicatella sanguinis* do not show activity for this enzyme. Neither species shows activity for arginine dihydrolase, alkaline phosphatase,

glycyl tryptophan arylamidase, *N*-acetyl- β -glucosaminidase, or urease. *Globicatella sulfidifaciens* produces hydrogen sulfide in Kligler's iron agar whereas *Globicatella sanguinis* does not (Vandamme et al., 2001).

Globicatella sulfidifaciens is resistant to neomycin and to the macrolide antibiotics erythromycin, clindamycin, and lincomycin (Vandamme et al., 2001).

Globicatella sanguinis has been isolated from a variety of human clinical specimens, including blood cultures (patients with sepsis, meningitis, and bacteremia), urine of patients with urinary tract infections, cerebrospinal fluid, and wounds (Collins et al., 1992; Facklam and Elliott, 1995). This species has been isolated in pure culture from blood and brain samples from lambs with meningoencephalitis (Vela et al., 2000). The habitat of *Globicatella sanguinis* is not known. *Globicatella sulfidifaciens* has been isolated from purulent joint and lung infections in calves, from a lung lesion of a sheep, and from a joint infection of a pig (Vandamme et al., 2001).

Isolation procedures

Globicatella species may be isolated on rich agar-containing media, such as brain heart infusion agar, with or without animal blood at 37°C. They can be cultivated under aerobic or anaerobic conditions. There is no information on selective media for these organisms.

Maintenance procedures

Strains can be maintained on media such as brain heart infusion agar or Columbia agar containing 5% (v/v) blood. Strains can be stored on cryogenic beads at -70°C or lyophilized for long-term preservation.

Taxonomic comments

The genus *Globicatella* was described to accommodate some coccus-shaped strains which somewhat resembled viridans-like streptococci and which also shared properties in common with aerococci (Collins et al., 1992). Until recently, *Globicatella* was monospecific containing the single species *Globicatella sanguinis*, but a second species, *Globicatella sulfidifaciens*, recovered from purulent infections in domestic animals, has been assigned to the genus by Vandamme et al. (2001). *Globicatella sanguinis* and *Globicatella sulfidifaciens* are genetically closely related exhibiting approximately 99.2% 16S rRNA sequence similarity (Vandamme et al., 2001). Very high levels of chromosomal DNA-DNA relatedness (mean DNA binding value of 68%) have

been reported between the two species. The DNA-binding value is very close to the 70% guideline generally used for species delineation (Wayne et al., 1987). Although it is highly likely that *Globicatella sanguinis* and *Globicatella sulfidifaciens* are different species, the high DNA relatedness between these species and the method used (photobiotin-labeled probes in microplate wells as described by Ezaki et al., 1989) indicate that this finding should be re-examined using more high-fidelity techniques including ΔT_m determinations. Phylogenetically, the genus *Globicatella* forms a distinct subline among the catalase-negative, Gram-stain-positive cocci and is far removed from both streptococci and aerococci. The closest phylogenetic relatives of *Globicatella sanguinis* and *Globicatella sulfidifaciens* are *Facklamia* species, *Ignavigranum ruoffiae*, *Dolosicoccus paucivorans*, *Eremococcus coleocola*, and *Abiotrophia defectiva* (Collins et al., 1999c, 1999f).

Differentiation of the genus *Globicatella* from other genera

Globicatella sanguinis can be distinguished from viridans streptococci in being pyrrolidonyl- β -naphthylamide-positive and leucine aminopeptidase-negative and in growing in broth containing 6.5% NaCl (Facklam and Elliott, 1995). Aerococci also possess these characteristics but can be distinguished from *Globicatella* by cellular morphology. Aerococci form pairs and tetrad cellular arrangements, whereas *Globicatella sanguinis* and *Globicatella sulfidifaciens* form short chains of cocci. *Globicatella sanguinis* does not produce leucine aminopeptidase, which readily distinguishes it from *Ignavigranum ruoffiae* and *Facklamia* species. *Globicatella sanguinis* and *Globicatella sulfidifaciens* hydrolyze esculin and starch, and grow in broth containing 6.5% NaCl, which serves to distinguish them from *Dolosicoccus paucivorans* which is negative for these tests. Both *Globicatella* species also differ markedly from *Dolosicoccus paucivorans*, *Ignavigranum ruoffiae*, and *Facklamia* species in fermenting a wide range of carbohydrates.

Differentiation of the species of the genus *Globicatella*

Globicatella sulfidifaciens differs from *Globicatella sanguinis* in several biochemical reactions, such as fermenting inulin, failing to produce acid from mannitol, ribose, methyl β -glucoside, and maltotriose, and by producing β -glucuronidase. In addition, *Globicatella sulfidifaciens* is highly unusual in producing H₂S in Kligler's iron agar stabs (Vandamme et al., 2001). *Globicatella sanguinis* and *Globicatella sulfidifaciens* can readily be distinguished from each other by using the commercially available API Rapid ID32 Strep system. Useful distinguishing tests are listed in Table 99.

TABLE 99. Tests distinguishing *Globicatella sanguinis* and *Globicatella sulfidifaciens*^a

GenBank accession number (16S rRNA gene): AJ297627.

Genus VII. ***Ignavigranum*** Collins, Lawson, Monasterio, Falsen, Sjöden and Facklam 1999e, 100^{VP}

MATTHEW D. COLLINS

Ig.na.vi.gra'num. L. adj. *ignavus* lazy, non-reacting; L. neut. n. *granum* grain, kernel; N.L. neut. n. *Ignavigranum* lazy grain.

Cells are ovoid, occurring in pairs, groups, or chains. Gram-positive and nonmotile. No spores are formed. **Facultatively anaerobic and catalase-negative. Grows in 6.5% NaCl broth. No growth at 10°C; most strains do not grow at 45°C.** Gas is not produced. **Negative bile-esculin reaction.** Acid is produced from D-glucose and some other sugars. **Pyroli-donylarylamidase and leucine aminopeptidase are produced. Vancomycin-sensitive. Cell-wall murein is based on L-lysine (type Lys-direct).**

DNA G+C content (mol%): 40 (T_m).

Type species: ***Ignavigranum ruoffiae*** Collins, Lawson, Monasterio, Falsen, Sjöden and Facklam 1999e, 100^{VP}

Further descriptive information

The genus contains only one species, *Ignavigranum ruoffiae*, and therefore the characteristics provided here refer to this species. Grows on 5% (v/v) horse or sheep blood agar producing a weak α - or γ -hemolytic reaction. Cells are nonpigmented. Esculin and hippurate are not hydrolyzed. Voges-Proskauer negative. Acid is produced from very few carbohydrates.

Using the API Rapid ID32 Strep system, a few strains may produce acid from mannitol and sucrose. Acid is not produced from L-arabinose, D-arabitol, cyclodextrin, glycogen, lactose, maltose, melezitose, melibiose, pullulan, raffinose, ribose, sorbitol, tagatose, or trehalose. Hippurate is not hydrolyzed. Arginine dihydrolase, pyroglutamic acid arylamidase, and urease are detected, but alanine phenylalanine proline arylamidase, alkaline phosphatase, α -galactosidase, β -galactosidase, β -glucosidase, β -glucuronidase, glycyl tryptophan arylamidase, N-acetyl- β -glucosaminidase, and β -mannosidase are not detected. Using the API ZYM system, leucine arylamidase is detected. Activity for acid phosphatase, esterase C4, ester lipase C8, and phosphoamidase may or may not be detected. No activity is found for alkaline phosphatase, cystine arylamidase, chymotrypsin, α -fucosidase, α -galactosidase, β -galactosidase, α -glucosidase, β -glucosidase, β -glucuronidase, N-acetyl- β -glucosaminidase, lipase C14, α -mannosidase, valine arylamidase, or trypsin.

Ignavigranum has been isolated from human clinical specimens (blood, wound, ear abscess). Habitat is not known.

Isolation procedures

Strains can be isolated on a variety of rich agar-containing media (such as heart infusion agar) supplemented with 5% (v/v) animal blood (sheep or horse). Strains grow at 37°C in ambient atmospheres or under anaerobic conditions.

Maintenance procedures

Strains can be maintained on agar media (such as heart infusion or Columbia agar) supplemented with blood (5% v/v). Strains grow in brain heart infusion broth. For long-term preservation, strains can be stored at -70°C on cryogenic beads or lyophilized.

Taxonomic comments

The genus *Ignavigranum* was proposed in 1999 for some Gram-positive, catalase-negative, chain-forming cocci recovered from human clinical specimens (Collins et al., 1999e). According to the revised roadmap for Volume 3 (Ludwig et al., this volume) *Ignavigranum* has been placed in the new family *Aerococcaceae* in the phylum *Firmicutes*. Although *Ignavigranum ruoffiae* is a distinct species, comparative 16S rRNA gene sequencing shows it is closely related to the genus *Facklamia* (Hoyles et al., 2001). Treeing analysis shows the branching position of *Ignavigranum ruoffiae* is uncertain, with the species sometimes branching close to the periphery of the genus *Facklamia*, and in other cases phylogenetically intermingling with *Facklamia* species. Although *Ignavigranum ruoffiae* branches within the bounds of the genus *Facklamia* as presently defined, *Ignavigranum* probably merits separate genus status, whereas the genus *Facklamia* is in need of revision and should be restricted to the type species *Facklamia hominis* and its closest relatives (*Facklamia languida* and *Facklamia microungae*) (Hoyles et al., 2001).

Differentiation of the genus *Ignavigranum* from related genera

Ignavigranum resembles *Dolosigranulum pigrum* and *Facklamia* species in being nonmotile, pyrrolidonyl- β -naphthylamide, and leucine aminopeptidase-positive, growing in 6.5% NaCl broth, not growing at 10 or 45°C, having a negative bile-esculin reaction, being susceptible to vancomycin, and showing α - or γ -hemolytic reactions on sheep blood (LaClaire and

Facklam, 2000b). It can, however, be distinguished from these taxa by using a combination of classical phenotypic tests (Facklam and Elliott, 1995) as outlined in Table 97. In addition, *Ignavigranum ruoffiae* can be identified readily by using the commercially available API Rapid ID32 Strep system. Miniaturized API Rapid ID32 Strep tests that are useful in distinguishing *Ignavigranum ruoffiae* from *Facklamia* species are shown in Table 98.

List of species of the genus *Ignavigranum*

1. ***Ignavigranum ruoffiae*** Collins, Lawson, Monasterio, Falsen, Sjöden and Facklam 1999e, 100^{VP}
ru.off'iae. N.L. gen. n. *ruoffiae* named after Kathryn L. Ruoff, an American microbiologist.

DNA G+C content (mol%): 40 (T_m).

Type strain: 1607-97, ATCC 700630, CCUG 37658, CIP 105896.

GenBank accession number (16S rRNA gene): Y16426.

Family III. Carnobacteriaceae fam. nov.

WOLFGANG LUDWIG, KARL-HEINZ SCHLEIFER AND WILLIAM B. WHITMAN

Car.no.bac.te.ri.a'ce.ae. N.L. neut. n. *Carnobacterium* type genus of the family; suff. -aceae ending denoting family; N.L. fem. pl. n. *Carnobacteriaceae* the *Carnobacterium* family.

The family *Carnobacteriaceae* is circumscribed for this volume on the basis of phylogenetic analyzes of the 16S rRNA sequences and includes the genus *Carnobacterium* and its close relatives. It is composed of Gram-stain-positive rods or cocci that do not form endospores. Usually facultatively anaerobic, but some species grow aerobically or microaerophilically.

Usually catalase-negative. May be motile or nonmotile. The cell wall may contain the diamino acids lysine, ornithine or meso-diaminopimilate. Species may be psychrotolerant, halotolerant or alkaliphilic.

Type genus: Carnobacterium Collins, Farrow, Phillips, Feresu and Jones 1987, 314^{VP}.

Genus I. *Carnobacterium* Collins, Farrow, Phillips, Feresu and Jones 1987, 314^{VP}

WALTER P. HAMMES AND CHRISTIAN HERTEL

Car.no.bac.te'ri.um. L. gen. n. *carnis* of flesh; N.L. neut. n. *bacterium* small rod; N.L. neut. n. *Carnobacterium* small rod from flesh.

Cells are **short to slender rods**, sometimes curved. Usually occurring singly or as pairs, sometimes short chains. **May or may not be motile. Nonsporeforming. Gram-stain-positive. Produces predominantly L(+)-lactic acid** from glucose. **One species** (*Carnobacterium pleistocenium*) **produces no lactate** but ethanol, acetic acid, and CO₂. **Gas production** from glucose is **variable** (dependent on substrate), frequently negative. **Facultatively anaerobic.**

Psychrotolerant. Most strains grow at 0°C but not at 45°C. No growth at 8% NaCl. **No growth on acetate (SL) agar or broth at pH 5.4, good growth at pH 9. Catalase- and oxidase-negative; some species exhibit catalase activity in the presence heme. Nitrate is not reduced** to nitrite. The **peptidoglycan is of the meso-diaminopimelic acid-direct type**. Major fatty acids are of the straight-chain saturated and monounsaturated types; cyclopropane ring containing derivatives may occur.

Found in vacuum packaged meat and related products, cheese, fish, meromictic antarctic lake, and pleistocenian ice in permafrost.

DNA G+C content (mol%): 33–42.

Type species: Carnobacterium divergens (Holzapfel and Gerber 1983) Collins, Farrow, Phillips, Feresu and Jones 1987, 315^{VP} (*Lactobacillus divergens* Holzapfel and Gerber 1983, 530.).

Further descriptive information

Introductory remarks. The genus *Carnobacterium* comprises nine species as shown in Table 100. The genus is phylogenetically a member of the lactic acid bacteria group with a close relationship to the genera *Desenzia*, *Trichococcus*, and *Isobaculum* located in the *Carnobacterium* clade (Figure 97). Six species are associated with food of animal origin and/or living fish and three species have been isolated from cold environments with a low content of nutrients such as antarctic ice lakes and permafrost ice. Based on these quite different habitats, two ecological groups, I and II, respectively (Table 100) can be defined. The organisms within each group are adapted to their respective habitats in such a way that culturing of group I species requires rich media whereas rather simple media support the growth of group II species. This ecological grouping does not correlate with the phylogenetic relationship shown in Figure 98.

Cell morphology. The cell morphology varies depending on the species and age of the culture from coccobacilli (e.g., *Carnobacterium pleistocenium* and *Carnobacterium funditum*) to filaments of 13 µm and 20 µm in older cultures of *Carnobacterium funditum* and *Carnobacterium viridans*, respectively (Figure 99). Like lactobacilli, older cultures may lose their motility and Gram-stain-positive staining character. Otherwise, all carnobacteria stain clearly Gram-stain-positive. Motility by monotrichous polar to subpolar flagella occurs in *Carnobacterium mobile*, *Carnobacterium inhibens*, *Carnobacterium funditum*, and *Carnobacterium alterfunditum*. Nonmotile strains of *Carnobacterium mobile* have also been described (Laursen et al., 2005).

Culture characteristics. Colonies on agar are commonly white to creamy or buff, convex, and shiny. When grown on a semi-complex agar, *Carnobacterium pleistocenium* forms characteristic colonies that are conical in shape, with a denser consistency in the center and a darker color on the perimeter. The surface is granulated and rough with thinner, irregular, torn edges (Pikuta et al., 2005). The diameter of the colonies varies from 0.5–2 mm on optimal agar (e.g., MRS without acetate). *Carnobacterium funditum* and *Carnobacterium alterfunditum* produce a slightly yellow water-soluble pigment upon incubation for 2–4 weeks.

Clearing zones were described for *Lactobacillus maltaromicus* in assays for DNase and RNase activity (Miller et al., 1974) and for caseinolytic activity (Baya et al., 1991). Specific odors of cultures were described for *Carnobacterium alterfunditum* upon growth in Py-amgdalin medium (seeds of ripe plums), and for *Lactobacillus maltaromicus* in TSB medium and skim milk, a strong malty aroma is observed (Miller et al., 1974). By gas chromatography, 2-methylpropanal, 3-methylpropanal, 2-methylpropanol, and 3-methylpropanol were identified. These compounds are well known for their malty flavor. Carnobacteria are involved in the spoilage of food of animal origin, and numerous aroma active compounds are formed in addition therein, e.g., NH₃ from arginine catabolism (Leisner et al., 1994), acetic acid, and diacetyl (Joffraud et al., 2001).

Metabolism. Compared with the body of knowledge that has been accumulated in recent years for the metabolism of lactococci and lactobacilli, little is known about carnobacteria. Carnobacteria

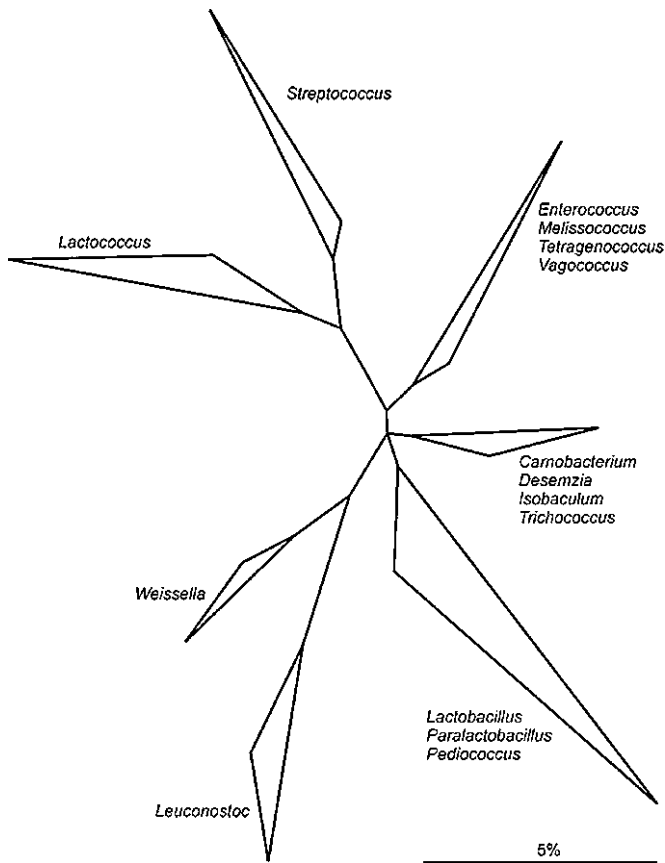

FIGURE 97. Phylogenetic tree depicting the position of carnobacteria in relation to lactic acid bacteria. The consensus tree is based on distance matrix analyses of all available, at least 90% complete 16S rRNA sequences of Gram-stain-positive bacteria. The topology was evaluated and corrected according to the results of maximum-parsimony and maximum-likelihood analyses with various datasets. Alignment positions sharing identical residues in at least 50% of all sequences of the depicted and closely related genera were considered. Multifurcations indicate that a common branching order could not be significantly determined or was not supported performing different alternative treeing approaches. The bar indicates 5% estimated sequence divergence.

TABLE 100. The species of the genus *Carnobacterium*

Species	Source of isolation ^a	Ecological group ^b
<i>C. divergens</i>	M, F, D	I
<i>C. alterfunditum</i>	A	II
<i>C. funditum</i>	A	II
<i>C. gallinarum</i>	M	I
<i>C. inhibens</i>	F	I
<i>C. maltaromaticum</i>	M, F, D	I
<i>C. mobile</i>	M	I
<i>C. pleistocenium</i>	P	II
<i>C. viridans</i>	M	I

^aM, meat (meat products, poultry); F, fish; D, dairy products, including cheese; A, arctic ice lake; P, pleistocenian permafrost.

^bI, associated with animals and products of animal origin; II, present in cold environment containing few nutrients.

are facultatively anaerobic and gain their energy by fermentation. However, they grow well in the presence of oxygen, and the growth yield of *Carnobacterium maltaromaticum* increases 10-fold when heme is added to the aerobically growing culture (Meisel et al., 1994). The authors showed that under these conditions, functional cytochromes of the *b* and *d* types can be detected. Similarly, cytochromes can be induced in lactococci and enterococci (Ritchey and Seely, 1976; Sijpesteijn, 1970). In *Lactococcus lactis*, *cydAB* genes encode a single cytochrome oxidase (bd) (Gaudu et al., 2002). Thus, when heme is available, *Carnobacterium maltaromaticum* has a potential for a respiratory metabolism and also exhibits catalase activity (Kloos and Wolfshohl, 1991). The latter property is common to all *Carnobacterium* species (Ringo et al., 2002) except *Carnobacterium pleistocenium* which was not investigated for this property. Respiration is connected with increased oxygen consumption, reduced lactate formation, and increased acetoin and CO₂ production.

The metabolism of carbohydrates by carnobacteria is facultatively heterofermentative as they ferment hexoses and pentoses. With the exception of *Carnobacterium pleistocenium*, hexoses are metabolized to L(+)-lactate, but CO₂, acetate, and ethanol are also formed. In addition, formate is produced anaerobically (Borch and Molin, 1989) and acetoin is produced aerobically. Pentoses are metabolized to L(+)-lactate, acetate, and ethanol (Holzapfel and Gerber, 1983). Glucose is metabolized via the glycolytic pathway (De Bruyn et al., 1988; De Bruyn et al., 1987). For the species of ecology group I, 75% of the lactate produced was shown to be derived from glucose and less than 10% was derived from formate and from acetate. The other products were assumed to originate from endogenous substrates in the rich growth medium. Differences exist for species of group II. For *Carnobacterium pleistocenium*, ethanol, acetate, and CO₂ (but no lactate) were found to be the products of carbohydrate fermentation. Thus, the physiological definition of lactic acid bacteria would not apply to this species and rather a metabolism similar to the Embden–Meyerhof pathway in yeast may be operative. Similarly, *Carnobacterium funditum* and *Carnobacterium alterfunditum* also do not produce lactate from glycerol; they produce only formate, ethanol, and acetate. Polysaccharides are hydrolyzed and fermented by some species or strains. Inulin is used by *Carnobacterium divergens*, *Carnobacterium gallinarum*, and certain strains of *Carnobacterium maltaromaticum*. Amyolytic activity is also found and is reported as utilization of starch for *Carnobacterium pleistocenium* or utilization of glycogen for *Carnobacterium mobile* and *Carnobacterium gallinarum*.

The presence of starch in plants and consequently in the intestinal tract of fish may be consistent with an adaption of carnobacteria to that habitat. Arginine hydrolysis produces an additional source of ATP generation and is a property of most carnobacteria, but is missing in *Carnobacterium viridans* and *Carnobacterium maltaromaticum*. The formation of biogenic amines creates a proton motive force in the bacteria (Konings, 2002). It is, however, of hygienic concern and is an essential contribution of carnobacteria to food spoilage (Laursen et al., 2005). *Carnobacterium divergens* and *Carnobacterium maltaromaticum* especially have a potential for tyramine formation (Straub et al., 1995).

Pathogenicity. *Lactobacillus piscicola* was the first *Lactobacillus* isolated from diseased trout (Cone, 1982) and later also from other farmed fish, fulfilling Koch's postulates. Isolates from

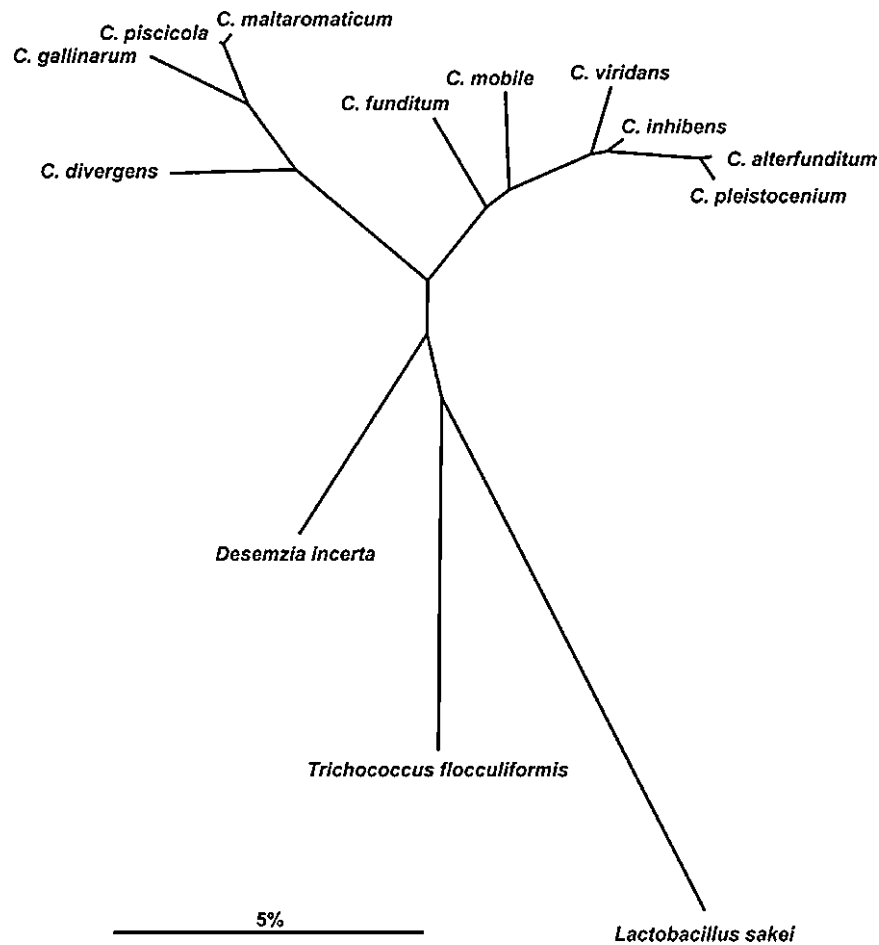

FIGURE 98. Phylogenetic tree reflecting the relationships of *Carnobacterium* species. The tree was reconstructed applying the maximum-parsimony analysis of all available at least 90% complete 16S rRNA sequences of *Lactobacillaceae*, carnobacteria, and close related species. Alignment positions sharing identical residues in at least 50% of all sequences of the depicted genera were considered. The bar indicates 5% estimated sequence divergence.

diseased striped bass (*Morone saxatilis*), but not from channel catfish (*Ictalurus punctatus*) or brown bullheads (*Ictalurus nebulosus*), killed fingerling rainbow trout (*Onchorynchus mykiss*) (LD_{50} of two strains of *Lactobacillus piscicola*, 1.4×10^6 and 2.3×10^6 c.f.u./g, respectively), administered peritoneally (Baya et al., 1991). The dead or carrier state trout showed serious lesions of the inner organs. Striped bass were resistant, although the injected bacteria could be reisolated after two weeks from the kidneys, as was the case with moribund and dead trout. Thus, there appear to exist unknown strain specific virulence factors and specific, sensitive hosts. In general, diseased fish contain mixed infections in which carnobacteria are found together with *Aeromonas hydrophila* and *Pseudomonas fluorescens*. In addition, stress conditions, such as handling or spawning, cause a predisposition to infection by carnobacteria.

Remarkably, *Carnobacterium piscicola* has been isolated from human pus (Chmelar et al., 2002), and one of the strains investigated by Collins (1987) has been isolated from human blood plasma. Similar to the situation in lactobacilli, pathogenicity factors such as production of elastase, phospholipase, or hemolytic activity were not detected (Baya et al., 1991) with the exception of

hemolytic activity detected in *Carnobacterium viridans*. It can be concluded that true fish pathogenicity exists in certain strains of *Carnobacterium maltaromaticum* whereas for humans and warm blooded animals, carnobacteria are not pathogenic.

Ecology. Two ecological groups of *Carnobacterium* species have been introduced (see above). Group I species are associated with the man-made habitat of food of animal origin as well as with the natural habitats of intestines and gills of fish. Group II species occur in arctic ice lakes or pleistocenian ice. The group I species have been known since 1957 (Thornley, 1957) and were grouped as atypical lactobacilli ("Streptobacteria"; Reuter (1970, 1981); Hitchener et al., 1982; Holzapfel and Gerber, (1983); Shaw and Harding, 1984) mainly because they resemble lactobacilli in their morphology and especially in their phenotype, but do not grow on SL-agar (Rogosa et al., 1951). When associated with food, these carnobacteria frequently share their habitat with other lactic acid bacteria, especially with lactobacilli and leuconostocs.

Meat, meat products, and poultry. Meat, meat products, and poultry are substrates with a favorable pH (around neutral) and

FIGURE 99. Electron micrograph of *Carnobacterium divergens* cells (bar = 5 μm).

high water activity, and they are rich in nutrients. They are, therefore, highly sensitive to spoilage and are stored refrigerated and often packaged in air-tight materials, sometimes under vacuum or controlled atmosphere. These conditions are selective for lactic acid bacteria and especially for carnobacteria. The preferred species isolated from meat and meat products are *Carnobacterium divergens* and *Carnobacterium maltaromaticum* (Laursen et al., 2005) which can grow to numbers of 10^6 – 10^8 c.f.u./g and cause spoilage. *Lactobacillus divergens* (now *Carnobacterium divergens*) was isolated from refrigerated beef (von Holy, 1983) and described as a heterofermentative *Lactobacillus* (*divergens*) species. Further isolates were originally allotted to *Lactobacillus carnis* and *Lactobacillus piscicola* and later became reclassified as *Carnobacterium maltaromaticum*. Spoiled products are characterized by discoloration, souring, and off-flavor, and include unprocessed meat, cooked ham, smoked pork loin, frankfurter sausage, and bologna type sausage. A green discolored bologna sausage was the source of isolation of *Carnobacterium viridans* (Hammes and Hertel, 2003; Schillinger and Holzapfel, 1995). During cold storage of meat, successions of lactic acid bacteria develop (Jones, 2004). Carnobacteria (*Carnobacterium divergens*) became the predominant element within four weeks, followed by other lactic acid bacteria. *Carnobacterium maltaromaticum* and *Carnobacterium divergens* were also isolated from poultry as were *Carnobacterium gallinarum* and *Carnobacterium mobile*, which were described as new species by Collins (1987). The strain employed in the species description was originally isolated by Thornley (1957) from poultry samples subjected to irradiation.

Fish and seafood. The intestines and gills of fish are natural habitats of carnobacteria. *Carnobacterium maltaromaticum*

(*Lactobacillus piscicola*) was isolated from diseased salmonoid fish, striped bass, and catfish (Hammes and Hertel, 2003). This species, *Carnobacterium divergens*, and *Carnobacterium inhibens* (Ringo and Gatesoupe, 1998) are commonly associated with healthy sea and fresh water fish of various species. Their numbers depend on nutritional and environmental factors (e.g., polyunsaturated fatty acids in the feed and stress). The presence of carnobacteria (*Carnobacterium piscicola*-like) on gills of Atlantic charr at numbers of approximately 3×10^4 c.f.u./g has been shown (Ringo and Holzapfel, 2000). Some isolates exhibit a strong inhibitory activity against other fish pathogens. *Carnobacterium maltaromaticum*, *Carnobacterium divergens*, and *Carnobacterium mobile* are associated also with seafood, e.g., shrimp, gravid fish, cold smoked salmon, and seafood in vacuum packages or under modified atmosphere (Laursen et al., 2005; Leroi et al., 1998; Mauguin and Novel, 1994).

Dairy products including cheese. *Lactobacillus maltaromicus* was described by (Miller et al., 1974) as a species isolated from milk samples that had developed a distinct malty aroma. A greater reservoir of carnobacteria is cheese such as surface mold ripened soft cheese made from nonpasteurized milk. Brie cheese has a surface pH of 6.8–7.6 and enables the bacteria to grow to numbers of 10^8 – 10^9 c.f.u./g. *Carnobacterium divergens* and *Carnobacterium maltaromaticum* are also major components in the lactic acid bacteria association in the curd of mozzarella cheese made from nonpasteurized milk (Morea et al., 1999).

Ecological Group II carnobacteria. *Carnobacterium funditum* and *Carnobacterium alterfunditum* were isolated from the Antarctic Ace Lake. In that meromictic lake, the salinity increased from 0.6% at the surface to 4.3% at the bottom depth of 24 m where the sample was taken (Franzmann et al., 1991). The temperature varied little and was 1–2 °C. The organisms are adapted to that environment but grow best at 22–23 °C in a medium of 1.7 (*Carnobacterium funditum*) or 0.6% (*Carnobacterium alterfunditum*) salinity. It is assumed that the carnobacteria create a reduced environment and provide electron donors for exploitation of associated sulfate reducing bacteria. *Carnobacterium pleistocenium* was isolated from a pleistocenian ice sample from the permafrost tunnel in Fox, Alaska. The age was estimated to be 32,000 years. The organism grows optimally at 24 °C and has a unique carbohydrate metabolism that produces no lactic acid from glucose.

Sensitivity to chemotherapeutics. The pathogenicity of strains of *Carnobacterium maltaromaticum* to fish produced in aquaculture raised the interest in the sensitivity of carnobacteria to chemotherapeutics. The use of those compounds in aquaculture has been reviewed by Ringo and Gatesoupe (1998). Lai and Manchester (2000) determined the resistance of 97 isolates including all carnobacteria species except *Carnobacterium inhibens* and *Carnobacterium pleistocenium* and for numerous species found high resistance values (close to 100%) against ampicillin, cloxacillin, gentamicin, kanamycin, neomycin, and streptomycin. The results confirm the findings of Baya et al. (1991) who investigated the sensitivity of eight isolates of *Carnobacterium piscicola* from diseased fish and additionally found resistance to chlorotetracyclin, trimethoprim, furazolidon, nitrofurazone, and nitrofurantoin. All strains were sensitive to erythromycin, and the majority of strains were sensitive to penicillin and ampicillin. Similar results were reported by Ringo and Holzapfel,

(2002) who also included *Carnobacterium inhibens* in their study. A complete sensitivity to deferroxamin and resistance to vancomycin were also reported. It is notable that *Carnobacterium pleistocenum* that was isolated from a human-free environment established 32,000 years ago is sensitive to commonly used antibiotics such as ampicillin, kanamycin, gentamicin, tetracycline, rifampin, and chloramphenicol.

Antagonistic potential. A protective effect of carnobacteria used as probiotics against competing micro-organisms in fish has been observed by Robertson et al. (2000). Carnobacteria species isolated from Atlantic salmon exhibited *in vitro* activity against numerous Gram-stain-negative pathogens. The culture applied to rainbow trout (fry, fingerling) and small Atlantic salmon of 15 g improved the survival of the fish challenged with pathogens, e.g., for Atlantic salmon exposed to *Aeromonas salmonicida*, *Vibrio anguillarum*, *Vibrio ordalii*, and *Yersinia ruckerii*. Cultures were studied with the aim to protect food from growth of pathogens, especially *Listeria monocytogenes*, or to prevent spoilage (Brillet et al., 2004; Yamazaki et al., 2003). As carnobacteria do not acidify strongly, this undesired sensory effect is less pronounced. The strains used commonly form bacteriocins. These proteinaceous compounds were detected and attributed to lantibiotics (group I bacteriocins) and to group II compounds (Klaenhammer, 1993; Ouwehand, 1998; Tahiri et al., 2004). The bacteriocin formation is not always decisive for the protective effect, especially against *Listeria monocytogenes*, as on cold smoked salmon, a nonproducer exhibited the positive effect and producer strains enhanced it (Nilsson et al., 1999, 2004).

Enrichment, isolation, and cultivation procedures

The species of the ecological group I are similar to lactobacilli in their nutritional requirements. They are, however, not aciduric and either do not grow or do not readily grow on acetate rich media, e.g., SI-medium (Rogosa et al., 1951). The omission of acetate from MRS-medium (De Man et al., 1960) is commonly a favorable choice for isolation. Neutral to alkaline media in the range 6.8–9.0 favors their growth and pH 8.0–9.0 commonly prevents the growth of lactobacilli that are found in association with carnobacteria in food. For *Carnobacterium piscicola* isolates from diseased fish, a requirement for folic acid, riboflavin, pantothenate, and niacin but not for vitamin B₁₂, biotin, thiamine, or pyridoxal (Hiu et al., 1984) has been demonstrated. *Carnobacterium divergens* and *Carnobacterium piscicola* isolates from meat do not require thiamine (De Bruyn et al., 1987). The species of ecological group II are less fastidious. *Carnobacterium alterfunditum* and *Carnobacterium funditum* grow on mineral salts, a carbohydrate source, and yeast extract. These organisms do not grow on MRS-medium without acetate. *Carnobacterium pleistocenum* needs mineral salts, yeast extract, and peptone. Vitamins are also added to the medium, however, it is not known whether or not they are essential. To isolate ecological group I bacteria from environments dominated by carnobacteria, direct streaking or plating onto nonselective universal media is possible. For isolation from diseased fish, brain heart infusion or tryptic soy agar has been used (Hiu et al., 1984), and for isolation from vacuum packaged meat, standard-I-agar (Merck) (pH 7.2–7.5), caso-medium (Merck), or tryptic soy agar (Difco) with 0.3% added yeast extract and aerobic incubation at 25 °C for 3 d or 7 °C for 10 d is recommended (Hammes and Hertel, 2003).

When counting carnobacteria on the universal media, the pH should be adjusted to 8.0 to suppress growth of lactobacilli. The identity of typical catalase-negative bacteria needs verification by microscopy and the criteria in Table 101. The absence of heme has to be checked, as the group I species form the apoenzyme that becomes active in the presence of heme (see above). Selective cresol Red Thallium Acetate Sucrose (CTAS) as a selective medium for isolation and counting of *Carnobacterium divergens* and *Carnobacterium piscicola* was recommended by WPCM (1989). The preparation of that medium and the colony morphology seen on that medium have been described by Hammes and Hertel, (2003). For cultivation of the axenic cultures, APT medium (Evans and Niven, 1951) at pH 7.0, caso-medium with 0.3% yeast extract, or standard-I-medium can be used. In general and especially for more fastidious strains, d-MRS (pH 8.0–8.5) (Hammes et al., 1992) and incubation at 25 °C for 24–48 h, aerobically or in slightly reduced atmosphere, are recommended. d-MRS corresponds mainly with MRS-medium but does not contain acetate, and sucrose substitutes for glucose. According to Lai and Manchester, (2000), some strains of *Carnobacterium divergens* (cluster B) do not ferment sucrose and need, therefore, resubstitution of sucrose by glucose.

Cultivation of the group II bacteria *Carnobacterium funditum* and *Carnobacterium alterfunditum* is best performed under anaerobic conditions. The organisms grow poorly aerobically. Rich media such as SI-medium or MRS-medium without acetate do not support growth. Best growth is observed in medium 141 YF (Franzmann et al., 1991) consisting of mineral salts with added trace salts (141 salts) and vitamins, cysteine hydrochloride, Na₂S, 1% yeast extract, and 1% fructose. The optimum temperature and pH are 22–23 °C and 7.0–7.4, respectively. For optimal growth, *Carnobacterium funditum* and *Carnobacterium alterfunditum* require 1.7% and 0.6% NaCl, respectively (Franzmann et al., 1991). *Carnobacterium pleistocenum* (Pikuta et al., 2005) is cultured at optimum pH 7.3–7.5 and temperature 24 °C aerobically or anaerobically, in medium consisting of mineral salts, trace of vitamins and salts, 0.2 g/l yeast extract, and 3 g/l peptone. For determination of the utilization of carbohydrates, the mineral salt base medium with 0.1% yeast extract is supplemented with the respective carbohydrate at a concentration of 3 g/l.

Maintenance. The maintenance of cultures of carnobacteria can be performed as for lactobacilli. Care has to be taken that the pH does not drop markedly below 6.0. The organism grown in the above described media can be kept at 1–4 °C in stab culture for 2–3 weeks. The addition of 5% calcium carbonate can improve the vitality of the cultures. For long-term storage, lyophilization is the best choice. As cryoprotectives, skim milk, lactose, or horse serum are recommended. The dried cultures should be stored in sealed glass ampoules at 8–12 °C. This culture can be kept for years. Effective storage is also achieved by harvesting late logarithmic cells by centrifugation, resuspending in growth medium containing 20% glycerol, and storage in screw caps at –80 °C.

Procedures for testing special characteristics

The composition of the fatty acids has been used to differentiate groups or even species of carnobacteria. The composition of *Carnobacterium viridans* is, however, not known. Oleic acid is present in all species and is dominant in *Carnobacterium*

TABLE 101. Selected physiological characteristics of species of the genus *Carnobacterium*^a

maltaromaticum, *Carnobacterium divergens*, *Carnobacterium mobile*, and *Carnobacterium gallinarum* (Collins et al., 1987; Ringo et al., 2002). *Carnobacterium divergens* also contains the biosynthetically related cyclopropane derivative 9,10 methylenoctadecanoic acid, and in summing up these two compounds, C_{18:1} fatty acid constitute 40–50% of the total fatty acids. C_{16:1} fatty acids are also present in all species in substantial amounts and were identified as ω9 isomers in *Carnobacterium divergens*, *Carnobacterium maltaromaticum*, *Carnobacterium mobile*, *Carnobacterium gallinarum*, and *Carnobacterium inhibens*, whereas in *Carnobacterium funditum*, *Carnobacterium alterfunditum*, and *Carnobacterium pleistocenium*, the ω7 isomer was detected. The group II species also contain eicosanoic acid (C_{20:1}) in the amount of 0.6–1.6%.

Except for the composition of fatty acids, the determination of classical biochemical and chemical characteristics are of limited value. Key criteria are compiled in Table 101. In a recent study (Laursen et al., 2005), 120 carnobacteria (mainly *Carnobacterium divergens* and *Carnobacterium maltaromaticum*) isolated from meat and seafood were subjected to numerical taxonomy relying on classical biochemical reactions as well as

genotypic methods. These included carbohydrate fermentation and inhibition tests, SDS-PAGE electrophoresis of whole-cell proteins (protein profiling), plasmid profiling, intergenic space region (ISR) analysis, and examination of amplified-fragment length polymorphism (AFLP). The authors concluded that none of the phenotypic tests included in their study permitted a clear differentiation between *Carnobacterium divergens* and *Carnobacterium maltaromaticum*. Only the use of large numbers of phenotypic tests and data evaluation by numerical taxonomy would allow the identification of carnobacteria to the species level. The criteria listed in Table 101 can be obtained by using standard procedures such as the determination of the pattern of carbohydrate fermentation with the aid of automated systems, e.g., API 50 CH (bioMerieux).

For strain characterization, Laursen et al. (2005) used SDS-PAGE of whole-cell protein extracts as a nongenotypic identification method (Pot et al., 1994). For strain characterization, the authors had also included plasmid profiling according to Leisner et al. (2001) in their study. As about half of the strains of *Carnobacterium divergens* and *Carnobacterium maltaromaticum*

do not contain plasmids, this identification method is applicable only to a limited number of strains.

Genotypic identification methods

As described in the chapter on the genus *Lactobacillus*, genotypic methods are increasingly applied for species identification. Most of these methods rely on the rRNA gene sequences, e.g., multiplex PCR for simultaneous identification of *Carnobacterium divergens*, *Carnobacterium gallinarum*, and *Carnobacterium maltaromicum* (Macian et al., 2004). Recently, it was demonstrated that the restriction fragment length polymorphism of the 16S–23S rRNA gene intergenic spacer region can be useful to identify carnobacteria at the species level (Laursen et al., 2005; Rachman et al., 2004). Nevertheless, the comparative 16S rRNA gene sequence analysis still remains a suitable tool for the rapid and reliable identification of *Carnobacterium* species. An exception is *Carnobacterium alterfunditum* and *Carnobacterium pleistocenium*, which show 99.7% sequence similarity.

Differentiation of the genus *Carnobacterium* from closely related taxa

Carnobacteria can be differentiated from coccoid lactic acid bacteria by microscopy. The reduced tolerance to low pH and the ability to grow at pH 9 differentiates the carnobacteria from the rod-shaped genera *Lactobacillus*, *Paralactobacillus*, and *Weissella*.

The latter is, in addition, obligately heterofermentative producing D- or DL-lactic acid and does not possess *meso*-diaminopimelic acid in the peptidoglycan. This characteristic amino acid is also absent in the other rod-shaped genera within the *Carnobacterium* clade (*Isobaculum* and *Desemzia*).

Taxonomic comments

Carnobacteria belong to the group of lactic acid bacteria and are closely related to species of the genera *Desemzia*, *Isobaculum*, and *Trichococcus*, forming together the *Carnobacterium* clade (Figure 97). Taken into consideration that phylogenetic distances vary with the dataset and methods used for tree construction, it is still an open question whether the closest relatives among the lactic acid bacteria are located in the *Lactobacillus* clade or *Enterococcus* clade. The phylogenetic relationship among the carnobacteria can only roughly be estimated because the positioning of species, especially of the genera *Desemzia* and *Trichococcus*, varies with the sequence positions selected and methods used for tree construction. As an example a tree constructed by applying the maximum-parsimony analysis is depicted in Figure 98. Interestingly, *Carnobacterium divergens*, *Carnobacterium gallinarum*, *Carnobacterium piscicola*, and *Carnobacterium maltaromicum* remained in one group in most of the phylogenetic trees constructed by varying the sequence positions and treeing methods.

List of species of the genus *Carnobacterium*

1. ***Carnobacterium divergens*** (Holzapfel and Gerber 1983) Collins, Farrow, Phillips, Feresu and Jones 1987, 315^{VP} (*Lactobacillus divergens* Holzapfel and Gerber 1983, 530.)

di.ver'gens. L. part. adj. *divergens* deviate, diverge.

Nonmotile, straight, slender and relatively short rods with rounded ends; generally 0.5–0.7 × 1.0–1.4 μm, occurring singly, in pairs, and short chains. Colonies cream colored to white, convex, shiny, varying from 0.5–1.5 mm on Standard I-agar and MRS-agar without acetate. Growth in acetate-containing media is suppressed in the presence of citrate and glucose, but is stimulated when ribose or fructose is added. Surface growth is generally affected by aerobiosis. Under certain conditions, heterofermentative, producing L(+)-lactic acid, CO₂, ethanol, and acetate from hexoses. In addition to L(+)-lactic acid, acetate and ethanol are produced from ribose. Grows in 10% NaCl. Final pH reached in MRS-broth (without acetate) between 5.0 and 5.3 after 4 d. No production of slime from sucrose or mannitol from fructose. No gas production from gluconate or malate. Produces catalase on heme-containing media. Gelatinase, indole, and H₂O₂ not produced. Additional physiological and biochemical properties are presented in Table 101.

Isolated from vacuum-packaged, refrigerated meat, fish.

DNA G+C content (mol%): 33.7–36.4 (T_m).

Type strain: 66, ATCC 35677, CCUG 30094, CIP 101029, DSM 20623, NBRC 15683, JCM 5816, JCM 9133, LMG 9199, NCIMB 11952, NRRL B-14830.

GenBank accession number (16S rRNA gene): M58816, X54270.

2. ***Carnobacterium alterfunditum*** Franzmann, Höpfl, Weiss and Tindall 1993, 188^{VP} (Effective publication: Franzmann, Höpfl, Weiss and Tindall 1991, 261.)

al'ter.fun.dí'tum. L. adj. *alter* another; L. adj. *funditus* from the bottom; N.L. neut. adj. *alterfunditum* another [carnobacterium] from the [lake] bottom.

Cells are rods (1.3 × 2.5–12.5 μm) occurring singly, in pairs, or short chains (typically of four cells), motile by a single sub-polar flagellum. Old cells usually stain Gram-stain-stain-negative and are nonmotile. Anaerobic, with better growth at 20°C. L(+)-Lactic acid is the major end product from D(+)-glucose with traces of ethanol, acetic acid, and formic acid. D(-)-Ribose is fermented to lactic acid and moderate amounts of ethanol, acetic acid, and formic acid. Glycerol is mainly fermented to acetic acid and formic acid, and traces of ethanol are produced. Gas is not produced. No growth in MRS or SL broths. Growth occurs in media containing 0.1% yeast extract without added sodium salts; the optimum concentration of NaCl is 0.1 M. Chopped meat medium and litmus milk remain unchanged. The optimum initial pH for growth is 7.0–7.4. Pyruvate, lactate, formate, acetate, methanol, betaine, trimethylammonium, chloride, glycine, and an atmosphere of H₂:CO₂ (2 bar, 80:20) do not stimulate growth. Gelatinase-negative. Additional physiological and biochemical characteristics are presented in Table 101. The cell wall contains *meso*-diaminopimelic acid. C_{18:109c} is a major component of its fatty acids. Respiratory lipoquinones are not produced. The spent fermentation broth of PY-amygdalin-2% NaCl smells similar to the seeds of dried prunes.

Isolated from the anaerobic monimolimnion of an antarctic lake (with approximately the salinity of sea water) and rainbow trout.

DNA G+C content (mol%): 32–36 (T_m).

Type strain: pf4, ACAM 313, ATCC 49837, CCUG 34643, CIP 105796, DSM 5972, NBRC 15548, JCM 12498, LMG 13520.

GenBank accession number (16S rRNA gene): not available.

3. **Carnobacterium funditum** Franzmann, Höpfl, Weiss and Tindall 1993, 188^{VP} (Effective publication: Franzmann, Höpfl, Weiss and Tindall 1991, 260.)

fun.dí'tum. L. neut. adj. *funditum* from the bottom.

Cells are rods (0.8–1.3 × 1.7–0.8 μm) occurring singly, in pairs, or short chains (typically of four cells), motile by a single subpolar flagellum. Old cells usually stain Gram-stain-stain-negative and are nonmotile. Anaerobic, with better growth at 20 °C. (+)-Lactic acid is the major end product from D(+)-glucose with traces of ethanol, acetic acid, and formic acid. D(-)-Ribose is fermented to lactic acid and moderate amounts of ethanol, acetic acid, and formic acid. Glycerol is mainly fermented to acetic acid and formic acid, and traces of ethanol are produced. Gas is not produced. No growth in MRS or SL broths. At least 0.1% yeast extract is required for good growth. Chopped meat medium and litmus milk remain unchanged. Gelatinase-negative. The optimum initial pH for growth is between 7.0 and 7.4. Sodium is required for growth with optimal growth at 1.7%. Pyruvate, lactate, formate, acetate, methanol, betaine, trimethyl-ammonium, chloride, glycine, and an atmosphere of H₂:CO₂ (2 bar, 80:20) do not stimulate growth. Additional physiological and biochemical characteristics are presented in Table 101. C_{18:1 09c} is a major component of its fatty acids. Respiratory lipoquinones are not produced.

Isolated from the anaerobic monimolimnion of an antarctic lake of about sea water salinity.

DNA G+C content (mol%): 32–35 (T_m).

Type strain: pf3, ACAM 312, ATCC 49836, CCUG 34644, CIP 106503, DSM 5970, NBRC15549, JCM 12499, LMG 14461.

GenBank accession number (16S rRNA gene): S86170.

4. **Carnobacterium gallinarum** Collins, Farrow, Phillips, Feresu and Jones 1987, 315^{VP}

gal.li.na'rum. L. fem. n. *gallina* a hen; L. fem.gen.p.n. *gallinarum* of hens.

Gram-stain-positive, nonsporeforming, straight, slender rods which occur singly or in short chains. Cells are nonmotile. Colonies are white, convex, shiny, and circular. Facultatively anaerobic. L-(+)-Lactic acid is produced. No gas is produced from glucose. Lysine decarboxylase, ornithine decarboxylase, tryptophan desaminase, and urease-negative. Indole and H₂S are not produced. Additional physiological and biochemical characteristics are presented in Table 101. The cellular fatty acids are of the straight-chain saturated and monounsaturated types with tetradecanoic, hexadecanoic, and 9,10-octadecenoic acids predominating.

Isolated from ice slush from around chicken carcasses and various meat products.

DNA G+C content (mol%): 34.3–35.4 (T_m).

Type strain: MT44, ATCC 49517, CCUG 30095, CIP 103160, DSM 4847, JCM 12517, LMG 9841, NCIMB 12848, NRRL B-14832.

GenBank accession number (16S rRNA gene): AJ387905, X54269.

5. **Carnobacterium inhibens** Jöborn, Dorsch, Olsson, Westerdahl and Kjelleberg 1999, 1897^{VP}

in.hi'bens. L. part. adj. *inhibens* inhibiting, referring to the growth-inhibitory activity that the bacterium shows.

Cells are motile (monotrichous), nonsporeforming rods occurring singly, in pairs, or as chains of four cells. No growth on MRS medium. Colonies (TSA, 20 °C) are 1–2 mm in diameter. Circular, entire, convex, and semitranslucent. The color of

the colonies is whitish at aerobic growth conditions and buff at anaerobic growth conditions. pH range supporting growth 5.5–9.0. Catalase is produced on heme-containing media. H₂S not produced and nitrate not reduced. Hydrolyzes hippurate. Additional physiological and biochemical characteristics are presented in Table 101. The most abundant cellular fatty acids are C_{16:0} (31.1%), C_{16:1} (24.2%), and C_{18:1 09c} (23.4%). Other fatty acids are C_{18:2 06,9c} or C_{18:0} (10.8%), C_{14:0} (5.4%), and C_{18:0} (3.5%). The peptidoglycan type is not known.

Habitat is the intestines of healthy fish.

DNA G+C content (mol%): not determined.

Type strain: KI, CCUG 31728, CIP 106863, DSM 13024.

GenBank accession number (16S rRNA gene): Z773313.

6. **Carnobacterium maltaromaticum** (Miller, Morgan and Libbey 1974) Mora, Scarpellini, Franzetti, Colombo and Galli 2003, 677^{VP} (*Lactobacillus maltaromicus* Miller, Morgan and Libbey 1974, 352; *Lactobacillus piscicola* Hiu, Holt, Sriranganathan, Seidler and Fryer 1984, 399; *Lactobacillus carnis* Shaw and Harding 1985, 296; *Carnobacterium piscicola* Collins, Farrow, Phillips, Feresu and Jones 1987, 315.)

malt.a.ro.mat.ic'um. N.L. neut. n. *maltum-i* malt; L. adj. *aromaticus -a -um* aromatic, fragrant; N.L. neut. adj. *maltaromaticum* possessing a malt-like aroma.

Cells are rods (0.5–0.7 × 3.0 μm) occurring singly or in chains. Nonmotile. Facultatively anaerobic. L-(+)-Lactic acid, ethanol, and acetate are produced heterofermentatively. Gas production is weak and frequently undetectable. Grows in MRS, TSBY, and brain heart infusion media. Additional physiological and biochemical characteristics are presented in Table 101. Major cellular fatty acids are straight-chain saturated and monounsaturated acids, with tetradecanoic, hexadecanoic, and 9- and 10-octadecenoic acids predominating.

Isolated from dairy products, meat, fish (healthy and diseased), and human plasma and pus.

DNA G+C content (mol%): 33.7–36.4 (T_m).

Type strain: ATCC 27865, CCUG 30142, CIP 103135, DSM 20342, JCM 1154, LMG 6903, NRRL B-14852.

GenBank accession number (16S rRNA gene): M58825, X54420.

7. **Carnobacterium mobile** Collins, Farrow, Phillips, Feresu and Jones 1987, 315^{VP}

mo'bi.le. L. neut. adj. *mobile* movable or motile.

Gram-stain-positive, nonsporeforming, straight, slender rods which occur singly or in short chains. Cells are motile. Colonies are white, convex, shiny, and circular. Facultatively anaerobic. L-(+)-Lactic acid is produced heterofermentatively. Gas production from glucose is observed for most strains in arginine-MRS broth. All strains are lysine decarboxylase, ornithine decarboxylase, tryptophan desaminase, and urease-negative. Additional physiological and biochemical characteristics are presented in Table 101. The cellular fatty acids are of the straight-chain saturated and monounsaturated types, with hexadecanoic, hexadecenoic, and 9,10-octadecenoic acids predominating.

Isolated from irradiated chicken meat and from shrimp.

DNA G+C content (mol%): 35.5–37.2 (T_m).

Type strain: MT37L, ATCC 49516, CCUG 30096, CIP 103159, DSM 4848, JCM 12516, LMG 9842, NCIMB 12847, NRRL B-14831.

GenBank accession number (16S rRNA gene): AB083414, X54271.

8. **Carnobacterium pleistocenium** Pikuta, Marsic, Bej, Tang, Krader and Hoover 2005, 477^{VP}

plei.sto.ce'ni.um. N.L. neut. adj. *pleistocenium* belonging to the Pleistocene, a geological epoch.

Cells are motile, small rods with rounded ends, 0.7–0.8 × 1.0–1.5 μm. Gram-stain-positive. Growth occurs at 22 °C in the pH range of 6.5–9.5. Range of NaCl for growth is 0–5% (w/v); optimum growth at 0.5% (w/v) NaCl. Facultatively anaerobic. Growth occurs with starch, peptone, Bacto tryptone, Casamino acids, and yeast extract. End products of growth are acetate, ethanol, and traces of carbon dioxide. Additional physiological and biochemical characteristics are presented in Table 101.

Isolated from a sample of permafrost from Fox Tunnel, Alaska.

DNA G+C content (mol%): 42 ± 1.5 (T_m).

Type strain: FTR1, ATCC BAA-754, CIP 108033, JCM 12174.

GenBank accession number (16S rRNA gene): AF450136.

9. **Carnobacterium viridans** Holley, Guan, Peirson and Yost 2002, 1884^{VP}

vi'ri.dans. N.L. adj. *viridans* from L. v. *viridare* to make green, referring to the production of a green color in cured meat by the organism.

Cells are nonmotile, slightly curved rods, singly or in pairs, or as straight rods (0.8 × 3.6 ± 0.6 μm). Facultatively anaerobic. Grows satisfactorily in BHI, APT, M5, and CTSI media, but poorly on a variety of media including MRS and SL agar. Grows over a range of pH from 5.5–9.1. Produces predominantly L(+)-lactic acid from glucose and neither gas nor H₂S. Does not grow in 4% (w/v) NaCl but will tolerate 26.4% (w/v) NaCl (saturated brine) for long periods at 4 °C. Additional physiological and biochemical characteristics are presented in Table 101. The cell-wall peptidoglycan contains *meso*-DAP.

Isolated from green, discolored vacuum packaged Bologna type sausage.

DNA G+C content (mol%): not determined.

Type strain: MPL-11, ATCC BAA-336, DSM 14451, JCM 12222.

GenBank accession number (16S rRNA gene): AF425608.

Genus II. **Alkalibacterium** Ntougias and Russell 2001, 1169^{VP}

SPYRIDON NTOUGIAS AND NICHOLAS J. RUSSELL

Al.ka.li.bac'te.ri.um. N.L. n. *alkali* (from Ar. article *al* the; Ar. n. *qaliy* ashes of saltwort) alkali; L. neut. n. *bacterium* a small rod; N.L. neut. n. *Alkalibacterium* bacterium living under alkaline conditions.

Cells are **rods** up to 0.4–1.2 × 0.7–3.7 μm in both liquid culture and on plates. Cells occur singly, in pairs, or in clusters of up to five cells. **Gram-stain-positive. Motile by polar or peritrichous flagella. Endospores are not formed.** Facultatively anaerobic. Catalase- and oxidase-negative. Produce DL-lactate from glucose. On plates, forms round (0.5–2.5 mm diameter) **white colonies. Obligately alkaliphilic, growing only above pH 8.0 and up to pH 11 or higher. Halotolerant** with growth up to 15–17 % NaCl and often a broad optimum from 0 to 13 % NaCl. **Mesophilic (often psychrotolerant)** with growth from 4–15 to 35–45 °C and optimal growth at 20–37 °C. The major phospholipids are phosphatidylglycerol, diphosphatidylglycerol, phosphatidylserine, and an unknown phospholipid; glycolipids are also present. The cellular **fatty acids are saturated and unsaturated even-carbon chain**, with *n*-hexadecanoic, hexadecenoic, and octadecenoic acids as the major components. **Quinones are not present.**

DNA G+C content (mol%): 39.7–47.8.

Type species: ***Alkalibacterium olivapovliticus*** corrig. Ntougias and Russell 2001, 1169^{VP}.

Further descriptive information

Although colonies on plates are white, centrifuged biomass is yellow or orange. The peptidoglycan type is variable (A4β or A4α).

Enrichment and isolation procedures

Alkalibacterium species have been isolated from naturally alkaline habitats (e.g., soda lakes) as well as biotechnological processes (e.g., edible-olive wash-waters and indigo production). Both cultured and uncultured (clones) isolates have been reported.

Maintenance procedures

Cultures can be maintained on slants of agar (2%, w/v), containing 0.05 M L-sodium glutamate, 0.5% (w/v) yeast extract,

0.1 M sodium carbonate, 1 mM dipotassium hydrogen phosphate, 7.6 mM ammonium sulfate, and 0.1 mM magnesium sulfate for up to 2 months. Alternatively, reinforced clostridial broth (RCB) or agar (RCA) media containing 100 mM NaHCO₃/Na₂CO₃ buffer, pH 10 (alkali-RCB or alkali-RCA) can be used. NaHCO₃/Na₂CO₃ buffer should be sterilized separately by autoclaving. Cultures of *Alkalibacterium olivapovliticus* should be subcultured every 15 d. Viability of stored cultures on beads in glycerol media is poor. The best method of storing cultures is by freeze-drying; such cultures can be kept for more than 1 year.

Differentiation of the genus *Alkalibacterium* from other genera

Alkalibacterium is distinguishable from the closely related *Marinilactibacillus* on the basis of structure of the V6 region of 16S rRNA, the pH optimum and range of pH for growth, and minimum growth temperature (Ishikawa et al., 2003).

Alkalibacterium can be distinguished from the phylogenetically related genus *Alloiococcus* by differences in cellular morphology, motility, oxygen requirement, growth at pH 7, catalase reaction, and DNA base composition; from the genus *Dolosigranulum* by cellular morphology, pH tolerance, temperature and salt concentration ranges for growth, and peptidoglycan type; and from the genus *Carnobacterium* by pH and salt concentration ranges for growth, G+C content of DNA, and peptidoglycan type.

Taxonomic comments

The genus *Alkalibacterium* aligns with the lactic acid bacteria. Lactate and formate are the main end products of glucose fermentation, followed by acetate and ethanol. The amount of formate production increases relative to lactate at higher pH values (Ishikawa et al., 2003).

The peptidoglycan type of *Alkalibacterium psychrotolerans* and *Alkalibacterium iburiense* is A4 α , instead of A4 β , as recently re-examined (Yumoto et al., 2008).

The species *Alkalibacterium psychrotolerans* can be distinguished from the closely related species *Alkalibacterium olivapovliticus* on the basis of its flagellar position and strength of motility, pH range for growth, sugar fermentation pattern, and peptidoglycan type; and from *Marinilactibacillus psychrotolerans* on the basis of its optimum pH and range for growth, sugar fermentation pattern, colony color, peptidoglycan type and G+C content of DNA. The DNA–DNA similarity of *Alkalibacterium olivapovliticus* and *Alkalibacterium psychrotolerans* is 24.3 %.

The species *Alkalibacterium iburiense* can be distinguished from the closely related species *Alkalibacterium olivapovliticus* on the basis of its flagellar position and strength of motility, pH range for growth, temperature upper limit for growth, antibiotic sensitivity, peptidoglycan type and G+C content of DNA; from *Alkalibacterium psychrotolerans* on the basis of sugar fermentation pattern, peptidoglycan type and G+C content of DNA; and from *Marinilactibacillus psychrotolerans* on the basis of its optimum pH and range for growth, temperature lower limit for growth, sugar fermentation pattern, colony color, peptidoglycan type and G+C

content of DNA. The fatty acid composition of *Alkalibacterium iburiense* is similar to that of *Alkalibacterium olivapovliticus* rather than that of *Alkalibacterium psychrotolerans* and *Marinilactibacillus psychrotolerans*. The DNA–DNA similarities of *Alkalibacterium iburiense* with *Alkalibacterium psychrotolerans* and *Alkalibacterium olivapovliticus* are 14.1 % and 7.3 %, respectively.

The species *Alkalibacterium indicireducens* can be distinguished from the closely related species *Alkalibacterium olivapovliticus* on the basis of its flagellar position, pH range for growth, temperature range and optimum for growth, hydrolysis of cellulose, sugar fermentation pattern, antibiotic sensitivity, peptidoglycan type and G+C content of DNA; from *Alkalibacterium psychrotolerans* on the basis of its temperature range and optimum for growth, hydrolysis of cellulose, sugar fermentation pattern, sensitivity to trimethoprim and G+C content of DNA; from *Alkalibacterium iburiense* on the basis of its temperature range and optimum for growth, hydrolysis of cellulose, sugar fermentation pattern, peptidoglycan type and G+C content of DNA. The DNA–DNA similarities of *Alkalibacterium indicireducens* with *Alkalibacterium psychrotolerans*, *Alkalibacterium iburiense* and *Alkalibacterium olivapovliticus* are 40 %, 34 % and 21 %, respectively.

List of species of the genus *Alkalibacterium**

1. *Alkalibacterium olivapovliticus* corrig. Ntougias and Russell 2001, 1169^{VP}

o.li.va.pov'lit.i.cus. L. n. *oliva* olives; Gr. n. *apovlito* waste disposal; N.L. gen. n. *olivapovliticus* from the waste of the olives.

Rods (0.4–0.6 \times 1.3–2.9 μ m) in liquid culture and on plates. Cells occur singly, in pairs, or in small clusters. Cells stain Gram-stain-negative but show Gram-stain-positive cell wall behavior in the KOH test and the aminopeptidase test. Weakly motile by polar flagella. Endospores are not formed. Colonies are small, round, and glistening, with diameter of 0.8–1.0 mm, appearing as pale white due to their small size, although the color of bulk biomass observed after centrifugation is yellow or orange. Obligately alkaliphilic, growing above pH 8–11 or higher and an optimum of pH 9–10. Halotolerant, growing in up to 15% NaCl with an optimum of 3–5% NaCl for the type strain and 0–10% NaCl for other strains. Psychrotolerant, growing over the range 4–37 °C with an optimum of 27–32 °C. The major phospholipids are phosphatidylglycerol, diphosphatidylglycerol, phosphatidylserine, and an unknown phospholipid; there are also four unidentified glycolipids. The cellular fatty acids are mainly saturated and unsaturated even-carbon chain, with hexadecanoic (C_{16:0}), hexadecenoic (C_{16:1 09c}), and octadecenoic (C_{18:1 09c}) acids as the major components. No quinones could be detected. Sugars which are metabolized include D(+)-glucose, D(+)-glucose-6-phosphate, maltose, D(+)-cellobiose, sucrose, mannose, and trehalose. Amino acids are not utilized as sole carbon and energy sources. Yeast extract could be utilized as the sole carbon and energy source. Cells are catalase- and oxidase-negative. Culture growth is inhibited by ampicillin, carbenicillin, chloramphenicol, penicillin G, kanamycin, streptomycin, and trimethoprim. Some strains are sensitive to amoxicillin or to miconazole and neo-

mycin. The peptidoglycan type is A4 β , L-Orn–D-Asp. The natural habitat is the wash waters of edible olives. Reference strains include DSM 12937, NCIMB 13711 (strain WW2-SN4c; GenBank accession no. 16S rRNA gene, AF143512), DSM 12938, NCIMB 13712 (strain WW2-SN5; GenBank accession no. 16S rRNA gene, AF14513).

DNA G+C content (mol %): 39.7 (HPLC).

Type strain: WW2-SN4a, DSM 13175, NCIMB 13710.

GenBank accession number (16S rRNA gene): AF143511.

2. *Alkalibacterium psychrotolerans* Yumoto, Hirota, Nodasaka, Yokota, Hoshino and Nakajima 2004, 2382^{VP}

psy.chro.to'le.rans. Gr. adj. *psychros* cold; L. part. adj. *tolerans* tolerating; N.L. neut. part. adj. *psychrotolerans* tolerating cold environments.

Cells are straight rods, 0.4–0.9 \times 0.7–3.1 μ m, stain Gram-stain-positive, and have peritrichous flagella. Endospores are not produced. Cells grow aerobically and anaerobically. Catalase- and oxidase-negative. Reduces indigo dye. Colonies are circular, convex, and pale white. Obligately alkaliphilic with growth at pH 9–12 but not pH 7–8 and an optimal pH of 9.5–10.5 at 27 °C. Halotolerant, growing at 0–17 % (w/v) NaCl with a broad optimum concentration of 2–12 %. Psychrotolerant, growing between 5 and 45 °C with an optimum growth temperature around 34 °C. The major cellular fatty acids are tetradecanoic (C_{14:0}), hexadecanoic (C_{16:0}), hexadecenoic (C_{16:1 07c}) and octadecenoic (C_{18:1 09c}) acids. Starch and gelatin are not hydrolyzed. Cells ferment D(+)-arabinose, D(+)-xylose, D(+)-glucose, and maltose, but do not ferment D(+)-melibiose, D(+)-raffinose, myo-inositol, mannitol, erythritol, sorbitol, xylitol, adonitol, dulcitol, sucrose, D(+)-galactose, inulin, and L(+)- or D(+)-rhamnose. Lactate is the major end product of glucose fermentation. No quinones can be detected. The peptidoglycan type is A4 α , L-Lys (L-Orn)–D-Asp. Isolated from Polygonum Indigo (*Polygonum tinctorium* Lour.) produced in Date-city, Hokkaido, Japan.

*Four novel species, named *Alkalibacterium thalassium*, *Alkalibacterium pelagium*, *Alkalibacterium putridalgalicola*, and *Alkalibacterium kapii*, which were isolated from marine organisms and salted foods collected in Japan and Thailand, have been accepted for publication in IJSEM in 2009 by M. Ishikawa et al.

DNA G+C content (mol%): 40.6 (HPLC).

Type strain: IDR2-2, JCM 12281, NCIMB 13981.

GenBank accession number (16S rRNA gene): AB125938.

3. **Alkalibacterium iburiense** Nakajima, Hirota, Nodasaka and Yumoto 2005, 1529^{VP}

i.bu.ri.en'se. N.L. neut. adj. *iburiense* from Iburi, the place where the micro-organism was isolated.

Cells are Gram-stain-positive, peritrichously flagellated, straight rods (0.5–0.7 × 1.3–2.7 µm). Endospores are not produced. Cells grow aerobically and anaerobically. Aminopeptidase, catalase- and oxidase-negative. Reduces indigo dye. Colonies (2–2.5 mm in diameter) are circular, convex, and pale white. Obligately alkaliphilic with growth at pH 9–12 but not pH 7–8 and an optimal pH of 9.5–10.5 at 27 °C. Halotolerant, growing at 0–16 % (w/v) NaCl with a broad optimum concentration of 3–13 %. Psychrotolerant, growing between 5 and 45 °C with an optimum growth temperature of 30–37 °C. Gelatin and starch are not hydrolyzed. Cells ferment D-arabinose, glycogen and N-acetylglucosamine, but do not ferment arbutin, D-galactose, D-mannitol, D-sorbitol, melibiose, myo-inositol or raffinose. Fermentation of D-fructose, D-mannose, D-xylose, L-rhamnose, maltose, sucrose and trehalose is variable (all positive for the type strain). Lactate is the major end product of glucose fermentation. Culture growth is inhibited by amoxicillin (10 µg), ampicillin (10 µg) and penicillin G (1 IU), but is not inhibited by chloramphenicol (2 µg), kanamycin (10 µg), ketoconazole (25 µg), miconazole (25 µg), sulfamethoxazole (25 µg) and trimethoprim (25 µg). The major cellular fatty acids are hexadecanoic (C_{16:0}), hexadecenoic (C_{16:1 ω9c}) and octadecenoic (C_{18:1 ω9c}) acids. No quinones can be detected. The peptidoglycan type is A4α, L-Lys-D-Asp. Strain M3 was isolated from a contaminated culture in alkali broth, and reference strains 41A (GenBank accession no. 16S rRNA gene, AB188092) and 41C (GenBank accession no. 16S rRNA gene, AB188093) were isolated from polygonum indigo (*Polygonum tinctorium* Lour.) fermentation liquor produced in Date-city, Iburi, Hokkaido, Japan.

DNA G+C content (mol%): 42.6–43.2 (HPLC).

Type strain: M3, JCM 12662, NCIMB 14024.

GenBank accession number (16S rRNA gene): AB188091.

4. **Alkalibacterium indicireducens** Yumoto, Hirota, Nodasaka, Tokiwa and Nakajima 2008, 904^{VP}

in.di.ci.re.du'cens. L. n. *indicum* indigo; L. part. adj. *reducens* bringing or leading back, reducing; N.L. part. adj. *indicireducens* indigo-reducing.

Cells are Gram-stain-positive, peritrichously flagellated, straight rods (0.4–1.2 × 1.7–3.7 µm). Endospores are not produced. Cells grow aerobically and anaerobically. Aminopeptidase, catalase- and oxidase-negative. Reduces indigo dye. Colonies (0.5–2.0 mm in diameter) are circular, convex, and pale white. Obligately alkaliphilic with growth at pH 9–12.3 but not pH 7–8 and an optimal pH of 9.5–11.5. Halotolerant, growing at 0–15 % (w/v) NaCl with a broad optimum concentration of 1–11 %. Temperature range for growth is 15–40 °C with an optimum of 20–30 °C. Hydrolyzes starch, xylan and cellulose, but not casein or gelatin. Cells ferment D-glucose and sucrose, but do not ferment D-arabinose, D-galactose, D-mannose, D-xylose, inositol, L-rhamnose, maltose, melibiose, raffinose, sorbitol and trehalose. Fermentation of D-fructose is variable (positive for the type strain). Lactate is the major end product of glucose fermentation. Culture growth is inhibited by amoxicillin (10 µg), ampicillin (2 µg) and penicillin G (1 IU), but is not inhibited by chloramphenicol (10 µg), kanamycin (10 µg), ketoconazole (25 µg), miconazole (2 µg), sulfamethoxazole (25 µg) and trimethoprim (25 µg). The major cellular fatty acids are hexadecanoic (C_{16:0}), hexadecenoic (C_{16:1 ω9c}) and octadecenoic (C_{18:1 ω9c}) acids. No quinones can be detected. The peptidoglycan type is A4α, L-Lys (L-Orn)-D-Asp. The type strain A11 and the reference strains F11 (GenBank accession no. 16S rRNA gene, AB268550) and F12 (GenBank accession no. 16S rRNA gene, AB268551) were isolated from *Polygonum Indigo* (*Polygonum tinctorium* Lour.) fermentation liquor samples obtained from Tokushima City and Aizumi-cho, Itanogun (Japan), respectively.

DNA G+C content (mol%): 47.0–47.8 (HPLC).

Type strain: A11, JCM 14232, NCIMB 14253.

GenBank accession number (16S rRNA gene): AB268549.

Genus III. **Allofustis** Collins, Higgins, Messier, Fortin, Hutson, Lawson and Falsen 2003, 813^{VP}

PAUL A. LAWSON

Al.lo.fus'tis. Gr. prefix *allos* another, the other; L. masc. n. *fustis* stick; N.L. masc. n. *Allofustis* the other stick or rod.

Cells are **Gram-stain-positive, nonsporeforming and rod-shaped. Facultatively anaerobic. Catalase- and oxidase-negative.** Arginine dihydrolase, leucine arylamidase, and pyroglutamic acid arylamidase are produced. Indole-negative. Nitrate is not reduced. Voges-Proskauer-negative. The long-chain cellular fatty acids are of the straight-chain saturated and monounsaturated types. **The cell-wall murein is type L-lysine-direct (A1α).** The genus is classed in the family *Carnobacteriaceae*. Isolated from porcine semen.

DNA G+C content (mol%): 39.

Type species: **Allofustis seminis** Collins, Higgins, Messier, Fortin, Hutson, Lawson and Falsen 2003, 813^{VP}.

Isolation and maintenance procedures

Allofustis phocae has been isolated on sheep blood agar at 37 °C under anaerobic conditions. There is no information on enrichment or selective media for this species. The organism grows

well on agar media (such as brain heart infusion or Columbia agar) supplemented with blood (5 % v/v). Grows well on chocolate agar in CO₂. The organism grows in brain heart infusion broth with serum (5 % v/v). Can be stored on cryogenic beads at –70 °C or lyophilized for long-term preservation.

Taxonomic comments

The genus *Allofustis* was created in 2003 to accommodate phylogenetically distinct catalase-negative, rod-shaped organisms encountered in porcine semen specimens (Collins et al., 2003). The genus is monospecific and phylogenetically belongs to the order *Lactobacillales* in the phylum *Firmicutes*, according to the revised roadmap to Volume 3 of the *Systematics* (Ludwig et al., this volume). Phylogenetic analysis using 16S rRNA gene sequences shows that *Allofustis seminis* clusters within a suprageneric grouping that includes *Alkalibacterium* species, *Alloiococcus otitis*,

FIGURE 100. Unrooted neighbor-joining dendrogram depicting the estimated phylogenetic relationships of *Allofustis seminis* and its close relatives. The numbers on the branches refer to bootstrap values, determined from 1000 replications. Only values above 90% or higher are shown. Bar = 1% sequence divergence.

Atopostipes suicloacale, *Dolosigranulum pigrum*, and *Marinilactibacillus psychrotolerans*. *Allofustis seminis* forms a distinct subline within this grouping and does not display a particularly close affinity with any of the aforementioned taxa. A tree depicting the phylogenetic relationships of *Allofustis seminis* is shown in Figure 100. The predicted secondary structure of the V6 region of the 16S rRNA is also useful in the assignment of organisms within this suprageneric cluster of organisms (see Figure 101). In particular, nucleotides at positions 457–462 and the complementary nucleotide sequence at positions 471–476 appear to especially informative at the genus level. However, it remains

to be seen if these pairings found in *Allofustis seminis* are shown to be stable, as additional strains/species of the genus are isolated and described.

Differentiation of the genus *Allofustis* from other genera

In addition to differentiation by 16S rRNA gene sequence analysis, *Allofustis seminis* can be readily distinguished from its closest phylogenetic relatives *Alkalibacterium* species, *Alloiococcus otitis*, *Atopostipes suicloacale*, *Dolosigranulum pigrum*, and *Marinilactibacillus psychrotolerans* using a combination of morphological, biochemical, and chemotaxonomic criteria (see Table 102).

List of species of the genus *Allofustis*

1. ***Allofustis seminis*** Collins, Higgins, Messier, Fortin, Hutson, Lawson and Falsen 2003, 813^{VP}

sem.in'is. L. n. *semen* seed; L. gen. n. *seminis* of semen.

Cells stain Gram-positive and are rod-shaped. Nonspore-forming. β -Hemolytic reaction on sheep blood. Facultatively anaerobic; grows well on chocolate agar anaerobically or in CO_2 , at 37°C. Catalase and oxidase-negative. Acid is not produced from L-arabinose, D-arabitol, cyclodextrin, glycogen, lactose, maltose, mannitol, mannose, melibiose, melezitose, pullulan, raffinose, D-ribose, sorbitol, sucrose, D-tagatose, or trehalose. Arginine dihydrolase, arginine arylamidase, acid phosphatase, alkaline phosphatase, alanine arylamidase, alanine

phenylalanine proline arylamidase, glycine arylamidase, glycyL tryptophan arylamidase, histidine arylamidase, leucyl glycine arylamidase, leucine arylamidase, phosphoamidase, proline arylamidase, phenyl alanine arylamidase, pyroglutamic acid arylamidase, β -mannosidase, serine arylamidase, tyrosine arylamidase, and valine arylamidase are produced. Activity for α -arabinosidase, esterase C4, ester lipase C8, α -galactosidase, β -galactosidase, β -galactosidase-6-phosphate, α -glucosidase, β -glucuronidase, glutamic acid decarboxylase, glutamyl glutamic acid arylamidase, lipase C14, α -mannosidase, chymotrypsin, trypsin, and urease is not detected. α -Fucosidase, β -glucosidase, and N-acetyl- β -glucosaminidase may or may not be detected.

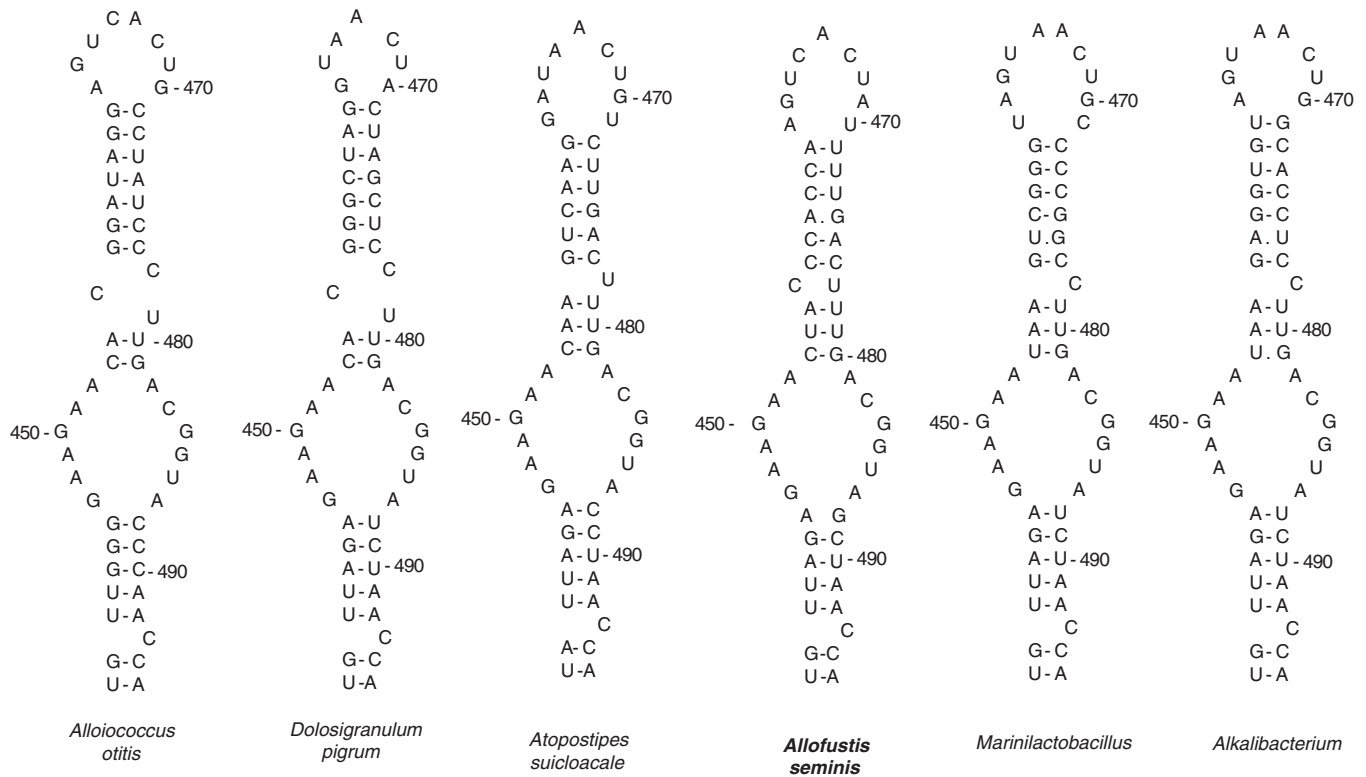

FIGURE 101. Nucleotide sequences and predicted secondary structure of the V6 region of the 16S rRNA of *Allofustis seminis* and its closest phylogenetic relatives. Numbers correspond to positions in the *Escherichia coli* sequence.

TABLE 102. Criteria that are useful in distinguishing the genus *Allofustis* from phylogenetically closely related taxa

Characteristics	<i>Allofustis</i>	<i>Alkalibacterium</i> ^b	<i>Alloiococcus</i> ^c	<i>Atopostipes</i> ^d	<i>Dolosigranulum</i> ^e	<i>Marilactobacillus</i>

^fData from Ishikawa et al. (2003).

Hippurate and esculin are not hydrolyzed. Indole and acetoin are not produced, and nitrate is not reduced. The major long-chain cellular fatty acids are C_{16:0}, C_{16:1}, C_{18:0} and C_{18:1 w9c}. The cell wall murein is based on L-lysine variation A1α (type: L-Lys-direct) (see Schleifer and Kandler, (1972) for nomenclature).

The only known source from which *Allofustis seminis* has been isolated is porcine semen. Habitat is not known.

DNA G+C content (mol%): 39 (HPLC).

Type strain: 01-570-1, CCUG 45438, CIP 107425, DSM 15817.

GenBank accession number (16S rRNA gene): AJ410303, AJ458446.

Genus IV. *Alloiococcus* Aguirre and Collins 1992a, 83^{VP}

MATTHEW D. COLLINS

Alloiococcus. Gr. adj. *allos* different; N.L. n. *coccus* coccus; N.L. masc. n. *Alloiococcus* different coccus, referring to the phylogenetic distinctiveness of the organism.

Cells are ovoid in shape and divide on an irregular plane giving rise to pairs, tetrads, and clusters. Gram-stain-positive and nonmotile. Nonsporeforming. **Nutritionally fastidious.** Grows in 6.5% NaCl (slowly) but not in 10% NaCl. **No growth at 10 or 45 °C. Aerobic.** Catalase may or may not be produced. Oxidase-negative. **Gas is not produced. Acid is not produced from glucose and other carbohydrates. Pyrrolidonyl arylamidase and leucine aminopeptidase-positive. Vancomycin sensitive.** Long-chain cellular fatty acids are of the straight-chain saturated and unsaturated types.

DNA G+C content (mol%): 44–45 (T_m).

Type species: *Alloiococcus otitis* Aguirre and Collins 1992a, 83^{VP}.

Further descriptive information

The genus contains only one species, *Alloiococcus otitis*, and therefore the characteristics provided below refer to this species. Colonies formed on BHIA with 5% (v/v) rabbit blood are small, moist, and slightly yellow at 3 d. After 4 d, colonies become darker yellow, dense, hard, involuted, and adherent to agar. Nonhemolytic, but cultures may become α -hemolytic after extended incubation. They grow on brucella agar supplemented with 5% (v/v) sheep blood but not without blood. Cultures grow in heart infusion and brain heart infusion broths very slowly, often requiring 2 d or more of incubation for growth. *Alloiococci* do not normally grow under anaerobic atmospheres, although some atypical strains have been reported to produce weak growth anaerobically (Miller et al., 1996). Catalase reaction is variable; cultures may give a negative or a weak catalase reaction, but they do not contain cytochrome enzymes. Acid is not formed from carbohydrate broth. Hippurate may or may not be hydrolyzed. Starch and esculin are not hydrolyzed. Most strains are capable of growing on bile-esculin medium but do not give positive reactions. Pyroglutamic acid arylamidase is produced and most strains are β -galactosidase-positive. Arginine dihydrolase, alanine phenylalanine proline arylamidase, glycyl tryptophan arylamidase, *N*-acetyl- β -glucosaminidase, pyrazinamidase, β -mannosidase, and urease are not produced. Voges–Proskauer-negative.

Polyamines are not detected in *Alloiococcus otitis* (Hamana, 1994). The long-chain fatty acids are of the straight-chain saturated and monounsaturated types, with $C_{16:0}$ (26–34%) and $C_{18:1\omega 9c}$ (14–15%) predominating (Bosley et al., 1995).

Alloiococci are β -lactamase-negative. All strains tested are resistant to trimethoprim-sulfamethoxazole, and, except for a single strain, to erythromycin. *Alloiococci* are susceptible or intermediately resistant to penicillin and ampicillin (range, 0.06 to 0.5 mg/ml). (Bosley et al., 1995).

Alloiococci have been isolated from human middle ear fluids (Bosley et al., 1995; Facklam and Elliott, 1995; Faden and Dryja, 1989). *Alloiococcus otitis* has been associated with chronic otitis media with effusion (Beswick et al., 1999; Faden and Dryja, 1989; Fraise et al., 2001; Hendolin et al., 1999). Several 16S rDNA PCR/probe based tests have been described for identifying and/or detecting *Alloiococcus otitis*

(Aguirre and Collins, 1992b; Beswick et al., 1999; Hendolin et al., 1999, 2000). PCR-based methods have detected *alloiococci* in culture negative specimens (Beswick et al., 1999; Hendolin et al., 1999).

Isolation procedures

Alloiococci do not grow on many commonly used microbiological media. They grow well in brain heart infusion broth supplemented with 0.07% lecithin and 0.5% Tween 80 (BHIS broth) and on brain heart infusion agar (BHIA) with 5% rabbit blood at 37 °C.

Maintenance procedures

Alloiococcus otitis grows in brain heart infusion broth with 0.07% lecithin and 0.5% Tween80 (BHIS broth) and on brain heart infusion agar (BHIA) or heart infusion agar (HIA) with 5% rabbit blood. Most strains do not grow on trypticase soy agar with 5% sheep blood or in thioglycolate or Todd–Hewitt broths. Strains can be stored on cryogenic beads at –70 °C or lyophilized for long-term preservation.

Taxonomic comments

The first strains of *alloiococci* were isolated from typanocentesis fluid collected from middle ears of children suffering from otitis media (Faden and Dryja, 1989). Based on the results of a phylogenetic study by Aguirre and Collins (1992a), a new genus and species *Alloiococcus otitis*, was proposed. Phylogenetically, *Alloiococcus otitis* is a member of the family *Carnobacteriaceae*, order *Lactobacillales* in the phylum *Firmicutes*, according to the revised roadmap to Volume 3 of the *Systematics* (Ludwig et al., this volume). *Dolosigranulum pigrum* is the nearest taxonomically named phylogenetic relative of *Alloiococcus*. However, several cloned 16S rDNA sequences derived from some uncultured bacteria associated with the sheep mite *Psoroptes ovis* display a closer phylogenetic affinity (approx. 4% 16S rRNA sequence divergence) with *Alloiococcus* than does *Dolosigranulum pigrum* (Hogg and Lehane, 1999). A tree depicting the phylogenetic relationships of *Alloiococcus otitis* is shown in Figure 102.

Differentiation of the genus *Alloiococcus* from other genera

Alloiococci can be readily identified in the routine laboratory. Using conventional tests (Facklam and Elliott, 1995), they resemble *Dolosigranulum*, *Ignavigranum*, and *Facklamia* species in being susceptible to vancomycin, nonmotile, pyrrolidonyl- β -naphthylamide and leucine aminopeptidase-positive, growing in 6.5% NaCl broth, not growing at 10 or 45 °C, having a negative bile-esculin reaction, and showing α - or γ -hemolytic reaction on sheep blood (LaClaire and Facklam, 2000b). *Alloiococci*, however, can be readily distinguished from these other taxa by not growing anaerobically and by their fastidious growth requirements. In addition, *alloiococci* do not produce acid from carbohydrates.

FIGURE 102. Neighbor-joining tree based on 16S rRNA sequences depicting the phylogenetic position of *Alloiococcus otitis* among its close relatives. Bootstrap values determined from 500 replicates.

List of species of the genus *Alloiococcus*

1. ***Alloiococcus otitis*** Aguirre and Collins 1992a, 83^{VP}

o.ti'tis. N.L. gen. n. *otitis* of ear inflammation.

The species epithet of *Alloiococcus otitis* is incorrect and should be *otitidis* (of the ear inflammation) (Von Graevenitz, 1993).

This proposed change has, however, not been validated.

DNA G+C content (mol%): 44–45 (T_m).

Type strain: 7760, ATCC 51267, CCUG 32997, CIP 103508, NBRC 15545, NCIMB 702890.

GenBank accession number (16S rRNA gene): X59765.

Genus V. ***Atopobacter*** Lawson, Foster, Falsen, Ohlén and Collins 2000, 1758^{VP}

MATTHEW D. COLLINS AND PAUL A. LAWSON

A.to.po.bac'ter. Gr. adj. *atopos* having no place, strange; L. masc. n. *bacter* rod; M.L. masc. n. *Atopobacter* strange rod.

Cells are Gram-stain-positive, short, nonsporeforming, irregular rods. Facultatively anaerobic and catalase-negative. No growth at 45 °C. Gas is not produced. Acid is produced from D-glucose and some other sugars. Arginine dihydrolase, pyroglutamic acid arylamidase, and pyrrolidonyl arylamidase are produced. Esculin, gelatin, hippurate, and urea are not hydrolyzed. Nitrate is not reduced. Voges-Proskauer-negative. The cell-wall murein is type L-ornithine-D-aspartic acid (A4β).

Type species: ***Atopobacter phocae*** Lawson, Foster, Falsen, Ohlén and Collins 2000, 1759^{VP}.

Further descriptive information

The genus contains only one species, *Atopobacter phocae*, and therefore the characteristics provided below refer to this species. Cells consist of short, irregular rods. On Columbia agar supplemented with 5% horse blood, small (pin-sized), gray-colored,

smooth colonies are formed after 24 h at 37 °C. Nonhemolytic. Growth occurs at 25 °C but not at 45 °C. Acid, but no gas, is produced from D-glucose. Acid is also formed from glycogen, maltose, pullulan, and D-ribose. Acid may or may not be formed from cyclodextrin, lactose, sucrose, and trehalose. Acid is not produced from D-arabitol, L-arabinose, mannitol, melibiose, melezitose, methyl-β-D-glucopyranoside, raffinose, sorbitol, tagatose, or D-xylose. Esculin, gelatin, hippurate, and urea are not hydrolyzed. Activity is detected for acid phosphatase, alkaline phosphatase, arginine dihydrolase, esterase C4, ester lipase C8, pyroglutamic acid arylamidase, pyrazinamidase, and pyrrolidonyl arylamidase. Activity is not detected for chymotrypsin, cystine arylamidase, α-fucosidase, α-galactosidase, α-glucosidase, β-glucosidase, β-glucuronidase, glycine tryptophan arylamidase, α-mannosidase, β-mannosidase, lipase C14, N-acetyl β-glucosaminidase, trypsin, or valine arylamidase. Activity for alanyl phenylalanine proline arylamidase, β-galactosidase, and leucine arylamidase may or may not be detected. Nitrate is not reduced. The cell wall contains an L-ornithine-D-aspartic acid type murein (variation A4 β).

Atopobacter phocae was originally recovered from dead common seals (Lawson et al., 2000). The species has, however, been isolated subsequently in mixed culture from an otter head abscess (Foster, Lawson, and Collins, unpublished results). The habitat of *Atopobacter phocae* is not known.

Isolation

Atopobacter phocae has been isolated on sheep blood agar at 37 °C in air or in air plus 5% CO₂. There is no information on enrichment or selective media for this species.

Maintenance procedures

Strains grow well on blood-based agar at 37 °C; they also grow on suitable solid media without blood. Suitable liquid media for growth include brain heart infusion and Todd-Hewitt broth. Strains can be stored on cryogenic beads at -70 °C or lyophilized for long-term preservation.

Taxonomic comments

The genus *Atopobacter* was created by Lawson et al. (2000) to accommodate a novel Gram-stain-positive, facultatively anaerobic, catalase-negative, rod-shaped bacterium isolated from dead common seals. *Atopobacter* forms a distinct phylogenetic subline, within a radiation of taxa that includes *Carnobacterium*, *Desemzia*, *Enterococcus*, *Granulicatella*, *Isobaculum*, *Lactosphaera*, *Melissococcus*, *Tetragenococcus*, and *Vagococcus*. The closest phylogenetic relative of *Atopobacter* based on 16S rRNA gene sequencing appears to be the genus *Granulicatella*, but there is considerable uncertainty in the branching position of *Atopobacter* and bootstrap resampling analysis indicates its association with *Granulicatella* is not statistically significant (Lawson et al., 2000). *Atopobacter* displays 16S rRNA sequence divergence values of greater than 6% with its nearest relatives (i.e., *Carnobacterium*, *Desemzia*, *Enterococcus*, *Granulicatella*, *Isobaculum*, *Lactosphaera*, *Melissococcus*, *Tetragenococcus*, and *Vagococcus*). A tree depicting the phylogenetic relationships of *Atopobacter phocae* is shown in Figure 103.

Differentiation of the genus *Atopobacter* from other genera

Atopobacter phocae can be readily distinguished from its closest phylogenetic relatives using a combination of morphological,

FIGURE 103. Unrooted tree showing the phylogenetic relationships of *Atopobacter phocae* and its closest relatives. The tree was constructed using the neighbor-joining method. Bootstrap values, expressed as a percentage of 500 replications, are given at the branching points.

biochemical, and chemotaxonomic criteria. *Atopobacter phocae* forms rod-shaped cells which distinguish it from *Granulicatella* species, which consist of cocci, occurring singly, in pairs, or in short chains. In addition, some granulicatellae are fastidious and require supplements such as L-cysteine and/or pyridoxal. *Atopobacter phocae* also differs from *Granulicatella* species in forming acid from a broader range of sugars (such as ribose and glycogen). *Atopobacter phocae* can be differentiated from *Lactosphaera pasteurii* as the latter consists of coccus-shaped cells. Also, *Atopobacter phocae* does not produce acid from L-arabinose, mannitol, melezitose, methyl- β -D-glucopyranoside, raffinose, or sorbitol, whereas *Lactosphaera pasteurii* does form acid from these substrates. In addition, *Atopobacter phocae* produces alkaline phosphatase and pyroglutamic acid arylamidase but not α -galactosidase, β -glucosidase, or β -glucuronidase, whereas *Lactosphaera pasteurii* produces the opposite reactions. The cell wall murein type of *Lactosphaera pasteurii* (variation A4

α , type L-lysine-D-aspartic acid) (Janssen et al., 1995) also differs from that of *Atopobacter phocae* (variation A4 β , type L-ornithine-D-aspartic acid) (Lawson et al., 2000). *Atopobacter phocae* can be distinguished from *Desemzia incerta*, another catalase-negative, rod-shaped species, by not hydrolyzing hippurate; producing acid from glycogen, pullulan, and ribose; and by failing to ferment methyl- β -D-glucopyranoside and raffinose. By contrast, *Desemzia incerta* hydrolyzes hippurate and produces acid from methyl- β -D-glucopyranoside and raffinose but not from glycogen, pullulan, or ribose. *Atopobacter phocae* also differs from *Desemzia incerta* by displaying activity for alkaline phosphatase but failing to produce α -galactosidase, β -glucosidase, β -glucuronidase, β -mannosidase, and N-acetyl β -glucosaminidase whereas *Desemzia incerta* produces the opposite reactions. *Desemzia incerta* also differs from *Atopobacter phocae* in possessing a murein based on L-lysine-D-glutamic acid (variation A4 α) (Stackebrandt et al., 1999).

List of species of the genus *Atopobacter*

1. ***Atopobacter phocae*** Lawson, Foster, Falsen, Ohlén and Collins 2000, 1759^{VP}

pho'cae. L. gen. n. *phocae* of or pertaining to the common seal *Phoca vitulina*, from which the organism was first isolated.

Type strain: M1590/94/2, ATCC BAA-285, CCUG 42358, CIP 106392.

GenBank accession number (16S rRNA gene): Y16546.

Genus VI. ***Atopococcus*** VI. Collins, Wiernik, Falsen and Lawson 2005, 1695^{VP}

PAUL A. LAWSON

A.to.po.coc'cus. Gr. adj. *atopos* having no place, strange; Gr. n. *coccus* a grain or berry; N.L. masc. n. *Atopococcus* a strange coccus.

Cells are cocci that occur in pairs or short chains. Gram-stain-positive. Nonmotile and spores are not formed. **Aerobic and catalase-negative.** Optimum growth temperature is 28–32 °C; no growth above 32 °C. **Acid is produced from D-glucose and some other carbohydrates.** Pyroglutamic acid arylamidase is produced. Arginine dihydrolase is not produced. Urease-negative. Nitrate is not reduced. The major long-chain fatty acids are the straight-chain and monounsaturated types. **The cell wall murein contains L-Lys, type A4 α (L-Lys-D-Asp).** Isolated from moist, powdered tobacco.

DNA G+C content (mol%): 46.0.

Type species: Atopococcus tabaci Collins, Wiernik, Falsen, and Lawson 2005, 1695^{VP}.

Further descriptive information

The genus contains only one species, *Atopococcus tabaci*, and therefore the characteristics provided below refer to this species. Grows on Columbia blood agar base supplemented with 5% horse blood. α -Hemolytic on horse blood agar. Grows aerobically but not anaerobically. Optimal growth temperature on tryptic soy agar is 30 °C. Halotolerant, growing in 8–9% NaCl. Using API test kits, acid is produced from glucose, lactose, maltose, ribose, sucrose, and trehalose but not from L-arabinose, D-arabitol, cyclodextrin, glycogen, mannitol, melibiose, melezitose, methyl β -D-glucopyranoside, pullulan, raffinose, sorbitol, tagatose, or D-xylose. Esculin and hippurate are hydrolyzed but not gelatin. Activity is detected for acid phosphatase, esterase C4, β -glucosidase, β -galactosidase, leucine arylamidase, valine arylamidase, pyroglutamic acid arylamidase, and N-acetyl- β -

glucosaminidase. Activity may be detected for alkaline phosphatase, α -glucosidase, and urease. Alanine phenylalanine proline arylamidase, arginine dihydrolase, ester lipase C8, lipase C14, chymotrypsin, trypsin, phosphoamidase, cystine arylamidase, β -glucuronidase, glycol tryptophan arylamidase, α -fucosidase, α -mannosidase, and β -mannosidase are not detected. Nitrate is not reduced, and the Voges-Proskauer test is negative. The fatty acid content is: C_{10:0} (0.7%), C_{12:0} (2.6%), C_{14:0} (8.3%), C_{14:1} (4.5%), C_{16:1^{o9c}} (41.9%), C_{16:0} (15.8%), *iso*-C_{17:1} (5.3%), C_{18:1^{o9c}} (9.0%), and *iso*-C_{19:1} (1.9%). No respiratory quinones were detected using TLC and HPLC as described by Collins et al. (1977). The cell wall contains A4 α -type murein composed of L-Lys-L-Glu (for nomenclature, see Schleifer and Kandler, 1972). The amino acids lysine, alanine, and glutamic acid are present in molar ratios of 1.0 Lys:1.9 Ala:2.4 Glu. The partial hydrolysate contains the peptides L-Ala-D-Glu and L-Lys-D-Ala. Dinitrophenylation reveals that the N-terminus of the interpeptide bridge is glutamate. Since the peptide D-Ala-D-Glu was not detected, it is likely that the N-terminal glutamic acid is of the L-configuration. The only known source from which *Atopococcus tabaci* has been isolated is powdered tobacco (Collins et al., 2005).

Isolation procedures

Atopococcus tabaci was isolated from a sample of moist snuff tobacco from an undisclosed industrial source and was cultured on Columbia blood agar base supplemented with 5% horse blood at 37 °C under aerobic conditions. There is no information on enrichment or selective media for this species.

Maintenance procedures

Strains grow well on Columbia blood agar base supplemented with 5% horse blood at 37 °C under aerobic conditions. For long-term preservation, strains can be maintained in the same medium containing 15–20% glycerol at –70 °C or lyophilized.

Taxonomic comments

The genus *Atopococcus* was created to accommodate a phylogenetically distinct Gram-stain-positive, aerobic, catalase-negative, coccus originating from tobacco (Collins et al., 2005). Phylogenetic analysis using 16S rRNA gene sequences shows that *Atopococcus tabaci* is related to the *Lactobacillales* of the *Firmicutes*. In particular, the organism forms a loose cluster with *Alkalibacterium*, *Alloiococcus*, *Allofustis*, *Atopostipes*, *Dolosigranulum*, and *Marinilactibacillus*, within the family *Carnobacteriaceae* (Figure 3, Ludwig et al., this volume).

Differentiation of the genus *Atopococcus* from other genera

In addition to differentiation by 16S rRNA gene sequence analysis, a combination of morphology, biochemical, and chemotaxonomic criteria is used to distinguish *Atopococcus tabaci* from its closest phylogenetic relatives, *Alkalibacterium* species,

Alloiococcus otitis, *Allofustis seminis*, *Atopostipes suicloacale*, *Dolosigranulum pigrum*, and *Marinilactibacillus* species. In particular, it can be distinguished from *Alkalibacterium olivoapooliticus* and *Marinilactobacillus psychrotolerans* because it is not alkaliphilic or rod-shaped. In addition, the cell walls of *Atopococcus tabaci* possess L-lysine (type L-Lys–L-Glu) whereas the walls of *Alkalibacterium olivoapooliticus* and *Marinilactobacillus psychrotolerans* contain ornithine as their dibasic amino acid (types Orn–D-Asp and Orn–D-Glu, respectively) (Ishikawa et al., 2003; Ntougias and Russell, 2001). Similarly, *Atopococcus tabaci* differs from *Alloiococcus otitis*, *Allofustis seminis*, and *Dolosigranulum pigrum* in having a growth temperature optimum of 30 °C. These other species all grow optimally at 37 °C (Aguirre and Collins, 1992a; Aguirre et al., 1993; Collins et al., 2003). In addition, *Alloiococcus otitis* is nutritionally very fastidious, and *Dolosigranulum pigrum* possesses the L-Lys–D-Asp type of cell wall murein (Aguirre and Collins, 1992a; Aguirre et al., 1993; Miller et al., 1996). *Allofustis seminis* is further differentiated from *Atopococcus tabaci* by its rod shape and cell-wall murein composed of directly cross-linked L-Lys (Collins et al., 2003). *Atopococcus tabaci* is also easily differentiated from *Atopostipes suicloacale*, which is a facultative anaerobe that requires rumen fluid for growth (Cotta et al., 2004b)

List of species of the genus *Atopococcus*

1. *Atopococcus tabaci* Collins, Wiernik, Falsen and Lawson 2005, 1695^{VP}

ta.ba'ci. N.L. gen. neut. n. *tabaci* of/from tobacco.

Cells stain Gram-positive, are coccoid in shape, and occur in pairs or short chains. Endospores are not formed, and cells are nonmotile. Aerobic. Catalase-negative. Acid is produced from glucose and some other sugars. Nitrate is not

reduced, and the Voges–Proskauer test is negative. The predominant long-chain fatty acids are C_{14:0}, C_{16:1 ω 9c}, C_{16:0}, and C_{18:1 ω 9c}. Other characteristics are as given for the genus. Isolated from powdered tobacco.

DNA G+C content (mol%): 46.0 (HPLC).

Type strain: CCUG 48253, CIP 108502, DSM 17538.

GenBank accession number (16S rRNA gene): AJ634917.

Genus VII. *Atopostipes* Cotta, Whitehead, Collins and Lawson 2004a, 1425^{VP} (Effective publication: Cotta, Whitehead, Collins and Lawson 2004b, 193.)

TERENCE R. WHITEHEAD, PAUL A. LAWSON AND MICHAEL A. COTTA

A.to.po.sti'pes. Gr. adj. *atopos* having no place, strange; L. masc. n. *stipes* rod; N.L. masc. n. *Atopostipes* a strange rod, referring to its distinct phylogenetic position.

Cells are short rods. Gram-stain-positive. Nonmotile and spores are not formed. **Facultatively anaerobic and catalase-negative.** Optimum growth temperature is 28–32 °C; **no growth occurs above 32 °C.** **Acid is produced from D-glucose and some other carbohydrates.** The end products of glucose metabolism are lactate, acetate, and formate. Urease-negative. Nitrate is not reduced. Indole is not formed. The cell-wall murein **contains L-Lys, type A4 α (L-Lys–D-Asp).** Isolated from swine manure.

DNA G+C content (mol%): 43.9.

Type species: *Atopostipes suicloacalis* Cotta, Whitehead, Collins and Lawson 2004a, 1425^{VP} (Effective publication: Cotta, Whitehead, Collins and Lawson 2004b, 194) (*Atopostipes suicloacale* [sic] Cotta, Whitehead, Collins and Lawson 2004b, 194).

Further descriptive information

The genus contains only one species, *Atopostipes suicloacalis*, and therefore the characteristics provided below refer to this species.

Grows on brain heart infusion agar supplemented with 10% rumen fluid. Cells are nonmotile rods. Colonies are pinhead to 0.5 mm in diameter, gray, smooth, circular, and entire after 48 h of incubation. Optimum growth temperature is 28–30 °C, with no growth observed above 32 °C. Acid is produced from glucose, and end products of glucose metabolism are lactate, acetate, and formate. Amygdalin, cellobiose, esculin, glucose, lactose, maltose, mannose, raffinose, and sucrose are utilized as carbon sources; grows weakly on lactate. Arabinose, cellulose, inulin, inositol, melibiose, rhamnose, sorbitol, trehalose, and xylose are not utilized as carbon sources. α -Arabinosidase, α -galactosidase, β -glucosidase, and N-acetyl- β -glucosaminidase activities are found in cells grown on glucose; in addition, β -galactosidase and 6-phospho- β -galactosidase are detected from cells grown on lactose. Arginine dihydrolase, arginine arylamidase, alkaline phosphatase, alanine arylamidase, α -fucosidase, α -glucosidase, β -glucuronidase, glycine arylamidase, glutamic acid decarboxylase, glutamyl glutamic acid arylamidase,

histidine arylamidase, leucine arylamidase, leucyl glycine arylamidase, phenylalanine arylamidase, proline arylamidase, pyrroglutamic acid arylamidase, serine arylamidase, tyrosine arylamidase, and urease are not produced. Nitrate is not reduced and indole is not produced. The only known source from which *Atopostipes suicloacalis* has been isolated is swine manure (Cotta et al., 2004b).

Isolation procedures

Atopostipes suicloacalis was isolated from a manure storage pit near Eureka, Illinois, USA. A manure sample was serially diluted and plated onto medium containing 40% clarified rumen fluid under anaerobic conditions (Cotta et al., 2003). There is no information on enrichment or selective media for this species.

Maintenance procedures

Strains grow well on routine growth medium (RGM; Cotta et al., 2003) containing 40% rumen fluid at 30 °C. For long-term

preservation, strains can be maintained in medium containing 15–20% glycerol at –70 °C or lyophilized.

Taxonomic comments

The genus *Atopostipes* was created in 2004 to accommodate a phylogenetically distinct catalase-negative, Gram-stain-positive, rod-shaped bacterium originating from stored swine manure (Cotta et al., 2004b). Phylogenetic analysis using 16S rRNA gene sequences shows that *A. suicloacalis* is related to the *Lactobacillales* of the *Firmicutes*. In particular, the organism forms a loose cluster with *Alkalibacterium*, *Alloiococcus*, *Allofustis*, *Atopococcus*, *Dolosigranulum*, and *Marinilactibacillus*, within the family *Carnobacteriaceae* (Figure 104). It is clear from phylogenetic molecular profiling studies of environmental samples that, in addition to the diverse group of named organisms, some isolates and cloned sequences corresponding to as-yet uncultivated organisms are present in this phylogenetic grouping.

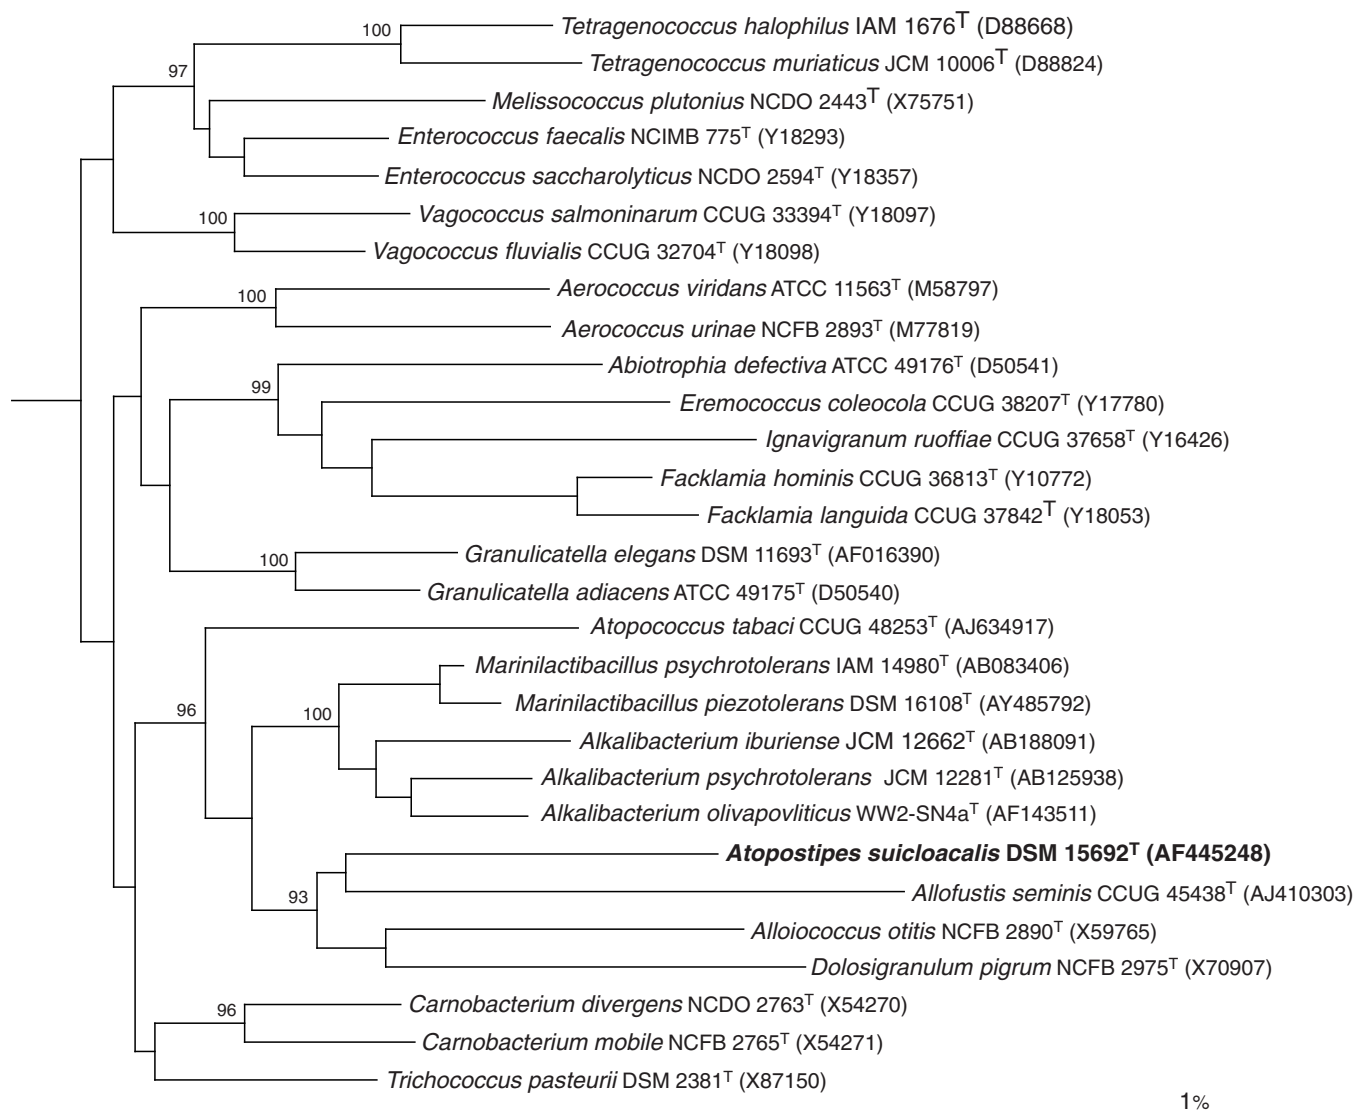

FIGURE 104. Unrooted phylogenetic tree of the 16S rRNA genes of *Atopostipes suicloacalis* and the lactic acid bacteria supra-generic cluster including the members of the families *Carnobacteriaceae*, *Aerococcaceae*, and *Enterococcaceae*. The phylogenetic tree was calculated by the neighbor-joining method. Bootstrap values greater than 90 are indicated. Bar = 1% sequence divergence.

Furthermore, many of the sequences cloned possess high similarity to those cloned from both animal and human sources (Leser et al., 2002; Paster et al., 2001). These sequences may represent novel taxa, including additional species of *Atopostipes*, that have not yet been described.

Differentiation of the genus *Atopostipes* from other genera

In addition to differentiation by 16S rRNA gene sequence analysis, *Atopostipes suicloacalis* can be readily distinguished from its closest phylogenetic relatives, *Alkalibacterium* species, *Alloiococcus otitis*, *Allofustis seminis*, *Atopococcus*, *Dolosigranulum pigrum*, and *Marinilactibacillus* species, using a combination of morphological, biochemical, and chemotaxonomic criteria.

Atopostipes suicloacalis differs from *Alkalibacterium* and *Marinilactibacillus* in cell-wall murein content: the former contains peptidoglycan type A4 α (L-Lys-D-Asp), whereas the latter two contain A4 β (Orn-D-Asp or Orn-D-Glu, Ishikawa et al., 2003; for nomenclature see Schleifer and Kandler, 1972). In addition, *Alkalibacterium* species are obligate alkalophiles, growing within a pH range of 8.5–10.8, with optimum growth at pH 9–10 (Ntougias and Russell, 2001). Similarly, *Alloiococcus otitis*, *Allofustis seminis*, and *Dolosigranulum pigrum* differ from *Atopostipes suicloacalis* in having higher growth temperature optima of around 37 °C and ovoid or coccoid morphologies (Aguirre and Collins, 1992a; Aguirre et al., 1993; Collins et al., 2003).

List of species of the genus *Atopostipes*

1. ***Atopostipes suicloacalis*** Cotta, Whitehead, Collins and Lawson 2004a, 1425^{VP} (Effective publication: Cotta, Whitehead, Collins and Lawson 2004b, 194.) (*Atopostipes suicloacale* [sic] Cotta, Whitehead, Collins and Lawson 2004b, 194.)

su.i.clo.a.ca'lis. L. n. *su* pig; L. adj. *cloacalis* -e pertaining to a sewer (manure canal); N.L. masc. n. *suicloacalis* pertaining to pig manure, referring to the isolation of the type strain.

Cells are short rods that stain Gram-stain-positive. No spores are observed and cells are nonmotile. Colonies

are pinhead to 0.5 mm in diameter, gray, smooth, circular, and entire after 48 h incubation on brain heart infusion agar supplemented with 10% rumen fluid. Optimum growth temperature is 28–30 °C, with no growth above 32 °C. Other characteristics are as given for the genus. Isolated from swine manure.

DNA G+C content (mol%): 43.9 (T_m).

Type strain: PPC79, NRRL 23919, DSM 15692.

GenBank accession number (16S rRNA gene): AF445248.

Genus VIII. *Desemzia* Stackebrandt, Schumann, Swiderski and Weiss 1999, 187^{VP}

ERKO STACKEBRANDT

De.sem'zi.a. N.L. fem. n. *Desemzia* arbitrary name, derived from the abbreviation DSMZ (Deutsche Sammlung von Mikroorganismen und Zellkulturen)

Short rods, occurring singly and occasionally in pairs. Gram-stain-positive. Cells from older cultures tend to lose the ability to retain the Gram stain. Microaerophilic. Nonsporeforming. Not acid-fast. Catalase-negative, oxidase-negative. Metabolism fermentative. **Peptidoglycan contains lysine as the diagnostic amino acid (peptidoglycan type L-lysine-D-glutamic acid; variation A4 α).** Mycolic acids and isoprenoid quinones absent. **Straight-chain saturated and monounsaturated fatty acids, hexadecanoic (C_{16:0}), hexadecenoic (C_{16:1}) and cis-vaccenic (C_{18:1 ω 7}) predominate.** The DNA G+C content is 40 mol%. Phylogenetically, a member of the family *Carnobacteriaceae*, order *Lactobacillales*, phylum *Firmicutes*, the genus *Carnobacterium* is the closest phylogenetic neighbor.

Type species: ***Desemzia incerta*** (Steinhaus 1941) Stackebrandt, Schumann, Swiderski and Weiss 1999, 187^{VP} ("*Bacterium incertum*" Steinhaus 1941; *Brevibacterium incertum* Breed 1953, 14.).

Sources of data

Morphological, cultural and physiological properties described below were published by Stackebrandt et al. (1999) who combined new data with the original data of Steinhaus (1941), Breed (1953) and Jones and Keddie (1986). Some physiological data and the Riboprint™ patterns were generated for this chapter. The chemotaxonomic data have been published by Schleifer and Kandler (1972) and Collins and Kroppenstedt (1983) while the phylogenetic data originate from Stackebrandt et al. (1999), reanalyzed for this study.

Further taxonomic information

As the genus currently contains a single species only, the description of the genus is that of the species. Only the type strain DSM 20581^T (=ATCC 8363^T, NCIB 9892^T) has been analyzed in detail.

Phylogenetic analysis of the 16S rDNA indicates the genus *Desemzia* to be closely related to some genera of *Lactobacillus*–*Streptococcus* group of the *Firmicutes* (Stackebrandt et al., 1999); and in the revised roadmap for Volume 3 of the *Systematics* (Ludwig et al., this volume), it has been classified as a member of the family *Carnobacteriaceae*, order *Lactobacillales*, in the phylum *Firmicutes*. Comparison of the almost complete 16S rDNA of strain DSM 20581^T (1510 bp; 98% of the *Escherichia coli* sequence, Brosius et al., 1978) to the homologous sequences of members of this group revealed that *Desemzia incerta* shows the highest similarity values to members of the genus *Carnobacterium* Collins et al. (1987) (95.1–96.2% sequence similarity), while those to members of *Enterococcus*, *Lactobacillus*, *Tetragenococcus*, *Trichococcus*, *Vagococcus*, *Weissella*, and related genera are distinctively lower (91–94.3% similarity). Phylogenetic dendrograms, reconstructed from evolutionary distance values (Jukes and Cantor, 1969), using the algorithm of De Soete (1983) and the neighbor-joining method (Felsenstein, 1993) shows *Desemzia incerta* to branch close to the deepest bifurcation point of *Carnobacterium* species. High bootstrap values found for the branching point of *Desemzia incerta* supports this phylogenetic affiliation (Figure 105, right dendrogram).

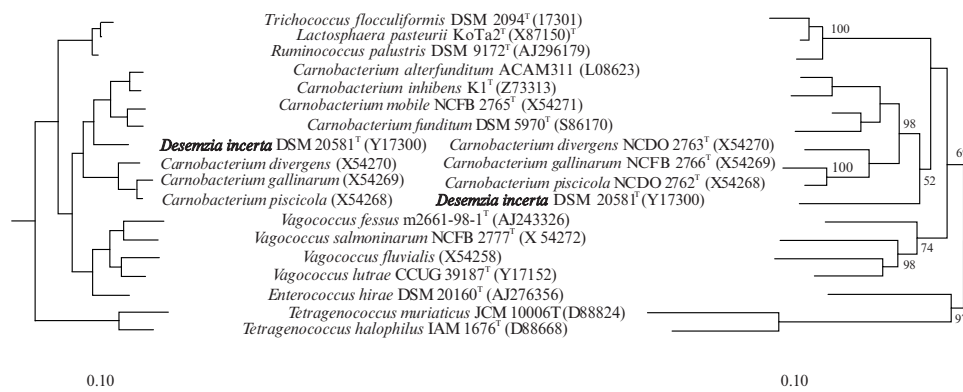

FIGURE 105. 16S rDNA sequence based phylogenetic dendrograms comparing the phylogenetic position of *Desemzia incerta* and related taxa by two different algorithms inferring phylogenetic relatedness. Phylogenetic analysis and 16S rDNA accession numbers of reference organisms have been described by Wallbanks et al. (1990), Franzmann et al. (1991), and Stackebrandt et al. (1999). Right dendrogram: Distance matrix algorithm of De Soete (1983). Bootstrap values (expressed as percentages of 100 replications) of 55% and higher are indicated at the branch points. Scale bar = 10 inferred nucleotide substitutions per 100 nucleotides. Left dendrogram: maximum-likelihood analysis (Felsenstein, 1993).

Using the same dataset but applying the maximum-likelihood analysis (Felsenstein, 1993) members of *Carnobacterium* form two groups, separated by the *Desemzia* lineage (Figure 105, left dendrogram). While the first group contains *Carnobacterium alterfunditum*, *Carnobacterium inhibens*, *Carnobacterium mobile* and *Carnobacterium funditum*, the other group contains *Carnobacterium divergens*, *Carnobacterium gallinarum*, and *Carnobacterium piscicola*. Analysis of the 16S rDNA primary structures of the carnobacteria species indeed show the occurrence of a small set of mutually exclusive nucleotides which would support the phylogenetic separation (Table 103). On the other hand, sufficient nucleotides exist which demonstrates the phylogenetic uniqueness of *Desemzia incerta* (Table 104).

Riboprint™ analyses of *Desemzia inserta* and *Carnobacterium* species (Figure 106) reveals that the patterns of all type strains of the two genera are distinct. Whether they are species-specific can only be assessed when more strains of the species were included in Riboprint™ analyses.

Physiological reactions of strain DSM 20581^T towards the substrate panel provided by the API ID32 Strep kit (API bioMérieux, Marcy l'Étoile, France) gave the following positive results: acid production from ribose, lactose, trehalose, raffinose, maltose, melibiose; sucrose; acids are not produced from mannitol, sorbitol, L-arabinose and melizitose. The reaction for fructose is different to that reported by Steinhaus (1941). Tests for β-glucosidase, β-glucuronidase, α-galactosidase, glycytryptophan arylamidase, and β-mannosidase were positive, whereas tests for arginine dehydrolase, β-glucosidase, and β-galactosidase were negative. Acetoin production was negative. Using the API ZYM system, strain DSM 20581^T hydrolyzed 2-naphtyl-butyrates, L-leucyl-2-naphtylamide and N-glutaryl-phenylalanine-2-naphtylamide. The Biolog identification system GP MicroPlate™ incubated under an atmosphere of 85% N₂ and 15% O₂, revealed that the following substrates were utilized: D-fructose, D-glucose, L-lactic acid, maltose, maltotriose, D-melibiose, D-mannose, D-trehalose, D-psicose, α-methyl D-glucoside and N-acetyl-D-glucosamine (reading after 48h of

incubation). Substrates not utilized are listed in the species description. These data complement physiological and nutritional data given by Steinhaus (1941), Breed (1953) and Jones and Keddie (1986).

DNA–DNA reassociation values obtained for four *Carnobacterium* species that showed higher than 96.5% 16S rDNA sequence similarity (Collins et al., 1987) were lower than 45%. These low values clearly supported the validity of these species and without performing DNA-hybridization experiments between *Desemzia incerta* and the type strains of *Carnobacterium* species it was concluded on the basis of even lower 16S rDNA similarities that the species status of *Desemzia incerta* is confirmed.

Large amounts of inoculum of *Desemzia incerta* killed guinea pigs in 10–15d but the organism was not pathogenic for rabbits (experiments performed with the original strain No. 41, originally classified as *Bacterium incertum* Steinhaus (1941). The pathogenic characteristics did not resemble those of *Listeria monocytogenes* and the ocular reaction indicative of *Listeria monocytogenes* was negative (Steinhaus, 1941).

Enrichment and isolation procedures

The following procedure has been indicated by Steinhaus (1941). The insect, *Tibicen linnei*, was etherized and the wings clipped off near the base. After washing the body for 1–2 min in a solution of 1:1000 mercuric chloride in 80 % alcohol, it was rinsed thoroughly in four washings of sterile saline. The sides of the abdomen were cut from near the posterior end up to the thorax with a pair of fine scissors which had been flamed. The top of the abdomen immediately back of the thorax was cut across, the resulting flap was then tilted back to leave the abdominal viscera exposed and the ovaries were examined. The ovaries were placed either directly on media in Petri dishes or into tubes of sterile saline to be streaked out on nutrient agar, glucose agar, North's gelatin chocolate agar (defibrinated blood added to medium at 80 °C) and blood agar and cultivated at 37 °C.

The pattern was generated by the Riboprint™ robot (Qualicon, Wilmington, Delaware, USA), in which DNA was cleaved by *Eco*RI, the resulting fragments were separated on a membrane and fragments of the *rrn* operons visualized by hybridization with a fluorescent *rrn* operon probe. The scale bar on top of the fragments indicate the length (in kb) of the fluorescence-positive fragments.

Maintenance procedures

Desemzia incerta is routinely maintained in the DSMZ-German Collection of Microorganisms and Cell Cultures in medium DSM 240 at 30 °C (DSMZ, 1998). Medium 240 is listed as “*Corynebacterium* medium with blood”, containing per liter distilled 10.0 g water casein peptone, tryptic digested, 5.0 g yeast extract, 5.0 g glucose, 5.0 g NaCl and agar 15.0 g, pH 7.2–7.4. Following sterilization and cooling to about 45 °C, 5% defibrinated blood is added. The culture can be maintained long term under liquid nitrogen or freeze-dried.

The organism grows well on Columbia blood agar (Benson Dickenson, no. 4354005) within 24 h, while good growth is also observed in Caso medium (Oxoid, no. CM 129) and in PYG medium (DSM catalog of strains, medium no. 104) after 48 h. L-Lactate but no D-lactate (Hohorst, 1966) is produced from glucose in the latter two media, lowering the pH to 6.3. Growth temperature range on Columbia blood agar confirmed the data given by Jones and Keddie (1986).

Differentiation of *Desemzia* from other taxa

Desemzia incerta resembles *Carnobacterium* species in morphology, fermentative metabolism, base composition of DNA, and the composition of fatty acids, comprising predominantly straight-chain saturated and monounsaturated acids (Collins et al., 1987; Collins and Kroppenstedt, 1983). While neither phylogenetic analyses nor physiological and morphological properties of per se exclude the reclassification of *Desemzia incerta* as a member of *Carnobacterium* (Figure 105), the marked differences in the composition of the peptidoglycan and in the isomeric type of octadecenoic acid as predominant fatty acid are interpreted as being of sufficient high taxonomic significance to maintain the classification the genus *Desemzia* (Stackebrandt et al., 1999). *Desemzia incerta* and *Carnobacterium* species differ significantly in the amino acid composition of peptidoglycan. While *Desemzia incerta* possesses peptidoglycan of the L-lysine–D-glutamic acid type, variation A4 α (Schleifer and Kandler, 1972), carnobacteria exhibit the meso-diaminopimelic acid direct cross-linked type, variation A1 γ (Collins et al., 1987). Likewise, *Desemzia incerta* contains major amounts of vaccenic acid (C_{18:1 ω 7}), while *Carnobacterium* species contain oleic acid (C_{18:1 ω 9}) as the octadecenoic acid isomer. *Desemzia incerta* lacks isoprenoid quinones (Collins and Kroppenstedt, 1983) using high-performance liquid chromatography as described by Groth et al. (1996) and electron-impact mass spectrometry (Collins, 1994). None of the substances extracted by a method developed for lipoquinone analysis (Tindall, 1990) gave rise to chromatographic patterns of menaquinones or ubiquinones or to mass spectral nuclear fragments or molecular ions characteristic for isoprenoid quinones (Collins, 1994). No data on isoprenoid quinones are available for species of *Carnobacterium*.

The type strain of *Desemzia incerta* can be distinguished from the type strains of *Carnobacterium* species by several physiological

reactions in which substrates are provided by the Biolog GP MicroPlate™ panel (Table 105).

Taxonomic comments

In the course of a study on bacteria isolated from seven orders of the class *Hexapoda*, a Gram-stain-positive bacterium was isolated by Steinhaus (1941) from the ovaries of the lyreman cicada, *Tibicen linnei*. Although the physiologic and cultural characteristics resembled those of the genus *Listeria* the isolate was tentatively classified as *Bacterium incertum* due to the taxonomic uncertainty which surrounded the *Listeria* group (Steinhaus, 1941) at that time. Breed (1953) transferred this species to the genus *Brevibacterium* as *Brevibacterium incertum* which over the years became a dumping ground for misclassified strains with superficial morphological and physiological similarities. Mainly on chemotaxonomic and phylogenetic grounds several species have been transferred to other genera such as *Arthrobacter* (*Brevibacterium protophormiae* (Stackebrandt et al., 1983), *Aureobacterium* (now *Microbacterium*, Takeuchi and Hatano, 1998) (*Brevibacterium saperdae*, *Brevibacterium testaceum* (Collins et al., 1983a), *Cellulomonas* (*Brevibacterium fermentans*,

Brevibacterium lyticum (Stackebrandt et al., 1982), *Curtobacterium* (*Brevibacterium albidum*, *Brevibacterium citreum*, *Brevibacterium luteum*, *Brevibacterium pusillum* (Yamada and Komagata, 1972), *Corynebacterium* (*Brevibacterium ammoniagenes* (Collins, 1987), *Brevibacterium divaricatum*, *Brevibacterium vitarumen* (Laneelle et al., 1980), *Exiguobacterium* (*Brevibacterium acetylicum* (Farrow et al., 1994), and *Microbacterium* (*Brevibacterium imperiale* (Collins et al., 1983b), *Brevibacterium oxydans* (Schumann et al., 1998). Analysis of the amino acid composition of peptidoglycan of *Brevibacterium incertum* (Schleifer and Kandler, 1972) revealed the presence of L-lysine while strains of the type species *Brevibacterium linens* contained meso-diaminopimelic acid. Subsequent studies on the composition of isoprenoid quinones and fatty acids (Collins and Kroppenstedt, 1983) confirmed the misclassification of *Brevibacterium incertum* as, in contrast to *Brevibacterium linens*, menaquinones were absent and fatty acids contained substantial amounts of monounsaturated fatty acids of the *cis*-vaccenic acid series. Collins and Kroppenstedt (1983) pointed out that the lack of isoprenoid quinones suggests a relatedness of *Brevibacterium incertum* to certain other Gram-stain-positive taxa, such as *Erysipelothrix*, *Gemella*, *Lactobacillus*, or *Streptococcus*

which lack respiratory quinones (Collins and Jones, 1981), while the type of fatty acids indicated a relationship to the lactic acid bacteria (see Kroppenstedt and Kutzner, 1978; Collins and Kroppenstedt, 1983). Subsequently, the species *Brevibacterium incertum* was listed as species *incertae sedis* in *Bergey's Manual of Systematic Bacteriology* (Jones and Keddie, 1986).

In order to determine the phylogenetic affiliation, the taxonomic position of *Brevibacterium incertum* was analyzed recently with respect to 16S rDNA nucleotide sequence (Rainey et al., 1996), base composition of DNA (Marmur, 1961; Mesbah et al., 1989), and isoprenoid quinones (Groth et al., 1996; Tindall, 1990). As a result of these studies *Brevibacterium incertum* was reclassified as *Desemzia incerta* by Stackebrandt et al. (1999).

List of species of the genus *Desemzia*

1. ***Desemzia incerta*** (Steinhaus 1941) Stackebrandt, Schumann, Swiderski and Weiss 1999, 187^{VP} ("*Bacterium incertum*" Steinhaus 1941; *Brevibacterium incertum* Breed 1953, 14.)

in.cert'ae. L. fem. adj. *incerta* not firmly established, uncertain, undetermined, doubtful, dubious.

The description includes data compiled by Jones and Keddie (1986), Stackebrandt et al. (1999) and data generated in this study.

Short rods about 0.5–0.8 by 1.0–1.5 µm, with rounded ends and cocco-bacillary forms. Occur singly, in pairs or in chains. Gram-stain-positive; cells from older cultures tend to lose the ability to retain the Gram-stain. Not acid-fast. Endospores are not formed. Motile with one or two flagella. After 48 h generally nonmotile. On PYE media colonies are tiny with no distinctive pigmentation. On chocolate agar colonies are filiform, thin, and transparent; the color of medium changes becoming yellowish-green. On blood agar alpha hemolysis at first; after 3 d very strong beta hemolysis. Microaerophilic. Metabolism fermentative. L-lactic but no D-lactic acid is produced from glucose. Acid is produced from glucose, fructose, lactose, maltose, mannose, sucrose, raffinose, melibiose, ribose and trehalose. No acid is produced from galactose, rhamnose, mannitol, dulcitol, inositol, sorbitol, L-arabinose and melizitose. D-fructose, D-glucose, L-lactic acid, maltose, maltotriose, D-melebiose, D-mannose, D-trehalose, D-psicose, α-methyl-D-glucoside and N-acetyl-D-glucosamine are

utilized under an atmosphere of 85% N₂ and 15% O₂. The following substrates were not utilized under an atmosphere of 85% N₂ and 15% O₂: dextrin, glycogen, inulin, mannan, Tween 40, Tween 60, N-acetyl-D-mannosamine, amygdalin, L-arabinose, D-arabitol, arbutin, cellobiose, L-fucose, D-galactose, D-galacturonic acid gentobiose, D-gluconic acid, meso-inositol, α-D-lactose, lactulose, D-mannitol, D-melezitose, D-raffinose, L-rhamnose, D-ribose, D-sorbitol, sucrose, xylose, glycerol, acetic acid, propionic acid, pyruvic acid, succinic acid, DL-alanine, L-serine, L-glutamic acid, adenosine, inosine, thymidine, and uridine.

Catalase-negative, oxidase-negative. Sodium hippurate, 2-naphthyl-butylate, L-leucyl-2-naphthylamide and N-glutaryl-phenylalanine-2-naphthylamide are hydrolyzed. Gelatin, casein, and starch are not hydrolyzed. Cellulose is not degraded. Urease is not produced. DNase, arginine dehydrolase, β-glucosidase, and β-galactosidase-negative are not produced. Reactions for β-glucosidase, β-glucuronidase, α-galactosidase, glycyl-tryptophan arylamidase, and β-mannosidase are positive. Acetyl methyl carbinol, indol and H₂S are not produced. Nitrates are not reduced to nitrites. Acetoin production negative. The chemotaxonomic properties are as given for the genus.

Isolated from the ovaries of the lyreman cicada, *Tibicen linnei*.

DNA G+C content (mol%): 40 (HPLC).

Type strain: DSM 20581^T (ATCC 8363, NCIB 9892).

GenBank accession number (16S rRNA gene): Y17300.

- Genus IX. ***Dolosigranulum*** Aguirre, Morrison, Cookson, Gay and Collins 1994, 370^{VP} (Effective publication: Aguirre, Morrison, Cookson, Gay and Collins 1993, 610.)

MATTHEW D. COLLINS

Do.lo.si.gra'nu.lum. L. adj. *dolosus* crafty, deceitful; L neut. n. *granulum* a small grain; N.L. neut. n. *Dolosi-granulum* a deceptive small grain.

Cells are ovoid, occurring in pairs, tetrads, or groups. Gram-stain-positive and nonmotile. Nonsporeforming. Facultatively anaerobic and catalase-negative. **Growth in 6.5% NaCl. No growth at 10 or 45 °C. Negative bile-esculin reaction. Gas is not produced in MRS broth. Acid is produced from D-glucose and some other sugars. Pyrrolidonylarylamidase and leucine aminopeptidase are produced.** Alanine phenylalanine proline arylamidase and urease are negative. **Does not deaminate arginine. Vancomycin-sensitive.** Pyruvate is not utilized. Voges-Proskauer-negative. **Cell-wall murein is based on L-lysine (type Lys-D-Asp).**

DNA G+C content (mol%): 40.5 (T_m).

Type species: ***Dolosigranulum pigrum*** Aguirre, Morrison, Cookson, Gay and Collins 1994, 370^{VP} (Effective publication: Aguirre, Morrison, Cookson, Gay and Collins 1993, 610.)

Further descriptive information

The genus contains only one species, *Dolosigranulum pigrum*, and therefore the characteristics described below refer to this species. Grows on 5% (v/v) horse or sheep blood agar producing a weak α- or γ-hemolytic reaction. Cells are nonpigmented. Some strains grow better in aerobic conditions. Using the API Rapid ID32 Strep system, acid is produced from maltose, and

most strains produce acid from sucrose. Acid is not formed from adonitol, D-arabitol, L-arabinose, cyclodextrin, glycogen, lactose, mannitol, melibiose, melezitose, pullulan, raffinose, sorbitol, tagatose, or trehalose. Acid production from ribose and methyl β -D-glucopyranoside is variable. Activity is detected for β -galactosidase and pyroglutamic acid arylamidase. Activity may or may not be detected for N-acetyl- β -glucosaminidase and glycytryptophan arylamidase. No activity is found for alkaline phosphatase, alanine phenylalanine proline arylamidase, arginine dihydrolase, α -galactosidase, β -glucosidase, β -glucuronidase, β -mannosidase, or urease. Hippurate is not hydrolyzed.

Antimicrobial susceptibilities of 27 strains of *Dolosigranulum pigrum* have been reported by LaClaire and Facklam (2000a). All were susceptible to amoxicillin, cefotaxime, cefuroxime, clindamycin, levofloxacin, meropenem, penicillin, quinupristin-dalfopristin, rifampin, tetracycline, and vancomycin. A single isolate was resistant to trimethoprim-sulfamethoxazole. Fifteen strains showed intermediate resistance to chloramphenicol. Two strains were susceptible, ten showed intermediate resistance, and 15 were resistant to erythromycin.

Strains of *Dolosigranulum pigrum* were originally recovered from spinal cord (removed at autopsy) of a person with acute multiple sclerosis and from eye and lens swabs (Aguirre et al., 1993). The species has also been recovered from other clinical sources such as eye, sputum, nose discharges, urine, and blood (LaClaire and Facklam, 2000a). The habitat of *Dolosigranulum pigrum* is not known.

Isolation procedures

Dolosigranulum pigrum may be isolated on rich agar-containing media such as heart infusion or Columbia agar containing 5% (v/v) animal blood at 37°C, under aerobic or anaerobic conditions. There is no information on selective media for this species.

Maintenance procedures

Strains grow on blood-based agars such as Columbia agar containing 5% (v/v) horse blood, heart infusion agar supple-

mented with 5% (v/v) rabbit blood, or brucella agar with 5% sheep blood. They also grow well in brain heart infusion and Todd-Hewitt broth at 37°C. For long-term preservation, strains can be stored on cryogenic beads at -70°C or lyophilized.

Taxonomic comments

The genus *Dolosigranulum* was described for some *Gemella*-like organisms recovered from human clinical specimens (Aguirre et al., 1993). Phylogenetic analyses presented in the revised road-map to Volume 3 of the *Systematics* (Ludwig et al., this volume) show that *Dolosigranulum* belongs in the family *Carnobacteriaceae*, order *Lactobacillales*, phylum *Firmicutes*. The nearest described phylogenetic relative of *Dolosigranulum* is *Alloiococcus otitis*. Cloned 16S rDNA sequences derived from some uncultured bacteria associated with the sheep mite *Psoroptes ovis* also show a close phylogenetic affinity with *Dolosigranulum* (Hogg and Lehane, 1999).

Differentiation of the genus *Dolosigranulum* from other genera

Dolosigranulum pigrum can be distinguished from other catalase-negative, Gram-stain-positive cocci using a combination of phenotypic tests. Using conventional biochemical tests (see Facklam and Elliott, 1995), *Dolosigranulum pigrum* is pyrrolidonyl- β -naphthylamide (PYR) and leucine aminopeptidase (LAP) positive, grows in 6.5% NaCl broth, does not grow at 10 or 45°C, gives a negative bile-esculin reaction, and does not produce gas (LaClaire and Facklam, 2000b). This combination of characters is not unique to the *Dolosigranulum* genus but is shared by *Alloiococcus*, *Facklamia* species, and *Ignavigranum* (LaClaire and Facklam, 2000b). *Alloiococcus* can be distinguished from *Dolosigranulum* in being fastidious, by not growing anaerobically, and by not producing acid from sugars. *Dolosigranulum pigrum* differs from *Facklamia* species and *Ignavigranum* in conventional tests by hydrolyzing esculin (LaClaire and Facklam, 2000b). Biochemical tests which are useful in distinguishing *Dolosigranulum pigrum* from *Facklamia* species and *Ignavigranum ruoffiae* using the API Rapid ID32 Strep system are shown in Table 106.

 GenBank accession number (16S rRNA gene): X70907.

Genus X. ***Granulicatella*** Collins and Lawson 2000, 367^{VP}

PAUL A. LAWSON

Gra.nu.li.ca.tel'la. L. neut. dim. n. *granulum* small grain; L. fem. dim. n. *catella* small chain; N.L. fem. dim. n. *Granulicatella* small chain of small grains.

Cocci that occur as single cells, in pairs, or in short chains. Gram-stain-positive. Nonmotile. Nonsporeforming. **Facultatively anaerobic. Catalase- and oxidase-negative. Acid but not gas is produced from glucose. No growth at 10 or 45 °C. Pyrrolidonyl arylamidase and leucine arylamidase are produced.** Alkaline phosphatase, α -galactosidase, β -galactosidase, and urease are not produced. Acetoin is not produced. Found as part of the normal oral flora of the human pharynx and the human urogenital and intestinal tracts.

DNA G+C content (mol%): 36–37.5.

Type species: ***Granulicatella adiacens*** (Bouvet, Grimont and Grimont 1989) Collins and Lawson, 2000, 367^{VP} (*Streptococcus adjacens* Bouvet, Grimont and Grimont 1989, 293; *Abiotrophia adiacens* Kawamura, Hou, Sultana, Liu, Yamamoto and Ezaki 1995, 802.).

Further descriptive information

The cell morphology is dependent on the culture conditions. Cocci in pairs or chains are observed under optimal nutritional conditions, but pleomorphic, elongated, swollen cells may be seen when growth conditions are suboptimal.

Some species are fastidious and grow poorly in media used routinely for streptococci, e.g., blood trypticase soy agar, and they require supplements such as L-cysteine and/or pyridoxal. Some grow as satellite colonies adjacent to other organisms such as *Staphylococcus epidermidis*. *Granulicatella elegans* requires L-cysteine and will not grow with only the addition of pyridoxal. *Granulicatella balaenopterae* does not require the addition of pyridoxal or L-cysteine to the blood agar or satellitism to support growth. Usually grow as small alpha-hemolytic colonies on chocolate agar but not on sheep blood agar unless the medium is supplemented or other bacteria are present to provide the compounds required for growth.

The cell-wall murein of *Granulicatella adiacens* is based on L-lysine variation A3 α (type: L-Lys-L-Ala) (Kawamura et al., 1995), whereas the murein of *Granulicatella balaenopterae* is based on L-ornithine variation A4 α (type: L-Orn-D-Asp) (Lawson et al., 1999). The murein type for *Granulicatella elegans* has not been determined (see Schleifer and Kandler, (1972) for nomenclature).

When discussing *Granulicatella* species, it is pertinent to include *Abiotrophia* due to their historical relationships, the habitats from which they are both isolated, and the similarity in phenotypic characteristics which may cause confusion in their initial identification. Both genera form part of the normal oral flora of the human pharynx and the human urogenital and intestinal tracts (Ruoff, 1991). A review of the literature shows

a growing number of case reports in which nutritionally variant streptococci (NVS) have been isolated from a range of sources and are responsible for a number of clinical and veterinary conditions (Christensen and Facklam, 2001). Like other viridans group streptococci, NVS cause sepsis and bacteremia and are responsible for a substantial proportion of cases of infective endocarditis (Bouvet, 1995, 1980, 1981; Ruoff, 1991), including most of the so-called blood-culture negative cases of endocarditis (Casalta et al., 2002; Fournier and Raoult, 1999; Roberts et al., 1979). NVS have been implicated in a variety of other infections that are anatomically related to their natural habitats (Ruoff, 1991), for example, *Abiotrophia defectiva* and *Granulicatella adiacens* were isolated from two elderly patients with vitreous infections following cataract extraction (Namdari et al., 1999). In addition, NVS strains have been isolated from humans with infectious crystalline keratopathy (Ormerod et al., 1991) and from horses with corneal ulcers (Da Silva Curies et al., 1990). In a review of 30 cases of infective endocarditis caused by NVS isolates, Stein and Nelson (1987) noted that the clinical manifestations often were more severe than that in cases caused by enterococci or viridans streptococci. The infections were difficult to treat and had a relapse rate of 41% despite treatment with appropriate antibiotics.

In many laboratories, current methods of identification of organisms rely on phenotypic tests such as those developed in miniaturized biochemical kits including the API ID 32 Strep system (bioMérieux, France). However, a number of potential problems are inherent in the use of these phenotypic tests. Not all strains within a given species may be positive for a common trait (Beighton et al., 1991; Kilian et al., 1989) and a single strain may exhibit biochemical variability (Hillman et al., 1989; Teng et al., 2002). In addition, commercially available products are capable of identifying clinically isolated organisms, but the accuracy of these products for identifying the plethora of recently described genera and species of catalase-negative, Gram-stain-positive cocci is not established. Rapidly changing taxonomy within this group has made it difficult to keep the databases of identification products up-to-date. Tests for some of the phenotypic characteristics used to differentiate new genera and species may not be included in some of the commercially available products. As a result, routine identification based solely on phenotypic tests does not allow for an unequivocal identification of certain species. Consequently, molecular methods are increasingly being used in concert with phenotypic criteria as diagnostic tools in the identification of these organisms. Ohara-Nemoto et al. (1997) used PCR-RFLP using *Hae*III and *Msp*I to detect and discriminate 92 isolates with 11 strains of

Abiotrophia defectiva and 81 strains of *Granulicatella adiacens* from clinical specimens. However, use of this method did not allow the detection and identification of *Abiotrophia* species among bacteria in mixed cultures or the detection of atypical strains or unknown species. Primer sets for detection and identification by PCR have been described and tested by Roggenkamp et al. (1998). Four strains of *Granulicatella elegans*, eight strains of *Granulicatella adiacens*, and three strains of *Abiotrophia defectiva* strains in addition to 57 non-NVS strains were examined and the PCR strategy succeeded in separating NVS strains from non-NVS strains and correctly identifying the NVS strains. Furthermore, Kanamoto et al. (2000) investigated 45 *Abiotrophia* strains (including the type strains of *Abiotrophia defectiva*, *Granulicatella adiacens*, and *Granulicatella elegans*) from endocarditis patients by DNA–DNA hybridization, PCR of genomic DNA sequences, 16S rRNA gene PCR-restriction fragment length polymorphism analysis, 16S rRNA gene sequence homology, and phenotypic characteristics. The endocarditis isolates could be divided into four genetic groups representing the three type strains and a new group closely related to *Granulicatella adiacens*. These investigators proposed that this new group be named “*Abiotrophia para-adiacens*”. The 45 endocarditis isolates were identified as 9 strains of *Abiotrophia defectiva*, 15 strains of *Granulicatella adiacens*, 13 strains of *Abiotrophia para-adiacens*, and 8 strains of *Granulicatella elegans*. Casalta et al. (2002) used PCR and 16S rRNA gene sequencing to identify *Granulicatella elegans* as the pathogen responsible for the damage caused to the cardiac valve of a patient with culture-negative endocarditis. Although sequence data, PCR primers, and probes have, for the most part, been derived from the 16S rRNA genes, alternative chromometers are used in the identification of Gram-stain-positive taxa. For example, *rpoB*, the gene encoding the highly conserved subunit of bacterial RNA polymerase, has previously been demonstrated to be a suitable target on which to base the identification of micro-organisms and has been used to identify enteric bacteria (Mollet et al., 1997). Drancourt et al. (2004) employed a single specific primer pair for PCR and sequencing method based on the sequence of the *rpoB* gene in the molecular identification of aerobic, Gram-stain-positive, catalase-negative species of the genera *Abiotrophia*, *Enterococcus*, *Gemella*, *Granulicatella*, and *Streptococcus*.

In addition to the authentication of the preliminary identification of both *Granulicatella* and *Abiotrophia* strains isolated in the laboratory, molecular tools are increasingly being used as the primary method of identifying these organisms. This is becoming especially relevant in the clinical environment where a high throughput of samples is encountered (Bosshard et al., 2004; Woo et al., 2001). Thus, these extremely powerful tools can unequivocally identify organisms with fastidious nutritional requirements and phenotypic similarities, which would previously have eluded detection using traditional cultivation techniques.

Isolation procedures

Strains can be isolated on blood agar at 37 °C anaerobically or in air enriched with CO₂. Growth occurs in Todd–Hewitt broth or brain heart infusion broth with the addition of 10 mg pyridoxal or 100 mg cystine per liter. *Granulicatella elegans* requires L-cysteine and will not grow with only the addition of pyridoxal. *Granulicatella balaenopterae* does not require the addition of pyridoxal or L-cysteine to the blood agar or satellitism for growth.

Maintenance procedures

Strains can be maintained on agar media (such as heart infusion or Columbia agar) supplemented with blood (5% v/v). Growth occurs in Todd–Hewitt broth or brain heart infusion broth with the addition of 10 mg pyridoxal or 100 mg cystine per liter. For long-term preservation, strains can either be stored at –70 °C on cryogenic beads or lyophilized.

Taxonomic comments

Nutritionally variant streptococci (NVS) were originally described by Frenkel and Hirsch (1961) as a new type of viridans group streptococci that exhibited satellitism around the colonies of other bacteria. Throughout the literature, these organisms have been referred to by a variety of terms, such as NVS (Bouvet et al., 1981; Cooksey et al., 1979), nutritionally deficient streptococci (Bouvet et al., 1980), satelliting streptococci (McCarthy and Bottone, 1974), vitamin B₆-dependent streptococci (Carey et al., 1975), and pyridoxal-dependent streptococci (Roberts et al., 1979) because of their fastidious nutritional requirements. The taxonomic status of these fastidious organisms was greatly clarified by Bouvet et al. (1989), who demonstrated the existence of two distinct species within the NVS by chromosomal DNA–DNA hybridizations; these species were named *Streptococcus adiacens* and *Streptococcus defectivus*. The studies of Bouvet et al. (1989) revealed *Streptococcus adiacens* and *Streptococcus defectivus* shared less than 10% DNA–DNA reassociation with each other and with other streptococcal species. Kawamura et al. (1995) used 16S rRNA gene sequencing to show that *Streptococcus adiacens* and *Streptococcus defectivus* formed a distinct clade that was phylogenetically far removed from the streptococci and proposed these species be transferred to the new genus *Abiotrophia* as *Abiotrophia adiacens* and *Abiotrophia defectiva*, respectively. The phylogenetic separateness of these NVS from authentic streptococci together with nutritional considerations, satellitism, and pyrrolidonyl-arylamidase production were the primary reasons for creating the genus *Abiotrophia*.

It is pertinent to note that in the 16S rRNA sequence analysis conducted by Kawamura et al. (1995), the exclusion of NVS organisms from the genus *Streptococcus* was justified on phylogenetic grounds (e.g., from tree topology considerations and from 16S rRNA sequence divergence values of generally >11% with streptococcal species). Although it was evident from this study (Kawamura et al., 1995) that NVS organisms shared higher 16S rRNA relatedness with certain other catalase-negative taxa (e.g., *Aerococcus*, *Carnobacterium*, and *Enterococcus*) than with streptococci, aside from a 7% 16S rRNA sequence divergence between *Abiotrophia adiacens* and *Abiotrophia defectiva*, there was little evidence to suggest that the newly delineated genus was not monophyletic. Since the description of *Abiotrophia* by Kawamura et al. (1995), however, two further species of this genus have been characterized. *Abiotrophia elegans* (Roggenkamp et al., 1998) was recovered from a patient with endocarditis, and *Abiotrophia balaenopterae* (Lawson et al., 1999) was isolated from a minke whale (*Balaenoptera acutorostrata*). Both new species display a closer phylogenetic affinity with *Abiotrophia adiacens* (16S rRNA sequence divergence approximately 3%) than with *Abiotrophia defectiva* (sequence divergence approximately 7%). With the description of a number of novel taxa, it has become increasingly evident that *Abiotrophia defectiva*, the type species of the genus, is phylogenetically closer to several non-*Abiotrophia*

species including *Globicatella sanguinis*—a chain-forming coccus described by Collins et al. (1992) but not included in the study of Kawamura et al. (1995)—and species of the genera *Dolosicoccus* (Collins et al., 1999a), *Facklamia* (Collins et al., 1997), *Eremococcus* (Collins et al., 1999c), and *Ignavigranum* (Collins et al., 1999b), than to *Abiotrophia adiacens* and its close relatives. It is apparent that the genus is not monophyletic because there are two distinct lines within the *Abiotrophia* genus, namely *Abiotrophia defectiva* and a group comprising *Abiotrophia adiacens*, *Abiotrophia balaenopterae*, *Abiotrophia elegans*, and “*Abiotrophia para-adiacens*”. To reflect these relationships in this particular clade of the phylum *Firmicutes*, Collins and Lawson (2000) created the genus *Granulicatella* to accommodate *Abiotrophia adiacens*, *Abiotrophia balaenopterae*, and *Abiotrophia elegans*, thus restricting the genus *Abiotrophia* to the type species, *Abiotrophia defectiva*. Phylogenetic

tree topologies show that *Granulicatella* belongs to a cluster of organisms that include *Atopobacter phocae* and, more loosely, with members of the genus *Trichococcus* (Figure 107).

Differentiation of the genus *Granulicatella* from closely related genera

Atopobacter phocae can be readily distinguished from its closest phylogenetic relatives using a combination of morphological, biochemical, and chemotaxonomic criteria. *Granulicatella* species form coccus-shaped cells that occur singly, in pairs, or in short chains. These features distinguish *Granulicatella* species from *Atopobacter* species, which consist of rod-shaped cells. In addition, *Granulicatella* also differs from *Atopobacter* in forming acid from a narrower range of sugars (such as ribose and glycogen) and by failing to produce α -galactosidase.

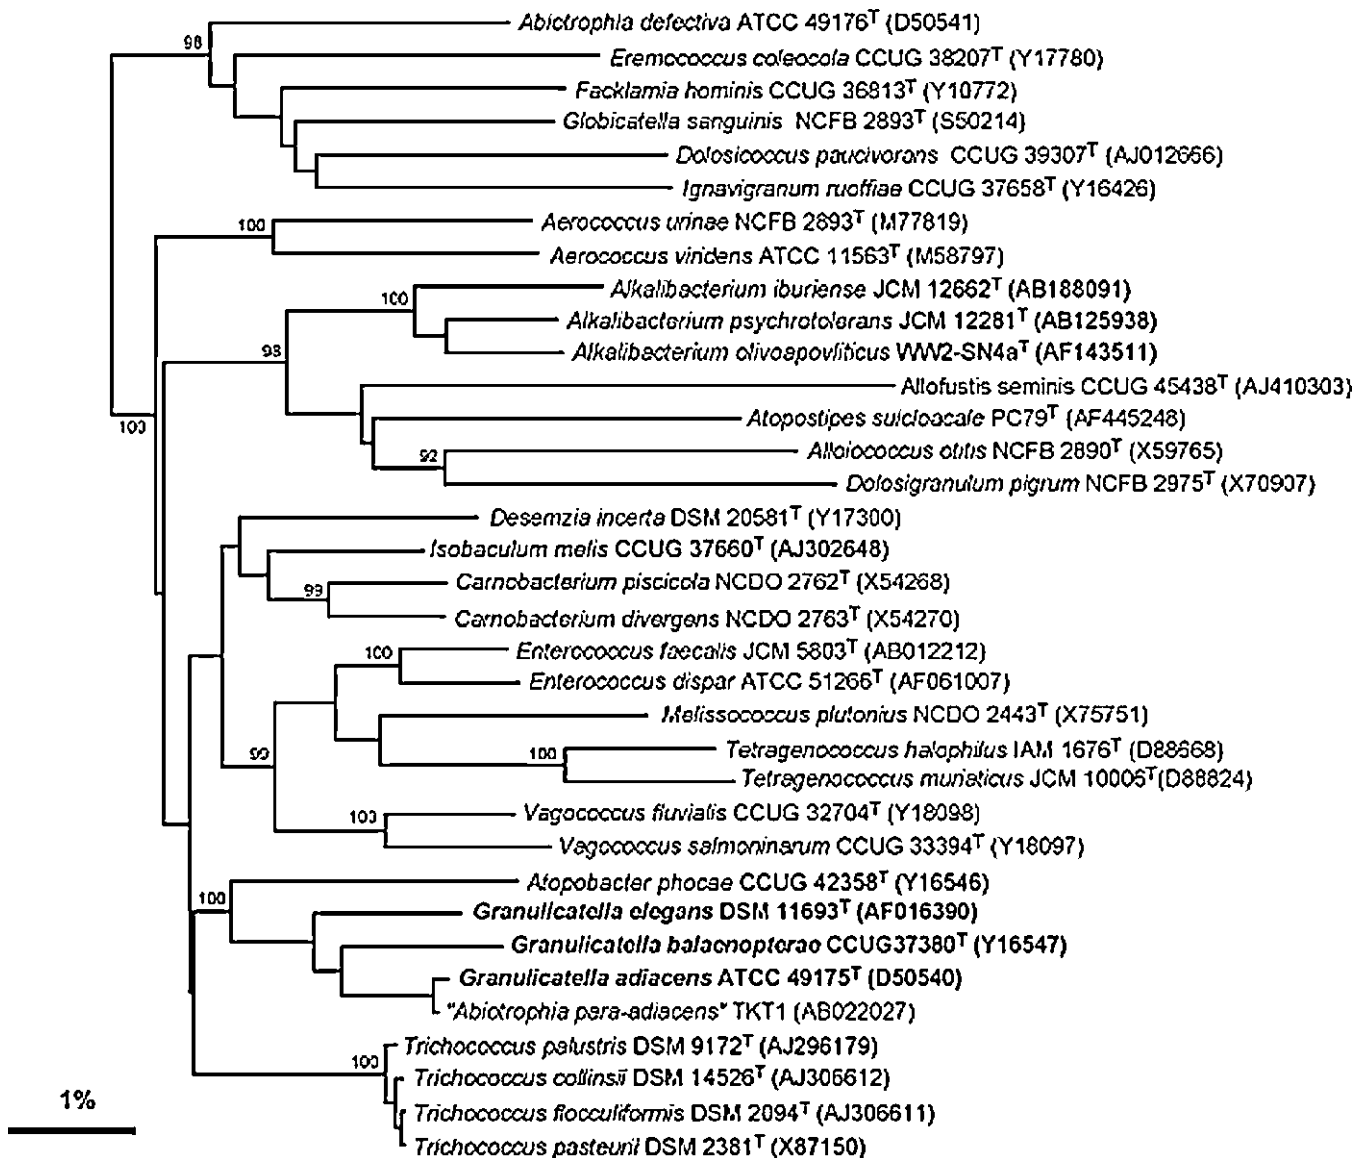

FIGURE 107. Neighbor-joining tree based on 16S rRNA sequences depicting the phylogenetic relationships of *Granulicatella* species and close relatives. Bootstrap values determined from 500 replications.

Granulicatella can be differentiated from *Trichococcus* by not producing acid from lactose and by their cell-wall murein structures. The former possesses either L-Orn-D-Asp (A4 β) or L-Lys-L-Ala (A3 β) whereas the latter contain L-Lys-D-Asp (A4 α). *Granulicatella* also possesses a lower DNA G+C content, with values ranging between 36 and 37.5 mol%, compared to *Trichococcus*, which has values between 45 and 49 mol%. Some granulicatellae are fastidious and require supplements such as L-cysteine and/or pyridoxal, further distinguishing these organisms from *Atopobacter* and *Trichococcus* species. Criteria that are useful in distinguishing the genus *Granulicatella* from phylogenetically closely related taxa are

shown in Table 107. In addition, 16S rRNA gene sequencing serves to discriminate *Granulicatella* clearly from all closely related genera.

Differentiation of the species of the genus *Granulicatella* and *Abiotrophia*

When considering tests that differentiate species of *Granulicatella*, it is pertinent to include *Abiotrophia*, because these two genera may be confused when first isolated in the laboratory. Species of the genus *Granulicatella* and *Abiotrophia* can be distinguished from each other using a number of useful tests that are shown in Table 108.

List of species of the genus *Granulicatella*

1. ***Granulicatella adiacens*** (Bouvet, Grimont and Grimont 1989) Collins and Lawson 2000, 367^{VP} (*Streptococcus adiacens* Bouvet, Grimont and Grimont 1989, 293; *Abiotrophia adiacens* Kawamura, Hou, Sultana, Liu, Yamamoto and Ezaki 1995, 802.)
ad'ia.cens. L. fem. adj. *adiacens* adjacent, indicating that this organism can grow as satellite colonies adjacent to other bacterial growth.

The characteristics are as given for the genus and as listed in Table 107 and Table 108 with the following additional information. Cellular morphology depends upon the conditions of growth; the organism is pleomorphic with chains including cocci, coccobacilli, and globular and rod-shaped cells when grown in cysteine- or pyridoxal-supplemented broth. Small ovoid cocci (diameter 0.4–0.6 μ m) occur singly,

in pairs, or in chains of variable length in CDMT medium. Some tendency towards rod formation is observed in the stationary phase. Facultatively anaerobic with complex growth requirements. Grows as satellite colonies adjacent to *Staphylococcus epidermidis* on horse-blood trypticase soy agar and on stored sheep-blood agar. α -Hemolysis occurs on sheep-blood agar. Tiny colonies up to 0.2 mm in diameter are formed on fresh sheep-blood agar or on blood agar supplemented with pyridoxal or L-cysteine. Growth occurs in Todd-Hewitt broth (THB) enriched with 10 mg pyridoxal or 100 mg cysteine per liter. Growth occurs in CDMT semi-synthetic medium (Bouvet et al., 1981) and a red chromophore can be visualized by boiling the bacterium at pH 2 for 5 min. Lactic acid is the predominant acid produced. Resistant to optochin and susceptible to vancomycin. No production of exopolysaccharide occurs on 5% sucrose. Pyrrolidonyl arylamidase is produced, but alkaline phosphatase, alanine-phenylalanine-proline arylamidase, glycyl-tryptophan arylamidase, α -galactosidase, and β -galactosidase are not produced. Tagatose and sucrose are fermented. D-Ribose, L-arabinose, D-mannitol, melibiose, melezitose, pullulan, sorbitol, lactose, D-rhamnose, trehalose, starch, and glycogen are not fermented. Inulin is fermented by some strains. Some strains produce β -glucuronidase. Leucine aminopeptidase is produced. Arginine and hippurate are not hydrolyzed. Acetoin is not produced. The cell wall is of the A3 α type. Isolated from the throat flora, urine, and blood of patients with endocarditis.

DNA G+C content (mol%): 36.6–37.4 (T_m).

Type strain: GaD, ATCC 49175, CCUG 27637 A, CCUG 27809, CIP 103243, DSM 9848, LMG 14496, NCTC 13000.

GenBank accession number (16S rRNA gene): D50540.

2. **Granulicatella balaenopterae** (Lawson, Foster, Falsen, Sjöden and Collins 1999) Collins and Lawson 2000, 368^{VP} (*Abiotrophia balaenopterae* Lawson, Foster, Falsen, Sjöden and Collins 1999, 505.)

bal.aen.op'ter.ae. N.L. fem. n. *balaenopterae* pertaining to the minke whale, *Balaenoptera acutorostrata*, from which the organism was isolated.

The characteristics are as given for the genus and as listed in Table 107 and Table 108, with the following additional information. Tiny colonies up to 0.2 mm in diameter are formed on blood agar at 37 °C. Facultatively anaerobic. Acid is produced from glucose, maltose, pullulan, and trehalose but not from L-arabinose, D-arabitol, cyclodextrin, glycogen, lactose, mannitol, melibiose, melezitose, D-raffinose, sucrose, sorbitol, tagatose, and D-xylose. Arginine dihydrolase, pyroglutamic acid arylamidase (weak reaction), N-acetyl-glucosaminidase, ester lipase (C4), leucine arylamidase, and urease (weak reaction) activities are detected. Alkaline phosphatase, acid phosphatase, alanine-phenylalanine-proline arylamidase, α -galactosidase, β -galactosidase, β -galacturonidase, β -glucuronidase, glycyl-tryptophan arylamidase, α -mannosidase, chymotrypsin, trypsin, α -fucosidase, and pyrazinamidase activities are not detected. Esculin is hydrolyzed but hippurate and gelatin are not. Nitrate is not reduced. The cell wall contains an L-Orn-D-Asp directly cross-linked murein (type A4 β). Isolated from the minke whale. Habitat is not known.

DNA G+C content (mol%): 37 (HPLC).

Type strain: M1975/96/1, ATCC 700813, CCUG 37380, CIP 105938.

GenBank accession number (16S rRNA gene): Y16547.

3. **Granulicatella elegans** (Roggenkamp, Abele-Horn, Trebesius, Tretter, Autenrieth and Heesemann 1998) Collins and Lawson 2000, 367^{VP} (*Abiotrophia elegans* Roggenkamp, Abele-Horn, Trebesius, Tretter, Autenrieth and Heesemann 1998, 103.)

e'le.gans. L. adj. *elegans* choice, elegant.

The characteristics are as given for the genus and as listed in Table 107 and Table 108, with the following additional information. Cellular morphology is dependent on nutritional state. In sufficiently supplemented nutritional broth, the bacterium appears coccoid in short chains. Lack of appropriate growth factors results in pleomorphism and the appearance of elongated, swollen forms. The organism grows as a facultative anaerobe with complex growth requirements. It grows as satellite colonies adjacent to *Staphylococcus epidermidis* on trypticase soy sheep-blood agar plates, with α -hemolysis. Tiny colonies up to 0.2 mm in diameter are formed on Schaedler sheep-blood agar plates after 48 h, but only minimal growth is visible on chocolate agar plates. Growth occurs at 27 and 37 °C but not at 20 or 42 °C. Growth occurs in THB or casein-soy peptone bouillon when supplemented with 0.01% L-cysteine hydrochloride, but not when supplemented with 0.001% pyridoxal hydrochloride. A red chromophore can be visualized by boiling the microorganism at pH 2 for 5 min. Pyrrolidonyl arylamidase, arginine dihydrolase, and leucine aminopeptidase are produced but alkaline phosphatase, α -galactosidase, β -galactosidase, β -glucuronidase, β -mannosidase, β -glucosidase, glycyl-tryptophan arylamidase, β -mannosidase, and urease are not produced. Hippurate may or may not be hydrolyzed. Raffinose and sucrose may or may not be fermented. Trehalose, inulin, pullulan, tagatose, lactose, starch, glycogen, D-Arabitol, sorbitol, mannitol, melibiose, melezitose, L-arabinose, and ribose are not fermented. Isolated from a patient with endocarditis. Habitat is not known.

DNA G+C content (mol%): not determined.

Type strain: B1333, ATCC 700633, CCUG 38949, CIP 105513, DSM 11693.

GenBank accession number (16S rRNA gene): AF016390.

Other organisms

1. "**Abiotrophia para-adiacens**" Kanamoto, Sato and Inoue 2000, 497.

Kanamoto et al. (2000) described four groups of *Abiotrophia* strains, three pertaining to each of the three known species and a fourth group for which the name "*Abiotrophia para-adiacens*" was proposed. Since the latter name has not been effectively published or validly published, it lacks standing in the nomenclature. The organism requires pyridoxal for growth and produces a chromophore. Arginine dihydrolase, α -galactosidase, and β -galactosidase are not produced. β -Glucosidase and N-acetyl- β -glucosaminidase may or may not be produced. Trehalose and pullulan are not fermented. Tagatose and sucrose may or may not be fermented. Based upon the results, the authors described four groups: three pertained to each of the three known species, and a fourth group for which the name "*Abiotrophia para-adiacens*" was proposed.

GenBank accession number (16S rRNA gene): AB022027.

Genus XI. *Isobaculum* Collins, Hutson, Foster, Falsen and Weiss 2002, 209^{VP}

MATTHEW D. COLLINS

Iso.bac'u.lum. Gr. adj. *isos* alike, similar; L. neut. n. *baculum* small rod; N.L. neut. n. *Isobaculum* the one like a stick or a rod.

Cells are nonsporeforming, nonmotile rods; filaments may be observed. Cells mainly stain Gram-positive, but some cells may appear Gram-negative. **Facultatively anaerobic and oxidase and catalase-negative.** Grows at 10 °C but not at 45 °C or in broth containing 6.5% NaCl. Gas is not produced in MRS broth (De Man et al., 1960). Acid is produced from D-glucose; acetate and L(+) lactate are the end products of glucose metabolism. Arginine dihydrolase and pyrrolydonyl arylamidase are produced. Pyruvate is not utilized. Esculin is hydrolyzed but starch, gelatin, and urea are not hydrolyzed. Nitrate is not reduced. Voges-Proskauer-negative. Sensitive to vancomycin. **The cell-wall murein is based on L-lysine (type A3 α).** Long-chain fatty acids are predominantly of the straight-chain saturated and monounsaturated types. Respiratory menaquinones are absent.

DNA G+C content (mol%): 39 (T_m).

Type species: *Isobaculum melis* Collins, Hutson, Foster, Falsen and Weiss 2002, 209^{VP}.

Further descriptive information

The genus contains only one species, *Isobaculum melis*, and therefore the characteristics provided below refer to this species.

Cells are rod-shaped and stain Gram-positive, although some cells decolorize easily and appear Gram-negative. Nonpigmented and nonhemolytic. Produces a positive bile-esculin reaction. Pyrrolydonyl arylamidase-positive and leucine aminopeptidase-negative. Hippurate, starch, and urea are not hydrolyzed using conventional methods (Facklam and Elliott, 1995). Acid is produced in litmus milk, but clotting is not observed. In conventional heart infusion base medium (Facklam and Elliott, 1995), acid is produced from D-glucose, glycerol, D-ribose, and trehalose. Acid is not produced from arabinose, inulin, lactose, maltose, melezitose, melibiose, D-raffinose, sorbitol, sorbose, or sucrose. Using API systems, acid is formed from D-glucose, trehalose, and D-ribose but not from L-arabinose, D-arabitol, cyclodextrin, glycogen, lactose, melibiose, melezitose, maltose, mannitol, methyl- β -D-glucopyranoside, pullulan, D-raffinose, sorbitol, sucrose, D-tagatose, or D-xylose. Activity is displayed for acid phosphatase, arginine dihydrolase, esterase C-4, ester lipase C8, β -glucosidase, pyroglutamic acid arylamidase, pyrrolydonyl arylamidase, phosphoamidase, and β -mannosidase but not for alanine phenylalanine proline arylamidase, chymotrypsin, cystine arylamidase, α -fucosidase, α -galactosidase, β -galactosidase, α -glucosidase, β -glucuronidase, glycine tryptophan arylamidase, α -mannosidase, leucine arylamidase, lipase C14, pyrazinamidase, trypsin, urease, or valine arylamidase. Activity for alkaline phosphatase and N-acetyl- β -glucosaminidase may or may not be detected. Nitrate is not reduced to nitrite. Sensitive to vancomycin (30 μ m disc). The major long-chain cellular fatty acids are C_{16:0}

C_{18:0} and C_{18:1 09c}. The cell-wall murein is of the type L-Lys-L-Thr-Gly. The small intestine of a dead badger killed in a road accident is the only known source from which *Isobaculum melis* has been isolated (Collins et al., 2002).

Isolation

Isobaculum melis can be isolated on blood agar at 30 or 37 °C under aerobic or anaerobic conditions.

Maintenance procedures

Isobaculum melis can be maintained on brain heart infusion agar or Columbia blood (5%, v/v) agar. It grows well in brain heart infusion broth. For long-term preservation, organisms can be stored on cryogenic beads (Pro-Lab Diagnostics, UK) at -70 °C or lyophilized.

Taxonomic comments

The genus *Isobaculum* was proposed to accommodate a phylogenetically distinct, facultatively anaerobic, catalase-negative, Gram-stain-positive, rod-shaped bacterium originating from the intestine of a badger (Collins et al., 2002). According to the phylogenetic analysis used for the roadmap to this volume (Ludwig et al., above), the genus *Isobaculum* belongs to family *Carnobacteriaceae* in the order *Lactobacillales*, phylum *Firmicutes*. The nearest phylogenetic relatives of the *Isobaculum* are the genera *Carnobacterium* and *Desemzia*.

Differentiation of the genus *Isobaculum* from other genera

The closest phylogenetic relatives of the genus *Isobaculum* are carnobacteria and *Desemzia incerta*. The long-chain cellular fatty acids of *Isobaculum* closely resemble those of carnobacteria. Both *Isobaculum* and *Carnobacterium* species synthesize major amounts of C_{18:1 09c} (oleic acid) whereas *Desemzia incerta* synthesizes major amounts of *cis*-vaccenic acid. The presence of an A3 α murein type (L-Lys-L-Thr-Gly) in *Isobaculum melis* serves to distinguish it from members of the genus *Carnobacterium* which invariably contain walls based on *meso*-diaminopimelic acid, and from *Desemzia incerta* which contains an L-Lys-D-Glutamic acid murein type (Collins et al., 1987; Stackebrandt et al., 1999). *Isobaculum melis* possesses a distinct biochemical profile. The API Rapid ID32 Strep profile 30120310040 and API CORYNE profile 4140300 readily serve to distinguish *Isobaculum melis* from *Carnobacterium* species, *Desemzia incerta*, and other asporogenous rod-shaped Gram-stain-positive taxa. Tests which are useful in distinguishing *Isobaculum melis* from its nearest phylogenetic relatives using the API Rapid ID32 Strep system are given in Table 109.

Genus XII. *Marinilactibacillus* Ishikawa, Nakajima, Yanagi, Yamamoto and Yamasato 2003, 719^{VP}

KAZUHIDE YAMASATO AND MORIO ISHIKAWA

Ma.ri.ni.lac.ti.ba.cil'lus. L. adj. *marinus* marine; L. n. *lac*, *lactis* milk; L. n. *bacillus* a small rod; N.L. masc. n. *Marinilactibacillus* marine lactic acid rodlet.

Cells are Gram positive, nonsporeforming, straight rods that occur singly, in pairs, or in short chains. **Motile with peritrichous flagella.** Facultative anaerobe. Catalase and oxidase negative. Negative for nitrate reduction and gelatin liquefaction. Hydrolyzes casein. Mesophilic and psychrotolerant. **Slightly halophilic and highly halotolerant. Alkaliphilic. L(+)**Lactic acid is the major end product from D(+)glucose; trace to small amounts of formate, acetate, and ethanol are produced with a molar ratio of approximately 2:1:1, without gas formation. The peptidoglycan is of the A4β, **Orn-D-Glu type.** Cellular fatty acids are primarily of the straight-chain saturated and monounsaturated even-carbon-numbered types. **The major fatty acids are C_{16:0}⁺, C_{16:1 07}⁺, C_{18:0}⁺, and C_{18:1 09}⁺ (oleic acid).** **Respiratory quinones and cytochromes are absent.**

DNA G + C content (mol %): 34.6–36.2.

Type species: Marinilactibacillus psychrotolerans Ishikawa, Nakajima, Yanagi, Yamamoto and Yamasato 2003, 719^{VP}.

Further descriptive information

Descriptive information is based on the characteristics of eight strains of *Marinilactibacillus psychrotolerans*. The genus *Marinilactibacillus* is a lactic acid bacterium, belonging to order *Lactobacillales*, class *Bacilli* in phylum *Firmicutes*.

Phylogenetic position of the genus *Marinilactibacillus* based on 16S rRNA gene sequence analysis is given in Figure 108. Phenotypic characteristics of *Marinilactibacillus psychrotolerans* are listed in Table 110, Table 111, and Table 112.

Lactate is the main end product of glucose fermentation under anaerobic cultivation. Lactate yields are 87–100% relative to the amount of consumed glucose. The ratio of the L(+) isomer to total lactate produced is 75–94% at optimum pH for growth. In addition

to lactate, trace to small amounts of formate, acetate, and ethanol are produced with a molar ratio of approximately 2:1:1 (Table 111). The pH of the fermented medium has a large effect on the relative amount of lactate versus the other three products. As the initial acidity of media increases, the proportion of lactate also increases, while those of the other three products decrease in parallel, and vice versa on the alkaline side. The 2:1:1 molar ratio among the three products other than lactate is retained. It is assumed that *Marinilactibacillus psychrotolerans* has two pyruvate pathways mediated by lactate dehydrogenase and pyruvate formate-lyase, and the pathway used would be affected by the pH value of the fermentation medium (Gunzalus and Niven, 1942; Janssen et al., 1995; Rhee and Pack, 1980).

Marinilactibacillus psychrotolerans metabolizes glucose oxidatively. When grown aerobically with shaking, lactate yield decreases and acetate yield increases without production of formate and ethanol (Table 112).

Marinilactibacillus psychrotolerans is slightly halophilic (Kushner, 1978; Kusher and Kanekura, 1988). The optimum NaCl concentration for growth in GYPF broth, pH 8.5 (for composition, see *Maintenance procedures*) is between 2.0% (0.34M) and 3.75% (0.64M) (3.0–5.0% for strain IAM 14980^T). For strain IAM 14980^T, the maximum specific growth rates, μ_{max} (h⁻¹), are 0.38 in 0%; 0.36 in 0.5%; 0.40 in 1.0%; 0.42 in 1.5%, 2.0%, and 2.5%; 0.47 in 3.0%; 0.51 in 3.75%; 0.46 in 5.0%; and 0.36 in 7.5% NaCl. *Marinilactibacillus psychrotolerans* is highly halotolerant, able to grow at 17.0–20.5% (2.9–3.5M) NaCl. Strain IAM 14980^T grows at 20% NaCl.

Marinilactibacillus psychrotolerans is alkaliphilic, having an optimum pH above 8.0 (Jones et al., 1994). For strain IAM 14980^T, the μ_{max} (h⁻¹) values are 0.44 at pH 7.0; 0.48 at pH 7.5; 0.53 at pH 8.0;

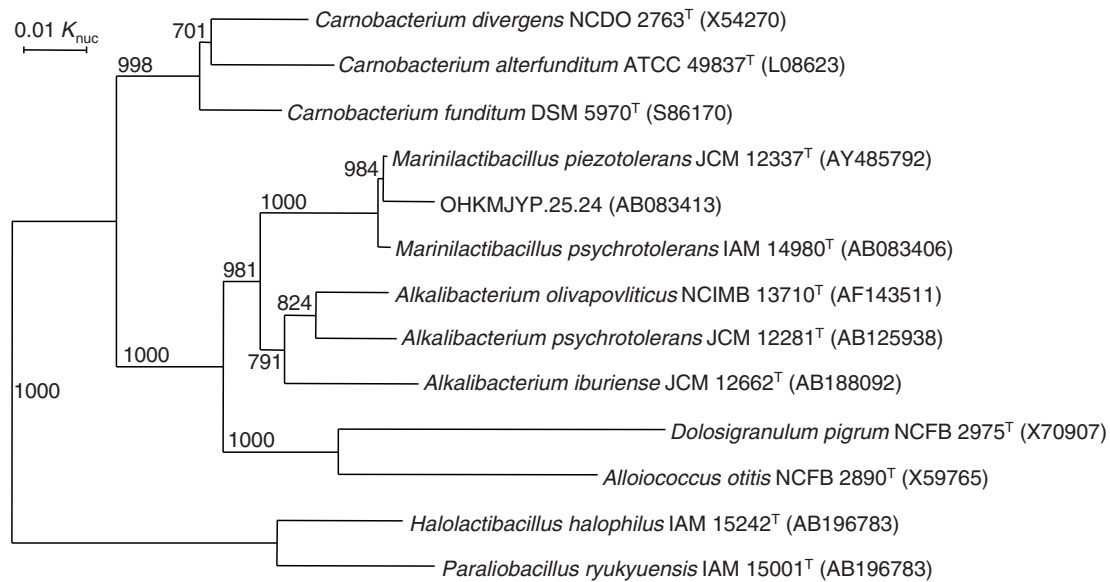

FIGURE 108. Phylogenetic relationships between *Marinilactibacillus* and some other related bacteria. The tree was constructed using the neighbor-joining method and is based on a comparison of approximately 1400 nt. Bootstrap values, based on 1000 replications, are given at the branching points.

Aerobic	33.2	ND	21.5	ND	40	ND	73
Anaerobic	38.6	ND	63.9	7.5	5.1	4.1	94

^aND, not detected.

^bData from Ishikawa et al. (2005).

0.50 at pH 8.5; 0.51 at pH 9.0; 0.50 at pH 9.5; and 0.34 at pH 10.0. When the isolates were grown in 2.5% NaCl GYPF broth, pH 8.5, the final pH could be as low as 4.7–5.2, which is 0.8–1.3 pH units lower than the minimum pH required to initiate growth.

Marinilactibacillus psychrotolerans is mesophilic. The μ_{\max} (h⁻¹) values for *Marinilactibacillus psychrotolerans* IAM 14980[†] are 0.36 at 25 °C; 0.52 at 30 °C; 0.60 at 37 °C; 0.42 at 40 °C; and 0.02 at 42.5 °C. It grows very well at lower temperatures with respect to the extent of maximum growth, although growth rates are low. For strain IAM 14980[†], OD₆₆₀ values are 0.78 at -1.8 °C (the freezing point of seawater; 21 d incubation), 0.70 at 0 °C (21 d), 0.89 at 5 °C (9 d), and 1.14 at 37 °C (the optimum temperature; 15 h).

Marinilactibacillus psychrotolerans ferments a fairly wide range of carbohydrates (pentoses, hexoses, and disaccharides) and related carbon compounds. Fermentation of sugar alcohols and polysaccharides are negative for most of strains except for glycerol (weak) and D-mannitol (Table 110).

For eight strains of *Marinilactibacillus psychrotolerans*, the compared sequences of 16S rRNA genes (1458–1479 nt) are identical and the DNA–DNA hybridization values are 74–100%. The sequence similarity between *Marinilactibacillus psychrotolerans* IAM 14980[†] and *Marinilactibacillus piezotolerans* (Toffin et al., 2005) JCM 12337[†] is 99.6%. The phylogenetically closest genus is *Alkalibacterium* (Ntougias and Russell, 2001): *Marinilactibacillus psychrotolerans* IAM 14980[†] has 96.2% similarity to *Alkalibacterium olivapolyticus* NCIMB 13710[†], 94.6% similarity to *Alkalibacterium iburiense* JCM 12662[†] (Nakajima et al., 2005), and 95.1% similarity to *Alkalibacterium psychrotolerans* JCM 12281[†] (Yumoto et al., 2004). The similarities of *Marinilactibacillus psychrotolerans* to *Carnobacterium funditum*, *Carnobacterium alterfunditum*, *Alloiococcus otitis*, *Dolosigranulum pigrum*, and *Desenzia incerta* are 93.2%, 92.8%, 91.1%, 90.9%, and 91.9%, respectively.

Marinilactibacillus psychrotolerans was isolated from a living sponge collected from the Oura beach, Miura Peninsula, Japan, and a raw Japanese ivory shell and decomposing alga collected from Okinawa, Japan. *Marinilactibacillus piezotolerans* was isolated from a sediment core collected at 4.15 m below the sea floor from a water depth of 4790.4 m in the Nankai Trough, off the coast of Japan in the Pacific Ocean (Toffin et al., 2004, 2005).

Halolactibacillus species (*Halolactibacillus halophilus* and *Halolactibacillus miurensis*; Ishikawa et al., 2005) were isolated from living and decaying marine organisms. *Halolactibacillus* is slightly halophilic with an optimum of 2.0–3.0%, and highly halotolerant with a range of 0–25.5%. *Halolactibacillus* is alkaliphilic with an optimum of pH 8.0–9.5 and a range of pH 6.0–10.0.

Carnobacterium funditum and *Carnobacterium alterfunditum* were isolated from water of possible seawater origin in Ace Lake in Antarctica (Franzmann et al., 1991). These two species grow preferably under conditions of low salinity. These members of *Marinilactibacillus*, *Halolactibacillus*, and *Carnobacterium* have adapted to marine environments characterized by salinity and slightly alkaline reaction and can be called marine lactic acid bacteria.

Enrichment and isolation procedures

Marinilactibacillus psychrotolerans was isolated by enrichment culture from marine organisms. For isolation, cultures are enriched and subcultured in 7% NaCl GYPF or GYPB isolation medium containing peptone, yeast extract, fish or beef extract, pH 9.5 or 10.0, at 30 °C under anaerobic conditions. The first enrichment culture, whose pH has decreased below 7.0, is subcultured. The second enrichment culture is incubated anaerobically; it is pour-plated with an agar medium supplemented with CaCO₃ and overlaid with an agar medium containing 0.1% sodium thioglycolate. Prolonged incubation in enrichment culture should be avoided, as cells tend to autolyse. Another enrichment medium used is GYPFSK isolation broth of similar composition containing 12% NaCl, pH 7.5. For the second enrichment, the same medium containing 18% NaCl is used. Incubation is conducted at 30 °C in standing culture, and the culture is pour-plated with 12% NaCl GYPFSK agar supplemented with CaCO₃. The compositions and preparation methods of media were described by Ishikawa et al. (2003).

Maintenance procedures

Marinilactibacillus psychrotolerans is maintained by serial transfer in a stab culture stored at 5–10 °C at 1–2 month intervals. The medium is 7% NaCl GYPF or GYPB agar supplemented

with 12 g Na₂CO₃, 3 g NaHCO₃, and 5 g CaCO₃ per liter. The 7% NaCl GYPF or GYPB agar is composed of (per liter) 10 g glucose, 5 g yeast extract, 5 g peptone, 5 g fish or beef extract, 1 g K₂HPO₄, 70 g NaCl, 1 g sodium thioglycolate, 5 ml salt solution (per ml, 40 mg MgSO₄·7H₂O, 2 mg MnSO₄·4H₂O, 2 mg FeSO₄·7H₂O), and 13 g agar. The final pH is 9.0. A solution of the main components, carbonate buffer compounds, and CaCO₃ are sterilized separately.

Marinilactibacillus psychrotolerans can be maintained in 2.5% NaCl GYPF or GYPB agar, pH 8.5, supplemented with 5 g CaCO₃ per liter. To prepare this medium, a double-strength solution of the main components is adjusted to pH 8.5, sterilized by filtration, and aseptically mixed with an equal volume of autoclaved 2.6% agar solution. Then, autoclaved CaCO₃ (as a slurry with a small amount of water) is added.

Strains are maintained by freezing at -80 °C or below in 2.5% GYPFK broth (i.e., GYPF broth in which the concentration of K₂HPO₄ is increased to 1%) supplemented with 10% (w/v) glycerol. Strains are kept by L-drying in an adjuvant solution composed of (per liter) 3 g sodium glutamate, 1.5 g adonitol, and 0.05 g cysteine hydrochloride in 0.1 M phosphate buffer (KH₂PO₄/K₂HPO₄), pH 7.0 (Sakane and Imai, 1986). Strains

can be kept by freeze-drying with a standard suspending fluid containing an appropriate concentration of NaCl.

Differentiation of *Marinilactibacillus* from other related genera and species

Characteristics used to differentiate *Marinilactibacillus psychrotolerans* from other marine lactic acid species isolated from saline/alkaline environments are listed in Table 113. For comparison, the catalase-positive, lactic-acid-producing *Paraliobacillus ryukyensis* is included in the table. *Marinilactibacillus psychrotolerans*, *Halolactibacillus halophilus*, and *Halolactibacillus miurensis* are marine lactic acid bacteria (Ishikawa et al., 2003, 2005), and *Paraliobacillus ryukyensis* is of marine origin and produces lactic acid as a main product from glucose under anaerobic conditions (Ishikawa et al., 2002). In addition to the phenotypic similarities (Table 113), these four species produce formate, acetate, and ethanol with a molar ratio of 2:1:1 as well as lactate. The amounts of these three products produced relative to the amount of lactate increase as acidity in fermentation medium decreases (Table 111; see chapter on *Halolactibacillus*, Table 24). Although they are catalase-negative, *Marinilactibacillus psychrotolerans* and *Halolactibacillus* species are similar in their ability

TABLE 113. Characteristics that distinguish *Marinilactibacillus psychrotolerans* from other lactic acid rods and *Paraliobacillus ryukyensis*, which are phenotypically similar and were isolated from saline/alkaline environments^a

to metabolize glucose oxidatively under aerobic conditions (Table 112; see Table 25 in the chapter on *Halolactibacillus*). In spite of physiological and biochemical similarities, *Marinilactibacillus* is phylogenetically distinguished from *Halolactibacillus* and *Paraliobacillus*. Both genera belong to the discrete cluster within *Bacillus* rRNA group 1 in the family *Bacillaceae*. *Marinilactibacillus psychrotolerans* is chemotaxonomically distinguished from *Halolactibacillus* and *Paraliobacillus* by its peptidoglycan type and cellular fatty acid composition and from *Paraliobacillus*, in addition, by sporeformation and lack of catalase production (Table 113).

Taxonomic comments

The description of the genus *Marinilactibacillus* is based on *Marinilactibacillus psychrotolerans*. Another validly published species of this genus is *Marinilactibacillus piezotolerans* (Toffin et al., 2005). The sequence similarity of the 16S rRNA gene between the two species is 99.6% (1287 nt) when calculated with the sequence for strain LT20^T (accession no. AY485792; Toffin et al., 2005) and is 99.5% (1456 nt) when calculated with

the sequence for strain JCM 12337^T (accession no. AB247277). The similarity between the two sequences of *Marinilactibacillus piezotolerans* is 99.2% (1338 nt). Several characteristics described for *Marinilactibacillus piezotolerans* differ from some experimental results obtained for strain JCM 12337^T (Yamasato and Ishikawa, unpublished data). Catalase activity is negative (described as positive); G + C content of the DNA is 35.5 mol% rather than 42 mol%; major cellular fatty acids are C₁₆ and C₁₈ acids rather than C₁₄ and C₁₆ acids; and fermentation of maltose, sucrose, and D-galactose is positive rather than negative. It may be the case that *Marinilactibacillus piezotolerans* is inadequately described, and further critical characterization is needed.

Bacterial strains identified as *Marinilactibacillus psychrotolerans* by molecular method have been isolated from deep-sea sediments (Inagaki et al., 2003), soft cheeses (Maoz et al., 2003; Feurer et al., 2004; Ishikawa et al., 2007), and spoiled dry-cured hams (Rastelli et al., 2005). In spoiled dry-cured hams and mold-ripened soft cheeses (Ishikawa et al., 2005), *Marinilactibacillus psychrotolerans* constituted a predominant flora.

List of species of the genus *Marinilactibacillus*

1. ***Marinilactibacillus psychrotolerans*** Ishikawa, Nakajima, Yanagi, Yamamoto and Yamasato 2003, 719^{VP}

psy.chro.to'le.rans. Gr. adj. *psychros* cold; L. part. adj. *tolerans* tolerating; N.L. adj. *psychrotolerans* tolerating cold temperature.

The characteristics are as described for the genus and as listed in Table 110, Table 111, and Table 112. The morphology is shown in Figure 109. Deep colonies in agar medium are pale yellow, opaque, and lenticular, with diameters of 2–4 mm. The cells are typically 0.4–0.5 × 2.3–4.5 μm and elongated in older cultures. Grows evenly throughout a column of semisolid agar medium.

Source: Deep subseafloor sediment.

DNA G + C content (mol %): 35.5 (HPLC).

Type strain: LT20, DSM 16108, JCM 12337.

GenBank accession number (16S rRNA): AY485792, AB247277.

FIGURE 109. Photomicrograph of a cell and peritrichous flagella of *Marinilactibacillus psychrotolerans* IAM 14980^T grown anaerobically at 30 °C for 1 d on 2.5% NaCl GYPFK agar. Bar = 2 μm.

Genus XIII. **Trichococcus** Scheff, Salcher and Lingens 1984b, 356^{VP} (Effective publication: Scheff, Salcher and Lingens 1984a, 118.) emend. Liu, Tanner, Schumann, Weiss, McKenzie, Janssen, Seviour, Lawson, Allen and Seviour 2002, 1124

FRED A. RAINEY

Tri.cho.coc.cus. Gr. n. *thrix* hair; L. masc. n. *coccus* a grain or berry; N.L. masc. n. *Trichococcus* a hair of cocci.

Pleiomorphic cells, can be spherical to ovoid, olive shaped with tapered ends or rod shaped. Cells are 0.75–2.5 µm × 0.7–1.5 µm. Cells occur singly, in pairs, or in short or long chains. Motility observed in some species. **Gram-stain-positive**. Nonspore-forming. Peptidoglycan type is A4α, L-Lys-D-Asp. **Aerotolerant**. **Fermentative metabolism**. Catalase and oxidase negative. **Psychroactive mesophile**; optimum temperature for growth is 23–30 °C. Growth occurs in the range –5 to 40 °C and pH 5.5–9.0. Indole is not produced. Under aerobic conditions lactate and acetate produced from glucose; under anaerobic conditions lactate, formate, acetate, and ethanol produced from glucose. Isolated from activated sludge, swamps, soil, hydrocarbon spill site, and penguin guano.

DNA G+C content (mol%): 45–49.

Type species: Trichococcus flocculiformis Scheff, Salcher and Lingens 1984b, 356^{VP} (Effective publication: Scheff, Salcher and Lingens 1984a, 118.) emend. Liu, Tanner, Schumann, Weiss, McKenzie, Janssen, Seviour, Lawson, Allen and Seviour 2002, 1124.

Further descriptive information

The species and strains assigned to this genus do not demonstrate a uniform morphology and the morphotype varies depending on the culture media used for growth (Liu et al., 2002). The morphologies of *Trichococcus flocculiformis* strains Echt^T, NDP, and Ben 200, *Trichococcus pasteurii* strain KoTa2^T and *Trichococcus collinsii* strains 37AN3^{*T} and 45AN2 were observed by scanning electron microscopy after growth on R2A and SR2A agar (Liu et al., 2001) and after growth in R2A broth with and without shaking (Liu et al., 2002). It was found that these strains are pleomorphic under different conditions of growth, and morphologies can differ from those presented in the original species descriptions. The type strain of the *Trichococcus flocculiformis* Echt^T was found to grow as regular cocci in chains on most culture media including SR2A, but it grew as larger tapered rod-shaped cells when cultured on R2A agar. These morphological differences were also observed for *Trichococcus*

pasteurii KoTa2^T when it was grown on R2A agar. *Trichococcus flocculiformis* strain NDP displayed cells with tapered ends in pairs when grown on both SR2A and R2A agar. These morphological differences were also observed in strains of the same species, *Trichococcus collinsii*; in the case of strains 37AN3^{*T} and 45AN2 in that cells of strain 37AN3^{*T} appeared swollen, often tapered, paired, and irregular on both R2A and SR2A while strain 45AN2 grew as regular single or paired cocci on SR2A and as larger cocci with tapered ends, often in pairs on R2A (Liu et al., 2002). Strain Ben 200 (*Trichococcus flocculiformis*) grew as regular cocci in chains on SR2A agar and pleiomorphic irregular cells in chains on R2A agar. Changes in morphology between strains grown in static and shaken broth cultures were also observed for strains Ben 77, Ben 200, Ben 201, KoTa2^T, 37AN3^{*T}, 45AN2, and NDP (Liu et al., 2002). No differences in cell morphology were observed between static or shaken cultures of *Trichococcus flocculiformis* Echt^T. No information on changes in morphology due to conditions of growth has been reported for *Trichococcus patagoniensis* (Pikuta et al., 2006).

The cell wall composition has been determined for all species of the genus with the exception of *Trichococcus patagoniensis* and found to be A4 with an L-Lys-D-Asp interpeptide bridge. Fatty acid profiles of 8 strains including the type strains of the species *Trichococcus flocculiformis*, *Trichococcus pasteurii*, and *Trichococcus collinsii* were determined for cells grown on Tryptic Soy agar at room temperature for 3 d (Liu et al., 2002). The fatty acid composition of *Trichococcus palustris* grown at both 6 and 25 °C was determined by Zhilina et al. (1995). In the study of Pikuta et al. (2006) the fatty acid profiles were determined for *Trichococcus patagoniensis* PmagG1^T and *Trichococcus pasteurii* ATCC 35945^T after growth on liquid medium incubated at 22 °C for 4 d. The fatty acid data of the type strains of the *Trichococcus* species from these studies is assembled and shown in Table 114.

Although different culture media and conditions were used in the cultivation of the strains compared in Table 114, the major fatty acids of the species of the genus *Trichococcus* are consistently C_{14:0}, C_{16:0}, and C_{16:1}. Interestingly, in the study of Lui

et al. (2002), one of the major fatty acids in all strains was C_{16:1}, while in the study of Pikuta et al. (2006), C_{16:1} was not detected in *Trichococcus patagoniensis* and C_{16:1 7c} was detected in both *Trichococcus patagoniensis* and *Trichococcus pasteurii*.

Species of the genus *Trichococcus* have been found to utilize a variety of sugars, sugar alcohols, and polysaccharides. These utilizations have been tested using a number of approaches including determination of growth, production of acid, and the metabolism of BIOLOG compounds. In the emended description of the genus *Trichococcus*, Liu et al. (2002) included a large number of BIOLOG system metabolism results as genus characteristics. This resulted in a very wide ranging genus description with respect to substrate utilization tests, and that may result in many genus description emendations as new species are added to the genus. With the addition of *Trichococcus patagoniensis*, for which no BIOLOG substrates have been tested, the genus description as presented by Liu et al. (2002) may require further emendation. Pikuta et al. (2006) demonstrated that the utilization patterns for a number of substrates (D-trehalose, lactate, citrate, D-ribose, maltose, and α -D-lactose) could be used to differentiate between the type strains of the five species of the genus *Trichococcus*. The substrates used or not used by the species of this genus are provided in the species descriptions below when available.

Fermentation of glucose by strains of this genus results in the production of lactate, formate, acetate, ethanol, and CO₂. In addition, traces of isobutyrate were detected as end products of the fermentation of glucose by *Trichococcus palustris* (Zhilina et al., 1995). Growth of strains under oxic conditions resulted in the production of lactate and acetate (Liu et al., 2002).

Enrichment, isolation and growth conditions

The strains assigned to the genus *Trichococcus* were isolated in the study of the microbial composition of sewage sludge and duck pond sediment (*Trichococcus flocculiformis* and *Trichococcus pasteurii*), or hydrocarbon contaminated sites (*Trichococcus collinsii*), or from studies aimed at the isolation of psychrophiles (*Trichococcus palustris* and *Trichococcus patagoniensis*). There is no clear selective isolation approach for the isolation of species of the genus *Trichococcus*, but considering all strains grow at 4 °C or below, it could be considered that incubation of enrichment cultures at temperatures less than 4 °C could select for these organisms. *Trichococcus flocculiformis* Eht^T was isolated by streaking a single drop of bulking sludge on UA medium and incubating the plates at 25 °C for several weeks. UA medium contained (g/l): peptone (Oxoid), 1g; glucose, 1g; urea, 20g; KH₂PO₄, 2g; phenol red, 0.012g; agar (Merck), 12g. Although isolated under aerobic conditions, this species grew under anaerobic conditions facilitated by the Anaerobic Generating System (Oxoid) as well as in agar deeps and in liquid culture under a layer of paraffin (Scheff et al., 1984b). Strains 37AN3^T and 45AN2, assigned to the species *Trichococcus collinsii*, were isolated from gas condensate-contaminated groundwater sediments (Gieg et al., 1999). Both aerobic and anaerobic heterotrophic organisms were isolated on tryptic soy broth with mineral salts and vitamins added (Gieg et al., 1999). The paper of Gieg et al. (1999) does not provide details on the temperatures or length of incubation of these enrichments. *Trichococcus pasteurii* was isolated from anoxic digester sludge from the municipal sewage plant of the city of Konstanz, Germany and described

as *Ruminococcus pasteurii* (Schink, 1984). The strain KoTa2^T, described as *Ruminococcus pasteurii*, was isolated in a study to enumerate tartrate fermenting bacteria. The anaerobic tartrate fermenting bacteria were enumerated by MPN methods in mineral medium containing 10 mM L-, D-, and m-tartrate (Schink, 1984). Pure cultures were obtained using serial dilution in agar shakes (Schink, 1984). In a study to isolate psychroactive bacteria from a swamp ecosystem in which organic matter is decomposed at -2 to -4 °C in winter but is exposed to much higher temperatures during the summer months, a coccoid organism strain Z-7189^T was isolated (Zhilina et al., 1995). This organism was initially assigned to the genus *Ruminococcus* as *Ruminococcus palustris* (Zhilina et al., 1995) and later transferred to the genus *Trichococcus* as *Trichococcus palustris* (Liu et al., 2002). Strain Z-7189^T was isolated from swamp samples collected in winter and maintained in a frozen state until used for inoculation (Zhilina et al., 1995). Enrichment cultures on glucose were established with 10% inoculum in bicarbonate Pfennig medium (Zhilina, 1978) supplemented with yeast extract, 2 g/l; trace element solution, 2 ml/l (Liu et al., 2002); vitamin solution, 10 ml/l (Wolin et al., 1963); Na₂S·9H₂O, 0.5 g/l; resazurin, 0.001 g/l and glucose, 0.5 g/l. The enrichment culture was incubated at 6 °C, and cultures were subsequently selected that had good growth rates at 6 °C but grew better at 20–30 °C (Zhilina et al., 1995). These organisms were considered to be psychroactive organisms and a coccoid organism designated Z-7189 was isolated using the serial dilution technique in liquid medium followed by colony isolation using agar roll-tubes (Zhilina et al., 1995). Penguin guano was the source of *Trichococcus patagoniensis* PmagG1^T (Pikuta et al., 2006). The guano was collected from a shallow marine tidal pool and stored at 4 °C until homogenized and used to inoculate a glucose-containing enrichment culture. The culture medium contained (g/l): NaCl, 30.0; KCl, 0.3; KH₂PO₄, 0.3; MgSO₄·7H₂O, 0.1; NH₄Cl, 1.0; CaSO₄·7H₂O, 0.0125; NaHCO₃, 0.4; Na₂S·9H₂O, 0.4; resazurin, 0.0001; yeast extract, 0.1; D-glucose, 5.0; vitamin solution (Wolin et al., 1963), 2 ml; and trace mineral solution (Whitman et al., 1982), 1 ml. The pH was 7.8 and the headspace gas N₂ (Pikuta et al., 2006). The culture was incubated at 4 °C and serially diluted to obtain a pure culture using the roll tube method.

Taxonomic comments

The genus *Trichococcus* currently comprises five species which form a phylogenetically coherent group within the *Firmicutes*. It was the lack of a 16S rRNA gene sequence for *Trichococcus flocculiformis* and the morphological differences between strains Eht^T and KoTa2^T that led to the description of KoTa2^T initially as a *Ruminococcus* species (Schink, 1984) and subsequently as the type species of the genus *Lactosphaera* (Jansen et al., 1995). With the determination of the 16S rRNA gene sequence of *Trichococcus flocculiformis* Eht^T, it became clear that *Lactosphaera pasteurii* KoTa2^T and *Ruminococcus palustris* Z-7189^T were members of the genus *Trichococcus* (Liu et al., 2002; Stackebrandt et al., 1999). In addition, the strains Ben 200, 37AN3^{*T}, 45AN2, and NDP were shown to group within the *Trichococcus* group (Liu et al., 2002). All of the 16S rRNA gene sequences available for *Trichococcus* strains share greater than 99% sequence similarity (Table 115). The closest relatives to species of the genus *Trichococcus* that are related at the 94–95% similarity level are *Isobaculum melis*

TABLE 115. 16S rRNA gene sequence similarities of the type strains of the five species of the genus *Trichococcus*

Sequence	<i>T. flocculiformis</i> Echt ^T	<i>T. collinsii</i> 37AN3 ST	<i>T. palustris</i> Z-7189 ^T	<i>T. pasteurii</i> KoTa2 ^T	<i>T. patagoniensis</i> PmagG1 ^T
AJ306611	–	–	–	–	–
AJ306612	99.6	–	–	–	–
AJ296179	99.0	99.3	–	–	–
X87150	99.8	99.9	99.1	–	–
AF394926	99.6	100	99.3	99.9	–

(Collins et al., 2002), *Desemzia incerta* (Stackebrandt et al., 1999), and the species of the genus *Carnobacterium*. Although these 16S rRNA gene sequence similarity values are high and in many situations would be considered to represent species of the same genus, there are distinct cell wall peptidoglycan type differences between the species of the genus *Trichococcus* which have an A4 α , L-Lys-D-Asp peptidoglycan and those of the genera *Carnobacterium* (meso-diaminopimelic acid), *Isobaculum* (A3 α , Lys-L-Thr-Gly), and *Desemzia* (A4 α , Lys-D-Glu) (Collins et al., 2002; Stackebrandt et al., 1999).

With such high 16S rRNA gene sequence similarities between all of the species of the genus *Trichococcus* and considering the 100% similarity between *Trichococcus collinsii* 37AN3ST and *Trichococcus patagoniensis* PmagG1^T, DNA-DNA studies were carried out by Liu et al. (2002) and Pikuta et al. (2006). The results of these DNA-DNA hybridizations demonstrated that strain 37AN3ST was a distinct species with DNA-DNA reassociation of 34, 58, and 45% to *Trichococcus palustris* Z-7189^T, *Trichococcus pasteurii* KoTa2^T, and *Trichococcus patagoniensis* PmagG1^T, respectively (Liu et al., 2002; Pikuta et al., 2006). Reassocia-

tion values of 40 and 47% were determined for *Trichococcus palustris* vs *Trichococcus pasteurii* and *Trichococcus patagoniensis*, respectively (Liu et al., 2002; Pikuta et al., 2006). *Trichococcus flocculiformis* Echt^T has not been hybridized with the type strain of any of the other species of the genus *Trichococcus*. However, *Trichococcus flocculiformis* Echt^T has been hybridized with strains Ben 77, Ben 200, Ben 201, and NDP demonstrating that those strains had DNA-DNA reassociation values greater than 70% and all belong to the species *Trichococcus flocculiformis* (Liu et al., 2002). Strain Ben 201 was hybridized with the type strains of the species *Trichococcus palustris*, *Trichococcus pasteurii*, and *Trichococcus collinsii*, and the result demonstrates that these strains (Ben 77, Ben 200, Ben 201, and NDP) all belong to the same species, i.e. *Trichococcus flocculiformis* (Liu et al., 2002). Phenotypic differentiation of the species of the genus *Trichococcus* is based on substrate utilization tests. In describing *Trichococcus patagoniensis*, Pikuta et al. (2006) demonstrated that the utilization patterns for the carbon sources D-trehalose, lactate, citrate, D-ribose, maltose, and α -D-lactose can be used to differentiate the species.

List of the species of the genus *Trichococcus*

The species descriptions presented here are a combination of characters presented in the original description of these species as well as data presented in subsequent publications.

- 1. *Trichococcus flocculiformis*** Scheff, Salcher and Lingens 1984b, 356^{VP} (Effective publication: Scheff, Salcher and Lingens 1984a, 118.) emend. Liu, Tanner, Schumann, Weiss, McKenzie, Janssen, Seviour, Lawson, Allen and Seviour 2002, 1124.

floc.cu.li'form.is. L. n. *floccus* a flock of wool; N.L. dim. adj. *floculus* like a small flock of wool; L. n. *forma* shape; L. adj. *flocculiformis* small-floc-shaped.

Cells are spherical to ovoid or rod shaped, 1.0–2.5 μ m \times 1.0–1.5 μ m. Occur in filaments of 20 to several hundred cells, as single cells, as pairs, or are rod shaped. Gram-stain-positive. Nonsporeforming. Colonies are white, opaque, circular, convex with lobate or erose margins on Nutrient Agar. The temperature range for growth is 4–39 °C with optimum growth at 25–30 °C. The pH range for growth is 5.8–9.0, with optimum growth at pH 8.0. Facultative anaerobe. Aerotolerant. Fermentative metabolism. Acid produced from fructose, galactose, glucose, mannose, ribose, xylose, cellobiose, lactose, maltose, sucrose, and trehalose. Acid is not produced from DL-arabinose, erythritol, galactitol, ribitol, starch, agar, esculin, casein, cellulose, chitin, DNA, gelatin,

pectin, tributyrin, Tween 80, and urea. Some strains produce acid from inositol, sorbitol, mannitol, raffinose, and adonitol. Nitrate reduction variable. Urease variable. Hydrogen sulfide not produced. Acetylmethylcarbinol not produced. Methyl red test positive. Fatty acids include C_{14:0} (8–14%), C_{16:0} (12–24%), C_{16:1} (39–50%), C_{17:1iso} (1–4%), C_{18:0} (1–3%), and C_{18:1 ω 9c} (14–23%).

Isolated from bulking sludge and duck pond sediment.

DNA G+C content (mol%): 46.8 (T_m).

Type strain: Echt, ATCC 51221, DSM 2094. Other strains include Ben 77, Ben 200, Ben 201, and NDP (Liu et al., 2002).

GenBank accession number (16S rRNA gene): AJ306611, Y17301.

- 2. *Trichococcus collinsii*** Liu, Tanner, Schumann, Weiss, McKenzie, Janssen, Seviour, Lawson, Allen and Seviour 2002, 1124^{VP} emend. Pikuta, Hoover, Bej, Marsic, Whitman, Krader and Tang 2006, 2060.

coll.ins'i.i. N.L. gen. n. *collinsii* referring to Matthew D. Collins, a contemporary English microbiologist who contributed significantly to our understanding of the lactic acid bacteria.

Cells are single or paired cocci or tapered cells. Small chains of cocci form in R2A broth. The temperature range

for growth is -5 to 36 °C with optimum growth at 25 – 30 °C. The pH range for growth is 6.0 – 9.0 , with optimum growth at pH 7.5 . Facultative anaerobe. Aerotolerant. Fermentative metabolism. Grow on citrate, D-malate, allantoin, and L-tartrate, and produce acid from mannitol. The type strain produces acid from inositol, sorbitol, raffinose, and adonitol. Nitrate reduction negative. Urease-negative.

Isolated from hydrocarbon spill site.

DNA G+C content (mol%): 47.0 (HPLC).

Type strain: 37AN3^{*}, ATCC BAA-296, DSM 14526. Another strain is 45AN2 (Liu et al., 2002).

GenBank accession number (16S rRNA gene): AJ306612.

3. **Trichococcus palustris** (Zhilina, Kotsyurbenko, Osipov, Kostrinka and Zavarzin 1995) Liu, Tanner, Schumann, Weiss, McKenzie, Janssen, Seviour, Lawson, Allen and Seviour 2002b, 1125^{VP} (*Ruminococcus palustris* Zhilina, Kotsyurbenko, Osipov, Kostrinka and Zavarzin 1995, 577.)

pa.lu'stris. L. adj. *palustris* swamp-inhabiting ruminococcus.

Cells are coccoid or elongated with slightly tapered ends, 0.75 – 1.3 μm \times 0.7 – 1.0 μm . Occur as single cells, or in pairs, short chains joined by a mucous capsule. Gram-stain-positive. Nonsporeforming. The temperature range for growth is 0 – 33 °C with optimum growth at 30 °C. The pH range for growth is 6.2 – 8.4 , with optimum growth at pH 7.5 . Facultative anaerobe. Aerotolerant. Fermentative metabolism. Ferments glucose, sucrose, fructose, mannose, maltose, raffinose, lactose, cellobiose, mannitol, sorbitol, pyruvate, and *N,N*-acetyl-D-glucosamine. Fucose, arabinose, rhamnose, xylose, sorbose, galactose, ribose, trehalose, melibiose, erythritol, adonite, ducitol, inositol, betaine, choline chloride, acetate, malate, formate, butyrate, propionate, lactate, succinate, fumarate, mono-, trimethylamine, L-histidine HCl, DL-methionine, DL-serine, L-glutamate, L-glutamine, Casamino acids, glycine, D-glucosamine HCl, glycogen, starch, microcrystalline cellulose, peptone, ethanol, butanol, propanol, methanol, glycerol, H₂ + CO₂ are not utilized. Nitrate not reduced. Urease-negative.

Isolated from a swamp in floodplain of the Yasnushka River near the Abramtsev settlement, Moscow Region, Russia.

DNA G+C content (mol%): 47.5 (*T_m*).

Type strain: Z-7189, CIP 105359, DSM 9172.

GenBank accession number (16S rRNA gene): AF296179.

4. **Trichococcus pasteurii** (Schink 1984) Liu, Tanner, Schumann, Weiss, McKenzie, Janssen, Seviour, Lawson, Allen and Seviour 2002b, 1124^{VP} (*Ruminococcus pasteurii* Schink, 1984, 413; *Lactosphaera pasteurii* Janssen, Evers, Rainey, Weiss, Ludwig, Harfoot and Schink 1995, 570.)

pas.teu'ri.i. N.L. gen. n. *pasteurii* referring to Louis Pasteur, who probably first enriched and observed this bacterium during studies on tartrate fermentation.

Cells are nonmotile cocci that form pairs or small irregular packets of cells, 1.0 – 1.5 μm in diameter. Spherical, ovoid, or olive shaped and occur as single cells, in pairs, in chains, or as irregular conglomerates. Nonsporeforming. The temperature range for growth is 0 – 42 °C with

optimum growth at 25 – 30 °C. The pH range for growth is 5.5 – 9.0 . Growth occurs up to 2% NaCl (w/v). Biotin is required as a growth factor. Aerotolerant. Fermentative metabolism. Nitrate, sulfate, sulfite, thiosulfate, sulfur, and fumarate are not reduced. L-Tartrate, pyruvate, oxaloacetate, malate, citrate, mannitol, sorbitol, glucose, galactose, mannose, L-rhamnose, fructose, maltose, lactose, sucrose, cellobiose, raffinose, trehalose, sorbose, starch, and oat spelt xylan are utilized. Laminarin is weakly used. D-Tartrate, meso-tartrate, xylose, ribose, arabinose, malonate, succinate, DL-3-hydroxybutyrate, lactate, amino acids, alcohols, chitin, gumkaraya, carboxymethyl cellulose, amorphous cellulose, mannan, lichenan, gum locust bean, pullulan, arabinogalactan, and glycogen are not utilized. The end products of L-tartrate, pyruvate, and citrate are acetate, formate, and CO₂. Glucose and other C-sources are fermented to L-lactate, acetate, formate, and ethanol. Urease and gelatin hydrolysis negative.

Isolated from anoxic digester sludge.

DNA G+C content (mol%): 45.0 (*T_m*).

Type strain: KoTa2, ATCC 35945, CCUG 37395, CIP 104580, DSM 2381.

GenBank accession number (16S rRNA gene): L76599, X87150.

5. **Trichococcus patagoniensis** Pikuta, Hoover, Bej, Marsic, Whitman, Krader and Tang 2006, 2060^{VP}

pa.ta.go.ni.en'sis. N.L. masc. adj. *patagoniensis* pertaining to Patagonia, the region of South America where the sample for the type strain was collected.

Cells are motile cocci with a diameter of 1.3 – 2.0 μm . Cells are spherical, ovoid, or olive shaped and occur as single cells, in pairs, in chains, or as irregular conglomerates. Gram-variable. After 14 d incubation at 4 °C, surface colonies are circular, slimy/mucoid, white, with entire margins, and 0.5 – 4.0 mm in diameter. The temperature range for growth is -5 to 35 °C with optimum growth in the range 28 – 30 °C. Slightly alkalophilic; pH range for growth is 6.0 – 10.0 , with optimum growth at pH 8.5 . Growth occurs at NaCl concentrations of 0 – 6.5 % (w/v), with optimum growth at 0.5 % NaCl. Facultative anaerobe. Heterotrophic growth occurs on D-glucose, D-fructose, maltose, D-mannitol, D-mannose, D-ribose, D-arabinose, sucrose, starch, pyruvate, and citrate. No growth occurs on formate, acetate, lactate, propionate, butyrate, ethanol, methanol, glycerol, acetone, betaine, trimethylamine, triethylamine, peptone, Bacto tryptone, Casamino acids, yeast extract, pectin, and D-trehalose. The metabolic end products are lactate, formate, acetate, ethanol, and CO₂. Sensitive to ampicillin, kanamycin, gentamicin, tetracycline, rifampicin (all at 250 $\mu\text{g}/\text{ml}$), and chloramphenicol (125 $\mu\text{g}/\text{ml}$).

Isolated from guano of Magellanic penguins (*Spheniscus magellanicus*) inhabiting the southern region of Chilean Patagonia.

DNA G+C content (mol%): 45.8 (HPLC).

Type strain: PmagG1, ATCC BAA-756, CIP 108035, JCM 12176.

GenBank accession number (16S rRNA gene): AF394926.

Family IV. *Enterococcaceae* fam. nov.

WOLFGANG LUDWIG, KARL-HEINZ SCHLEIFER AND WILLIAM B. WHITMAN

En.te.ro.coc.ca'ce.ae. N.L. masc. n. *Enterococcus* type genus of the family; suff. -*aceae* ending denoting family; N.L. fem. pl. n. *Enterococcaceae* the *Enterococcus* family.

The family *Enterococcaceae* is circumscribed for this volume on the basis of phylogenetic analyses of the 16S rRNA sequences and includes the genus *Enterococcus*, *Melissococcus*, *Tetragenococcus*, and *Vagococcus* (Figure 3). It is composed of ovoid cocci that contain a Gram-stain-positive cell wall. Endospores are not

formed. Facultative anaerobic, anaerobic or microaerophilic chemo-organotrophic growth. Catalase-negative. Some species are carboxyphilic or halophilic. May be resistant to bile.

Type genus: Enterococcus (ex Thiercelin and Jouhaud 1903) Schleifer and Kilpper-Bälz 1984, 32.

Genus I. *Enterococcus* (ex Thiercelin and Jouhaud 1903) Schleifer and Kilpper-Bälz 1984, 32^{VP}

PAVEL ŠVEC AND LUC A. DEVRIESE

En.te.ro.coc'cus. Gr. n. *enteron* intestine; L. masc. n. *coccus* a grain, berry; N.L. masc. n. *Enterococcus* intestinal coccus

Gram-positive. Cells are ovoid, occur singly, in pairs, or in short chains, and are frequently elongated in the direction of the chain. Nonsporeforming. Strains of some species may be motile by scanty flagella. Some species are yellow pigmented. Facultatively anaerobic. Certain species are carboxyphilic (CO₂-dependent). Catalase-negative, but some strains reveal pseudocatalase activity when cultivated on blood-containing agar media. Hemolytic activity is variable and largely species-dependent.

Optimal growth of most species at 35–37°C. Many, but not all, species are able to grow at 42 and even at 45°C, and (slowly) at 10°C. **Very resistant to drying.**

Chemo-organotrophic growth. Generally **complex nutrient requirements**. Fermentative metabolism. Homofermentative lactic acid fermentation. Predominant end product of glucose fermentation is L-(+)-lactic acid. Certain characteristics are common to all described species, although rare exceptions may occur and certain test results have not yet been reported in the lesser known species: **resistance to 40% (v/v) bile**, production of β-glucosidase, leucine arylamidase, hydrolysis of esculin, production of acid from N-acetylglucosamine, amygdalin, arbutin, cellobiose, D-fructose, galactose, β-gentiobiose, glucose, lactose, maltose, D-mannose, methyl β-D-glucoside, ribose, salicin and trehalose. The following tests are mostly negative: urease, production of acid from D-arabinose, **erythritol, D- and L-fucose**, methyl α-D-xyloside and L-xylose. It should be noted that **certain characteristics traditionally considered to be typical for the genus do not apply to several of the more recently described species**: Lancefield group D antigen, resistance to 0.4% sodium azide or 6.5% NaCl, growth at 10°C and 45°C, production of pyrrolidonyl arylamidase and acetoin.

Most species are part of the intestinal flora of mammals and birds, and (much less well-known) other animals as well. Other species are associated with plants, or have been isolated from water.

DNA G+C content (mol%): 35.1–44.9.

Type species: Enterococcus faecalis (Andrewes and Horder 1906) Schleifer and Kilpper-Bälz 1984, 33^{VP} (*Streptococcus faecalis* Andrewes and Horder 1906, 713.).

Further descriptive information

The genus *Enterococcus* has been separated from the genus *Streptococcus* on the basis of results of DNA–DNA and DNA–rDNA hybridization studies (Schleifer and Kilpper-Bälz, 1984).

Subsequent 16S rDNA studies (Ludwig et al., 1985; Schleifer and Kilpper-Bälz, 1987) not only confirmed this separation, but also demonstrated that the enterococci also differed from the genus *Lactococcus* and certain other Gram-positive cocci. The genera *Streptococcus* and *Lactococcus* are more distantly related to the genus *Enterococcus* than are the coccus- or rod-shaped bacteria of the genera *Vagococcus*, *Carnobacterium*, *Tetragenococcus*, *Aerococcus*, *Alloiococcus*, *Dolosigranulum*, *Facklamia*, *Globicatella*, *Granulicatella*, *Melissococcus*, *Eremococcus*, *Ignavigranum*, and *Abiotrophia*. Indeed, according to the 16S rRNA phylogenetic analysis in the revised roadmap to Volume 3 (Figure 1 and Figure 3; Ludwig et al., this volume), *Enterococcus*, *Melissococcus*, *Tetragenococcus*, and *Vagococcus* are in a new family, *Enterococcaceae*, within the order *Lactobacillales*.

The cell-wall peptidoglycan type is lysine-D-asparagine (with D-isosparagine as cross-bridge) as described for *Enterococcus avium*, *Enterococcus casseliflavus*, *Enterococcus dispar*, *Enterococcus durans*, *Enterococcus faecium*, *Enterococcus gallinarum*, *Enterococcus hirae*, *Enterococcus malodoratus*, *Enterococcus mundtii*, *Enterococcus pseudoavium* and *Enterococcus raffinosus*, except *Enterococcus faecalis*, which has a lysine-alanine₂₋₃-type peptidoglycan (Collins et al., 1989b, 1986, 1984, 1991a; Farrow and Collins, 1985; Schleifer and Kilpper-Bälz, 1984). Position 2 of the glycerol molecules that constitute the backbone of the teichoic acids is esterified either with the glucose disaccharide kojibiose (as in *Enterococcus faecalis*) or the glucose trisaccharide kojitriose (as in *Enterococcus faecium*). Long-chain fatty acids are predominantly of the straight-chain saturated or monounsaturated types. Several species produce cyclopropane ring acids (Collins et al., 1989b, 1986; Schleifer and Kilpper-Bälz, 1984). The type group D antigen is located between the cell wall and the cell membrane (Smith and Shattock, 1964). It is a teichoic acid polymer of glycerol phosphate containing a high proportion of glucose (Wicken et al., 1963). Its lipid component is a 1-kojibiosyl diglyceride, with the sugars linked to the diglyceride by a phosphatidyl substituent (Toon et al., 1972). This antigen has been traditionally considered to be a typical trait of the genus *Enterococcus* but not all species possess it and its production was not determined for a few recently described species. On the other hand it can be found in several streptococci such as *Streptococcus bovis*, *Streptococcus suis* and *Streptococcus alactolyticus*, certain leuconostocs and pediococci (Devriese et al., 1993b).

Although enterococci have complex nutritional requirements, their growth on commonly used bacteriological media is usually profuse. They require several amino acids, B vitamins and purine and pyrimidine bases (Garg and Mital, 1991). Colonies are always regular and circular with a smooth surface, up to 5 mm in diameter. Certain species produce a yellow carotenoid pigment on agar media. An unusual C₃₂ carotenoid aldehyde has been detected in the *Enterococcus casseliflavus* pigment by Taylor et al. (1971).

The enterococci are facultatively anaerobic with a preference for anaerobic conditions. They are not able to synthesize porphyrins and therefore lack cytochrome pigments, but they may have flavin-containing NADH peroxidases (Miller et al., 1990). Superoxide dismutase induced by molecular oxygen enables survival of *Enterococcus faecalis* in aerobic conditions (Gregory and Fridovich, 1973). Demethylmenaquinones with nine isoprenoid subunits may function as noncytochrome electron carriers in *Enterococcus faecalis*, while menaquinones with eight isoprenoid subunits have been detected in *Enterococcus casseliflavus* (Collins and Jones, 1979). Membrane-associated demethylmenaquinones of *Enterococcus faecalis* are involved in substantial production of cellular superoxide (O₂⁻) and reactive oxygen compounds (H₂O₂, hydroxyl radical). This reaction is inhibited by exogenous fumarate and hematin (Huycke et al., 2001). Enterococci can ferment a wide variety of substrates. The main route of energy production is the homofermentative formation of mainly L-lactic acid from glucose through the Embden–Meyerhof–Parnas pathway. Under the aerobic conditions glucose is metabolized to acetic acid, acetoin and CO₂. Pyruvate is stoichiometrically converted to lactate by *Enterococcus faecalis* at pH 5.0–6.0, but at neutral or slightly alkaline pH it is converted to formate, ethanol, and acetate at the ratio 2:1:1 (Gunsalus et al., 1955). In nutrient deficiency, pyruvate is converted to ethanol and acetate (Garg and Mital, 1991). *Enterococcus faecalis* metabolizes malate by an inducible NAD-specific malic enzyme and malate permease is formed in the presence of substrate (London and Meyer, 1970). Gluconate is phosphorylated to 6-phosphogluconate followed by its dissimilation to lactate and CO₂ as described for *Enterococcus faecalis* (Garg and Mital, 1991). In aerated glycerol media *Enterococcus faecalis* produces mainly acetic acid and CO₂ with trace amounts of acetylmethylcarbinol. *Enterococcus faecium* can oxidize glycerol to acetic acid, CO₂ and low amounts of hydrogen peroxide (London and Appleman, 1962). Hippurate is hydrolyzed to glycine and benzoic acid. Energy can be obtained by degradation of some amino acids, as are arginine, tyrosine, serine, agmatine, phenylalanine, and canavanine (Deibel, 1964).

The enterococcal chromosome represents a single circular DNA of a size ranging from 3000–3250 kb for *Enterococcus faecalis*, 2550–2995 kb for *Enterococcus faecium*, 3445 kb for *Enterococcus avium* and 3070 kb for *Enterococcus durans* as revealed by physical mapping. *Enterococcus faecium*, *Enterococcus avium*, and *Enterococcus durans* contains six *rrn* operons; *Enterococcus faecalis* four *rrn* operons (Oana et al., 2002). The full genome sequence of *Enterococcus faecalis* V583 is available (Paulsen et al., 2003) and genome sequencing of *Enterococcus faecium* ATCC BAA-472 is in progress (information available at <http://hgsc.bcm.tmc.edu/microbial/efaecium/> and <http://genome.ornl.gov/microbial/efae/>). The *Enterococcus faecalis* V583 chromosome contains 3,218,031 bp consisting of 87.9% coding sequences. A total of

3182 protein-coding genes were detected with a mean size of 889 bp. Among these, 1760 were similar to known protein-coding genes. Furthermore, 495 showed similarity with conserved hypothetical functions, 221 were of unknown function and 706 protein coding genes did not match to any known protein. Twelve rRNA- and 68 tRNA-coding genes were detected. A total of 35 probable PTS-type sugar transporters involved in acquisition and fermentation of substrates were found. A total of 519 proteins were found which are conserved in low-G+C Gram-positive bacteria and are known to be involved in transcription, translation, and protein synthesis. Proteins from large paralogous families such as the PTS and ABC transporter families were also detected (Paulsen et al., 2003; Tendolkar et al., 2003).

Enterococci harbor a wide variety of plasmids and transposons that are involved in transfer of antibiotic resistance and virulence factor determinants. Pheromone-responding plasmids (e.g., pAD1, pAM322, pCF10 or pPD1) are typical for *Enterococcus faecalis*. They encode a surface adhesin called “aggregation substance” which binds donor as well as recipient cells. This leads to formation of cellular aggregates, enabling direct cell contact and efficient plasmid transfer. Antibiotic- or UV-resistance genes or cytolysin-encoding genes may be carried by these plasmids. Inc18 are low-copy-number plasmids (less than 10 copies per cell) of size 25–30 kb. Rolling Circle Replicating (RCR) plasmids are high-copy-number plasmids smaller than 10 kb that replicate by a rolling-circle mechanism. Inc18 and RCR plasmids can be replicated in many other Gram-positive bacteria (Devriese et al., 1992a; Weaver, 2000, 2002).

Besides plasmids, a wide variety of transposons have been isolated in enterococci. Tn3-family transposons, composite transposons and conjugative transposons classes are generally recognized. Tn917 and Tn1546 transposons represent typical members of the Tn3 group. Tn917 carries macrolides-lincosamide-streptogramin resistance genes and Tn1546 encodes *vanA* vancomycin-resistance genes. Conjugative transposons encoding resistance at least to one antibiotic reveal a broad host range. They integrate into the host DNA by transposition, but their transfer to other cells is enabled by conjugation. This common group of transposons contains, e.g., Tn916, Tn918 or Tn1549-encoding VanB phenotype vancomycin-resistance genes. Composite transposons are DNA sequences mobilized by terminal insertion sequences. They may encode sequences involved in antibiotic resistance (aminoglycosides, vancomycin) or mercury resistance or they can bear parts of plasmids or other transposons (Devriese et al., 1992a; Tendolkar et al., 2003; Weaver, 2000; Weaver et al., 2002). About a quarter of the fully sequenced genome of *Enterococcus faecalis* V583 consists of mobile and exogenous DNA including conjugative and composite transposons, a pathogenicity island, phage regions, integrated plasmid remnants and 38 insertion sequence elements. This high number of mobile DNA elements probably significantly contributes to acquisition and accumulation of virulence and resistance factors (Paulsen et al., 2003).

Enterococci produce bacteriocins called “enterocins” that are active against other enterococci as well as other bacterial groups including *Listeria* spp. Genes responsible for their production are located both on chromosome as well as on plasmids. A few enterocins from *Enterococcus faecalis* (AS-48, cytolysins CylL₁ and CylL₂) and *Enterococcus faecium* (Bacteriocin 31 and Enterocins A, B, P, and 50) have been studied in detail. They generally

belong to class II bacteriocins characterized as small, heat-stable proteins that are synthesized on ribosomes but do not undergo post-translational modifications. Enterocin-producing enterococci have been isolated from dairy products, fermented meat, as well as vegetables and plants (Franz et al., 1999). Ott et al. (2001) found antagonistic activity in *Enterococcus faecalis*, *Enterococcus mundtii*, *Enterococcus casseliflavus*, and *Enterococcus faecium* isolated from grasses. Partially purified enterocins from these plant-associated strains were active against a wide range of lactic acid bacteria, clostridia, and *Listeria* strains. Pompei et al. (1992b) and Berlutti et al. (1993) detected bacteriolytic activity in most human clinical strains tested. Different strains produced bacteriolytic enzymes of different properties that enable, together with biochemical tests, identification to the species level.

Enterococcal bacteriophages isolated from small intestine of white rats were characterized by Rogers and Sarles (1963). Bachrach et al. (2003) isolated enterococcal bacteriophages from human saliva and all enterococcal strains tested by Tzanetis et al. (1970) were lysogenic. A lytic enzyme obtained from a phage-infected *Enterococcus faecalis* culture has been used to induce *Enterococcus faecalis* protoplast formation (Bleiweis and Zimmerman, 1961). Phage typing has been used for characterization and typing of enterococci (e.g., Smyth et al., 1987) but its application as described in literature is scanty.

Enterococci are intrinsically resistant to many β -lactams, fluoroquinolones, lincosamides, trimethoprim-sulfamethoxazole and low concentrations of aminoglycosides. Acquired antibiotic resistance mediated by extrachromosomal DNA elements (plasmids, transposons) includes resistance to chloramphenicol, tetracyclines, macrolides, lincosamides, streptogramins and quinolones as well as high-level resistance to aminoglycosides, β -lactams and glycopeptides (Cetinkaya et al., 2000; Devriese et al., 1992a; Teixeira and Facklam, 2003). Vancomycin-resistant strains are a serious problem. Six vancomycin-resistance phenotypes have been described and characterized as VanA, VanB, VanD, VanE, and VanG. They are determined by transposable elements or can be chromosomally encoded and nontransferable as in case of the VanC phenotype. The VanA phenotype displays high-level inducible resistance to vancomycin and teicoplanin; VanB is characterized by moderate inducible resistance to vancomycin. They occur most frequently in *Enterococcus faecalis* and *Enterococcus faecium*. The VanC phenotype genes encode intrinsic low-level vancomycin resistance typical of *Enterococcus gallinarum* and *Enterococcus casseliflavus*. The VanD phenotype characterized by moderate resistance levels to vancomycin and low-level resistance to teicoplanin has been found in *Enterococcus faecium*. VanE and VanG phenotypes exhibit low-level and moderate-level resistance to vancomycin, respectively, but both these phenotypes characterized in *Enterococcus faecalis* reveal full sensitivity to teicoplanin (Cetinkaya et al., 2000; McKessar et al., 2000; Tendolkar et al., 2003). Resistance to β -lactam antibiotics found in *Enterococcus faecalis* and *Enterococcus faecium* clinical strains is mediated mostly by production of penicillin-binding protein (PBP5). Production of β -lactamase by these two species is very rare. High-level aminoglycoside resistance is mediated by a single mutation within the 30S ribosomal subunit protein as in the case of streptomycin or through the production of aminoglycoside-modifying enzymes (Shepard and Gilmore, 2002). In general, *Enterococcus faecium* shows higher prevalence of resistance than *Enterococcus faecalis* and other enterococcus species.

Although enterococci are commensal inhabitants of humans, they are increasingly isolated from a variety of nosocomial and other infections. *Enterococcus faecalis* represents the most commonly isolated enterococcal species from human clinical material (80–90%) followed by *Enterococcus faecium* (8–16%). *Enterococcus avium*, *Enterococcus casseliflavus*, *Enterococcus cecorum*, *Enterococcus dispar*, *Enterococcus durans*, *Enterococcus gallinarum*, *Enterococcus gilvus*, *Enterococcus hirae*, *Enterococcus mundtii*, *Enterococcus pallens*, and *Enterococcus raffinosus* are rarely isolated (Teixeira and Facklam, 2003). Enterococci are found mainly in urinary tract and wound infections, bacteremias, and endocarditis. They are less frequently involved in respiratory, biliary tract, and central nervous system infections, otitis, sinusitis, septic arthritis, endophthalmitis and burn wounds (Jett et al., 1994; Teixeira and Facklam, 2003). Adherence of enterococcal cells to human cells and subsequent invasion of host tissues is supported by aggregation substance, surface carbohydrates, cytolysins, protease, hyaluronidase, lipase, gelatinase, and superoxide production (Elsner et al., 2000; Jett et al., 1994; Mundy et al., 2000). All these traits have been extensively characterized in *Enterococcus faecalis* but they are less well-known in *Enterococcus faecium* or other species.

Enterococci are important in septicemia, osteomyelitis, and endocarditis in poultry and ducks and they may cause sporadic infections in other animal species (Devriese et al., 1992a; Vancanneyt et al., 2001; Wood et al., 2002).

Enterococcus faecalis represents the prevailing enterococcal species colonizing the human digestive tract, although *Enterococcus faecium* may prevail in some persons or localities depending probably on age, diet, or physiological conditions of organisms (Devriese et al., 1992a; Devriese et al., 1995). One gram of human feces contains about 10^5 – 10^7 enterococcal cells (Murray and Weinstock, 1999). *Enterococcus gallinarum*, *Enterococcus casseliflavus*, and *Enterococcus mundtii* have been found in stool samples by Van Horn and Rodney (1998). Enterococci are less commonly isolated from the vagina and from oral cavity (Hardie and Whiley, 1997; Murray, 1990). More species are found in animals. Poultry is commonly inhabited by *Enterococcus faecium*, *Enterococcus cecorum*, *Enterococcus faecalis*, *Enterococcus hirae*, and *Enterococcus durans*; in contrast *Enterococcus gallinarum* and *Enterococcus avium* are rare (Devriese et al., 1991, 1987). *Enterococcus faecalis* is a prevailing species in rectum and tonsils of dogs and cats (Devriese et al., 1992b). Baele et al. (2002) found *Enterococcus columbae* to be a common inhabitant of pigeon intestines followed by *Enterococcus cecorum*. Mundt (1963a) and Mallon et al. (2002) found enterococci in feces of wild mammals, reptiles and birds. *Enterococcus casseliflavus* has been found to be a common inhabitant of the gut of garden snails (Charrier et al., 1998; Švec et al., 2002). Enterococci are often isolated from nectar-feeding insects (Martin and Mundt, 1972) and have been found in gut of termites (Bauer et al., 2000; Brune and Friedrich, 2000; Švec et al., 2006). The recently described *Enterococcus canis* (De Graef et al., 2003) and *Enterococcus hermanniensis* (Koort et al., 2004) have been isolated from canine tonsils, *Enterococcus canintestini* from dog feces (Naser et al., 2005c), *Enterococcus phoeniculiicola* from a Red-billed Woodhoopoe (Law-Brown and Meyers, 2003) and *Enterococcus devriesei* from bovine materials and from the air of a poultry slaughter by-product processing plant (Švec et al., 2005b).

Enterococci can also be isolated from food, plants, soil, and water. Although these bacteria are considered to be only a temporary part of the microflora of plants, in good conditions they can propagate on their surface (Mundt, 1961; Stirling and Whittenbury, 1963). *Enterococcus faecalis*, *Enterococcus faecium*, *Enterococcus hirae*, *Enterococcus mundtii*, *Enterococcus casseliflavus*, and *Enterococcus sulfureus* were isolated from plants (Müller et al., 2001; Ott et al., 2001). They are generally isolated more often from flowers than from buds or leaves. This indicates that insects are probably involved in the dissemination of enterococci. Soil can be contaminated by enterococci from animals and/or plants thanks to wind or rain (Mundt, 1961). It is not naturally inhabited by enterococci as shown by Medrek and Lidsky (1960) who isolated enterococci in only 8 out of 369 samples of soils that were unaffected by human activity. Occurrence of enterococci in waters is generally considered to be the result of fecal contamination. Typically, *Enterococcus faecalis*, *Enterococcus faecium*, *Enterococcus durans*, and *Enterococcus hirae* can be commonly found in contaminated waters; less often *Enterococcus avium*, *Enterococcus gallinarum*, *Enterococcus cecorum*, and *Enterococcus columbae* are isolated (Godfree et al., 1997; Pourcher et al., 1991). Pristine waters in Finland mainly contained *Enterococcus casseliflavus* (Niemi et al., 1993). Because of their long survival capacities, enterococci are used as indicators of distant contamination in water supplies. Environment-associated strains are often biochemically different from strains isolated from animals and many strains cannot be unequivocally assigned to known species (Devriese et al., 1992a; Martin and Mundt, 1972; Müller et al., 2001; Mundt, 1961, 1963b; Niemi et al., 1993; Ulrich and Müller, 1998).

Enterococci are a common part of many kinds of food – especially those of animal origin such as milk and milk products, meat, and fermented sausages. They are generally considered to be secondary contaminants of food often playing a role in its spoilage, although certain strains positively influence ripening and aroma development of some types of cheeses. They are even used as probiotic cultures in some products (Franz et al., 1999; Giraffa, 2002). On the other hand, presence of virulence factors in starter and food enterococcal strains as well as transfer of virulence determinants to starter strains has been demonstrated (Eaton and Gasson, 2001). Devriese et al. (1995) found *Enterococcus faecium* to prevail in cheese and cheese–meat combined foods. *Enterococcus faecalis* was common in crustaceans. Meat products contained mostly *Enterococcus faecium* followed by *Enterococcus faecalis*, and *Enterococcus durans/Enterococcus hirae*. Products containing turkey meat contained *Enterococcus gallinarum*. *Enterococcus hermanniensis* has been isolated from broiler meat (Koort et al., 2004) and *Enterococcus devriesei* from vacuum-packaged charcoal-broiled river lampreys (Švec et al., 2005b). Kirk et al. (1997) isolated *Enterococcus faecium* and *Enterococcus faecalis* as prevailing species from frozen chicken carcasses. Enterococci can contaminate milk and dairy products during various processing steps, where *Enterococcus faecalis* and *Enterococcus faecium* prevail (Garg and Mital, 1991; Mannu et al., 1999).

Enrichment and isolation procedures

As enterococci have complex nutritional requirements it is not possible to cultivate them in defined media, but they grow well on commonly used rich complex bacteriological media

(e.g., Todd–Hewitt, trypticase soy, brain heart infusion, starch agar, blood-containing agars). Some species grow very poorly on MRS broth and agar commonly used for cultivation of lactic acid bacteria. More than 60 different selective media have been described for isolation of enterococci. Unfortunately, they all allow growth of some other bacteria while many enterococcal species are completely or partially inhibited. The most frequently used media for isolation and enumeration of enterococci from various samples contain sodium azide as a selective agent.

Maintenance procedures

Lyophilization, coating of glass beads in -70°C , or storage in liquid nitrogen can be used for long-term preservation of enterococci. They can also be kept for 1–2 years at -20°C in lyophilization medium or tubes of stab-inoculated agar (YGLP, BHI) stored at 4°C . Maintenance in Litmus Milk plus chalk at 4°C is generally suitable for short-term preservation (3 months), although some strains can survive in these conditions for up to 5 years.

Differentiation of the genus *Enterococcus* from other genera

Classical biochemical identification of strains as belonging to the genus *Enterococcus* and their differentiation from other related genera is achieved primarily via the species identification. For practical purposes the following approach can be used: catalase-negative, Gram-positive cocci, showing good growth on enterococcus-selective media containing 0.4% sodium azide, and able to grow in 6.5% (w/v) NaCl broth, can be identified presumptively as belonging to the genus *Enterococcus*. Typically, only strains of the *Streptococcus bovis* species group show colony characteristics similar to those of the “classical” enterococci on these selective media, but these strains do not grow in 6.5% NaCl broth. However, it should be kept in mind that this procedure excludes several enterococcal species. Molecular identification methods generally obviate this type of difficulties.

Taxonomic comments

A most important phenomenon is the existence of species groups within the genus *Enterococcus* (Table 116, Figure 110). Certain species appear to form distinct lineages, but most others can be allotted to these groups (Švec et al., 2001; Tyrrell et al., 2002a; Vancanneyt et al., 2001; Williams et al., 1991). Members of such groups exhibit similar phenotypic characteristics, and species separation can be problematic. 16S rRNA gene sequence similarities between species can be as high as 99.8% within some groups. Despite these close relationships and similarities the species are well separated by DNA–DNA similarity determinations and certain molecular identification techniques. The *Enterococcus faecium* group contains *Enterococcus faecium*, *Enterococcus durans*, *Enterococcus canis*, *Enterococcus hirae*, *Enterococcus mundtii*, *Enterococcus ratti*, and *Enterococcus villorum*. These species mostly show identical growth and physiological characteristics. Discrimination of individual species of this group by biochemical tests is often unreliable. *Enterococcus durans*, *Enterococcus hirae*, and *Enterococcus villorum* are especially difficult to differentiate, although they can be clearly distinguished by whole-cell protein profile analysis using SDS-PAGE, tDNA-PCR and arbitrarily primed PCR analysis (Devriese et al., 2002). The *Enterococcus avium* group contains *Enterococcus*

Data obtained from Devriese et al., 1992a; Pompei et al., 1992b; Devriese et al., 1993b; Devriese and Pot, 1995; Teixeira et al., 1995; Manero and Blanch, 1999; Baele et al., 2002; Devriese et al., 2002; Teixeira and Facklam, 2003; Carvalho et al., 2004 as well as from the original descriptions of enterococcal species (for references see "List of species of the genus *Enterococcus*").

^aFor symbols see standard definitions; w, weak reaction.

^bRefers to discordant results appearing in literature; see the species description in the "List of species of the genus *Enterococcus*" for more details

^cEnantiomers are not stated in literature

FIGURE 110. Distance matrix tree based on 16S RNA gene sequence comparisons showing the phylogenetic relationships of *Enterococcus* species. *Vagococcus fluvialis* (X54258) sequence was used as the outgroup. Bootstrap percentage values (500 tree replications) higher than 50% are indicated at the branch points. The tree was constructed by the neighbor-joining method.

avium, *Enterococcus devriesei*, *Enterococcus gilvus*, *Enterococcus malodoratus*, *Enterococcus pseudoavium*, and *Enterococcus raffinosus*. These species form mostly small colonies with strong greening hemolysis and they often grow but only weakly on enterococcus selective media. Growth at 10°C, 45°C and in 6.5% NaCl as well as D antigen production may be negative. Members of this group are typically adonitol- and L-sorbose-positive. The *Enterococcus faecalis* group contains *Enterococcus faecalis*, *Enterococcus caccae*, *Enterococcus hemoperoxidus*, *Enterococcus moraviensis*, *Enterococcus silesiacus* and *Enterococcus termitis*. Although phylogenetic distances are larger in this group the six species share many phenotypic traits. They form similar dark red colonies with a metallic sheen on Slanetz–Bartley agar. Growth at 10°C, in 6.5% NaCl as well as production of D antigen is positive. Nevertheless, these species can be differentiated from each other by a few biochemical tests. The *Enterococcus gallinarum* group consists of *Enterococcus gallinarum* and *Enterococcus casseliflavus*. Intrinsic low-level vancomycin resistance and motility are typical for this group, although nonmotile strains may be rarely isolated (Clark et al., 1998; Patel et al., 1998; Vincent et al., 1991). *Enterococcus cecorum* and *Enterococcus columbae* species are more distantly phylogenetically related, but they show,

nevertheless, remarkable phenotypic similarities. They grow poorly on enterococcus-selective media and they are carboxyphilic: their growth is strongly enhanced by cultivation in a CO₂ atmosphere. The alkaline phosphatase that may be produced by these two species is a unique trait in the genus *Enterococcus*. The *Enterococcus italicus* group contains *Enterococcus italicus* and *Enterococcus camelliae*. These two recently described species reveal low biochemical activity in comparison with the other enterococcal species

Five species have been reclassified from the genus *Enterococcus* since it was established by Schleifer and Kilpper-Bälz (1984). *Enterococcus seriolicida* (Kusuda et al., 1991) was found to be synonymous with *Lactococcus garvieae* and reclassified by Teixeira et al. (1996). The species *Enterococcus porcinius* (Teixeira et al., 2001) was found to be a junior synonym of *Enterococcus villorum* and validly reclassified by De Graef et al. (2003). Similarly, *Enterococcus solitarius* (Collins et al., 1989b) was reclassified to the genus *Tetragenococcus* as *Tetragenococcus solitarius* (Ennahar and Cai, 2005). Recently, Naser et al. (2006) reclassified *Enterococcus flavescens* (Pompei et al., 1992a) as *Enterococcus casseliflavus* and *Enterococcus saccharominimus* (Vancanneyt et al., 2004) as *Enterococcus italicus*.

Miscellaneous comments

A number of schemes based on biochemical and physiological characteristics have been proposed for the identification of enterococci (e.g., Day et al., 2001; Devriese et al., 1993b; Facklam and Collins, 1989; Manero and Blanch, 1999). However, identification of enterococci based on biochemical tests only is difficult and often unreliable. The situation is complicated by different methodological approaches that provide different results for the same test, and discrepancies can be found between the conventional methods and various commercial kits (e.g., Hudson et al., 2003; Bosshard et al., 2004; Winston et al., 2004). Moreover, strains of the same species isolated from different sources may reveal different biochemical characteristics (Devriese et al., 1995; Švec et al., 2002). Generally speaking, it can be concluded that only *Enterococcus faecalis* is relatively easily and reliably identified using growth characteristics and biochemical testing. In sample types in which *Enterococcus faecium* is the only frequent representative of the *Enterococcus faecium* species group, identification is possible in this way. But in all other instances it is advisable to confirm identification of this important species by other means.

Full as well as partial 16S rRNA gene sequencing has been used for identification of enterococci (Monstein et al., 2001; Patel et al., 1998). This method is valuable for identification at the genus and species-group level but it should be kept in mind that 16S rRNA gene sequence similarities between species can be as high as 99.8% as in the case of *Enterococcus casseliflavus*–*Enterococcus gallinarum* or 99.7% for *Enterococcus faecium*–*Enterococcus durans* (Williams et al., 1991). However, the DNA–DNA similarity values of these species are low and clearly indicate their separate species status. The DNA–DNA hybridization method can be considered as a gold standard for description of novel enterococcus species, but this time-consuming technique is yet not applicable for routine identification. PCR methods based on detection of D-Ala:D-Ala ligase gene-targeted primers (*ddl*_{E.faecalis} and *ddl*_{E.faecium}) and *vanA*, *vanB*, and *vanC* genes are applied for differentiation of *Enterococcus faecalis*, *Enterococcus faecium*, *Enterococcus gallinarum*, and *Enterococcus casseliflavus* (Dudka-Malen et al., 1995). Differentiation of *Enterococcus durans* and *Enterococcus hirae* by the *ddl*-PCR was described by Knijff et al. (2001). Another method is based on partial sequencing of the D-Ala:D-Ala ligase gene (Ozawa et al., 2000).

tRNA intergenic spacer PCR (tDNA-PCR) followed by capillary electrophoresis of the PCR products proved to be a good tool for identification of all enterococcus species as shown by Baele et al. (2000). A related method uses PCR amplification of 16S–23S rRNA intergenic spacer (Tyrrell et al., 1997). Evaluation of repetitive sequence based PCR (rep-PCR) fingerprinting with the (GTG)₅ primer for identification of enterococci was described by Švec et al. (2005c). Arbitrarily primed PCR with a D11344 primer has been shown to be a useful method for species-specific identification of enterococci by Descheemaeker et al. (1997) and Devriese et al. (2002). Broad-range PCRs using 16S rDNA-targeted primers differentiate enterococci into species groups (Monstein et al., 1998). Hybridization of rRNA gene sequence-targeting probes was evaluated by Behr et al. (2000) and Manero and Blanch (2002). Application of multilocus sequence analysis (MLSA) using *rpoA*, *pheS* and *atpA* genes was evaluated for identification of enterococci by Naser et al. (2005a, 2005b).

Analysis of whole-cell protein profiles obtained by SDS-PAGE is a suitable method corresponding to DNA–DNA hybridization results (De Graef et al., 2003; Devriese et al., 2002; Koort et al., 2004; Merquior et al., 1994; Müller et al., 2001; Tyrrell et al., 2002a; Vancanneyt et al., 2001). Other biochemical and physical identification methods applied in enterococcus identification include long-chain fatty acid analysis (Fortina et al., 2004; Tyrrell et al., 2002a), cell membrane fatty acid methyl ester analysis (Lang et al., 2001), temperature-gradient gel electrophoresis (TGGE) and denaturing-gradient gel electrophoresis (DGGE) of 16S rDNA variable regions (Ercolini et al., 2001; Monstein et al., 2001) and vibrational spectroscopy (Kirschner et al., 2001).

List of species of the genus *Enterococcus*

1. ***Enterococcus faecalis*** (Andrewes and Horder 1906) Schleifer and Kilpper-Bälz 1984, 33^{VP} (*Streptococcus faecalis* Andrewes and Horder 1906, 713)

fae.ca'is. L. n. *faex* dregs; N.L. adj. *faecalis* relating to feces.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Usually nonhemolytic. Pseudocatalase may be produced when cultivated on blood-containing agar media. Strains survive heating at 60 °C for 30 min. Tetrazolium is reduced to formazan and typical red colonies are formed when grown on tetrazolium-containing selective media. Grows on media containing sodium azide. The cell-wall peptidoglycan is Lys–Ala₂₋₃ type. The major fatty acids are hexadecanoic, octadecenoic and

cis-11,12-methylenoctadecanoic. Most strains contain demethylmenaquinones with nine isoprene units. Malate, serine, citrate, gluconate and arginine are utilized as an energy source. Tyrosine is decarboxylated to tyramine.

Aberrant results may be seen in asaccharolytic variant strains from human clinical material, which may be glycerol-, lactose-, mannitol-, sucrose- and trehalose-negative (Facklam and Collins, 1989; Teixeira et al., 2001).

Isolated from human and veterinary clinical materials, from food, and the environment. Typically associated with intestines of humans and animals.

See generic description for further features.

DNA G+C content (mol%): 37.0–40.0 (*T_m*).

Type strain: ATCC 19433, ATCC 19433-U, CCM 7000, CCUG 19916, CIP 103015, DSM 20478, HAMBI 1711, JCM 5803, JCM 8726, LMG 7937, NBRC 100480, NBRC 100481, NCAIM B.01312, NCIMB 775, NCTC 775.

GenBank accession number (16S rRNA gene): AB012212, AJ301831.

2. **Enterococcus aquimarinus** Švec, Vancanneyt, Devriese, Naser, Snauwaert, Lefebvre, Hoste and Swings 2005a, 2186^{VP}
a.qui.ma.ri'nus. L. fem. n. *aqua* water; L. adj. *marinus* of the sea; N.L. masc. adj. *aquimarinus* pertaining to sea water

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Growth at 42 °C and in 6.5% NaCl is positive. Weak growth on Slanetz–Bartley medium.

Isolated from sea water.

DNA G+C content (mol%): 38.7 (HPLC).

Type strain: API 8407116, CCM 7283, LMG 16607.

GenBank accession number (16S rRNA gene): AJ877015.

3. **Enterococcus asini** de Vaux, Laguerre, Diviès and Prévost 1998, 386^{VP}

a.si'ni. L. gen. sing. *asini* of donkeys, *Equus asinus*.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Grows in 4% NaCl but not in 6.5% NaCl. Strains survive heating at 60 °C for 30 min.

Isolated from cecal contents of donkeys (*Equus asinus*).

See generic description for further features.

DNA G+C content (mol%): 39.4 (UV spectroscopy).

Type strain: AS2, ATCC 700915, CCM 4895, CCUG 44928, DSM 11492, LMG 18727, NBRC 100681.

GenBank accession number (16S rRNA gene): Y11621.

4. **Enterococcus avium** (ex Nowlan and Deibel 1967) Collins, Jones, Farrow, Kilpper-Bälz and Schleifer 1984, 220^{VP} (“*Streptococcus avium*” Nowlan and Deibel 1967, 295)

av.i'um. L. n. *avis* bird; L. gen. pl. n. *avium* of birds.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Mostly α -hemolytic. Folic acid is required for growth. H₂S production is positive.

Isolated from human and veterinary clinical materials, from food and the environment.

See generic description for further features.

DNA G+C content (mol%): 39.0–40.0 (*T_m*).

Type strain: Guthof E6844, ATCC 14025, CCM 4049, CCUG 44928, CIP 103019, DSM 20679, JCM 8722, LMG 10744, NBRC 100477, NCIMB 702369, NCTC 9938, VKM B-1673.

GenBank accession number (16S rRNA gene): Y18274, AJ301825, AF133535.

5. **Enterococcus caccae** Carvalho, Shewmaker, Steigerwalt, Morey, Sampson, Joyce, Barrett, Teixeira and Facklam 2006, 1507^{VP}

ca'cae. Gr. n. *kakke* feces; N.L. gen. n. *caccae* of feces.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Small colonies up to 0.5 mm in diameter are formed on sheep-blood agar at 37 °C. Growth at 45 °C and in 6.5% NaCl is positive.

Positive production of β -glucosidase, glycyl-tryptophan arylamidase, β -mannosidase, pyroglutamic acid arylamidase and N-acetyl- β -glucosaminidase. Negative production of alanine-phenyl-alanine-proline arylamidase, urease and acidification of cyclodextrin and pullulan. Hippurate hydrolysis negative in API Rapid ID 32 kit but positive using conventional testing.

Isolated from human stool samples.

DNA G+C content (mol%): 32.5 (*T_m*).

Type strain: 2215–02, SS-1777, ATCC BAA-1240, CCUG 51564, DSM 19114.

GenBank accession number (16S rRNA gene): AY943820.

6. **Enterococcus camelliae** Sukontasing, Tanasupawat, Moonmangmee, Lee and Suzuki 2007, 2153^{VP}

ca.mel.li'ae. N.L. gen. n. *camelliae* of *Camellia*, isolated from fermented tea (*Camellia sinensis*) leaves.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: The species contains DMK-7 (94.7%), DMK-8 (4.2%) and DMK-9 (1.1%) demethylmenaquinones. C_{16:1} (30.5%) and C_{18:1} (20.9%) are predominant straight-chain fatty acids. The species grows in pH 5–9.0, at 15–45 °C and in 2–6% NaCl. Riboflavin, niacin and calcium-pantothenate are required for growth. See generic description for further features.

Isolated from fermented tea (*Camellia sinensis*) leaves.

DNA G+C content (mol%): 37.8.

Type strain: FP15-1, KCTC 13133, NBRC 101868, NRIC 0105, TISTR 932, PCU 277.

GenBank accession number (16S rRNA gene): EF154454.

7. **Enterococcus canintestini** Naser, Vancanneyt, De Graef, Devriese, Snauwaert, Lefebvre, Hoste, Švec, Decostere, Haesebrouck and Swings 2005c, 2181^{VP}

can.in.tes'ti.ni. L. gen. n. *canis* of a dog; L. neut. n. *intestinum* gut; N.L. gen. n. *canintestini* of the gut of dog.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Growth at 42 °C is positive. Tetrazolium reduction on Slanetz–Bartley agar is positive. Positive for salicin and negative for methyl β -D-xylopyranoside acidification.

Isolated from feces of healthy dogs.

DNA G+C content (mol%): 36.0–37.0 (HPLC)

Type strain: CCM 7285, LMG 13590

GenBank accession number (16S rRNA gene): AJ888906

8. **Enterococcus canis** De Graef, Devriese, Vancanneyt, Baele, Collins, Lefebvre, Swings and Haesebrouck 2003, 1072^{VP}

ca'nis. L. gen. n. *canis* of a dog.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: α -hemolytic. Growth at 42 °C is positive. Pinpoint-sized colonies are formed on Slanetz–Bartley agar after 48 h without tetrazolium reduction. Urease may be produced.

Isolated from dog feces.

See generic description for further features.

DNA G+C content (mol%): 41.7–43.0 (HPLC).

Type strain: CCUG 46666, LMG 12316, CCM 7125, NBRC 100695.

GenBank accession number (16S rRNA gene): X76177.

9. **Enterococcus casseliflavus** (ex Vaughan, Riggsby and Mundt 1979) Collins, Jones, Farrow, Kilpper-Bälz and Schleifer 1984, 221^{VP} (*Streptococcus faecium* subsp. *casseliflavus* Mundt and Graham 1968, 2007; *Streptococcus casseliflavus* Vaughan, Riggsby and Mundt 1979, 212)

cass.el.i.flá'vus. N.L. n. *casseli* of Cassel (Cassel yellow); L. adj. *flavus* yellow; *casseliflavus* yellow-colored.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: α -hemolytic on horse blood. Growth at pH 9.6 is positive. Strains survive heating at 60 °C for 30 min. Tyrosine decarboxylation-negative. The species contains menaquinones; MK-7 and MK-8 are the major isoprenologs. Hexadecanoic and octadecenoic acids are the major nonhydroxylated long-chain fatty acids.

Originally described as D-raffinose acidification-negative but stated to be positive by Devriese et al. (1992a) and Teixeira and Facklam (2003). The species is generally considered to be motile and pigmented although nonmotile and non-pigmented strains have been reported from human clinical material (Clark et al., 1998; Vincent et al., 1991).

Isolated from human and veterinary clinical materials, from food, and the environment. It is considered to be typically plant-associated.

See generic description for further features.

DNA G+C content (mol%): 40.5–44.9 (T_m).

Type strain: ATCC 25788, CCUG 18657, CIP 103018, CCM 2478, DSM 20680, JCM 8723, LMG 10745, NBRC 100478, NCIMB 11449, NCTC 12361, NRRL B-3502, MUTK 20.

GenBank accession number (16S rRNA gene): AJ301826, Y18161.

10. **Enterococcus cecorum** (Devriese, Dutta, Farrow, Van de Kerckhove and Phillips 1983) Williams, Farrow and Collins 1989a, 495^{VP} (Effective publication: Williams, Farrow and Collins 1989b, 188.) (*Streptococcus cecorum* Devriese, Dutta, Farrow, Van de Kerckhove and Phillips 1983, 774)

ce.co'rum. L. n. *cecum* sacculated diverticulum of the large intestine (cecum); N.L. gen. pl. n. *cecorum* of ceca.

See Table 116 for most of the biochemical and physiological characteristics. Other traits are as follows: hemolytic on sheep-blood agar. Weak growth at pH 9.6. Strains do not survive 60 °C for 30 min. The species prefers an increased CO₂ content in atmosphere (carboxyphilic). No growth on Slanetz–Bartley medium and kanamycin esculin azide agar. Gelatinase- and tyrosinase-negative. Hexadecanoic and octadecenoic acids are the major nonhydroxylated long-chain fatty acids.

Originally described as alkaline phosphatase- and β -glucuronidase production-positive and mannitol and sorbitol acidification-negative, but strains revealing opposite results were described by Devriese et al. (1992b).

Isolated from animals, rarely from human clinical material and from water.

See generic description for further features.

DNA G+C content (mol%): 37.0–38.0 (T_m).

Type strain: A60, ATCC 43198, CCM 3659, CCUG 27299, CIP 103676, DSM 20682, JCM 8724, LMG 12902, NBRC 100674, NCIMB 702674, NCTC 12421.

GenBank accession number (16S rRNA gene): AF061009, AJ301827, X54290.

11. **Enterococcus columbae** Devriese, Ceysens, Rodrigues and Collins 1993a, 188^{VP} (Effective publication: Devriese, Ceysens, Rodrigues and Collins 1990, 251.)

co.lumb'ae. L. n. *columba* pigeon; L. gen. n. *columbae* of a pigeon.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: The species prefers an increased CO₂ content in atmosphere (carboxyphilic). No growth on Slanetz–Bartley medium. Grows on bile esculin agar in 3–10% CO₂ in air but not in the normal atmosphere.

Motility and growth in 6.5% NaCl are stated to be negative and alkaline phosphatase and leucine arylamidase to be positive in the original species description, but later tests revealed that the species is variably motile, grows in 6.5% NaCl and is mostly negative for alkaline phosphatase and leucine arylamidase production (Baele et al., 2002).

Dominant bacterium in the small intestines of pigeons; rarely isolated from water.

See generic description for further features.

DNA G+C content (mol%): 38.2 (T_m).

Type strain: STR 345, ATCC 51263, CCM 4376, DSM 7374, LMG 11740, NCIMB 13013.

GenBank accession number (16S rRNA gene): AF061006, AJ301828, X56422, Y18275.

12. **Enterococcus devriesei** Švec, Vancanneyt, Koort, Naser, Hoste, Vihavainen, Vandamme, Swings and Björkroth 2005b, 2482^{VP} de'vrie.se.i. N.L. gen. n. *devriesei* of Devriese, in honor of the Belgian microbiologist Luc A. Devriese.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: α -hemolysis on bovine blood agar. Positive growth on azide-containing selective media and bile-esculin agar. Slow growth at 4 °C. Positive salicin and negative methyl β -xyloside acidification.

Isolated from bovine materials, vacuum-packaged charcoal-broiled river lampreys and the air of a poultry slaughter by-product processing plant

DNA G+C content (mol%): 40.0 (HPLC).

Type strain: CCM 7299, LMG 14595.

GenBank accession number (16S rRNA gene): AJ891167.

13. **Enterococcus dispar** Collins, Rodrigues, Piggot and Facklam 1991b, 456^{VP} (Effective publication: Collins, Rodrigues, Piggot and Facklam 1991a, 97.)

dis'par. L. adj. *dispar* dissimilar, different.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Strains survive heating at 60 °C for 30 min.

Originally described as melibiose acidification-positive but stated as negative according to Devriese et al. (1993b).

Isolated from human clinical material and from dog feces.

See generic description for further features.

DNA G+C content (mol%): 39.0 (T_m).

Type strain: E18-1, ATCC 51266, CCM 4282, CCUG 33309, CIP 103646, DSM 6630, HAMBI 2231, LMG 13521, NBRC 100678, NCFB 2821, NCIMB 13000.

GenBank accession number (16S rRNA gene): AF061007, AJ301829, Y18358.

14. **Enterococcus durans** (*ex* Sherman and Wing 1937) Collins, Jones, Farrow, Kilpper-Bälz and Schleifer 1984, 222^{VP} (*Streptococcus durans* Sherman and Wing 1937)

du'rans. L. part. adj. *durans* hardening, resisting.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Strains may be α -hemolytic and rarely β -hemolytic. Respiratory quinones absent. Hexadecanoic and octadecenoic acids are the major nonhydroxylated long-chain fatty acids; substantial amounts of *cis*-11,12-methylenoctadecanoic are also present (approx. 10%).

Originally described as negative for melibiose and sucrose acidification, but strains positive for sucrose as well as melibiose acidification were described by Devriese et al. (2002). Melibiose-positive strains were isolated from human clinical material by Facklam and Collins (1989).

Isolated from human and veterinary clinical materials, from food and the environment.

See generic description for further features.

DNA G+C content (mol%): 38.0–40.0 (T_m).

Type strain: 98D, ATCC 19432, CCM 5612, CCUG 7972, CIP 55.125, DSM 20633, JCM 8725, LMG 10746, NBRC 100479, NCIMB 700596, NCTC 8307.

GenBank accession number (16S rRNA gene): AJ276354.

15. **Enterococcus faecium** (Orla-Jensen 1919) Schleifer and Kilpper-Bälz 1984, 33^{VP} (*Streptococcus faecium* Orla-Jensen 1919, 139)

fae'ci.um. L. n. *faex* dregs; L. gen. pl. n. *faecium* of the dregs, of feces.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Some strains may be α -hemolytic. Growth at pH 9.6 is positive. Survives heating at 60 °C for 30 min. Negative for citrate, malate and serine utilization and gelatin hydrolysis. Reduction of tellurite and tetrazolium-negative. The major fatty acids are hexadecanoic, octadecenoic and *cis*-11,12-methylenoctadecanoic. Cells do not contain menaquinones. The cell-wall peptidoglycan is Lys-D-Asp type.

Originally described as negative for D-xylose acidification, but most of the canine and bovine strains are positive (Devriese et al., 1987). Originally described as raffinose and sorbitol acidification-negative, but strains from poultry are usually raffinose-positive and strains from dogs as well as rare strains from humans are sorbitol-positive (Devriese et al., 1992b; Devriese et al., 1995).

Isolated from human and veterinary clinical materials, from food, and the environment.

See generic description for further features.

DNA G+C content (mol%): 37.0–40.0 (T_m).

Type strain: ATCC 19434, CCM 7167, CCUG 542, CIP 103014, CFBP 4248, DSM 20477, LMG 11423, HAMBI 1710, JCM 5804, JCM 8727, NBRC 100485, NCIMB 11508, NCTC 7171.

GenBank accession number (16S rRNA gene): AB012213, AJ276355, AJ301830, Y18294.

16. **Enterococcus gallinarum** (Bridge and Sneath 1982) Collins, Jones, Farrow, Kilpper-Bälz and Schleifer 1984, 222^{VP} (*Streptococcus gallinarum* Bridge and Sneath 1982, 414.)

gall.in.ar'um. L. fem. gen. pl. n. *gallinarum* of hens.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: β -hemolytic on horse-blood agar. Most strains survive heating at 60 °C for 15 min but not for 30 min. Gelatinase production-negative. Low levels of menaquinones produced, with MK-8 predominant. Hexadecanoic and octadecenoic acids are the major nonhydroxylated long-chain fatty acids; *cis*-11,12-methylenoctadecanoic is present in small amounts.

Originally described as negative for glycerol acidification, but stated to be positive by Devriese and Pot (1995) and variable by Devriese et al. (1983) and Collins et al. (1986). Originally described as positive for sorbitol acidification, but found to be negative by Devriese et al. (1992a) and Teixeira and Facklam (2003). Devriese and Pot (1995) concluded that this characteristic may be variable. Generally considered to be motile although it was originally described as nonmotile and nonmotile strains were isolated from human clinical material (Clark et al., 1998; Patel et al., 1998).

Isolated from human and veterinary clinical materials, from food and the environment.

See generic description for further features.

DNA G+C content (mol%): 39.0–40.0 (T_m).

Type strain: F87/276, ATCC 49573, CCM 4054, CCUG 18658, CIP 103013, DSM 20628, HAMBI 1717, JCM 8728, LMG 13129, NBRC 100675 = NCIMB 702313, NCTC 1142, NCTC 11428, NCTC 12359, PB218.

GenBank accession number (16S rRNA gene): AJ301833.

17. **Enterococcus gilvus** Tyrrell, Turnbull, Teixeira, Lefebvre, Carvalho, Facklam and Lovgren 2002b, 1075^{VP} (Effective publication: Tyrrell, Turnbull, Teixeira, Lefebvre, Carvalho, Facklam and Lovgren 2002a, 1143.)

gil.vus. L. adj. *gilvus* pale yellow, referring to the pale yellow pigmentation of the bacterium.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Tetrazolium reduction is positive. Black colonies are not produced on tellurite-containing media.

Isolated from human clinical material.

See generic description for further features.

DNA G+C content (mol%): not determined.

Type strain: PQ1, ATCC BAA-350, CCM 7168, CCUG 45553, DSM 15689, LMG 21841, NBRC 100696.

GenBank accession number (16S rRNA gene): AY033814.

18. **Enterococcus haemoperoxidus** Švec, Devriese, Sedláček, Baele, Vancanneyt, Haesebrouck, Swings and Doškař 2001, 1571^{VP}

hae.mo.per.o'xi.dus. Gr. n. *haema* blood; Gr. pref. *per* intensification; Gr. adj. *oxys* sour; N.L. adj. *haemoperoxidus* blood peroxide, derived from the ability of the species to decompose hydrogen peroxide into oxygen and water when cultivated on blood-agar media.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Growth is strongly inhibited at 42 °C. Positive catalase reaction when cultivated on blood-agar but negative when grown on non-blood-containing media.

Isolated from surface waters.

See generic description for further features.

DNA G+C content (mol%): 35.3–35.5 (HPLC).

Type strain: 440, ATCC BAA-382, CCM 4851, CIP 107129, LMG 19487, NBRC 100709.

GenBank accession number (16S rRNA gene): AF286832.

19. **Enterococcus hermanniensis** Koort, Coenye, Vandamme, Sukura and Björkroth 2004, 1826^{VP}

her.man.ni.en'sis. N.L. adj. *hermanniensis* pertaining to Hermann, a locality in Helsinki, Finland.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: α -hemolytic on bovine blood agar. Slow growth as maroon colonies on azide-containing media.

Isolated from broiler meat and canine tonsils.

See generic description for further features.

DNA G+C content (mol%): 36.6–37.1 (HPLC).

Type strain: CCUG 48100, CCM 7222, LMG 12317.

GenBank accession number (16S rRNA gene): AY396047.

20. **Enterococcus hirae** Farrow and Collins 1985, 74^{VP}

hir.ae. L. gen. sing. n. *hirae* of the intestine or gut.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Growth at pH 9.6 is positive. Hexadecanoic, octadecenoic, and *cis*-11,12-methylenoctadecanoic acids are the major nonhydroxylated long-chain fatty acids. Menaquinones are absent.

Originally described as positive for melibiose and sucrose acidification, but negative strains were described by Facklam and Collins (1989) and Devriese et al. (2002).

Isolated from human and veterinary clinical materials, from food and the environment.

See generic description for further features.

DNA G+C content (mol%): 37.0–38.0 (T_m).

Type strain: E.E. Snell strain R, ATCC 8043, ATCC 9790, CCM 2423, CCUG 1332, CCUG 18659, CCUG 19917, CIP 53.48, CFBP 4250, DSM 20160, HAMBI 644, HAMBI 1709, NBRC 3181, JCM 8729, LMG 6399, NCCB 46070, NCCB 58005, NCIMB 6459, NCTC 12367.

GenBank accession number (16S rRNA gene): AF061011, AJ276356, AJ301834, Y17302.

21. **Enterococcus italicus** Fortina, Ricci, Mora and Manachini 2004, 1720^{VP}

i.ta'li.cus. L. adj. *italicus* from Italy, where the bacterium was first isolated.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Positive α -hemolysis on blood-containing agar media. Growth is positive at 5% NaCl, pH 9.6 and 42 °C, variable in 6.0% NaCl but negative in 6.5% NaCl. Does not grow on kanamycin esculin azide agar.

Isolated from dairy products.

See generic description for further features.

DNA G+C content (mol%): 39.9–41.1 (T_m).

Type strain: DSM 15952, LMG 22039, TP1.5.

GenBank accession number (16S rRNA gene): AJ582753.

22. **Enterococcus malodoratus** (*ex* Pette 1955) Collins, Jones, Farrow, Kilpper-Bälz and Schleifer 1984, 222^{VP} (“*Streptococcus faecalis* subsp. *malodoratus*” Pette 1955)

mal.od.or.a'tus. L. n. *malus* ill; N.L. part. adj. *odoratus* odorous; N.L. adj. *malodoratus* ill-smelling.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Some strains produce slime. Survival at 60 °C for 30 min is mostly negative. H₂S is produced. Respiratory quinones absent. Hexadecanoic and tetradecanoic acids are the major nonhydroxylated long-chain fatty acids.

Isolated from dairy products.

See generic description for further features.

DNA G+C content (mol%): 40.0–41.0 (T_m).

Type strain: ATCC 43197, CCM 4056, CCUG 30572, CIP 103012, DSM 20681, HAMBI 1569, JCM 8730, LMG 10747, NBRC 100489, NCIMB 700846, NCTC 12365.

GenBank accession number (16S rRNA gene): AF061012, AJ301835, Y18339.

23. **Enterococcus moraviensis** Švec, Devriese, Sedláček, Baele, Vancanneyt, Haesebrouck, Swings and Doškař 2001, 1572^{VP}

mo.ra.vi.en'sis. N.L. adj. *moraviensis* pertaining to Moravia, the region in the Czech Republic.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Growth is strongly inhibited at 42 °C.

Isolated from surface waters.

See generic description for further features.

DNA G+C content (mol%): 35.6–36.3 (HPLC).

Type strain: 330, ATCC BAA-383, CCM 4856, CIP 107130, LMG 19486, NBRC 100710.

GenBank accession number (16S rRNA gene): AF286831.

24. **Enterococcus mundtii** Collins, Farrow and Jones 1986, 10^{VP}

mund'ti.i. N.L. gen. n. *mundtii* of Mundt; named after the late J.O. Mundt, an American microbiologist.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Growth at pH 9.6 is positive. The long-chain fatty acids are of the straight-chain saturated, monounsaturated and cyclopropane ring types. The major fatty acids are hexadecanoic, octadecenoic, and *cis*-11,12-methylenoctadecanoic acids.

The species is typically associated with plants but it was rarely isolated from human clinical material and from animals.

See generic description for further features.

DNA G+C content (mol%): 38.0–39.0 (T_m).

Type strain: ATCC 43186, CCM 4058, CCUG 18656, CFBP 4251, CIP 103010, DSM 4838, HAMBI 1570, JCM 8731, LMG 10748, MUTK 559, NBRC 100490, NCIMB 702375, NCTC 12363.

GenBank accession number (16S rRNA gene): AF061013, AJ301836, Y18340.

25. **Enterococcus pallens** Tyrrell, Turnbull, Teixeira, Lefebvre, Carvalho, Facklam and Lovgren 2002b, 1075^{VP} (Effective publication: Tyrrell, Turnbull, Teixeira, Lefebvre, Carvalho, Facklam and Lovgren 2002a, 1144.)

pall'ens. L. adj. *pallens* yellowish, referring to the yellow pigmentation of the bacterium.

See Table 116 for most of the biochemical and physiological characteristics. Originally described as positive for pyruvate utilization and arabinose acidification but stated as negative for these tests by Teixeira and Facklam (2003).

Isolated from human clinical material.

See generic description for further features.

DNA G+C content (mol%): not determined.

Type strain: PQ2, ATCC BAA-351, CCM 7169, DSM 15690, LMG 21842, CCUG 45554.

GenBank accession number (16S rRNA gene): AY033815.

26. **Enterococcus phoeniculicola** Law-Brown and Meyers 2003, 684^{VP}

phoe.ni.cu.li'co.la. N.L. n. *Phoeniculus* the genus of the woodhoopoe; L. suff. *-cola* inhabitant; N.L. masc. n. *phoeniculicola* growing in *Phoeniculus*.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Nonhemolytic. Does not grow in 6% NaCl and in the presence 40% bile.

Described as delayed positive (48 h) for mannitol, sorbitol and L-sorbose acidification and negative for D-raffinose acidification but opposite results of these tests were revealed in the type strain by Carvalho et al. (2004).

Isolated from the uropygial gland of a Red-billed Woodhoopoe (*Phoeniculus purpureus*).

See generic description for further features.

DNA G+C content (mol%): not determined.

Type strain: JLB-1, ATCC BAA-412, CCM 7236, CCUG 48923, DSM 14726, LMG 22471, KCTC 3818, NBRC 100711.

GenBank accession number (16S rRNA gene): AY028437.

27. **Enterococcus pseudoavium** Collins, Facklam, Farrow and Williamson 1989c, 371^{VP} (Effective publication: Collins, Facklam, Farrow and Williamson 1989b, 287.)

pseu.do. av.i'um. Gr. adj. *pseudēs* false; L. n. *avis* bird; L. gen. plur. *avium* of birds; N.L. neut. pl. n. *pseudoavium* false [*Enterococcus*] *avium*, owing to its similarity to this species.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: α -hemolytic. The long-chain cellular fatty acids are of the straight-chain saturated and mono-unsaturated types. The major types are tetradecanoic and hexadecanoic acids.

Habitat unknown. The type strain was isolated from bovine mastitis, however no other strains have been found despite intensive investigation of this habitat by several groups.

See generic description for further features.

DNA G+C content (mol%): 40.0 (T_m).

Type strain: ATCC 49372, CCUG 33310, CIP 103647, DSM 5632, CCM 4215, JCM 8732, LMG 11426, NCIMB 13084.

GenBank accession number (16S rRNA gene): AF061002, AJ301837, Y18356.

28. **Enterococcus raffinosus** Collins, Facklam, Farrow and Williamson 1989c, 371^{VP} (Effective publication: Collins, Facklam, Farrow and Williamson 1989b, 286.)

raf'fi.no.sus. N.L. adj. *raffinosis* of raffinose, referring to ability to metabolize raffinose.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: The long-chain cellular fatty acids are of the straight-chain saturated, monounsaturated and cyclopropane ring types. The major types are tetradecanoic and hexadecanoic acids.

Isolated from human clinical material and rarely from animal sources or from environmental samples.

See generic description for further features.

DNA G+C content (mol%): 39.0–40.0 (T_m).

Type strain: 1789/79, ATCC 49427, CCM 4216, CCUG 29292, CIP 103329, DSM 5633, JCM 8733, LMG 12888, NBRC 100492, NCTC 12192.

GenBank accession number (16S rRNA gene): Y18296.

29. **Enterococcus ratti** Teixeira, Carvalho, Espinola, Steigerwalt, Douglas, Brenner and Facklam 2001, 1742^{VP}
rat'ti. N.L. gen. masc. n. *ratti* of the rat.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Some strains may be α -hemolytic.

Isolated from intestines and feces of infant rats with diarrhea.

See generic description for further features.

DNA G+C content (mol%): not determined.

Type strain: DS 2705-87, ATCC 700914, CCUG 43228, CCM 7235, CIP 107173, DSM 15687, LMG 21828, NBRC 100698, NCIMB 13635.

GenBank accession number (16S rRNA gene): AF539705.

30. **Enterococcus saccharolyticus** (Farrow, Kruze, Phillips, Bramley and Collins 1984) Rodrigues and Collins 1991, 178^{VP} (Effective publication: Rodrigues and Collins 1990, 233.) (*Streptococcus saccharolyticus* Farrow, Kruze, Phillips, Bramley and Collins 1984, 480)

sac.cha.ro.ly'ti.cus. Gr. n. *sakchar* sugar; Gr. adj. *lyticus* able to loosen; M.L. adj. *saccharolyticus* sugar-digesting.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Nonhemolytic. Strains do not survive at 60 °C for 30 min. Gelatin hydrolysis is negative.

Isolated from cow feces and from straw bedding.

See generic description for further features.

DNA G+C content (mol%): 37.6–38.3 (T_m).

Type strain: ATCC 43076, CCM 4377, CCUG 27643, CCUG 33311, CIP 103246, DSM 20726, HF 62, JCM 8734, LMG 11427, NBRC 100493, NCIMB 702594.

GenBank accession number (16S rRNA gene): AF061004, AJ 301839, X55767, Y18357.

31. **Enterococcus silesiacus** Švec, Vancanneyt, Sedláček, Naser, Snauwaert, Lefebvre, Hoste and Swings 2006, 580^{VP}

si.le'si.a.cus. N.L. masc. adj. *silesiacus* pertaining to Silesia, the region in the Czech Republic from which the type strain originates.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: The species grows on kanamycin esculin azide agar and bile esculin agar with positive esculin reaction. Weak growth on Slanetz and Bartley agar in small dark-red colonies. Positive catalase

reaction when cultivated on blood-agar but negative when grown on non-blood-containing media. Salicin positive and methyl β -xylopyranoside negative acidification.

Isolated from surface waters.

DNA G+C content (mol%): 35.6–36.7 (HPLC).

Type strain: W442, CCM 7319, LMG 23085.

GenBank accession number (16S rRNA gene): AM039966.

32. **Enterococcus sulfureus** Martinez-Murcia and Collins 1991b, 580^{VP} (Effective publication: Martinez-Murcia and Collins 1991a, 72.)

sulfu're.us. L. adj. *sulfureus* of sulfur.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: Growth is positive at 40 °C, but not at 45 °C.

Isolated from plants.

See generic description for further features.

DNA G+C content (mol%): 38.0 (T_m).

Type strain: ATCC 49903, CCM 4283, CCUG 30571, CCUG 33313, CIP 104373, DSM 6905, HAMBI 2232, LMG 13084, MUTK 31, NBRC 100680, NCIMB 13117.

GenBank accession number (16S rRNA gene): AF061001, AJ301841, X55133, Y18341.

33. **Enterococcus termitis** Švec, Vancanneyt, Sedláček, Naser, Snauwaert, Lefebvre, Hoste and Swings 2006, 580^{VP}

ter.mi'tis. L. n. *termes -itis* a worm that eats wood, a wood-worm, and in zoology the name of a scientific genus; L. gen. n. *termitis* of a termite.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: The species grows on kanamycin esculin azide agar and bile esculin

agar with positive esculin reaction. Weak growth on Slanetz and Bartley agar in small dark-red colonies. Salicin positive and methyl β -xylopyranoside negative acidification.

Isolated from the gut of a termite.

DNA G+C content (mol%): 37.1 (HPLC).

Type strain: CCM 7300, LMG 8895.

GenBank accession number (16S rRNA gene): AM039968.

34. **Enterococcus villorum** Vancanneyt, Snauwaert, Cleenwerck, Baele, Descheemaeker, Goossens, Pot, Vandamme, Swings, Haesebrouck and Devriese 2001, 398^{VP} (*Enterococcus porcinius* Teixeira, Carvalho, Espinola, Steigerwalt, Douglas, Brenner and Facklam 2001, 1742).

vil.lo'rum. L.n. *villus* rough hair, anatomical term for flocculate structures in the small intestine; L. gen. pl. *villorum*.

See Table 116 for most of the biochemical and physiological characteristics. The other traits are as follows: α -hemolytic. Grows on azide-containing media but slower than related enterococci. Colonies on Slanetz–Bartley agar are pink.

Originally described as D-raffinose, sucrose and α -methyl-D-glucoside acidification-negative and melibiose acidification-positive but strains revealing opposite results were described by Devriese et al. (2002).

Isolated from pigs and from birds.

See generic description for further features.

DNA G+C content (mol%): 35.1–35.3 (HPLC).

Type strain: 88-5474, ATCC 700913, CCM 4887, CCUG 45025, DSM 15688, JCM 11557, LMG 12287, NBRC 100699.

GenBank accession number (16S rRNA gene): AF335596, AJ271329.

Genus II. **Melissococcus** Bailey and Collins 1983, 672^{VP} (Effective publication: Bailey and Collins 1982b, 216.)

LEON M. T. DICKS AND WILHELM H. HOLZAPFEL

Me.lis'so.coc'cus. Gr. n. *melissa* bee; Gr. n. *coccus* berry; N.L. masc. n. *Melissococcus coccus* of the (honey) bee.

Cells are lanceolate cocci and occur singly, in pairs, or in chains of varying lengths (Figure 111). Pleomorphic and rod-like forms have also been described. Individual cells measure 0.5–0.7 \times 1.0 μ m. Gram-positive, but destain easily. Stain negative with nigrosin. Nonmotile, catalase-negative, asporogenic, and non-acid-fast. No aerobic growth. Anaerobic to microaerophilic, with best growth in the presence of 1–5% (v/v) CO₂. CO₂ levels higher than 5% inhibit some strains, but inhibition may be overcome by inclusion of self-prepared autolyzed yeast extract.

Cell-wall peptidoglycan contains lysine and is of the Lys–Ala type. Respiratory quinones are absent. The long-chain fatty acids are primarily straight-chain, monounsaturated (cis-vaccenic acid type), and cyclopropane ring acids. There is only one species in the genus.

Type species: **Melissococcus plutonius** corrig. (ex White 1912) Bailey and Collins 1983, 672 (Effective publication: Bailey and Collins 1982b, 216.)

Further descriptive information

Based on 16S rRNA sequence analysis, *Melissococcus plutonius* is only remotely related (approx. 87–89% sequence similarity) to

the genus *Streptococcus* (Cai and Collins, 1994). The species is, however, phylogenetically closely related to the genus *Enterococcus* (94–96%, Figure 112) and is considered to be on the periphery of that genus. The close affinity between the two genera is further supported by the fact that they both belong to the Lancefield D antigen group (Glinski, 1972a). Close, albeit more distant, relationships were recorded with *Carnobacterium* species (92%), *Vagococcus* species (93%), and *Tetragenococcus halophilus* (approx. 94%). According to the 16S rRNA phylogenetic analysis in the revised roadmap to Volume 3 (Figure 1 and Figure 3; Ludwig et al., this volume), *Melissococcus* is classified in the new family *Enterococcaceae* along with the genera *Enterococcus*, *Tetragenococcus*, and *Vagococcus*, within the order *Lactobacillales*.

Stringent growth requirements, competition from other bacteria during isolation, and the small number of phenotypic characteristics whereby *Melissococcus plutonius* can be differentiated from other bacterial species, led to the developing of more reliable identification methods. Further differentiation of *Melissococcus plutonius* from *Streptococcus faecalis* and related enterococci is obtained by serological (Bailey and Gibbs, 1962) and chemical (Bailey and Collins, 1982a) methods. Enzyme-linked immunosorbent assay (ELISA) has proven a rapid and

Morphology of cells of *Melissococcus plutonius* under phase-contrast microscopy, after anaerobic growth at 30 °C in a special medium (0.25% Peptone, Oxoid L37, 1% glucose, 0.2% soluble starch, 0.25% yeast extract, Oxoid L21, 0.5% Neopeptone, Difco 0119, 0.2% Trypticase BBL 11921, 50ml 1M phosphate buffer, pH 7.6, 0.025% Cysteine-HCl-H₂O and 2% agar). Bar = 10 µm.

FIGURE 112. Dendrogram showing the phylogenetic relationships based on 16S rRNA gene, of *Melissococcus plutonius*, enterococci, and other members of the Firmicutes. Clustering was by the unweighted pair group method. T = *Tetragenococcus*, C = *Carnobacterium*, V = *Vagococcus*, E = *Enterococcus*. (Modified and reprinted with permission from Cai and Collins, *International Journal of Systematic Bacteriology* 44: 365–367, 1994.)

extremely sensitive method to identify strains of *Melissococcus plutonius* (Pinncock and Featherstone, 1984). Serological tests with polyclonal antisera have also been used to some extent (Allen and Ball, 1993).

A rapid PCR detection method, with primers designed from the 16S rRNA sequence of the type strain of *Melissococcus plutonius* (LMG 9003, NCDO 2443), was developed by Govan et al. (1998). The primers selected were 5' GAAGAGGAGT-TAAAAGGCGC 3' (primer 1) and 5' TTATCTCTAAGGCGT-TCAAAGG 3' (primer 2). An 812 bp fragment was generated by PCR. Detection was highly specific and allowed for the identification of *Melissococcus plutonius* among other bacterial strains present in bee larvae.

A hemi-nested PCR assay designed to detect *Melissococcus plutonius* was developed by Djordjevic et al. (1998). Three oligonucleotide primers were used. The first pair (MP1 and MP2) flanked the 16S rRNA gene from positions 893–1377, yielding a 486 bp fragment. The third primer amplified 25 nucleotides within the latter region (from 1144 to 1168). The resultant 276 bp fragment amplified was species specific with the ability to detect 1–10 cells per ml. The method proved reliable in the detection of *Melissococcus plutonius* in infected brood. The annealing temperatures used in the PCR reactions seem to be critical. PCR fragments of the same length were amplified from *Melissococcus plutonius* and *Enterococcus faecalis* when the annealing temperature was lowered by 5 °C (Djordjevic et al., 1998). However, digestion of the DNA fragments with *Hinf*I, clearly differentiated between DNA from *Melissococcus plutonius* and *Enterococcus faecalis*.

Behr et al. (2000) designed a comprehensive set of rRNA targeted species-specific oligonucleotide hybridization probes for the detection and identification of *Enterococcus* species. The array of probes used was designed from 16S and 23S rRNA sequences according to the multiple probe concept. Probe Mplu464 (5' GTCACGAGGAAAACAGTT 3') which spans position 465–483 of the 16S rRNA gene, and probe Enc01cV (5' AGGTTAAGT-GAACAAGG 3'), position 1–17 of the 23S rRNA, are specific for *Melissococcus plutonius* (Behr et al., 2000).

It is generally assumed that European foulbrood is caused by infection from *Melissococcus plutonius* via food intake. However, more recent studies (Kanbar et al., 2004) indicated that the mite *Varroa destructor* may also be a vector. The latter authors have identified strains of *Melissococcus plutonius* with strong tyramine production, of which the toxicity has been demonstrated by using the protozoan *Stylonychia lemnae*.

The cultural characteristics and serological relationships of strains of *Melissococcus plutonius* isolated from *A. mellifera* larvae from Brazil, China and the UK are discussed by Allen and Ball (1993). Nigrosin smears of cells clearly show the variation in morphology depicted for *Melissococcus plutonius*.

Enrichment and isolation procedures

Melissococcus plutonius only grows under anaerobic to microaerophilic conditions, with best growth in the presence of 1–5% (v/v) CO₂. Growth is greatly stimulated in the presence of self-prepared autolyzed yeast extract. Strains of this species are usually cultivated on complex growth media only. Two chemically defined growth media were developed by Bailey (1984). They differ slightly in amino acid composition, with the major differences in salts, carbohydrates (starch and glucose), and bases. The carbohydrates and salts, at double strength, are sterilized

separately at 116 °C for 20 min. The rest of the constituents, also at double strength, are filter-sterilized and then added to the melted agar at a 1:1 ratio. The medium is freshly prepared and the plates immediately used. Incubation is at 35 °C in anaerobic jars in the presence of 5% (v/v) CO₂.

Methionine, glucose, thymine, xanthine, pyridoxal HCl, and a number of vitamins (Bailey, 1984) are essential. Methionine cannot be substituted for by cysteine or cystine. The presence of yeast extract, Difco (1–3 g/l), or peptone, Oxoid L37 (10 g/l), maintains the growth of most strains (Bailey, 1984). Starch is not required by all strains. Glucose can be replaced by sucrose or melezitose for some strains, although glucose is preferred.

Isolation of *Melissococcus plutonius* from infected bee larvae is usually done by crushing the larvae in sterile distilled water, followed by streaking onto the following medium (g/100 ml): yeast extract (1.0), glucose (1.0%), soluble starch (1.0%), KH₂PO₄ (1.36%), and agar (2.0%) in distilled water, adjusted to pH 6.6 with 5 M KOH (Anderson, 1990; Bailey, 1981). The plates are incubated anaerobically at 37 °C for 9 d and then examined for the presence of white colonies.

A variation of the above medium, with filter-sterilized nalidixic acid added to a final concentration of 3 µg/ml, proved very selective for the isolation of *Melissococcus plutonius* from diseased material and honey contaminated with *Paenibacillus larvae* (Alippi, 1991; Hornitzky and Smith, 1998).

Maintenance procedures

A maintenance medium consisting of peptone (Neopeptone, Difco, or Oxoid Peptone L37), cysteine (0.1%), glucose (1%), soluble starch (1%), and KH₂PO₄ (1 mol/l), pH 6.6, was developed by Bailey and Collins (1982a), in which the yeast extract was exchanged for peptone (Bailey, 1984). Although some strains grow in the presence of Na₂HPO₄, it is not preferred. The medium is autoclaved in screw-capped bottles at 116 °C for 20 min, sealed, and used immediately. Cultures are streaked onto the surface of agar slopes (2% w/v) and incubated at 35 °C in the presence of hydrogen and 5% CO₂ (v/v).

Taxonomic comments

Melissococcus plutonius was first isolated from diseased honeybee larvae (*Apis mellifera*) with symptoms of European foulbrood. White (1912, 1920) classified the bacterium as *Bacillus pluton*, based on microscopic examinations. Upon a more detailed description of the organism, it was reclassified as *Streptococcus pluton* (Bailey, 1957). Strains closely related to *Streptococcus pluton* were subsequently also isolated from diseased larvae of *Apis indica* (Diwan et al., 1971), *Apis cerana* (Bailey, 1974), and *Apis laboriosa* (Allen et al., 1990). The species name “*Streptococcus pluton*” was never included in the Approved Lists of Bacterial Names (Skerman et al., 1980). Bailey and Collins (1982b) assigned “*Streptococcus pluton*” to a new genus, *Melissococcus*, based on phenotypic characteristics (Bailey and Collins, 1982a). The genus was subsequently listed in Validation List no. 11 (Bailey and Collins, 1983) and was treated as *Genus Incertae Sedis* in *Bergey's Manual of Systematic Bacteriology* (Hardie, 1986). The specific epithet “*pluton*” (Greek god of the underworld) was corrected to *plutonius*, pertaining to Pluto or the underworld (Trüper and de Clari, 1998).

The close phylogenetic relatedness recorded between the genera *Melissococcus* and *Enterococcus* (Behr et al., 2000; Cai and

Collins, 1994; Djordjevic et al., 1998; Lawson et al., 2000) suggests that they should be included in a single genus. According to the International Code of Nomenclature, Bailey and Collins (1982b) consider the genus name *Melissococcus* to have preference over the genus name *Enterococcus* (Schleifer and Kilper-Bälz, 1984). However, Cai and Collins (1994) argued that a change in genus name would only cause confusion. Still, it should be noted that the genus name *Enterococcus* was originally proposed by Thiercelin and Jouhaud (1903) for Gram-positive diplococci from intestinal origin, thus confirming the priority of the genus name *Enterococcus*. Today, the genus *Enterococcus* is well established, with more than 25 species, and is widely accepted by the scientific community. The fastidious cultural requirements of *Melissococcus plutonius*, its low G+C content (29–30 mol%), and its branching at the periphery of the *Enterococcus* cluster (Figure 112) warrant separate genus status. Confirmation of the latter was obtained from separate 16S rRNA and 23S rRNA sequence analyses (Figure 113).

Bailey (1974) noted that strains he isolated from *Apis cerana* differed distinctly from all known strains of “*Streptococcus pluton*” previously isolated from *Apis mellifera*. Based on the limited phenotypic data available at the time, he did, however, consider the strains to be more closely related to each other than to any other known bacterial species and therefore grouped them into a single species. The question of whether strains of *Streptococcus pluton* isolated from *Apis cerana* could be a variety of *Streptococcus pluton* from *Apis mellifera* was raised, but left unanswered. In a later study, Bailey (1984) noted that a strain isolated from bees in Brazil were slightly different from other strains of *Melissococcus plutonius* (then *Melissococcus pluton*), but only regarding their serological reactions and higher DNA base composition, recorded as 31.4 mol% G+C. The Brazil strains, however, were well separated from the genus *Streptococcus* (Bailey, 1984).

To date, *Melissococcus* is considered a monospecific genus. Some proof as to the genetic homogeneity of the genus came from an elaborate study conducted on strains of *Melissococcus plutonius* isolated from *Apis mellifera* collected from various states of Australia (Djordjevic et al., 1999). Although minor differences were observed in the restriction endonuclease (*Aha*I, *Cfo*I, *Rsa*I, and *Dra*I) profiles for a few strains, neither SDS-PAGE of whole-cell proteins nor immunoblotting revealed strain-specific patterns. This high degree of genetic (and phenotypic) homogeneity among *Melissococcus plutonius* isolates led the authors to hypothesize that the host (*Apis* species) exerts little selective pressure from its immune response to stimulate immune evasion mechanisms in the bacteria. This may well be the case, since *Melissococcus plutonius* only infects the larvae and pupal stages of the host, leaving the insect with little opportunity to develop an immune response (Djordjevic et al., 1999). The seemingly limited selective pressure from the environment may also contribute to the high degree of genetic homogeneity observed among strains of *Melissococcus plutonius*. It is tempting to assume that the homogeneous status of the species is also indicative of a low profile of genetic recombination events among strains. Furthermore, since no plasmids (at least none larger than 15 kb) could be isolated from any of the 49 strains studied (Djordjevic et al., 1999), it can be assumed that the differences recorded in DNA profiles, albeit small, are located on the genome. Alternative plasmid isolation methods may, however, prove this assumption wrong.

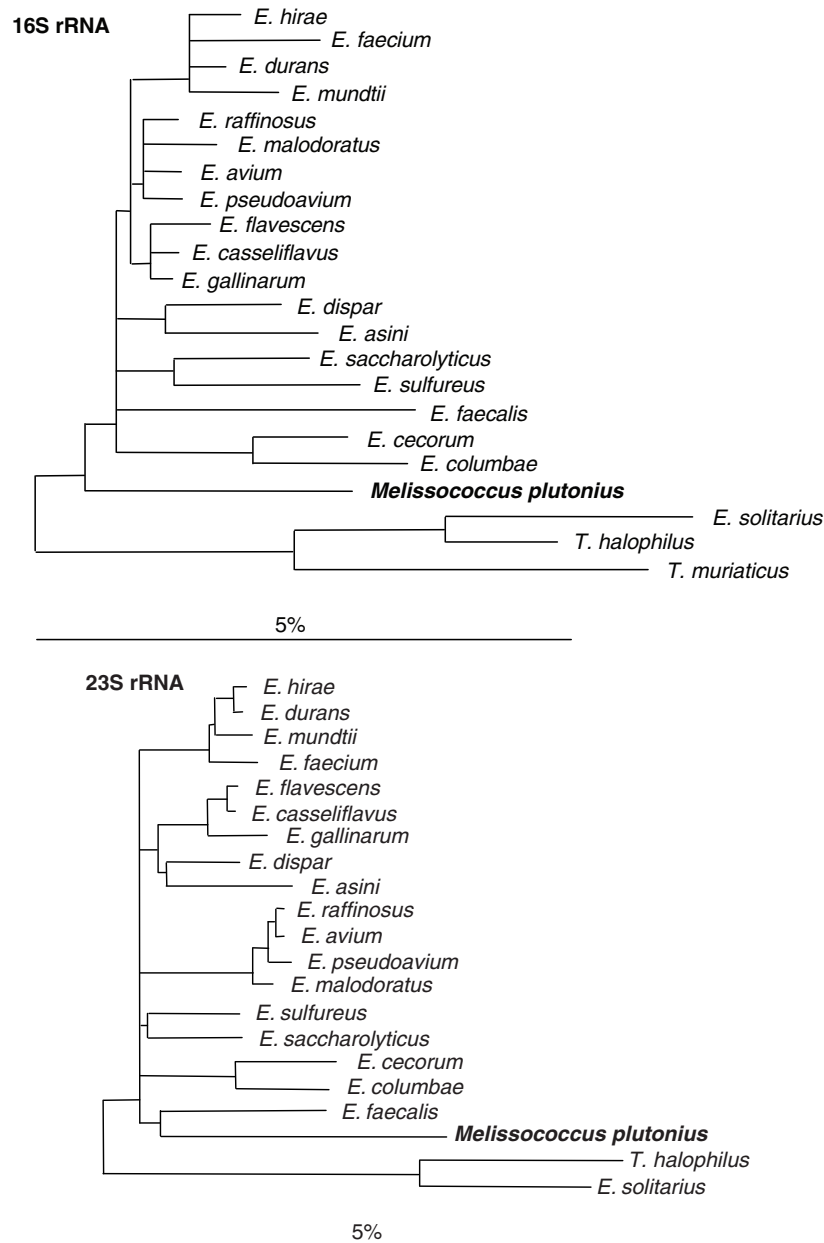

FIGURE 113. Phylogenetic relationships of *Melissococcus plutonius* and the type strains of *Enterococcus* species and *Tetragenococcus* species based on 16S rRNA and 23S rRNA. (Modified and reprinted with permission from Behr et al., *Systematic and Applied Microbiology* 23: 563–572, 2000.)

List of species of the genus *Melissococcus*

- Melissococcus plutonius*** corrig. (*ex* White 1912) Bailey and Collins 1983, 672^{VP} (Effective publication: Bailey and Collins 1982b, 216.)
 plu'ton.ius. L. masc. adj. *plutonius* of or belonging to Pluto, Roman god of the underworld.

The specific epithet "*pluton*" (Pluton, Greek god of the underworld) has been corrected to *plutonius* (Trüper and de Clari, 1998). The following is based on previous descriptions of "*Bacillus pluton*" (White, 1912, 1920), "*Streptococcus pluton*" (Bailey, 1963a, 1963b, 1974; Bailey and Collins, 1982a; Bailey and Gibbs, 1962; Gliniski, 1972b) and *Melissococcus pluton* (Bailey and Collins, 1982b).

Colony morphology varies, depending on the source of isolation. Colonies are usually easily visible (up to 1 mm in diameter), dense (opaque), white or granular, and dome-shaped. However, small, flat, transparent, umbonate colonies with clear centers and granular peripheries have also been described. Growth is enhanced if autolyzed yeast extract instead of standard Difco yeast extract is included in the medium, to the extent that small, flat, transparent colonies divert to dome-shaped, opaque, white colonies. Isolation and cultivation is difficult due to the extremely fastidious nature of the organism. Apart from yeast extract, the

growth medium usually contains a fermentable sugar, starch, peptone, cysteine or cystine, and potassium. The Na:K ratio required for growth is 1 or less. Glucose and fructose are the only sugars usually fermented. Some strains metabolize sucrose, melezitose, maltose, and salicin. Citrate is not metabolized. Lactic acid is the major organic acid produced, with small amounts of acetic, isobutyric, and succinic acids. Final pH in the growth medium is 5.3. Optimum growth at 35 °C, with some strains growing between 20 and 45 °C. Optimum pH is 6.5–6.6. Possess Lancefield group D antigen. Peptidoglycan type: Lys–Ala. The major fatty acids are hexadecanoic and lactobacillic acids.

Causative agent of European foulbrood of the honeybee. Isolated from larvae of *Apis mellifera* and *Apis cerana* with symptoms of European foulbrood. More recently, tyramine-producing strains of *Melissococcus plutonius* were isolated from the *Varroa destructor* mite (Kanbar et al., 2004) which is an indication that European foulbrood may also be transmitted by mites.

DNA G+C content (mol%): 29–30 (T_m).

Type strain: ATCC 35311, CIP 104052, LMG 20360, NCIMB 702443.

GenBank accession number (16S rRNA gene): AY862507, X75751.

Genus III. *Tetragenococcus* Collins, Williams and Wallbanks 1993, 188^{VP} (Effective publication: Collins, Williams and Wallbanks 1990b, 261.)

LEON M.T. DICKS, WILHELM. H. HOLZAPFEL, MASATAKA SATOMI, BON KIMURA AND TATEO FUJII

Tet.ra.geno.coccus. Gr. pref. *tetra* four; G. v. suff. *genes* producing or forming; Gr. n. *kokkos* a grain or berry; N.L. masc. n. *Tetragenococcus* tetrad arrangement of cells.

The cells are **nonmotile, spherical, and occasionally ovoid** and divide in two planes at right angles to **form tetrads**. Cells **may also form pairs or occur singly, especially during early or mid-exponential growth**. Individual cells measure 0.5–1.0 µm. The cells are Gram-positive, asporogenic, and catalase- and oxidase-negative. No cytochromes. **Homofermentative** with no CO₂ production from glucose. **Chemo-organotroph. Facultatively anaerobic. Moderately halophilic. Growth in the presence of 4–18% NaCl**, with optimum concentration of 5–10% NaCl; most of the strains will grow at 1% and 25% NaCl. **No growth at pH 4.5** and optimum pH is 7.0–8.0. **No growth at 10 and 45 °C**, optimum temperature of growth is 25–35 °C. Produces **L(+)-lactic acid from glucose**. Traces of D(–)-lactic acid may be produced and is species-specific. **Arginine is not hydrolyzed** and nitrate not reduced. *Tetragenococcus halophilus* requires the growth factors nicotinic acid, pantothenic acid, and biotin. Cellular fatty acids are long-chain saturated, monounsaturated, and cyclopropane-ring types, predominantly of the ω7 isomer (*cis*-vaccenic acid) type (Collins et al., 1990b). Peptidoglycan type is Lys–D-Asp (Satomi et al., 1997). There are four species in the genus: *Tetragenococcus halophilus* (type = ATCC 33315^T), *Tetragenococcus muriaticus* (type = JCM 10006^T), *Tetragenococcus koreensis* (type = DSM 16501^T; KCTC 3924^T), and *Tetragenococcus solitarius* (type = DSM 5634^T).

DNA G+C content (mol%): 34–36 mol% (T_m), 36–38.3 (HPLC).

Type species: ***Tetragenococcus halophilus*** (Mees 1934) Collins, Williams and Wallbanks 1993, 188^{VP} (Effective publication: Collins, Williams and Wallbanks 1990b, 261.) (*Pediococcus halophilus* Mees 1934, 96.).

Further descriptive information

The genus contains four species, *Tetragenococcus halophilus* (Collins et al., 1990b), *Tetragenococcus muriaticus* (Röling et al., 1999; Satomi et al., 1997), *Tetragenococcus koreensis* (Lee et al., 2005) and *Tetragenococcus solitarius* (Ennahar and Cai, 2005). The species *Tetragenococcus halophilus* was renamed from *Pediococcus halophilus* (Collins et al., 1990b) and is synonymous to “*Pediococcus soyae*” (Weiss, 1992). Strains from both species are found in the secondary fermentation of soy sauce, preceded by a fungal

fermentation, and in pickling brines (Back and Stackebrandt, 1978; Garvie, 1986; Kobayashi et al., 2000a; Satomi et al., 1997). The name *Tetragenococcus halophila*, as recorded in the Validation List no. 49 (1994) was later rejected and corrected to *Tetragenococcus halophilus* (Euzéby and Kudo, 2001). *Tetragenococcus koreensis* sp. nov. was isolated from kimchi, a traditional Korean dish (Lee et al., 2005). *Tetragenococcus solitarius* is a basonym of *Enterococcus solitarius*, isolated from humans and first described by Collins et al. (1989b). The description of the genus is based on the description of *Pediococcus halophilus* (Garvie, 1986) and *Tetragenococcus* gen. nov. (Collins et al., 1990b).

The cell morphology of *Tetragenococcus halophilus* and *Tetragenococcus muriaticus* is similar to that of *Pediococcus* species (Holzapfel et al., 2006). The cell morphology of *Tetragenococcus koreensis* and *Tetragenococcus solitarius* are similar and characteristic of the genus (Ennahar and Cai, 2005; Lee et al., 2005).

Tetragenococcus halophilus exhibits a low 16S rRNA sequence similarity with the “true” pediococci, i.e., *Pediococcus acidilactici* (89.7%), *Pediococcus pentosaceus* (88.3%), *Pediococcus damnosus* (88.7%), *Pediococcus parvulus* (87.4%), *Pediococcus dextrinicus* (88.6%), and *Pediococcus winaeaequi* (90.4%), indicating that it forms a distinct line of descent (Collins et al., 1990b). The phylogenetic relatedness of *Tetragenococcus halophilus* (*Pediococcus halophilus*) and *Tetragenococcus muriaticus* with other members of the lactic acid bacteria is indicated in Figure 114. This relatedness, particularly towards *Pediococcus* species, is also illustrated in *The Prokaryotes* chapter on the genus *Pediococcus* (Holzapfel et al., 2006). The 16S rDNA sequence of the type strain of *Tetragenococcus halophilus* (IAM 1676^T) is 93.4% homologous to the sequence of the type strain of *Tetragenococcus muriaticus* (JCM 10006^T), indicating that the two species belong to the same phylogenetic group (Satomi et al., 1997). The phylogenetic relatedness of *Tetragenococcus halophilus* and *Tetragenococcus muriaticus* with members of *Aerococcus*, *Enterococcus*, *Vagococcus*, *Carnobacterium*, *Pediococcus*, and *Lactococcus* is indicated in the dendrogram in Figure 115. A much closer relationship exists with enterococci and carnobacteria than with pediococci (Figure 114 and Figure 115). A more recent 16S rRNA phylogenetic analysis, presented in the revised roadmap to Volume 3 (Figure 1 and Figure 3;

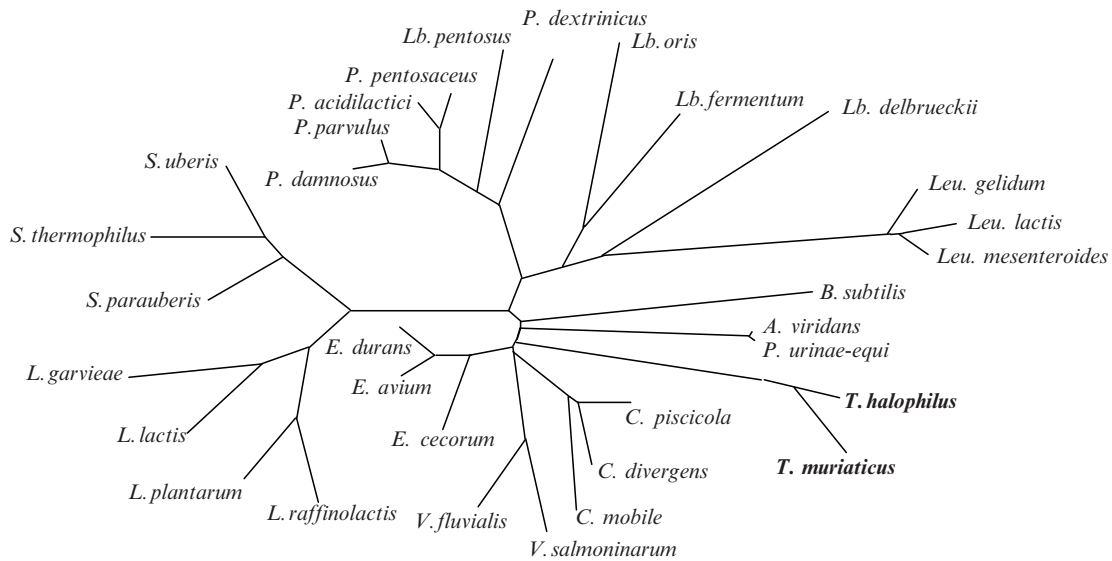

FIGURE 114. Unrooted tree showing the phylogenetic relationships based on 16S rRNA, among *Tetragenococcus halophilus* (*Pediococcus halophilus*), *Tetragenococcus muriaticus*, pediococci, aerococci, and other lactic acid bacteria. A total of 1340 nucleotides, positions 107 (G) to 1433 (A), based on the *Escherichia coli* numbering system, was compared. *T* = *Tetragenococcus*, *P* = *Pediococcus*, *A* = *Aerococcus*, *C* = *Carnobacterium*, *V* = *Vagococcus*, *L* = *Lactococcus*, *S* = *Streptococcus*, *Lb* = *Lactobacillus*, *Leu* = *Leuconostoc*, and *E* = *Enterococcus*. (Modified and reprinted with permission from Collins et al., FEMS Microbiology Letters 70: 255–262, 1990b.)

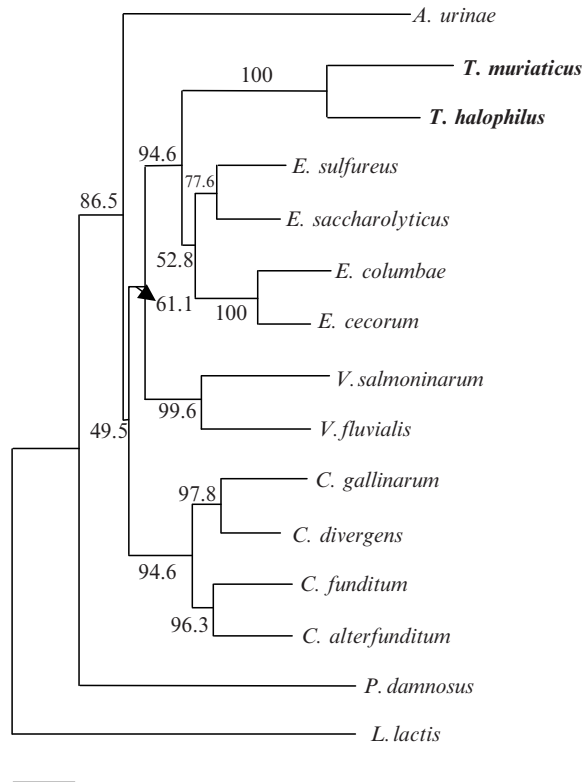

FIGURE 115. Phylogenetic tree based on 16S rDNA sequencing, showing the relationships among *Tetragenococcus halophilus*, *Tetragenococcus muriaticus*, and other lactic acid bacteria. *T* = *Tetragenococcus*, *A* = *Aerococcus*, *E* = *Enterococcus*, *V* = *Vagococcus*, *C* = *Carnobacterium*, *P* = *Pediococcus*, and *L* = *Lactococcus*. (Modified and reprinted with permission from Satomi et al., International Journal of Systematic Bacteriology 47: 832–836, 1997.)

Ludwig et al., this volume), classifies *Tetragenococcus* in the new family *Enterococcaceae* along with the genera *Enterococcus*, *Melissococcus*, and *Vagococcus*, within the order *Lactobacillales*.

Tetragenococcus koreensis shares 98.1% 16S rRNA sequence homology with the type strain of *Tetragenococcus halophilus* (IAM 1676, ATCC 33315, DSM 20339). However, the DNA–DNA relatedness of the two species is only 9.7% (Lee et al., 2005), indicating that they are genetically diverse. *Enterococcus solitarius* described by Collins et al. (1989b) is genetically closer related to the genus *Tetragenococcus* as the species revealed approximately 94% 16S rRNA sequence homology with *Tetragenococcus halophilus* and *Tetragenococcus muriaticus* (Ennahar and Cai, 2005). *Tetragenococcus solitarius* shares low DNA homology with *Tetragenococcus halophilus* (23%) and *Tetragenococcus muriaticus* (54%) and is thus a genetically distinct species (Table 117). On a phenotypic level *Tetragenococcus solitarius* is distinguished from *Enterococcus* spp. by its inability to ferment lactose (Ennahar and Cai, 2005). Strains of *Tetragenococcus halophilus* and *Tetragenococcus muriaticus* share a DNA similarity of less than 50% (Table 117). The phenotypic properties of the four species are listed in Table 118 and Table 119. The genetic relatedness of the four *Tetragenococcus* spp. based on 16S rRNA sequence analyses, is shown in Figure 116.

Glucose is metabolized homofermentatively to L(+)-lactate, probably by the Embden–Meyerhof pathway. At low growth rates, under glucose limiting conditions, and in the presence of 10% NaCl, *Tetragenococcus halophilus* shows a mixed acid fermentation with the production of two formates, one acetate, and one ethanol per glucose (Röling and van Verseveld, 1996, 1997).

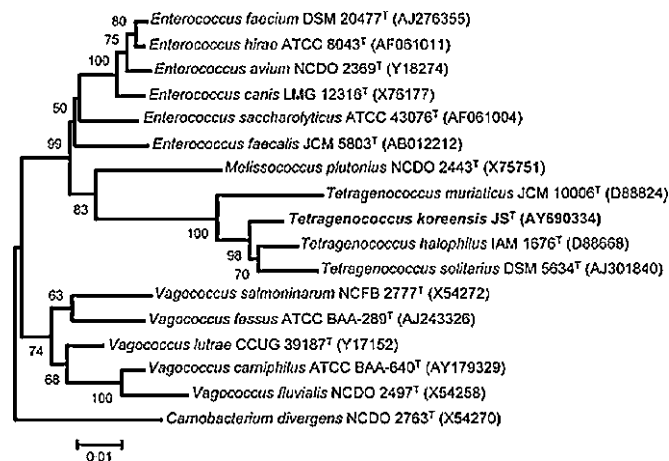

A cryptic plasmid (pUCL287), 8.7 kb in size and with a novel theta-type mechanism of replication, was isolated from *Tetragenococcus halophilus* ATCC 33315 (Benachour et al., 1995). The replicon, *Rep287*, has no homology with plasmids pAM β 1, pIP501, and pUCL22, representatives of the most common theta-type replicon groups in Gram-positive bacteria. Plasmid pD1, isolated

^bData from Ennahar and Cai (2005), Lee et al. (2005), Satomi et al. (1997).

**FIGURE 116.** Neighbor-joining tree, based on 16S rRNA gene sequences, showing the phylogenetic relatedness of *Tetragenococcus koreensis* and *Tetragenococcus solitarius* with *Tetragenococcus muriaticus*, *Tetragenococcus halophilus* and other related lactic acid bacteria (Taken from Lee et al., 2005).

from *Tetragenococcus halophilus* strain D10, encodes the decarboxylation of aspartate to alanine (Higuchi et al., 1998).

Infection by bacteriophages has been reported (Hanagata et al., 2003). Detailed information on sensitivity to drugs and antibiotics is not available. No strains are pathogenic to plants or animals.

Tetragenococci have been isolated from salted food such as anchovies, soy sauce, pickling brines, and fish sauce, indicating that tetragenococci are widely and commonly distributed in the environment, including in high concentrations of salt with carbohydrate, but with less relationship to a milk and dairy environment. *Tetragenococcus halophilus* is used as a starter in soy sauce.

Enrichment and isolation procedures

Members of the genus *Tetragenococcus* are halophilic and slightly alkaliphilic. For isolation, a medium is employed with high levels of NaCl, with glucose as carbon source, and with the pH adjusted to 7.0–8.0. Growth media generally described for pedio-

cocci, e.g., MRS (De Man et al., 1960) or Selective SL Medium (Rogosa et al., 1951), with the addition of 4–6% NaCl and pH adjusted to 7.0, may be used (Weiss, 1992). GYP medium (glucose yeast extract phosphate) supplemented with 10% NaCl, 1% MgSO₄, 0.1% KCl, and 0.3% CaCO₃, and adjusted to pH 7.0 with 1.0 N NaOH (Satomi et al., 1997) may also be used. Colonies on these media supplemented with 0.3% CaCO₃ and surrounded by a clear zone resulting from lactic acid production, are tentatively identified as *Tetragenococcus*. Growth at 30 °C may occur either aerobically or anaerobically. Cycloheximide may be added to suppress yeast growth. All members of the genus *Tetragenococcus* grow well in GYP broth (Garvie, 1978), supplemented with 5% NaCl (Collins et al., 1990b).

Histamine production is tested by inoculating the strains in modified GYP medium (Kimura et al., 2001) composed of 0.5% (w/v) Bacto Peptone, 0.2% (w/v) Lab-lemco powder, 1% (w/v) yeast extract, 1% (w/v) glucose, 0.2% (w/v) NaCOOH₃·3H₂O, 0.05% (w/v) Tween 80, 0.02% (w/v) MgSO₄·7H₂O, 0.001% (w/v) MgSO₄·3H₂O, 0.001% (w/v) FeSO₄·7H₂O, 7% (w/v) NaCl, 1% (w/v) histidine monohydrochloride, and 500 mM 2-morpholinoethansulfonic acid monohydrate (MES), adjusted to pH 6.5 before autoclaving. Incubation at 30 °C should be in an atmosphere of 90% N₂ and 10% CO₂.

Maintenance procedures

For short-term storage, cultures may be kept at 4 °C as stabs in appropriate growth media supplemented with 0.3% CaCl₂ as pH neutralizer, with monthly transfers to freshly prepared medium. For long-term storage, exponential-phase cultures may be mixed with an equal volume of 80% (v/v) sterile glycerol and stored in cryotubes at –20 or –80 °C. Lyophilization with sterile skim milk or storage in liquid nitrogen is recommended for longer-term storage.

Differentiation from closely related taxa

The main characteristics distinguishing *Tetragenococcus* species from the “true” pediococci, *Pediococcus acidilactici*, *Pediococcus clausenii*, *Pediococcus damnosus*, *Pediococcus inopinatus*, *Pediococcus parvulus*, and *Pediococcus pentosaceus* are their halophilic, non-aciduric, and facultative anaerobic growth (Holzapfel et al., 2006; Weiss, 1992). They are differentiated from the L(+)-lactic acid producing species *Pediococcus clausenii* and the atypical “pediococci” *Pediococcus dextrinicus* and *Pediococcus urinaeequi* by growth in the presence of 10% NaCl and the fermentation of melezitose, and from the tetrad-forming *Aerococcus viridans* and *Pediococcus urinaeequi* by growth at pH 5.0, no growth at pH 9.0, and being facultatively anaerobic and not microaerophilic (Holzapfel et al., 2006; Weiss, 1992). Resistance to vancomycin (30 μg, disk method), the production of pyrrolidonyl-arylamidase, and lack of leucine aminopeptidase, and the presence of the fatty acids C_{16:1} ^{09c} and C_{18:1} ^{09c} are further characteristics which differentiate *Tetragenococcus* species from *Aerococcus* species (Uchida and Mogi, 1972; Weiss, 1992). According to DNA similarity determination, *Tetragenococcus halophilus* is less than 20% related to the type strain of *Aerococcus viridans* (Bosley et al., 1990).

Taxonomic comments

Digestion of PCR amplified 16S rDNA with *AhaI*, *MboI* (Satomi et al., 1997), *AfaI*, and *MboI* (Kobayashi et al., 2000a) clearly differentiated strains of *Tetragenococcus halophilus* from *Tetragenococcus muriaticus*. The two species may also be differentiated by

^aSymbols: +, positive reaction or fermented; -, negative reaction or not fermented; ND, not determined.

^bData from Garvie (1986), Collins et al. (1990b), Röling and van Verseveld (1996), Satomi et al. (1997), Weiss (1992), Kobayashi et al. (2000b), Ennahar and Cai (2005), Lee et al. (2005). Sugar fermentation reactions are as indicated for the type strains.

their ability to ferment the carbohydrates amygdalin, arabinose, arabitol, arbutin, cellobiose, galactose, gluconate, maltose, sucrose, turanose and xylose (Table 118). Generally, the major difference in the sugar fermentation pattern of *Tetragenococcus muriaticus* from *Tetragenococcus halophilus* is the inability of *Tetragenococcus muriaticus* to ferment L-arabinose or sucrose and its ability to ferment D-mannitol (Kobayashi et al., 2000b; Satomi et al., 1997). However, variations of sugar fermentation patterns of *Tetragenococcus halophilus* are significant among strains (Röling and van Verseveld, 1996; Uchida, 1982). It is difficult to

distinguish between *Tetragenococcus halophilus* and *Tetragenococcus muriaticus* by using sugar fermentation patterns alone.

Histamine formation is characteristic for most strains of *Tetragenococcus muriaticus* with optimal production at pH 5.8, in the presence of 5–7% (w/v) NaCl, and glucose concentrations exceeding 1% (w/v) (Kimura et al., 2001), though the ability to produce histamine is strain specific (Kobayashi et al., 2000b). Histamine is also produced in the presence of 20% (w/v) NaCl, with maximum accumulation during late stationary growth, independent of NaCl concentrations.

List of species of the genus *Tetragenococcus*

1. ***Tetragenococcus halophilus*** (Mees 1934) Collins, Williams and Wallbanks 1993, 188^{VP} (Effective publication: Collins, Williams and Wallbanks 1990b, 261.) (*Pediococcus halophilus* Mees 1934, 96)

hal.o.phí'lus. Gr. n. hals, *halos* salt; Gr. adj. *philos* loving; N.L. adj. *halophilus* salt-loving.

The description of this species is based on the description of *Pediococcus halophilus* as by Garvie (1986) and Weiss (1992).

^a–, Not detected.

^bData from Lee et al. (2005).

The morphology is as described for the genus *Pediococcus* (Garvie, 1986) and for the genus *Tetragenococcus* (Collins et al., 1990b). Cells are spherical (0.6–1.0 μm in diameter) and occasionally ovoid. Cell division occurs in two planes at right angles to form tetrads. Cells may form pairs. L(+)-lactate is the major end product of glucose metabolism: traces of D(–)-lactate is formed (3–25%). Slow growth on agar, especially under aerobic conditions. Facultatively anaerobic, with slow growth in broth (typically 4–5 d).

Glucose, fructose, ribose, maltose, mannose, melezitose, ribose, and sucrose are usually fermented. The fermentation of arabinose, glycerol, maltotriose, mannitol, melibiose, raffinose, and trehalose varies among strains. Dextrin, lactose, sorbitol, starch, and xylose are usually not fermented.

Growth at 15 and 40 °C, but not at 45 °C. Optimal growth between 30 and 35 °C. Growth at pH 5.0–9.6, with optimal range between pH 7.0 and 8.0. The final growth pH is about 5.0. Growth occurs in 4–18% NaCl, with optimum concentration of 5–10% NaCl; 20–26% NaCl may be tolerated. Most strains are able to grow in the absence of NaCl.

Susceptible to vancomycin and pyrrolidonyl-arylamidase-positive (Bosley et al., 1990). The carbohydrates fermented by the type strain are listed in Table 118. Peptidoglycan type is Lys-D-Asp. The fatty acid profile is listed in Table 119. Isolated from soy sauce and pickling brines. Type species of the genus.

DNA G+C content (mol%): 34–36 (T_m), 36–37 (HPLC).

Type strain: ATCC 33315, CCUG 32204, CIP 102263, DSM 20339, IAM 1676, JCM 5888, LMG 11490, NBRC 10049, NCIMB 12011.

GenBank accession number (16S rRNA gene): D88668.

2. *Tetragenococcus muriaticus* Satomi Kimura, Mizoi, Sato and Fujii 1997, 835^{VP}

mu.ri.a'ti.cus. N.L. adj. *muriaticus* briny, pickled.

This description is based on Satomi et al. (1997). Cells are Gram-positive cocci, 0.5–0.8 μm in diameter and form tetrads or pairs. Colonies on 10% NaCl-GYP agar plates appear smooth, entire, white, convex, and 1–1.5 mm in diameter. Arginine is not hydrolyzed and nitrate not reduced to nitrite. Growth occurs at 15 to 40 °C, but not at 10 or 45 °C. Optimal growth between 25 and 30 °C. Growth at pH 5.0 to 9.6, but not at 4.2; optimal growth pH is between pH 7.5 and 8.0. Growth in the presence of 1–25% NaCl, with optimal growth between 7 and 10%. Requires Na⁺ for growth (no growth in the absence of NaCl). L(+)-lactate is the major end product of glucose metabolism.

Glucose, fructose, mannose, mannitol, ribose, and trehalose are usually fermented. The fermentation of maltose seems to be strain specific. Arabinose, dextrin, gluconate, glycerol, lactose, maltotriose, melezitose, raffinose, sorbitol, starch, sucrose, and xylose are usually not fermented. The carbohydrates fermented by the type strain are listed in Table 118. The fatty acid profiles are listed in Table 119. Isolated from fermented squid liver sauce.

DNA G+C content (mol%): 36–37 (HPLC).

Type strain: X-1, CIP 105747, JCM 10006, LMG 18498, NBRC 100499.

GenBank accession number (16S rRNA gene): AJ301843, D88824, D87680.

3. *Tetragenococcus koreensis* Lee, Kim, Vancanneyt, Swings, Kim, Kang and Lee 2005, 1412^{VP}

ko.re.en'sis. N.L. masc. adj. *koreensis* pertaining to Korea.

The description is according to Lee et al. (2005). Non-motile, nonsporeforming cocci (approx. 1 μm in length). Catalase and oxidase-negative. Grows on glucose yeast peptone (GYP) sodium acetate mineral salts agar (pH 7.0) and trypticase soy agar at 30 °C. Colonies develop aerobically and anaerobically on plates incubated in an anaerobic jar. No growth on R2A agar, nutrient agar or MacConkey agar at 30 °C under either aerobic or anaerobic conditions. Fatty acid profile: C_{18:1} ω7c (33.8%), C_{19:0} cyclo ω8c (26.8%) and C_{16:0} (22.4%). Growth occurs at 15–30 °C on GYP/sodium acetate/mineral salts agar but not at 4 °C or above 37 °C. Optimum growth temperature is 30 °C. Optimal pH is 9.0. Growth in the presence of 8% (w/v) NaCl, but 2–5% (w/v) is optimal. Facultatively aerobic. Homofermentative and produces mainly lactic acid. The peptidoglycan type is A4 α-Lys-D-Asp. Nitrate is not reduced to nitrite or nitrogen gas. β-Glucosidase- and β-galactosidase-positive, but protein is not hydrolysed. Characterized by the production of rhamnolipid biosurfactant.

Glucose, fructose, salicin and N-acetylglucosamine are usually fermented. L-fucose, 5-ketogluconate, lactose, D-xylose, D-melibiose, methyl β-D-xyloside, D-raffinose, L-rhamnose, L-xylose, glycogen, starch, adonitol, L-arabitol, erythritol, glycerol, sorbitol and inulin are not fermented. Carbohydrates fermented by the type strain are listed in Table 118. The fatty acid profiles are listed in Table 119. Isolated from the traditional Korean food kimchi in Daejeon, South Korea.

DNA G+C content (mol%): 38.3 (HPLC).

Type strain: JS^T (=KCTC 3924^T=DSM 16501^T=LMG 22864^T).

GenBank accession number (16S rRNA gene): AY690334.

4. **Tetragenococcus solitarius** Ennahar and Cai 2005, 592^{VP}
sol.i.tar.i'us. L. adj. solitarius alone, lonely.

Basonym: *Enterococcus solitarius* Collins et al., (1989b).

The description for the species *Tetragenococcus solitarius* comb. nov. is as described for *Enterococcus solitarius* by Collins et al. (1989b). A few additions and corrections to the description of the species was proposed by Ennahar and Cai (2005).

Glucose, fructose, mannose, salicin and *N*-acetylglucosamine are usually fermented. Adonitol, L-arabitol, eryth-

ritol, D-fucose, L-fucose, glycogen, 5-ketogluconate, D-lyxose, methyl β -D-xyloside, sorbose, L-xylose and xylitol are not fermented. Carbohydrates fermented by the type strain are listed in Table 118. *Enterococcus solitarius* was first isolated from humans (Collins et al., 1989b).

DNA G+C content (mol%): 38.0 (HPLC).

Type strain: 885/78^T (=ATCC 49428^T=CCUG 29293^T=CIP 103330^T=DSM 5634^T=JCM 8736^T=LMG 12890^T=NCTC 12193^T).

GenBank accession number (16S rRNA gene): AJ301840.

Genus IV. **Vagococcus** Collins, Ash, Farrow, Wallbanks and Williams 1990a, 212^{VP} (Effective publication: Collins, Ash, Farrow, Wallbanks and Williams 1989a, 459.)

MATTHEW D. COLLINS

Va.go.coc'cus. L. adj. *vagus* wandering; Gr. n. *kokkos* a grain, berry; N.L. masc. n. *Vagococcus* wandering coccus, referring to motility.

Cells are ovoid, occurring singly, in pairs, or chains. Gram-positive. May or may not be motile. Nonsporeforming. **Facultatively anaerobic and catalase-negative.** Grows at 10 °C but not at 45 °C. Gas is not produced in MRS broth. Acid is produced from D-glucose and some other sugars. **Pyrrolidonyl arylamidase and leucine arylamidase are produced. Arginine dihydrolase is not produced. Hippurate is not hydrolyzed. Susceptible to vancomycin.**

DNA G+C content (mol%): 34–40 (T_m).

Type species: **Vagococcus fluvialis** Collins, Ash, Farrow, Wallbanks and Williams 1990a, 212^{VP} (Effective publication: Collins, Ash, Farrow, Wallbanks and Williams 1989a, 459.).

Further descriptive information

Vagococci grow on 5% (v/v) horse or sheep blood agar producing an α -hemolytic reaction. Cells are ovoid in shape and are most commonly arranged in short chains or pairs. They are nonpigmented. Most strains of *Vagococcus fluvialis* are motile by means of peritrichous flagella; *Vagococcus salmoninarum* is nonmotile. Most strains of vagococci grow at 10 °C but not at 45 °C; strains of *Vagococcus salmoninarum* do not grow at 40 °C whereas *Vagococcus fluvialis* may or may not grow at this temperature. Vagococci generally do not grow in 6.5% NaCl but reports vary. *Vagococcus salmoninarum* is considered not to grow in 6.5% NaCl (Schmidtke and Carson, 1994), but Teixeira et al. (1997) reported growth at this salt concentration. *Vagococcus fluvialis* strains do not grow or occasionally produce very weak growth in 6.5% NaCl (Pot et al., 1994). Some strains of vagococci grow at pH 9.6, but others do not. Vagococci produce acid, but not gas, from glucose and some other sugars; acid production from sugars varies among species. L-Lactic acid is produced from glucose. None produce acid from D-arabitol, L-arabinose, glycogen, melibiose, melezitose, pullulan, or raffinose. Some strains of *Vagococcus salmoninarum* and *Vagococcus fluvialis* produce acid from starch; there are no published data on acid production from starch for *Vagococcus fessus* and *Vagococcus lutrae*. Vagococci do not produce alanine phenylalanine proline arylamidase or β -glucuronidase. *Vagococcus fessus*, *Vagococcus lutrae*, *Vagococcus salmoninarum*, and most strains of *Vagococcus fluvialis* produce

leucine arylamidase. Some vagococci produce acetoin (positive Voges–Proskauer test), whereas others do not. *Vagococcus salmoninarum*, *Vagococcus fessus*, and *Vagococcus lutrae* are Voges–Proskauer-negative, but some strains of *Vagococcus fluvialis* give a positive reaction. Vagococci do not hydrolyze gelatin and do not reduce nitrate to nitrite. Most strains of *Vagococcus fluvialis* and *Vagococcus salmoninarum* produce a positive bile-esculin reaction; there is no published data on the bile-esculin reactions of *Vagococcus fessus* and *Vagococcus lutrae*.

Vagococcus fluvialis is reported to react with Lancefield group N antisera. *Vagococcus salmoninarum* does not possess a Lancefield group N antigen (Schmidtke and Carson, 1994). Some isolates (including the type strain) of *Vagococcus fluvialis* and the type strain of *Vagococcus salmoninarum* have been reported to give a weak reaction with Lancefield group D antiserum (Teixeira et al., 1997). The cell-wall murein of *Vagococcus fluvialis* is type L-Lysine–D-Aspartic acid (Collins et al., 1989a). *Vagococcus fluvialis* contains poly (glycerophosphate) lipoteichoic acids solely substituted with D-alanine ester. The long-chain cellular fatty acids of *Vagococcus fluvialis* and *Vagococcus salmoninarum* are of the straight-chain saturated and monounsaturated types with C_{16:0}⁷, C_{16:1}⁰⁹, and C_{18:1}⁰⁹ predominating (Schleifer et al., 1985; Wallbanks et al., 1990).

The antimicrobial susceptibilities of only *Vagococcus fluvialis* and *Vagococcus salmoninarum* have been investigated. Teixeira et al. (1997) reported *Vagococcus fluvialis* (type strain plus seven other isolates) and *Vagococcus salmoninarum* (type strain) were susceptible to ampicillin, cefotaxime, trimethylprim-sulfamethoxazole, and vancomycin but resistant to clindamycin, lomefloxacin, and ofloxacin. Strain to strain variation was observed in relation to susceptibilities to 18 other antimicrobial agents (Teixeira et al., 1997). Schmidtke and Carson (1994) reported strains of *Vagococcus salmoninarum* were resistant to streptomycin but susceptible to ampicillin, co-trimoxazole, penicillin G, and vancomycin.

Vagococcus fluvialis was originally isolated from chicken feces and river water (Hashimoto et al., 1979, 1974). Subsequently, it has been recovered from diverse sources and may be an opportunistic pathogen of humans and animals. The species

has been isolated from a variety of human clinical specimens including blood, peritoneal fluid, cerebrospinal fluid, and wounds (Teixeira et al., 1997), and from various domestic animals, i.e., various lesions of pigs, lesions and tonsils of cattle and cats, and tonsils of horses (Pot et al., 1994; Teixeira et al., 1997). *Vagococcus salmoninarum* was originally isolated in the USA from diseased rainbow trout (*Oncorhynchus mykiss*). The diseased fish had a condition similar to post-spawning stress syndrome caused by *Carnobacterium piscicola*. *Vagococcus salmoninarum* has since been recovered from Atlantic salmon (*Salmo salar*) and rainbow trout in Tasmania and Australia and brown trout (*Salmo trutta*) in Norway, with peritonitis (Schmidtke and Carson, 1994). Little is known about the natural occurrence and distribution of *Vagococcus lutrae* and *Vagococcus fessus*. *Vagococcus lutrae* has, so far, only been reported to be isolated from a common otter (*Lutra lutra*) (Lawson et al., 1999), whereas *Vagococcus fessus* has been isolated from a seal and harbor porpoise (Hoyles et al., 2000).

Isolation

Vagococcus species can be isolated on blood-supplemented agars, such as brain heart infusion or Columbia agar containing 5% (v/v) bovine, horse, or sheep blood incubated at 37 °C in air or air with enhanced CO₂ (5–10%). For the isolation of *Vagococcus salmoninarum*, blood agar base no. 2 (Oxoid) supplemented with 7% (v/v) sheep blood and incubated in air at 25 °C, has been used (Schmidtke and Carson, 1994).

Maintenance procedures

Strains can be maintained on media such as brain heart infusion agar with or without animal blood (5% v/v). They can be stored on cryogenic beads at –70 °C or lyophilized for long-term preservation.

Taxonomic comments

The genus *Vagococcus* was proposed in 1989 to accommodate some motile, Lancefield group N cocci which were first described by Hashimoto et al. (1974) and which were phylogenetically distinct from lactococci (Collins et al., 1989a). The genus was originally monospecific, but subsequently three other species have been described. Phylogenetically, *Vagococcus* is a member of the family *Enterococcaceae* in the phylum *Firmicutes* and is closely related to, but distinct from, *Enterococcus*, *Melissococcus plutonius*, and *Tetragenococcus* (Hoyles et al., 2000).

Differentiation of the genus *Vagococcus* from other genera

When the genus *Vagococcus* was originally proposed, it was relatively easy to identify, but the expanded genus is difficult to differentiate from other related genera solely on the basis of phenotypic properties. *Vagococcus fluvialis* can be distinguished from lactococci by being motile (most strains), producing acid from glycerol, sorbitol, and starch, by failing to hydrolyze arginine, and by failing to grow (or producing sparse growth) in 6.5% NaCl. The differentiation of *Vagococcus fluvialis* strains from some enterococci can be problematic. *Vagococcus fluvialis* may be distinguished from motile enterococcal species, *Enterococcus casseliflavus* and *Enterococcus gallinarum*, in failing to produce acid from L-arabinose, melibiose, raffinose, or D-xylose (Pot et al., 1994; Teixeira et al., 1997). Similarly, most *Enterococcus* species show growth in 6.5% NaCl and at 45 °C, while most strains of *Vagococcus fluvialis* do not grow or are strongly inhibited in these conditions.

Differentiation of the species of the genus *Vagococcus*

The four described *Vagococcus* species can be distinguished readily from each other using commercially available API test systems. A summary of the most useful tests for differentiating *Vagococcus* species using the API Rapid ID32 Strep system is shown in Table 120.

List of species of the genus *Vagococcus**

1. ***Vagococcus fluvialis*** Collins, Ash, Farrow, Wallbanks and Williams 1990a, 212^{VP} (Effective publication: Collins, Ash, Farrow, Wallbanks and Williams 1989a, 459.)
flu.vi.al'is. L. adj. *fluvialis* belonging to a river.
Type strain: M-29C, ATCC 49515, CCUG 32704, CIP 102976, DSM 5731, LMG 9464, NCIMB 13038.
GenBank accession number (16S rRNA gene): X54258.
2. ***Vagococcus fessus*** Hoyles, Lawson, Foster, Falsen, Ohlén, Grainger and Collins 2000, 1154^{VP}
fes.sus. L. adj. *fessus* weary, pertaining to the general biochemical unreactivity of the organism.
Type strain: M2661/98/1, ATCC BAA-289, CCUG 41755, CIP 106499.
GenBank accession number (16S rRNA gene): AJ243326.
3. ***Vagococcus lutrae*** Lawson, Foster, Falsen, Ohlén and Collins 1999, 1254^{VP}
lu'trae. L. fem. gen. n. *lutrae* of an otter, pertaining to the common otter, *Lutra lutra*, the mammal from which the bacterium was isolated.
Type strain: M1134/97/1, ATCC 700839, CCUG 39187, CIP 106118.
GenBank accession number (16S rRNA gene): Y17152.
4. ***Vagococcus salmoninarum*** Wallbanks, Martinez-Murcia, Fryer, Phillips and Collins 1990, 229^{VP}
sal.mo.ni.na'rum. M.L. *salmoninae* subfamily of the *Salmonidae*; M.L. gen. n. *salmoninarum* of the *Salmonidae*.
Type strain: OS1-68, ATCC 51200, CCUG 33394, CIP 104684, DSM 6633, LMG 11491, NCFB 2777, NCIMB 13133.
GenBank accession number (16S rRNA gene): X54272.

* *Editorial note*: Since the acceptance of this chapter, two more *Vagococcus* species have been described, *Vagococcus carniphilus* (Shewmaker et al., 2004) and *Vagococcus carniphilus* (Lawson et al., 2007).

TABLE 120. Tests based on the API Rapid ID32 Strep system which is useful in distinguishing species of the genus *Vagococcus*^{a,b}

Test	<i>V. fluvialis</i>	<i>V. fessus</i>	<i>V. lutrae</i>	<i>V. salmoninarum</i>
<i>Acid from:</i>				
Cyclodextrin	+	d	+	-
Lactose	d	-	-	-
MBDG	d	-	+	-
Maltose	+	d	+	d
Mannitol	+	-	-	-
Sorbitol	+	-	+	-
Sucrose	d	-	+	d
D-Tagatose	d	-	-	-
Trehalose	+	-	+	+
<i>Production of:</i>				
α-GAL	-	-	+	-
β-GAL	-	-	+	-
GTA	+	-	+	+
β-NAG	d	-	+	-
PAL	d	-	+	-
URE	d	d	-	-

^aSymbols: +, >85% positive; d, different strains give different reactions (16–84% positive); -, 0–15% positive. Abbreviations: PAL, alkaline phosphatase; α-GAL, α-galactosidase; β-GAL, β-galactosidase; GTA, glycyl tryptophan arylamidase; β-NAG, N-acetyl-β-glucosaminidase; URE, urease.

^bAll species fail to produce acid from D-arabitol, L-arabinose, glycogen, melibiose, melezitose, pullulan, or raffinose; produce pyroglutamic acid arylamidase; do not produce arginine dihydrolase, alanine phenylalanine proline arylamidase, or β-glucuronidase; and do not hydrolyze hippurate.

Family V. *Leuconostocaceae* fam. nov.

KARL-HEINZ SCHLEIFER

Leu.co.nos.to.ca'ce.ae. N.L. neut. n. *Leuconostoc* type genus of the family; suff. *-aceae* ending denoting family; N.L. fem. pl. n. *Leuconostocaceae* the *Leuconostoc* family.

The family *Leuconostocaceae* is circumscribed in this volume on the basis of phylogenetic analyses of 16S rRNA sequences and includes the genera *Leuconostoc*, *Oenococcus*, and *Weissella*.

Cells are Gram-stain-positive, nonmotile and asporogenous. Usually ellipsoidal to spherical cells, often elongated. Cells of *Weissella* are either short rods or ovoid. Occur in pairs or short

chains. Facultatively anaerobic, catalase-negative, devoid of cytochromes. Glucose is fermented heterofermentatively to lactate, CO₂, acetate and ethanol. With the exception of some DL-lactate producing *Weissella* D-lactate is a typical end product of glucose fermentation.

Type genus: Leuconostoc Van Tieghem 1878, 198^{AL}.

Genus I. *Leuconostoc* van Tieghem 1878, 198^{AL} emend. mut. char. (Hucker and Pederson 1930), 66^{AL}

WILHELM. H. HOLZAPFEL, JOHANN A. BJÖRKROTH AND LEON M. T. DICKS

Leu.co.nos'toc. Gr. adj. *leucus* clear, light; N.L. neut. n. *Nostoc* algal generic name; N.L. neut. n. *Leuconostoc* colorless nostoc.

The genus *Leuconostoc* comprises 10 species, with three subspecies for *Leuconostoc mesenteroides*. *Leuconostoc paramesenteroides* has been reclassified as *Weissella paramesenteroides* (Collins et al., 1993) and *Leuconostoc oenos* has been assigned to the genus *Oenococcus* as *Oenococcus oeni* sp. nov. (Dicks et al., 1995a).

The description for the genus is as published by Garvie (1986).

The cells are Gram-stain-positive, nonmotile and asporogenous. **Ellipsoidal to spherical cells, often elongated**, usually in pairs or chains. Cells grown in a glucose medium are elongated and appear morphologically closer to lactobacilli than to streptococci. Most strains form coccoid cells when cultured in milk. Cells may occur singularly or in pairs, and form short to medium length chains. When grown on solid medium, cells are elongated and can be mistaken for rods. True cellular capsules are not formed. Certain strains of *Leuconostoc mesenteroides* produce extracellular dextran, which forms an electron-dense coat on the cell surface.

Chemo-organotrophic, facultatively anaerobic, catalase-negative, no cytochromes present. Nonproteolytic. Nitrate is not reduced. Nonhemolytic. Indole is not formed. Arginine is not hydrolyzed and milk is usually not acidified and curdled. Although growth may occur at pH 4.5, the species are **nonacidophilic** and prefer an initial medium pH of 6.5. The optimal growth temperature is between 20 and 30 °C, but growth may occur at 5 °C. Grows in rich media supplemented with growth factors and amino acids. All species require nicotinic acid, thiamine, biotin and either pantothenic acid or its derivative 4'-O-(α -glucopyranosyl)-D-pantothenic acid. Cobalamin and p -aminobenzoic acid are not required. Growth in broth is stimulated by the addition of 0.05% cysteine-HCl. Growth is uniform, except when cells in long chains sediment. In stab cultures growth is more concentrated in the lower two thirds. **Growth on surface plates is poor, but is stimulated when incubated in the presence of a gas mixture of 19.8% CO₂, 11.4% H₂, and nitrogen as balance.** Colonies develop usually only after 3–5 d, are smooth, round grayish white and less than 1 mm in diameter. Glucose is fermented to equimolar amounts of **D(-)-lactic acid**, CO₂, and ethanol or acetate via a combination of the hexose-monophosphate and phosphoketolase pathways. Fructose 1,6-diphosphate aldolase is absent. All species contain

an active glucose-6-phosphate dehydrogenase (G-6-P-DH). Carbon dioxide and D-ribulose-5-P are produced from glucose. Xylulose 5-P phosphoketolase converts fermentable sugars to ethanol and D(-)-lactic acid. Some strains may produce additional acetate instead of ethanol when grown in the presence of oxygen. **L-malate is decarboxylated to L(+)-lactate by some strains and only in the presence of a fermentable carbohydrate.** Polysaccharides and alcohols, except mannitol, are not metabolized. **Nicotinamide adenine dinucleotide (NAD)-dependent G-6-P-DH is present.** Nonpathogenic to humans, animals and plants. The phenotypic characteristics used to differentiate the genus *Leuconostoc* from other genera of the LAB are listed in Table 121. It is evident that the genera *Leuconostoc* and *Weissella* cannot be separated by physiological means only.

The amino acids in the cross-linking peptide of the cell-wall peptidoglycan are a combination of alanine, serine and lysine; information on the peptidoglycan type is given under the description of each species.

DNA G+C content (mol%): 38–44 (*T_m* and Bd).

Type species: Leuconostoc mesenteroides (Tsenkovskii 1878) van Tieghem 1878, 191^{AL} (*Ascococcus mesenteroides* Tsenkovskii 1878, 159.).

Further descriptive information

Leuconostocs require a rich and complex growth medium (Garvie, 1967a, 1986; Reiter and Oram, 1962). Best growth is obtained under facultatively anaerobic conditions, in the presence of 0.05% (w/v) cysteine-HCl and 19.8% CO₂, 11.4% H₂ and N₂ as balance (Dellaglio et al., 1995). Optimal growth is achieved at pH 6–7, depending on the medium used (Dellaglio et al., 1995). Growth of *Leuconostoc mesenteroides* stops when the internal pH decreases to 5.4–5.7 (McDonald et al., 1990). Optimal growth is obtained between 20 and 30 °C, with minimum growth for most species at 5 °C (Garvie, 1986). However, growth at 1 °C has been recorded for strains of *Leuconostoc gelidum* and *Leuconostoc carnosum* (Shaw and Harding, 1989) and at 4 °C for strains of *Leuconostoc gasicomitatum* (Björkroth et al., 2000). All three species originate from cold-stored modified atmosphere packaged meat products (Björkroth et al., 2000; Shaw and Harding, 1989). Strains of *Leuconostoc mesenteroides* subsp. *mesenteroides* have a relatively short generation time and good

TABLE 121. Major phenotypic characteristics differentiating members of the genus *Leuconostoc* from other genera of the lactic acid bacteria (LAB) (Björkroth and Holzapfel, 2006; modified)^a

Characteristic	Homofermentative

^aSymbols: +, positive reaction; -, negative reaction; +/-, mostly positive; -/+, mostly negative.

^bAbbreviations: Lys, lysine; Ala, alanine; Ser, serine; Asp, aspartate; *m*-A2pm, 2,6-diaminopimelic acid (2,6-diaminoheptanedioic acid).

^cNo Lys-Asp-types, but differentiations of Lys-Ala/Ser types, with the exception of *Weissella handleri*.

^dRelated to those of *Leuconostoc* and *Weissella*.

growth is obtained within 24 h of incubation at 30 °C. *Leuconostoc mesenteroides* subsp. *cremoris* may require 48 h of incubation, and grows preferably at 22–30 °C.

Carbohydrate fermentation patterns vary considerably among *Leuconostoc* species (Table 122), are often strain dependent and thus of limited value in species differentiation. Furthermore, the fermentation of sugars also depends on culture conditions. Certain strains of *Leuconostoc*, when grown under acidic conditions, ferment sucrose (Garvie, 1967b). Nonpoly-saccharide producing strains of *Leuconostoc mesenteroides* form dextran in media containing tomato juice or orange juice (Langston and Bouma, 1959; Pederson and Albury, 1955). *Leuconostoc mesenteroides* subsp. *cremoris* is easily distinguished from the other species by the fermentation of only glucose, galactose, and lactose.

The electrophoretic banding patterns of the NAD-dependent D-LDHs are quite uniform (Garvie, 1969, 1980; Gasser, 1970; London, 1976), with little variation between *Leuconostoc mesenteroides* and *Leuconostoc lactis*. *Leuconostoc* species have a single NAD-dependent lactate dehydrogenase (D(-)nLDH). Several strains have NAD-independent L(+)- and D(-)-LDHs (L(+)-iLDH and D(-)-iLDH). However, the D(-)-iLDH seems to be more active *in vitro* (Garvie, 1980).

Leuconostoc mesenteroides is classified into five immunological groups with antisera prepared from G-6-P-DH of *Leuconostoc mesenteroides* and *Leuconostoc lactis* (Gasser and Hontebeyrie, 1977; Hontebeyrie and Gasser, 1975). *Leuconostoc mesenteroides* subsp. *dextranicum* and *Leuconostoc mesenteroides* subsp. *mesenteroides* belong to a single G-6-P-DH immunological group.

Leuconostoc species are clearly differentiated based on their soluble cell protein profiles. Groupings obtained by numerical analysis of the banding patterns corresponded well with results obtained by DNA–DNA hybridization (Dicks et al., 1993, 1990). The method proved valuable in the differentiation of *Leuconostoc* species from *Weissella* species (Dicks, 1995; Tsakalidou et al., 1994) and *Oenococcus oeni* (Dicks et al., 1995a). Numerical analysis of 16 and 23S rRNA gene RFLP patterns have also proved to be a good tool for differentiation of *Leuconostoc* species. This approach with *Hind*III as the restriction endonuclease was found to provide species-specific patterns for leuconostocs (Björkroth et al., 2000).

The major fatty acids recorded for *Leuconostoc* species are myristic (tetradecanoic) acid (C_{14:0}), palmitic (hexadecanoic) acid (C_{16:0}), palmitoleic (9-hexadecanoic) acid (C_{16:1 07}), oleic (*cis*-9-octadecanoic) acid (C_{18:1 09}) and dihydrosterculic (*cis*-9,10-methyleneoctadecanoic) acid (C_{19 cycl09}) (Schmitt et al., 1989; Shaw and Harding, 1989; Tracey and Britz, 1989). *Leuconostoc* species differ from the other lactic acid bacteria in containing oleic acid, and not vaccenic acid, as the dominant C_{18:1} fatty acid (Tracey and Britz, 1989). *Leuconostoc carnosum* and *Leuconostoc gelidum* are clearly differentiated based on their fatty acid profiles (Shaw and Harding, 1989).

The 16S rRNA relatedness among *Leuconostoc* species is shown in Table 123. DNA–DNA hybridization results obtained with the different reassociation techniques, i.e., Brenner's hydroxylapatite method (Hontebeyrie and Gasser, 1977), Denhardt's membrane filter method (Farrow et al., 1989; Garvie, 1976; Vescovo et al., 1979), De Ley's spectrophotometric method (Schillinger et al., 1989), and Crosa's S1 nuclease procedure (Shaw and Harding, 1989) corresponded well.

Metabolism

Leuconostocs have complex nutritional requirements (Garvie, 1967a, 1967b, 1986; Holzapfel and Schillinger, 1992; Reiter and Oram, 1962; Tracey and Britz, 1989; Weiler and Radler, 1970, 1972). Nicotinic acid, thiamine, biotin, and pantothenic acid (or its derivatives) are generally required for growth (Garvie, 1986). Leuconostocs do not require cobalamin or p-aminobenzoic acid (Garvie, 1986). *Leuconostoc lactis* does not require folic acid, whereas *Leuconostoc mesenteroides* subsp. *mesenteroides* requires glutamic acid and valine for growth (Garvie, 1967a). *Leuconostoc* species can be divided in two groups according to their amino acid requirements, namely the dextran forming strains of *Leuconostoc mesenteroides* subsp. *dextranicum* and *Leuconostoc mesenteroides* subsp. *mesenteroides* which require up to eight amino acids, and the non-dextran-forming strains which require more than eight amino acids. Methionine, valine, and glutamic acid are required by all strains. Riboflavin and folic acid are often required and some strains do not grow in the absence of adenine, guanine, xanthine, and uracil. None of the leuconostocs require alanine. All strains require thiamine, pantothenic acid, and biotin (Garvie, 1967a).

^bData for *Leuconostoc mesenteroides* are from Garvie (1986), for *Leuconostoc argentinum* from Dicks et al. (1993), for *Leuconostoc carnosum* from Shaw and Harding (1989) for *Leuconostoc citreum* from Farrow et al. (1989) and Schilling et al. (1989), for *Leuconostoc duroniis* from Leisner et al. (2005), for *Leuconostoc fallax* from Martınez-Murcia and Collins (1991) and Barrangou et al. (2002), for *Leuconostoc ficulneum* and *Leuconostoc fructosum* from Antunes et al. (2002), for *Leuconostoc gascomitatum* from Björkroth et al. (2000), for *Leuconostoc gelidium* from Shaw and Harding (1989), for *Leuconostoc inhae* from Kim et al. (2003), for *Leuconostoc kinchii* from Kim et al. (2000b), for *Leuconostoc lactis* from Garvie (1986), and for *Leuconostoc pseudomesenteroides* from Farrow et al. (1989). The peptidoglycan type of *Leuconostoc carnosum*, *Leuconostoc gelidium*, and *Leuconostoc argentinum* was obtained from the German Collection of Microorganisms and Cell Cultures (DSMZ), Braunschweig, Germany.

TABLE 123. Percentage sequence similarities for a 1491-nucleotide region of 16S rRNA of some species of the genus *Leuconostoc*, compared to *Weissella paramesenteroides* (compiled from Björkroth and Holzapfel, 2006)^a

^aThe sequence data used for constructing this table originates from the National Centre for Biotechnology Information Entrez database (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=Nucleotide>).

^bStrains used are as follows: *Leuconostoc argentinum*, LMG 18534[†]; *Leuconostoc carnosum*, LMG 11498[†]; *Leuconostoc citreum*, LMG 9824[†]; *Leuconostoc fallax*, LMG 13177[†]; *Leuconostoc gelidum*, LMG 9850[†]; *Leuconostoc lactis*, LMG 8894[†]; *Leuconostoc mesenteroides* subsp. *cremoris*, LMG 6909[†]; *Leuconostoc mesenteroides* subsp. *mesenteroides*, LMG 6893[†]; *Leuconostoc pseudomesenteroides*, LMG 11482[†]; *Weissella paramesenteroides* LMG 9852[†]

Growth is dependent on the metabolism of a fermentable carbohydrate (Garvie, 1986). Under microaerophilic conditions, glucose is converted to equimolar amounts of D(-)-lactate, ethanol and CO₂ via a combination of the hexose-monophosphate (6-P-gluconate) and pentose phosphate pathways, with glucose-6-phosphate dehydrogenase and xylulose-5-phosphoketolase as the key enzymes (Cogan, 1987; De Moss et al., 1951; Garvie, 1986; Schmitt et al., 1992). Fructose 1,6-diphosphate aldolase is absent. Reduced NAD (NADH) is regenerated to NAD by lactic dehydrogenase (LDH), acetaldehyde dehydrogenase, and alcohol dehydrogenase (Condon, 1987). However, in the presence of oxygen, strains of *Leuconostoc mesenteroides* use NADH oxidases and NADH peroxidases as alternative mechanisms to regenerate NAD (Condon, 1987). Acetate, instead of ethanol, and double the amount of ATP are produced (Condon, 1987; Ito et al., 1983; Johnson and McCleskey, 1957; Keenan, 1968).

Fructose is fermented by all *Leuconostoc* species except *Leuconostoc mesenteroides* subsp. *cremoris* and some strains of *Leuconostoc argentinum* (Table 122). If fructose serves as hydrogen acceptor, mannitol is formed instead of ethanol (Kandler et al., 1983).

Lactose is fermented by all strains of *Leuconostoc mesenteroides* subsp. *dextranicum*, *Leuconostoc lactis* (Garvie, 1986), and *Leuconostoc argentinum* (Dicks et al., 1993). Variable results were recorded for *Leuconostoc mesenteroides* subsp. *mesenteroides* and subsp. *cremoris* and for *Leuconostoc pseudomesenteroides* (Garvie, 1986). *Leuconostoc gelidum*, *Leuconostoc carnosum*, *Leuconostoc citreum*, and *Leuconostoc gasicomitatum* do not ferment lactose (Garvie, 1986). Most lactobacilli transport lactose and galactose into the cell via specific permeases (Lawrence and Thomas, 1979). It is not yet known if *Leuconostoc* species contain such a transport system. It is also not known if the Leloir pathway exists in *Leuconostoc* species.

Since phosphoketolase is one of the key enzymes in the heterolactic fermentation pathway (Kandler et al., 1983), it is assumed that pentoses are, as a rule, fermented by all *Leuconostoc* species. However, the fermentation profile of arabinose, ribose, and xylose were different for each of the *Leuconostoc* species (Table 122). It might be that the genes encoding pentose fermentation are plasmid linked.

The formation of dextran from sucrose has been recorded for *Leuconostoc mesenteroides* subsp. *mesenteroides* and subsp. *dextranicum* (Garvie, 1986), *Leuconostoc carnosum*, *Leuconostoc citreum*, *Leuconostoc gelidum* (Shaw and Harding, 1989), and *Leuconostoc gasicomitatum* (Björkroth et al., 2000) but not *Leuconostoc mesenteroides* subsp. *cremoris*, *Leuconostoc lactis* (Garvie, 1986), and *Leuconostoc argentinum* (Dicks et al., 1993). The ability to form dextran is often lost when serial transfers are made in media of increasing salt concentrations (Pederson and Albury, 1955). Non-dextran-producing leuconostocs may be reverted to producing dextran when inoculated in media containing tomato or orange juice (Pederson and Albury, 1955).

Citrate and malate are the most frequently fermented organic acids. All strains of *Leuconostoc mesenteroides* subsp. *cremoris* and most of the dairy leuconostocs (*Leuconostoc mesenteroides* subsp. *mesenteroides*, *Leuconostoc mesenteroides* subsp. *dextranicum* and *Leuconostoc lactis*) ferment citrate in the presence of a fermentable carbohydrate (Garvie, 1986; Schmitt et al., 1997). It is not known if *Leuconostoc gelidum*, *Leuconostoc carnosum*, (Shaw and Harding, 1989), *Leuconostoc gasicomitatum* (Björkroth et al., 2000), *Leuconostoc citreum*, *Leuconostoc pseudomesenteroides* (Farrow et al., 1989), and *Leuconostoc argentinum* (Dicks et al., 1993) are able to ferment citrate and malate. Malate is converted into L(+)-lactate and CO₂ by strains of *Leuconostoc mesenteroides* subsp. *mesenteroides*. Citrate is metabolized to acetate and lactate. At low pH, however, diacetyl and acetoin may be produced from

citrate (Cogan et al., 1981). All strains of *Leuconostoc mesenteroides* subsp. *cremoris* utilized citrate (Garvie, 1984). By contrast, acetate and tartrate are not utilized. Increased flavor production occurs at reduced pH, and is especially associated with citrate-lyase-positive strains in the presence of citrate (Cogan, 1975; Collins and Speckman, 1974; Speckman and Collins, 1968), although considerable variations were reported in the amount of diacetyl produced among strains of *Leuconostoc mesenteroides* subsp. *cremoris* (Walker and Gilliland, 1987).

Additional pyruvic acid formed during the co-metabolism of citrate and glucose is used to reoxidize NADH and NADPH (Cogan, 1987). Because of this, acetaldehyde is not reduced to ethanol, and acetyl-phosphate is converted to acetate and ATP by an active acetate kinase. The increased level of ATP results in more rapid growth compared with cells grown on glucose without citrate. Apart from generating more ATP, citrate could serve as a carbon source for the synthesis of lipids and possibly other essential cell constituents (Schmitt et al., 1992).

Little is known about the production of biogenic amines by leuconostocs. No tyramine formation was detected in strains of *Leuconostoc* species isolated from fresh and vacuum-packaged meat (Edwards et al., 1987). Some strains of *Leuconostoc mesenteroides* subsp. *mesenteroides* produce tyramine and tryptamine (Bover-Cid and Holzapfel, 1999, 2000; Bover-Cid et al., 1999).

Certain strains isolated from sourdough degrade phytic acid. In one study, *Leuconostoc mesenteroides* strain 38 improved the Ca²⁺ and Mg²⁺ solubility during a 9 h fermentation of phytate-rich whole wheat flour (Lopez et al., 2000).

Habitat

Leuconostocs are obligately fermentative chemo-organotrophs (Garvie, 1967a, 1986). They are fastidious in their nutrient requirements and share numerous natural and artificial habitats with other LAB, and particularly with the lactobacilli, pediococci and carnobacteria (Holzapfel and Schillinger, 1992).

Reports on the association of leuconostocs and weissellas with humans and animals are relatively rare and mainly refer to the digestive tract. In the small and large intestines, the numbers of leuconostocs may range around 10⁵/g. Several workers have reported the isolation of vancomycin-resistant leuconostocs from clinical sources (Coovadia et al., 1987, 1988; Hardy et al., 1988; Horowitz et al., 1987; Isenberg et al., 1988; Luetticken and Kunstmann, 1988; Rubin et al., 1988; Ruoff et al., 1988; Wenocur et al., 1988).

Leuconostoc species are associated with a wide variety of meat products, including fresh and vacuum packaged meat, poultry and processed and fermented meat (Holzapfel, 1998; Holzapfel and Schillinger, 1992; Reuter, 1975; Von Holy and Holzapfel, 1989). *Leuconostoc carnosum*, *Leuconostoc gasicomitatum*, and *Leuconostoc gelidum* are known to cause spoilage in certain meat products (Björkroth et al., 2000, 1998; Dykes et al., 1994). Spoilage of cold-smoked salmon or trout by *Leuconostoc mesenteroides* subsp. *mesenteroides* and *Leuconostoc citreum* has been reported (Hansen and Huss, 1998; Lyhs et al., 1999), although only on a few occasions. *Leuconostoc citreum* has been isolated from low-salt fermented fish products (Paludan-Muller et al., 1999).

Leuconostoc mesenteroides and *Leuconostoc lactis* are used as starter cultures in the production of buttermilk, butter, quarg (cream cheese), Gouda and Edam (Collins, 1972; Collins and Speckman, 1974; Garvie, 1984; Quist et al., 1987). Their use in

formulated starter cultures for kefir production has also been reported (Duitschaever et al., 1987; Marshall and Cole, 1985). *Leuconostoc argentinum* has been isolated from Argentine raw milk (Dicks et al., 1993).

Leuconostoc mesenteroides subsp. *mesenteroides* plays an important role in the fermentation of vegetables such as sauerkraut and cucumbers. Although not the dominant species, *Leuconostoc mesenteroides* subsp. *mesenteroides* initiates the fermentation of sauerkraut and is then succeeded by the more acid-tolerant lactobacilli (Pederson, 1930; Stamer, 1975). Meanwhile, it has been shown that, in addition to *Leuconostoc mesenteroides* subsp. *mesenteroides*, *Leuconostoc fallax* is also involved in the early stages of sauerkraut fermentation, with growth and fermentation patterns of *Leuconostoc fallax* strains highly similar to those of *Leuconostoc mesenteroides* (Barrangou et al., 2002). A final pH of 3.5 was reached during cabbage juice fermentation, with lactic acid, acetic acid, and mannitol as the main fermentation end products for both species. None of the *Leuconostoc fallax* strains exhibited the malolactic reaction, a characteristic of most *Leuconostoc mesenteroides* strains. Thus, the microbial ecology of sauerkraut fermentation may be more complex than previously indicated (Barrangou et al., 2002). *Leuconostoc citreum*, *Leuconostoc gelidum*, *Leuconostoc kimchi*, and *Leuconostoc mesenteroides* dominate the early stage of fermentation in kimchi, a traditional Korean food produced from Chinese cabbage, radishes and cucumbers (Choi et al., 2003; Kim et al., 2000a, 2000b).

Leuconostoc mesenteroides subsp. *mesenteroides* and subsp. *dextranicum* are associated with tapai, a sweet, fermented glutinous rice or cassava and chili bo, a nonfermented chili and cornstarch (Björkroth et al., 2002). *Leuconostoc mesenteroides* subsp. *dextranicum* plays a role in sour-dough fermentation (Lönner and Prove-Akesson, 1989). *Leuconostoc mesenteroides* subsp. *mesenteroides* is found in acidic leavened breads and pancake-like products such as idli or dosa and tef (Gashe, 1985; Mukherjee et al., 1965; Soni et al., 1986; Steinkraus, 1983).

Leuconostoc mesenteroides subsp. *mesenteroides* is present in high numbers in vegetable products such as Sayur-Asin prepared from mustard cabbage (Puspito and Fleet, 1985) and in starchy products such as cassava (Okafor, 1977) or kocho, produced from *Ensete ventricos* (Gashe, 1987). *Leuconostoc mesenteroides* subsp. *mesenteroides* is also involved in the submerged fermentation of coffee beans (Frank and Dela Cruz, 1964; Jones and Jones, 1984; Müller, 1996).

Leuconostoc mesenteroides subsp. *mesenteroides* is also found in sugarcane, where it produces polysaccharides and causes souring (Tilbury, 1975; van Tieghem, 1878).

Enrichment and isolation procedures

Most leuconostocs are relatively insensitive to oxygen, although more prolific growth is often observed under reduced atmospheres. Microaerophilic to anaerobic conditions are recommended. Incubation in the presence of N₂, H₂ or CO₂, or with anaerobic gas-generating kits such as GasPak (Oxoid) or Anaerocult A (Merck) is advisable. Cysteine hydrochloride (0.05–0.1%, m/v) may be added to liquid media.

Various enrichment and growth media have been described, of which most are listed by Holzapfel and Schillinger (1992) and Schillinger and Holzapfel (2002).

Some of the more general growth media include MRS (De Man et al., 1960), Rogosa SL-medium (Rogosa et al., 1951),

glucose-yeast extract (Whittenbury, 1965b), acetate medium (Whittenbury, 1965a), yeast extract-glucose-citrate (YGC) broth (Garvie, 1967b), and HP Medium (Pearce and Halligan, 1978).

Tetrazolium-sucrose (TS) medium (Cavett et al., 1965), thal-lous-acetate-tetrazolium-sucrose (TTS) medium (Cavett et al., 1965), and HHD-medium (McDonald et al., 1987) have been used in the isolation of leuconostocs from plant material. For isolations from meat, MRS medium, adjusted to pH 5.7 and supplemented with 0.2% of potassium sorbate (Reuter, 1970, 1985), and thallium acetate medium (Barnes, 1956) have been used. For the collective enumeration of leuconostocs and *Lactococcus lactis* subsp. *diacetylactis* in fermented dairy products, a whey-containing calcium lactate and Casamino acids (WACCA) medium has been suggested (Galesloot et al., 1961). For the selective isolation and enumeration of *Leuconostoc* strains from mixed starter cultures, a chemically defined medium was developed by Foucaud et al. (1997). The medium contains lactose, Mn²⁺, Mg²⁺, 12 amino acids, 8 vitamins, adenine, uracil, and Tween 80.

Maintenance procedures

Strains may be stored as stab cultures in MRS medium (1%, w/v agar) for 1–2 weeks at 4 °C. Alternatively, cultures may be stored for several months in yeast glucose litmus milk supplemented with calcium carbonate (Sharpe, 1981). Long-term preservation (6–24 months) may be obtained by storing dehydrated cultures on granular pumice stone at room temperature (Juven, 1979). *Leuconostoc lactis* and *Leuconostoc mesenteroides* subsp. *cremoris* were stored at –30 °C for 3 months without loss of viability (Oberman et al., 1986). Initial freezing was at –70 °C. Sterile milk or cream (18%) yielded equally good results as protecting agents. Most strains can be kept at –80 °C. Best results are obtained when the strains are grown in optimal growth medium, harvested by centrifugation, washed in a phosphate buffer (e.g., quarter-strength Ringer's solution), resuspended in the fresh growth medium containing 10–15% sterile glycerol, and distributed in small cryotubes before freezing. Strains lyophilized in the presence of 40% (w/v) sterile skim milk and stored at 4–8 °C remain viable for several years.

Taxonomic comments

According to the 16S rRNA phylogenetic analysis in the revised roadmap to Volume 3 (Figure 1 and Figure 3; Ludwig et al., this volume), *Leuconostoc*, *Oenococcus*, and *Weissella* are in a new family, *Leuconostocaceae*, within the order *Lactobacillales*. Earlier studies on the 23S rRNA elongation factor Tu and the β-subunit of ATPase showed that the genus *Leuconostoc* groups with the genera *Weissella*, *Lactobacillus*, *Lactococcus*, *Enterococcus*, and *Carnobacterium* (Ludwig et al., 1993; Ludwig and Schleifer, 1994), consistent with the current roadmap for the *Firmicutes*. *Lactobacillus*, *Paralactobacillus* and *Pediococcus* species are phylogenetically closely related to each other, forming the family *Lactobacillaceae*, and also to the *Leuconostocaceae* (Figure 3).

Based on 16S rRNA analyses (Collins et al., 1993; Martinez-Murcia and Collins, 1990, 1991) and 23S rRNA sequencing (Martinez-Murcia et al., 1993), the *Leuconostoc* group is divided into the three distinct evolutionary lines *Leuconostoc sensu stricto*, *Leuconostoc paramesenteroides*, and *Leuconostoc oenos*. *Leuconostoc paramesenteroides* has been reclassified as *Weissella paramesenteroides*

(Collins et al., 1993) and *Leuconostoc oenos* as *Oenococcus oeni* (Dicks et al., 1995a).

The *Leuconostoc sensu stricto* species *Leuconostoc argentinum*, *Leuconostoc carnosum*, *Leuconostoc citreum*, *Leuconostoc gasicomitatum*, *Leuconostoc gelidum*, *Leuconostoc kimchii*, *Leuconostoc lactis*, *Leuconostoc mesenteroides* (subsp. *cremoris*, subsp. *dextranicum* and subsp. *mesenteroides*), and *Leuconostoc pseudomesenteroides* display 97.1–99.5% 16S rRNA sequence similarity. *Leuconostoc fallax* possesses 94–95% 16S rRNA similarity with the latter species (Martinez-Murcia and Collins, 1991). The *Leuconostoc sensu stricto* line is further divided into three evolutionary branches including *Leuconostoc carnosum*, *Leuconostoc gasicomitatum*, and *Leuconostoc gelidum* in the first branch, *Leuconostoc citreum* and *Leuconostoc lactis* in the second, and *Leuconostoc mesenteroides* and *Leuconostoc pseudomesenteroides* in the third branch. *Leuconostoc argentinum* joins the *Leuconostoc citreum* - *Leuconostoc lactis* branch.

Phenotypically, the leuconostocs, lactobacilli, and pediococci share many characteristics and are often isolated from the same habitat (Garvie, 1976; Sharpe et al., 1972). Based on 16S rRNA sequences, *Leuconostoc mesenteroides* subsp. *cremoris*, *Leuconostoc lactis*, *Leuconostoc mesenteroides*, *Lactobacillus confusus* (now *Weissella confusa*), *Lactobacillus viridescens* (*Weissella viridescens*), *Lactobacillus halotolerans* (*Weissella halotolerans*), *Lactobacillus kandleri* (*Weissella kandleri*), *Lactobacillus minor* (*Weissella minor*), *Oenococcus oeni*, and *Leuconostoc paramesenteroides* (*Weissella paramesenteroides*) form a natural phylogenetic group, referred to as the “leuconostoc branch” of the lactobacilli (Yang and Woese, 1989). Included in the latter phylogenetic group are some of the other *Leuconostoc* species more recently described, including *Leuconostoc carnosum*, *Leuconostoc citreum*, *Leuconostoc gasicomitatum*, *Leuconostoc gelidum*, and *Leuconostoc pseudomesenteroides*. Information on 16S rRNA gene sequences for most *Leuconostoc* species is given in Table 124.

TABLE 124. 16S rRNA gene sequence information for *Leuconostoc* spp. (modified from Barrangou et al., 2002; Antunes et al., 2002; Kim et al., 2003; Leisner et al., 2005)

^aGenBank accession numbers do not necessarily refer to the ATCC type strain. Accession numbers and corresponding nucleotide sequences are from the National Center for Biotechnology Information.

Leuconostoc mesenteroides, *Leuconostoc dextranicum*, and *Leuconostoc cremoris* are genetically closely related and were reclassified as subspecies of *Leuconostoc mesenteroides* (Garvie, 1986). DNA–DNA hybridizations indicated that *Leuconostoc lactis* and *Leuconostoc paramesenteroides* are genetically not closely related to the other *Leuconostoc* species (Dicks et al., 1990; Fantuzzi et al., 1992; Farrow et al., 1989; Garvie, 1976; Hontebeyrie and Gasser, 1977; Schillinger et al., 1989; Shaw and Harding, 1989). In DNA-rRNA hybridizations, *Leuconostoc lactis* clustered with *Leuconostoc mesenteroides*, *Leuconostoc amelibiosum*, and *Leuconostoc fructosus* (Garvie, 1981; Schillinger et al., 1989). These results are in good agreement with the 16S rRNA sequence analyses which indicated that the leuconostocs are phylogenetically related to *Weissella confusa*/*Weissella viridescens*, the former so-called “leuconostoc branch” of the lactobacilli (Yang and Woese, 1989).

According to the DNA similarity values obtained by Farrow et al. (1989), *Leuconostoc pseudomesenteroides* is genetically not closely related to *Leuconostoc citreum*, *Leuconostoc lactis*, *Leuconostoc mesenteroides* subsp. *mesenteroides*, and *Leuconostoc mesenteroides* subsp. *dextranicum*. However, Dicks et al. (1990) and Fantuzzi et al. (1992) recorded DNA similarity values of 78 and 82% between *Leuconostoc pseudomesenteroides*, and *Leuconostoc mesenteroides* subsp. *mesenteroides* and *Leuconostoc mesenteroides* subsp. *dextranicum*, respectively. The taxonomic status of *Leuconostoc pseudomesenteroides* is, therefore, uncertain.

Specific DNA probes, some designed from variable regions V1 and V3 of 16S rRNA (Klijn et al., 1991) have been useful in the identification of leuconostocs, especially isolates from meat (Nissen et al., 1994) and dairy products (Ward et al., 1995).

Ribotyping proved valuable in the identification of *Leuconostoc carnosum* strains isolated from ham and processed meat and the description of *Leuconostoc gasicomitatum* (Björkroth et al., 2000) and *Weissella cibaria* (Björkroth et al., 2002). Villiani et al. (1997), on the other hand, found the technique less reliable in the identification of *Leuconostoc mesenteroides*. However, they did not utilize a numerical approach in interpreting the patterns. They also found that *Leuconostoc lactis* shares same pattern with *Leuconostoc mesenteroides* subsp. *dextranicum* and *mesenteroides* and that the pattern of *Leuconostoc mesenteroides* subsp. *cremoris* is very different from the patterns of other leuconostocs, all findings are not supported by other studies (Björkroth et al., 2000, 1998). Barrangou et al. (2002) used *RsaI* digestion of ITS-PCR products and sequencing of a 350-bp variable region of the 16S rRNA gene for identification of *Leuconostoc fallax* strains from sauerkraut fermentation at the genus and species levels; RAPD typing could differentiate isolates at the strain level. Barrangou et al. (2002)

indeed suggested that the lack of molecular identification methods for *Leuconostoc fallax* could be responsible for earlier failure to distinguish *Leuconostoc fallax* from *Leuconostoc mesenteroides*. This may also be exemplified by earlier reports indicating *Leuconostoc mesenteroides* to predominate in fermented rice cake (Cooke et al., 1987), whereas later *Leuconostoc fallax* was shown to be the prevalent *Leuconostoc* species (Kelly et al., 1995).

Macrorestriction patterns separated by using pulsed field gel electrophoresis (PFGE) were used to differentiate among *Leuconostoc mesenteroides* subsp. *mesenteroides*, *Leuconostoc pseudomesenteroides*, *Leuconostoc citreum*, and *Leuconostoc fallax* (Kelly et al., 1995) and in the characterization of *Leuconostoc carnosum* (Björkroth et al., 1998). Good results were obtained with *ApaI* and *SmaI* digests. According to the current knowledge, the strength of this method lies in distinguishing different clonal lineages.

Lee et al. (2000) developed a multiplex polymerase chain reaction (PCR) assay for the identification of *Leuconostoc* species, by using species-specific primers targeted to the genes encoding 16S rRNA. Strains are differentiated within 3 h. The technique also proved reliable in the differentiation of leuconostocs from *Carnobacterium* species, *Lactobacillus curvatus*, and *Lactobacillus sakei* (Yost and Nattress, 2001).

List of species of the genus *Leuconostoc*

1. ***Leuconostoc mesenteroides*** (Tsenkovskii 1878) van Tieghem 1878, 198^{AL} (*Ascococcus mesenteroides* Tsenkovskii 1878, 159) me.sen.ter.oí’des. Gr. n. *mesenterium* the mesentery; L. suff. *oides* resembling, similar; N.L. adj. *mesenteroides* mesentery-like.
Gram-stain-positive, catalase-negative, nonmotile, asporogenous, spherical or lenticular cells (especially when grown on agar), arranged in pairs or chains. Colonies are small (less than 1.0 mm in diameter), smooth and grayish white. Growth is facultatively anaerobic, with sedimentation when long chains of cells are formed. Growth occurs between 5 °C

and 30 °C, with optimum growth between 20 °C and 30 °C. Arginine is not hydrolyzed and milk is seldom acidified and curdled. Nonproteolytic, indole is not formed and nitrates are not reduced. Acetate and tartrate are not fermented. Growth at pH 6.5, but not at pH 4.8 and not in the presence of 10% (v/v) ethanol. Nonhemolytic.

Three subspecies have been proposed including *Leuconostoc mesenteroides* subsp. *mesenteroides*, *Leuconostoc mesenteroides* subsp. *dextranicum*, and *Leuconostoc mesenteroides* subsp. *cremoris* (Garvie, 1983).

- 1a. **Leuconostoc mesenteroides subsp. mesenteroides** (Tsenkovskii 1878) van Tieghem 1878, 198^{AL} (*Ascococcus mesenteroides* Tsenkovskii 1878, 159)

Morphology as described for the species. Dextran is produced from the fermentation of sucrose, especially when incubated between 20 °C and 25 °C. Colonies are not uniform on sucrose agar and depend on the chemical structure of the dominant type of dextran formed. These differences do not have taxonomic value. Some strains produce a heme-requiring catalase (Whittenbury, 1964). Cells cultured in a glucose-containing broth are killed after 30 min at 55 °C but may withstand heating to 80 °C and 85 °C in a polysaccharide-containing medium. Growth occurs from 10 °C to 37 °C (optimum, 20–30 °C). Growth in the presence of 3.0% (m/v) NaCl. Some strains grow in the presence of 6.5% (m/v) NaCl. Milk supplemented with yeast extract and glucose is acidified and curdled, but not by all strains. Gas production in yeast glucose litmus milk has been recorded for some strains. Glutamic acid and valine are required. Some strains convert L-malate to L-lactate. Acid is produced from arabinose, fructose, galactose, maltose, mannose, ribose, sucrose, and trehalose. Variable reactions have been recorded for the fermentation of amygdalin, arbutin, cellobiose, lactose, mannitol, melibiose, raffinose, salicin, xylose, and esculin. Some strains ferment citrate. The requirements for riboflavin, pyridoxal, and folic acid seem to be strain-specific. Tween 80, uracil, and a combination of uracil, guanine, adenine, and xanthine are not required for growth. The murein type is L-Lys-L-Ser-L-Ala₂ and L-Lys-L-Ala₂, respectively.

DNA G+C content (mol%): 37.0–39.0, but values of 40.0 and 41.0 have been recorded for some strains (T_m).

Type strain: 12954, ATCC 8293, DSM 20343, CCUG 30066, CIP 102305, HAMBI 2347, JCM 6124, LMG 6893, NBRC 100496, NRRL B-1118, NRRL B-3470, VKM B-1601.

GenBank accession number (16S rRNA gene): M23035.

- 1b. **Leuconostoc mesenteroides subsp. cremoris** (Knudsen and Sørensen 1929) Garvie 1983, 118^{VP} (*Leuconostoc cremoris* (Knudsen and Sørensen 1929) Garvie 1960, 288; *Betacoccus cremoris* Knudsen and Sørensen 1929, 81)

cre.mor'is. L. n. cremor cream; L. gen. n. cremoris of cream.

Morphology as described for the species. Cells may form long chains with resultant flocculent growth in broth. Dextran is not produced from the fermentation of sucrose. Citrate is metabolized to acetoin and diacetyl (Speckman and Collins, 1968). The latter end products are not always detected, because pyruvate is an electron donor in the regeneration of NAD and the formation of D(-)-lactate. Most strains do not ferment sucrose, but mutants have been reported (Whittenbury, 1966). Compared to the other two subspecies, a limited number of carbohydrates are fermented. All strains ferment glucose and lactose. Amygdalin, arabinose, arbutin, cellobiose, fructose, mannitol, mannose, melibiose, raffinose, salicin, sucrose, trehalose, and xylose are not fermented. Esculin is not hydrolyzed. The fermentation of galactose and maltose is strain-specific. A large number of vitamins and amino acids are required. Riboflavin, pyridoxal, folic acid, uracil, and a combination of uracil,

guanine, adenine, and xanthine are required by all strains. Glucose litmus milk is acidified and curdled by some strains. Gas production in litmus milk has not been described. Growth is facultatively anaerobic, and optimal between 18 °C and 25 °C. All known strains have been isolated from dairy products and it would appear that the strains have adapted from *Leuconostoc mesenteroides* subsp. *mesenteroides*. It is not always possible to differentiate between *Leuconostoc mesenteroides* subsp. *cremoris* and *Leuconostoc mesenteroides* subsp. *dextranicum* on a phenotypic level. The murein type is L-Lys-L-Ser-L-Ala₂.

DNA G+C content (mol%): 38.0–40.0 (T_m).

Type strain: ATCC 19254, CCUG 21965, CIP 103009, DSM 20346, LMG 6909, NCIMB 12008, NRRL B-3252, VKM B-1420.

GenBank accession number (16S rRNA gene): M23034.

- 1c. **Leuconostoc mesenteroides subsp. dextranicum** (Beijerinck 1912) Garvie 1983, 118^{VP} (*Leuconostoc dextranicum* (Beijerinck 1912) Hucker and Pederson 1930, 67; *Lactococcus dextranicus* Beijerinck 1912, 27)

dex.trá'ni.cum. N.L. n. dextranum dextran; N.L. neut. adj. dextranicum relating to dextran.

Morphology as described for the species. Dextran is produced from sucrose, but less actively than by *Leuconostoc mesenteroides* subsp. *mesenteroides*. Fewer carbohydrates are fermented than by *Leuconostoc mesenteroides* subsp. *mesenteroides*. More amino acids and vitamins are required for growth than are required by *Leuconostoc mesenteroides* subsp. *mesenteroides*. Growth occurs from 10 °C to 37 °C (optimum, 20–30 °C). Glucose litmus milk is acidified and curdled and gas production may be formed but not by all strains. Glucose, fructose, lactose, maltose, sucrose and trehalose are fermented by all strains. Variable reactions have been recorded for the fermentation of amygdalin, cellobiose, galactose, mannitol, mannose, melibiose, raffinose, salicin, xylose, and esculin. Arabinose and arbutin are not fermented. L-malate is not metabolized. The requirements for riboflavin, pyridoxal, and folic acid seems to be strain-specific. Uracil is not required for growth, however, a combination of uracil, guanine, adenine, and xanthine are required by some strains. The murein type is L-Lys-L-Ser-L-Ala₂.

DNA G+C content (mol%): 37.0–40.0 (T_m).

The type strain is ATCC 19255, CCUG 21966, CCUG 30065, CIP 102423, DSM 20484, JCM 9700, LMG 6908, NCIMB 12007, NBRC 100495, NCAIM B.01658, NCIMB 12007, NRRL B-3469, VKM B-1225.

GenBank accession number (16S rRNA gene): not available.

2. **Leuconostoc argentinum** Dicks, Fantuzzi, Gonzalez, Du Toit and Dellaglio 1993, 348^{VP}

ar.gen.tí'num. N.L. adj. argentinum pertaining to Argentina, where the bacterium was isolated.

According to Vancanneyt et al. (2006), *Leuconostoc argentinum* is a later synonym of *Leuconostoc lactis*.

Gram-stain-positive coccus, nonmotile, nonsporulating, catalase-negative and oxidase-negative. Spherical and sometimes lenticular cells, usually in pairs and short chains. Colonies on MRS agar are round, smooth, grayish white and usually small (less than 1.0 mm in diameter). Growth occurs between 10 and 39 °C. Optimum growth temperature is between 27 °C

and 30 °C. Facultative anaerobic. Heterofermentative, with production of carbon dioxide from D-glucose. More than 97% of the lactate is produced as the D-(–)-isomer. Arginine and esculin are not hydrolyzed. Voges–Proskauer-negative. Indole is not formed and nitrate is not reduced. Polysaccharides are not produced from sucrose. Milk is coagulated without added yeast extract, but only after extended incubation (48 h) at optimal growth temperature. All strains produce acid from galactose, D-glucose, D-mannose, maltose, N-acetylglucosamine, lactose, melibiose, and sucrose. Most strains produce acid from D-fructose and D-raffinose. Some strains produce acid from L-arabinose, D-xylose, mannitol, α -methyl-D-glucoside, cellobiose, trehalose, α -gentiobiose, and D-turanose. Acid is not produced from ribose, amygdalin, arbutin, salicin, D-tagatose, glycerol, erythritol, D-arabinose, L-xylose, adonitol, α -methyl-xyloside, sorbose, rhamnose, dulcitol, inositol, sorbitol, α -methyl-D-mannoside, inulin, melezitose, starch, glycogen, xylitol, D-lyxose, D-fucose, L-fucose, D-arabitol, gluconate, 2-ketogluconate, and 5-ketogluconate.

DNA G+C content (mol%): 40.5 (T_m).

Isolated from raw milk in Argentina. Represents 7–10% of the *Leuconostoc* species isolated.

Type strain: LL76, CCUG 38887, CIP 103889, DSM 8581, JCM 11052.

GenBank accession number (16S rRNA gene): AF175403.

Note: The description of the type strain corresponds to that of the species, except that acid is typically produced from α -methyl-D-glucoside, trehalose, and D-turanose and acid is not produced from L-arabinose, D-xylose, cellobiose, and β -gentiobiose.

3. ***Leuconostoc carnosum*** Shaw and Harding 1989, 222^{VP}
car.no'sum. L. neut. adj. *carnosum* pertaining to flesh.

Gram-stain-positive, nonmotile, nonspore-forming, spherical cells arranged in pairs or chains. Some cells are lenticular. Colonies are small, smooth, round, and grayish-white. Growth occurs at 10 °C. Most strains do not grow at 37 °C. Carbon dioxide and D-(–)-lactate are produced from D-glucose. Catalase is not produced. Arginine is not hydrolyzed. Some strains hydrolyze esculin. All strains are β -galactosidase and Voges–Proskauer-negative. Deoxyribonuclease-positive. Tween 20 and Tween 80 are not hydrolyzed, but some strains hydrolyze Tween 40 and Tween 60. Most strains produce dextran from sucrose. Acid is produced from D-fructose, D-glucose, α -methyl-D-glucoside, sucrose, and trehalose. Acid is not produced from amygdalin, D-arabinose, L-arabinose, arbutin, dulcitol, erythritol, galactose, gluconate, glycerol, lactose, mannitol, D-melezitose, raffinose, rhamnose, sorbitol, L-sorbose, or D-xylose. Some strains produce acid from cellobiose, maltose, D-mannose, melibiose, ribose, and salicin. The cellular fatty acid are of the straight-chain saturated, monounsaturated, and cyclopropane ring types, with tetradecanoic, hexadecanoic, *cis*-9,10-hexadecenoic, *cis*-11,12-octadecenoic, and *cis*-11,12-methyleneoctadecanoic acids predominating. Some strains produce methylenehexadecanoic acid.

DNA G+C content (mol%): 39.0 (T_m).

Isolated from vacuum-packaged meat stored at low temperatures.

Type strain: ATCC 49367, CCUG 30059, CIP 103319, DSM 5576, JCM 9695, LMG 11498, NCIMB 12898 (formerly NCFB 2776), SML40.

GenBank accession number (16S rRNA gene): X95977.

Note: The description of the type strain corresponds to that of the species, except that no growth occurs at 37 °C, dextran is produced from sucrose, esculin is not hydrolyzed, Tween 40 and Tween 60 are not hydrolyzed, acid is produced from D-mannose and ribose, and acid is not produced from cellobiose, maltose, melibiose, or salicin.

4. ***Leuconostoc citreum*** Farrow, Facklam and Collins 1989, 280^{VP}

cit're.um. N.L. adj. *citreum* lemon-colored.

Gram-stain-positive, nonmotile, spherical or lenticular cells (approx. 0.5–0.7 \times 0.7–1.2 μ m), arranged in pairs or short chains. Colonies produce a lemon yellow pigment. Grows occurs at 10 °C and 30 °C. Some strains grow at 37 °C, but not at 40 °C. Acid is produced from N-acetylglucosamine, esculin, D-fructose, glucose, D-mannose, maltose, α -methyl-D-glucoside, sucrose, trehalose, and D-turanose. The majority of strains produce acid from amygdalin, arbutin, L-arabinose, cellobiose, β -gentiobiose, gluconate, D-mannitol, and salicin. A few strains produce acid from 2-ketogluconate, galactose, and D-xylose. Acid is not produced from adonitol, D-arabitol, L-arabitol, D-arabinose, dulcitol, erythritol, D-fucose, L-fucose, glycerol, glycogen, inositol, inulin, 5-ketogluconate, lactose, D-xylose, melezitose, melibiose, α -methyl-D-mannoside, β -methyl-xyloside, raffinose, ribose, L-rhamnose, sorbitol, L-sorbose, starch, D-tagatose, xylitol, or L-xylose. Arginine dihydrolase, β -D-xylosidase, and urease-negative.

Isolated from food and clinical sources.

DNA G+C content (mol%): 38.0–40.3 (T_m).

The type strain is ATCC 49370, CCUG 30060, CIP 103315, DSM 5577, JCM 9698, LMG 9849, NCIMB 13121.

GenBank accession number (16S rRNA gene): AF111948.

Note: In most respects the description of the type strain corresponds to the description of the species. The type strain produces acid from amygdalin, L-arabinose, arbutin, cellobiose, β -gentiobiose, gluconate, mannitol, and salicin. Acid is not produced from melibiose, raffinose, or D-xylose.

Leuconostoc amelibiosum is a later heterotypic synonym of *Leuconostoc citreum* (Takahashi et al., 1992).

5. ***Leuconostoc amelibiosum*** Schillinger, Holzappel and Kandler 1989, 495^{VP} (Effective publication: Schillinger, Holzappel and Kandler 1989, 54.)

a'me.li.bi.o'sum, Gr. pref. *a* not; N.L. adj. *melibiosum* referring to the disaccharide melibiose; *amelibiosum* not fermenting melibiose.

Gram-stain-positive, nonmotile, catalase-negative, nonspore-forming, elongated cocci (0.8–1.0 \times 1.0–1.2 μ m), arranged in pairs or short chains. Facultatively anaerobic. Growth at 15 °C but not at 5 °C or 45 °C. Heterofermentative, producing CO₂, acetic acid (ethanol) and D-(–)-lactate from hexoses and gluconate. Arabinose, cellobiose, fructose, glucose, maltose, sucrose, salicin, and trehalose are fermented. Lactose, mannitol, melibiose, raffinose, rhamnose, ribose, sorbitol, and xylose are not fermented. Dextran is produced from sucrose. Peroxide is not produced. Arginine is not hydrolyzed and nitrate is not reduced. The murein type is Lys–Ala₂.

Isolated from sugar refineries.

DNA G+C content (mol%): 41.6 (T_m).

Type strain: CCUG 30058, DSM 20188, LMG 9824.

GenBank accession number (16S rRNA gene): X53963.

5. **Leuconostoc durionis** Leisner, Vancanneyt, Van der Meulen, Lefebvre, Engelbeen, Hoste, Laursen, Bay, Rusul, De Vuyst and Swings 2005, 1269^{VP}

du.ri.o'nis. N.L. gen. n. *durionis* of *Durio*, the generic name of *Durio zibenthinus*, the durian fruit).

Gram-stain-positive, catalase-negative, nonspore-forming rods. Single cells, as pairs or in chains. Nonmotile in APT broth. Colonies on APT agar are off-white, round with smooth surfaces and 1–2 mm in diameter. Colonies develop on Rogosa agar but not on STA agar. Optimal growth at 30 °C. Growth occurs at 5 °C and 35 °C, but not at 45 °C. Growth usually occurs at pH 3.9 in APT broth, but not below pH 4.15 in La broth. Growth in the presence of 8.0% NaCl. Nitrate is not reduced and ammonia is not produced from arginine. D(–)-lactic acid and acetic acid are produced from D-glucose. Carbon dioxide is produced from the fermentation of fructose, but not from D-glucose. Cell growth is not affected by nisin produced by *Lactococcus lactis* ATCC 11454 or pediocin PA-1 produced by *Pediococcus acidilactici* PAC-1.0. Ribose, D-glucose, D-fructose, mannitol, sucrose, trehalose, D-turanose, and gluconate are fermented, as recorded after 5 d of incubation at 30 °C. The following carbohydrates are not fermented: glycerol, erythritol, D-arabinose, L-arabinose, D-xylose, L-xylose, adonitol, methyl-β-xyloside, galactose, D-mannose, L-sorbose, rhamnose, dulcitol, inositol, sorbitol, methyl α-D-mannoside, methyl-α-D-glucoside, N-acetylglucosamine, amygdalin, arbutin, esculin, salicin, cellobiose, maltose, lactose, melibiose, inulin, melezitose, D-raffinose, starch, glycogen, xylitol, β-gentiobiose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, 2-ketogluconate, and 5-ketogluconate. Strain LMG 22557 ferments methyl-α-D-glucoside and maltose, but only weakly.

DNA G+C content (mol%): 44 (HPLC).

Isolated from tempoyak, a Malaysian acid-fermented condiment made from pulp of the durian fruit.

Type strain: D-24, CCUG 49949, LAB 1679, LMG 22556.

GenBank accession number (16S rRNA gene): AJ780981.

Note: The type strain and strains LMG 22557 (LAB1663, D-6) and LMG 22558 (LAB 1674, D-18) were all isolated from pulp of the durian fruit.

6. **Leuconostoc fallax** Martinez-Murcia and Collins 1992, 191^{VP} (Effective publication: Martinez-Murcia and Collins 1991, 59.)

fal'lax. L. adj. *fallax* deceptive.

Gram-stain-positive, nonmotile, spherical or lenticular cells, 1.0–1.2 × 2.0–2.4 μm, arranged in pairs and short chains. Facultatively anaerobic. Growth at 10 °C and 40 °C but not at 45 °C. In glucose broth, *Leuconostoc fallax* grows and lowers the pH to 3.9. It is resistant to 9% (v/v) ethanol, and tolerates 5% (w/v) salt. No malolactic fermentation (Barrangou et al., 2002; Middelhoven and Klijn, 1997). The cell-wall murein is type A3α, L-Lys–L-Ala–L-Ala. Arginine, is not hydrolyzed. D(–)-lactate is produced from D-glucose. Acid is produced from N-acetylglucosamine, D-fructose, D-glucose, D-mannose, α-methyl-D-glucoside, maltose, ribose, sucrose, and D-turanose. Delayed acid production from mannitol and trehalose. Acid is not produced from adonitol, arabinose, arabitol, cellobiose, arbutin, amygdalin, cellobiose, dulcitol,

erythritol, fucose, galactose, glycerol, lactose, melezitose, melibiose, D-raffinose, rhamnose, salicin, sorbitol, L-sorbose, D-tagatose, and xylose.

Originally isolated from sauerkraut.

DNA G+C content (mol%): 40 (*T_m*) for type strain DSM 20189.

Type strain: ATCC 700006, CCUG 30061, CIP 104855, DSM 20189, JCM 9694, LMG 13177.

GenBank accession number (16S rRNA gene): S63851.

7. **Leuconostoc ficulneum** Antunes, Rainey, Nobre, Schumann, Ferreira, Ramos, Santos and da Costa 2002, 653^{VP}

fi.cul'ne.um. L. adj. *ficulneum* pertaining to figs and fig trees.

Cells are Gram-stain-positive, short rods 0.4–1.0 μm by 1.8–2.9 μm, nonmotile and asporogenous. Catalase is produced, but cytochrome oxidase is absent. Colonies are small, smooth, round and grayish-white. Optimum growth is at 30 °C. No growth at 6 °C and 40 °C. The optimum pH ranges between 6.5 and 7.0. No growth at pH 4.5. Growth occurs in the presence of 7.0% (m/v) NaCl and 40% (m/v) glucose. The cell-wall murein is type A3α, variation L-Lys←L-Ala. The predominant cellular fatty acids are hexadecanoic acid (C_{16:0}) and 11,12-octadecenoic acid (C_{18:1 07c}). Arginine, elastin, fibrin, gelatin, casein, starch, and esculin are not hydrolyzed. Dextran is produced from the fermentation of sucrose. Fructose (5%, m/v) is fermented to lactate via the Embden–Meyerhof–Parnas pathway to lactate. Other fermentation products from fructose are mannitol and acetate. D(–)-lactate is produced from D-glucose. Gluconate, mannitol, and trehalose are fermented, albeit slowly. Sucrose and D-turanose are fermented, but not actively. Acid is not produced from D-arabinose, L-arabinose, D-arabitol, L-arabitol, cellobiose, erythritol, D-fucose, L-fucose, galactitol, galactose, gluconate, N-acetylglucosamine, methyl-α-D-glucoside, β-gentiobiose, 2-ketogluconate, 5-ketogluconate, glycerol, glycogen, inositol, inulin, lactose, D-lyxose, maltose, D-mannose, methyl-D-mannoside, melezitose, melibiose, D-raffinose, rhamnose, ribitol, ribose, L-sorbose, starch, sucrose, D-tagatose, trehalose, D-turanose, D-xylose, methyl-β-xyloside, L-xylose, and xylitol.

Isolated from a ripe fig bought in Portugal.

DNA G+C content (mol%): 42.6 (HPLC).

Type strain: FS-1, DSM 13613, NRRL B-23447, JCM 12225.

GenBank accession number (16S rRNA gene): AF360736.

8. **Leuconostoc fructosum** (Kodama 1956) Antunes, Rainey, Nobre, Schumann, Ferreira, Ramos, Santos and da Costa 2002, 654^{VP} (Basonym: *Lactobacillus fructosus* Kodama 1956.)

fruc.to'sum. N.L. adj. *fructosum* of fructose, pertaining to fructose.

The description is based on the results of Kodama (1956, 1963), Schillinger et al. (1989), and Antunes et al. (2002).

Gram-stain-positive, short, rod-shaped (0.5–0.8 μm by 2.0–4.0 μm), nonmotile, asporogenous cells. Colonies are small, smooth, round and grayish-white. The optimum growth temperature is 30 °C. Growth at 6 °C and 40 °C, but not at 45 °C. Growth occurs in the presence of 8.0% (m/v) NaCl and 40% (m/v) glucose. The cell-wall murein is type A3α, variation L-Lys←L-Ala. The predominant cellular fatty acids are 9,10-octadecanoic acid (C_{18:1 09c}) and 11,12-octadecanoic acid (C_{18:1 07c}). Arginine, elastin, fibrin, gelatin, casein, starch,

and esculin are not hydrolyzed. Dextran is not produced from the fermentation of sucrose. Fructose is metabolized via the Embden–Meyerhof–Parnas pathway. D(-)-lactate is produced from D-glucose. Mannitol is fermented. Acid is not produced from D-arabinose, L-arabinose, D-arabitol, L-arabitol, cellobiose, erythritol, D-fucose, L-fucose, galactitol, galactose, gluconate, N-acetylglucosamine, methyl- α -D-glucoside, β -gentiobiose, 2-ketogluconate, 5-ketogluconate, glycerol, glycogen, inositol, inulin, lactose, D-lyxose, maltose, D-mannose, methyl-D-mannoside, melezitose, melibiose, D-raffinose, rhamnose, ribitol, ribose, L-sorbose, starch, sucrose, D-tagatose, trehalose, D-turanose, D-xylose, methyl- β -xyloside, L-xylose, and xylitol.

Isolated from flowers in Japan.

DNA G+C content (mol%): 43.4 (HPLC).

The type strain is ATCC 13162, CCUG 32246, CIP 102985, DSM 20349, JCM 1119, LMG 9498, NBRC 3516, NCIB 10784, NRRL B-2041.

GenBank accession number (16S rRNA gene): AF360737, X61140.

9. **Leuconostoc gasicomitatum** Björkroth, Geisen, Schillinger, Weiss, De Vos, Holzappel, Korkeala and Vandamme 2001, 264^{VP} (Effective publication: Björkroth, Geisen, Schillinger, Weiss, De Vos, Holzappel, Korkeala and Vandamme 2000, 3771.)

ga.si.co.mi.ta'tum. N.L. neut. n. *gasum* gas, L. neut. adj. *comitatum* accompanied, N.L. adj. *gasicomitatum* accompanied by gas, referring to the association with gaseous spoilage.

Gram-stain-positive, nonmotile, nonspore-forming spherical or oval cells (0.5–1.0 μ m in diameter). Colonies are small and grayish-white. Catalase is not produced. Growth occurs at 4 °C and 15 °C, is slow at 30 °C, and does not occur at 37 °C. Metabolism is heterofermentative. Carbon dioxide and D(-)-lactate are produced from D-glucose. Arginine is not hydrolyzed. Exopolysaccharides are produced from the fermentation of sucrose. No growth in the presence of 6.5–12.0% (m/v) NaCl. The murein type is A3 α , L-Lys-L-Ala-L-Ala. L-arabinose, ribose, D-xylose, glucose, fructose, mannose, methyl- α -D-glucoside, N-acetylglucosamine, esculin, cellobiose, maltose, melibiose, sucrose, trehalose, raffinose, gentiobiose, turanose, and 5-ketogluconate are fermented. Some isolates ferment galactose and gluconate. Glycerol, erythritol, D-arabinose, L-xylose, adonitol, β -methyl-D-xyloside, galactose, sorbose, rhamnose, dulcitol, inositol, mannitol, sorbitol, α -methyl-D-mannoside, amygdalin, arbutin, salicin, lactose, inulin, melezitose, starch, glycogen, xylitol, D-lyxose, D-tagatose, fucose, arabitol, gluconate, and 2-ketogluconate are not fermented. β -Galactosidase is produced.

Isolated from MA-packaged, tomato-marinated broiler meat strips showing extreme gaseous spoilage.

DNA G+C content (mol%): 37 (T_m).

Type strain: TB 1-10, JCM 12535, LMG 18811.

GenBank accession number (16S rRNA gene): AF231131.

Note: The description of the type strain corresponds to that of the species with the exception that esterase (C_4), esterase lipase (C_8), lipase (C_{14}), acid phosphatase and naphthol-AS-BI-phosphohydrolase activities are also present. Galactose and gluconate are fermented. The type strain and strains LMG 18812, LMG 18813, and LMG 18889 have been deposited in the BCCM/LMG Bacteria Collection.

10. **Leuconostoc gelidum** Shaw and Harding 1989, 222^{VP}

ge'li.dum. L. neut. adj. *gelidum* cold (referring to the ability to grow on chill-stored meat).

Gram-stain-positive, nonmotile, asporogenous spherical cells (may be lenticular), arranged in pairs or chains. Colonies are small, smooth, round and grayish-white. Growth occurs at 1 °C. Most strains do not grow at 37 °C. Carbon dioxide and D(-) lactate are produced from glucose. Catalase-negative. Arginine is not hydrolyzed. All strains hydrolyze esculin and are β -galactosidase-positive. Voges–Proskauer-negative. Deoxyribonuclease-positive. Tweens 20, 40, 60, and 80 are not hydrolyzed. Most strains produce dextran from sucrose. Acid is produced from amygdalin, L-arabinose, arbutin, cellobiose, D-fructose, D-glucose, D-mannose, melibiose, α -methyl-D-glucoside, raffinose, salicin, sucrose, trehalose and D-xylose. Acid is not produced from D-arabinose, dulcitol, erythritol, galactose, gluconate, glycerol, inositol, lactose, mannitol, D-melezitose, rhamnose, sorbitol, and L-sorbose. Some strains produce acid from maltose and ribose. The cellular fatty acids are of the straight-chain saturated, monounsaturated, and cyclopropane ring types, with tetradecanoic, hexadecanoic, *cis*-9,10-hexadecenoic, *cis*-11,12-octadecenoic, and *cis*-11,12-methyleneoctadecanoic acids predominating. Small quantities of methylenehexadecanoic acid are also present.

Isolated from vacuum-packaged meat stored at low temperatures.

DNA G+C content (mol%): 37 (T_m).

Type strain: SML9, ATCC 49366, CCUG 30198, CCUG 32249, CCUG 32696, CIP 103318, DSM 5578, JCM 9697, LMG 18297, NCIMB 12897.

GenBank accession number (16S rRNA gene): AF175402.

Note: The description of the type strain corresponds to that of the species, except that no growth occurs at 37 °C, dextran is produced from sucrose, and ribose is fermented, but maltose is not.

11. **Leuconostoc inhae** Kim, Lee, Jang, Kim and Han 2003, 1125^{VP}

in'ha.e. N.L. gen. n. *inhae* of Inha, from the Inha University, Republic of Korea.

Gram-stain-positive, spherical or lenticular cells (0.8–1.0 by 0.8–1.8 μ m), single or arranged in pairs. Colonies on MRS agar are small (1.0–1.5 mm in diameter), round, smooth, convex, opaque and grayish-white. Some strains produce exopolysaccharides. Cells are nonmotile and do not produce endospores. Growth is facultatively anaerobic and metabolism obligately heterofermentative. Catalase is not produced. Arginine is not hydrolyzed. Growth occurs in the presence of 3% (m/v) NaCl but not in the presence of 7% (m/v) NaCl. Growth is recorded at pH 4.8 but not at pH 3.8. All strains grow at 25 °C and 30 °C but not at 37 °C. Good growth is obtained at 1–5 °C. D-Lactic acid is produced from D-glucose. Acid is produced from L-arabinose, cellobiose, esculin, D-fructose, β -gentiobiose, D-glucose, D-mannose, mannitol, maltose, methyl- α -D-glucoside, N-acetylglucosamine, ribose, sucrose, and trehalose. Acid is not produced from adonitol, D-arabinose, D-arabitol, arbutin, 2-ketogluconate, 5-ketogluconate, dulcitol, erythritol, D-fucose, L-fucose, glycerol, glycogen, inositol, inulin, lactose, D-lyxose, melezitose, melibiose, methyl

α -D-mannoside, methyl- β -xyloside, D-raffinose, rhamnose, sorbitol, L-sorbose, starch, D-tagatose, xylitol, D-xylose, and L-xylose. Some strains produce acid from amygdalin, galactose, gluconate, salicin, and D-turanose.

Isolated from kimchi.

DNA G+C content (mol%): 39.99 \pm 0.5 (HPLC).

Type strain: IH003, DSM 15101, KCTC 3774.

GenBank accession number (16S rRNA gene): AF439560.

Note: The description of the type strain corresponds to the description of five other isolates, except that no growth occurs at pH 3.8 and exopolysaccharides are not produced from sucrose. Amygdalin, galactose, gluconate, salicin, and D-turanose are also not fermented.

12. **Leuconostoc kimchii** Kim, Chun and Han 2000b, 1918^{VP} kim'chi.i. N.L. gen. n. *kimchii* of kimchi, a traditional Korean food made by fermentation of Chinese cabbage.

Gram-stain-positive, spherical or ovoid cells, single or in pairs. Nonmotile and asporogenous. Catalase is not produced. Growth is facultatively anaerobic at 15 °C and 37 °C but not at 45 °C. Growth occurs in the presence of 7% (m/v) NaCl but not in the presence of 10% (m/v) NaCl. Dextran is produced from the fermentation of sucrose. Carbon dioxide and D-lactate are produced from D-glucose. Arginine is not hydrolyzed. Amygdalin, arabinose, cellobiose, galactose, gluconate, lactose, mannitol, ribose, salicin, trehalose, turanose, fructose, maltose, mannose and sucrose are fermented. Melezitose, sorbitol, starch, rhamnose, inulin, melibiose, raffinose, and xylose are not fermented. The majority of cellular fatty acids are straight-chain saturated, mono-unsaturated, and cyclopropane rings.

Isolated from kimchi.

DNA G+C content (mol%): 37 (T_m) (HPLC).

Type strain: IH25, KCTC 2386, IMSNU 11154.

GenBank accession number (16S rRNA gene): AF173986.

Note: The type strain is the only strain available.

13. **Leuconostoc lactis** Garvie 1960, 290^{AL}

lac'tis. L. n. *lac* milk; L. gen.n. *lactis* of milk.

Gram-stain-positive, catalase-negative, nonmotile, asporogenous, spherical or lenticular cells (especially when grown on agar), arranged in pairs or chains. Colonies are small (less than 1.0 mm in diameter), smooth and grayish white. Dextran is not produced from sucrose. The amino acid requirements are complex. Lactose is fermented more readily than by other species and strains may acidify and even clot unsupplemented milk. Citrate may be dissimulated and acetoin and diacetyl formed (Cogan et al., 1981). Fructose, galactose, glucose, lactose, maltose, and sucrose are fermented. Amygdalin, arabinose, arbutin, cellobiose, mannitol, trehalose, and xylose are not fermented. Esculin is not hydrolyzed. Guanine, ade-

nine, xanthine, pyridoxal, and folic acid are not required for growth. Glucose litmus milk is acidified and curdled by some strains, albeit weakly. Gas production in litmus milk has not been described. Growth occurs in the presence of 3.0% (m/v) NaCl but not in the presence of 6.5% (m/v) NaCl. Growth occurs at pH 6.5 and 4.8. Heat resistance is higher than in other species and cells may survive 60 °C for 30 min. The species may not be widely distributed as recorded isolations are few and are mostly from dairy sources.

DNA G+C content (mol%): 43–45 (T_m) (Garvie, 1986), or 43 (HPLC) (Vancanneyt et al., 2006).

Type strain: ATCC 19256, DSM 20202, CCUG 30064, CIP 102422, HAMBI 2346, JCM 6123, LMG 8894, NCIMB 13091, NRRL B-3468.

GenBank accession number (16S rRNA gene): AB023968, M23031.

14. **Leuconostoc pseudomesenteroides** Farrow, Facklam and Collins 1989, 283^{VP}

pseu.do.me.sen.ter.oi'des. Gr. adj. *pseudes* false; Gr. n. *mesenterium* the mesentery; Gr. suff. *eides* form, shape; N.L. adj. *pseudomesenteroides* not the true mesenteroides.

Gram-stain-positive, nonmotile, spherical or lenticular cells (ca. 0.5–0.7 \times 0.7–1.2 μ m), arranged in pairs or short chains. Most strains are nonpigmented. Growth occurs at 10 °C and 37 °C. Acid is produced from N-acetylglucosamine, D-fructose, D-glucose, maltose, D-mannose, melibiose, α -methyl-D-glucoside, raffinose, ribose, trehalose, and D-xylose. Most strains produce acid from L-arabinose, cellobiose, esculin, galactose, β -gentiobiose, lactose, sucrose, and D-turanose. A few strains produce acid from amygdalin, arbutin, 2-ketogluconate, 5-ketogluconate, and mannitol (after 7 d). Acid is not produced from adonitol, D-arabinose, D-arabitol, L-arabitol, dulcitol, erythritol, D-fucose, L-fucose, glycerol, inositol, inulin, D-lyxose, melezitose, α -methyl-D-mannoside, L-rhamnose, L-sorbose, sorbitol, D-tagatose, L-xylose, and xylitol. Arginine is not hydrolyzed. Urease, L-isoleucine arylamidase, and L-proline arylamidase-negative.

Isolated from dairy sources, food, and clinical sources.

DNA G+C content (mol%): 38.1–40.8 (T_m).

Type strain: ATCC 12291, DSM 20193, CCUG 30063, CIP 103316, JCM 9696, LMG 11482, NCCB 83005, NCIMB 8699.

GenBank accession number (16S rRNA gene): AB023237, X95979.

Note: In most respects the description of the type strain resembles the description of the species. The type strain produces acid from L-arabinose, cellobiose, 2-ketogluconate, 5-ketogluconate, galactose, β -gentiobiose, gluconate, and lactose. Acid is not produced from amygdalin arbutin, mannitol (after 7 d), salicin, or starch.

Genus II. **Oenococcus** Dicks, Dellaglio and Collins 1995a, 396^{VP}

LEON M. T. DICKS AND WILHELM H. HOLZAPFEL

oe.no.coc'cus. Gr. n. *oinos* wine; Gr. masc. n. *kokkos* berry, little round thing; N.L. masc. n. *oenococcus* little round thing from wine.

Cells are Gram-stain-positive, nonmotile, and asporogenous. **Ellipsoidal to spherical in shape**, usually arranged in pairs or chains. Cell morphology varies with strain and is influenced by

growth medium and age. Chemo-organotrophic, facultatively anaerobic, catalase-negative, no cytochromes present. Usually nonproteolytic. Exoprotease activity has been reported for a

strain isolated from a red wine produced in Argentina (Manca de Nadra et al., 2005). Nitrate is not reduced. Nonhemolytic. Indole is not formed. **Acidophilic (prefers an initial growth pH of 4.8) or non-acidophilic (growth at pH 5.0–7.5; pH 6.0–6.8 as optimum), depending on the species.** Growth in media supplemented with 5% (v/v) ethanol is usual, but growth in the presence of 10% (v/v) ethanol depends on the species. Growth in broth is slow and usually uniform. **Surface growth is enhanced by incubation in a 10% CO₂ atmosphere.** Colonies usually develop only after 5 d and are less than 1 mm in diameter. Grows between 20 and 30 °C. Requires a rich medium with complex growth factors and amino acids. **Tomato juice, grape juice, pantothenic acid, or 4'-O-(β-glucopyranosyl)-D-pantothenic acid may be required for growth and depends on the species.** Glucose is fermented to equal amounts of **D(-)-lactic acid, CO₂, and ethanol or acetate via a pathway not yet fully elucidated.** **L-malate is decarboxylated to L(+)-lactate in the presence of a fermentable carbohydrate.** **Polysaccharides and most alcohols are not metabolized.** **Nicotinamide adenine dinucleotide (NAD)-dependent glucose-6-phosphate dehydrogenase (G-6-P-DH) not present.** Habitat: wine, cider and distilled shochu residue.

DNA G+C content (mol%): 37–43 (*T_m* and HPLC).

Type species: *Oenococcus oeni* (Garvie 1967b) Dicks, Dellaglio and Collins 1995a, 397^{VP} (*Leuconostoc oeni* corrig. Garvie 1967b, 431).

Further descriptive information

Oenococcus oeni is distinguished from *Leuconostoc* species by growth at an initial pH of 4.8 and in media containing 10% (v/v) ethanol, requirement of a tomato juice growth factor

(most strains), and the lack of NAD-dependent G-6-P-DH (Garvie, 1986). The electrophoretic mobilities of D(-)-lactate dehydrogenase (D-LDH), 6-P-G-DH, and alcohol dehydrogenase (ADH) also clearly distinguish *Oenococcus oeni* from *Leuconostoc* species (Garvie, 1986). Antisera prepared from *Oenococcus oeni* show no cross-reactivity with anti-G-6-P-DH and anti-D(-)-LDH of *Leuconostoc lactis* and anti-G-6-P-DH of *Leuconostoc mesenteroides* subsp. *mesenteroides* (Gasser and Hontebeyrie, 1977). *Oenococcus oeni* is further distinguished from *Leuconostoc* species by total soluble cell protein patterns (Dicks, 1989, 1995; Dicks et al., 1990).

Evidence for separate genotypic status of *Oenococcus oeni* comes from DNA–DNA hybridization studies (Dicks et al., 1990; Farrow et al., 1989; Garvie, 1976; Hontebeyrie and Gasser, 1977; Schillinger et al., 1989), confirmed by DNA-rRNA hybridization (Garvie, 1984; Schillinger et al., 1989) and rRNA sequence analyses (Martinez-Murcia and Collins, 1990; Yang and Woese, 1989). Comparative 16S rRNA (Martinez-Murcia and Collins, 1990; Yang and Woese, 1989) and 23S rRNA sequencing analyses (Martinez-Murcia et al., 1993) have clearly shown that *Oenococcus oeni* forms a distinct line of descent, separate from the *Leuconostoc sensu stricto* (including *Leuconostoc mesenteroides*) and the *Leuconostoc paramesenteroides* (now *Weissella paramesenteroides*) groups of species (Figure 117).

Considerable variation in carbohydrate fermentation profiles has been recorded for strains of *Oenococcus oeni*, despite the genetically homogeneous nature of the species. This variation in phenotype is further emphasized by the differences recorded in fatty acid profiles (Tracey and Britz, 1989).

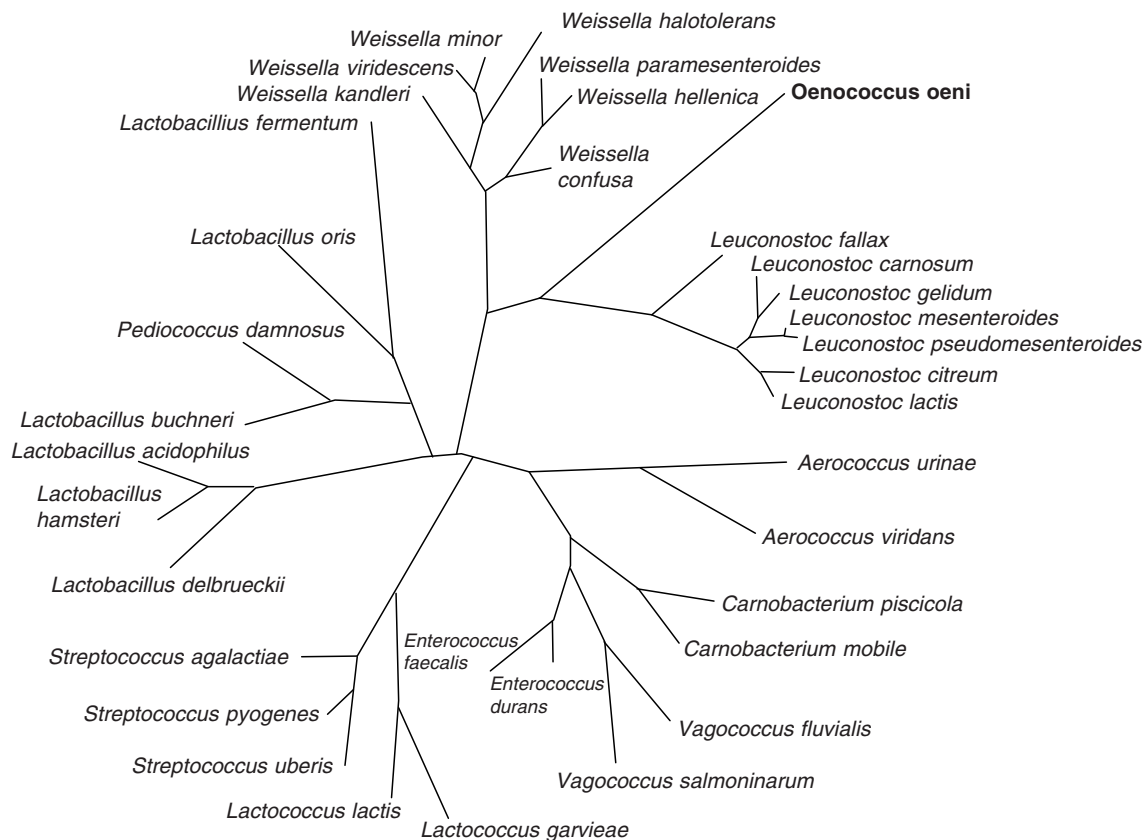

FIGURE 117. Unrooted phylogenetic tree showing the relationship of *Oenococcus oeni* and lactic acid bacteria based on 16S rRNA sequences. (Modified and reprinted from Dicks et al., 1995. *International Journal of Systematic Bacteriology* 45: 395–397)

Numerical analysis of these profiles have grouped the strains into four clusters defined at $r = 0.92$, with five strains unassigned. The phenotypic characteristics which distinguish *Oenococcus oeni* from *Leuconostoc* species and *Weissella paramesenteroides* are listed in Table 125.

The development of ethanol resistance in *Oenococcus oeni* is a complex and multi-layered phenomenon. It depends on the severity and duration of the ethanol shock and on culture conditions such as medium composition, pH, and temperature (Bauer and Dicks, 2004; Desroche et al., 2005). The synthesis of low-molecular-mass stress proteins is induced and may be involved in cell adaptation (Bourdineaud et al., 2004; Guzzo et al., 1997, 2000; Teixeira et al., 2002; Tourdot-Marechal et al., 2000).

Proteolytic activities and the resulting effects in wine fermentation have been studied by Manca de Nadra et al. (1999, 1997a, 1997b). The ability of *Oenococcus oeni* strains to metabolize methionine in wine with the formation of volatile sulfur compounds was reported by Pripis-Nicolau et al. (2004).

Oenococcus kitaharae is distinguished from *Oenococcus oeni* by the following characteristics: L-malate is not decarboxylated to L(+)-lactate in the presence of a fermentable carbohydrate, acid is produced from the fermentation of maltose, optimal growth at pH 6.0–6.8 and at 30 °C, and no growth in the presence of 10% (v/v) ethanol (Endo and Okada, 2006). Growth is not stimulated in the presence of tomato juice and cells can be cultured in MRS or BHI medium (Endo and Okada, 2006).

Metabolism

The metabolic pathway has not been fully elucidated and the following pertain to *Oenococcus oeni*, unless stated otherwise. Glucose-6-phosphate dehydrogenase and xylulose-5-phosphoketolase are the key metabolic enzymes (Garvie, 1986). NAD and NADP serve as coenzymes of the glucose-6-phosphate dehydrogenase, but only NADP is required (Garvie, 1975). Glucose is phosphorylated and then oxidized to 6-phosphogluconate, followed by decarboxylation. The resulting pentose phosphate is converted to lactic acid and ethanol and/or acetic acid (Garvie, 1986).

Oenococcus oeni and *Oenococcus kitaharae* prefer a complex growth medium, which contains vitamins, nucleotide bases, and amino acids. Nicotinic acid, thiamine, biotin, and pantothenic acid may be required and depends on the species. Most strains of *Oenococcus oeni* require a gluco-derivative of pantothenic acid (Amachi et al., 1971), also known as tomato juice factor (TJF) (Garvie and Mabbitt, 1967). All strains of *Oenococcus oeni* grow at a pH of 3.9 (optimal pH 4.8) and are resistant to ethanol levels of 10% (v/v) (Garvie, 1986). *Oenococcus kitaharae* is less acidophilic and grows at pH 5.0–7.5 (pH 6.0–6.8 as optimum) and is less resistant to ethanol (growth in the presence of 5%, v/v, ethanol but not 10%, v/v, ethanol). Growth of *Oenococcus kitaharae* is not stimulated in the presence of tomato juice and cells can be cultured in MRS or BHI medium (Endo and Okada, 2006). Glucose is fermented by all species, but *Oenococcus oeni* prefers fructose. In the absence of FDP-aldolase, hexoses are fermented by a combination of the hexose monophosphate system and the phosphoketolase pathway, yielding equimolar amounts of D(-)-lactate, ethanol/acetate, and CO₂ (De Moss et al., 1951; Gunsalus and Gibbs, 1952). All strains ferment lactose, maltose, and sucrose (Garvie, 1967a, 1967b, 1986).

Malic acid is actively metabolized and converted to L(+)-lactic acid and CO₂ by *Oenococcus oeni*, a process which seems to be regulated by glucose. As little as 2 mM glucose inhibits malolactic fermentation by 50%, with 5 mM or higher leading to a 70% inhibition (Miranda et al., 1997). Similar results were obtained in the presence of galactose, trehalose, and maltose, but ribose and 2-deoxyglucose had no effect on the conversion of L-malic acid (Miranda et al., 1997). The inhibition exerted by glucose is reversed by the addition of fructose or citrate, which leads to an increase in intracellular concentrations of glucose 6-phosphate, 6-phosphogluconate, and glycerol 3-phosphate. The effect of glucose 6-phosphate, 6-phosphogluconate, NAD(P)H, and NADP⁺ on the malolactic enzyme is discussed by Miranda et al. (1997). Gallic acid (3,4,5-trihydroxybenzoic acid - C₆H₂(OH)₃CO₂H - a colorless crystalline organic acid found in gallnuts, sumac, tea leaves, oak bark, and many other plants, both in its free state and as part of the tannin molecule) and free anthocyanins activate cell growth and the rate of malic acid degradation (Vivas et al., 1997). Phenolic compounds, typically associated with red wine fermentation, reduce the rate of sugar consumption by *Oenococcus oeni* but enhance citric acid consumption, thereby resulting in an increased yield of acetic acid (Rozès et al., 2003). The genes encoding the malolactic enzyme and malate permease (*mleA*, *mleP*) have been sequenced (Labarre et al., 1996). *Oenococcus kitaharae* does not decarboxylate L-malate to L(+)-lactate in the presence of a fermentable carbohydrate (Endo and Okada, 2006).

Little is known about the production of biogenic amines. Tyramine formation could not be detected for most *Oenococcus oeni* isolated from wine (Cilliers and van Wyk, 1985). Moreno-Arribas et al. (2003) could also not detect any potential among *Oenococcus oeni* strains to form biogenic amines. However, Gardini et al. (2005) reported tyramine formation by a strain of *Oenococcus oeni* isolated from Italian red wine. Coton et al. (1998) reported that approximately 50% of the *Oenococcus oeni* strains they studied contain the histidine decarboxylase gene, thus are capable of histamine production in wine. Guerini et al. (2002) found that >60% out of 44 *Oenococcus oeni* strains, isolated from different Italian wines, were able to produce histamine at concentrations ranging from 1.0 to 33 mg/l, while about 16% showed an additional capability to form both putrescine and cadaverine. The formation of putrescine from arginine by some strains could be demonstrated. Marcobal et al. (2004) identified the ornithine decarboxylase gene in the putrescine producer *Oenococcus oeni* BIFI-83. The gene was found to contain a 2235-nucleotide open-reading frame encoding a protein with 745 amino acid residues and a deduced molecular mass of 81 kDa.

Practical importance of malolactic fermentation by *Oenococcus oeni*. Malolactic fermentation (MLF) is important in wines with a low pH, as is often found in cooler viticultural regions. This secondary fermentation not only renders the wine microbiologically stable (Davis et al., 1985b; Wibowo et al., 1985), but also decreases the acidity and often enhances the organoleptic properties of the wine (Rodriguez et al., 1990; Rossi et al., 1978, 1993). However, in wines with a low acidity, a further increase in pH may render the wine unpalatable. Under these conditions, and also after bottling, *Oenococcus oeni* may be considered a spoilage organism. The increase in pH may also lead to spoilage by

^a+, 90% or more of strains positive; -, 90% or more of strains negative; d, 11–98% of strains positive; (); delayed reaction; ND, no data; D, 90% or more of the lactic acid is D(-). Data for *Leuconostoc mesenteroides*, *Leuconostoc lactis*, and *Oenococcus oeni* is from Garvie (1986) and *Oenococcus kitaharae* from Endo and Okada (2006). Data for *Leuconostoc carnosum* and *Leuconostoc gelidium* is from Shaw and Harding (1989), *Leuconostoc pseudomesenteroides* from Farrow et al. (1989), for *Leuconostoc citreum* from Farrow et al. (1989) and Schillinger et al. (2006), for *Leuconostoc argentinum* from Dicks et al. (1993), for *Leuconostoc fallax* from Martínez-Murcia and Collins (1991) and for *Leuconostoc gasicomitatum* from Björkroth et al. (2000). The peptidoglycan type of *Leuconostoc carnosum*, *Leuconostoc gelidium*, and *Leuconostoc argentinum* was obtained from the German Collection of Microorganisms and Cell Cultures (DSMZ, Braunschweig).

^bHydrolysis of arginine is negative for all species. All representatives are heterofermentative and produce D(-)lactic acid from glucose, in addition to CO₂ and ethanol and/or acetic acid.

^cGlucose-6-phosphate dehydrogenase.

various other *Lactobacillus* and *Leuconostoc* species (Dittrich, 1993). Selected strains of *Oenococcus oeni* are used as starter cultures for improved control of the MLF, and are commercially available in the major wine-growing areas of industrialized countries.

Habitat

Oenococcus oeni is almost exclusively found in grape must, wine, and fortified wine (Davis et al., 1985a; Dicks et al., 1995b; Wibowo et al., 1985), where it plays an important role in the decarboxylation of L-malic acid to L-(+)-lactic acid. *Oenococcus oeni* was also found to be the predominant species among lactic acid bacteria (LAB) in South African brandy base wines produced without sulfur dioxide (du Plessis et al., 2004). *Oenococcus oeni* strains were found to exert a more favorable influence on the quality of base wine and distillates than other LAB. Bacteriophages specific to *Oenococcus oeni* have been isolated from sugar cane (Nel et al., 1987), which would indicate that the species may also be associated with habitats rich in sugar. However, isolation of strains of *Oenococcus oeni* from habitats other than wine and cider has not been reported. All known strains of *Oenococcus kitaharae* have been isolated from a composting distilled shochu residue collected at a shochu distillery in Miyazaki Prefecture in the Southern Kyushu area of Japan.

Enrichment and isolation procedures

Growth is supported by a complex combination of amino acids, peptides, fermentable carbohydrates, fatty acids, nucleic acids, and vitamins. Biotin, nicotine, thiamine, and pantothenic acids, or derivatives thereof, are required by most strains.

Growth on plates is greatly enhanced by semi-anaerobic or microaerophilic incubation, i.e., in the presence of 5% CO₂, N₂, and H₂, or in an anaerobic jar with GasPak (Oxoid) or Anaerocult A (Merck). Cysteine hydrochloride (0.05–0.1%) is often added to broth media. Incubation is usually between 20 and 30 °C. Depending on the strain and other growth factors, an incubation period from 48 h up to 10 d may be necessary.

Several growth media have been described for *Oenococcus oeni* (summarized in Table 126), all of which are acidic with an initial pH between 4.8 and 5.5. The acidic tomato broth (ATB) medium described by Garvie (1967b) contains 25% (v/v) tomato juice. A modification of the latter medium, described by Dicks et al. (1990) contains 25% (v/v) grape juice (acidic grape medium). Weiler

and Radler (1970) described a more complex medium which, in addition to glucose, contains yeast extract and peptone, Tween 80 (0.1%, v/v), diammonium hydrogen citrate (0.2%, w/w), and sodium acetate (0.5%, w/v). The pH of the latter medium is 5.4 and contains sorbic acid (0.05%, w/v, final concentration) to suppress the growth of yeast. Davis et al. (1985b) used MRS (De Man et al., 1960) or tomato juice medium (Ingraham et al., 1960), adjusted to pH 5.5 and supplemented with cycloheximide (50 µg/ml). The same medium, supplemented with wine (40–80%, v/v), enhanced growth (Davis et al., 1985a). Cavin et al. (1988) incorporated Tween 80, D-fructose (3.5%, w/v), and L-malic acid (1%, w/v) to their medium (FT medium), which they buffered by adding CaCl₂ (0.013%, w/v) and KH₂PO₄ (0.06%, w/v). A modification of the FT-medium, which contains lower concentrations of fructose (0.04%, w/v) and glucose (0.01%, w/v), cellulose MN 300 (10%, w/v), and bromocresol green (0.01%, w/v) was used to differentiate malolactic strains from strains unable to conduct the fermentation (Cavin et al., 1989). Sugar fermentation reactions may be studied by using the “sugar basal broth” described by Garvie (1984), modified by adjusting the pH to 5.2, and substituting bromocresol purple with bromocresol green (0.004%, w/v).

Oenococcus kitaharae is less fastidious and grows in MRS and BHI (brain heart infusion) medium (Endo and Okada, 2006).

Maintenance procedures

For short-term maintenance stab cultures in ATB, pH 4.8 (Garvie and Mabbitt, 1967), may be used. The addition of CaCO₃ neutralizes acid formation. Most strains survive storage at –80 °C in the presence of 40% (v/v) glycerol (final concentration) for at least a year. Cells may also be lyophilized. Since surface growth is often poor, best results are obtained by growing the cells in 10 ml liquid medium to mid-exponential phase. The cells are then harvested by centrifugation, resuspended in 1 ml sterile saline and an equal volume of sterile 40% (w/v) skim milk, frozen, and then lyophilized.

Taxonomic and nomenclatural comments

The genus *Oenococcus* contains two species, *Oenococcus oeni*, which was formerly considered to belong to the genus *Leuconostoc* as *Leuconostoc oenos*, and *Oenococcus kitaharae*. When the *Leuconostoc oenos* taxon was assigned to the genus *Leuconostoc* by

TABLE 126. Summary of media used for the isolation of *Oenococcus oeni* from wine^a

Medium	pH	Selectivity	Most important components	Reference
Acidic Tomato Broth (ATB)	4.8	Semi-selective	Tomato juice (25%)	Garvie (1967a)
Weiler and Radler medium	5.3–5.4	Semi-selective	Sodium acetate (0.5%), Tween 80 (0.1%), sorbic acid (0.05%)	Weiler and Radler (1970)
M104 medium	4.5	Selective	Tomato juice (25%), DL-malic acid (1%), Tween 80 (0.1%)	Barilli�re (1981)
Tomato juice-Glucose-Fructose-Malate Broth (TGFMB)	5.5	Selective	Tomato juice (diluted), fructose (0.3%), malate (0.2%), Tween 80, cycloheximide (0.005%)	Izuagbe et al. (1985)
Fructose and Tween 80 (FT 80) medium	5.2	Semi-selective	Fructose (3.5%), L-malic acid (1%), Tween 80 (0.1%)	Cavin et al. (1988)
Enriched tomato juice broth (ETJB)	4.8	Semi-selective	Tomato juice broth (Difco) (2%), Tween 80 (0.1%), cysteine (1%)	Britz and Tracey (1990)
UBA-agar		Selective	Apple juice (20%), cycloheximide (0.005%)	Rodr�guez et al. (1990)

^aData from Schillinger and Holzappel (2002). *Oenococcus kitaharae* does not require tomato juice in the growth medium and can be cultured in MRS (De Man et al., 1960) and BHI (brain heart infusion) medium (Endo and Okada, 2006).

Garvie (1967b), the specific epithet was incorrectly presented as *oenos*, which is the nominative form of this noun where the genitive is required. It is also incorrectly Latinized as a nominative. The correct latinization is *oimus*. The specific epithet *oenos* was changed to the correct Latin genitive form *oeni* by Dicks et al. (1995a). The description for the genus is as published by Garvie (1986) and amended by Dicks et al. (1995a).

Various DNA reassociation techniques have been used to clarify the taxonomic status of *Oenococcus oeni*, *Leuconostoc* species, and *Weissella* species (Farrow et al., 1989; Garvie, 1976; Hontebeyrie and Gasser, 1977; Schillinger et al., 1989; Shaw and Harding, 1989; Vescovo et al., 1979). All DNA–DNA similarity studies indicate that *Oenococcus oeni* is a genetically distinct and homogeneous species (Table 127).

Phylogenetically, *Oenococcus oeni* is well separated from the leuconostocs (the *Leuconostoc sensu stricto* group), the *Weissella* (“*Leuconostoc*”) *paramesenteroides* group, and all other LAB. *Oenococcus oeni*, *Leuconostoc*, and *Weissella* species group into three distinct evolutionary lines, as shown by 16S rRNA (Collins et al., 1993; Martinez-Murcia and Collins, 1990, 1991) and 23S rRNA (Martinez-Murcia et al., 1993) analyses. Furthermore, results obtained by 16S and 23S rRNA sequence analyses (Martinez-Murcia et al., 1993), DNA–DNA hybridizations (Dicks et al., 1995b; Garvie, 1981; Schillinger et al., 1989), and total soluble-cell-protein profiles (Dicks et al., 1995b), clearly distinguish strains of *Oenococcus oeni* from all leuconostocs. In the 16S rRNA phylogenetic analysis presented in the revised roadmap to Volume 3 (Figure 1 and Figure 3; Ludwig et al., this volume), *Oenococcus*, *Weissella*, and *Leuconostoc* form a new family, *Leuconostocaceae*, within the order *Lactobacillales*.

Applying molecular and chemotaxonomic techniques, Sato et al. (2001) studied the intraspecific diversity of *Oenococcus oeni* strains isolated during red wine-making in Japan. They found high DNA–DNA relatedness and a strong similarity among 16S rDNA sequences of the studied isolates with the type strain of *Oenococcus oeni*, thereby confirming that *Oenococcus oeni* comprises one species. Using pulsed-field gel electrophoresis (PFGE), four patterns could be identified among the strains, while three

different patterns of lactate dehydrogenase mobility were seen with a strong correlation between PFGE pattern and mobility.

The hypothesis that *Oenococcus oeni* is a “fast-evolving” or “tachyelic” species (Yang and Woese, 1989) was proven wrong by sequencing of the *rpoC* gene (Morse et al., 1996). The latter is shown in Figure 118.

A number of molecular taxonomic methods have been applied to differentiate *Oenococcus oeni* from other LAB. This includes *in situ* hybridization with DNA probes derived from genomic sequences (Sohier and Lonvaud-Funel, 1998) and spacer regions of 16S/23S sequences (LeJeune and Lonvaud-Funel, 1997; Zavaleta et al., 1997a), ribotyping (Viti et al., 1996; Zavaleta et al., 1997b), 16S rDNA RFLP (Sato et al., 2000), restriction endonuclease analysis of genomic DNA (Daniel et al., 1993; Kelly et al., 1993; Lamoureux et al., 1993; Tenreiro et al., 1994; Viti et al., 1995), RAPD-PCR analyses (Zapparoli et al., 2000; Zavaleta et al., 1997b), and plasmid profiling (Prévost et al., 1995). Rodas et al. (2003) developed a 16S-ARDRA protocol for identification of LAB from grape must and wine. The protocol is based on the direct amplification of 16S rDNA followed by digestion with the restriction enzymes *BfaI*, *MsaI*, and *AclI*, in sequence, and could discriminate 32 of the 36 LAB reference species tested, while allowing the identification of 342 isolates from musts and wines. Pinzani et al. (2004) developed a real-time polymerase chain reaction (PCR) method for rapid detection and quantification of *Oenococcus oeni* in wine. It stated that this rapid quantification of *Oenococcus oeni* will allow prompt corrective measures to regulate the bacterial growth, and thus contributes to improving the malolactic fermentation in wines. Reguant and Bordons (2003) applied a multiplex RAPD-PCR for the typification of *Oenococcus oeni* and the study of population dynamics during malolactic fermentation. The method is based on the combination of one random 10-mer and one specific 23-mer oligonucleotide in a single PCR. Fröhlich (2002) and Fröhlich et al. (2002) developed gene probes for the specific detection and identification of *Oenococcus oeni* in wine production, and also used FISH and micromanipulation. The gene probe invention has been patented (Fröhlich et al., 2003). The construction of the probes provides a suitable signal for detection, e.g., by a good fluorescent yield.

Oenococcus kitaharae has only recently been described (Endo and Okada, 2006) and differ from *Oenococcus oeni* by being less

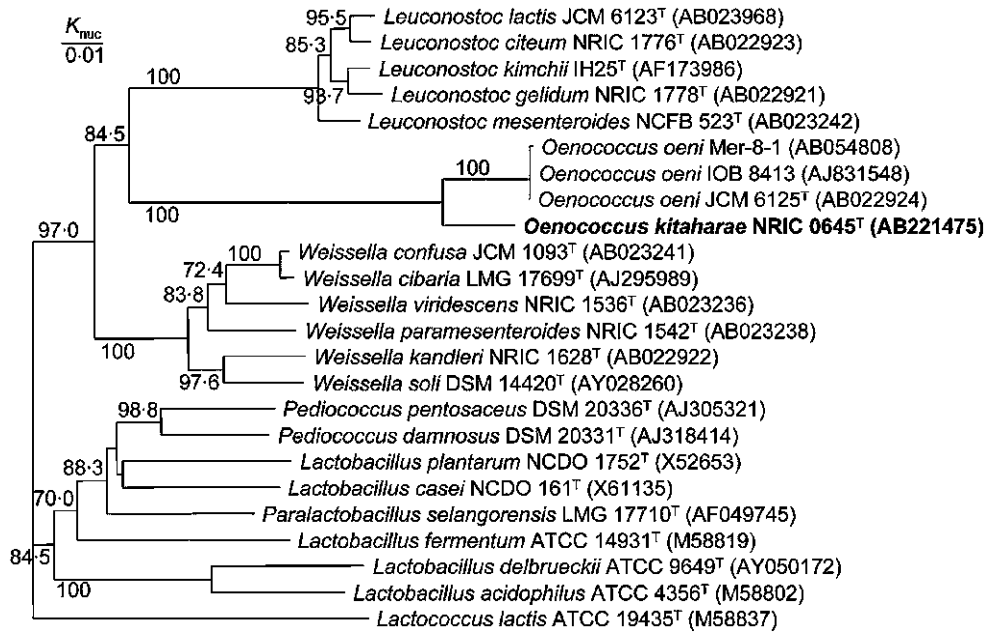

FIGURE 119. Neighbor-joining phylogenetic tree showing the relationship between *Oenococcus kitaharae*, *Oenococcus oeni* and related taxa (Reprinted with permission from Endo and Okada, 2006. International Journal of Systematic and Evolutionary Microbiology 56: 2345–2348)

acidophilic, less resistant to ethanol and not able to convert L-malate to L(+)-lactate. The species is also less fastidious and grows in MRS and BHI medium not supplemented with addi-

tional growth factors such as tomato juice (Endo and Okada, 2006). *Oenococcus kitaharae* is 96.0% related to *Oenococcus oeni*, based on 16S rRNA sequence analyses (Figure 119).

List of species of the genus *Oenococcus*

1. ***Oenococcus oeni*** (Garvie 1967b) Dicks, Dellaglio and Collins 1995a, 397^{VP} (*Leuconostoc oeni* corrig. Garvie 1967b, 431) *oe’ni*. Gr. gen. n. *oinou* of wine; N.L. gen. n. *oeni* of wine.

Acidophilic and grows in grape must and wine at pH 3.5–3.8. Prefers an initial growth pH of 4.8. Growth is not inhibited in the presence of 10% (v/v) ethanol. Optimum growth temperature is 22 °C. Growth at 15 °C is slow. Requires a rich growth medium supplemented with grape juice, tomato juice, pantothenic acid, or a glucose derivative of pantothenate. Converts L-malate to L(+)-lactate and CO₂ in the presence of a fermentable carbohydrate. Glucose is fermented to D(-)-lactic acid, CO₂, and ethanol or acetate. Metabolically inactive and ferments only a few carbohydrates. Prefers fructose and usually ferments trehalose. In grape must or wine, pentose sugars (arabinose or xylose) are fermented before glucose, resulting in diauxic growth. Variable reactions have been recorded for arabinose, cellobiose, galactose, mannose, melibiose, salicin, and xylose fermentations. Sucrose, lactose, maltose, mannitol, and raffinose are not fermented. Esculin is hydrolyzed. Arginine is hydrolyzed by certain strains, but only in wine or related habitats. Some strains ferment citrate in the presence of a fermentable carbohydrate, but this characteristic is often lost when strains are subcultured. Glucose-6-phosphate dehydrogenase activity is only obtained in the presence of NADP. D(-)-LDH migrates slowly and at least nine electrophoretically different D(-)-LDH bands have been obtained. Growth in yeast glucose milk is unusual, but, if it occurs, acid and gas are not produced. Certain strains produce extracellular polysaccharides in medium supplemented with grape juice.

Oenococcus oeni is a phylogenetically homogeneous species based on 16S–23S-rDNA intergenic sequence analysis (Zavaleta et al., 1997a). Isolated from wine. The amino acid sequence of the interpeptide bridge of cell-wall peptidoglycan is L-Lys–L-Ala–L-Ser or L-Lys–L-Ser–L-Ser.

DNA G+C content (mol%): 38–42 (*T_m*).

Type strain: ATCC 23279, CUG 30199, CUG 32250, CIP 106144, DSM 20252, JCM 6125, LMG 9851, NBRC 100497, NCIMB 11648, NRRL B-3472.

GenBank accession number (16S rRNA gene): AB022924, M35820, X95980.

2. ***Oenococcus kitaharae*** (Endo and Okada 2006)

ki.ta.ha’rae. N.L. gen. n. *kitaharae* of Kitahara, in honor of the Japanese microbiologist Kakuo Kitahara.

Cells are Gram-stain-positive, nonmotile and small ellipsoidal cocci (0.2–0.4 by 0.5–0.8 μm), usually arranged in pairs. Growth on agar medium is enhanced when incubated anaerobically. Colonies are white, smooth and approximately 1 mm in diameter on MRS and BHI (brain heart infusion) agar and less than 1 mm in diameter on MRS agar under aerobic conditions after 7 d at 30 °C. Incubation under anaerobic conditions yield colonies of approximately 2 mm in diameter after 5 d at 30 °C. Heterofermentative and produce lactic acid, carbon dioxide and ethanol or acetic acid from D-glucose. D(-)- and L(+)-lactate are produced (9:1). Nitrate is not reduced. Acid is produced from D-glucose, D-fructose, D-galactose, D-mannose, maltose, melibiose and D-trehalose. D-ribose, D-gluconate and raffinose are weakly fermented. L-arabinose, D-xylose, L-rhamnose, lactose, sucrose, D-melezitose, D-mannitol, D-sorbitol and starch are not fermented. Fermentation of cellobiose and D-salicin is strain-dependent. Dextran is not formed from sucrose. L-malate is not decarboxylated to L-lactate in the presence of a fermentable carbohydrate. Growth between 20 and 30 °C, but not at 15 or 37 °C. Optimum temperature for growth is 30 °C. All strains grow at pH values ranging from 5.0 to 7.5; some strains grow at pH 4.5. Optimum pH for growth is between 6.0 and 6.8. Growth is not stimulated in the presence of tomato juice. Growth is observed in MRS and BHI broth containing 1 % (w/v) NaCl but not 2.5 % (w/v) NaCl. Growth is observed in broth containing 5 % (v/v) ethanol but not 10 % (v/v) ethanol. All known strains were isolated from a composting distilled shochu residue collected at a shochu distillery in Miyazaki Prefecture in the Southern Kyushu area of Japan.

DNA G+C content (mol%): 41–43 mol% (type strain, 41 mol%) (HPLC).

Type strain: NRIC 0645^T (=JCM 13282^T=DSM 17330^T).

Genus III. *Weissella* Collins, Samelis, Metaxopoulos and Wallbanks 1994, 370^{VP}
(Effective publication: Collins, Samelis, Metaxopoulos and Wallbanks 1993, 597.)

JOHANNA BJÖRKROTH, LEON M.T. DICKS AND WILHELM. H. HOLZAPFEL

Weiss.el'la. N.L. dim. fem. n. named after Norbert Weiss, a German microbiologist known for his many research contributions to the taxonomy of the lactic acid bacteria.

The description for the genus is as published by Collins et al. (1993). The cells are **either short rods with rounded tapered ends** (see Figure 120 for *Weissella cibaria*) **or ovoid** and occur in pairs or in short chains. A tendency toward pleomorphism may be found for strains in species such as *Weissella minor* (see Figure 121). **Gram-stain-positive, nonmotile, and asporogenous.** Chemo-organotrophic, facultatively anaerobic, catalase-negative, and devoid of cytochromes. Obligately fermentative chemo-organotrophs; **ferment glucose heterofermentatively** and have **complex nutritional requirements.** The genus *Weissella*

FIGURE 120. Transmission electron micrograph of negatively stained (1% of phosphotungstic acid) cells of *Weissella cibaria* LMG 17699^T.

FIGURE 121. Scanning electron micrograph of a strain of *Weissella minor*, showing irregular and pleomorphic morphology. Bar = 5 μm.

belongs to lactic acid bacteria (LAB) because of their metabolism and phylogenetic position. Carbohydrate fermentation via the hexose-monophosphate and the phosphoketolase pathways. End products of glucose fermentation are CO₂, ethanol, and/or acetate. The configuration of lactic acid is either DL- or D(-), depending on the species. Amino acids, peptides, fermentable carbohydrates, fatty acids, nucleic acids, and vitamins are generally required for growth. Biotin, nicotine, thiamine, and pantothenic acid or its derivatives are required by all strains. Arginine is not hydrolyzed by all species. Growth occurs at 15 °C, with some species growing at 42–45 °C. Cell-wall peptidoglycan is based on lysine as diamino acid, and, with the exception of *Weissella kandleri*, all contain alanine or alanine and serine in the interpeptide bridge. In addition, the interpeptide bridge of *Weissella kandleri* (Lys-L-Ala-Gly-L-Ala₂) contains glycine (Holzapfel and van Wyk, 1982). The phenotypic characteristics of *Weissella* spp. are listed in Table 128.

DNA G+C content (mol%): 37–47 (*T_m* and Bd).

Type species: *Weissella viridescens* (Niven and Evans, 1957) Collins, Samelis, Metaxopoulos and Wallbanks 1994, 370^{VP} (Effective publication: Collins, Samelis, Metaxopoulos and Wallbanks 1993, 601.) (*Lactobacillus viridescens* Niven and Evans 1957, 758; *Lactobacillus corynoides* subsp. *corynoides* Kandler and Abo-Elnaga 1966, 753)

Further descriptive information

According to the 16S rRNA phylogenetic analysis in the revised roadmap to Volume 3 (Figure 1 and Figure 3; Ludwig et al., this volume), *Weissella*, *Leuconostoc*, and *Oenococcus* are in a new family, *Leuconostocaceae*, within the order *Lactobacillales* in the phylum *Firmicutes*, i.e., Gram-positive bacteria with a DNA base composition of less than 50 mol% G+C. It has been concluded from the 16S and 23S rRNA sequence analyses (Martinez-Murcia and Collins, 1990) that *Leuconostoc paramesenteroides* is phylogenetically distinct from *Leuconostoc mesenteroides* and forms a natural grouping with the heterofermentative former *Lactobacillus* species *Lactobacillus confusus*, *Lactobacillus kandleri*, *Lactobacillus minor*, and *Lactobacillus viridescens*.

Table 129 shows 16S rRNA-encoding gene sequence similarity levels within *Weissella*. *Weissella confusa*, *Weissella cibaria*, *Weissella halotolerans*, *Weissella hellenica*, *Weissella kandleri*, *Weissella koreensis*, *Weissella minor*, *Weissella paramesenteroides*, *Weissella soli*, *Weissella thailandensis* and *Weissella viridescens* have 93.9–99.2% 16S rRNA-encoding gene sequence similarity over the length of 1400–1500 bp determined. Based on the sequences encoding the 16S rRNA genes, the genus *Weissella* is differentiated into four main phylogenetic branches. The first branch contains *Weissella hellenica*, *Weissella paramesenteroides*, and *Weissella thailandensis*. The second branch consists of *Weissella confusa* and *Weissella cibaria* (Björkroth et al., 2002; Choi et al., 2002). *Weissella minor*, *Weissella viridescens*, and *Weissella halotolerans* form a third branch with a 16S rDNA similarity of 96.8–99.1%. The fourth branch comprises *Weissella kandleri* and the newly described

^bData for *Weissella confusus*, *Weissella halotolerans*, *Weissella hellenica*, *Weissella kandleri*, *Weissella minor*, *Weissella paramesenteroides*, and *Weissella viridescens* are from Collins et al. (1993); for *Weissella thailandensis* from Tanasupawat et al. (2000); for *Weissella cibaria* from Björkroth et al. (2002); for *Weissella soli* from Magnusson et al. (2002); and data for *Weissella korensis* from Lee et al. (2002).

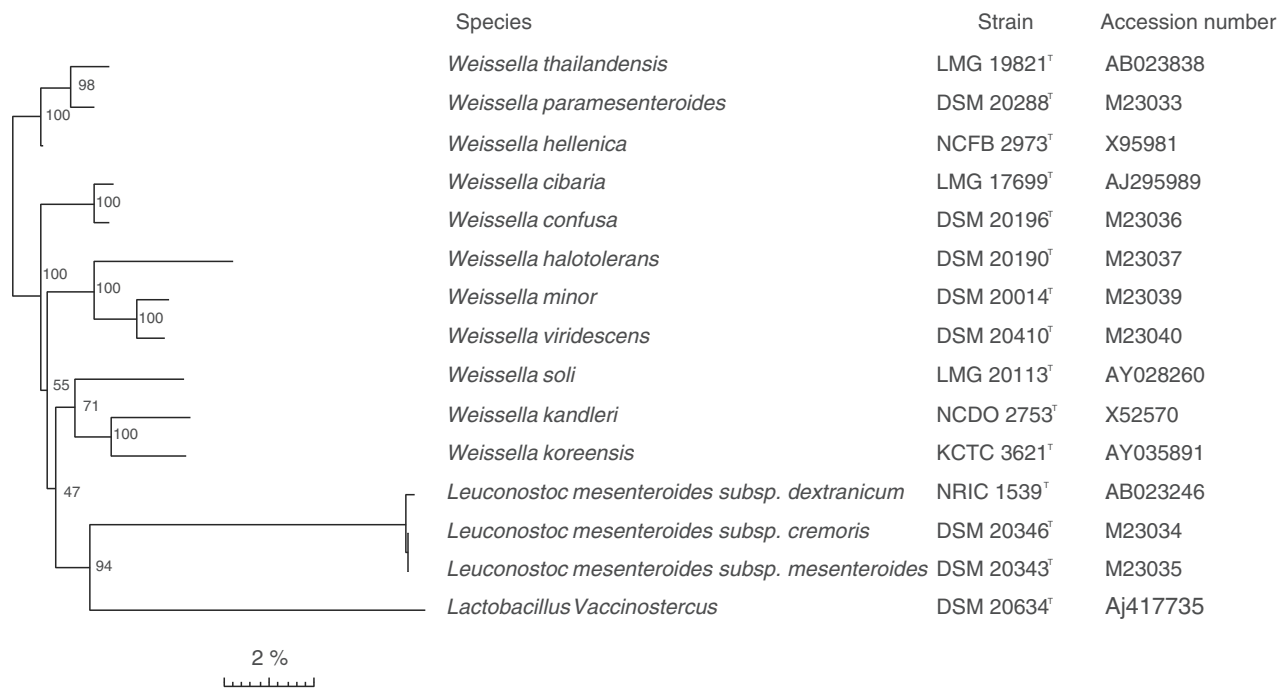

FIGURE 122. Phylogenetic tree based on almost entire 16S rRNA gene sequences of *Weissella* and related species. Bootstrap probability values from 1000 trees resampled are given at the branch points.

species *Weissella soli* and *Weissella korensis*. A phylogenetic tree for *Weissella*, based on almost entire 16S rRNA sequences, is shown in Figure 122.

For some *Weissella* species, species-specific sequences have been located in helix 1007/1022 of the variable region V6 in the 16S rRNA gene (Collins et al., 1993). Rapid identification of *Weissella* species is possible by comparison of DNA patterns generated after restriction enzyme digests (*Mn*I, *Mse*I, and *Bce*AI) of a 725-bp 16S rDNA fragment (Jang et al., 2002).

Numerical analyses of macromolecule patterns have proved useful in the identification of *Weissella* species. The relatedness between

Weissella species and *Leuconostoc* species has been studied by comparison of total soluble cell protein patterns (Dicks, 1995; Tsakalidou et al., 1997). This method and rRNA gene restriction patterns (ribotypes) differentiate *Weissella confusa* from *Weissella cibaria* and group the strains into species-specific clusters (Björkroth et al., 2002). Comparison of cellular fatty acid profiles of *Weissella* species (Samelis et al., 1998) correspond well with results recorded in other taxonomic studies and prove valuable in the differentiation of *Weissella viridescens*, *Weissella paramesenteroides*, *Weissella hellenica*, and typical arginine-negative *Weissella* strains isolated from meat. *Weissella viridescens* is identified based on the presence of eicose-

noic (C_{20:1}) acid. Unlike *Weissella paramesenteroides*, *Weissella hellenica* does not contain cyclopropane fatty acids with 19 carbon atoms (i.e., dihydrostercularic or lactobacillic acid), and *Weissella viridescens* does not contain these fatty acids or has very low quantities. Meat isolates identified as *Weissella viridescens* or *Weissella hellenica* share similar fatty acid profiles with the respective type strains, whereas the “wild” atypical *Weissella* isolates more closely resemble *Weissella paramesenteroides* and *Leuconostoc mesenteroides* subsp. *mesenteroides*. Major cellular fatty acids associated with *Weissella thailandensis* and *Weissella koreensis* include straight-chained C_{16:0} and C_{20:1} (Tanasupawat et al., 1998, 2000) and C_{18:1:oc} and C_{16:0}, respectively.

Levels of DNA–DNA reassociation among some type strains of *Weissella* species, *Leuconostoc* species, and *Oenococcus oeni* are shown in Table 130. Five strains of *Weissella thailandensis* possess DNA–DNA reassociation levels of 84.6–106.1% (Tanasupawat et al., 2000). The type strain of *Weissella thailandensis* has DNA–DNA similarity levels of 16.7–21.5% with the type strains of *Weissella paramesenteroides*, *Weissella hellenica*, and *Weissella confusa* (Tanasupawat et al., 2000). *Weissella cibaria* has 76–100% DNA–DNA similarity levels within the species and 22–49% with *Weissella confusa* (Björkroth et al., 2002), its closest phylogenetic neighbor. In the study by Vescovo et al. (1979), *Weissella confusa* LMG 18507 (NCFB 1937) was reported to possess a DNA–DNA reassociation level of 93% with the type strain of *Weissella confusa* (ATCC 10881). However, Björkroth et al. (2002) detected a DNA–DNA reassociation level of 100% between this strain and the type strain of *Weissella cibaria*, suggesting that this strain belongs to *Weissella cibaria*. This was also warranted by the other results of this polyphasic taxonomic study.

Weissella viridescens FemX (FemX(Wv)) belongs to the Fem family of nonribosomal peptidyl transferases that use aminoacyl-tRNA as the amino acid donor to synthesize the peptide cross-bridge found in the peptidoglycan of many species of pathogenic Gram-stain-positive bacteria. The crystal structure of FemX(Wv) in complex with the peptidoglycan precursor UDP-MurNAc-pentapeptide has recently been determined and the site-directed mutagenesis of nine residues located in the binding cavity for this substrate has been reported (Maillard et al., 2005). Two substitutions, Lys36Met and Arg211Met, depressed FemX(Wv) transferase activity below detectable levels without affecting pro-

tein folding. Analogs of UDP-MurNAc-pentapeptide lacking the phosphate groups or the C-terminal D-alanyl residues are not substrates of the enzyme. These results indicate that Lys36 and Arg211 participate in a complex hydrogen bond network that connects the C-terminal D-Ala residues to the phosphate groups of UDP-MurNAc-pentapeptide and constrains the substrate in a conformation that is essential for transferase activity.

A physical and genetic map of *Weissella paramesenteroides* DSM 20288^T chromosome has been constructed. A total of 21 recognition sites of the restriction enzymes *AscI*, *I-CeuI*, *NotI*, and *SfiI* were mapped on the chromosome which was found to be circular with an estimated size of 2026 kb. The localization of important chromosomal regions such as *oriC* and *terC* have been addressed and a total of 23 genetic markers have been mapped, including eight *rrn* operons that were precisely assigned in 37% of the *Weissella paramesenteroides* chromosome. The transcription direction of *rrn* loci was determined and three different *rrn* clusters were recognized regarding the presence/absence of tRNA genes in ITS regions.

Isolation and maintenance of *Weissella* spp.

Weissella are routinely cultured using the general growth media for lactic acid bacteria, such as MRS (De Man et al., 1960) and Rogosa SL-medium (Rogosa et al., 1951). There is no specific selective medium or enrichment method for *Weissella* species. The intrinsic resistance to vancomycin may be useful in certain approaches (Björkroth and Holzapfel, 2003). Strains can be maintained as described in the chapter for *Leuconostoc*. For more information, see also Schillinger and Holzapfel (2002).

Distinguishing the genus *Weissella* from *Leuconostoc* spp. and other lactic acid bacteria

Table 121 in the genus *Leuconostoc* chapter, above, shows the main criteria for distinguishing *Weissella* from other LAB. Clearly, it is most difficult to distinguish *Weissella* from *Leuconostoc* and heterofermentative *Lactobacillus* by phenotypic characteristics; this poses a great challenge for the development of genus-specific molecular methods for discrimination among these three genera. For species identification, classical phenotypic criteria may not be sufficient, warranting the use of molecular

^bND, not determined.

approaches such as the numerical analysis of macromolecule patterns and sequencing and employment of specific signature bases in the rRNA-encoding genes.

Metabolism

All species are heterofermentative and produce CO₂, ethanol, and/or acetate while fermenting glucose. Carbohydrate fermentation is via the hexose-monophosphate and the phosphoketolase pathways. The configuration of lactic acid is either DL or D(-), depending on the species. There is, however, variation between the species in the production of D(-)- or DL-lactic acid isomers (Table 128).

Habitat

The habitats of *Weissella* species are variable. *Weissella viridescens*, *Weissella halotolerans*, and *Weissella hellenica* have been associated with meat and meat products. *Weissella viridescens* may cause spoilage of cured meat due to green discoloration (Niven and Evans, 1957). This species is also considered as heat resistant (Niven et al., 1954), a property not very common for lactic acid bacteria (LAB). *Weissella cibaria*, *Weissella confusa*, and *Weissella korensis* have been described for fermented foods of vegetable origin (Björkroth et al., 2002; Lee et al., 2002), whereas *Weissella confusa* is also associated with Greek cheese (Samelis et al., 1994), Mexican pozol (Ampe et al., 1999), and Malaysian chili bo (Leisner et al., 1999). *Weissella soli* (Magnusson et al., 2002) is the only species known to originate in soil.

Weissella confusa forms part of the normal microbiota in human intestines (Stiles and Holzapfel, 1997; Tannock et al., 1999; Walter et

al., 2001). *Weissella cibaria* and *Weissella confusa* have also been associated with clinical samples of humans and animals (Björkroth et al., 2002). In addition, *Weissella confusa* has been documented as a cause for a systemic infection in a healthy primate (*Cercopithecus mona*; Vela et al., 2003). A vancomycin-resistant strain of *Weissella confusa* has also been reported to have caused an abscess (Bantar et al., 1991).

Taxonomic comments

The genus *Weissella* was proposed in 1993 (Collins et al., 1993), mainly as a result of phylogenetic studies targeting both 16S (Collins et al., 1993; Martinez-Murcia and Collins, 1990; Martinez-Murcia et al., 1993) and 23S (Martinez-Murcia et al., 1993) rRNA sequences. Based on these results, *Leuconostoc paramesenteroides* (Garvie, 1967a), *Lactobacillus viridescens* (Kandler and Abo-Elnaga, 1966; Niven and Evans, 1957), *Lactobacillus confusus* (Holzapfel and Kandler, 1969), *Lactobacillus kandleri* (Holzapfel and van Wyk, 1982), *Lactobacillus minor* (Kandler et al., 1983), and *Lactobacillus halotolerans* (Kandler et al., 1983) were reclassified as *Weissella paramesenteroides*, *Weissella viridescens*, *Weissella confusa*, *Weissella kandleri*, *Weissella minor*, and *Weissella halotolerans*, respectively. Subsequent designations to the genus include *Weissella hellenica* (Collins et al., 1993), *Weissella thailandensis* (Tanasupawat et al., 2000), *Weissella cibaria* (Björkroth et al., 2002), *Weissella soli* (Magnusson et al., 2002), and *Weissella korensis* (Lee et al., 2002). *Weissella kimchii* proposed by Choi et al. (2002) has been found to be a later heterotypic synonym of *Weissella cibaria* (Ennahar and Cai, 2004).

List of species of the genus *Weissella*

1. ***Weissella viridescens*** (Niven and Evans 1957) Collins, Samelis, Metaxopoulos and Wallbanks 1994, 370^{VP} (Effective publication: Collins, Samelis, Metaxopoulos and Wallbanks 1993, 601.) (*Lactobacillus viridescens* Niven and Evans 1957, 758; *Lactobacillus corynoides* subsp. *corynoides* Kandler and Abo-Elnaga 1966, 753)

vi.ri.des'cens. L. pres. part. *viridescens* growing green, greening.

Small, often slightly irregular rods, generally 0.7–0.9 × 2.0–5.0 μm, with rounded to tapered ends occurring singly or in pairs. Gram-stain-positive, nonmotile, and nonspore-forming. The interpeptide bridge of the peptidoglycan structure is Lys–Ala–Ser. The configuration of lactic acid produced is DL. Growth factor requirements: pantothenic acid, niacin, thiamine, riboflavin, and biotin are essential; folic acid and pyridoxal may be stimulatory. Does not produce ammonia from arginine; dextran production from sucrose has not been studied. Detected in discolored cured meat products and pasteurized milk.

DNA G+C content (mol%): 41–44 (Bd, T_m).

Type strain: ATCC 12706, CCM 56, BCRC 11650, CCUG 21533, CCUG 30502, CECT 283, CIP 102810, DSM 20410, IAM 13546, JCM 1174, LMG 3507, NCCB 71015, NCFB 1655, NCIMB 8965, NRIC 1536, NRRL B-1951, VKM B-1528.

GenBank accession number (16S rRNA gene): AB023236, M23040, X52568.

Additional remarks: *Lactobacillus viridescens* is incorrectly cited on the Approved Lists of Bacterial Names as *Lactobacillus viridescens* Kandler and Abo-Elnaga 1966, 573.

2. ***Weissella cibaria*** Björkroth, Schillinger, Geisen, Weiss, Hoste, Holzapfel, Korkeala and Vandamme 2002, 147^{VP}

ci.ba'ri.a. L. adj. *cibarius* pertaining to food.

Cells are short rods growing in pairs, 0.8–1.2 × 1.5–2 μm. Gram-stain-positive, nonmotile, and nonspore-forming. The interpeptide bridge of the peptidoglycan structure is Lys–Ala–(Ser)–Ala. The configuration of lactic acid produced is DL. Growth occurs at 45 °C and at 15 °C but not at 4 °C. Dextran is produced from sucrose and ammonia from arginine.

Isolated from Malaysian fermented foods and other food sources but also from clinical samples including human gall, otitis smear (dog), and human feces.

DNA G+C content (mol%): 44 (T_m).

Type strain: LMG 17699, CCUG 41967, JCM 12495.

GenBank accession number (16S rRNA gene): AJ295989.

3. ***Weissella confusa*** (Holzapfel and Kandler 1969) Collins, Samelis, Metaxopoulos and Wallbanks 1994, 370^{VP} (Effective publication: Collins, Samelis, Metaxopoulos and Wallbanks 1993, 599.) (*Lactobacillus coprophilus* subsp. *confusus* Holzapfel and Kandler 1969, 665; *Lactobacillus confusus* Sharpe, Garvie and Tilbury 1972, 396)

con.fu'sus. L. v. *confundere* to confuse; L. past part. *confusus* confused, an allusion to its original confusion with *Leuconostoc*.

Short rods, 0.8–1.0 × 1.5–3.0 μm, with tendency to thicken at one end; occurring singly, rarely in short chains. Gram-stain-positive, nonmotile, and nonspore-forming. The interpeptide bridge of the peptidoglycan structure is Lys–Ala. The configuration of lactic acid produced is DL.

Growth at 45 °C is variable, some strains grow well. Dextran is produced from sucrose and ammonia from arginine.

Isolated from sugarcane, carrot juice, and fermented foods, occasionally found in raw milk, saliva, sewage, and clinical samples.

DNA G+C content (mol%): 45–47 (T_m).

Type strain: TCC 10881, ATCC 10881, BCRC 14002, CCUG 30113, CIP 103172, CIP 54.169, DSM 20196, JCM 1093, LMG 9497, NCIMB 9311, NRRL B-1064.

GenBank accession number (16S rRNA gene): AB023241, M23036.

4. **Weissella halotolerans** (Kandler, Schillinger and Weiss 1983) Collins, Samelis, Metaxopoulos and Wallbanks 1994, 370^{VP} (Effective publication: Collins, Samelis, Metaxopoulos and Wallbanks 1993, 599.) (*Lactobacillus halotolerans* Kandler, Schillinger and Weiss, 1983, 283)

ha.lo.to'le.rans. Gr. n. *hals* salt; L. pres. part. *tolerans* tolerating, enduring; N.L. part. adj. *halotolerans* salt-tolerating.

Irregular, short, or coccoid rods with rounded to tapered ends, generally $0.5\text{--}0.7 \times 1.0\text{--}3\ \mu\text{m}$, sometimes longer, with tendency to form coiling chains, clumping together. Gram-stain-positive, nonmotile, and nonspore-forming. The interpeptide bridge of the peptidoglycan structure is Lys–Ala–Ser. The configuration of lactic acid produced is DL. No growth at 45 °C. Good growth in the presence of 12% NaCl and very weak growth in the presence of 14% NaCl. Does not produce ammonia from arginine; dextran production from sucrose has not been studied.

Isolated from meat products.

DNA G+C content (mol%): 45 (T_m).

Type strain: R61, ATCC 35410, BCRC 14050, CCUG 33457, CECT 573, CIP 103005, DSM 20190, JCM 1114, LMG 9469, NRIC 1627.

GenBank accession number (16S rRNA gene): AB022926, M23037.

5. **Weissella hellenica** Collins, Samelis, Metaxopoulos and Wallbanks 1994, 370^{VP} (Effective publication: Collins, Samelis, Metaxopoulos and Wallbanks 1993, 601.)

hel.len'ic.a. Gr. adj. *Hellenikos* Greek; N.L. fem. adj. *hellenica* Greece, where the bacterium was isolated.

Spherical but sometimes lenticular cells occurring in pairs or short chains, with a tendency to form clusters. Gram-stain-positive, nonmotile, and nonspore-forming. The interpeptide bridge of the peptidoglycan structure is Lys–Ala–Ser. The configuration of lactic acid produced is D(–). No growth occurs at 37 °C; all strains grow at 10 °C and 4 °C (delayed). Dextran is not formed from sucrose; ammonia is not formed from arginine.

Isolated from fermented sausages.

DNA G+C content (mol%): 39–40 (T_m)

Type strain: LV346 (= ATCC 51523 = CCUG 33494 = DSM 7378 = NBRC 15553 = JCM 10103 = LMG 15125 = NCIMB 702973.

GenBank accession number (16S rRNA gene): X95981.

6. **Weissella kandleri** (Holzapfel and van Wyk 1982) Collins, Samelis, Metaxopoulos and Wallbanks 1994, 370^{VP} (Effective publication: Collins, Samelis, Metaxopoulos and Wallbanks 1993, 599.) (*Lactobacillus kandleri* Holzapfel and van Wyk, 1982, 501)

kand'le.ri. N.L. gen. n. *kandleri* of Kandler; named for Otto Kandler, a German microbiologist.

Partly irregular rods, generally $0.6\text{--}0.8 \times 3.0\text{--}15\ \mu\text{m}$, occurring singly or in pairs, seldom in short chains. Gram-stain-pos-

itive, nonmotile, and nonspore-forming. The interpeptide bridge of the peptidoglycan structure is Lys–Ala–Gly–Ala₂. The configuration of lactic acid produced is DL. No growth at 45 °C. Dextran is produced from sucrose and ammonia is produced from arginine.

Isolated from a desert spring.

DNA G+C content (mol%): 39 (T_m)

Type strain: L250, ATCC 51149, BCRC 14624, CCUG 32237, CIP 102809, DSM 20593, JCM 5817, LMG 18979, NCIMB 702753, NRIC 1628.

GenBank accession number (16S rRNA gene): AB022922, M23038.

7. **Weissella koreensis** Lee, Lee, Ahn, Mheen, Pyun and Park 2002, 1260^{VP}

ko.re.en'sis. N.L. adj. *koreensis* of Korea, where the novel organisms were isolated.

Cells are irregular short rod-shaped or coccoid. Gram-stain-positive, nonmotile, and nonspore-forming. The interpeptide bridge of the peptidoglycan structure is Lys–Ala–Ser. The configuration of lactic acid produced is mainly D(–). Growth occurs between 10 and 37 °C but not at 42 °C. Ammonia is produced from arginine and dextran is produced from sucrose.

Detected in kimchi, a Korean fermented food product.

DNA G+C content (mol%): 37 (HPLC).

Type strain: S-5623, JCM 11263, KCCM 41516, KCTC 3621.

GenBank accession number (16S rRNA gene): AY035891.

8. **Weissella minor** (Kandler, Schillinger and Weiss 1983) Collins, Samelis, Metaxopoulos and Wallbanks 1994, 370^{VP} (Effective publication: Collins, Samelis, Metaxopoulos and Wallbanks 1993, 599.) (*Lactobacillus minor* Kandler, Schillinger and Weiss 1983, 284; *Lactobacillus corynoides* subsp. *minor* Abo-Elnaga and Kandler 1965, 128; *Lactobacillus viridescens* subsp. *minor* Kandler and Abo-Elnaga 1966, 754)

mi'nor. L. comp. adj. *minor* smaller.

Irregular short rods with rounded to tapered ends (see Figure 121), generally $0.6\text{--}0.8 \times 1.5\text{--}2.0\ \mu\text{m}$, sometimes longer, often bent with unilateral swellings, occurring in pairs or short chains, with a tendency to form loose clusters. Gram-stain-positive, nonmotile, and nonspore-forming. The interpeptide bridge of the peptidoglycan structure is Lys–Ser–Ala₂. The configuration of lactic acid produced is DL. Does not produce dextran from sucrose, but produces ammonia from arginine. No growth at 45 °C.

Isolated from the sludge of milking machines.

DNA G+C content (mol%): 44 (T_m).

Type strain: 3, ATCC 35412, BCRC 14049, CCUG 30668, CECT 572, CIP 102978, DSM 20014, JCM 1168, LMG 9847, NCIMB 701973, NRIC 1625.

GenBank accession number (16S rRNA gene): M23039.

9. **Weissella paramesenteroides** (Garvie 1967a) Collins, Samelis, Metaxopoulos and Wallbanks 1994, 370 (Effective publication: Collins, Samelis, Metaxopoulos and Wallbanks 1993, 601.) (*Leuconostoc paramesenteroides* Garvie 1967a, 446)

pa.ra.me.sen.ter.oi'des. Gr. prep. *para* resembling; N.L. *mesenteroides* a specific epithet, mesentery-like; N.L. adj. *paramesenteroides* resembling *Leuconostoc mesenteroides*.

Spherical but often lenticular cells usually occurring in pairs and chains. Gram-stain-positive, nonmotile, and nonspore-forming. The interpeptide bridge of the peptidoglycan structure is Lys-Ala₂; Lys-Ser-Ala₂. The configuration of lactic acid produced is D(-). Does not produce ammonia from arginine. Dextran is not formed from sucrose, and amino acid requirements are complex and variable. Many cells grow well at 30 °C but some prefer reducing conditions and a temperature of 18–24 °C (Garvie, 1967a). Pseudocatalase may be present if organisms are grown in a medium with a low glucose content (Whittenbury, 1964). Tolerates NaCl well, and some strains may be detected in foods possessing high levels of salt. Tolerates acidic pH and may grow in media with an initial pH below 5.0.

Before reclassification as *Weissella*, *Weissella paramesenteroides* strains were considered to be nondextran-forming *Leuconostoc mesenteroides* strains. Phenotypic differentiation of *Weissella paramesenteroides* and nondextran-forming strains of *Leuconostoc mesenteroides* is difficult.

DNA G+C content (mol%): 37–38 (T_m).

Type strain: ATCC 33313, CCUG 30068, CIP 102421, DSM 20288, JCM 9890, LMG 9852, NCIMB 13092, NRIC 1542, NRRL B-1186, NRRL B-3471.

GenBank accession number (16S rRNA gene): AB023238, M23033, X95982.

10. ***Weissella soli*** Magnusson, Jonsson, Schnürer and Roos 2002, 833^{VP}

so'li. L. n. *solum* soil; L. gen. n. *soli* of the soil.

Cells are rods, often thickened at one end, occurring singly or in pairs, 0.9 × 1.2–3.0 μm. The cells in a pair are often different size. Gram-stain-positive, nonmotile, and nonspore-forming. The interpeptide bridge of the peptidoglycan structure has not been determined. The configuration of lactic acid produced is mainly D(-). Growth occurs between 4 and 40 °C but not at 45 °C. Ammonia is produced from arginine, but no dextran is produced from sucrose.

Detected in soil.

DNA G+C content (mol%): 43 (HPLC).

Type strain: Mi268, DSM 14420, JCM 12536, LMG 20113.

GenBank accession number (16S rRNA gene): AY028260.

11. ***Weissella thailandensis*** Tanasupawat, Shida, Okada and Komagata 2000, 1484^{VP}

thai.lan'den.sis. N.L. fem. adj. *thailandensis* pertaining to Thailand where the strains were first isolated.

Cells are spherical, 0.5 × 0.7 μm. Gram-stain-positive, nonmotile, and nonspore-forming. The interpeptide bridge of the peptidoglycan structure is Lys-Ala₂. The configuration of lactic acid produced is D(-). Grows between 25 and 37 °C but not at 42 °C. Does not produce dextran from sucrose or ammonia from arginine.

Detected in pla-ra, a fermented Thai fish product.

DNA G+C content (mol%): 38–41 (method not disclosed).

Type strain: FS61-1, PCU 210, HSCC 1412, CIP 106751, JCM 10695, KCTC 3751, NRIC 0298, TISTR 1384.

GenBank accession number (16S rRNA gene): AB023838.

Family VI. **Streptococcaceae** Deibel and Seeley 1974, 490^{AL}

THE EDITORIAL BOARD

Strep.to.coc.ca'ce.ae. N.L. masc. n. *Streptococcus* type genus of the family; -aceae ending to denote family; N.L. fem. pl. n. *Streptococcaceae* the *Streptococcus* family.

The family *Streptococcaceae* is circumscribed on the basis of 16S rDNA sequence analysis; and contains the genera *Streptococcus*, *Lactococcus*, and *Lactovum* (see Figure 1 and Figure 3). It is composed of Gram-positive, ovoid or spherical cocci. When it has been determined, cell walls have been found to contain the

diamino acid lysine. Endospores are not formed. Facultative anaerobes that may require CO₂ for growth and are catalase-negative.

DNA G+C content (mol%): 33–46 mol%.

Type genus: **Streptococcus** Rosenbach 1884, 22.

Genus I. **Streptococcus** Rosenbach 1884, 22^{AL}

ROBERT A. WHILEY AND JEREMY M. HARDIE

Strep.to.coc'cus. Gr. adj. *streptus* pliant; Gr. n. *kokkos* a grain, berry; N.L. masc. n. *Streptococcus* pliant coccus.

Streptococcus strains are normally **spherical or ovoid**, less than 2 µm in diameter, **occurring in chains or in pairs** when grown in liquid media. Cells are **nonmotile**. **Endospores are not formed**. **Gram-positive**. Virtually all species are **facultatively anaerobic**, some requiring additional CO₂ for growth. **Chemo-organotrophic with fermentative metabolism**. Carbohydrates are fermented to **produce mainly lactic acid** but no gas. **Catalase-negative**. Nutritional requirements are complex and variable. **The peptidoglycan is of group A** (Schleifer and Kandler, 1972) with L-lysine as the diamino acid in position 3 of the peptide subunit. Menaquinones are not present. Cell-wall polysaccharides form the basis of the Lancefield serological grouping scheme (Lancefield, 1933). Rhamnose is a common constituent of almost all streptococcal cell walls and its notable absence among members of the Mitis species group which includes *Streptococcus pneumoniae*, together with the presence of significant amounts of ribitol, are valuable chemotaxonomic markers for these taxa.

Temperature optimum usually about 37°C, but maximum and minimum temperatures vary somewhat among species. Many species exist as commensals or parasites on man and animals, some are highly pathogenic.

DNA G+C content (mol%): 33–46.

Type species: **Streptococcus pyogenes** Rosenbach 1884, 23^{AL}.

Further descriptive information

Phylogenetic position. Based on 16S rRNA gene sequence analysis the genus *Streptococcus* belongs within the low (< 50 mol%) G+C (*Clostridium–Bacillus*) branch of the Gram-positive eubacteria (Ludwig et al., 1985; Schleifer and Ludwig, 1995), and is a member (type genus) of the family *Streptococcaceae*. Following extensive taxonomic revision of *Streptococcus* (Collins et al., 1984b; Schleifer and Kilpper-Bälz, 1984, 1987), the genus currently consists of over 50 recognized species which, for the most part, fall within “species groups” named “Pyogenic”, “Bovis”, “Mutans”, “Mitis”, “Anginosus”, and “Salivarius” (Bentley et al., 1991; Kawamura et al., 1995b).

Cell morphology. *Streptococcus* cells are usually spherical or ovoid in shape and are arranged in chains or pairs. Chain formation is best seen in liquid cultures. Some species (e.g., *Streptococcus mutans*) grow as short rods under certain cultural conditions,

and several of the oral streptococci appear to be pleomorphic on primary isolation. Growth is by elongation in the axis of the chain with cell division in one plane, at right angles to the long axis. Chain length varies considerably between species and strains and is also dependent on medium composition; long chains of over 50 cells may be produced. Cells of *Streptococcus pneumoniae* characteristically form pairs (diplococci).

A recently described species, *Streptococcus minor* (Vancanneyt et al., 2004), has cells arranged predominantly in small groups.

Cell-wall composition. The cell-wall composition is characteristic of Gram-positive bacteria, consisting mainly of peptidoglycan to which are attached a variety of carbohydrate, teichoic acid, and surface-protein antigens. The peptidoglycan is of group A (Schleifer and Kandler, 1972) with L-lysine as the diamino acid in position 3 of the peptide subunit. The most common peptidoglycan type is Lys–Ala_n, where an interpeptide bridge consisting of one up to four L-alanine residues is present. In some species the alanine residues can be partly replaced by L-threonine and/or L-serine. A few species, e.g., *Streptococcus acidominimus*, *Streptococcus canis* and some strains of *Streptococcus salivarius* and *Streptococcus bovis* have no alanine residues in their interpeptide bridge. Several species, e.g., *Streptococcus oralis* and *Streptococcus suis*, lack an interpeptide bridge and have a directly cross-linked peptidoglycan.

The qualitative composition of the cell-wall polysaccharides is known for many of the streptococcal species and these form the basis of Lancefield serological grouping (Schleifer and Kilpper-Bälz, 1987), in which strains are designated by a letter of the alphabet according to which cell-wall associated group antigen they possess (Lancefield, 1933). The amino sugars glucosamine and muramic acid are always present, while galactosamine is a variable component. The common reducing sugars are glucose, galactose, and rhamnose, which occur in various combinations in different species (Colman and Williams, 1965). The absence of rhamnose together with the presence of ribitol in *Streptococcus pneumoniae*, *Streptococcus oralis*, and *Streptococcus mitis* are chemotaxonomic markers for these species (Kilpper-Bälz et al., 1985; Price et al., 1986), while the polyols glucitol (sorbitol) and glycerol are present in *Streptococcus agalactiae* and *Streptococcus rattus*, respectively (Pritchard et al., 1981; Schleifer et al., 1984). Serological groups A, A-variant, and C all contain

a backbone of α -1,3- and α -1,2-glycosidically linked rhamnose residues in which the group A-variant polysaccharide is not substituted, the group A carries *N*-acetylglucosamine residues, and group C contains *N*-acetylgalactosamine residues as immunodominant substitutions (Braun, 1983; Coligan et al., 1978). The group-B-specific polysaccharide found in *Streptococcus agalactiae* consists of a rhamnose, glucitol, and a phosphate-containing backbone with trisaccharide side chains of rhamnose, galactose, and *N*-acetylglucosamine linked to the 4-position of a rhamnose in the backbone of the polysaccharide (Pritchard et al., 1984). Rhamnose has been found to contribute to the immunodominant structure of group B and G polysaccharides, possibly explaining occasional cross-reactions between groups B and G (Schleifer and Kilpper-Bälz, 1987).

Serological classification has formed a major part of streptococcal taxonomy since the grouping scheme of Lancefield (1933) based on group-specific polysaccharide antigens (also referred to as C-substances) associated with the cell wall (originally groups D and N streptococci, now classified as *Enterococcus* and *Lactococcus* spp. respectively in which the group-specific antigens are teichoic acids, were included in *Streptococcus*). The Lancefield grouping scheme, where strains are designated by an upper-case letter of the alphabet (A, B, C, E, F, G, etc.), has been, and still is, extremely useful for differentiating between β -hemolytic streptococci from human and animal infections. The system is not comprehensive in that non-hemolytic and α -hemolytic species in particular may not possess recognized Lancefield grouping antigens or may be heterogeneous with respect to the group antigens possessed by different strains of a species.

Not all species form capsules. Some may form hyaluronic acid capsules during the early phase of growth, while an antigenically distinct polysaccharide capsule type has been identified on the surface of 90 different pneumococci (Henrichsen, 1995). Several streptococcal species produce soluble and insoluble extracellular polysaccharides when grown in the presence of sucrose, but these do not necessarily form morphologically distinctive capsules.

Important to the success of streptococci as commensals and pathogens is the expression of arrays of adhesins on their surface that mediate binding to a wide range of substrates available within the mammalian host. Several species, particularly those found within the oral cavity, can bind salivary glycoproteins and bacteria-derived salivary components. Examples of the latter include the antigen I/II family of adhesions expressed by *Streptococcus mutans*, *Streptococcus sobrinus*, *Streptococcus gordonii*, *Streptococcus oralis*, and *Streptococcus intermedius* and the Iral family expressed by *Streptococcus sanguis* and *Streptococcus parasanguis* (Jenkinson and Demuth, 1997; Whittaker et al., 1996). Among pyogenic and oral streptococcal species adhesins are expressed that recognize extracellular matrix and serum components, particularly fibronectin and plasminogen, as well as host and other microbial cells. The literature on streptococcal binding and colonization and the relevance to pathogenicity has been extensively reviewed by Jenkinson and Lamont (1997). Cell-wall-associated protein adhesins often contain repeating blocks of amino acids and binding can take place both within the repeating blocks and within non-repeating regions (Fischetti, 1989; McNab et al., 1994). Sequences and functions of these proteins have become assorted through gene-duplication and

horizontal transfer between populations (Jenkinson and Lamont, 1997).

Nutrition and growth. Streptococci are facultatively anaerobic with some species such as *Streptococcus mutans*, members of the Anginosus species group, *Streptococcus pneumoniae*, and many others requiring the addition of 5% CO₂ to the atmosphere for growth. Streptococci are characteristically susceptible to vancomycin, unable to produce gas from glucose in MRS broth, mainly unable to produce pyrrolidonyl arylamidase (PYR), able to produce leucine arylaminopeptidase with only occasional exceptions, and exhibit variable reactions for growth in 6.5% NaCl-containing broth and the hydrolysis of esculin in the presence of 40% bile. These tests, together with the absence of motility and chain formation, serve to distinguish streptococci from other genera of facultatively anaerobic, catalase-negative, Gram-positive cocci (Facklam and Elliott, 1995, 2002; Ruoff, 2003).

All streptococci ferment carbohydrates, producing predominantly lactic acid; minor amounts of acetic and formic acids, ethanol, and CO₂ may also be produced. Although all species ferment glucose, a wide range of other carbohydrates is utilized and variations in fermentation patterns between species can be used for identification purposes. Streptococci are catalase-negative with the exception of the recently described species *Streptococcus didelphis* which, on initial isolation on blood agar, gives vigorous catalase activity that is lost on subsequent subculturing (Rurangirwa et al., 2000).

The complex nutritional requirements, generally including amino acids, peptides, purines, pyrimidines, and vitamins, are normally provided by using complex media. For optimal growth in liquid media, addition of a fermentable carbohydrate is also necessary.

Colonial and cultural characteristics. Growth on solid media is often enhanced by the addition of blood, serum, or glucose. Colonies on glucose are usually 0.5–1.0 mm in diameter after 24 h at 37°C and show little or no increase after prolonged incubation. Virtually all species are non-pigmented with the exception of some strains of *Streptococcus agalactiae*, which may have a yellow, orange, or brick-red pigment. Growth in liquid media is increased greatly by the addition of glucose, but the rapid fall in pH quickly inhibits growth unless the medium is highly buffered, as in Todd-Hewitt broth (Todd and Hewitt, 1932), or the medium is pH-controlled by the continuous addition of alkali. In batch culture, some strains produce a granular type of growth in broth with a clear supernatant fluid; these are usually found to have produced long chains. Other strains tend to produce a more diffuse growth, even turbidity. In continuous culture, both the macroscopic and microscopic appearance of the growth may vary according to the dilution rate and the limiting nutrient (Ellwood et al., 1974). Several types of reaction on blood agar are produced by different streptococci. These are visualized from surface growth on layered blood agar plates (Parker, 1983); sheep or horse blood is generally used. Reducing sugars may inhibit hemolysis by *Streptococcus pyogenes* (Facklam and Wilkinson, 1981).

β -Hemolysis is characterized by a sharply defined zone of clearing around the colonies with the zone size varying from strain to strain. With α -hemolysis, a zone of greenish discoloration occurs around the colony, usually 1–3 mm in width, and

the margin is indistinct. A third type of hemolysis, α -prime, has also been described and resembles α -hemolysis with an obvious outer ring of clearing around the zone of discolored (green) erythrocytes (Parker, 1983). Non-hemolytic (or γ -hemolytic) streptococci have no effect on blood agar. Both the type and extent of hemolysis are influenced by the composition of the basal medium, the type and concentration of blood used and the cultural conditions. In the United States, 5% sheep blood agar is generally used for recognition of hemolytic streptococci, especially as the medium does not support the growth of hemolytic *Hemophilus* species. Most laboratories in the United Kingdom prefer 5% horse blood agar, on which good hemolytic zones may be seen around the surface colonies.

Genomes. The size range for completed streptococcal genomes is 1.85 (*Streptococcus pyogenes*) to 2.21 (*Streptococcus agalactiae*) Mbp. *Streptococcus mutans* (2.03 Mbp) and *Streptococcus pneumoniae* (2.04–2.16 Mbp) have also been sequenced. Sequences of the genomes of representative strains of several more species are due for completion; these species include *Streptococcus equi*, *Streptococcus gordonii*, *Streptococcus mitis*, *Streptococcus suis*, *Streptococcus thermophilus*, and *Streptococcus uberis*.

16S rRNA. The genus as a whole is very diverse and 16S rRNA gene sequencing has shown it to be divided into “species-groups” that encompass the majority of the total of 55 species at the time of writing (Bentley et al., 1991; Kawamura et al., 1995b; Tapp et al., 2003); see Figure 123.

Horizontal gene transfer. Horizontal gene transfer and recombination of genes have played a major role in generating streptococcal diversity both in the oral streptococci, particularly within the Mitis and Anginosus species groups, and among the pyogenic, β -hemolytic streptococci (Dowson et al., 1989; Kalia et al., 2001; Kehoe et al., 1996; Lunsford, 1998). Competence for transformation is not constitutive in streptococci but is regulated by genes *comA–comE* from two *com* operons: these operons include i) *comC*, encoding a competence-stimulating peptide (or pheromone) (CSP) together with *comD* and *comE*, encoding a two-component regulatory system, and ii) *comA* and *comB*, encoding the CSP-secretion apparatus (Håvarstein et al., 1996; Morrison, 1997; Whatmore et al., 1999). Recently, a strain of *Streptococcus infantis* (Atu-4) has been shown to be competent in the absence of the competence-pheromone gene *comC* (Ween et al., 2002). Competence in this strain was not regulated by cell density; loss of *comE* gene function resulted in loss of competence, indicating that mutations in *comD* or *comE* have given rise to a phenotype where competence is achieved without production of CSP. *Streptococcus mutans* has also been shown to contain a peptide-secretion-like apparatus (Petersen and Scheie, 2000) and to possess the *comCDE* operon (Ajdic et al., 2002). This species, like *Streptococcus gordonii*, has been shown to possess genes for DNA uptake (*comYA* and *comYB*) (Ajdic et al., 2002; Lunsford and Roble, 1997). *Streptococcus mutans* strain UA159, like sequenced *Streptococcus pneumoniae* strains TIGR4 and R6, both naturally transformable species, contain no temperate bacteriophage genomes. This is in contrast to *Streptococcus pyogenes* in which transformation via a competence pathway has not been described and in which approximately 10% of the genome is accounted for by bacteriophage and transposon genes (Ferretti et al., 2001).

Bacteriophages. Active virulent and temperate phages have been described. Phages are present within a high proportion of strains of group A streptococci and contribute to the pathogenic potential of this species (Ferretti et al., 2001; Hynes et al., 1995). The pyrogenic exotoxins SpeA and SpeC are bacteriophage-encoded (Cunningham, 2000). Sequencing of the *Streptococcus pyogenes* entire genome has revealed the presence of complete or partial sequences of four bacteriophage genomes containing genes for one or more previously undiscovered superantigen-like proteins (Desiere et al., 2001; Ferretti et al., 2001): at least six potential virulence factors are encoded and the importance of bacteriophages in horizontal gene transfer and the possible contribution of these events to the generation of new strains with increased pathogenic potential is recognized. Genes encoding proteins Pb1A and Pb1B involved in the binding of *Streptococcus mitis* to human platelets, with obvious relevance to the pathogenesis of infective endocarditis, are encoded by a lysogenic bacteriophage (Bensing et al., 2001).

Bacteriocins. Several species of streptococcus have been shown to be able to inhibit closely related strains through the production of bacteriocins (Tagg et al., 1976). Bacteriocin typing systems for *Streptococcus mutans* have been used to study the distribution of particular types within individuals and among family groups, and also to investigate transmission between mothers and fathers and their children (Berkovitz and Jordan, 1975; Kelstrup et al., 1970; Rogers, 1976; van Loveren et al., 2000). The ability of a particular strain of *Streptococcus mutans* to inhibit other bacteria is thought to play an important role in its successful transmission and subsequent colonization of a new host (Gronroos et al., 1998), and production of bacteriocin-like inhibitory substances (BLISs) by members of the normal oral flora have suggested an important role for these in protection against *Streptococcus pyogenes* infection (Dierksen et al., 2000).

Antibiotic sensitivity. On the whole, streptococci remain susceptible to most prescribed antibiotics although there are important exceptions. The MIC of penicillin to group A streptococci has not significantly changed over the past 70 or 80 years (Macris et al., 1998), whereas macrolide resistance has been reported to be increasing in Europe (Kaplan et al., 1999). A major cause for concern is the emergence and steady increase of penicillin-resistance within *Streptococcus pneumoniae* since the late 1970s (Casal, 1982). This has been due to the emergence of altered forms of penicillin-binding proteins (PBPs) PBP1a, PBP2x, and PBP2b, having decreased affinity for the antibiotic due to interspecies recombinational events involving viridans streptococcal species including *Streptococcus mitis* and *Streptococcus oralis* (Coffey et al., 1996; Dowson et al., 1994; Sibold et al., 1994). PBP-derived penicillin resistance in *Streptococcus pneumoniae* is associated with the emergence of extremely diverse resistant isolates as well as the geographic spread of resistant clones, notably capsular serotypes 23F 6B, 9V, and 19F clones (Coffey et al., 1995; Dowson et al., 1994).

Ecology and pathogenicity. Streptococci are associated with warm-blooded animals and birds. Most species can be regarded as commensal, being usually found on mucosal surfaces in the oral cavity, upper respiratory tract, and gastrointestinal tract, and under appropriate conditions can cause localized and systemic infections. The success of streptococci as commensals and potential pathogens has been attributed to i) “the ability

FIGURE 123. Phylogenetic tree of the streptococci based on 16S rRNA gene sequence comparisons over 1239 aligned bases. The tree was constructed using the neighbor-joining method after distance analysis of aligned sequences. Numbers represent bootstrap values for each branch, based on data for 100 trees. The scale bar shows the number of nucleotide substitutions per site.

to adhere to almost any surface present within their natural environment”, ii) “the ability to rapidly utilize available nutrients under fluctuating environmental conditions”, and iii) “the ability to tolerate, resist, or even destroy host immune defences” (Jenkinson and Lamont, 1997). The pyogenic streptococci together with *Streptococcus pneumoniae* are the major pathogens. *Streptococcus pyogenes* can colonize the throat or skin and can cause a number of suppurative infections and non-suppurative sequelae. This species is the most common cause of bacterial pharyngitis, impetigo, and scarlet fever as well as erysipelas and other spreading infections. Group A streptococci have been found to be responsible for streptococcal-associated necro-

tizing fasciitis and streptococcal toxic-shock syndrome. Post-streptococcal infection sequelae associated with this organism include acute rheumatic fever, glomerulonephritis, and reactive arthritis. Group A streptococci have also been associated with Tourette’s syndrome, tics, and movement and attention-deficit disorders (Cunningham, 2000). Studies have suggested that group A streptococci are able to invade as well as adhere to epithelial cells (LaPenta et al., 1994). Other pyogenic streptococci including those of Lancefield groups C and G are widely distributed in animals and man, where they exist as commensals and can cause serious infections including septicemia, endocarditis, septic arthritis, pneumonia, meningitis, pharyngitis,

otitis media, and cellulitis. These streptococci share several features with group A streptococci, including the possession of M protein antigens, C5a peptidase, hyaluronic acid capsule, streptokinase, and other virulence factors (Efstratiou, 1997). *Streptococcus pneumoniae* causes pneumonia, meningitis, otitis media, and septicemia and is a serious pathogen among patients with underlying illness and compromised immunity (Ross, 1996). This species is the commonest cause of pneumonia, accounting for approximately 30% of community acquisitions (Brown and Lerner, 1998; Fedson, 1997).

Enrichment and isolation procedures

Streptococci are isolated from a wide range of clinical specimens. Viability is maintained during the transport of clinical specimens to the laboratory if recommended procedures are followed (Isenberg et al., 1985; Ruoff et al., 1999). It has been recommended that throat swabs for culturing group A streptococci (*Streptococcus pyogenes*) be transported directly to the laboratory, but a suitable transport medium should be employed where a delay of more than 2 h is anticipated before processing (Ruoff et al., 1999). Alternative, commercially available, systems for extended transport times are recommended (Facklam and Carey, 1985). Although nutritionally fastidious, streptococci can be cultured on most commonly used complex agar media. Incorporation of 5% defibrinated animal blood (horse or sheep) into agar media allows determination of hemolysis and hemolytic colonies can readily be picked off for subculturing although their presence may be masked if large numbers of other organisms are present. Detailed isolation procedures from clinical specimens have been described by Ruoff et al. (1999). Growth of streptococci is enhanced by incubation under anaerobic conditions at 37°C and an anaerobic atmosphere is essential for detection of hemolysis from *Streptococcus pyogenes* as air and CO₂ will interfere with the hemolytic reaction. Incubation in elevated levels of CO₂ is optimal for the recovery of capnophilic streptococci.

Selective media. Selective media have been described for the isolation of streptococci and media for specific groups of streptococci are also available. The oral streptococci can be isolated and partially characterized through the production of extracellular polysaccharide by plating on sucrose-containing agar media such as Trypticase-Yeast Extract Cystine (TYC) 5% sucrose agar (de Stoppelaar et al., 1967) or Mitis Salivarius agar containing the selective agents trypan blue (75 mg/l), crystal violet (0.8 mg/l), and potassium tellurite (3.5 mg/l) in addition to 5% sucrose. Selective media for isolating the cariogenic streptococcus *Streptococcus mutans* have been developed based on TYC and Mitis Salivarius media. These employ the use of increased levels of sucrose and the addition of bacitracin (Gold et al., 1973; Ikeda and Sandham, 1972; Linke, 1977; Tanzer et al., 1983; Van Palenstein Helderman et al., 1983; Wade et al., 1986). Members of the Anginosus species group can be isolated on a semi-selective agar medium (NAS) containing 40 g/l Sensitivity Agar (Lab M) + 30 µg/ml nalidixic acid, 1 mg/ml sulfamethazine, and 5% (v/v) defibrinated horse blood (Whiley et al., 1993). NAS will also select for *Streptococcus mutans* and *Streptococcus sobrinus* although recovery of the latter is strain-dependent. Isolation of *Streptococcus pyogenes* on sheep-blood agar plus trimethoprim-sulfamethoxazole incubated anaerobically and other media have been compared (Kellogg, 1990). Enhanced

recovery of β-hemolytic streptococci on an alkaline pH-adjusted agar medium that interferes with the production and/or release of bacteriocin-like inhibitory molecules from *Streptococcus salivarius* has been described (Dierksen et al., 2000).

Maintenance procedures

Most strains can be maintained for short periods by weekly subculturing on appropriate media. For long-term maintenance, strains can be preserved either deep frozen at -70 to -80°C or in liquid nitrogen. Freezing cultures on glass beads is particularly useful since one or two beads can be removed whenever the culture needs to be regenerated. Cells for freezing are harvested from blood agar and suspended in a diluent containing 1% tryptone, 0.5% yeast extract, 0.1% glucose, 0.1% cysteine-HCl, and 2% bovine serum (Bowden and Hardie, 1971). Commercially available deep-freeze storage vial systems are also well suited for storing streptococcal strains. The most reliable method for long-term preservation is lyophilization using standard methods (Kirsop and Snell, 1984).

Procedures for testing special characteristics

Hemolysis. Determined on a blood agar base medium such as Todd-Hewitt, brain heart infusion, proteose peptone, etc., plus 5% defibrinated horse or sheep blood. Streak, stab, or pour plates are used. For streak-plating, layered plates are prepared with a thin layer of blood agar poured on top of a nutrient agar base. Inoculation is by streaking with the loop and deep growth can be obtained by stabbing the loop into the medium. Anaerobic incubation is recommended but not with a candle jar or CO₂ incubator (Facklam and Wilkinson, 1981). Pour plates are prepared by adding the inoculum to 15 ml melted agar base cooled to 50–55°C, and then adding 0.6 ml defibrinated blood, mixing, and pouring into a Petri dish. It has been recommended that plates be examined microscopically (60× magnification) so that unlysed erythrocytes can be recognized within zones. This is especially important for recognizing α-prime hemolysis (a zone of partial hemolysis surrounded by a zone of complete hemolysis). In practice, plates are usually examined macroscopically in the clinical laboratory.

Streptococcus agalactiae strains show a marked enlargement of the zone of β-hemolysis when, after 18 h anaerobic incubation at 37°C, they are removed to 4°C for 6 h and then reincubated anaerobically at 37°C (Okazaki et al., 2003).

Serological determination. Established by Lancefield (1933) as one of the most important characteristics in identifying β-hemolytic streptococci, serological determination of group-specific carbohydrate antigens present in the cell walls of isolates has remained an important routine identification technique. Traditional antigen extraction includes growth of isolates in Todd-Hewitt or other suitable broth followed by antigen extraction with agents that have variously included hot hydrochloric acid, hot formamide, heat (autoclave), Pronase B, nitrous acid, or *Streptomyces albus* enzymes with or without lysozyme (Ruoff et al., 1999). Antigen identification has been achieved using ring precipitation in small capillary tubes, double diffusion in gels (Rotta et al., 1971), countercurrent electrophoresis (Dajani, 1973), coagglutination, or immunofluorescence (Cars et al., 1975; Christensen et al., 1973). More recently commercial streptococcal grouping kits have become available and are widely used especially for routine diagnostic

purposes. These are based on latex agglutination where latex particles are coated with a Lancefield-group-specific antiserum and mixed with extracted antigens. Positive reactions are visualized by clumping of the particles.

Streptococcus pyogenes (Lancefield group A streptococcus, GAS) is divided into serotypes on the basis of streptococcal surface M proteins with more than 80 types currently known of which types 1, 3, 11, 12, and 28 are most common in invasive and toxic infections (Cunningham, 2000; Lancefield, 1928). The difficulties associated with M protein serotyping (difficulty reading results, the discovery of new serotypes and the high cost of antiserum production) have largely been overcome by molecular approaches, including M protein gene (*emm*) typing and multilocus sequence typing (Beall et al., 1996; Enright et al., 2001). Streptococci of Lancefield group C and G have been shown to express M proteins with high sequence homology to those of *Streptococcus pyogenes* (for a review of the literature, see Cunningham, 2000), where they are presumed to have the same function (M protein inhibits activation of the alternative complement pathway and phagocytosis by polymorphonuclear leukocytes).

T and R proteins are also present on the surface of *Streptococcus pyogenes* (see the description of *Streptococcus pyogenes*, this chapter). T typing is an important adjunct to M typing and is particularly useful when the M type is not known. Associations between certain T and M types in particular strains have been useful in speeding up M or *emm* typing (Beall et al., 1998). In contrast to the M protein, the T protein molecule has its most conserved region towards the amino-terminal and T proteins are not present in Lancefield group C or G streptococci (Jones et al., 1991).

Serological typing of *Streptococcus pneumoniae* depends on recognition of different capsular polysaccharide antigens by means of the Quellung reaction. Culture suspension and a capsule-specific antiserum are mixed on a slide with saturated aqueous methylene blue. After 10 min under a cover slip the slides are examined under the microscope for swelling and increased visibility of the capsule around the cocci (Austrian, 1976).

Biochemical and physiological tests. A wide range of tests has been used for characterizing streptococci, including carbohydrate fermentations, production of acetyl methyl carbinol (acetoin) from glucose in the Voges–Proskauer reaction, production of ammonia from arginine, hydrolysis of esculin, hippurate, and starch, reduction of litmus milk, production of H₂O₂, tolerance to NaCl and bile, and formation of extracellular polysaccharide from sucrose (Facklam and Wilkinson, 1981; Parker, 1983). Conventionally these tests have been carried out in meat extract or serum water broths with appropriate additives (Cowan and Steel, 1974). Nowadays, identification schemes for the streptococci frequently rely on the inclusion of tests designed to detect preformed enzyme activities after a few hours of incubation by using chromogenic or fluorogenic substrates including glycosides, aminoglycosides, and peptidases. Commercially available test identification kits designed specifically for streptococci have been developed and include preformed enzyme tests as well as miniaturized formats for carbohydrate fermentation and other traditional biochemical tests. These test systems are particularly useful in the clinical laboratory although they may lag behind in facilitating the identification of more recently recognized species. Commer-

cial test kits arguably also have the advantage of enabling standardization of test methods used in different laboratories and thus can help avoid interlaboratory discrepancies in reported test reactions for a given species. However, care must be taken to specify exactly which test format and substrate type is being used as results may vary for a given enzyme (Ahmet et al., 1995; Kilian et al., 1989b).

Several key tests are particularly useful to presumptively identify streptococci, particularly in the clinical laboratory. Bacitracin (0.04U disks) and sulfamethoxazole (SXT) (23.75 µg SXT plus 1.25 µg trimethoprim, disks) can be placed on a blood agar plate with a β-hemolytic streptococcus. *Streptococcus pyogenes* is usually bacitracin-sensitive and SXT-resistant, group B streptococci (*Streptococcus agalactiae*) are resistant to both of these agents, and group C and G large-colony forming streptococci are usually bacitracin-resistant and SXT-susceptible (Facklam and Carey, 1985). Group B streptococci can also be distinguished by the CAMP test for detecting a diffusible extracellular protein referred to as the CAMP factor: a single streak of the streptococcus is made perpendicular to, but not touching, a streak of β-lysin-producing *Staphylococcus aureus*, either on sheep or bovine blood agar. After incubation aerobically or in a candle jar, CAMP-positive strains produce an arrowhead-shaped enlargement of the zone of lysis around the staphylococcus at the junction between the two streaks of growth. Detection of the enzyme pyrrolidonyl arylamidase (PYR) has been found to be more specific than bacitracin sensitivity for *Streptococcus pyogenes* identification (Facklam et al., 1982). This test is carried out in PYR broth (Todd–Hewitt broth supplemented with 0.01% L-pyrrolidonyl-β-naphthylamide) inoculated and incubated at 36°C for 4 h. On addition of PYR reagent (*N,N*-dimethylaminocinnamaldehyde), a positive reaction is indicated by the formation of a deep red color due to reaction of liberated β-naphthylamine with the PYR reagent.

Streptococcus pneumoniae can be distinguished from other α-hemolytic streptococci on the basis of its sensitivity to a 5 µg optochin (ethylhydrocupreine) disk on a blood agar plate. Sensitivity is indicated by an inhibition zone of >14 mm with a 6 mm disk or >16 mm with a 10 mm disk (Facklam and Carey, 1985). The bile solubility test in which colonies are covered with 10% deoxycholate also differentiates this species by the lysis of pneumococcal colonies, but is considered by some to be more complicated and less reliable than the optochin test (Lund, 1959).

The hydrolysis of sodium hippurate is a character shared by several species that include *Streptococcus acidominimus*, *Streptococcus agalactiae*, *Streptococcus devriesei*, *Streptococcus didelphis*, *Streptococcus hyovaginalis*, *Streptococcus oligofermentans*, *Streptococcus plurimalium*, *Streptococcus uberis*, and some strains of *Streptococcus thoraltensis*. A rapid test (Hwang and Ederer, 1975) has been described in which a loopful of an overnight culture of streptococcus grown on blood agar is suspended in 0.4 ml 1% aqueous sodium hippurate. After 2 h incubation at 37°C, 0.2 ml 3.5% ninhydrin made up in a 1:1 mixture of butanol and acetone is added. After further incubation for 10 min a deep purple color, due to the reaction of ninhydrin with glycine, indicates a positive reaction.

Production of extracellular polysaccharides (ECPs), i.e., glucans (dextrans) and fructans (levans) from sucrose is an important characteristic of several of the oral streptococci, including *Streptococcus mutans*, *Streptococcus salivarius*, *Streptococcus sanguis*,

and *Streptococcus oralis*, together with some slime-producing strains designated *Streptococcus bovis*. Such polysaccharides can be detected in the supernatant of cultures in buffered 5% sucrose broth, either by observing gel formation in some cases or by differential precipitation with ethanol. A precipitate after addition of 1.2 volumes ethanol indicates glucan formation, whereas fructans are precipitated by 2.5 volumes (Hehre and Neill, 1946). Standardization of the tests for polysaccharide production can prove to be difficult in practice. A useful indication of the presence of these products can be obtained more simply by observation of colonial morphology on 5% sucrose agar plates (Colman and Ball, 1984; Parker, 1983).

Streptococci of group D are differentiated from *Enterococcus* species by the ability of the latter to hydrolyze esculin in the presence of 40% bile and to grow in the presence of 6.5% NaCl.

Taxonomic comments

Since the publication of Volume 2 of the First Edition of *Bergey's Manual of Systematic Bacteriology*, in which not only facultatively anaerobic but also several strictly anaerobic *Streptococcus* species were included (Hardie, 1986c), the genus *Streptococcus* has undergone considerable taxonomic revision. The period since has seen the application of chemotaxonomic techniques, whole-genomic DNA hybridization and 16S rRNA sequencing (Bentley et al., 1991; Kawamura et al., 1995b; Schleifer and Kilpper-Bälz, 1987). These methods have given insight into the natural (phylogenetic) relationships between *Streptococcus* and other genera, revealed the natural grouping of species into "species groups" and form the basis of species delineation (Stackebrandt et al., 2002). These approaches have surmounted the difficulties faced by previous workers who were, in the main, reliant on the biochemical, physiological, and serological characterization of strains, but who had often been well aware of the limitations of the approaches then available and of the undue emphasis sometimes given to them in streptococcal classification and identification (Jones, 1978). *Streptococcus* was divided into three genera that included *Streptococcus* (*sensu stricto*), *Enterococcus*, and *Lactococcus* (Schleifer and Kilpper-Bälz, 1984; Schleifer et al., 1985). *Streptococcus*, comprising the pyogenic and oral species included both human and animal pathogenic and saprophytic streptococci, *Lactococcus* was formed from the lactic streptococci (Kilpper-Bälz et al., 1982; Schleifer et al., 1985), and *Enterococcus* from the enterococci (Collins et al., 1984b; Schleifer and Kilpper-Bälz, 1984).

The anaerobic species previously included within *Streptococcus* (*Streptococcus parvulus*, *Streptococcus morbillorum*, *Streptococcus hansenii*, and *Streptococcus pleomorphus*) have, for the most part, been excluded and assigned to other genera. *Streptococcus parvulus* was removed to the genus *Atopobium* as *Atopobium parvulus* (comb. nov.) (Collins and Wallbanks, 1992), *Streptococcus morbillorum* was reclassified as *Gemella morbillorum* comb. nov. (Kilpper-Bälz and Schleifer, 1988), and *Streptococcus hansenii* has been proposed as a member of the genus *Ruminococcus* (Ezaki et al., 1994). The latter proposal has been argued against on the grounds that the *Ruminococcus* type species, *Ruminococcus flavefaciens*, belongs to a separate phyletic group to that containing "*Ruminococcus hansenii*" (Rainey and Janssen, 1995; Willems and Collins, 1995). In the case of *Streptococcus pleomorphus* (Barnes et al., 1977), 16S rRNA gene sequence cataloging (Ludwig et al.,

1988) and 16S rRNA sequencing (Kawamura et al., 1995b) have placed this species outside the genus *Streptococcus* and indicated that *Streptococcus pleomorphus* is most closely related to *Clostridium innocuum*. Recent analysis has placed this species within the family *Erysipelotrichaceae* together with *Eubacterium bifforme* and *Eubacterium cylindroides* (W. Wade, personal communication. See the *Eubacterium* section of this volume).

Nutritionally variant streptococci (Cooksey et al., 1979; Freney et al., 1992), originally referred to as "thiol-dependent", "vitamin B6-dependent" and "symbiotic", streptococci have been excluded from *Streptococcus* and reclassified as *Abiotrophia defectiva* (Kawamura et al., 1995a), *Granulicatella adiacens*, *Granulicatella balaenopterae*, and *Granulicatella elegans* (Collins and Lawson, 2000). These organisms have been isolated from clinical specimens including blood, abscesses, oral ulcers, and urethral samples (Christensen and Facklam, 2001).

By 16S rRNA gene sequence analysis and reassociation data the species within *Streptococcus sensu stricto* comprise distinct "species groups" along with several species remaining ungrouped (Bentley et al., 1991; Kawamura et al., 1995b; Schleifer and Kilpper-Bälz, 1987). The species groups have been designated "Pyogenic", "Bovis", "Mutans", "Mitis", "Anginosus", and "Salivarius" and comprise the majority of described species. The oral streptococci include the "Salivarius", "Mutans", "Anginosus", and "Mitis" species groups of Bentley et al. (1991) and Kawamura et al. (1995b) of which the latter two groups formed subgroups within a single "Oralis group" according to the classification of Schleifer and Kilpper-Bälz (1987).

Several streptococcal species and species groups have confused taxonomic and nomenclatural histories that require clarification if the present classification and nomenclature of the genus are to be understood.

Nomenclatural note. Several nomenclatural changes to established streptococcal species epithets have recently been made (Trüper and de Clari, 1997, 1998) in the interests of grammatical correctness and in accordance with the International Code of Nomenclature of Bacteria (Lapage et al., 1992). These include *Streptococcus cricetus*, *Streptococcus crista*, *Streptococcus rattus*, *Streptococcus sanguis*, and *Streptococcus parasanguis* which have been changed to *Streptococcus criceti*, *Streptococcus cristatus*, *Streptococcus rattus*, *Streptococcus sanguinis*, and *Streptococcus parasanguinis*, respectively. Argument against this development has, quite correctly in the opinion of these authors, been put forward on the basis that changes in names of species long-standing in the literature causes unnecessary confusion and therefore cannot be justified (Kilian, 2001). The Judicial Commission of the International Committee on Systematic Bacteriology ruled recently that priority be given to the stabilization of nomenclature over orthographic correctness and that names on the Approved Lists of Bacterial Names, the Validation Lists and the Notification Lists should not be changed on grammatical grounds (Amendment to Rule 61 of the Bacteriological Code, Minute 7. Session 1 of the meeting of the Judicial Commission held 14, 15, and 18 August 1999, Sydney, Australia, published in the *International Journal of Systematic and Evolutionary Microbiology* [2000], vol. 50, pp. 2239–2244). Despite the present authors' misgivings concerning these changes, the corrected specific epithets are becoming more frequently used in the literature and therefore are employed in this chapter.

Streptococcal species groups

Pyogenic group. In the previous edition of the *Manual* six named species were included within the “pyogenic hemolytic streptococci”: *Streptococcus pyogenes* (Lancefield group A and “group A-variant”), *Streptococcus agalactiae* (Lancefield group B), *Streptococcus equi* (Lancefield group C), *Streptococcus iniae*, *Streptococcus dysgalactiae* (Lancefield group C), and *Streptococcus pneumoniae* together with other streptococci of Lancefield groups C, G, and L, and groups E, P, U, and V (Rotta, 1986). These streptococci largely comprised β -hemolytic species usually containing a polysaccharide Lancefield group antigen in the cell wall and producing pyogenic infections in man and animals. Exceptions to these characteristics were acknowledged at the time, particularly the inclusion of *Streptococcus pneumoniae* which previous authors had listed either as a separate group (Jones, 1978) or within the viridans streptococci (Bridge and Sneath, 1983). With the exception of *Streptococcus pneumoniae*, all the taxa listed previously in the “pyogenic hemolytic streptococci” are included within the Pyogenic group here. All are associated with pyogenic infections in man and/or animals. The species within the present Pyogenic species group include *Streptococcus pyogenes*, *Streptococcus agalactiae*, *Streptococcus canis*, *Streptococcus equi*, *Streptococcus iniae*, *Streptococcus uberis*, *Streptococcus parauberis*, *Streptococcus phocae*, *Streptococcus urinalis*, and *Streptococcus didelphi* with strains of Lancefield groups C, G, and L, and groups E, P, U, and V comprising *Streptococcus dysgalactiae* and *Streptococcus porcinus*, respectively. *Streptococcus uberis* and *Streptococcus parauberis* strains were previously both included as distinct genotypes within *Streptococcus uberis* by DNA–DNA hybridization and designated *Streptococcus uberis* types I and II, respectively (Collins et al., 1984a; Fuller et al., 2001, 1979a). 16S rRNA gene sequence analysis later demonstrated that type I and II strains were sufficiently dissimilar to warrant separate species status (Williams and Collins, 1990a).

Within the Pyogenic group, the β -hemolytic streptococci of Lancefield group C, large-colony type of Lancefield group G and related strains, previously assigned to *Streptococcus dysgalactiae*, “*Streptococcus equisimilis*”, *Streptococcus equi*, and *Streptococcus zooepidemicus*, have perhaps the most confused taxonomic background. The β -hemolytic streptococci of Lancefield group C isolated from human respiratory tracts, vaginas, and skin were originally called *Streptococcus equisimilis* (Frost and Engelbrecht, 1936) and the name *Streptococcus dysgalactiae* was given to non- β -hemolytic strains of bovine origin that were otherwise identical to *Streptococcus equisimilis* (Breed et al., 1948). Neither species was included in the Approved Lists of Bacterial names (Skerman et al., 1980), but later the name *Streptococcus dysgalactiae* was revived for α -hemolytic, Lancefield group C strains (Garvie et al., 1983). Subsequently DNA–DNA hybridization studies demonstrated that α - and β -hemolytic Lancefield group C strains, large-colony type strains of Lancefield group G and β -hemolytic Lancefield group L streptococci together with isolates previously classified as *Streptococcus dysgalactiae* and “*Streptococcus equisimilis*” belonged within a single species (Farrow and Collins, 1984a; Kilpper-Bälz and Schleifer, 1984) for which the name *Streptococcus dysgalactiae* was proposed and an emended description given (Farrow and Collins, 1984a). Vandamme et al. (1996) divided *Streptococcus dysgalactiae* strains into two clusters (named clusters I and III in that study) based on whole-cell-derived polypeptide patterns by SDS-PAGE. Cluster I strains, isolated from animal sources, were

of Lancefield groups C and L, whereas cluster III strains were of human origin, belonged to Lancefield C and G and, unlike cluster I strains, produced streptokinase activity on human plasminogen. Clusters I and III were named *Streptococcus dysgalactiae* subsp. *dysgalactiae* and *Streptococcus dysgalactiae* subsp. *equisimilis* (cluster III strains, i.e., of human origin), respectively. Vieira et al. (1998) used DNA–DNA reassociation, multilocus enzyme electrophoresis (MLEE), and physiological characterization to also recognize these two subspecies within *Streptococcus dysgalactiae* in close agreement with Vandamme et al. (1996). Despite the evidence from DNA–DNA hybridization experiments and overall close phenotypic similarity some authors prefer to differentiate human group C and group G strains as separate species and to subdivide strains primarily according to habitat and pathogenicity (Efstratiou, 1997, 1994). The pivotal DNA–DNA hybridization studies of Kilpper-Bälz and Schleifer (1984) and Farrow and Collins (1984a) also demonstrated that Lancefield-group-C-reacting strains, *Streptococcus equi* (Sand and Jensen, 1888) and “*Streptococcus zooepidemicus*” (Frost and Engelbrecht, 1936) belonged to a single species. Farrow and Collins (1984a) argued that the separate identity of “*Streptococcus zooepidemicus*” be maintained on phenotypic grounds, specifically the latter’s ability to produce acid from sorbitol but not from trehalose and to hydrolyze esculin, and they therefore proposed the names *Streptococcus equi* subsp. *equi* and *Streptococcus equi* subsp. *zooepidemicus*. A high level of similarity (98.9%) observed between fragments of manganese-dependent superoxide dismutase genes from *Streptococcus equi* subsp. *equi* and subsp. *zooepidemicus* has also been taken to indicate that these do indeed belong to a single species (Poyart et al., 1998).

Biochemical, physiological, and antigenic characteristics of species within the Pyogenic species group are given in Table 131 and Table 132.

Mutans group. The mutans streptococci are associated with dental plaque in man and several animal species and includes the species *Streptococcus mutans* (Clarke, 1924), generally implicated as the primary pathogen in the etiology of human dental caries (Hamada and Slade, 1980). 16S rRNA data place *Streptococcus mutans*, *Streptococcus sobrinus*, *Streptococcus criceti*, *Streptococcus rattii*, *Streptococcus downei*, and *Streptococcus macacae* together to form the loose conglomeration of species referred to as the “Mutans group” (Bentley et al., 1991; Kawamura et al., 1995b; Schleifer et al., 1984). *Streptococcus ferus* is a peripheral member of this species group by DNA–DNA hybridization (Schleifer et al., 1984) but has been found to cluster closest to *Streptococcus sanguinis* by MLEE (Gilmour et al., 1987). In addition, there is no strong evidence to support the inclusion of *Streptococcus ferus* within the Mutans group by 16S rRNA or *sodA* sequence comparisons alone (Whatmore and Whaley, 2002), although combined analysis of 16S rRNA and the RNase P RNA gene (*rnpB*) supported inclusion of this species (Täpp et al., 2003). The organism designated *Streptococcus mutans* which was first isolated from carious human teeth by Clarke (1924), was not included in the Eighth Edition of the *Manual of Determinative Bacteriology* but was later added to the Approved Lists of Bacterial Names. Studies on the etiological agent of dental caries prompted renewed interest in *Streptococcus mutans* in the 1960s. Evidence of biochemical, serological, and genetic (G+C determinations and DNA–DNA reassociations) heterogeneity among strains resulted initially in the proposal of four subspecies of *Streptococcus*

mutans, namely subsp. *mutans*, subsp. *sobrinus*, subsp. *rattus*, and subsp. *cricketus* (Coykendall, 1974). This was followed by a proposal for the recognition of *Streptococcus mutans*, *Streptococcus sobrinus*, *Streptococcus cricketus*, *Streptococcus rattus*, and *Streptococcus ferus* as distinct species (Coykendall, 1977, 1983) to which were later added two more “mutans-like” species, *Streptococcus macacae* and *Streptococcus downei*, from the dental plaque of monkeys (Beighton et al., 1984; Whiley and Hardie, 1988) (for reviews of the literature, see Hamada and Slade, (1980), and Whiley and Beighton, 1998). Measured by molecular methods the Mutans group overall is a relatively loose one with the member species having deep lines of descent.

Another species named *Streptococcus orisratti* (Zhu et al., 2000), isolated from the teeth of laboratory rats, had the highest overall 16S rRNA sequence similarity (1265 bases) (94.1%) with *Streptococcus rattus*, although the combined phenotypic and molecular data on this species does not whole-heartedly support its inclusion within this relatively loose species-group (see Figure 123).

At the time of writing, a further member of this species group has been described, *Streptococcus devriesei*, isolated from equine teeth (Collins et al., 2004).

Recent nomenclatural changes have taken effect within the Mutans group, with the names *Streptococcus rattus* and *Streptococcus cricketus* being changed to *Streptococcus rattus* and *Streptococcus criceti*, respectively, on grammatical grounds (Trüper and de Clari, 1997, 1998).

Biochemical, physiological, and antigenic characteristics of species within the Mutans group are given in Table 131 and Table 133.

Anginosus group. The Anginosus group includes streptococci isolated from the oral cavity, upper respiratory, intestinal, and urogenital tracts, that are associated with purulent infections at oral and non-oral sites (Gossling, 1988). The three species currently included here are *Streptococcus intermedius*, *Streptococcus anginosus*, and *Streptococcus constellatus* (subsp. *constellatus* and subsp. *pharyngis*) together with additional centers of variation for which species epithets have not yet been proposed. The classification of the streptococci listed here has a convoluted history involving several nomenclatural changes: the group includes the non-hemolytic strains isolated from dental abscesses, originally given the name “*Streptococcus milleri*” (Guthof, 1956), together with the non-hemolytic streptococci from the human respiratory tract called “*Streptococcus MG*” (Mirick et al., 1944), the minute-colony-forming streptococci of Lancefield groups F and G (Bliss, 1937; Long and Bliss, 1934), hemolytic and non-hemolytic isolates possessing the “type antigens” of Lancefield group F (Ottens and Winkler, 1962), *Streptococcus intermedius* (Holdeman and Moore, 1974), *Streptococcus anginosus* (Andrewes and Horder, 1906; Deibel and Seeley, 1974), *Streptococcus constellatus* (Holdeman and Moore, 1974), “*Streptococcus anginosus-constellatus*”, and “*Streptococcus MG-intermedius*” (Facklam, 1977), the “*Streptococcus milleri*-group” (Gossling, 1988), and *Streptococcus anginosus*, *Streptococcus constellatus*, and *Streptococcus intermedius*, according to the emended descriptions given for these species by Facklam (1984, 1985). These earlier attempts at classification relied heavily on phenotypic characteristics with considerable emphasis given to hemolytic reactions on blood agar, possession of Lancefield group antigens or type antigens, and fermentation of lactose (Whiley and

Beighton, 1998; Whiley and Hardie, 1989). Overall these studies produced a conflicting picture with evidence reported both for and against the separation of “*Streptococcus milleri*” strains into more than one species (see Whiley and Beighton, 1998). Later studies based on DNA–DNA reassociation data were also somewhat contradictory, with some authors concluding that strains resembling “*Streptococcus milleri*” be included within a single species (Coykendall et al., 1987; Ezaki et al., 1986; Farrow and Collins, 1984a; Welborn et al., 1983) and others proposing that more than one species be recognized (Kilpper-Bälz and Schleifer, 1984; Knight and Shlaes, 1988; Whiley and Hardie, 1989). The situation may not have been helped by differences in the stringencies of the experimental methods employed and the selection of collections of strains not representative of the “*Streptococcus milleri*-group” as a whole (Ezaki et al., 1986; Knight and Shlaes, 1988). Studies using the S1-nuclease DNA–DNA hybridization method under optimum and stringent conditions have demonstrated that three closely related but distinct species are present within these streptococci, namely *Streptococcus anginosus*, *Streptococcus constellatus*, and *Streptococcus intermedius*, each with an emended description (Whiley and Beighton, 1991), and have also shown that the phenotypic characteristics emphasized in earlier studies, namely hemolytic reaction, lactose fermentation, and Lancefield grouping are not discriminatory at the species level (Whiley et al., 1990a). Similar studies have revealed further centres of taxonomic variation within *Streptococcus anginosus* and *Streptococcus constellatus*, particularly β -hemolytic strains of Lancefield group C (Whiley et al., 1997, 1999), and subsequently it has been proposed that *Streptococcus constellatus* constitutes two subspecies, *Streptococcus constellatus* subsp. *constellatus*, isolated from a relatively broad clinical background, and *Streptococcus constellatus* subsp. *pharyngis*, mainly from the human throat and cases of pharyngitis (Whiley et al., 1999). Additionally, two DNA similarity groups were demonstrated within *Streptococcus anginosus* and were also centered on β -hemolytic strains of Lancefield group C, although lack of discriminating biochemical characteristics for the identification of fresh isolates prevented a formal taxonomic proposal from being made. Support for the present division of the Anginosus group into the three species *Streptococcus anginosus*, *Streptococcus constellatus*, and *Streptococcus intermedius* has also been provided by 16S rRNA gene sequence data (Bentley et al., 1991; Kawamura et al., 1995b; Poyart et al., 1998) and further heterogeneity has been demonstrated by ribotyping, serotyping, and macrorestriction fingerprinting by pulsed-field gel electrophoresis (PFGE) (Bartie et al., 2000; Doit et al., 1994; Inoue et al., 1998; Jacobs et al., 2000a). However, in a recent study based solely on whole-cell-derived polypeptide patterns the case for inclusion of all these strains into a single species has been revived (Vandamme et al., 1998).

An unusual population of strains reacting to oligonucleotide probes to the species-specific, 213–231-bp region of the 16S rRNA gene from both *Streptococcus intermedius* and *Streptococcus constellatus* (Jacobs et al., 1996) was recently shown by DNA–DNA hybridization to belong to *Streptococcus constellatus* (Jacobs et al., 2000b). Further support for the recognition of the streptococci comprising the Anginosus group into distinct species has been the demonstration of a human-specific cytotoxin, intermedilysin, the gene for which is only present in strains of *Streptococcus intermedius* (Nagamune et al., 1996, 2000).

Biochemical, physiological, and antigenic characteristics of species within the Anginosus group are given in Table 131, Table 132, and Table 133.

Salivarius group. The close relationships between two oral species, *Streptococcus salivarius* and *Streptococcus vestibularis*, and *Streptococcus thermophilus*, a species isolated from dairy sources but of unknown habitat, have been demonstrated in several studies using DNA–DNA reassociation and by the presence of significant amounts of eicosenoic acid (12–17%) (Farrow and Collins, 1984b; Kilpper-Bälz et al., 1982; Whiley and Hardie, 1988). Initially a proposal was made for recognition of *Streptococcus salivarius* and *Streptococcus thermophilus* as subsp. *salivarius* and subsp. *thermophilus*, respectively (Farrow and Collins, 1984b). Subsequent data supported the recognition of *Streptococcus salivarius* and *Streptococcus thermophilus* as distinct species (Schleifer et al., 1991, 1987), and was followed by the addition of *Streptococcus vestibularis* as the third member of this group (Whiley and Hardie, 1988).

Phenotypic similarities between *Streptococcus salivarius* and *Streptococcus bovis* have been noted as a possible source of confusion in routine identification. Similarities with some biochemical reactions, reaction of some strains of *Streptococcus salivarius* with Lancefield group D antiserum and growth of both species on bile-esculin agar (Coykendall and Gustafson, 1985) have been highlighted, although extended physiological characterization has been shown to differentiate them (Ruoff et al., 1989).

Biochemical, physiological, and antigenic characteristics of species within the Salivarius group are given in Table 131 and Table 133.

Mitis group. This species group currently includes *Streptococcus mitis*, *Streptococcus oralis*, *Streptococcus sanguinis*, *Streptococcus gordonii*, *Streptococcus parasanguinis*, *Streptococcus cristatus*, *Streptococcus peroris*, *Streptococcus infantis*, *Streptococcus australis*, *Streptococcus sinensis*, and *Streptococcus oligofermentans*, mainly isolated from the normal oral and pharyngeal flora in man, together with the potentially highly pathogenic species *Streptococcus pneumoniae* that may also be found resident in the upper respiratory tract of healthy humans. Further centres of variation have been described within these streptococci (Kawamura et al., 2000). *Streptococcus mitis* (biovar 1) (Kilian et al., 1989b) and *Streptococcus oralis* comprise the majority of the earliest, “pioneer” species to colonize the mouths of healthy human neonates (Pearce et al., 1995), while *Streptococcus sanguis*, *Streptococcus oralis*, and *Streptococcus gordonii* were found to be the most common streptococci isolated from bacterial endocarditis patients (Douglas et al., 1993), and *Streptococcus oralis* and *Streptococcus mitis*, together with *Streptococcus salivarius*, have been found to be a major cause of infections in neutropenic patients (Beighton et al., 1994; Elting et al., 1992; Jacobs et al., 1995). The taxonomic histories of several of the species included here, particularly those referred to in the past as “*Streptococcus viridans*”, “*Streptococcus sanguis* type II”, “*Streptococcus mitior*” and *Streptococcus mitis*, have frequently been sources of confusion involving nomenclatural changes and accompanying definitions (see Whiley and Beighton, 1998). Despite the inclusion of the name *Streptococcus mitis* and exclusion of “*Streptococcus mitior*” (Colman and Williams, 1972) from the Approved Lists of Bacterial Names (1980), the previous edition of the *Manual* did not

list *Streptococcus mitis* on the grounds that this species had always been ill-defined (Andrewes and Horder, 1906; Sherman et al., 1943) with the name “*Streptococcus mitior*” instead preferred “for a group of α -hemolytic streptococci that can be defined with a reasonable degree of precision” (Hardie, 1986a). The history of these streptococci is best traced commencing with *Streptococcus sanguis* (White and Niven, 1946) a species isolated from blood and endocarditis vegetations, able to hydrolyze arginine and esculin and form dextran from sucrose, which resembled streptococci also referred to as “*Streptococcus s.b.e.*” (Loewe et al., 1946; Washburn et al., 1946). Serological analyses resulted in the recognition of *Streptococcus sanguis* types I, I-II, and II (Washburn et al., 1946), and the description of dextran-forming strains belonging to Lancefield group H from bacterial endocarditis (Hehre and Neill, 1946). Confusion surrounding the precise strain used in producing the original Lancefield group H antiserum understandably led to disagreement regarding the relationship between strains called *Streptococcus sanguis* and possession of a Lancefield group H antigen (Dodd, 1949; Farmer, 1954; Porterfield, 1950), with *Streptococcus sanguis* recognized as including both dextran-producing and non-producing strains by these authors. Evidence of heterogeneity within *Streptococcus sanguis* came from the demonstration of a lack of rhamnose but presence of significant amounts of anhydrosorbitol in the cell walls of the type II strains (Colman and Williams, 1965) and the separation of the latter from the remainder of *Streptococcus sanguis* strains by numerical taxonomy (Carlsson, 1968; Colman, 1968). Dextran formation was a variable characteristic of all clusters. Colman and Williams (1972) used the name “*Streptococcus mitior*” for those strains unable to hydrolyze arginine or esculin and without rhamnose in their cell walls. Subsequently, confusion arose through the adoption of an alternative nomenclature in the USA, in which strains referred to as *Streptococcus sanguis* by Colman and Williams (1972) were called *Streptococcus sanguis* biotype I and “*Streptococcus mitior*” strains were divided into *Streptococcus sanguis* biotype II and *Streptococcus mitis* on the basis of fermentation and non-fermentation of raffinose, respectively (Facklam, 1977). The data from DNA–DNA hybridizations continued to provide unremitting evidence of heterogeneity amongst these streptococci, with those similarity groups obtained that corresponded to *Streptococcus sanguis* according to Colman and Williams’ definition (1972) remaining distinct from those corresponding to “*Streptococcus mitior*” (Coykendall and Munzenmaier, 1978; Coykendall and Specht, 1975; Schmidhuber et al., 1987; Welborn et al., 1983). The fact that more than one similarity group was present within strains of both of these “species” provided irrefutable evidence that several taxa existed. Differentiation at the species level on the basis of raffinose fermentation was not upheld by these studies. *Streptococcus sanguis* and *Streptococcus mitis* both appeared in the Approved Lists of Bacterial Names according to descriptions from the Eighth Edition of *Bergey’s Manual of Determinative Bacteriology* (Deibel and Seeley, 1974; Skerman et al., 1980). The type strains assigned were NCTC 7863 (ATCC 10556) for *Streptococcus sanguis* and NCTC 3165 (ATCC 33399) for *Streptococcus mitis* although the latter strain was phenotypically more typical of *Streptococcus sanguis* in being able to hydrolyze arginine and esculin and with only 40% overall DNA similarity demonstrated between it and other, typical *Streptococcus mitis* strains (Kilpper-Bälz et al., 1985; Welborn et al., 1983). Strain NCTC 3165 was

eventually pronounced inappropriate as the *Streptococcus mitis* type strain, reassigned to the species *Streptococcus gordonii* and replaced with strain NS51 (NCTC 12261) (Kilian et al., 1989a).

Further confusion of the overall taxonomic picture of this group was caused by the description of *Streptococcus oralis*, based on the results of a numerical taxonomic study (Bridge and Sneath, 1982). This species was later redefined by Kilpper-Bälz et al. (1985) and restricted to strains with cell walls containing directly cross-linked peptidoglycan with lysine as the diamino acid (Lys-direct), with ribitol and choline as characteristic cell-wall constituents but with rhamnose absent. Several strains previously referred to as "*Streptococcus viridans*" were included within *Streptococcus oralis* (Kilpper-Bälz et al., 1985). The omission of the name "*Streptococcus mitior*" from the Approved Lists of Bacterial Names (Skerman et al., 1980) and the subsequent valid publication of the species epithet *oralis*, albeit originally for a heterogeneous collection of strains encompassing more than one species, meant that the name "*Streptococcus mitior*" had no official standing in the literature. Kilian et al. (1989b) studied 151 viridans streptococci that included reference and type strains from earlier studies together with clinical isolates. These were examined using biochemical and physiological tests and serological reactions including the presence of the Lancefield group H antigen derived from several candidate strains. This study provided much of the current view of the classification of the Mitis group of streptococci and resulted in emended descriptions of *Streptococcus sanguis*, *Streptococcus oralis*, and *Streptococcus mitis*, together with the proposal of a new species, *Streptococcus gordonii*, and incorporated strain NCTC 3165, which had previously been rejected as the type strain of *Streptococcus mitis*.

It needs to be noted here that in the case of *Streptococcus mitis*, efforts to delineate the species more clearly have continued with its division into biotypes (Kilian et al., 1989b), by comparison of whole cell-derived polypeptide patterns by SDS-PAGE (Vandamme et al., 1998), and by sequence analysis of housekeeping genes (Whatmore et al., 2000). These studies and others have demonstrated heterogeneity within *Streptococcus mitis*, particularly biovar 2 strains (Kilian et al., 1989b) which the data indicate are of disparate taxonomic affiliation (De Gheldre et al., 1999; Kikuchi et al., 1995; Vandamme et al., 1998).

Further additions to the Mitis species group have included *Streptococcus parasanguinis* (*Streptococcus parasanguis*, Whiley et al., 1990b) isolated originally from human clinical specimens, *Streptococcus cristatus* (*Streptococcus crista*; Handley et al., 1991), *Streptococcus peroris*, *Streptococcus infantis* (Kawamura et al., 1998), *Streptococcus australis* (Willcox et al., 2001), and *Streptococcus oligofermentans* (Tong et al., 2003), all isolated from the human oral cavity, together with *Streptococcus sinensis* from the blood of an endocarditis patient (Woo et al., 2002). The DNA G+C content for the latter species was determined to be 53 ± 2.9 mol% which would appear to be high for a streptococcus.

An example of further taxa within the group is the "tufted mitior" strains originally described by Handley et al. (1985) on the basis of unusual tufted surface fibrils seen by electron microscopy. "Tufted mitior" strains were shown to constitute a distinct taxon at the species level by DNA-DNA hybridization and 16S rRNA gene sequence comparisons, but the lack of suitable biochemical tests for differentiation from other streptococci, in particular *Streptococcus mitis*, so far precludes any formal taxonomic proposals (Kawamura et al., 2000).

Despite listing *Streptococcus pneumoniae* within the "pyogenic hemolytic streptococci" in the previous edition of the *Manual*, the close relationships between *Streptococcus pneumoniae* and members of the Mitis group, in particular *Streptococcus oralis* and *Streptococcus mitis*, have been recognized for some time (Bentley et al., 1991; Kawamura et al., 1995b, 1999; Kilpper-Bälz et al., 1985). These three species share over 99% 16S rRNA gene sequence similarity although the estimated level of sequence similarity over their entire genomes is $< 60\%$. Interspecies recombination events have been shown to have taken place involving *Streptococcus pneumoniae*, *Streptococcus oralis*, and *Streptococcus mitis*, a process particularly evident in genes under relatively intense selective pressure, such as the PBPs (Dowson et al., 1997, 1993, 1994).

The names *Streptococcus sanguis*, *Streptococcus parasanguis*, and *Streptococcus crista* have been changed on grammatical grounds to *Streptococcus sanguinis*, *Streptococcus parasanguinis*, and *Streptococcus cristatus*, respectively (Trüper and de Clari, 1997).

Biochemical, physiological, and antigenic characteristics of species within the Mitis group are given in Table 131 and Table 133.

Bovis group. The species within this group represent a collection of streptococci of human and animal origin whose classification has long been problematic and is currently undergoing considerable revision in the light of data from molecular methods. The two earliest recognized species names here that are still in use today are *Streptococcus bovis* (Andrewes and Horder, 1906) and *Streptococcus equinus* (Orla-Jensen, 1919; Sherman and Wing, 1937). Both of these species were listed in the Approved Lists of Bacterial Names (Skerman et al., 1980) and in the previous edition of *Bergey's Manual of Systematic Bacteriology* (Hardie, 1986b). Differentiation of *Streptococcus equinus* and *Streptococcus bovis* by acid from lactose and raffinose and production of α -galactosidase by *Streptococcus bovis* correlated with the isolation of *Streptococcus equinus* from horse feces and *Streptococcus bovis* from bovine feces, mastitis, human feces, and human clinical sources (Colman, 1990; Schlegel et al., 2000). *Streptococcus bovis* strains of human origin were described as "typical" (Facklam, 1972) or "biotype I" (Parker and Ball, 1976) when able to produce acid from mannitol and inulin but rarely from sorbitol or arabinose, and to produce copious amounts of extracellular polysaccharide (glucan) from sucrose (see Coykendall (1989a) for review of the literature). Strains unable to ferment mannitol or produce glucans were called "variant" (Facklam, 1972) or "biotype II" (Parker and Ball, 1976). Coykendall and Gustafsson (1985) subdivided biotype II strains into biotypes II/1 and II/2 on the ability of biotype II/2 strains to produce acid from trehalose, to produce β -glucuronidase and β -galactosidase more frequently and to less frequently split starch.

Successive classification studies, initially based on phenotypic characteristics and more recently using nucleic acid based approaches (Coykendall and Gustafsson, 1985; Farrow et al., 1984; Knight and Shlaes, 1985; Osawa et al., 1995; Poyart et al., 2002; Schlegel et al., 2000) have resulted in the gradual recognition of several additional species. Consequently the name "bovis", long familiar in the streptococcal literature, is increasingly associated with a group of species sometimes variously referred to as the "Bovis group" (Kawamura et al., 1995b), the "*Streptococcus bovis*/*Streptococcus equinus* complex" (Schlegel et al., 2000) and the "*Streptococcus bovis*/*Streptococcus equinus* group"

(Poyart et al., 2002). In addition, DNA–DNA hybridization studies have demonstrated that the type strains of *Streptococcus bovis* and *Streptococcus equinus* belong to the same similarity group, leading to the recognition of the names *Streptococcus equinus* and *Streptococcus bovis* as subjective synonyms with the specific epithet *Streptococcus equinus* having priority under Rule 19 of the International Code of Nomenclature of Bacteria (Farrow et al., 1984; Kilpper-Bälz et al., 1982; Nelms et al., 1995). This latter development may not be welcomed by many clinical bacteriologists who usually associate the names “bovis” and “equinus” with human and animal (equine) sources, respectively.

Currently the species included within the “bovis/equinus” complex are i) *Streptococcus equinus* (Farrow et al., 1984), which encompasses mainly mannitol-negative strains that previously would have been described as *Streptococcus bovis* biotype II/1, ii) *Streptococcus galloyticus* (Osawa et al., 1995), originally comprising strains previously identified as *Streptococcus bovis* biotype I from human clinical and animal sources and currently also including strains previously assigned to *Streptococcus caprinus* by Brooker et al. (1994), *Streptococcus macedonicus* (Tsakalidou et al., 1998), and strains previously designated *Streptococcus waiius* (Flint et al., 1999; Manachini et al., 2002; Poyart et al., 2002), iii) *Streptococcus infantarius* (Bouvet et al., 1997; Poyart et al., 2002) which currently includes *Streptococcus bovis* biotype II/1 strains previously given subspecific status as *Streptococcus infantarius* subsp. *infantarius* (Schlegel et al., 2000), iv) *Streptococcus alactolyticus* (Farrow et al., 1984), v) *Streptococcus lutetiensis* which includes strains previously described as *Streptococcus infantarius* subsp. *coli* (Poyart et al., 2002; Schlegel et al., 2000), and vi) *Streptococcus pasteurianus* (Poyart et al., 2002), comprising strains previously identified as *Streptococcus bovis* biotype II/2.

Recent studies employing DNA–DNA reassociation and gene sequence data support the inclusion of *Streptococcus macedonicus* and *Streptococcus waiius* within *Streptococcus galloyticus*, with the latter having nomenclatural priority (Poyart et al., 2002; Schlegel et al., 2003). The present authors agree with this proposal although the levels of DNA reassociation, occasionally obtained marginally below the generally accepted 70% cut-off for inclusion within a single species, will no doubt continue to fuel debate. Further, Schlegel et al. (2003) have also proposed that strains previously classified as *Streptococcus pasteurianus* be included within *Streptococcus galloyticus* with the proposed recognition of *Streptococcus galloyticus* subsp. *galloyticus*, subsp. *macedonicus*, and subsp. *pasteurianus*. On balance, the present authors would agree with two of the latter proposals with the exception of the case for *Streptococcus galloyticus* subsp. *pasteurianus* where the evidence for inclusion is less clear overall. *Streptococcus pasteurianus* is recognized as a separate species here.

In the often-quoted DNA–DNA hybridization study of bovis/equinus strains by Farrow et al. (1984), six similarity groups were delineated of which their group 3 has yet to be assigned to a named species. A representative strain of group 3 remained ungrouped in a study using ribotyping and DNA–DNA hybridization (Schlegel et al., 2000). Group 3 strains were isolated from raw milk and bovine mastitis cases and included strain NCDO 2127, previously described as an anomalous strain of *Streptococcus bovis* (Garvie and Bramley, 1979a).

Biochemical, physiological, and antigenic characteristics of species within the Bovis group are given in Table 131 and Table 134.

“Hyovaginalis group”. *Streptococcus hyovaginalis*, *Streptococcus thoralensis* (Devriese et al., 1997), and *Streptococcus pluranimallium* (Devriese et al., 1999) are isolated from the genital and respiratory tracts of domestic animals and birds and together comprise another species group by 16S rRNA gene sequence analysis.

Biochemical, physiological, and antigenic characteristics of species within the Hyovaginalis group are given in Table 131 and Table 135.

Species not assigned to recognized species groups

Included here are the species that i) remain ungrouped, forming separate lines of descent, ii) are only weakly affiliated to one of the main species groups already listed above, or iii) are associated phylogenetically with each other and may be regarded as members of additional, previously unnamed, species groups.

Biochemical, physiological, and antigenic characteristics of species included here are given in Table 131 and Table 135.

Streptococcus ovis (Collins et al., 2001), isolated from abscesses and other clinical conditions in sheep, and *Streptococcus hyointestinalis* (Devriese et al., 1988), from the intestines of pigs, both remain ungrouped by 16S rRNA gene sequence analysis. *Streptococcus minor* (Vancanney et al., 2004), a species from dogs, cats, and cattle, shares the highest 16S rRNA gene sequence homology with *Streptococcus ovis*.

Streptococcus acidominimus a generally non-pathogenic species associated with cattle, the pathogenic species from pig infections *Streptococcus suis*, together with a recently described species *Streptococcus entericus* isolated from cows with catarrhal enteritis (Vela et al., 2002) are closest neighbors to each other by 16S rRNA gene sequence analysis and form a loose species group. It should be noted however that in one study *Streptococcus suis* clustered together with the Pyogenic group by 16S rRNA gene sequence comparisons (Flint et al., 1999) and in Figure 123 of this chapter *Streptococcus acidominimus*, *Streptococcus suis*, *Streptococcus entericus*, and *Streptococcus gallinaceus* (Collins et al., 2002) are loosely associated.

Streptococcus ferus, although discussed previously within the context of the Mutans group, was originally isolated from the teeth of rats in sugar cane fields and has also been isolated from the tonsils and nasal conchae of piglets (Baele et al., 2003). In several studies this species appears peripheral to the Mutans species group (Gilmour et al., 1987; Schleifer et al., 1984; Whatmore and Whiley, 2002).

Identification of streptococci

Routine identification of isolates is mainly carried out by biochemical testing using commercially available test kits. However, the recent addition of new species and reporting of as-yet-unnamed genospecies means that problematic areas persist, notably between certain members of the Mitis species group (Kawamura et al., 1999; Kikuchi et al., 1995) and the Anginosus group (Whiley et al., 1999). Incorporation of chromogenic and fluorogenic substrates has greatly improved the resolving power of biochemical test schemes (Beighton et al., 1991; Freney et al., 1992; Kikuchi et al., 1995; Kilian et al., 1989b) and has led to the description of biovars or biotypes within several species which need to be accounted for in any proposed identification scheme (Beighton et al., 1991; Kilian et al., 1989b).

Alternative approaches have been used although none have been successfully applied to all the currently recognized species within the genus and are often useful within particular groups of species. Examples include whole cell polypeptide signatures by SDS-PAGE (Vandamme et al., 1998), pyrolysis-mass spectroscopy (Magee et al., 1997), Fourier transform infrared spectroscopy (van der Mei et al., 1993), monoclonal antibodies (De Soet and De Graaff, 1990), RFLP patterns, ribotyping (Rudney and Larson, 1993, 1994; Rudney et al., 1992) and PCR-based approaches (Alam et al., 1999; Li et al., 2001; Rudney and Larson, 1999; Truong et al., 2000). Sequence analysis of internal fragments of the manganese-dependent superoxide dismutase gene (*sodA_{int}*) has considerable potential as a gene-based approach to identification (Hoshino et al., 2005; Kawamura et al., 1999; Poyart et al., 1998; Whatmore and Whiley, 2002). Comparison between sequence similarities of 16S rRNA and *sodA_{int}* have shown the latter to constitute a more discriminating target, particularly for differentiating closely related species such as *Streptococcus pneumoniae*, *Streptococcus oralis*, and *Streptococcus mitis* within the Mitis group.

Recent analysis of the gene encoding the RNA subunit of endoribonuclease P, *mvpB*, has shown this to be potentially extremely useful for phylogenetic analysis and species discrimination (Tapp et al., 2003). A similar tree topology to that derived from 16S rRNA was obtained for *mvpB*. From this study it was concluded that a combined approach with both *mvpB* and 16S rRNA gene sequence data included in the analysis would result in a better phylogenetic hypothesis for the genus *Streptococcus*. More recently still, evidence has been published of two other genes (*dnaJ*, a member of the Hsp70 family and *gyrB*, which encodes the B-subunit protein of DNA gyrase (topoisomerase type II)) showing sufficient intra species divergence to be useful for identification and for discriminating between closely related streptococcal strains (Itoh et al., 2006). However, studies indicate that reliance on single gene sequence data for discrimination may result in a degree of misidentification of some strains due to previous horizontal gene transfer events,

notably within *Streptococcus sanguinis*, members of the anginosus species group, *Streptococcus mitis*, *Streptococcus parasanguinis*, *Streptococcus thoraltensis* and *Streptococcus criceti* (Hoshino et al., 2005; Itoh et al., 2006) with some authors recommending multilocus sequence analysis for optimal results (Hoshino et al., 2005).

The extent to which these transfer events have occurred remains to be elucidated and no doubt will be found to be much more frequent within some species than in others.

High-speed, microarray-based technology may provide the basis for streptococcal species identification in the not too distant future; the study by Tung et al. (2006) used a panel of immobilized oligonucleotide probes designed from rDNA intergenic spacer (ITS) regions to hybridize with PCR amplified ITS regions from strains with promising results.

Differential characteristics tables in this chapter. Differential biochemical tests for the streptococcal species are given in Table 132, Table 133, Table 134, and Table 135. The tests listed in each table have been selected from Table 131, i.e., from the collected data obtained from the literature, and do not form a working laboratory test scheme currently in use. Facklam (2002) has recently published a comprehensive set of tables for identifying the majority of the species described in this chapter. These are compiled from empirical data on relatively large numbers of human isolates examined (i.e., excluding animal and environmental isolates) at the Centers for Disease Control and Prevention (CDC), Atlanta, GA, USA, and as such may more accurately represent the properties of the human pathogens.

List of species of the genus *Streptococcus*

1. *Streptococcus pyogenes* Rosenbach 1884, 23^{AL}

py.og'en.es. Gr. n. *pyum* pus; Gr. v. *gennaio* beget; N.L. adj. *pyogenes* pus-producing.

Constitutes Lancefield's (1933) group A streptococci (GAS). Cells are spherical and 0.5–1.0 μm in diameter; ovoid forms may occur usually in older cultures. Growth in chains of short or moderate length, in clinical material may also occur in pairs with long chains frequently observed in broth cultures. After overnight growth on blood agar three major visual colony types exhibiting β- (complete) hemolysis may form: mucoid, matte (dehydrated mucoid) or glossy. The colony type depends largely on production of hyaluronic acid and on growth conditions. Growth does not occur at 10°C, 45°C, in the presence of 6.5% NaCl, at pH 9.6, or in the presence of 40% bile. The optimum temperature for growth is 37°C. Growth is enhanced by supplementation of broth with blood or serum. A chemically defined medium has been described (Ginsburg and Grossowicz, 1957).

Energy metabolism is fermentative and the final pH in glucose broth is 4.8–6.0. Acid is produced from *N*-acetylglucosamine, fructose, glucose, galactose, lactose, maltose, salicin, sucrose, methyl D-glucoside, and trehalose. Acid is not produced from adonitol, amygdalin, arbutin, arabinose, arabitol, dulcitol, cyclodextrin, erythritol, gluconate, melibiose, methyl D-mannoside, sorbose, xylose, inulin, mannitol, raffinose, ribose, sorbitol, tagatose, melezitose, methyl D-xyloside.

Strains produce alkaline phosphatase and pyrrolidonyl arylamidase. Few strains produce β-glucuronidase. Strains do not produce α-galactosidase, β-galactosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, or glycyL-tryptophan arylamidase.

Arginine is hydrolyzed. Hippurate is not hydrolyzed. Esculin hydrolysis is a variable characteristic. Acetoin (Voges-Proskauer reaction) is not produced. Urease is not produced.

Chemically the cell wall is made up of four constituents: protein, polysaccharide, and peptidoglycan are interwoven

rather than arranged in separate concentric layers as assumed previously; the fourth component is teichoic acid. Cell-wall thickness is about 20 nm. On the outer layer of the cell wall is a fringe of fimbriae, earlier referred to as a microcapsule. In some strains the cell wall with fimbriae can be enveloped by a capsule of hyaluronic acid. The rigidity of the cell wall is provided by peptidoglycan. The peptidoglycan molecule is of the A3 α -type, Lys-Ala₁₋₃ (Schleifer and Kandler, 1972), containing a polysaccharide polymer with tetrapeptide subunits that consist of L-Ala, D-is-Gln, L-Lys, and D-Ala cross-linked through a tetrapeptide bridge L-Ala-L-Ala located between the terminal D-Ala and the subterminal L-Lys. Some of the peptide subunits are not cross-linked, possess one more D-Ala and thus form pentapeptides. The cell-wall polysaccharide ("C" polysaccharide), which is specific to the species (group A-specific), is attached to the peptidoglycan by phosphate-containing bridges composed of one or more units having glycerol or glyceryl-rhamnoside as an organic moiety. The antigens of the protein layer are linked to the peptidoglycan by covalent bonds.

Cell-wall antigenic components. Antigenic components essential in classification and diagnosis are located mainly in the cell wall. The group A specificity of *Streptococcus pyogenes* is due to the presence of a polysaccharide, a multibranch structure and composed of N-acetylglucosamine and rhamnose in a molar ratio of 1:2.47, formula weight 8000. The immunodominant component of the polysaccharide is N-acetylglucosamine, located in the terminal positions of the molecule. Enzymic or chemical degradation of this compound unmasks the subterminal rhamnose-rhamnose structure, which is also antigenic and represents the immunodeterminant structure of the "group A-variant" polysaccharide.

M-protein type antigen. These are situated at the cell surface and constitute heat-stable, trypsin-sensitive protein fibrils extending some 50–60 nm from the cell wall at the N terminus, mainly of an alpha-helical coiled-coil structure with heptad repeats (Fischetti, 1989). From the end of the molecule distal to the cell surface the M protein consists of a non-helical region followed by a coiled-coil region extending for some 50 nm to the cell wall. A proline-glycine-rich region is located within the peptidoglycan with a short section of the coiled-coil rod within the group carbohydrate portion of the wall. The anchor region or membrane anchor segment extends through the cell membrane projecting a charged tail of six amino acid residues into the cytoplasm at the C terminus of the molecule. Those regions concerned with anchorage are highly conserved and non-immunogenic. Domains in the middle of the M protein sequence are weakly immunogenic, semiconserved tandemly repeated linear sequences. The region distal to the cell surface is hypervariable, immunogenic, and responsible for the type specificity of these organisms. Lysin-extracted M protein from GAS strains examined by Western blotting using a broadly cross-reactive monoclonal antibody demonstrated that different serotypes varied in size within the range 41–80 kDa with M6 strains isolated over a period of 40 years exhibiting a similar size range. This has been explained on the basis of the presence of extensive DNA sequence repeats leading to the likelihood of recombinational events or replicative slippage which

generate deletions and duplications within the M-protein gene (*emm*) leading to the production of different sized M proteins. More than 80 different serological M protein types within GAS are recognized, each of which is associated with specific T-antigen patterns, and together typing based on these antigens has formed a basis for epidemiological studies of GAS. M protein serotype identification was originally described by Lancefield (1928) in a tube precipitin test using standardized typing antisera. The approach is prone to difficulties and impracticalities including the cost of antiserum preparation for all known serotypes, raising antisera with sufficiently high titer against opacity-factor-positive strains, ambiguities in results, the expression of new and therefore untypable M proteins by strains, and untypability due to lack of reactivity with available antisera (Beall et al., 1997, 1996; Facklam, 1977). Rapid sequencing *emm*-specific PCR products (cycle sequencing) of the variable 5' *emm* gene regions in order to accurately deduce *emm* types corresponding to GAS M serotypes has proven to be a practical alternative approach. This has been shown to be effective in surveying the sequence variability of the M virulence protein and combined with T typing to be a useful tool for monitoring GAS diversity (Beall et al., 1997, 1996).

T-protein antigens. The T protein antigen is a relatively stable, trypsin-resistant surface protein of unknown function but is well defined in >95% of GAS, which provides a valuable additional strain characteristic for epidemiological studies. It is detected by the agglutination reaction using T-specific antisera. Although expressed independently of M proteins certain T proteins occur only in association with specific M serotypes (Beall et al., 1997, 1998) and in some instances more than one T protein is to be found on a single strain (Griffith, 1934). Strains producing untypable or no M protein may be typed by T protein typing. The T6 protein structural and sequence characteristics have been described in detail (Schneewind et al., 1990) and have revealed a protein consisting of 537 amino acids (M_r 57,675) with an N terminus exhibiting features of a typical signal peptide and a C terminus having a high degree of homology with the membrane anchor region of surface proteins found in other Gram-positive bacteria, including streptococcal M protein, wall-associated protein precursor wapA from *Streptococcus mutans* and staphylococcal protein A. The T6 protein appears to be a compact molecule, unlike the fibrillar M protein and despite the presence of typical cell-surface-associated C-terminal domains. It also contains an unusually high proportion (21%) of serine and threonine residues.

R protein antigens are also trypsin-resistant and occur in some strains of some types only. They have been found in some strains of Lancefield groups other than A (i.e., groups B, C, and G) and have been identified in four antigenic forms, the most common being R28 and R3 (Wilkinson, 1972). They have no known relation to virulence.

Pathogenicity. *Streptococcus pyogenes* (GAS) is an important human pathogen which colonizes the throat or skin, causing suppurative infections and non-suppurative sequelae. GAS cause pharyngitis, scarlet fever, impetigo, cellulitis including erysipelas septicemia, and invasive diseases including streptococcal "toxic-shock" syndrome and necrotizing fasciitis. Post-infection conditions include glomerulonephritis (a seasonal condition associated with skin strains), acute rheumatic fever

and rheumatic heart disease, and streptococcal reactive arthritis. Recent associations with GAS include Tourette's syndrome, tics, and movement and attention-deficit disorders (Cunningham, 2000). Patterns of association between M serotypes and clinical conditions are discernable: M serotypes including M types 1, 3, 5, 6, 14, 18, 19, and 24 are associated with throat infection and rheumatic fever, M types 2, 49, 57, 59, 60, and 61 with pyoderma and acute glomerulonephritis (Bisno, 1980, 1995; Stollerman, 1975, 1997) and several M serotypes are associated with invasive and toxic disease including M types 1, 3, 11, 12, and 28.

Extracellular surface molecules and virulence factors. GAS are surrounded with a hyaluronic acid capsule. This consists of glucuronic acid and *N*-acetylglucosamine repeating units, is weakly immunogenic due to antigenic similarity with the host and serves to make the bacterium resistant to phagocytosis. Experiments have shown non-encapsulated GAS mutants to be important in adherence in the pharynx through binding to CD44 on epithelial cells and also to be less virulent in a mouse skin model (Schrager et al., 1998, 1996).

M proteins function in the resistance of GAS to phagocytosis and are a primary virulence mechanism for survival in host tissues. This is at least in part due to the ability to bind plasma fibrinogen at the N terminal of the M protein which in turn effectively masks complement receptors on the streptococcal cell, thus preventing opsonization via the alternative complement pathway (Jacks-Weis et al., 1982). M proteins are divided into Class I and Class II based on their reaction with antibodies against the M protein C repeat region. Class I M protein serotypes have been reported to contain the surface-exposed epitope that reacts with antibodies against the C repeat region and are opacity factor negative while the opposite is true for Class II M proteins. Studies have shown an association between the presence of the Class I epitope and the production of rheumatic fever by strains (Bessen et al., 1989, 1990). Antibodies to the M protein confer immunity to infection but persons may be repeatedly infected with GAS of different M protein serotypes. Multilocus sequence typing (MLST) based on housekeeping genes has indicated that *Streptococcus pyogenes emm* types define clones or clonal complexes (Enright et al., 2001).

Lipoteichoic acid (LTA) an amphipathic molecule associated with M proteins is thought to account for around 60% of the adhesion of GAS to epithelial cells through interaction with fatty-acid binding sites on fibronectin and the epithelial cell surface. At least 11 adhesins have been proposed as contributors to GAS adhesion (Cunningham, 2000).

Plasminogen-binding proteins. These are thought to enhance the invasive potential of GAS by enabling movement through normal tissue barriers. Plasminogen-plasmin-binding proteins include extracellular streptokinase together with glyceraldehyde-3-phosphate dehydrogenase and enolase on the cell surface (Lottenberg et al., 1994; Pancholi and Fischetti, 1998; Winram and Lottenberg, 1996). Streptokinase has been associated with the pathogenesis of acute post-streptococcal glomerulonephritis (Holm et al., 1992).

Exotoxins and superantigens. Factors associated with invasive disease include pyrogenic exotoxins A, B, C, and F (Norrby-Teglund et al., 1994a), and streptococcal superantigen (Mollick et al., 1993; Norrby-Teglund et al., 1994a, 1994b). The latter include several recently described superantigens with strong

mitogenic activity (Kamezawa et al., 1997; Proft et al., 1999). The genes for pyrogenic exotoxins A and C are bacteriophage-encoded (Weeks and Ferretti, 1984) while exotoxin B (streptococcal proteinase) is chromosomally encoded. Exotoxins A, B, and C are probably important in the clinical manifestations of streptococcal toxic-shock syndrome. They are also responsible for the signs seen in cases of scarlet fever which include rash, strawberry tongue, and desquamation of the skin. Exotoxin B may contribute to survival of GAS in the host through increased resistance to phagocytosis and dissemination to organs (Lukomski et al., 1998).

C5a peptidase inhibits the recruitment of phagocytes to infection sites by cleavage and inactivation of the complement-derived chemotaxin C5a at its polymorphonucleargranulocyte (PMN)-binding site.

Streptolysin O (SLO) and streptolysin S (SLS) are among the GAS proteins involved in the breakdown of host tissues and cells and are able to lyse red blood cells, inhibit normal cell function, and destroy cells and tissues. Streptolysin O (SLO) is a secreted, oxygen-sensitive, thiol-activated, multi-subunit pore-forming toxin that interacts with cholesterol in the target cell. SLO is related to other thiol-activated cytotoxins such as pneumolysin, listeriolysin, and perfringolysin. Streptolysin S (SLS), like SLO, is produced by the majority of *Streptococcus pyogenes* strains, but in contrast is oxygen-stable. SLS is responsible for the β -hemolytic reaction around colonies on blood agar and has recently been shown to be encoded by a contiguous nine-gene locus (*sagA-sagI*) and sequence homology suggests SLS to be related to the bacteriocin family of microbial toxins (Nizet et al., 2000).

Genome analysis. The complete genome sequence for M1 strain SF370 (GenBank accession no. AE004092) has been published (Ferretti et al., 2001) and can be accessed at <http://www.genome.ou.edu/strep.html>. The 1.85-Mbp sequence contains 1752 predicted protein-encoding genes of which approximately one-third were reported to have no identifiable function. The remaining predicted genes fell into known function categories. Forty-six encoded virulence factor associated genes were reported reflecting the versatile pathogenic potential of the organism. Virulence-factor-encoding genes were scattered throughout the genome with the exception of those in the *emm* region although this region does not appear to have the organization typical of a pathogenicity island. A minimum of six new superantigen-like protein-encoding genes were found associated in many cases with mobile genetic elements. These proteins have at least one related protein in other Gram-positive species and thus suggest that they may have spread through horizontal gene transfer.

16S rRNA gene sequence analysis places this species within the Pyogenic species group.

DNA G+C content (mol%): 34.5–38.5 (method not stated); genome sequencing of M1 strain SF370 gave a mean G+C content of 38.5mol%.

Type strain: SF 130, ATCC 12344, NCTC 8198, DSM 20565, IMET 3002, T1.

GenBank accession number (16S rRNA gene): AB002521.

- 2. *Streptococcus acidominimus*** Ayers and Mudge 1922, 49^{AL}. a.ci.do.mi'ni.mus. L. adj. *acidus* sour, acid; L. sup. adj. *minimus* very least; N.L. masc. adj. *acidominimus* probably intended to mean that this organism produces the least amount of acid.

Cells are coccoid and occur in short chains. Growth on blood agar produces α -hemolysis. Grows only on complex media; minimal nutritional requirements are unknown. Growth does not occur in 6.5% NaCl-containing broth.

Strains are weakly fermentative with, in most cases, the final pH of carbohydrate-containing broths not falling below 6.0 making the determination of fermentation reactions difficult. Acid is produced from fructose, glucose, inulin, lactose, mannitol, and sucrose. Inulin and mannitol fermentation are both delayed. Adonitol, arabinose, D-cyclodextrin, dulcitol, erythritol, D- and L-fucose, methyl α -D-glucoside, 2- and 5-ketogluconates, gluconate, glycogen, inositol, lyxose, methyl α -D-mannoside, pullulan, rhamnose, ribose, L-sorbose, sorbitol, starch, trehalose, D-turanose, D- and L-xylose, xylitol, and methyl β -xyloside are not fermented. Leucine arylamidase, β -glucuronidase, pyrrolidonyl arylamidase, and alanine-phenylalanine-proline arylamidase are produced and 4-methyl-umbelliferyl (4MU)-phosphate, L-phenylalanine 7 amido-4-coumarin (AMC), and L-tryptophan AMC are hydrolyzed. Esculin is hydrolyzed but arginine and hippurate are not. Acetoin is not produced (Voges-Proskauer reaction). Alkaline phosphatase, β -mannosidase, and urease are not produced. No group-specific antigen has been demonstrated although reaction with group E antiserum has been reported previously (Wilson and Miles, 1975). The peptidoglycan type is Lys-Ser-Gly.

Strains are isolated from the bovine vagina, occasionally found on the skin of calves and in raw milk.

Similarities between the biochemical characteristics of this species and another member of the bovine genital flora, *Streptococcus plurianimalium*, have been investigated further by Devriese et al. (1999) who described improved identification criteria. Human isolates previously identified as *Streptococcus acidominimus* have been identified as *Facklamia soureki* (Facklam, 2002; LaClaire and Facklam, 2000). On the basis of whole-cell-derived polypeptide patterns by SDS-PAGE and 16S rRNA gene sequence comparisons, only a distant relationship was found between these two species. 16S rRNA analysis shows a loose association between *Streptococcus acidominimus*, *Streptococcus suis*, and *Streptococcus entericus* (Vela et al., 2002), although insufficient for them to be regarded as forming a species group.

DNA G+C content (mol%): 39.7 (T_m).

Type strain: ATCC 51725, DSM 20622, CUG 27296, CIP 82.4, LMG 17755, NCIMB 702025, NCTC 12957.

GenBank accession number (16S rRNA gene): X58301.

3. ***Streptococcus agalactiae*** Lehmann and Neumann 1896, 126^{AL} nom. cons. Opin. 8 Jud. Comm. 1954, 152.

a.ga.lac'ti.ae. Gr. n. *agalactia* want of milk; N.L. gen. n. *agalactiae* of *agalactia*.

Constitutes Lancefield's (1933) group B streptococci. Cells are spherical or ovoid, 0.6–1.2 μ m in diameter, occurring in chains of seldom less than four cells and frequently very long. Grows readily on blood agar and exhibits various types of hemolysis viz. typical β -hemolysis, but with a narrow zone, α -double zone, or no hemolysis. Some strains produce a characteristic opaque β -hemolysis, probably due to a soluble hemolysin with low hemolytic activity. This hemo-

lysin is different from both hemolysin O and S. The CAMP factor (Christie et al., 1944) produced by most group B streptococci binds to erythrocyte membrane altered by *Staphylococcus aureus* sphingomyelinase C and this results in enhanced lysis of erythrocytes. The CAMP factor is not totally specific for group B streptococci since it has also been found in group C, F, and G streptococci. Many strains can grow in media containing 40% bile. Some strains produce a yellow, orange, or brick-red pigment and production may be enhanced by addition of starch to the medium or by anaerobic incubation. Energy-yielding metabolism is fermentative with lactic acid constituting the major end product. The final pH in glucose broth is 4.2–4.8. Acid is produced from glucose, maltose, ribose, sucrose, and trehalose. Glycerol is fermented only aerobically. Acid from lactose and salicin are variable characteristics of this species. Acid is not produced from xylose, arabinose, raffinose, inulin, mannitol, or sorbitol. Strains produce alkaline phosphatase. Production of α -galactosidase and β -glucuronidase are variable characteristics. Pyrrolidonyl arylamidase is not produced. Acetoin (Voges-Proskauer reaction) has been reported both as a positive (Hardie, 1986a) and as a negative (Facklam, 2002) characteristic. Strains hydrolyze arginine and hippurate but not esculin.

The group B-specific polysaccharide antigen is composed of rhamnose, N-acetylglucosamine, and galactose (Curtis and Krause, 1964). Serological cross-reaction may be encountered with group G strains of streptococci due to the presence of rhamnose in the immunodominant portion of the polysaccharides. The peptidoglycan type is Lys-Ala₁₋₃(Ser).

Serotypes Ia, Ib, II, III, IV, V, and VI are recognized based on the capsular polysaccharide antigen and surface protein antigen. The serotype-specific capsular polysaccharides are essential for pathogenesis (Rubens et al., 1987). Types I, II, III, and V cause the majority of neonatal disease in humans (Baker, 2000; Blumberg et al., 1996). Serotype III strains are important in that they cause approximately 60% of invasive neonatal infections although they represent only approximately one-third of strains isolated from asymptotically colonized individuals (Baker and Barrett, 1974; Dillon et al., 1987).

Pathogenicity and virulence factors. Initially recognized as a cause of puerperal sepsis, in man group B streptococci can produce a variety of clinical conditions, some of them very serious. Disease can be invasive (normally defined as occurring when group B streptococci can be isolated from usually sterile site such as blood or cerebrospinal fluid) or non-invasive. Among pregnant women, infection ranges from mild urinary tract infection, amnionitis, and endometritis to sepsis and meningitis. Wound infections, cellulitis, fasciitis, endocarditis, and osteomyelitis may occur. In neonates and children may cause sepsis, pneumonia, meningitis, and pyelonephritis. Neonatal infections are divided into early and late-onset. In the former, occurrence is usually within the first 7 d of life where prolonged rupture of the membranes and chorioamnionitis features pneumonia, septicemia, or meningitis. The organism may be cultured from the mother's genital tract. Late-onset disease occurs in the first 3 months of life in otherwise healthy individuals and features septicemia, meningitis, and other foci of infection.

Fatality rates in both early and late-onset disease is around 5.8% of cases in the USA (Schuchat, 1998; Zangwill et al., 1992). In animals these organisms represent a highly contagious, economically important, obligate pathogen of the mammary gland and are one of the main causes of bovine mastitis. Sources of infection in man are the vaginal mucosa, the upper respiratory tract, urine, stool, and, in animals, milk and udder tissue. Virulence factors include the serotype-specific polysaccharide capsule, secreted enzymes hyaluronidase and C5a-peptidase, and a surface-associated beta-antigen protein able to bind human immunoglobulin A via the Fc portion. Experiments involving a gene knock-out mutant of the superoxide dismutase gene (*sodA*) in *Streptococcus agalactiae* demonstrated increased susceptibility to killing by macrophages and therefore indicated production of superoxide dismutase to be a contributing factor in virulence (Poyart et al., 2001). Restriction digest pattern (RDP) analysis of serotype III strains divided these into three separate lineages. RDP type III-3 strains differed in relatively circumscribed areas of the genome containing virulence genes *scpB* (C5A-ase), *lmb* (laminin-binding protein), *hyla* (hyaluronate lyase), and *cps* (putative cell-surface protein) (Bohnsack et al., 2002).

Taxonomic note and further comment: A non-hemolytic streptococcus pathogenic for fish, causing meningoencephalitis, was described and named *Streptococcus difficile* (Eldar et al., 1994). Despite relative binding ratios as low as 30.8 % with *Streptococcus agalactiae* in DNA–DNA hybridization experiments, later studies have placed these strains within *Streptococcus agalactiae*, belonging to the capsular type Ib (Berridge et al., 2001; Vandamme et al., 1997). RFLP analysis of whole-cell DNA probed with rRNA, fragments of genes encoding hyaluronidase, C5a peptidase, α -antigen, β -antigen, and two randomly selected genomic DNA fragments combined with data from MLEE studies and serotyping demonstrated *Streptococcus agalactiae* to be predominantly clonal in population structure, consisting of six lineages. Association was found between specific lineages and putative virulence factors but not with pathogenic potential (Hauge et al., 1996). It was notable that capsular serotype III strains divided into two distant evolutionary lineages, one of which lacked expression of hyaluronidase activity. MLEE analysis has also revealed two lineages within group III strains (Quentin et al., 1995).

Kilpper-Bälz and Schleifer (1984) demonstrated by DNA–DNA hybridization that a strain of Lancefield group M belonged to *Streptococcus agalactiae*.

16S rRNA sequencing places this species within the Pyogenic species group.

Genome analysis. The genomes of serotype V strain 2603 V/R (2.16 Mbp) (Tettelin et al., 2002) and serotype III strain NEM316 (ATCC 12403) (2.21 Mbp) (Glaser et al., 2002) have been sequenced, 2175 and 2118 predicted genes were identified, respectively, of which 61.3% (2603 V/R) and 62% (NEM 316) were assigned predicted functions, 28.6% (2603 V/R) and 25% (NEM 316) matched proteins of unknown function, and 10% (2603 V/R) and 9% (NEM 316) were unique to *Streptococcus agalactiae*.

These studies revealed extensive similarity with the human pathogenic streptococci *Streptococcus pyogenes* and *Streptococcus pneumoniae*. Many of the genes unique to *Streptococcus agalactiae* were associated with islands containing putative virulence genes and mobility elements supporting the acquisition of virulence traits via horizontal gene transfer.

Comparative genome hybridizations using microarray technology revealed considerable heterogeneity among strains, even of the same serotype, providing evidence that genetic acquisition, duplication, and reassortment events have provided this species with the diversity required for it to adapt to new environments and become a successful human pathogen (Tettelin et al., 2002).

DNA G+C content (mol%): 34 (T_m).

Type strain: G19, ATCC 13813, CCUG 4208, CIP 103227, DSM 2134, JCM 5671, LMG 14694 NCTC 8181.

GenBank accession number (16S rRNA gene): AB002479, AB175037, X59032.

4. **Streptococcus alactolyticus** Farrow, Krueze, Phillips, Bramley and Collins 1985, 224^{VP} (Effective publication: Farrow, Krueze, Phillips, Bramley and Collins 1984, 480.)

a.lac.to.ly'ti.cus. Gr. pref. *a* not; L. n. *lac lactis* milk; Gr. adj. *lyticus* dissolving; N.L. masc. adj. *alactolyticus* not milk-digesting.

Cells are cocci, occurring mostly in pairs or short chains. Colonies on blood agar are circular, smooth and entire, α -hemolytic, or non-hemolytic. Growth occurs at 45°C but not at 50°C or in 6.5% NaCl.

Chemo-organotroph: metabolism fermentative. Acid is produced from cellobiose, fructose, galactose, D-glucose, D-mannose, maltose, N-acetylglucosamine, D-raffinose, and sucrose. The majority of strains produce acid from melibiose and salicin. Acid is not produced from D-arabitol, L-arabitol, D-arabinose, L-arabinose, adonitol, cyclodextrin, 2-ketogluconate, 5-ketogluconate, dulcitol, erythritol, D-fucose, L-fucose, gluconate, glycerol, glycogen, inulin, lactose, D-lyxose, methyl α -D-mannoside, methyl β -xyloside, melezitose, pullulan, rhamnose, ribose, L-sorbose, sorbitol, D-tagatose, D-xylose, L-xylose, and xylitol. Acid production from amygdalin, arbutin, mannitol, methyl α -D-glucoside, starch, trehalose, and D-turanose are variable characteristics of this species. Strains produce urease, α -galactosidase, and leucine arylamidase. Alkaline phosphatase, arginine dehydrolase, β -galactosidase, β -glucuronidase, glycol tryptophan arylamidase, N-acetyl- β -glucosamine, and pyrrolidonyl arylamidase are not produced. Esculin is hydrolyzed but hippurate is not. Acetoin is produced (Voges–Proskauer reaction). Strains contain the Lancefield group D antigen. Occasionally strains belong to Lancefield group G (Robinson et al., 1988; Vandamme et al., 1999). Strains are isolated from the intestines of pigs and feces of chickens.

DNA G+C content (mol%): 39.9–41.3 (T_m).

Type strain: GP2, ATCC 43077, CCUG 27297, CIP 103244, DSM 20728, HAMBI 1719, LMG 14808, NCIMB 701091.

GenBank accession number (16S rRNA gene): AF201899, X58319.

Additional comments: Ureolytic streptococci isolated from pig feces and colons and with broadly similar biochemical characteristics were proposed as *Streptococcus intestinalis* (Robinson et al., 1988). Differences in phenotype between *Streptococcus intestinalis* and *Streptococcus alactolyticus* (Farrow and Collins, 1984a) included β -hemolysis on blood agar, possession of Lancefield group G antigen or ungroupable against Lancefield grouping antisera,

together with the inability to produce acid from mannitol and raffinose, for the former. In a subsequent study (Vandamme et al., 1999), strains representing both species were studied by biochemical testing and by comparison of whole-cell-derived polypeptide patterns by SDS-PAGE. These authors found strains of both species to be "phenotypically indistinguishable" and were unable to confirm the reported β -hemolysis given on blood agar or reaction of some strains to Lancefield group G antiserum and therefore concluded that the name *Streptococcus intestinalis* (Robinson et al., 1988) is a junior synonym of *Streptococcus alactolyticus*.

16S rRNA gene sequence analysis places *Streptococcus alactolyticus* within the Bovis species group.

5. ***Streptococcus anginosus*** (Andrewes and Horder 1906) Smith and Sherman 1938, 189^{Al}. emend. Whiley and Beighton 1991, 4 (Andrewes and Horder 1906, 367.)

an.gi.no'sus. N.L. adj. *anginosus* pertaining to angina.

Cells are cocci, small (0.5–1.0 μ m diameter), forming short chains. Colonies on blood (horse) agar are 0.5–2.0 mm in diameter, white or translucent, convex, and entire; some strains produce colonies that are 0.5–1.0 mm in diameter, white, and matte. Growth is reduced under aerobic conditions, is frequently enhanced by the addition of CO₂ with some strains requiring anaerobic incubation. Most strains give α -hemolysis or no hemolysis on blood agar with some strains giving β -hemolysis. No extra-cellular polysaccharides are produced on sucrose-containing medium. Strains produce alkaline phosphatase and leucine arylamidase. Virtually all strains produce β -glucosidase. α -Galactosidase and α -glucosidase are sometimes produced. Strains do not produce α -fucosidase, β -fucosidase, β -glucuronidase, β -*N*-acetylglucosaminidase, β -*N*-acetylgalactosaminidase, pyrrolidonyl arylamidase, or sialidase. Over 50% of strains have been reported to produce β -galactosidase when incubated in CO₂ (Ahmet et al., 1995). Acid is produced from amygdalin, arbutin, maltose, and glucose, and is frequently produced from cellobiose, lactose, salicin, and trehalose. Strains of this species that are able to produce acid from mannitol, raffinose, and melibiose are frequently associated with the human female genital tract. Strains do not ferment arabinose, glycerol, glycogen inulin, ribose, sorbitol, or tagatose. Arginine and esculin are hydrolyzed but urea and hippurate are not. Acetoin is produced (Voges–Proskauer reaction). Hydrogen peroxide production is sometimes detected. Hyaluronidase is produced by a few strains only. The majority of strains are either serologically ungroupable or belong to Lancefield group F although strains can possess the Lancefield group A, C, or G antigen. The cell-wall peptidoglycan type is Lys–Ala₁₋₃. Strains are isolated from the human oral cavity, upper respiratory tract, and vagina. Strains of this species are isolated from a variety of human purulent infections.

DNA G+C content (mol%): 38–40 (T_m).

Type strain: Havill III, ATCC 33397, CCUG 27298, CCUG 35776, CIP 102921, DSM 20563, HAMBI 1525, LMG 14502, NCTC 10713.

GenBank accession number (16S rRNA gene): AF104678, X58309.

Additional comments: The often confusing history of the classification of strains currently designated *Streptococcus anginosus* together with the collection of closely related strains variously referred to in the past as "*Streptococcus milleri*" (Guthof, 1956), "*Streptococcus MG*" (Mirick et al., 1944), the minute-colony-forming streptococci of Lancefield groups F and G (Bliss, 1937; Long and Bliss, 1934), hemolytic and non-hemolytic isolates possessing the "type antigens" of Lancefield group F (Ottens and Winkler, 1962), *Streptococcus intermedius* (Holdeman and Moore, 1974), *Streptococcus anginosus* (Andrewes and Horder, 1906; Deibel and Seeley, 1974), *Streptococcus constellatus* (Holdeman and Moore, 1974), "*Streptococcus anginosus–constellatus*", "*Streptococcus MG–intermedius*" (Facklam, 1977), the "*Streptococcus milleri*-group" (Gossling, 1988), and *Streptococcus anginosus*, *Streptococcus constellatus*, and *Streptococcus intermedius* (Facklam, 1984, 1985), is detailed in the previous section on the Anginosus species group.

DNA–DNA hybridization studies have demonstrated centers of variation within strains designated *Streptococcus anginosus*, requiring further characterization before formal taxonomic proposals can be made (Whiley et al., 1999).

16S rRNA gene sequence analysis places *Streptococcus anginosus* within the Anginosus species group.

6. ***Streptococcus australis*** Willcox, Zhu and Knox 2001, 1281^{VP}

aus.tra'lis. L. masc. adj. *australis* of the south, southern, relating to the region in which the organism was isolated.

Cells are cocci, forming short chains. Colonies are approximately 0.5–1.0 mm on blood agar plates and are α -hemolytic on Columbia blood (sheep) agar. Facultatively anaerobic. The following biochemical characteristics were obtained using Rapid ID32 Strep kits (bioMerieux). All strains produce alkaline phosphatase, alanine-phenylalanine-proline arylamidase, and glycyl-tryptophan arylamidase, produced acid from lactose, maltose, pullulan, and sucrose, and hydrolyzed arginine. No strains are able to produce acetoin (Voges–Proskauer reaction), α -galactosidase, β -glucosidase, β -glucuronidase, methyl β -D-glucopyranoside, pyroglutamic acid arylamidase, *N*-acetyl- β -glucosaminidase, β -mannosidase, or urease. β -Galactosidase production is dependent on the substrate used: 2-naphthyl β -D-galactopyranoside (–), or *p*-nitrophenyl β -D-galactopyranoside (+). Strains are unable to produce acid from L-arabinose, D-arabinose, glycogen, mannitol, melibiose, melezitose, methyl β -D-glucopyranoside, raffinose, ribose, sorbitol, tagatose, or trehalose. Hippurate is not hydrolyzed. Neuraminidase is not produced. Strains have been isolated from the saliva of healthy children between 8 and 12 years but not from adults. The peptidoglycan type is Lys–Ala–Gly. Strains do not react with Lancefield grouping antisera.

16S rRNA gene sequence analysis places this species within the Mitis species group.

DNA G+C content (mol%): 43.5 (T_m) (for the type strain AI-1^T).

Type strain: AI-1, ATCC 700641, CIP 107167, NCTC 13166.

GenBank accession number (16S rRNA gene): AF184974, AY485604.

7. ***Streptococcus canis*** Devriese, Hommez, Kilpper-Bälz and Schleifer 1986, 424^{VP}

ca'nis. L. gen. n. *canis* of a dog.

Cells are cocci, occurring in pairs or short chains. Wide zones of β -hemolysis produced on blood (sheep) agar and colonies are large, circular with entire edges. A precipitate and clear supernatant are formed in broth cultures. CAMP factor-negative. Growth does not occur in the presence of 6.5% NaCl or 40% bile. Strains produce acid from *N*-acetylglucosamine, *D*-fructose, galactose, *D*-glucose, lactose, maltose, *D*-mannose, ribose, salicin, starch, and sucrose. Acid is not produced from adonitol, amygdalin, *L*-arabinose, *D*-arabinose, *D*-arabitol, dulcitol, erythritol, *D*-fucose, *L*-fucose, β -gentiobiose, gluconate, 2-ketogluconate, inositol, inulin, *D*-lyxose, mannitol, methyl α -*D*-mannoside, melezitose, melibiose, *D*-raffinose, rhamnose, sorbitol, *L*-sorbitose, *D*-tagatose, *D*-turranose, xylitol, *D*-xylose, *L*-xylose, or methyl β -xyloside. Acid production from methyl *D*-glucoside is a variable characteristic of this species. A few strains produce acid from trehalose and some give weak acid from glycogen. Strains produce *L*-aminopeptidase, alkaline phosphatase, leucine arylamidase, and arginine dehydrolase. Most strains produce β -galactosidase, a few produce hyaluronidase and β -glucuronidase. α -Galactosidase is a variable characteristic of this species. Strains do not produce pyrrolidonyl arylamidase or acetoin (Voges-Proskauer reaction) and do not hydrolyze hippurate, fibrinolysin, tyrosine, or starch. Esculin and arginine are hydrolyzed.

The peptidoglycan type is Lys-Thr-Gly. Strains belong to Lancefield group G. Strains are isolated from the skin, upper respiratory tract, anus, and genitals of dogs, cow udders, and the genital tracts of female cats. Responsible for infections in animals including toxic shock and necrotizing fasciitis in dogs. *Streptococcus pyogenes* has been isolated from human infections (wound infection and bacteremia) and it has been speculated that the incidence of this streptococcus in the human population may be underestimated (Whatmore et al., 2001).

16S rRNA gene sequence analysis places this species within the Pyogenic species group.

DNA G+C content (mol%): 39–40 (T_m).

Type strain: STR-T1, ATCC 43496, CCUG 27661, CIP 103223, DSM 20715, LMG 15890.

GenBank accession number (16S rRNA gene): AB002483, X59061.

8. ***Streptococcus constellatus*** (Prévot 1924) Holdeman and Moore 1974, 266^{AL} emend. Whiley, Hall, Hardie and Beighton 1999, 1448 ("*Diplococcus constellatus*" Prévot (1924).)

con.stel.la'tus. L. adj. *constellatus* studded with stars.

Cells are cocci, 0.5–1.0 μ m in diameter, forming short chains. Colonies on blood agar are 0.5–2.0 mm in diameter, white or translucent, convex, and entire. Some strains produce colonies that are 0.5–1.0 mm diameter, white, and matte. Growth is reduced under aerobic conditions and is frequently enhanced by the addition of CO₂. Some strains require anaerobic conditions for growth. Alkaline phos-

phatase and leucine arylamidase are produced. Most strains produce α -glucosidase. A few produce β -galactosidase, β -glucosidase, β -fucosidase, β -*N*-acetylgalactosaminidase, and β -*N*-acetylglucosaminidase. Pyrrolidonyl arylamidase, α -galactosidase, β -glucuronidase, α -*L*-fucosidase, and sialidase are not produced. Arginine and esculin are hydrolyzed but urea and hippurate are not. Few strains produce hydrogen peroxide. Most produce hyaluronidase, but neuraminidase (sialidase) is not produced. Acetoin is produced (Voges-Proskauer reaction). Acid is produced from glucose and *N*-acetylglucosamine and is frequently produced from salicin and trehalose. Acid production from lactose and amygdalin are variable characteristics of this species. A few strains produce acid from arbutin, cellobiose, mannitol, melibiose, and raffinose. Strains do not produce acid from arabinose, glycerol, inulin, or sorbitol.

Strains are frequently either β -hemolytic and of Lancefield group F or non-hemolytic (non- β) and serologically ungroupable using Lancefield grouping antisera. Strains may also possess the Lancefield group A, C, or G antigens. Habitats are the oral cavity and upper respiratory tract in man. Strains are isolated from purulent infections in man.

For a description of the often confusing history of the classification of strains currently designated *Streptococcus constellatus* together with closely related strains, see section on the Anginosus species group.

Recently *Streptococcus constellatus* was divided into subsp. *pharyngis* and subsp. *constellatus* based on DNA-DNA hybridization and which display different clinical associations (Whiley et al., 1999).

8a. ***Streptococcus constellatus* subsp. *constellatus*** Whiley, Hall, Hardie and Beighton 1999, 1448^{VP}

The description of this subspecies corresponds to that given above for *Streptococcus constellatus* with the exception that β -*N*-acetylglucosaminidase, β -*N*-acetylgalactosaminidase, β -*D*-glucosidase, β -galactosidase, and β -*D*-fucosidase are not produced. Lactose is sometimes fermented.

Strains of *Streptococcus constellatus* subsp. *constellatus* are recovered from a wide range of anatomical and infection sites compared to subsp. *pharyngis*.

DNA G+C content (mol%): 37–38 (T_m).

Type strain: ATCC 27823, CCUG 24889, CIP 103247, DSM 20575, LMG 14507, NCIMB 702226, NCTC 11325.

GenBank accession number (16S rRNA gene): AF104676, X58310.

8b. ***Streptococcus constellatus* subsp. *pharyngis*** Whiley, Hall, Hardie and Beighton 1999, 1448^{VP}

pha.ryn'gis. Gr. n. *pharynx* throat; N.L. gen. n. *pharyngis* of the throat.

Strains are β -hemolytic and belong to Lancefield group C. β -*N*-acetylgalactosaminidase, β -*D*-fucosidase, β -galactosidase, and α - and β -glucosidases are produced. The majority of strains produce β -*N*-acetylglucosaminidase. Strains do not produce α -galactosidase, β -glucuronidase, pyrrolidonyl arylamidase, or sialidase (neuraminidase). Acid is produced from amygdalin, arbutin, lactose, glucose, and β -*D*-*N*-acetylglucosamine. Acid is not produced from inulin, mannitol, melibiose, raffinose, or sorbitol. The

majority of strains produce hyaluronidase. Strains exhibit a predilection for sites within the throat and have mainly been isolated from human throat infections (pharyngitis) with one strain from an abdominal mass.

DNA G+C content (mol%): 35–37 (T_m).

Type strain: MM9889a, NCTC 13122.

GenBank accession number (16S rRNA gene): AY309095.

9. ***Streptococcus criceti*** corrig. Coykendall 1977, 28^{AL}

cri'ce.ti. N.L. gen. n. *criceti* of the hamster.

Cells are coccoid, 0.5 μ m in diameter, occurring in pairs or chains. Colonies on sucrose agar are approximately 1 mm in diameter, rough, heaped, often glossy and may be surrounded by liquid containing soluble extracellular glucan. Colonies on blood agar are 2–3 mm in diameter, smooth, and round with the majority of strains producing no hemolysis. Some strains produce α -hemolysis or are non-hemolytic. Strains are facultatively anaerobic, growing best in an atmosphere with reduced O₂ and added CO₂. Human isolates are susceptible to 2U/ml bacitracin. Acid is produced from *N*-acetylglucosamine, amygdalin, arbutin, cellobiose, galactose, glucose, inulin, lactose, maltose, mannitol, mannose, melibiose, raffinose, salicin, sorbitol, and sucrose. Acid is not produced from arabinose, glycerol, glycogen, melezitose, methyl β -glucoside, rhamnose, ribose, starch, or xylose. Acid from lactose and trehalose are variable characteristics of this species. The final pH in glucose broth is 4.1–4.2. Ammonia is not produced from arginine. Acetoin is produced (Voges–Proskauer reaction). Esculin is usually hydrolyzed but hippurate and starch are not. Extracellular polysaccharide is produced from sucrose-containing medium. Hydrogen peroxide is not produced. Most strains possess the *a* antigen of the serological scheme of Bratthall (1970), but some rat isolates lack it (Coykendall, 1977). The peptidoglycan type is Lys–Thr–Ala.

Strains have been isolated from the mouth of hamsters, wild rats, and, occasionally, man.

16S rRNA gene sequence analysis places this species within the Mutans species group of cariogenic streptococci.

DNA G+C content (mol%): 42–44 (T_m).

Type strain: HS6, NCTC 12277, ATCC 19642, CCUG 27300, CIP 102510, DSM 20562, HAMBI 1517, LMG 14508.

GenBank accession number (16S rRNA gene): AJ420198, X58305.

Additional comments: *Streptococcus criceti* is the corrected name for strains previously called *Streptococcus cricetus* by Coykendall (1977) (Trüper and de Clari, 1998).

10. ***Streptococcus cristatus*** corrig. Handley, Coykendall, Beighton, Hardie and Whiley 1991, 546^{VP}

cris'ta.tus. L. adj. *cristatus* ornamented by a crest.

Cells are coccoid, approximately 1 μ m in diameter, and grow in chains. Cells have tufts of fibrils in a lateral position. Colonies grown for 2 d at 37°C on blood agar are grayish, white, glossy, entire, 1–2 mm in diameter, and are α -hemolytic. Glucan production on sucrose-containing medium is a variable characteristic. Acid is produced from arbutin, maltose, trehalose, and *N*-acetylglucosamine. The majority of strains produce acid from galactose and lactose

but not from lactulose, or pullulan. Acid is not produced from amygdalin, arabinose, inulin, mannitol, melibiose, melezitose, raffinose, rhamnose, ribose, sorbose, sorbitol, tagatose, turanose, or xylitol. Strains are able to produce β -*N*-acetylglucosaminidase, β -*N*-acetylgalactosaminidase, and α -fucosidase. Strains do not produce α -arabinosidase, β -*D*-fucosidase, α -galactosidase, α -glucosidase, β -glucosidase, sialidase (neuraminidase), or alkaline phosphatase. Some strains produce β -galactosidase. Arginine is hydrolyzed by the majority of strains but esculin and urea are not. Acetoin is not produced (Voges–Proskauer reaction). Hydrogen peroxide is not produced. Salivary amylase is bound.

16S rRNA gene sequence analysis places this species within the Mitis species group.

DNA G+C content (mol%): 42.6–43.2 (T_m).

Type strain: CR311, ATCC 51100, CCUG 33481, CIP 105954, DSM 8249, LMG 16320, NCTC 12479.

GenBank accession number (16S rRNA gene): AB008313, AY188347, AY584476.

Additional comments: *Streptococcus cristatus* is naturally transformable, is involved in “corn cob” formation within dental plaque in association with *Fusobacterium nucleatum* (Correia et al., 1996), and may play a significant role *in vivo* in the establishment of periodontopathic plaque through its ability to adhere to several periodontal pathogens (Yao et al., 1996).

Isolated from human throats and oral cavities.

Streptococcus cristatus is the corrected name for strains previously called *Streptococcus crista* by Handley et al. (1991) (Trüper and de Clari, 1997).

11. ***Streptococcus devriesei*** Collins, Lundström, Welinder-Olsson, Hansson, Wattle, Hudson and Falsen 2004, 631^{VP} (Effective publication: Collins, Lundström, Welinder-Olsson, Hansson, Wattle, Hudson and Falsen 2004, 150.)

de.vries.e.i. N.L. gen. n. *devriesei* of Devriese, to honor Luc A. Devriese, a contemporary Belgian microbiologist, in recognition of his outstanding contributions to the taxonomy of streptococci and related organisms.

Strains are cocci, occurring singly, in pairs or short chains. α -hemolysis is formed on blood agar. Acid is produced (NVI Streptococci kit) from esculin, inulin, lactose, mannitol, raffinose, sucrose, salicin, and trehalose; sorbitol is a variable characteristic; glycerine is not fermented. Acid is produced (API 50 CH kit) from amygdalin, *D*-arabitol, arbutin, cellobiose, esculin, fructose, galactose, β -gentiobiose, glucose, gluconate, lactose, maltose, mannose, melibiose, *D*-raffinose, salicin, sorbitol, sucrose, *D*-tagatose, and trehalose; no acid is formed from adonitol, *D*- or *L*-arabinose, 2-ketogluconate, 5-ketogluconate, erythritol, *D*- or *L*-fucose, glycerol, glycogen, inositol, *D*-lyxose, melezitose, methyl α -*D*-glucoside, methyl α -*D*-mannoside, methyl β -xyloside, *N*-acetylglucosamine, *D*-ribose, rhamnose, starch, *D*-turanose, xylitol, or *D*- or *L*-xylose; some strains ferment dulcitol, inulin, and *L*-sorbose. Acid is produced (API Rapid ID 32 Strep system) from lactose, maltose, mannitol, melibiose, methyl β -*D*-glucopyranoside, *D*-raffinose, sorbitol, tagatose, trehalose, and sucrose; acid is not produced from *D*-arabitol, *L*-arabinose, cyclodextrin, glycogen, melezitose, *N*-acetylglucosamine, pullulan, or *D*-ribose. Alanil-phenylalanine-proline arylamidase, α -galactosidase,

β -glucosidase, β -mannosidase (weak) are produced. Strains do not produce alkaline phosphatase, arginine dihydrolyase, β -galactosidase, β -glucuronidase, glycyl-tryptophan arylamidase, pyroglutamic acid arylamidase, or urease. Acetoin is produced (Voges–Proskauer reaction). Nitrate is not reduced.

Isolated from the teeth of horses.

16S rRNA gene sequence analysis places this species within the Mutans group of streptococci.

Type strain: CCUG 47155, CIP 107809.

DNA G+C content (mol%): 42 (HPLC).

GenBank accession number (16S rRNA gene): AJ564067.

12. ***Streptococcus didelphis*** Rurangirwa, Teitzel, Cui, French, McDonough and Besser 2000, 765^{VP}

di.del'phis. N.L. Gr.-derived n. *Didelphis* taxonomic genus name of the American opossum; N.L. gen. n. *didelphis* of the opossum.

Strains are coccoid, forming chains in broth culture. Growth on Columbia blood agar (sheep blood) produces small, translucent colonies giving β -hemolysis. Does not grow on MacConkey agar. On isolation on blood agar and initial passages on non-blood-containing media, vigorous catalase activity is detected but is lost after several passages. All strains produce acid from ribose and trehalose. The majority are unable to produce acid from lactose and raffinose. Strains are unable to produce acid from arabinose, glycogen, inulin, mannitol, salicin, or sorbitol. Alkaline phosphatase, β -glucuronidase, and leucine arylamidase are produced. α -Galactosidase production is a variable characteristic of this species. β -Galactosidase and pyrrolidonyl arylamidase are not produced. Hippurate is hydrolyzed but esculin is not. The majority of strains hydrolyze arginine. Acetoin is not produced (Voges–Proskauer reaction). Strains are non-groupable with Lancefield antisera. Long-chain fatty acid methyl ester analysis has demonstrated the presence of 12:0, 14:0, 15:0, 16:1 ω 9 c , 16:1 ω 5 c , 16:0, 17:0 anteiso, 17:1 ω 8 c , 17:0, 18:1 ω 9 c , 18:1 ω 7 c , 18:0, 20:4 ω 6,9,12, 15 c , summed feature 3 (16:1 ω 7 c /15 iso 2-OH and 15:0 iso 2-OH/16:1 ω 7 c) and summed feature 5 (18:2 ω 6, 9 c /18:0 anteiso and 18:0 anteiso/18:2 ω 6,9 c), where summed feature are groups of FAMES that cannot be resolved by G+C analysis due to peak overlap.

Streptococcus didelphis is isolated from the tissues of opossums with suppurative dermatitis and hepatic fibrosis.

16S rRNA gene sequence analysis demonstrated that the closest relative of *Streptococcus didelphis* is *Streptococcus dysgalactiae* within the Pyogenic species group.

Type strain: WADDL 94-11374-1, ATCC 700828, CCUG 45419, CIP 106980.

DNA G+C content (mol%): not determined.

GenBank accession number (16S rRNA gene): AF176103.

13. ***Streptococcus downei*** Whaley, Russell, Hardie and Beighton 1988, 27^{VP}

down.e.i. N.L. gen. n. *downei* Downe, the village in Kent, United Kingdom, where the type strain was isolated.

Cells are coccoid, forming chains. Colonies on 5% sucrose agar (TYC) are large, 2–3 mm in diameter, white, and conical with an erose edge surrounded by a distinct halo. Colonies on Mitis-Salivarius agar are small, dark blue,

crinkled, up to 1 mm in diameter, with an erose edge that slightly pits the agar, but are easily dislodged though difficult to disperse. No growth occurs at 45°C, at pH 9.6, or in the presence of 6.5% NaCl. Variable growth is obtained on 10% and 40% bile agar. Acid is produced from glucose, sucrose, fructose, galactose, mannose, mannitol, lactose, maltose, salicin, trehalose, and inulin. Acid is not produced from adonitol, melezitose, melibiose, sorbose, cellobiose, glycogen, soluble starch, inositol, xylitol, sorbitol, glycerol, arabinose, pullulan, or raffinose. Starch, esculin, and hippurate are not hydrolyzed. Ammonia is not produced from arginine. Hydrogen peroxide and intracellular polysaccharides are not produced. Extracellular polysaccharide is produced on sucrose agar and in sucrose broth although could not be demonstrated by ethanol precipitation in the original description (Beighton et al., 1981). Acetoin is produced (Voges–Proskauer reaction). Strains possess a serologically distinct polysaccharide antigen designated h (Beighton et al., 1981). The peptidoglycan type is Lys–Thr–Ala. Cellular long-chain fatty acid composition consists of major amounts of hexadecanoic (C_{16:0}, palmitic), octadecanoic (C_{18:0}, stearic), octadecenoic (C_{18:1}, vaccenic), and eicosenoic (C_{20:1}) acids together with minor amounts of tetradecenoic (C_{14:0}, myristic), hexadecenoic (C_{16:1}, palmitoleic), octadecenoic (C_{18:1}, oleic), eicosanoic (C_{20:0}, arachidic), and cyclopropane (*cis*-9,10-methyleneoctadecanoic) acids. Strains have been isolated from the dental plaque of monkeys (*Macaca fascicularis*) and are cariogenic when monoassociated with germ-free rats.

16S rRNA gene sequence analysis places this species within the Mutans species group.

DNA G+C content (mol%): 41–42 (T_m).

Type strain: MFe28, ATCC 33748, CCUG 24890, CIP 103222, DSM 5635, LMG 14514, NCTC 11391.

GenBank accession number (16S rRNA gene): AJ, 420200, AY188350, X58306.

14. ***Streptococcus dysgalactiae*** (*ex* Diernhofer 1932) Garvie, Farrow and Bramley 1983, 404^{VP}

dys.ga.lac'ti.ae. Gr. pref. *dys* ill, hard; Gr. n. *galactia* pertaining to milk; N.L. n. *dysgalactia* loss or impairment of milk secretion; N.L. gen. n. *dysgalactiae* of dysgalactia.

Cells are coccoid or ovoid occurring in pairs or chains. Strains may produce α , β , or no hemolysis on blood agar. The optimum temperature for growth is approximately 37°C. Growth does not occur at 10°C or at 45°C, in 6.5% NaCl, or 0.1% methylene blue milk, or at pH 9.6. Does not survive heating at 60°C for 30 min. Chemo-organotroph: metabolism fermentative. Growth occurs only on complex media. Acid is produced from glucose, maltose, ribose, starch, sucrose, and trehalose. Most strains produce acid from glycerol when incubated aerobically. A few strains produce acid from sorbitol. Variable results are obtained for acid production from glycogen, lactose, and salicin. Acid is not produced from arabinose, inulin, mannitol, or raffinose. The majority of strains do not hydrolyze hippurate. Esculin hydrolysis is a variable characteristic. Most strains produce hyaluronidase. Arginine is hydrolyzed. Acetoin is not produced (Voges–Proskauer reaction). Leucine arylamidase and β -D-glucuronidase are produced. Alkaline phosphatase, α -galactosidase, and pyrrolidonyl arylamidase

are not produced. β -Galactosidase is a variable characteristic of the species. Major non-hydroxylated long-chain fatty acids are hexadecanoic ($C_{16:0}$), and octadecenoic ($C_{18:1}$) acids; cyclopropane-ring-containing fatty acids are absent. Menaquinones are not produced. Peptidoglycan contains lysine as diamino acid (type Lys-Ala₁₋₃). Strains may react with Lancefield group C, G, or L (and occasionally A) antisera.

Habitats include the respiratory and genital tracts of various animals, miscellaneous infections of humans and domestic animals. Strains isolated from humans share several virulence determinants in common with *Streptococcus pyogenes* (Efstratiou, 1997), including M protein antigens (Efstratiou, 1997; Lawal et al., 1982; Maxted and Potter, 1967), C5a peptidase (Chen and Cleary, 1990), a hyaluronic acid capsule (Balke et al., 1985), production of streptokinase and streptolysin O (Okumura et al., 1994) and the ability to bind mammalian proteins (Tewodoros and Kronvall, 1993).

16S rRNA gene sequence analysis places *Streptococcus dysgalactiae* within the Pyogenic species group.

DNA G+C content (mol%): 38.1–40.2 (T_m).

Additional comments: The confused taxonomic history of strains included here is summarized in the section describing the Pyogenic species group. The weight of evidence supports the inclusion of strains previously designated *Streptococcus dysgalactiae* and *Streptococcus equisimilis* into a single species, each with subspecies status, i.e., *Streptococcus dysgalactiae* subsp. *dysgalactiae* and *Streptococcus dysgalactiae* subsp. *equisimilis*, respectively (Vandamme et al., 1996).

14a. ***Streptococcus dysgalactiae* subsp. *dysgalactiae*** Vandamme, Pot, Falsen, Kersters and Devriese 1996, 780^{VP}

The description for *Streptococcus dysgalactiae* subsp. *dysgalactiae* is as given above for the species with the exception that strains are α -hemolytic and non-hemolytic, isolated commonly from bovine sources. Strains may react with Lancefield group C antiserum. Streptokinase activity on human plasminogen and proteolytic activity do not occur. Hippurate is not hydrolyzed. Glycogen is not fermented. β -D-Galactosidase and α -L-glutamate aminopeptidase are not produced. Sorbitol fermentation is a variable characteristic of this subspecies. Bacitracin sensitive. Strains are commonly associated with bovine mastitis and are isolated from the bovine vagina.

DNA G+C content (mol%): 38.5–39.8 (T_m).

Type strain: 134, ATCC 43078, CCUG 27301, CIP 102914, DSM 20662, LMG 15885, LMG 16023, NCIMB 702023.

GenBank accession number (16S rRNA gene): AB002485, AY584478, X59030.

14b. ***Streptococcus dysgalactiae* subsp. *equisimilis*** Vandamme, Pot, Falsen, Kersters and Devriese 1996, 780^{VP}

The description for *Streptococcus dysgalactiae* subsp. *equisimilis* is as given above for the species with the exception that strains are β -hemolytic and may react with Lancefield group A, C, G, or L antisera. Streptokinase activity occurs on human plasminogen and proteolytic activity on human fibrin is a variable characteristic of this subspecies. Hippu-

rate hydrolysis is a variable characteristic (see below). Acid is not produced from sorbitol. Glycogen fermentation is a variable characteristic. α -L-glutamate aminopeptidase and β -D-galactosidase are produced. Bacitracin sensitivity is variable.

Vieira et al. (1998) characterized *Streptococcus dysgalactiae* subsp. *equisimilis* strains as follows: Human groups C and G (glycogen fermentation and hippurate hydrolysis both negative, proteolytic activity observed on human fibrin, bacitracin-resistant); Animal group C (differing from human group C strains in being able to ferment glycogen, but unable to produce proteolytic activity on human fibrin); group L (as animal group C strains, but with hippurate hydrolysis a variable characteristic and strains sensitive to bacitracin).

Recently, workers have isolated Lancefield group A-antigen-carrying strains of *Streptococcus dysgalactiae* subsp. *equisimilis* from human blood (Bert and Lambert-Zechovsky, 1997; Brandt et al., 1999).

DNA G+C content (mol%): 38.1–40.2 (T_m).

Type strain: CCUG 36637, CCUG 36913, CIP 105120, LMG 16026, NCIMB 701356, NCTC 4540.

GenBank accession number (16S rRNA gene): AB008926.

15. ***Streptococcus entericus*** Vela, Fernández, Lawson, Latre, Falsen, Domínguez, Collins and Fernández-Garayzábal 2002, 668^{VP}

en.te'ri.cus. N.L. adj. *entericus* from Gr. n. *enteron* gut, pertaining to the gut.

Cells are coccoid, arranged in short chains. Colonies after 24 h incubation on blood agar are circular and 1 mm in diameter, and produce α -hemolysis. Growth occurs at 30°C, at 37°C, and at pH 9.6, but not at 10°C, 45°C, or in broth containing 6.5% NaCl. Bile-esculin test is negative.

Acid is produced from starch, cyclodextrin, glycogen, lactose, maltose, trehalose, sucrose, and methyl β -D-glucopyranoside. Acid is not produced from D-arabitol, L-arabinose, inulin, mannitol, melibiose, melezitose, pululan, ribose, raffinose, sorbitol, or tagatose. Produces β -glucosidase, leucine arylamidase, β -galactosidase, alanine-phenylalanine-proline arylamidase, and glycyl-tryptophan arylamidase. Does not produce β -glucuronidase, α -galactosidase, alkaline phosphatase, pyroglutamic acid arylamidase, N-acetyl- β -glucosaminidase, or β -mannosidase.

Esculin is hydrolyzed but arginine, hippurate, and urea are not. Acetoin is not produced (Voges-Proskauer reaction).

The single strain examined reacts with Lancefield group D antiserum. Vancomycin-sensitive.

At the time of writing only two isolates, presumed to be of the same clinical strain, from a calf have been studied.

Isolated during post-mortem examination from feces and jejunum of a Holstein-Friesian calf diagnosed with catarrhal enteritis. Habitat is unknown.

16S rRNA gene sequence analysis does not place *Streptococcus entericus* within an established species group. *Streptococcus acidominimus* is the nearest described relative.

DNA G+C content (mol%): not reported.

Type strain: CECT 5353, CCUG 44616, JCM 12180.

GenBank accession number (16S rRNA gene): AJ409287.

16. ***Streptococcus equi*** Sand and Jensen 1888, 436^{AL}
e'qui. L. n. *equus* horse; L. gen. n. *equi* of a horse.

Cells are spherical or ovoid, occurring in pairs or chains. Growth on blood agar plates produces colonies that are surrounded by a wide zone of β -hemolysis. The optimum temperature for growth is around 37°C. Growth does not occur at 10°C or at 45°C, in 6.5% NaCl, in 10% bile, in 0.1% methylene blue, or at pH 9.6. Cells do not survive heating at 60°C for 30 min. Growth only occurs on complex media; minimal nutritional requirements are unknown. Chemo-organotroph: metabolism fermentative. Final pH in glucose broth is around 4.6–5.0. Acid is produced from glucose, glycogen, maltose, pullulan, salicin, sucrose, and starch. Acid production from lactose, trehalose, and sorbitol is a characteristic of some strains (see below). Acid is not produced from arabinose, glycerol, inulin, mannitol, melezitose, raffinose, or xylose. Reports of acid from ribose vary in the literature. Strains produce alkaline phosphatase, leucine arylamidase, and β -glucuronidase. Both α - and β -galactosidase, *N*-acetyl- β -glucosaminidase, and pyrrolidonyl arylamidase are not produced. Most strains do not produce β -galactosidase. Arginine is hydrolyzed. Esculin hydrolysis is a variable characteristic. Hippurate is not hydrolyzed. Gelatin is not liquefied. Acetoin is not produced (Voges-Proskauer reaction).

Strains react with Lancefield group C antiserum. The major non-hydroxylated long-chain fatty acids are hexadecanoic (C_{16:0}) and octadecenoic (C_{18:1}) acids; cyclopropane-ring-containing fatty acids are absent. Menaquinones are absent. Capsules may be produced.

Causes infections in animals and humans. Animal infections include equine strangles with the organisms being isolated from submaxillary glands and mucopurulent discharges of the upper respiratory system of horses and from their immediate environment. Causes bovine mastitis.

16S rRNA gene sequence analysis places *Streptococcus equi* within the Pyogenic species group.

The close relationship between strains previously designated *Streptococcus equi* and *Streptococcus zooepidemicus* has resulted in the proposal that they should be included within a single species but be given subspecies status (Farrow and Collins, 1984a). Details are given in the section on the Pyogenic species group.

The genome currently being sequenced is approximately 2.3 Mb, with a G+C content of around 41 mol%.

- 16a. ***Streptococcus equi* subsp. *equi*** (Sand and Jensen 1888) Howey, Lock and Moore 1990, 318^{VP}

The description for this subspecies is as above with the exception that strains are not able to produce acid from lactose, ribose, trehalose, or sorbitol. The cell-wall peptidoglycan is type Lys-Ala₁₋₃. Isolated from horses with equine strangles.

DNA G+C content (mol%): 40.7 (type strain) (*T_m*).

Type strain: C 15, ATCC 33398, CCUG 23255, CIP 102910, DSM 20561, LMG 15886, NCTC 9682.

GenBank accession number (16S rRNA gene): AB002515, X58314.

- 16b. ***Streptococcus equi* subsp. *zooepidemicus*** (ex Frost and Engelbrecht 1936) Farrow and Collins 1985, 224^{VP} (Effective publication: Farrow and Collins 1984a, 491.)

zo.ö.e.pi.démi.cus. Gr. n. *zoon* an animal; Gr. adj. *epidemius* among people; prevalent, epidemic; M.L. adj. *zooepidemicus* prevalent among animals.

The description for this subspecies is as above with the exception that strains are able to produce acid from lactose and sorbitol. Reports of acid from ribose vary in the literature. Acid from trehalose is a variable characteristic. The cell-wall peptidoglycan is type Lys-Ala₂₋₃.

Strains are isolated from the blood stream, inflammatory exudates, and lesions of diseased animals. Frequent cause of bovine mastitis. Isolated from human infections usually traceable to the consumption of contaminated dairy products (Facklam, 2002).

DNA G+C content (mol%): 41.3–42.7 (*T_m*).

Type strain: S 34, ATCC 43079, CCUG 23256, CIP 103228, DSM 20727, LMG 16030, NCIMB 701358, NCTC 4676.

GenBank accession number (16S rRNA gene): AB002516.

Additional comments: The type strain is β -galactosidase-negative, and does not hydrolyze esculin or hippurate.

17. ***Streptococcus equinus*** Andrewes and Horder 1906, 712^{AL}
e.qui'nus. L. adj. *equinus* pertaining to a horse.

Cells are spherical or ovoid, occurring in pairs to moderately long chains. Colonies on blood agar are small, circular, and entire with the majority of strains producing an α -hemolytic reaction of varying intensity. Growth occurs at 45°C but not at 10°C or at 50°C. Some strains survive heating at 60°C for 30 min. No growth occurs in 6.5% NaCl, 0.1% methylene blue milk, or at pH 9.6. Growth occurs in 40% bile. Chemo-organotroph: metabolism fermentative. Acid is produced from glucose, amygdalin, arbutin, cellobiose, fructose, galactose, D-mannose, maltose, *N*-acetylglucosamine, salicin, and sucrose. The majority of strains produce acid from β -gentiobiose. Variable results are obtained for acid production from glycogen, inulin, lactose, melibiose, D-raffinose, starch and trehalose. Strains do not produce acid from D- or L-arabinose, D- or L-arabitol, 2-ketogluconate, 5-ketogluconate, dulcitol, erythritol, D- or L-fucose, glycerol, gluconate, inositol, D-lyxose, mannitol, methyl β -xyloside, melezitose, ribose, rhamnose, L-sorbose, sorbitol, D-turanose, D-tagatose, D- or L-xylose, or xylitol. Esculin is hydrolyzed but arginine, hippurate, and gelatin are not. Acetoin is produced (Voges-Proskauer reaction). Strains produce leucine arylamidase. Strains do not produce alkaline phosphatase, pyrrolidonyl arylamidase, β -galactosidase, or β -glucuronidase. Strains contain the Lancefield group D antigen.

Isolated mainly from animals, including the alimentary tract of cows, horse, sheep, and other ruminants. Rarely from human clinical specimens.

16S rRNA gene sequence analysis places *Streptococcus equinus* within the Bovis species group.

DNA G+C content (mol%): 36.2–38.6 (*T_m*).

Type strain: HI2B, ATCC 9812, CCUG 27302, CIP 102504, DSM 20558, HAMBI 1572, JCM 7879, LMG 14897, NBRC 12553 NCTC 12969.

GenBank accession number (16S rRNA gene): AF429765, AJ301607, X58318.

Additional comments: The description given above encompasses Lancefield group D strains that would

previously have been identified as *Streptococcus equinus* (Andrews and Horder, 1906) and *Streptococcus bovis* (Orla-Jensen 1919, 137; *emend. mut. char.* Sherman and Wing 1937, 57^{AL}). DNA–DNA hybridization has led to the recognition that the names *Streptococcus equinus* and *Streptococcus bovis* are subjective synonyms with the specific epithet *Streptococcus equinus* having priority.

The “bovis/equinus” complex currently includes the following species: (i) *Streptococcus equinus* (Farrow et al., 1984), (ii) *Streptococcus galloyticus* (Osawa et al., 1995), (iii) *Streptococcus infantarius* (Bouvet et al., 1997; Poyart et al., 2002), (iv) *Streptococcus alactolyticus* (Farrow et al., 1984), (v) *Streptococcus lutetiensis*, and (vi) *Streptococcus pasteurianus* (Poyart et al., 2002). The classification of the streptococci included here is detailed in the section on the Bovis group.

18. ***Streptococcus ferus*** Coykendall 1983, 883^{VP} *emend.* Baele, Devriese, Vancanneyt, Vaneechoutte, Snauwaert, Swings and Haesebrouck 2003, 145.

ferus. L. adj. *ferus* wild, referring to wild rats from which the organism was isolated.

Cells are relatively small, lanceolate coccobacilli that occur singly or in pairs or forming short chains. Colonies on blood agar are small, dry, white, and adhering to, pitting, and corroding the agar surface. Growth is slightly enhanced in the presence of 5% CO₂, is strongly inhibited at 25°C and to a lesser extent at 30°C. Growth is equally good at 42°C and 37°C. Cells precipitate in brain heart infusion broth and strains are unable to grow in the presence of 6.5% NaCl or 20 µg/ml bacitracin. Growth occurs in the presence of 0.0013 g/l crystal violet plus 0.33 g/l thallosulfate (Edwards medium) and in the presence of 0.4 g/l sodium azide plus 0.1 g/l tetrazolium chloride (Slanetz–Bartley medium) where white colonies are formed. Strains are resistant to bile (bile–esculin agar). Acid is produced from *N*-acetylglucosamine, esculin, amygdalin, cellobiose, *D*-fructose, galactose, *D*-glucose, glycogen, β-gentiobiose, lactose, *D*-mannose, maltose, maltotriose, sucrose, salicin, starch, and trehalose. Variable results are obtained for acid from *D*-tagatose, arbutin, inulin, mannitol, melibiose, *D*-raffinose, and sorbitol. Raffinose fermentation was previously recorded as a negative characteristic for this species (Coykendall, 1977, 1983), but strains isolated from pigs are able to produce acid from this carbohydrate (Baele et al., 2003). No acid is produced from adonitol, *D*- or *L*-arabinose, *D*- or *L*-arabitol, dulcitol, erythritol, *D*- or *L*-fucose, gluconate, glycerol, inositol, 2- or 5-ketogluconate, *D*-lyxose, melezitose, methyl β-glycoside, methyl α-*D*-glycoside, rhamnose, ribose, *L*-sorbose, *D*-turanoose, xylitol, or *D*- or *L*-xylose. Strains produce leucine arylamidase and β-*D*-glucosidase and give positive tests for enzymic hydrolysis of *L*-valine 7-amido-4-methylcoumarin (AMC), *L*-phenylalanine AMC, *L*-tryptophan AMC, methyl α- and β-glycoside, *p*-nitrophenyl (pNP) β-*D*-glucoside, pNP β-*D*-cellobioside, proline and leucine *p*-nitroanilide, pNP phosphate, and pNP α-*D*-maltoside. The majority of strains are positive for the production of acetoin (Voges–Proskauer reaction), *L*-arginine AMC, and *L*-isoleucine AMC. Variable reactions are obtained for alkaline phosphatase and α-galactosidase. Negative test results are obtained for the hydrolysis of hippurate, the pro-

duction of pyrrolidonyl arylamidase, β-glucuronidase, and β-galactosidase, hydrolysis of arginine, *L*-pyroglutamic acid AMC, 4MU *N*-acetyl-β-*D*-glucosaminide, 4MU phosphate, and 4MU β-*D*-glucuronide.

The cell-wall peptidoglycan type is Lys–Ala₂₋₃.

Strains have been isolated from the oral cavities of wild rodents and from the tonsils and nasal conchae of piglets.

DNA G+C content (mol %): 43–45 (T_m).

Type strain: 8S1, ATCC 33477, CCUG 34784, CCUG 34834, CIP 103225, DSM 20646, HAMBI 1522, LMG 16520, NCTC 12278.

GenBank accession number (16S rRNA gene): AJ420197, AY058218, AY584479.

Additional comments: Strains of this species were originally isolated from the oral cavities of wild rats living in sugar cane fields and eating a sucrose-rich diet (Coykendall, 1974). Strains gave colonies on sucrose agar that were approximately 1 mm in diameter, raised, somewhat adherent, but not showing drops of glucan-containing liquid on or around the colony. Strains were inhibited by bacitracin (20 U/ml). Growth did not occur at 45°C or in the presence of 6.5% NaCl. Acid was produced from mannitol and sorbitol but not from raffinose. The final pH in glucose broth was 4.2–4.5. Arginine is not hydrolyzed to produce ammonia. Both extracellular and intracellular polysaccharides were produced from sucrose. Strains possessed the c antigen of the serological scheme of Bratthall (1970) for mutans group streptococci.

Although originally proposed as a species by Coykendall (1977), the name *Streptococcus ferus* did not appear in the Approved Lists of Bacterial Names (Skerman et al., 1980) but was later accorded species status (Coykendall, 1983). The biochemical and physiological resemblance of *Streptococcus ferus* to other member species of the Mutans group of streptococci has given rise to the view that this constitutes a further member of the group. However, the demonstration that *Streptococcus ferus* was most closely related to *Streptococcus sanguinis* (*Streptococcus sanguis*), according to genetic distance measured by MLEE, casts doubt on this view. In addition 16S rRNA gene sequence analysis has not shown *Streptococcus ferus* clearly to belong to any species group (Whatmore and Whitley, 2002). However, analysis of combined sequence data from 16S rRNA and endoribonuclease P (RNase P) genes does place *Streptococcus ferus* within the Mutans group (Tapp et al., 2003).

Recently an emended description of *Streptococcus ferus* was published to take into account isolates obtained from the tonsils and nasal conchae of piglets (Baele et al., 2003).

19. ***Streptococcus gallinaceus*** Collins, Hutson, Falsen, Inganäs and Bisgaard 2002, 1163^{VP}

gal.li.na'ce.us. L. n. *gallus* rooster, genus name of the chicken; L. masc. adj. *gallinaceus* pertaining to a domestic fowl.

Cells are coccoid and occur singly, in pairs, or in short chains. Colonies are 0.5–1.0 mm in diameter after 24 h on sheep and horse blood agar and α-hemolysis is produced. Using commercial API systems strains produce acid from *D*-glucose, lactose, maltose, mannitol, melibiose, methyl β-*D*-glucopyranoside, pullulan, *D*-raffinose, *D*-ribose, trehalose, and sucrose. Acid is not produced from *D*-arabitol, *L*-arabinose, cyclodextrin, glycogen, melezitose, sorbitol,

D-tagatose, or xylose. Strains produce alanyl-phenylalanine-proline arylamidase, arginine dihydrolase, α -galactosidase, β -galactosidase, α -glucosidase, β -glucosidase, and glycyl-tryptophan arylamidase. Strains do not produce alkaline phosphatase, β -glucuronidase, β -mannosidase, pyroglutamic acid arylamidase, or urease. *N*-Acetyl- β -glucosaminidase and pyrazinamidase are either weakly positive or negative. Esculin is hydrolyzed. Gelatin and hippurate are not hydrolyzed. Acetoin is not produced (Voges-Proskauer reaction). Nitrate is not reduced.

Strains are isolated from chickens with sepsis. Habitat is unknown.

16S rRNA gene sequence analysis places this species outside the recognized species groups, representing a new subline within *Streptococcus*, in loose association with *Streptococcus acidominimus*.

DNA G+C content (mol%): 40.5.

Type strain: CCUG 42692, CIP 107087, DSM 15349, JCM 12181.

GenBank accession number (16S rRNA gene): AJ307888.

20. ***Streptococcus gallolyticus*** Osawa, Fujisawa and Sly 1995, 362^{VP} (Effective publication: Osawa, Fujisawa and Sly 1995, 78.)

gal.lo.ly'ti.cus. Gr. n. *gallo* gallate; Gr. adj. *lyticus* able to loosen; N.L. adj. *gallolyticus* gallate-digesting.

Cells are coccoid, mostly in pairs or short chains. Some strains require CO₂. Colonies on blood (horse) agar or brain heart infusion agar are 1 mm diameter at 24 h, α - or non-hemolytic, circular, smooth, unpigmented, and entire. Some strains give growth at 10°C and 45°C. The optimum temperature for growth is around 37°C. Growth in the presence of 6.5% NaCl is a variable characteristic. Chemo-organotroph. Some strains can decarboxylate gallic acid or produce tannase activity. Acid is produced from lactose, maltose, and sucrose. A few strains produce acid from arabinose. Acid is not produced from arabinol, cyclodextrin, melezitose, tagatose, ribose, or sorbitol. Acid production from amygdalin, glycogen, inulin, mannitol, melibiose, methyl D-glucopyranoside, pullulan, raffinose, starch, and trehalose are variable characteristics of this species as is esculin hydrolysis. Hippurate, urea, and arginine are not hydrolyzed. Acetoin is produced (Voges-Proskauer reaction). Leucine arylamidase and alanyl-phenylalanine-proline arylamidase are produced. Most strains produce α -galactosidase. β -Galactosidase, β -glucosidase, β -glucuronidase, and β -mannosidase activities are variable characteristics. Alkaline phosphatase and pyrrolidonyl arylamidase are not produced. Some strains carry the Lancefield group D antigen.

Strains are isolated frequently from the alimentary tracts of various animals, dairy products, and from human clinical sources, including blood, feces, and endocarditis associated with colonic cancer.

DNA G+C content (mol%): 34.6–38 (*T_m*).

Additional comments: Strains phenotypically resembling *Streptococcus gallolyticus* that had been isolated from feral goats grazing tannin-rich *Acacia* species were proposed as *Streptococcus caprinus* (Brooker et al., 1994). Subsequent comparison of type strains by phenotype, 16S rRNA

gene sequence similarity and DNA–DNA hybridization demonstrated that *Streptococcus gallolyticus* and *Streptococcus caprinus* were subjective synonyms and that under Rule 24b(2) of the International Code of Nomenclature of Bacteria, according to the order of receipt of their respective effective publications for validation, higher priority be given to *Streptococcus gallolyticus* (Sly et al., 1997). Poyart et al. (2002) used DNA–DNA reassociation, 16S rRNA and *sodA* gene sequence analyzes to demonstrate that a single cluster is formed by strains assigned to *Streptococcus gallolyticus* and *Streptococcus macedonicus*. In the opinion of those authors strains originally classified as *Streptococcus macedonicus* constitute an esculin-negative “variant” of *Streptococcus gallolyticus*. Strains previously described as *Streptococcus wainus* (Flint et al., 1999) are also included here as these were recently reclassified as *Streptococcus macedonicus* (Manachini et al., 2002). Schlegel et al. (2003) have proposed that the strains thus grouped together within *Streptococcus macedonicus* were sufficiently closely related to *Streptococcus gallolyticus* to deserve subspecies status and have proposed the recognition of *Streptococcus gallolyticus* subsp. *macedonicus* alongside subsp. *gallolyticus*. These authors have also proposed that “*Streptococcus bovis*” biotype II/2 strains be recognized as subsp. *pasteurianus*, but the evidence for this is less convincing.

The classification of species comprising the Bovis group or complex is detailed above.

- 20a. ***Streptococcus gallolyticus* subsp. *gallolyticus*** (Osawa, Fujisawa and Sly 1996) Schlegel, Grimont, Ageron, Grimont and Bouvet 2003, 643^{VP} (*Streptococcus gallolyticus* Osawa, Fujisawa and Sly 1996, 362)

Strains are non-hemolytic and do not grow in the presence of 6.5% NaCl. Strains produce tannase activity and can decarboxylate gallate. Acid is produced from glycogen, mannitol, methyl D-glucoside, trehalose, and starch. Acid production from inulin, pullulan, and raffinose are variable characteristics. Esculin is hydrolyzed. α -Galactosidase and β -glucosidase are produced. β -Galactosidase and β -mannosidase are variable characteristics. Extracellular polysaccharide is produced in 5% sucrose-containing medium.

Strains are isolated from the alimentary tracts of various animals including marsupials (koala bear, kangaroos, brushtails, and possums) and mammals, septicemia of pigeons, and human clinical cases, including blood from endocarditis following colonic cancer and feces.

DNA G+C content (mol%): 37–38 (*T_m*).

Type strain: ACM 3611, CCUG 35224, CIP 105428, HDP 98035, JCM 10005, LMG 16802.

GenBank accession number (16S rRNA gene): X94337.

- 20b. ***Streptococcus gallolyticus* subsp. *macedonicus*** (Tsakalidou, Zoidou, Pot, Wassill, Ludwig, Devriese, Kalantozopoulos, Schleifer and Kersters 1998) Schlegel, Grimont, Ageron, Grimont and Bouvet 2003, 643^{VP} (*Streptococcus macedonicus* Tsakalidou, Zoidou, Pot, Wassill, Ludwig, Devriese, Kalantozopoulos, Schleifer and Kersters 1998, 525.) ma.ce.do'ni.cus. L. adj. *macedonicus* of Macedonia, northern Greece, where the bacterium was first isolated.

Strains are mostly α -hemolytic with a minority of non-hemolytic reported. Growth in the presence of 6.5% NaCl is a variable characteristic. Strains do not produce tannase activity and cannot decarboxylate gallate. Acid is not produced from glycogen, inulin, mannitol, pullulan, raffinose, trehalose, and starch. Acid production from methyl D-glucoside and starch and are variable characteristics. Esculin is not hydrolyzed. β -Galactosidase is produced (β -GAR test) and α -galactosidase is produced by most strains. β -Glucosidase and β -mannosidase are not produced and esculin is not hydrolyzed.

Strains originally called *Streptococcus macedonicus* have been isolated from dairy products, including Greek Kaseri cheese and Italian cheese, and from sour mash, while strains originally named *Streptococcus wainus* were isolated from biofilms on stainless steel samples exposed to pasteurized skim milk and dairy products.

DNA G+C content (mol%): 34.6–38 (T_m).

Type strain: ACA-DC 206, ATCC BAA-249, CCUG 39970, CIP 105683, HDP 98362, JCM 11119, LAB 617, LMG 18488.

GenBank accession number (16S rRNA gene): Z94012.

21. ***Streptococcus gordonii*** Kilian, Mikkelsen and Henriksen 1989b, 481^{VP}

gor.don'i.i. N.L. gen. n. *gordonii* of Gordon, in honor of British microbiologist Mervyn H. Gordon, who pioneered classification of viridans streptococci by fermentation tests.

Cells are coccoid and grow in short chains in serum broth. Growth on blood (horse) agar produces α -hemolysis and pronounced greening on chocolate agar.

Strains are not able to grow in 4% (w/v) NaCl. Metabolism is fermentative: acid is produced from galactose, N-acetylglucosamine, amygdalin, arbutin, fructose, glucose, lactose, salicin, esculin, maltose, mannose, D-cellobiose, sucrose, and trehalose. Inulin is fermented by the majority of strains. Some strains produce acid from inulin, methyl D-glucoside, raffinose, melibiose, and tagatose. Acid is not produced from arabinose, arabitol, adonitol, cyclodextrin, dulcitol, gluconate, glycerol, glycogen, mannitol, sorbitol, D-melezitose, pullulan, rhamnase, ribose, sorbose, xylose, or xylitol. Reported acid production from starch varies in the literature. Strains produce acid phosphatase, alkaline phosphatase, alanyl-phenylalanyl-proline arylamidase, chymotrypsin, leucine aminopeptidase, β -mannosidase, α -D-fucosidase, β -D-lactosidase, α -maltosidase, phospho- β -galactosidase, valine aminopeptidase, β -D-glucosaminidase, and N-acetyl- β -D-glucosaminidase. Strains do not produce α -mannosidase, β -maltosidase, α -L-fucosidase, β -D-fucosidase, β -D-glucuronidase, α -L-arabinosidase, N-acetyl- α -D-glucosaminidase, α - or β -xylosidase, or neuraminidase (sialidase). Glycyl-tryptophan arylamidase, methyl β -D-glucopyranoside, and N-acetylgalactosaminidase are variable characteristics. The percentages of strains testing positive for the following glycoside hydrolase activities is variable and dependent on the substrates used (i.e., the chromogenic naphthol- or nitrophenol-derivatives, or the fluorogenic derivative 4-methyl-umbelliferyl-) – therefore caution should be observed when incorporating these for characterizing or identifying isolates: α -galactosidase, β -D-galactosidase, α -glucosidase, β -D-glucosidase (see Kilian

et al., (1989b), Beighton et al., (1991). Arginine and esculin are hydrolyzed. Hippurate and urea are not hydrolyzed. The majority of strains hydrolyze starch. Acetoin is not produced (Voges–Proskauer reaction). H_2O_2 is produced. Virtually all strains produce extracellular polysaccharide (dextran) from sucrose and all bind salivary amylase. Strains do not produce IgA1 protease or hyaluronidase.

The cell walls contain glycerol teichoic acid and rhamnose. The peptidoglycan type is Lys-Ala₁₋₃. Some strains react with Lancefield group H antiserum or are ungroupable. Detection of the group H antigen is dependent on the source of the group H antiserum due to differences in immunizing strains used in antiserum production (Kilian et al., 1989b). Strains are inhibited by nitrofurazon but not by bacitracin or sulfafurazole.

Kilian et al. (1989b) described three biovars (1–3) within *Streptococcus gordonii* with the following differential characteristics: biovar 1 was able to produce acid from melibiose, inulin, and raffinose, and produce extracellular polysaccharide (dextran) from sucrose; biovars 2 and 3 were unable to ferment melibiose, or raffinose; the fermentation of inulin and the production of extracellular polysaccharide were variable characteristics of biovar 2 and 3, respectively. Strains are isolated from the human oral cavity and pharynxes, and constitute one of the early tooth colonizing (pioneer) species.

16S rRNA gene sequence analysis has placed *Streptococcus gordonii* within the Mitis species group.

The genome (strain Challis) is currently being sequenced.

DNA G+C content (mol%): 40–43 (T_m).

Type strain: SK3, ATCC 10558, CCUG 25608, CCUG 33482, CCUG 35801, CIP 105258, DSM 6777, LMG 14518, NCTC 7865.

GenBank accession number (16S rRNA gene): AF003931, AY485606, D38483.

22. ***Streptococcus hyointestinalis*** Devriese, Kilpper-Balz and Schleifer 1988, 440^{VP}

hy.o.in.tes.ti.na'lis. Gr. n. *hyos* pig; L. adj. *intestinalis* associated with intestine; N.L. adj. *hyointestinalis* associated with pig intestines.

Cells are coccoid, occurring in chains and forming a sediment with a clear supernatant in broth culture. Colonies on blood (ox) agar are transparent, 1–1.5 mm diameter after 1 d incubation, 1.5–2.5 mm diameter after 3 d incubation, circular, with entire edges and with narrow zones of incomplete hemolysis. The optimum growth temperature is 37°C. Strains do not grow in the presence of 6.5% NaCl or 40% bile. Acid is formed from glucose, fructose, mannose, galactose, lactose, N-acetylglucosamine, arbutin, salicin, maltose, sucrose, trehalose, and starch. Acid is not produced from adonitol, D- and L-arabinose, D- and L-arabitol, dulcitol, erythritol, L-fucose, gluconate, 2- and 5-ketogluconate, glycerol, glycogen, inositol, L-lyxose, mannitol, methyl α -D-glucoside, methyl α -D-mannoside, pullulan, ribose, rhamnose, sorbitol, L-sorbose, D-tagatose, D-turanose, D- and L-xylose, methyl α -xyloside, or xylitol. Variable reactions are obtained for the fermentation of raffinose, amygdalin, and cellobiose. Strains produce amylase, alkaline phosphatase, and leucine arylamidase. β -Glucuronidase, β -galactosidase,

pyrrolidonyl arylamidase, arginine dehydrolase, and hyaluronidase are not produced. Variable reactions are obtained with α -galactosidase and β -gentiobiose activity tests. Acetoin is produced (Voges–Proskauer reaction). Esculin is hydrolyzed but hippurate and gelatin are not. Hydrolysis of starch is positive or weakly positive (on Mueller–Hinton medium). No dextran or levan are produced from sucrose. No reaction is obtained with streptococcal group A, B, C, D, F, and G antisera. The peptidoglycan type is Lys–Ala (Ser).

Habitat: the intestines of pigs.

16S rRNA sequence analysis places this species outside the recognized species groups.

DNA G+C content (mol%): 42–43 (T_m).

Type strain: S93, ATCC 49169, CCUG 27888, CIP 103372, DSM 20770, LMG 14579, NCTC 12224.

GenBank accession number (16S rRNA gene): AB002518, AF201898, X58313.

23. **Streptococcus hyovaginalis** Devriese, Pot, Vandamme, Kersters, Collins, Alvarez, Haesebrouck and Hommez 1997, 1077^{VP}

hy.o.va.gi.na'lis. Gr. n. *hyos* pig; L. n. *vagina* sheath, vagina; N.L. masc. adj. *hyovaginalis* associated with pig vaginas.

Cells are coccoid, occurring as long chains and forming sediment with a clear supernatant in broth culture. Growth on blood (bovine) agar produces colonies that are regular, ≤ 0.5 mm diameter, non-pigmented, translucent, and surrounded by a sharply demarcated zone of α -hemolysis. Growth at 37°C is better than at 25°C, 30°C, or 42°C, and is enhanced somewhat by the presence of 5% CO₂. Growth does not occur in the presence of 6.5% NaCl, bile–esculin, or on Slanetz–Bartley agar. Acid is produced from cellobiose, galactose, D-glucose, N-acetylglucosamine, D-fructose, lactose, maltose, D-mannose, mannitol, salicin, sucrose, sorbitol, and trehalose. Strains do not produce acid from D- and L-arabitol, amygdalin, D- and L-arabinose, dulcitol, erythritol, D- and L-fucose, gluconate, glycerol, glycogen, β -gentiobiose, inositol, inulin, 2- and 5-ketogluconate, D-lyxose, methyl α -D-mannoside, methyl α -D-glucoside, melibiose, melezitose, D-raffinose, rhamnose, L-sorbose, starch, D-tagatose, D-turanose, pullulan, xylitol, D- and L-xylose, and methyl β -xyloside. Variable reactions for acid production from β -glucosidase, methyl β -glucopyranoside, and ribose. Ungroupable in Lancefield serological testing. Strains produce alkaline phosphatase, alanine phenylalanine proline arylamidase, N-acetyl- β -glucosaminidase, β -galactosidase, and β -glucuronidase. Leucine arylamidase (often weak) is produced. Pyrrolidonyl arylamidase, α -galactosidase, arginine dihydrolase, glycytryptophan arylamidase, β -mannosidase, and urease are not produced. Acetoin is produced (Voges–Proskauer reaction). Hippurate is hydrolyzed.

Strains are associated with pigs, in particular the vaginal fluids. Involvement of this species with pathological processes is unclear.

16S rRNA gene sequence analysis has shown *Streptococcus hyovaginalis* to form a distinct subline within the streptococci in association with but distinct from *Streptococcus thoraltensis* and peripherally associated with the Pyogenic species group.

DNA G+C content (mol%): 40 (type strain LMG 14710 (T_m)).

Type strain: SHV515, ATCC 70086, CCUG 37866, CIP 105517, DSM 12219, LMG 14710.

GenBank accession number (16S rRNA gene): Y07601.

24. **Streptococcus infantarius** Schlegel, Grimont, Collins, Régnault, Grimont and Bouvet 2000, 1432^{VP}

in.fan.ta'ri.us. L. adj. *infantarius* relating to infants, the source of the type strain.

Cells are coccoid occurring in pairs or short chains. Colonies on blood agar are circular, 1 mm diameter after 24 h incubation, unpigmented, and α -hemolytic. Growth is enhanced in a 5% CO₂ atmosphere. Homogeneous growth occurs in buffer glucose and brain heart infusion broths. Growth occurs in MRS broth without gas production. No growth occurs in 6.5% NaCl broth. All strains produce acid from glycogen, lactose, maltose, melibiose, starch, and sucrose. Acid is not produced from arabinose, arabitol, cyclodextrin, inulin, D-mannitol, melezitose, ribose, sorbitol, D-tagatose, or trehalose. Acid production from glycogen, melibiose, methyl β -D-glucopyranoside, pullulan, D-raffinose, and starch are variable characteristics of this species. Most strains produce acid from lactose and pullulan. Strains produce leucine aminopeptidase arylamidase and alanyl-phenylalanyl-proline arylamidase. Virtually all strains are α -galactosidase-positive. Strains are negative for N-acetyl- β -glucosaminidase, β -galactosidase, β -glucuronidase, glycytryptophan arylamidase, β -mannosidase, alkaline phosphatase, and pyrrolidonyl arylamidase activities. Most strains are negative for β -glucosidase and methyl β -D-glucopyranoside. Arginine, hippurate, and urea are not hydrolyzed. Most strains do not hydrolyze esculin. Acetoin is produced (Voges–Proskauer reaction). Approximately 40% of strains carry the Lancefield group D antigen. Extracellular polysaccharide is not produced on 5% sucrose containing media. The type strain is esculin- and β -glucosidase-negative, produces acid from glycogen, pullulan, D-raffinose, and starch but not from melibiose or methyl β -D-pyranoside.

Strains are isolated from clinical specimens, including blood and a case of endocarditis, or from food products (dairy and frozen peas). The type strain was isolated from the feces of an infant human.

16S rRNA gene sequence analysis places *Streptococcus infantarius* within the Bovis species group.

DNA G+C content (mol%): not reported.

Type strain: HDP 90056, ATCC BAA-102, CCUG 43820, CIP 103233 NCIMB 700599.

GenBank accession number (16S rRNA gene): AF429762.

Additional comments: Strains of *Streptococcus infantarius* that produced β -glucosidase, hydrolyzed esculin and did not ferment glycogen, starch, melibiose, or pullulan were designated a separate subspecies, *Streptococcus infantarius* subsp. *coli* (Schlegel et al., 2000). These have since been proposed as a distinct species, *Streptococcus lutetiensis*, and the evidence from DNA–DNA reassociation supports this (Poyart et al., 2002).

25. **Streptococcus infantis** Kawamura, Hou, Todome, Sultana, Hirose, Shu, Ezaki and Ohkuni 1998, 926^{VP}

in.fan.tis. L. n. *infans* infant; L. gen. n. *infantis* of a human infant, from whom the organism was isolated.

Cells are coccoid, approximately 0.6–1.0 μm in diameter and grow singly or in short chains. Facultatively anaerobic. α-hemolysis is produced on Columbia blood (sheep) agar with pin-point colonies being formed at 37°C under aerobic conditions for 1 d and approximately 0.3–0.8 mm diameter colonies after 2 d incubation. Strains produce acid from lactose, maltose, sucrose, and tagatose. Acid is not produced from amygdalin, L-arabinose, D-arabinose, arabinol, arbutin, cyclodextrin, glycogen, mannitol, methyl β-D-glucopyranoside, melibiose, melezitose, pullulane, raffinose, ribose, sorbitol, or trehalose. Acid production from inulin is a variable characteristics of this species (the type strain is positive for these tests). Strains produce β-galactosidase (with both 2-naphthyl β-D-galactopyranoside and *p*-nitrophenyl β-D-galactopyranoside substrates) and alanyl-phenylalanyl-proline arylamidase, but do not produce alkaline phosphatase, α-galactosidase, β-glucosidase, β-mannosidase, β-glucuronidase, glycine-tryptophan arylamidase, or urease. β-D-Fucosidase, *N*-acetyl-β-glucosaminidase, and pyrrolidonyl arylamidase are variable characteristics of this species. Arginine, esculin, and hippurate are not hydrolyzed. Acetoin is not produced (Voges–Proskauer reaction).

Strains have been isolated from the human tooth surface and pharynx.

16S rRNA gene sequence analysis places *Streptococcus infantis* within the *Mitis* species group.

DNA G+C content (mol%): 39.9–40.4 (HPLC).

Type strain: 0-122, ATCC 700779, CCUG 39817, CIP 105949, DSM 12492, GTC 849, JCM 10157, LMG 18720.

GenBank accession number (16S rRNA gene): AB008315, AY485603.

Additional comments: Competence for genetic transformation has been observed in the absence of the *comC* gene which encodes streptococcal competence pheromone (Ween et al., 2002).

26. ***Streptococcus iniae*** Pier and Madin 1976, 547^{AL}

in'i.ae. N.L. gen. n. of the dolphin, *Inia*.

Cells are coccoid, encapsulated, up to 1.5 μm in diameter and are arranged in long chains when cultured in broth. Colonies on blood (sheep) agar are small (up to 1 mm diameter), white, umbonate with an entire opaque border, an opaque center spot and a translucent ring of growth separating the border and the center. A small to moderate area of β-hemolysis is produced on sheep blood agar with a diffuse zone of α-hemolysis beyond while α-hemolysis is produced on human and bovine blood agar. Characteristic growth in Todd–Hewitt broth produces coarse, white, granular sediment with clear supernatant. Acid is produced from dextran, fructose, galactose, glucose, maltose, mannitol, mannose, salicin, sucrose, and trehalose. Acid is not produced from arabinose, dulcitol, glycerol, inositol, inulin, lactose, melibiose, raffinose, rhamnose, sorbitol, or xylose. The original description of *Streptococcus iniae*, above, was taken from the reactions of the type strain (ATCC 29178). From the description of multiple strains given by Eldar et al. (1995), *Streptococcus iniae* is able to produce acid from ribose, galactose, D-glucose, D-fructose, D-mannose, man-

nitol, methyl D-mannoside, *N*-acetylglucosamine, arbutin, esculin, salicin, cellobiose, maltose, sucrose, melezitose, starch, glycogen, and gentiobiose. Strains are unable to produce acid from adonitol, D- and L-arabinose, galactose, methyl D-glucoside, L-sorbose, D- and L-xylose, methylxyloside, rhamnose, lactose, D-raffinose, D- and L-fucose, glycerol, sorbitol, inositol, dulcitol, erythritol, adonitol, xylitol, D- and L-arabitol, amygdalin, inulin, lyxose, gluconate, 2-ketogluconate, 5-ketogluconate, turanose, or tagatose. Strains produce pyrrolidonyl arylamidase, alkaline phosphatase, leucine arylamidase, and arginine dihydrolase. α- and β-Galactosidases are not produced. Esculin and starch are hydrolyzed but hippurate is not. Acetoin is not produced (Voges–Proskauer reaction). Strains are non-groupable with Lancefield antisera.

The peptidoglycan type is Lys–Ala₁₋₃.

The species was initially isolated from abscess foci in an Amazonian freshwater dolphin (*Inia geoffrensis*) and also causes meningoencephalitis in a variety of fish species, is associated with disease outbreaks in aquaculture farms and has been linked with transmission from fish to humans, causing severe infection in the latter host (cellulitis). Virulence in this species has been shown to be associated with a distinct genetic profile as shown by PGFE (Fuller et al., 2001).

16S rRNA gene sequence analysis places *Streptococcus iniae* within the Pyogenic species group.

DNA G+C content (mol%): 32.9 (*T_m*).

Type strain: PW, ATCC 29178, CCUG 27303, CIP 102508, DSM 20576, LMG 14520.

GenBank accession number (16S rRNA gene): AF335572.

Additional comments: A streptococcus that causes meningoencephalitis in fish in Israeli farms was given the name *Streptococcus shiloi* which was subsequently shown to be a junior synonym of *Streptococcus iniae* (Eldar et al., 1994, 1995).

27. ***Streptococcus intermedius*** Prévot 1925, 417^{AL} emend. Whiley and Beighton 1991, 2.

in.ter.me'di.us. L. adj. *intermedius* intermediate.

Cells are small (0.5–1.0 μm in diameter), coccoid, and grow in short chains. Colonies on blood agar are 0.5–2.0 mm in diameter, white or translucent, convex and entire. Some strains also produce colonies that are 0.5–1.0 mm diameter, white and matte. The majority of strains are non-hemolytic or α-hemolytic on blood (horse or sheep) agar with occasional strains giving β-hemolysis. β-Hemolysis is always observed when *Streptococcus intermedius* is grown on agar plates containing human blood mainly due to the production of the human-specific cytotoxin intermedilysin (Nagamune et al., 1996, 2000). Growth is reduced under aerobic conditions and is frequently enhanced by the addition of CO₂. Some strains require anaerobic conditions for growth. Extracellular polysaccharide is not produced on sucrose-containing media. Strains produce alkaline phosphatase, β-fucosidase, β-galactosidase, α-glucosidase, β-*N*-acetylgalactosaminidase, β-*N*-acetylglucosaminidase, leucine arylamidase, and neuraminidase (sialidase). β-Glucosidase production is a variable characteristic of this species. α-Galactosidase, β-glucuronidase, and pyrrolidonyl arylamidase are not produced. Acid is produced from

glucose and trehalose, virtually all strains produce acid from lactose. The majority of strains produce acid from amygdalin, cellobiose, and salicin. Acid is not produced from arabinose, glycerol, inulin, or sorbitol. Acetoin is produced (Voges-Proskauer reaction) and arginine and esculin are hydrolyzed but urea and hippurate are not. Virtually all strains produce hyaluronidase. Hydrogen peroxide is not produced.

Most strains are serologically ungroupable with Lancefield grouping antisera, but strains are isolated that react with Lancefield groups F and C.

Habitats are the human oral cavity and upper respiratory tract, and this species has been reported to occur in feces. Strains are isolated from human purulent infections, notably liver and brain abscesses.

16S rRNA gene sequence analysis places *Streptococcus intermedius* within the Anginosus species group.

DNA G+C content (mol%) of the DNA: 37–38 (T_m).

Type strain: ATCC 27335, CCUG 17827, CCUG 32759, CIP 103248, DSM 20573, HAMBI 1571, LMG 17840, NCTC 11324.

GenBank accession number (16S rRNA gene): AF104671, X58311.

Additional comments: For a description of the often confusing history of the classification of strains currently designated *Streptococcus intermedius* together with closely related strains see the section on the Anginosus species group.

28. ***Streptococcus lutetiensis*** Poyart, Quesne and Trieu-Cuot 2002, 1253^{VP}

lu.te'ti.en.sis. L. fem. n. *lutetia*, Lutèce, Paris; N.L. masc. adj. *lutetiensis* pertaining to Paris, where the species was characterized

Cells are coccoid, occurring in pairs or short chains. Colonies on blood agar or nutrient agar are circular, smooth, entire, non-pigmented, and produce α -hemolysis. Homogeneous growth is obtained in brain heart infusion and in glucose broths after 18 h incubation at 37°C. Growth occurs in MRS broth without gas production. No growth occurs in the presence of 6.5% NaCl.

Acid is produced from lactose, maltose, methyl β -D-glucopyranoside, raffinose, and sucrose. Acid is not produced from L-arabinose, D-arabitol, cyclodextrin, glycogen, inulin, D-mannitol, melezitose, melibiose, pullulan, ribose, sorbitol, tagatose, or trehalose.

Acid production from starch is a variable characteristic. Strains produce alanyl-phenylalanyl-proline arylamidase, leucine aminopeptidase, α -galactosidase, and β -glucosidase. Strains do not produce arginine dihydrolase, alkaline phosphatase, pyrrolidonyl arylamidase, β -galactosidase, β -glucuronidase, β -mannosidase, N-acetyl- β -glucosaminidase, or glycytryptophan arylamidase.

Esculin is hydrolyzed but hippurate and urea are not. Acetoin is produced (Voges-Proskauer reaction). Some strains react with Lancefield group D antiserum. No extracellular polysaccharide is produced on 5% sucrose medium.

Strains have been isolated from human specimens, including feces, blood (including infective endocarditis), urine, and cerebrospinal fluid. The type strain is of unknown human origin.

16S rRNA gene sequence analysis places *Streptococcus lutetiensis* within the Bovis species group.

DNA G+C content (mol%) of the DNA: has not been determined.

Type strain: NEM 782, CIP 106849, DSM 15350.

GenBank accession number (16S rRNA gene): AJ297215.

Additional comments: Strains of *Streptococcus lutetiensis* were previously designated *Streptococcus infantarius* subsp. *coli* (Schlegel et al., 2000). However, despite the close relationship between these and strains designated *Streptococcus infantarius* subsp. *infantarius* the level of DNA similarity between the two groups has consistently fallen below 70% in different studies (Poyart et al., 2002; Schlegel et al., 2000), indicating that separate species status is appropriate.

The classification of *Streptococcus lutetiensis* and close relatives within the Bovis group is detailed above.

29. ***Streptococcus macacae*** Beighton, Hayday, Russell and Whiley 1984, 333^{VP}

ma.cacae. N.L. fem. n. *Macaca* genus name of the macaque; N.L. gen. n. *macacae* of macaque.

Cells are coccoid and grow in chains. Strains grow poorly in air, but growth is stimulated by CO₂; hence growth occurs in candle jars and anaerobic jars in an atmosphere of 90% H₂ and 10% (v/v) CO₂. Strains produce greening of (horse) blood agar plates. On sucrose-containing medium, coherent colonies are produced that are easily detachable from the agar surface, transparent, and 1–2 mm in diameter after 3 d incubation. In addition, on sucrose agar a less frequent colonial form is observed which is vivid white, <1 mm diameter, erose, crumbly, and detachable. The transparent colonial type gives rise to the two observed colony forms but the vivid white type retains the original form. Growth occurs on media containing 10% or 40% (w/v) bile but not in the presence of 6.5% NaCl, at 45°C, or at pH 9.6. Acid is produced from N-acetylglucosamine, amygdalin, cellobiose, fructose, glucose, galactose, maltose, mannitol, raffinose, sucrose, and trehalose. Sorbitol is fermented slowly. Acid is not produced from adonitol, arabinose, dextrin, glycerol, glycogen, inositol, inulin, melizitose, melibiose, ribose, starch, sorbose, xylitol, or xylose. Esculin is hydrolyzed, starch and blue dextran are weakly hydrolyzed, but arginine is not hydrolyzed. H₂O₂ is not produced. Strains do not grow in the presence of 20 μ g/ml bacitracin. *Streptococcus macacae* strains possess the serotype c antigen described by Bratthall (1970). Cell-wall carbohydrates include glucose and rhamnose. Extracellular polysaccharide is produced from sucrose.

Strains are isolated from oral samples, primarily dental plaque, of monkeys (*Macaca fascicularis*)

16S rRNA gene sequence analysis places *Streptococcus macacae* within the Mutans group.

DNA G+C content (mol%): 35–36 (T_m).

Type strain: 25-1, ATCC 35911, CCUG 27653, CIP 102912, DSM 20724, LMG 15097, NCTC 11558.

GenBank accession number (16S rRNA gene): AJ420199 AY188351, X58302.

30. ***Streptococcus minor*** Vancanneyt, Devriese, Graef, Baele, Lefebvre, Snauwaert, Vandamme, Swings and Haesebrouck 2004, 451^{VP}

mi'nor. L. masc. adj. *minor* smaller.

Cells are ovoid, very small (<1 µm in diameter), and arranged predominantly in small groups. On Columbia sheep blood agar colonies are nonpigmented, regular, translucent, approximately 0.5 mm in diameter, producing α-hemolysis in a narrow zone around the colonies. Incubation in 5% CO₂ slightly enhances growth. Growth at 37°C is better than at 42°C with growth at 25°C almost equal to that observed at 30°C or 37°C. Homogeneous growth is obtained in brain heart infusion broth (Oxoid). Growth is obtained on Edwards medium (Oxoid) but not on Slanetz–Bartley agar (Oxoid). Blackening is observed on bile–esculin agar (Oxoid).

Acid is produced from *N*-acetylglucosamine, cellobiose, D-fructose, galactose, β-gentiobiose (often delayed), D-glucose, glycogen, lactose, D-mannose, mannitol (often delayed), maltose, salicin, sucrose, and trehalose. Acid is not produced from adonitol, DL-arabinose, DL-arabitol, dulcitol, erythritol, DL-fucose, gluconate, glycerol, inositol, 2- and 5-ketogluconate, D-lyxose, methyl α-D-mannoside, methyl α-glucoside, methyl β-xyloside, melibiose, melezitose, rhamnose, ribose, L-sorbose, D-turanose, DL-xylose, or xylitol. Acid from amygdalin, arbutin, inulin, D-raffinose, starch, sorbitol, and D-tagatose is strain-dependent.

Strains produce leucine arylamidase and are able to hydrolyze L-valine-AMC, L-phenylalanine-AMC, 4MU-α-D-glucoside, L-tryptophan-AMC, L-arginine-AMC, L-isoleucine-AMC, and esculin. Strains do not produce pyrrolidonyl arylamidase, β-glucuronidase, or β-galactosidase. Hippurate is not hydrolyzed. Production of α-galactosidase (often weak) and alkaline phosphatase and hydrolysis of *p*-nitrophenyl phosphate are variable characteristics.

Strains do not react with Lancefield groups A, B, C, D, G, or F antisera.

Strains are isolated from the tonsils and intestinal tract of dogs and tonsils of cats and cattle.

The highest 16S rRNA gene sequence similarity is with *Streptococcus ovis* (95.9%).

DNA G+C content (mol%): 40.6–41.5 (HPLC).

Type strain: ON59, LMG 21734, CCUG 47487.

GenBank accession number (16S rRNA gene): AY232832.

31. ***Streptococcus mitis*** Andrewes and Horder 1906, 712^{AL} emend. Kilian, Mikkelsen and Henrichsen 1989b, 483. *mi'tis*. L. adj. *mitis* mild.

Cells are coccoid, growing in pairs or short chains in serum broth. Growth on blood (horse) agar produces α-hemolysis and pronounced greening on chocolate agar. Strains unable to grow in the presence of 6.5% NaCl. A few strains may grow in 4% NaCl. Metabolism is fermentative. Acid is produced from galactose, glucose, *N*-acetylglucosamine, fructose, lactose, mannose, and sucrose. Acid production from sorbitol, salicin, D-cellobiose, maltose, D-melibiose, pullulan, D-trehalose, D-raffinose, and ribose are variable characteristics of this species. Strains do not produce acid from amygdalin, arabinose, arbutin, arbutin, cyclodextrin, dulcitol, esculin, glycerol, glycogen, mannitol, methyl D-glucoside, D-melezitose, rhamnose, L-sorbose, starch, tagatose, or xylose. Reports of acid from inulin and melibiose vary in the literature. Strains produce leucine aminopeptidase, alanyl-phenylalanyl-proline arylamidase, valine aminopeptidase, α-D-glucosidase,

N-acetyl-β-D-glucosaminidase, and chymotrypsin. Production of alkaline phosphatase, acid phosphatase, phosphoamidase, α-glucosidase, α-maltosidase, β-D-fucosidase, β-glucosaminidase, glycyL-tryptophan-arylamidase, α- and β-D-galactosidases, lactosidase, phospho-β-galactosidase, and sialidase are variable characteristics. Strains do not produce *N*-acetyl-α-D-glucosaminidase, *N*-acetylgalactosaminidase, α- or β-mannosidases, β-maltosidase, β-D-glucosidase, β-D-glucuronidase, α-L-arabinosidase, pyrrolidonyl arylamidase, hyaluronidase or α-L-fucosidase, or α- or β-xylosidases.

The percentage of strains testing positive for the following glycoside hydrolase activities is variable and dependent on the substrates used (i.e., the chromogenic naphthol- or nitrophenol-derivatives, or the fluorogenic derivative 4-methyl-umbelliferyl-) – therefore caution should be observed when incorporating these for characterizing or identifying isolates: α-galactosidase, β-D-galactosidase, α-glucosidase, β-D-glucosidase, and β-D-fucosidase (see Kilian et al., 1989b; Beighton et al., 1991). Acetoin is not produced (Voges–Proskauer reaction). Extracellular polysaccharide is not produced. Hydrogen peroxide is produced. Strains do not hydrolyze esculin, urea, or hippurate, and do not bind salivary amylase. Arginine and starch hydrolysis and the production of IgA₁ protease are variable characteristics. The cell wall contains ribitol teichoic acid and lacks significant amounts of rhamnose. The peptidoglycan type is Lys-direct. Some strains react with Lancefield group K and O antisera.

Kilian et al. (1989b) described two biovars (1 and 2) within *Streptococcus mitis* with the following differential characteristics: biovar 1 was able to ferment trehalose more often, unable to hydrolyze arginine or produce β-glucosaminidase (positive characteristics of biovar 2), unable to ferment sorbitol or produce phospho-β-galactosidase or β-lactosidase (a variable characteristic of biovar 2), was less often able to ferment maltose, melibiose, and raffinose, or to hydrolyze starch (positive characteristics of biovar 2), and was sometimes able to produce IgA₁ protease (negative characteristic of biovar 2). Biovar 2 was positive for the production of α- and β-galactosidase (variable characteristics of biovar 1) and included certain strains able to produce β-glucosidase (a negative characteristic of biovar 1).

Strains are isolated from the human oral cavity (dental plaque and mucosal surfaces) and pharynges. *Streptococcus mitis* biovar 1 constitutes one of the earliest colonizers of the tooth surface in the development of dental plaque (Fransen et al., 1991). This species is a significant cause of life-threatening infection in immunocompromised patients (Beighton et al., 1994). Evidence from MLEE suggests the existence of both transient and persistent clones of *Streptococcus mitis* biovar 1 in adults with persistence maintained by successive clones rather than stable strains (Hohwy et al., 2001).

16S rRNA gene sequence analysis places *Streptococcus mitis* within the Mitis group.

It is anticipated that genome sequencing will be completed for strain NCTC 12261 in 2005.

DNA G+C content (mol%): 39–41 (*T_m*).

Type strain: NS51, ATCC 49456, CCUG 35790, CCUG 31611, CIP 103335, DSM 12643, NCTC 12261.

GenBank accession number (16S rRNA gene): AB002520, AF003929, D38482.

Additional comments: Data from several sources have shown *Streptococcus mitis* biovar 2 to be heterogeneous species comprising strains of disparate taxonomic affiliation requiring further study (De Gheldre et al., 1999; Kikuchi et al., 1995; Vandamme et al., 1998; Whatmore et al., 2000).

The classification of *Streptococcus mitis* and relatives is detailed in the section on the Mitis species group.

The present type strain, NS51^T, replaced strain NCTC 3165, which was shown to belong to *Streptococcus gordonii* (Coykendall, 1989b; Kilian et al., 1989a).

32. ***Streptococcus mutans*** Clarke 1924, 144^{Al}.

mu'tans. L. part. adj. *mutans* changing.

Cells are coccoid, approximately 0.5–0.75 µm in diameter, occurring in pairs or as short- to medium-length chains without capsules. In acid conditions in broth and on some solid media, *Streptococcus mutans* may form short rods (1.5–3.0 µm in length) and rod-shaped morphology may be evident on primary isolation from oral specimens. Growth on blood agar after incubation anaerobically for 2 d produces colonies that are white or gray, circular or irregular, 0.5–1.0 mm in diameter, sometimes rather hard and tending to adhere to the surface of the agar and slightly pitting into the agar surface. Hemolytic reaction on blood agar is usually α-hemolytic or non-hemolytic with very occasionally strains giving β-hemolysis. Growth on sucrose-containing agar typically produces rough, heaped colonies, about 1 mm in diameter with soluble extracellular polysaccharide visible as beads, droplets, or puddles of liquid on or surrounding the colonies. Some strains may form smooth or mucoid colonies (Edwardsson, 1968, 1970). Facultatively anaerobic; while most strains grow in air growth is optimum at 37°C under anaerobic condition with some strains CO₂-dependent. A few strains have been reported to grow at 45°C, but no growth occurs at 10°C. Acid is produced from arbutin, D-cellobiose, esculin, galactose, glucose, inulin, lactose, maltose, mannitol, mannose, N-acetylglucosamine, salicin, sorbitol, sucrose, trehalose, and D-raffinose. Melibiose and amygdalin fermentation are variable characteristics of *Streptococcus mutans* with strains that cannot ferment melibiose being less frequently able to produce acid from raffinose or amygdalin. Acid is not produced from adonitol, arabinose, cyclodextrin, dulcitol, erythritol, glycerol, glycogen, gluconate, inositol, methyl D-glucoside, methyl D-mannoside, methyl D-xyloside, melezitose, rhamnose, ribose, sorbose, starch, or xylose. Strains hydrolyze esculin but not arginine. Starch is hydrolyzed by the majority of strains but hippurate and urea are not. Strains produce leucine aminopeptidase, valine aminopeptidase, chymotrypsin, phosphoamidase, α- and β-glucosidase, α-galactosidase, and β-lactosidase. Strains do not produce alkaline phosphatase, β-glucosaminidase, gly-cyl tryptophan arylamidase, N-acetyl-β-D-galactosaminidase, N-acetyl-β-D-glucosaminidase, β-D-glucuronidase, α-L-fucosidase, β-D-fucosidase, β-mannosidase, β-maltosidase, α-arabinosidase, pyrrolidonyl arylamidase, urease, hyaluronidase, orneuraminidase (sialidase). α-maltosidase is a variable characteristic of this species. Melibiose non-

fermenting strains do not produce α-galactosidase or α-glucosidase. Test results for β-D-galactosidase production have been shown to vary depending on the substrate derivative employed (Kilian et al., 1989b). Acetoin is produced by the majority of strains. Hydrogen peroxide is not produced. Strains are non-groupable with Lancefield grouping antisera. Strains contain the cell-wall polysaccharide-typing antigens c, e, or f, according to the serological scheme of Bratthall (1970) and Perch et al. (1974). Extracellular polysaccharide (dextran) is produced from sucrose. The majority of strains are resistant to bacitracin.

Strains are isolated from the oral cavity where the primary habitat is the tooth surface (dental plaque) and colonization is favored by high levels of dietary sucrose. Strains have been isolated from feces.

16S rRNA gene sequence analysis places this species within the Mutans species group.

DNA G+C content (mol%): 36–38 (*T_m* and buoyant density).

Type strain: ATCC 25175, CCUG 6519, CCUG 11877, CCUG 17824, CIP 103220, DSM 20523, HAMB1 1519, JCM 5705, LMG 14558, NBRC 13955, NCTC 10449.

GenBank accession number (16S rRNA gene): AJ243965, AY188348, X58303.

Additional comments: The complete genome sequence has been determined for strain UA159 (GenBank accession no. AE0141333) composed of 2,030,936 bp with a mean G+C content of 36.82 mol%. The genome contains 1963 open reading frames (ORFs) of which 63% were assigned putative functions at the time of publication (Ajdic et al., 2002). Analysis has shown that almost 15% of the genome is accounted for by non-oxidative pathways for carbohydrate metabolism and associated transport systems and reinforces the suggestion that *Streptococcus mutans* is able to metabolize a wider range of carbohydrates than any other Gram-positive bacterium sequenced to date.

A recent publication has described an additional serotype (k) within this species. Serotype k strains were isolated from the dental plaque of children and were less susceptible to phagocytosis than other serotypes (Nakano et al., 2004).

33. ***Streptococcus oligofermentans*** Tong, Gao and Dong 2003, 1103^{VP}

o.li.go.fer.men'tans. Gr. adj. *oligos* little, scanty; L. part. adj. *fermentans* fermenting; N.L. part. adj. *oligofermentans* fermenting few compounds.

Cells are coccoid, approximately 0.7 µm in diameter after 24 h growth in brain heart infusion medium at 37°C, arranged in short chains. Colonies on BHI blood agar are approximately 0.5–1.0 mm in diameter after 24 h, even, locally rough, dark yellow, and α-hemolytic. Optimum growth temperature is 37°C with a temperature range for growth of 25–41°C. Optimum pH for growth is 7.0 with a pH range for growth of 5.3–8.95. Acid is produced from sucrose, D-glucose, mannose, and maltose. Fermentation of lactose, trehalose, and raffinose is variable. Acid is not produced from mannitol, salicin, sorbitol, arabinose, inulin, melibiose, cellobiose, arbutin, amygdalin, ribose, starch, or glycogen. Hippurate is hydrolyzed. Arginine and esculin are

not hydrolyzed. Acetoin is not produced (Voges–Proskauer reaction). Differential biochemical test data from Tong et al. (2003) indicates that the minority (11–49%) of strains produce alkaline phosphatase and α -galactosidase with no strain producing β -galactosidase. Strains produce leucine arylamidase but not β -glucuronidase or pyrrolidonyl arylamidase.

Habitat is dental plaque and saliva of humans.

16S rRNA gene sequence data indicates that *Streptococcus oligofermentans* is a member of the Mitis group of species and is related most closely to *Streptococcus sinensis* (Woo et al., 2002). DNA–DNA relatedness between type strain LMG 21535 and other closely related, Mitis group species was 7.1–16.4%.

DNA G+C content (mol%): 39.5 ± 0.8 (39.9 mol% for the type strain) (T_m).

Type strain: CGMCC (China General Microbiological Culture Collection Center, Beijing) AS 1.3089, LMG 21535.

GenBank accession number (16S rRNA gene): AY099095.

34. ***Streptococcus oralis*** Bridge and Sneath 1982, 414^{VP} emend. Kilpper-Bälz, Wenzig and Schleifer 1985, 487 emend. Kilian, Mikkelsen and Henrichsen 1989b, 482.

oralis. N.L. adj. *oralis* of the mouth.

Cells are coccoid, non-encapsulated, and arranged in short chains. α -hemolysis is produced on blood (horse) agar often with pronounced greening. Growth occurs in the presence of 0.0004% crystal violet but not with 3% NaCl. Tetrazolium (0.1%) and nitrite are reduced, and lysine is not decarboxylated. Gluconate is usually not oxidized. Tetraionate reductase is usually produced, lipase production is variable, and deoxyribonuclease production is negative. Metabolism is fermentative. Acid is produced from fructose, galactose, glucose, *N*-acetylglucosamine, lactose, maltose, pullulan, and sucrose. Acid production from raffinose, tagatose, and erythritol are variable characteristics of this species as are acid from glycerol, melibiose, ribose, salicin, and starch, with the percentages of strains giving positive results in the latter tests varying between reports in the literature. A minority of strains produce acid from *D*-trehalose and melezitose. Acid is not produced from amygdalin, arabinose, arabinol, arbutin, cellobiose, cyclodextrin, dulcitol, esculin, glycogen, inulin, mannitol, melezitose, methyl *D*-glucoside, rhamnose, sorbitol, or sorbose. Melibiose has been reported as being fermented weakly with terminal pH between 5.6 and 6.2 (Kilian et al., 1989b).

Strains produce alkaline phosphatase, acid phosphatase, leucine aminopeptidase, valine aminopeptidase, chymotrypsin, α -*D*-glucosidase, sialidase (neuraminidase), *N*-acetyl- β -*D*-glucosaminidase, *N*-acetyl- β -*D*-galactosaminidase, glycyl tryptophan arylamidase, and β -glucosaminidase. The production of α -*D*-galactosidase and β -*D*-galactosidase are variable characteristics of this species with the proportion of positive strains varying between reports and dependent upon the test method employed (Beighton et al., 1991; Kilian et al., 1989b). Phospho- β -galactosidase, α -arabinosidase, alanine-phenylalanyl-proline arylamidase, α -*L*-fucosidase, β -*D*-fucosidase, β -*D*-glucosidase, β -maltosidase, β -mannosidase, β -glucuronidase, β -lactosidase, α - and β -xylosidase, and hyaluronidase are not produced.

Arginine and esculin are not usually hydrolyzed although a minority of strains has been reported as positive for esculin (Beighton et al., 1991; Facklam, 2002). Urea and hippurate are not hydrolyzed. Acetoin production is usually reported as negative although this was not the case in the emended description given for this species by Kilpper-Bälz et al. (1985). Hydrogen peroxide is produced. The methyl red reaction, growth with sodium azide, and dextran production are variable. IgA1 protease is produced. Strains do not bind salivary amylase.

The cell walls contain ribitol teichoic acid and choline. Galactose or glucose or both and galactosamine or glucosamine or both are present as major sugar constituents. Rhamnose is absent or present only in minor amounts. The peptidoglycan type is the Lys-direct type.

Strains are isolated from the human mouth. This species is a significant cause of life-threatening infections in immunocompromised patients (Beighton et al., 1994), is one of the commonest streptococci isolated from infective endocarditis (Douglas et al., 1993) and is a primary colonizer of dental plaque (Fransen et al., 1991). The demonstration of a distinct acidoduric population of *Streptococcus oralis* strains means that a more significant role may eventually be recognized for this species in the etiology of dental caries (Alam et al., 2000).

16S rRNA gene sequence analysis places *Streptococcus oralis* within the Mitis species group. The classification of this species is detailed in the section on the Mitis group.

DNA G+C content (mol%): 38–42 (T_m).

Type strain: LVG1, SK23, PB 182, ATCC 35037, CCUG 13229, CCUG 24891, CIP 102922, DSM 20627, LMG 14532, NCTC 11427.

GenBank accession number (16S rRNA gene): AF003932, AY485602, X58308.

35. ***Streptococcus orisratti*** Zhu, Willcox and Knox 2000, 60^{VP} *orisratti*. L. gen. n. *oris* of the mouth; N.L. gen. masc. n. *ratti* of the rat; N.L. gen. n. *orisratti* of the mouth of the rat.

Cells are coccoid, occurring in pairs or short chains. Cells are Gram-positive and catalase-negative. Colonies on sheep-blood agar are 0.5–1.0 mm diameter, white, circular or irregular, and are α -hemolytic. Strains grow at 45°C, in 40% bile, and at pH 9.6, but not at 50°C or in the presence of 6.5% NaCl. Growth in glucose-containing culture gives a terminal pH of 4.3–4.4. Acid is produced from amygdalin, arbutin, cellobiose, fructose, galactose, glucosamine, glucose, glycogen, inulin, lactose, maltose, mannose, melibiose, raffinose, salicin, starch, sucrose, and trehalose but not from arabinose, mannitol, melezitose, or sorbitol. Esculin and starch are hydrolyzed but arginine is not. Glucosyl-transferase and fructosyl-transferase are not produced. *Streptococcus orisratti* belongs to Lancefield group A.

Despite an overall phenotypic resemblance to previous descriptions of *Streptococcus bovis*, and the inability to ferment mannitol or sorbitol, and lack of glucosyl- and fructosyltransferase activities, 16S rRNA gene sequence analysis places *Streptococcus orisratti* as a phylogenetically distinct taxon within the relatively loose cluster that is the “Mutans group” of species (Tapp et al., 2003; Zhu et al., 2000).

Strains have been isolated from the tooth surface of laboratory rats.

DNA G+C content (mol%): 39.6–43.5 (T_m).

Type strain: A63, ATCC 700640, CIP 106965.

GenBank accession number (16S rRNA gene): AF124350.

36. ***Streptococcus ovis*** Collins, Hutson, Hoyles, Falsen, Nikolaitchouk and Foster 2001, 1149^{VP}

o'vis. L. gen. n. *ovis* of the sheep.

Cells are coccoid, occurring singly, in pairs or short chains. Colonies are approximately 0.5–1.0 mm diameter on sheep and horse blood agar plates and are α -hemolytic. Esculin-positive colonies are produced on Edwards medium. Biochemical characteristics were obtained using API commercial test systems. Strains produce alanyl-phenylalanine-proline arylamidase, α -glucosidase, β -glucosidase, esterase C-4 (weak reaction), leucine arylamidase, and phosphoamidase (weak reaction). Strains do not produce alkaline phosphatase, chymotrypsin, ester lipase C8, lipase C14, α -fucosidase, β -galactosidase, β -glucuronidase, α -mannosidase, β -mannosidase, *N*-acetyl- β -glucosaminidase, pyroglutamic acid arylamidase, trypsin, or urease. Variable reactions are obtained for acid phosphatase, arginine dihydrolase, α -galactosidase, cystine arylamidase, valine arylamidase, and glycyl-tryptophan arylamidase. Strains do not hydrolyze hippurate or produce acetoin (Voges-Proskauer reaction). Strains produce acid from glucose, glycogen, lactose, maltose, mannitol, raffinose, trehalose, sorbitol, and sucrose. The majority of strains produce acid from *D*-tagatose but not from cyclodextrin. Acid is not produced from *D*-arabitol, *L*-arabinose, melibiose, melezitose, methyl β -*D*-glucopyranoside, pullulan, or ribose.

Strains have been isolated from clinical specimens of sheep but are of unknown habitat.

16S rRNA gene sequence analysis has shown that *Streptococcus ovis* forms a distinct subline within the genus and does not display a close association with any other described species.

DNA G+C content (mol%): 38 (T_m).

Type strain: S 369/98/1, CCUG 39485, LMG 19174, CIP 107097.

GenBank accession number (16S rRNA gene): Y17358.

37. ***Streptococcus parasanguinis*** corrig. Whiley, Fraser, Douglas, Hardie, Williams and Collins 1990c, 321^{VP} (Effective publication: Whiley, Fraser, Douglas, Hardie, Williams and Collins 1990b, 120.)

pa.ra.san'guin.is. L. gen. n. *sanguinis* of the blood, specific epithet of *Streptococcus sanguinis*; N.L. gen. n. *parasanguinis* alongside of *Streptococcus sanguinis*, indicating the close similarity between the two species.

Cells are coccoid, approximately 0.8–1.0 μ m in diameter, occurring in chains. α -Hemolysis is produced on blood agar. Most strains grow at 45°C and in the presence of 40% bile but not in the presence of 4% NaCl. Acid is produced from *N*-acetylglucosamine, fructose, galactose, glucose, lactose, maltose, and sucrose. Virtually all strains produce acid from raffinose, melibiose, and salicin. A few strains produce acid from amygdalin, sorbitol, or starch. Acid is not produced from adonitol, arabinose, glycerol, glycogen, inulin, mannitol, melezitose, or xylose. Acid production from cellobiose, arbutin, and trehalose are variable characteristics of this species. Strains produce leucine arylamidase, β -*N*-acetylglucosaminidase,

β -*N*-acetylglucosaminidase, β -galactosidase, and α -glucosidase. α -Galactosidase and alkaline phosphatase are produced by most strains. β -*D*-Fucosidase, α -*L*-fucosidase, β -glucosidase, and arabinosidase are variable characteristics of *Streptococcus parasanguinis*. Pyrrolidonyl arylamidase and sialidase are not produced. Arginine is hydrolyzed but urea is not. Some strains hydrolyze esculin. Acetoin is not produced (Voges-Proskauer reaction). Hydrogen peroxide is produced. Extracellular polysaccharide is not produced. Cells bind salivary amylase.

Strains have been isolated from human clinical sources that include throat, blood, and urine.

16S rRNA gene sequence analysis places *Streptococcus parasanguinis* within the *Mitis* species group.

DNA G+C content (mol%): 40.6–42.7 (T_m).

Type strain: 55898, ATCC 15912, CCUG 30417, CIP 104372, DSM 6778, LMG 14537.

GenBank accession number (16S rRNA gene): AF003933, AY485605.

Additional comments: Immunization of rats with lipoprotein receptor protein (FimA) from *Streptococcus parasanguinis* confers protection against endocarditis infection indicating that FimA may represent a promising vaccinogen to control infective endocarditis (Kitten et al., 2002).

Streptococcus parasanguinis is the corrected name for strains previously called *Streptococcus parasanguis* (Trüper and de Clari, 1997; Whiley et al., 1990b).

38. ***Streptococcus parauberis*** Williams and Collins 1990b, 470^{VP} (Effective publication: Williams and Collins 1990a, 486.)

para.u'ber.is. Gr. pref. *para* alongside of or near; L. gen. n. *uberis* of an udder, specific epithet of *Streptococcus uberis*; N.L. gen. n. *parauberis* alongside of *Streptococcus uberis*, indicating the close similarity between the two species.

Cells are coccoid, occurring as pairs or chains of moderate length. Growth on blood agar produces weak α -hemolysis or no hemolysis. The optimum temperature for growth is around 35–37°C. Strains may or may not survive heating at 60°C for 30 min. Growth occurs in the presence of 4% NaCl but not 6.5% NaCl, nor at pH 9.6. Acid is produced from arbutin, fructose, galactose, glucose, lactose, maltose, mannose, *N*-acetylglucosamine, salicin, sucrose, and trehalose. Some strains produce acid from dulcitol, inulin, melezitose, raffinose, starch and *D*-tagatose. Acid is not produced from adonitol, *D*- or *L*-arabinose, erythritol, *D*- or *L*-fucose, glycerol, glycogen, gluconate, 2-ketogluconate, 5-ketogluconate, inositol, lyxose, melibiose, methyl α -*D*-glucoside, methyl α -*D*-mannoside, methyl α -xyloside, rhamnose, sorbose, turanose, xylitol, *D*- or *L*-xylose. Acid production from amygdalin, cellobiose, β -gentiobiose, mannitol, ribose, and sorbitol are variable characteristics of this species. Alkaline phosphatase, leucine arylamidase, and pyrrolidonyl arylamidase are produced. Some strains produce α -galactosidase and β -glucuronidase. β -Galactosidase is not produced. Arginine and esculin are hydrolyzed, hippurate hydrolysis is a variable characteristic of this species, and tyrosine is not decarboxylated. Acetoin is produced (Voges-Proskauer reaction). The cell-wall peptidoglycan type is Lys-Ala₁₋₃.

Serologically heterogeneous, including strains reacting with Lancefield E, P, and U antisera. The V2 region of 16SrRNA of this species contains the sequence UAA GUA CAC AUG UAC UNA AUU UAA AAG GAG CAA U (positions 187–220) which serves to distinguish it from *Streptococcus uberis*. *Streptococcus parauberis* is found on the lips and skin of cows, in raw milk, and on udder tissue. It causes mastitis in cows.

16S rRNA gene sequence analysis places *Streptococcus parauberis* within the Pyogenic species group.

DNA G+C content (mol%): 34.8–36.5 (method not reported).

Type strain: BC45 RH, CCUG 39954, CIP 103956, DSM 6631, LMG 12174, NCIMB 702020.

GenBank accession number (16S rRNA gene): AY584477; X89967 (isolated from turbot, *Scophthalmus maximus*).

Additional comments: Strains of *Streptococcus uberis* and *Streptococcus parauberis* were previously referred to as *Streptococcus uberis* types I and II, respectively on the basis of DNA–DNA similarity data (Collins et al., 1984a; Garvie and Bramley, 1979b). These two species are physiologically and biochemically indistinguishable and species-specific probes have been designed to differentiate them (Bentley et al., 1993).

39. ***Streptococcus pasteurianus*** Poyart, Quesne and Trieu-Cuot 2002, 1253^{VP}

pas.teu'ri.an.us. N.L. masc. adj. *pasteurianus* pertaining to the Pasteur Institute, where the species was characterized.

Cells are coccoid, occurring in pairs or short chains. Colonies on blood agar or nutrient agar are circular, smooth, entire, non-pigmented, and produce α -hemolysis. Homogeneous growth is obtained in brain heart infusion and in glucose broths after 18 h incubation at 37°C. Growth occurs in MRS broth without gas production. No growth occurs in the presence of 6.5% NaCl.

Acid is produced from lactose, maltose, melibiose, methyl D-glucoside, raffinose, sucrose, and trehalose. Acid from tagatose is a variable characteristic of this species. Acid is not produced from L-arabinose, D-arabitol, cyclodextrine, glycogen, inulin, D-mannitol, melezitose, pullulan, ribose, sorbitol, or starch.

Strains produce alanyl-phenylalanyl-proline arylamidase, leucine aminopeptidase, α -galactosidase, β -galactosidase, β -glucosidase, β -glucuronidase, and β -mannosidase. Strains do not produce arginine dihydrolase, alkaline phosphatase, glycytryptophan arylamidase, pyrrolidonyl arylamidase, or N-acetyl- β -glucoaminidase.

Acetoin is produced (Voges–Proskauer reaction). Esculin is hydrolyzed but hippurate and urea are not.

Isolated from human clinical specimens including cerebrospinal fluid, blood, and urine.

16S rRNA gene sequence analysis places this species within the Bovis species group.

Streptococcus pasteurianus comprises strains previously assigned to *Streptococcus bovis* biotype II/2 and also proposed as *Streptococcus gallolyticus* subsp. *pasteurianus* (Schlegel et al., 2003). The classification of this species and its close relatives is detailed in the section on the Bovis species group.

DNA G+C content (mol%) of the DNA: has not been determined.

Type strain: NEM 1202, CIP 107122, DSM 15351, JCM 12261.

GenBank accession number (16S rRNA gene): AJ297216.

40. ***Streptococcus peroris*** Kawamura, Hou, Todome, Sultana, Hirose, Shu, Ezaki and Ohkuni 1998, 926^{VP}

per.or.is. L. adj. *per* through; L. n. *os oris* oral cavity; L. adj. *peroris* pertaining to the oral cavity, from where the organism was isolated.
