Population Policies in Côte d'Ivoire

AMOAKON ANOH

École nationale supérieure de statistique et d'économie appliquée (ENSEA), Abidjan, Côte d'Ivoire

INTRODUCTION

Côte d'Ivoire, in West Africa, lies along the Guinea Gulf, over a surface of 322,463 square kilometers. The natural environment has favored the development of an export-oriented agricultural economy based on coffee and cocoa production on the one hand, and forestry on the other hand. The country experienced exceptional economic development before it was hit by the economic crisis that affected many African countries in the 1980s, and has been subjected to structural adjustment programs since 1981.

Due to a decrease in economic investments since the early 1980s, the prevalence of poverty has been increasing, and social inequality becoming more serious: poverty rose from 10% in 1985 to 37% in 1995 and 38% in 2002. Poverty affects all regions in the country, though at various levels. According to the 2002 survey on living standards, poverty prevalence varies from 15% in the city of Abidjan to 64% in the western part of the country.

As in many other Francophone African countries, demographic policies were predominantly pronatalist in Côte d'Ivoire up until the early 1990s. However, the first official population program of action, which was endorsed in March 2002, was aimed at reducing demographic growth, thus confirming a complete ideological reversal—quite a belated one since, as Joseph Chamie (1988) recalled, awareness of the problems due to fast demographic growth first became apparent through an official statement made in Accra in 1971, during the first African Conference on Population.

The main purpose of this chapter is to describe the evolution of the population policy in Côte d'Ivoire. A summary of the demographic evolution in the country from the 1950s will be presented in the first section. In the second section the demographic ideas and the measures taken in conformity with the pronatalist principles that prevailed before 1991 will be analyzed. The third section covers how the authorities' attitudes and policies radically changed beginning in the early 1990s. In the last section the new reproductive health policy will be described in detail.

I. THE MAIN DEMOGRAPHIC TRENDS SINCE 1950

According to the most recent census, in 1998, the population of Côte d'Ivoire was 15.4 million. United Nations sources suggest that the population increased from 2.8 million in 1950 to 15.8 million in 2000 (Table 116–1).

The growth rate, though currently declining, is still high: 3.3% a year over the period between the last two censuses (1988–1998). The rapid demographic growth results from high natural growth and high levels of immigration (in 1998, 26% of the population were foreign born). Both factors, however, have been substantially reduced in recent times.

1. A Recent Halt in the Decline of Mortality

The average life expectancy has considerably improved from the late 1950s to the late 1980s. According to UN sources, it rose from a bare 35 years in 1950 to over 50 years in the late 1980s, which means a 15 years improvement within thirty years (Figure 116–1). However, the progress was arrested by the emergence of the AIDS epidemic and since then, there has been a significant decline in life expectancy. According to the United Nations, the life expectancy at birth was only 43.2 years in 1995–2000 (United Nations, 2003).

TABLE 116–1 The Evolution of the Population of Côte d'Ivoire since 1950

Years	Population (in thousands)
United Nations estimates (United Nations, 2003)	
1950	2775
1955	3229
1960	3803
1965	4527
1970	5521
1975	6754
1980	8427
1985	10,460
1990	12,505
1995	14,365
2000	15,827
Population censuses[a]	
1975	6,709,600
1988	10,815,694
1998	15,366,672

[a] Three population census operations have been conducted in Côte-d'Ivoire: the General Population Census in 1975 (15 April to 15 May), the General Population and Housing Census in 1988 (known as RGPH, March 1–31) and the 1998 RGPH (November 21–December 21). Concerning the more distant past, some population estimates were provided through the administrative censuses during the colonial period and the regional surveys conducted from 1962 to 1965 by the Ministry of Finance, Economic Affairs, and Planning to serve as a basis for the regional planning of economic development. A summary of such regional surveys was made by Louis Roussel (1967).

During the phase of progress, improved life expectancy was due mainly to a decline in child mortality. The evolution of the various indicators concerning the latter clearly mirrored that of the life expectancy up to the mid-1980s (Table 116–2) (see also Vimard *et al*., 2002). Since then, the part played by child mortality in the fresh decrease of life expectancy has not been so clear. In particular, judging from the UN estimates (Figure 116–2), in recent years, infant mortality seems to have remained unchanged since the early 1990s, which would not have been enough to account for the decline in life expectancy. Though the results of the 1998–1999 Demographic and Health Survey (DHS) are far worse than those of the 1994 DHS, and seem to suggest a sharp rise in infant mortality in very recent times, the decline in life expectancy, as observed from the late 1980s, was probably due more to a fresh upsurge of adult mortality related to the AIDS epidemic.

It is not unlikely, however, that besides the AIDS epidemic, the reversal in mortality trends observed in recent years may be related to a deterioration of social and economic conditions, which among other consequences may have affected child mortality. This, however, came later than the epidemic. And it has been proved that, at least in its first phases, the economic crisis in the 1980s did not have much impact over child mortality (Barbieri and Vallin, 1996). However, as difficulties deepened and health resources grew ever scarcer, it seemed that the crisis began to affect children in Côte d'Ivoire. That, combined with the effects of mother-to-child HIV transmission, probably caused infant mortality to rise sharply again in the late 1990s. Nevertheless, the fresh upsurge of AIDS-related adult mortality is what initially halted the progress in life expectancy and later caused it to decline.

There is no precise estimate of the extent of the pandemic because not all sites are equipped to monitor cases of AIDS. The number of reported cases (the first case of AIDS having been diagnosed in 1985) is conse-

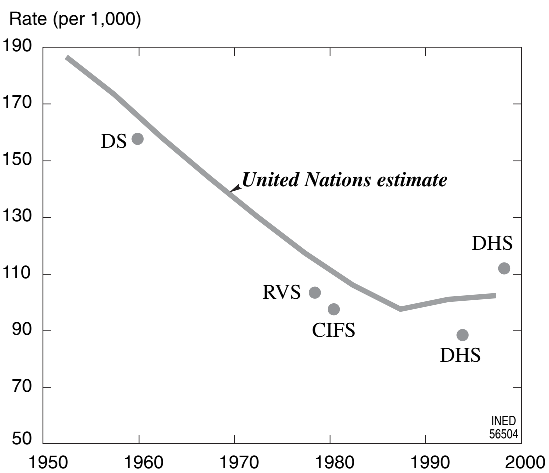

FIGURE 116–2 The evolution of child mortality rates since 1950. (Source: see Table 116–2.)

quently below the actual level (Vimard *et al*., 2002). According to the data available, Côte d'Ivoire is one of the countries most severely affected in Western Africa, and AIDS has been the primary cause of death in the country since the early 1990s. According to the newsletter published by the Ministry for AIDS Control, there are currently 1 million HIV-positive people in Côte d'Ivoire, with the prevalence rate ranging from 10% to 12% (Ministry for AIDS Control, 2003).

2. A Slight Rise before a Rapid Decline in Fertility

There are various estimates of fertility in Côte d'Ivoire in the 1950s. According to the surveys from that time, the total fertility rate (TFR) was 6.5 in 1958 (Roussel, 1967, quoted in Antoine, 1985) and 6.4 in 1962–1964 (Roussel, 1967) (data drawn from the regional studies). According to a current estimate by the United Nations, it was 7 in 1950 (United Nations, 2003). UN estimates, as well as comparison between past surveys and those conducted during the 1980s 7.2 according to the 1980–1981 Côte d'Ivoire Fertility Survey (Ahonzo *et al*., 1984) and 6.8 according to the 1988 General Population and Housing Census (N'cho *et al*., 1995), clearly suggest that there was a slight rise in fertility in the 1960s and 1970s (Figure 116–3). In the past, the level of fertility resulted from a combination of early first marriages among women, rapid remarriage among widows and divorcees—which meant that virtually all women were married—and traditions of breast-feeding (which lengthened the period of postpartum amenorrhea) and sexual abstinence after delivery (which entailed longer intervals between births) (Caldwell, 1993).

The pattern began to change in the 1950s and 1960s, with reduced intervals between births, as a result of the decline of those traditions. The fertility rates by age after 25 increased up to the early 1980s (Figure 116–4).

On the other hand, the effects of the reduced intervals between births were combined with a decline in sterility and a longer life span among couples, as a result of improved health conditions. All of these factors contributed to an increase in fertility and a boost in the natural growth of the population, though the latter was mainly due to reduced mortality, particularly among children.

Beginning in the late 1980s, however, fertility began to decline rapidly, as UN estimates and the results of recent surveys show. From 7.4 children per woman in 1980–1985, according to the United Nations, the fertility level dropped down to 5.3 in 1995–2000, and even to 5.2 in 1998–1999 according to the latest DHS. Though the decline includes all age groups, it is particularly sharp among the youngest (Figure 116–4), which is a sign that the use of contraception has expanded.

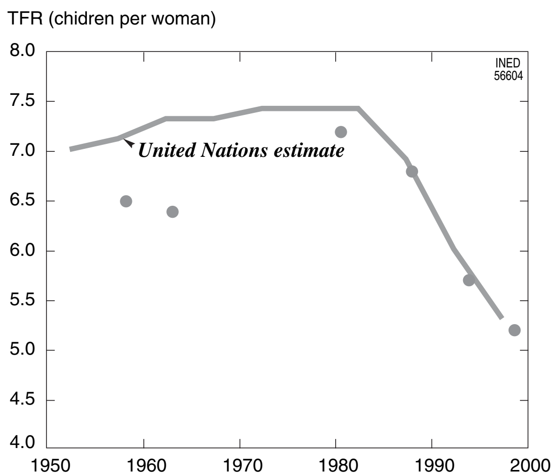

FIGURE 116–3 The evolution of the total fertility rate since 1950. (Sources: 1958: Roussel 1967, quoted in Antoine, 1985; later: N'cho *et al*., 1995; INS and ORC Macro, 2001.)

3. Migration Flows Abruptly Reversing

It is not easy to trace the evolution of migratory flows accurately. To make things as simple as possible in this brief outline of demographic trends in Côte d'Ivoire, we refer to the UN estimates for the annual rate of net immigration (Figure 116–5). From 1950 to 1985, net rates of immigration were 4 to 11 per 1,000. According to Georges Tapinos (2002), the annual rate of net immigration was even as high as 1.3% in 1978–1979. This period of high immigration levels was followed by a period of complete reversal of the situation, with a net immigration rate that was almost nil in 1995–2000.

4. The Incipient Evolution in the Population Pyramid

Due to the influence of those various factors, the age distribution of the population has changed since the

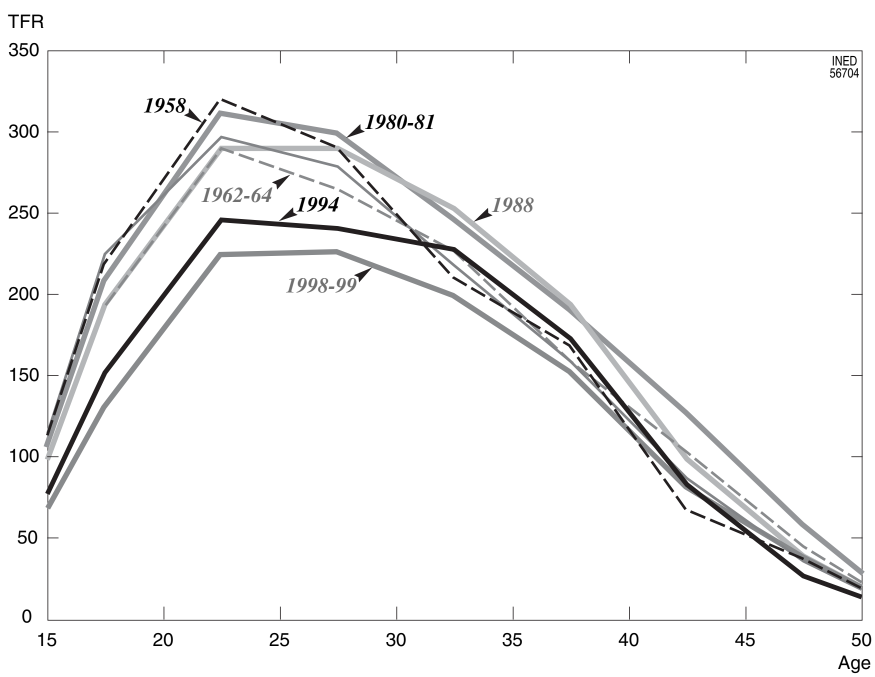

FIGURE 116–4 The evolution of fertility by age from 1958 to 1999. (Sources: 1958: Roussel 1967, quoted in Antoine, 1985; later: N'cho *et al*., 1995; INS and ORC Macro, 2001.)

1950s. The population pyramid, the base of which was very broad in 1950, had evolved by 2000 into quite different a pyramid, with a base clearly narrower and adult age brackets clearly more substantial (Figure 116–6). However, the evolution went through several contrasted phases. This is easily made apparent by tracing the evolution in time of the proportions of people aged under 15 and of adults aged 15 to 64. (The proportion of elderly people aged over 65 remained very small throughout the period.)

From the 1950s to the mid-1960s, the proportion of young people decreased while that of adults increased (Figure 116–7) because the effects of declining child mortality and increasing fertility—which result in making the population younger—were not as strong as the expansion of the adult population, which occurred as a result of immigration. From the mid-1960s to the late 1980s, however, the two factors were perfectly balanced. Though immigration was at its highest, the high birthrate among the native population was heightened by that of immigrant families. In the last phase, from the early 1990s, with the halt in immigration and despite the fall in fertility and the fresh upsurge in child mortality, the proportion of young people has risen again. In fact, by cursorily comparing the 1950 and the 2000 pyramids, we might have come to a wrong conclusion: the aging of the population, due to the recent decline in fertility, is certainly not the main factor of change, and its effects still largely remain to be felt.

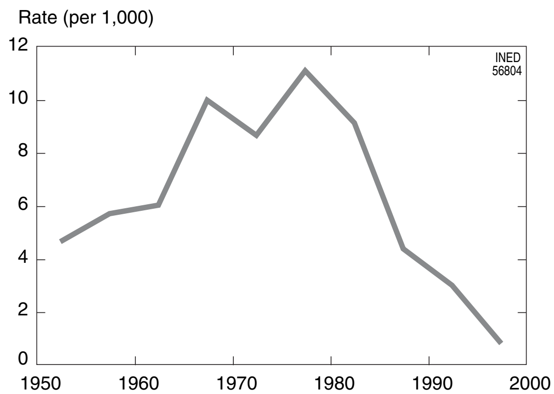

FIGURE 116–5 The evolution of net immigration rates from 1950 according to United Nations estimates. (Source: United Nations, 2003.)

5. The Arrested Urbanization Process

One consequence of the growth of the population was that the density of the population also increased. From 13 people per square kilometer in 1965, the density rose to 21 in 1975 and 48 in 1998. The evolution, however, was very unequal from one region to another (Figure 116–8). For example, the forest areas had their population grow faster, and they are currently more densely populated than the savannah areas. This is the result of intense immigration from the North of the country and from Burkina Faso. The migration began during the colonial period, when it was encouraged by the colonial authorities in a bid to meet the demand for labor in southern Côte d'Ivoire, where plantation economy was being developed, as well as various economic infrastructures. The migration continued after independence, as the various construction projects launched in the South required plenty of labor. Moreover, a succession of dry seasons in the North urged large numbers of people to leave the North and move to the South.

At first the migrants mostly headed for the Southeast, where the plantation economy and the forest industry had begun. Later, they changed their destination, spreading along the Cocoa Belt and more generally following the drift of the plantation economy and the forest industry, which had moved from the East to the West in the early 1970s. Thus it came about that in certain areas in the Southwest, which were practically empty up to the mid-1970s,

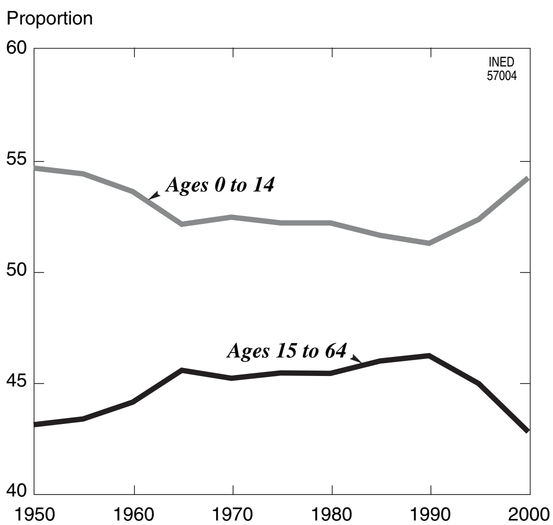

FIGURE 116–7 The evolution of the proportion of people aged under 15 and of those aged 15 to 64 in the population of Côte d'Ivoire, from 1950 to 2000. (Source: United Nations, 2003.)

the population densities are currently higher than the national average.

Urbanization[1] remained negligible until the mid-20th century. In 1948 only 9% of the population of Côte d'Ivoire was living in urban settlements (Table 116–3). However, urbanization was on the way, and in the early 1920s, when the lands of the colony were first developed, the urban population was a bare 2%. Urban growth subsequently gathered speed. It even soared in the 1950s, 1960s, and 1970s, as a combined result of migration, natural growth, and the inclusion of some rural areas among urban settlements. However, the pace of the urban population growth has been slowing down since the 1980s, mostly as a result of migratory flows changing their destination, which in turn was the result of a decline in economic investment.

There are wide disparities from one *département* to another. According to the data from the 1998 population census, some had been through urban transition (Abidjan, Bouaké, Katiola, Grand-Bassam, Dimbokro, Yamoussokro), whereas urbanization was still insignificant in more than half the *départements*.

The urban structure of Côte d'Ivoire is characterized by the overwhelming predominance of the huge city of Abidjan. In 1998 its population was about 2.8 million, whereas that of Bouaké, the second largest town, was under half a million. The number of towns with a population of over 100,000 rose from two in 1975 to five in 1988 and eight in 1998 (Figure 116–8 and Appendix 116–1). Half those larger towns are located in the southwest and the midwest regions of the country, and expanded only as recently as the 1980s and 1990s. Located as they are in the new Cocoa Belt, their expansion is mostly due to high levels of immigration there.

[1] The way "urban population" is defined with respect to Côte d'Ivoire has varied. During the colonial period the definition was mostly an administrative one. From 1960 the size of the population too was taken into consideration. In 1975 a more sophisticated definition was chosen as a result of a consultation process: settlements with a population of over 10,000 were considered urban settlements, but so too were those with a population ranging from 4,000 to 10,000 but where over 50% of the heads of households were engaged in nonagricultural activities. In the 1998 census, the urban world was made up of administrative centers at the level of *départements*, as well as *sous-préfectures* whose population is either over 10,000 or between 4,000 and 10,000 but with over 50% of the heads of households in nonagricultural activities.

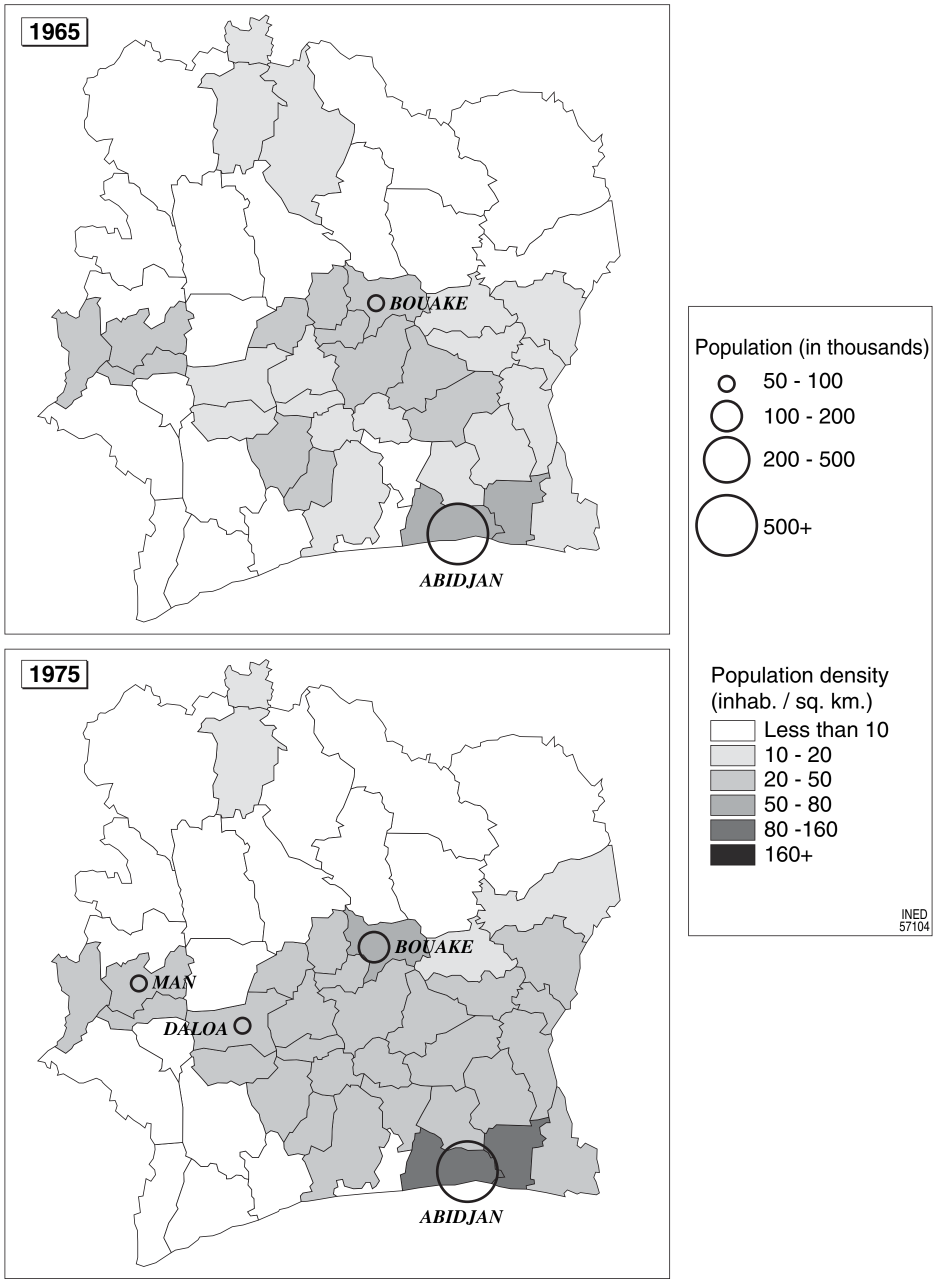

FIGURE 116–8 Population densities by *département* and location of major towns by size in 1965 and 1975. (Source: INS.)

II. A DECLAREDLY PRONATALIST POLICY UP TO 1991

1. The Views in Favor of Population Growth and Their Foundations

The UN permanent surveys with governments suggest that in 1974 Côte d'Ivoire, along with such countries as Gabon, Libya, Morocco, the Central African Republic, Cameroon, and Cape Verde (Makinwa-Adebusoye, 1993), considered that the growth rate of its population was too low. In 1976, however, the government of Côte d'Ivoire stated that the level of fertility and the rate of natural growth were satisfactory and that it did not intend to take any measures to influence them in any way. Most of the African countries who had participated in the UN survey had the same position, particularly the Francophone ones, including neighboring countries such as Burkina Faso, Mali, Guinea, Togo, and Benin. As far as Côte d'Ivoire

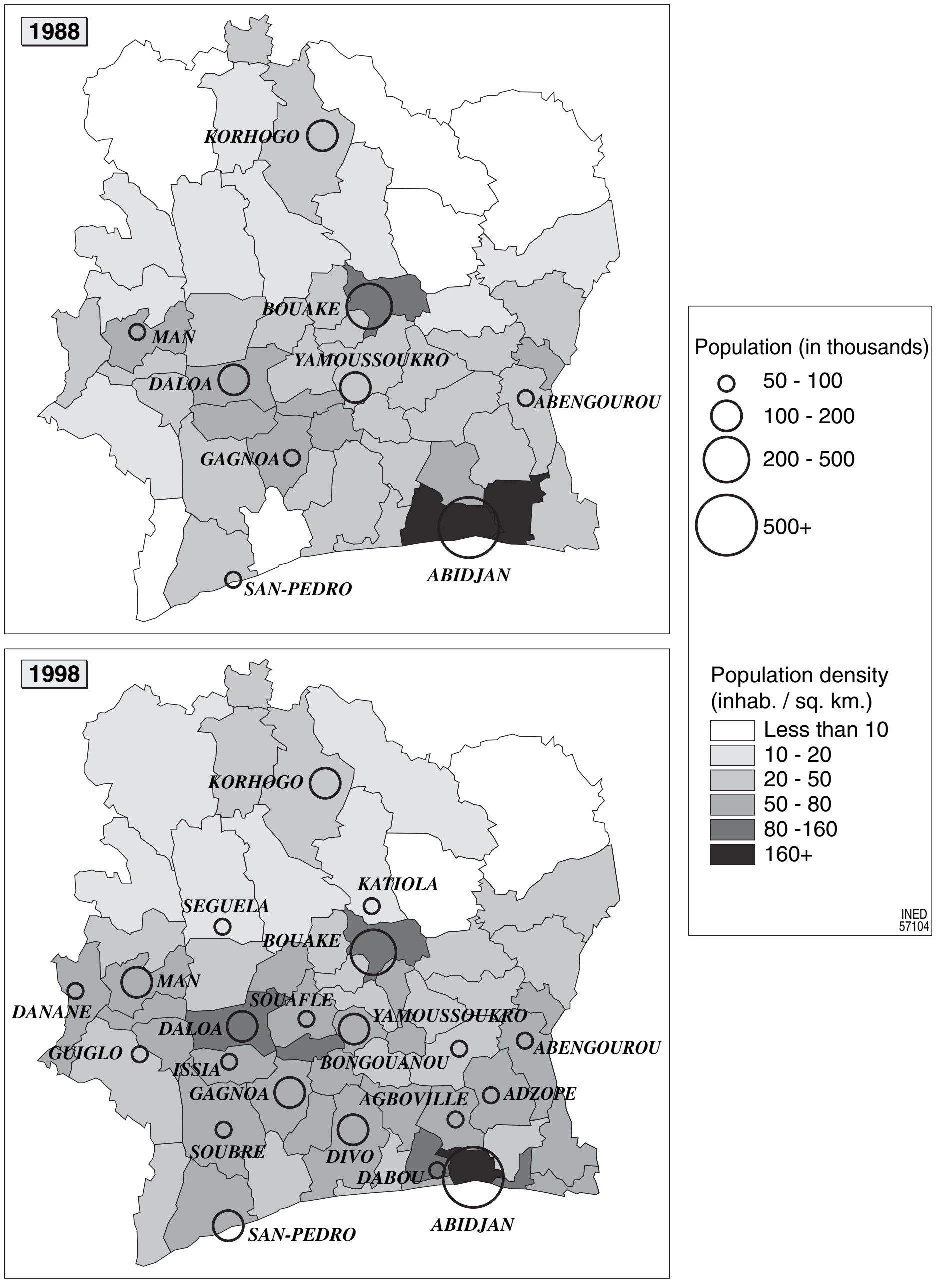

FIGURE 116–8 (*Continued*) Population densities by *département* and location of major towns by size in 1988 and 1998 (Source: INS.)

was concerned, this was a turnaround in policy. The change in attitude was probably due to improved knowledge of demographic facts, which in turn entailed awareness of the fact that, in view of declining mortality, the fertility level was still very high, and thus it was unrealistic to say that the rate was too low.

Through the results of subsequent UN surveys, which were published in the 1980s (1983, 1986, 1989), it appeared that although the government of Côte d'Ivoire was still content with the fertility level and the natural growth rate, it was considering new actions to keep them from growing any higher. In that respect, Côte d'Ivoire was sharing the same position as Mali, Togo, and São Tomé and Principe. Among its Francophone neighbor countries, however, Mali alone officially maintained an identical position as that of Côte d'Ivoire, as Guinea (in 1986) and Burkina Faso (in 1989) had begun to find that the fertility and natural growth were exceedingly high, and stated that they intended to intervene so as to reduce them (Sala Diakanda, 2000).

However, the government's official statements, as reported in UN surveys, were somewhat different from the statements made in such technical documents as the five-year development plans, in 1976–1980 and 1981–1985. In the 1976–1980 planning document, significantly demographic events were taken into account in development planning for the first time, and one objective was to "achieve increased awareness and harmony in population growth, both at family and at national level." According to the planners, such an objective was intended to entail a "quantitative increase in the number of children alive for the benefit of all mothers," on the one hand, and "qualitative improvement in the health level of mothers as well as children," on the other hand (Ministry of Planning, 1980, p. 474–477).

That the government persistently intended the population to keep rapidly growing can be illustrated through three examples of positions expressed in the 1980s. These examples are revealing of how the ideology prevailing among the political class had remained unchanged since the 1960s, in a single-party regime characterized by single political thought and discourse.

In December 1982, in his closing speech at the seminar "Population and Development in Côte d'Ivoire," held in Abidjan, the Minister of Health declared:[2]

> As we have said, the population is the primary element in development. And as you experts have established, the population in our country, which is currently estimated about 8 million, including the native and the immigrant population, is not large enough if compared to the surface of the country. Comparing our population with those of countries with similar surfaces, in 1980 the population of Italy was estimated 57 million for a surface of 310,000 square kilometers. During the same period, the population of Japan was 117 million for a surface of 372,000 square kilometers. If we take only that factor into account, we realize that there is no threat of demographic explosion in our country. (*Fraternité Matin*, December 21, 1982)

Along the same line, the director for Statistics at the Ministry of Planning said, in July 1987, on the occasion of the celebration of population of the planet reaching 5 billion:

> There is no population problem in Côte d'Ivoire. Though certain areas have been identified [. . .] where the population density is very high, with all the social problems it entails, other areas are virtually empty. [. . .] There is no demographic problem; the problem is rather how to use our population. (*Fraternité Matin*, July 13, 1987)

In January 1989, the Minister for Women's Advancement also stated how the authorities thought it desirable that the population grew larger, in her opening speech at the seminar in Abidjan on approaches to birth spacing programs:

> For a long time to come, there will be no overpopulation problem in Côte d'Ivoire. [. . .] It is unnecessary to try to limit childbirths in order to lift concerns that may result from a growth rate among the African population that may be deemed over high, so as to create an obsessive fear of "the Black peril," for example.

In the view of the national authorities of the time, there was no such thing as a population problem, nor was there any need to slow down the population growth in the country. Far from that, a high rate of population growth was deemed desirable. Such views in favor of population growth in Côte d'Ivoire were similar to those previously expressed by civil society representatives in "*Côte d'Ivoire 2000*, the first National Long-Term Perspective Study, which was conducted from October 1973 to June 1974.

The authorities' position was underlain by several factors. Firstly, the government believed that population growth would have positive effects on economic and social development. The alleged advantages of a large population were of various kinds—economy of scale, an urge to work hard and be creative, and so forth. Population density was perceived as a means through which population growth determined the wealth of nations. In that view, low population density at national level (17 people per sq. km. in 1970, 25 in 1980, and 36 in 1990), combined with wide regional disparities, contributed to the authorities continuing to think of population growth as desirable. The abovementioned comparison between Côte d'Ivoire and a few countries such as Japan or Italy, which had a far different point of view concerning population density, and still more so from that of economic power, is revealing of the terms of the argument of the time, in which population density was believed to be synonymous with economic development.

Such an attitude among the authorities was further confirmed by ideological and socioeconomic motivations among individuals. In the common people's view, the birth of a child is always perceived as a positive event. From a cultural point of view, in the people's beliefs, a child bears the soul of some member of the community of ancestors. This is the reason why birth limitation remained all but taboo. Also, from a socioeconomic point of view, the parents wanted to

[2] The seminar was held in Abidjan December 13–19, 1982, and jointly organized by the Ministries of Planning and Industry, and of Public Health and Population, on the one hand, and the United Nations Economic Commission for Africa (ECA) on the other hand. The Minister's speech was read by the Minister of State for Industry.

have a large family because children represent ready-made labor, a guarantee of security for their old age, and social prestige (attached to the large number of their descendants).

One more factor that accounted for continued pronatalist attitudes in Côte d'Ivoire was the fact that it belonged to the group of former French colonies. Not only had France left its colonies with a pronatalist legislation very much like its own, but most importantly, it tended to hold a qualified position in international conferences on population and development. For example in Bucharest in 1974 the French delegate, Michel Durafour, then Minister of Labor and Population, steered a middle course between those countries that advocated family planning programs (such as the United States, India, Indonesia, and Bangladesh) and those that believed that development was the best of contraceptives (Algeria and Argentina, among others) (see *Fraternité Matin*, August 22, 1974).

The pronatalist position of Côte d'Ivoire thus appears to be underlain by many different reasons, not only economic and material, but also political, cultural, and religious ones. Such a variety of factors account for the fact that, despite improved knowledge of the relations between rapid population growth and economic and social development, on the one hand, and the economic crisis and the consequences of the structural adjustment programs that have been enforced since the early 1980s, on the other, it took a long time for the political authorities to change their official position.

The pattern for development in Côte d'Ivoire, which was particularly interventionist, largely relied on planning, which required good knowledge of the socioeconomic and demographic situation. The combined efforts of the Ministry of Planning and multilateral and bilateral cooperation made it possible to improve demographic knowledge. For example, regional surveys were conducted all over the country from 1962 to 1964 in preparation for the first five-year plan. Also, Côte d'Ivoire participated in the African Census Program (population censuses in 1975, 1988, and 1998), the World Fertility Survey (with a fertility survey in 1980), and the Demographic and Health Surveys (1984, 1998–1999).

2. The Social Measures Intended to Encourage the Natural Growth of the Population

The first social measures taken immediately after the independence of Côte d'Ivoire, particularly in the areas of women's education and health, for "the promotion of man in Côte d'Ivoire and improved adequacy of the economic, social, and cultural system" (Ministry of Planning, 1980, p. 455–487) were reinforced from the second five-year plan (1976–1980) with a view to promoting "more awareness and harmony in demographic growth, both at family and at national level" (Ministry of Planning, 1980).

As far as education was concerned, an ambitious policy had been decided on immediately after independence, with a school enrollment rate of 100% by 1980 as its main objective. (For more on the development of education in Côte d'Ivoire, see, e.g., Anygbayere, 1992). Measures were taken to urge families to send their children to school. A slogan was launched—"A man who cannot read is like a blind man in the forest" (Any-Gbayere, 1992, p. 2)—and the government contributed to expenses for children's schooling. In addition, infrastructure was expanded, particularly during the 1970s, salaries were made more attractive (by giving teachers special rates, different from those of other civil servants), and teachers were supplied with lodgings, which ensured that educational and training services were available. The budget for the sector was constantly on the rise, from 12.5% in 1960 to 40% in 1980 (Ministry of National Education, quoted by Zanou, 1994).

Those efforts resulted in significant reduction of illiteracy among the adult population, particularly among women. The literacy rate among adult women rose from 5% in 1970 to 24% in 1990. During the same period, the rate among men increased from 35% to 44%.

The influence of education on fertility depends on supply and demand. Education changed people's notions about fertility-related matters and provided better knowledge of biomedical norms of procreation. Education also mechanically postponed the beginning of reproductive life and broadened access to health care, which was favorable to mothers' and children's health. Besides, it broadened access to information on the existence and proper use of modern contraceptive methods.

Health-related measures were also taken with a view toward encouraging people to have many descendants while improving child survival. From the 1976–1980 plan, the health system was firmly geared to promote preventive medicine, social hygiene, and health education, based mostly on the approach to basic health care advocated by the international community in the 1970s. Although the priority was preventive medicine, curative medicine was not neglected. The health infrastructure was thus expanded, particularly in Abidjan and certain regional administrative centers such as Bouaké, Abengourou, Korhogo, Yamoussoukro, and Daloa. Specific programs in mothers' and children's protection were implemented. For example, the Expanded Immunization Program was developed, with a view to immunizing children from the most serious transmittable diseases and pregnant women from tetanus.

The pronatalist legislation inherited from France, particularly the act passed in France just after the war (July 31, 1920) in an effort to stop the fall in fertility, banning abortion as well as advertisements of contraceptive products and their importation and sales in Côte d'Ivoire, was relaxed in the early 1980s, with a view to ensuring that women and children were in better health. The 1920 act was repealed through Article 11 in Act 81-640 (dated July 31, 1981), instituting the new penal code (*Journal Officiel de la République de Côte d'Ivoire*, January 4, 1982). Access to reversible contraceptive methods was made easier, and new laws were enforced that slightly relaxed the former laws on abortion. The complete ban on abortion was lifted, only to be replaced with an extremely restrictive system, in which abortion was allowed only to save the life of a pregnant woman. Two doctors, besides the general practitioner, were required to confirm that the abortion was necessary to save the mother's threatened life. In all other conditions, abortion was considered a crime, and so were advertisements on and sales of abortive substances (Articles 366 to 369 in the penal code). Sterilization remained prohibited. Although the ban on the more common reversible methods, such as the pill, injections, intrauterine devices, and condoms, was lifted, they received no direct support from the government until the late 1980s. Neighboring countries such as Ghana and Mali, and pioneering ones like Kenya, had moved far ahead of Côte d'Ivoire in that respect, as they have been directly supporting the distribution of contraceptive methods since the 1970s.

Though the repressive pronatalist legislation was relaxed, because of the prevailing pronatalist ideology, no family planning program was implemented in Côte d'Ivoire during that period. In the view of the authorities, family planning in Côte d'Ivoire, as the Minister for the Promotion of Women put it, could only be

> synonymous with birth spacing, with the preservation of mothers' and children's health as its main objective, as defined by WHO, i.e. such general condition of physical, social and psychological welfare as is likely to preserve family balance and provide youth with natural means for their protection. (Aka-Anghui, 1989)

A few dissenters were sternly brought back into line, for example, during the Population and Development in Côte d'Ivoire seminar in Abidjan in 1982 (Zanou, 1994), and after the speech on family planning by the Chairman of the Côte d'Ivoire Family Welfare Association (known as AIBEF) at the pilot center at Port-Bouët (in the Commune of Abidjan) for the young people of the commune on August 18, 1988. Following the report in the August 24, 1988, issue of the daily newspaper *Fraternité Matin*, the Minister of Health, as directed by the President of the Republic, called to order AIBEF Chairman, Professor Samba Diarra, and had a conference scheduled for the members of the Economic and Social Council cancelled (Samba Diarra, personal communication, March 1999).

Among those interventions implemented to actualize the pronatalist attitude, women's education, the new laws on the family, and the health measures were ambivalent, as they did not necessarily induce such higher natural growth rate as the national authorities were bent on achieving.

The new laws on the family provide a good example of the ambivalent measures taken during the pronatalist period in Côte d'Ivoire. Beginning in the early 1960s, the authorities undertook to develop laws on the family, with a view to unifying the existing legal rules at the national level and also to adjusting customary and traditional rules to economic and social evolution. The new laws, which were inspired by the French Civil Code and which instituted the national civil law, were passed in 1964. The laws, which were passed in the National Assembly on October 7, 1964, and promulgated on December 8, 1964, were published in the *Journal Officiel de la République de Côte d'Ivoire* on October 27 and December 17, 1964 (Raulin, 1968).

The provisions concerning marriage, divorce, and inheritance granted women more autonomy and laid the basis for the notion of the family to change from "extended" to "conjugal." The law on marriage (Law 64–375), in which legal age for first marriage was 18 for women and 20 for men, made the personal consent of each of the prospective spouses mandatory, prohibited polygamy, and abolished matrimonial compensation (which consisted of offering material benefits to the prospective bride's extended family). Those provisions were intended to allow time for girls to achieve a degree of maturity before they got married. It was now impossible to marry girls off without their consent, which meant a complete break from the traditions of early, forced marriage, particularly of the polygamous type. In 1983 the reform was complemented, as men and women were granted the same rights and duties in the family (Law 83–800, August 2, 1983). Also, in the 1964 law on divorce (Law 64–376), infertility and impotence were barred as grounds for divorce. (According to the Ten-Year Perspective Study 1960–1970, there was a significant proportion of infertile women in the early 1960s.) This was a significant change, in which procreation was no longer viewed as the primary objective of marriage; however, in the traditional system, infertility did not necessarily entail divorce, as it usually encouraged men to become polygamous. Last, the conditions for inheritance were also amended (Law 4–379). The children and the wife of the deceased were now among his heirs, which was unthinkable in traditional systems, among patrilineal groups (the savannah and forest people, West of Bandama) as well as matrilineal ones (the forest people East of Bandama). However, concerning the means to enforce the new laws, the legislators did not provide for any sanction for trespassers, preferring educational methods to repressive ones (Raulin, 1968).

3. An Ultraliberal Immigration Policy

Immigration was the other component of the propopulationist policy in Côte d'Ivoire. That policy enforced during the first two decades after independence has often been termed ultraliberal. It was reflected in the speech by President Felix Houphouët-Boigny at the Sixth Congress of the Democratic Party of Côte d'Ivoire in 1985 (quoted by Brou and Charbit, 1994, p. 35):

> We have welcomed over two million of our brothers here. Many of them have settled for good, and will never go back home again. What we do in Côte d'Ivoire is welcome them. And we do so in a spirit of an African-style humanity inspired with a sense of brotherhood.

That liberal policy made Côte d'Ivoire the major immigration country in West Africa (United Nations, 1997, quoted by Tapinos, 2002). The flows were particularly high during the first two decades of independence. The net amount of international migration was estimated 450,000 people during the five years between 1976 and 1980. According to the data of the recurrent visit survey in 1978–1979, the net annual immigration rate was 1.3% in 1978–1979. However, due to the crisis and consequently scarcer economic investment, the immigration flows sharply decreased during the 1980s, and the net annual immigration rate was brought down to a bare 0.5% in the 1988–1992 period.

The data available show that although the flows were decreasing, the migratory stock still continued to go up. From 700,000 people in 1965—17% of the total population—the foreign population rose to 1.5 million (22%) in 1975, to 3.0 million (28%) in 1988 and 4 million (26%) according to the latest census in 1998.

Such immigration is not exactly the direct consequence of any ad hoc measures taken by the authorities. The two main interventions in that respect (the March 1960 Agreement between Côte d'Ivoire and Haute-Volta, and the Agreement of Cooperation between France and Côte d'Ivoire in 1961) (see Brou and Charbit, 1994) did not really have much effect in themselves. Nor did multilateral agreements such as those made by the *Conseil de l'Entente* (the Council of Accord, a West African organization for regional cooperation with five Francophone member countries: Benin, Burkina Faso, Côte d'Ivoire, Niger, and Togo) or the Economic Community of West African States (ECOWAS), which advocated free movement of people and goods. Immigration in Côte d'Ivoire is rooted in colonial strategies of land development as well as in the pattern for development decided on by the national authorities after independence. The migration was mostly labor based. At first, migrants came of their own free will. However, to thwart the tendency of the populations from the North, particularly from Haute-Volta, to go to the Gold Coast (now Ghana), where wages were more attractive, the colonial administration soon conscripted men from Haute-Volta for forced labor. The process was later reinforced during the war effort.

After forced labor was abolished in 1944, the employers formed an association, the Inter-Professional Union for Labor Recruitment (known as SIAMO), which started signing contracts with Mossi chieftains. The annual number of laborers recruited by SIAMO is estimated to be 20,000 people between 1953 and 1959. From 1919 to 1959 a total of 776,418 migrants from Haute-Volta were thus transplanted to Côte d'Ivoire.

After SIAMO stopped working in 1960, immigration continued, as encouraged in the March 1960 Agreement, in which foreign immigrants were recognized as an important component of the economy that the colonial power had left for the national authorities to manage. However, much of the migration went on without the institutional framework provided by the agreement, as spontaneous movements expanded, based on powerful social networks in the larger towns as well as in rural areas. After the immigrants were expelled from Ghana in 1969 and a crisis affected that country from the 1970s, Côte d'Ivoire became the first country for immigration in West Africa, superseding Ghana, which had been the main one in the subregion up until the early 1970s.

The ultraliberal, loudly advertised policy not only made it easy for immigrants to come to Côte d'Ivoire, but also to have access to employment, both in the private and the public sector, to enter the professions or to create agricultural concerns, particularly in the South where the forests were. Access to land property was also made easier for foreigners. However, the law published on March 20, 1963, according to which unregistered land should be considered as government property, could not be enforced, due to strong opposition from the traditional landholders, and was replaced with a mere statement by the President, who said that "lands belong to those who work on them, provided they are observant of the current laws and rules." In practice lands were distributed in accordance with customary rules, in which land is collectively owned, inalienable property. It cannot be sold off, but a portion of it can be allotted to a member of the clan or any other person who then holds the right to work on it. As a token of his gratitude, a person who acquires land in this way must offer a few bottles of liquor, a very small sum of money, and so on. Thus anyone could have access to land property without being particularly rich. This is how many foreigners who settled in Côte d'Ivoire created agricultural concerns, particularly in the new Cocoa Belt, to which most international and internal migrants rushed in the 1970s.

The political class, however, could never agree over that liberal option, about which reservations were made concerning certain aspects of the immigrants' integration. (The presence of foreigners has never been a problem in itself in Côte d'Ivoire society, which is reputedly very hospitable. It is the degree of integration that may cause reluctance.) This is the reason why in 1966 the Parliament of Côte d'Ivoire firmly opposed President Houphouët Boigny's proposition to allow nationals of the former French West Africa (AOF) to apply for double nationality (Dozon, 2000). And the reservations concerning the immigrants' integration were considerably heightened as the economic crisis affected the country and unemployment rose among educated youth in the 1980s.

The crisis and the structural adjustment programs (SAPs) caused a radical change to be effected in the population policy, reflected in both migration and fertility policies.

III. A SHIFT IN POPULATION POLICIES FROM 1991

1. From the Policy Statement on Human Resource Development to That on Population

The change in the government's attitude toward demographic issues was shown in the *Policy Statement on Human Resources Development* issued in 1991. The policy was one of the main components of the SAP during the period 1991–1993. There were three components in that phase of the SAP in Côte d'Ivoire: the Financial Sector Adjustment Program, the Competitiveness Adjustment Program, and the Human Resources Development Program. According to the government's policy statement, the human resources development policy consisted in implementing a population policy geared toward sustainable development (Republic of Côte d'Ivoire, Monitoring Committee on Human Resources Promotion, 1991).

Although the population density remained comparatively low and many factors that favored fertility were still enforced, the crisis, combined with pressure from the international institutions, caused the national authorities to take up new, neo-Malthusian views. However, besides the SAP, a conjunction of internal and external factors also urged the authorities to change tack in population policy.

At the national level, the advocacy by the national Association for Family Welfare (AIBEF), the seminars and colloquiums on population, the improvement of demographic knowledge, and population projections all influenced the public authorities' perception of population issues. For example, a national seminar was held for the members of Parliament on the theme of Health, Population, and Development in Abidjan in November 1987. The same theme was discussed in several other seminars, including the district conference for community leaders held in Bouaké on January 18, 1990. At the regional level, the African population conferences, both scientific and political (Accra 1971; Arusha 1984; Dakar 1988; Dakar/N'gor 1992), as well as the setting up of interest groups, such as the Council of African members of Parliaments on Population and Development (created in 1986), contributed to promote and strengthen a new understanding of population issues. At the global level, the international institutions had a decisive influence on the government's positions, particularly through the world population conferences organized by the United Nations, but also, in a more concrete way, through the action of the World Bank or the International Monetary Fund. Côte d'Ivoire did not attend the Bucharest conference, but it was present in Mexico in 1984, when it was represented by its ambassador to Mexico. Whereas its participation was still timid at the time, it was more determined in 1994 in Cairo, after the government had changed its position: that delegation, led by the Minister of Culture, included a dozen government and associations executives and five representatives from the media.

Both the persuasion strategies developed by the United Nations agencies and the AIBEF and the World Bank's human resources development policy clearly accelerated the change in the national authorities' perception; but it was the deterioration of the socioeconomic situation that basically provided favorable ground for the change in policy.

The human resources development policy resulted in the adoption, in March 1997, of a statement on the National Population Policy (Republic of Côte d'Ivoire, Ministère délégué auprès du Premier ministre chargé du Plan et du Développement industriel, 1997). Henceforth the situation of Côte d'Ivoire was similar to those of many other Francophone countries, the majority of which had defined a population policy no sooner than the 1990s.

The objectives and broad outline of the new National Population Policy (NPP) of Côte d'Ivoire were largely inspired by the principles and recommendations in the World Population Action Plan which, since the 1984 Conference in Mexico City, had been advocating an approach in which population programs were to be integrated in economic and social development strategies. The general objectives of the NPP were thus organized around three themes: the population movement; the economic, social, cultural, and environmental background; and the capacities in planning and managing population policies and programs.

At the institutional level, four bodies were created that were intended to manage population issues:

1. A decision body made up of the Council of Government ministers.
2. A consultative body, the National Population Council (known as CONAPO) the members of which were those Ministries involved in population issues and nongovernmental organizations (NGOs). At the regional level CONAPO was represented by Regional Population Councils (the COREPOs), which were made up of the regional representatives of the technical government departments who were members of the CONAPO.
3. An executive body made up of 14 technical government departments and those NGOs active in impacting on the demographic movement.
4. A technical body, the National Population Bureau (the BUNAP), which served as Secretariat to the CONAPO, coordinated the activities of the various sectors, provided technical support to the Government departments in resource mobilization, and prepared and submitted projects to development partners for funding.

As part of the implementation of the National Population Policy, a National Population Program of Action (known as the PNA) covering the period 2002–2006 was adopted in March 2002 (BUNAP, 2002).

2. The 2002–2006 National Population Program of Action (PNA)

The National Population Program of Action (PNA) for 2002–2006 was adopted too recently for any assessment of its implementation to be made yet. However, it is possible to assess its objectives, priority actions, and investments, as well as the institutional framework for the implementation of the program.

The objectives of the PNA were defined based on the population issues mentioned in the National Population Policy Statement and those identified during the report and diagnosis made while the PNA was being developed. A number of major demographic challenges were thus identified, for the 2002–2006 PNA to meet (BUNAP, 2002, p. 52):

Manage demographic growth
Manage migratory movements and refugees
Alleviate poverty
Alleviate the impact of AIDS
Ensure that the family's fundamental values are respected, reinforce women's autonomy, ensure that youth are the spearhead of the nation, and provide for the aged
Control urbanization, which is exceedingly rapid
Mobilize resources for the implementation of the program
Ensure efficient management of population programs

The five general objectives selected in the National Population Policy Statement have induced five operational subprograms to be defined, each of which is placed under the responsibility of a government department. The National Population Bureau (BUNAP) is in charge of the cross-sector coordination of activities (Figure 116–9). Each subprogram includes a number of Priority Actions and Investments (PAI), which in turn include immediate objectives, the term of which is 2006. The PAIs are the basic elements for the implementation of the National Action Program. Implementing the PAIs requires collaboration between several government departments, private associations, and NGOs committed to population issues.

We will take two subprograms related to demographic movements to illustrate how they work: controlling natural population growth and developing capacities in migratory movements management. The former is placed under the responsibility of the Ministry of Health and Population, and the latter of the Ministry of Home Affairs and

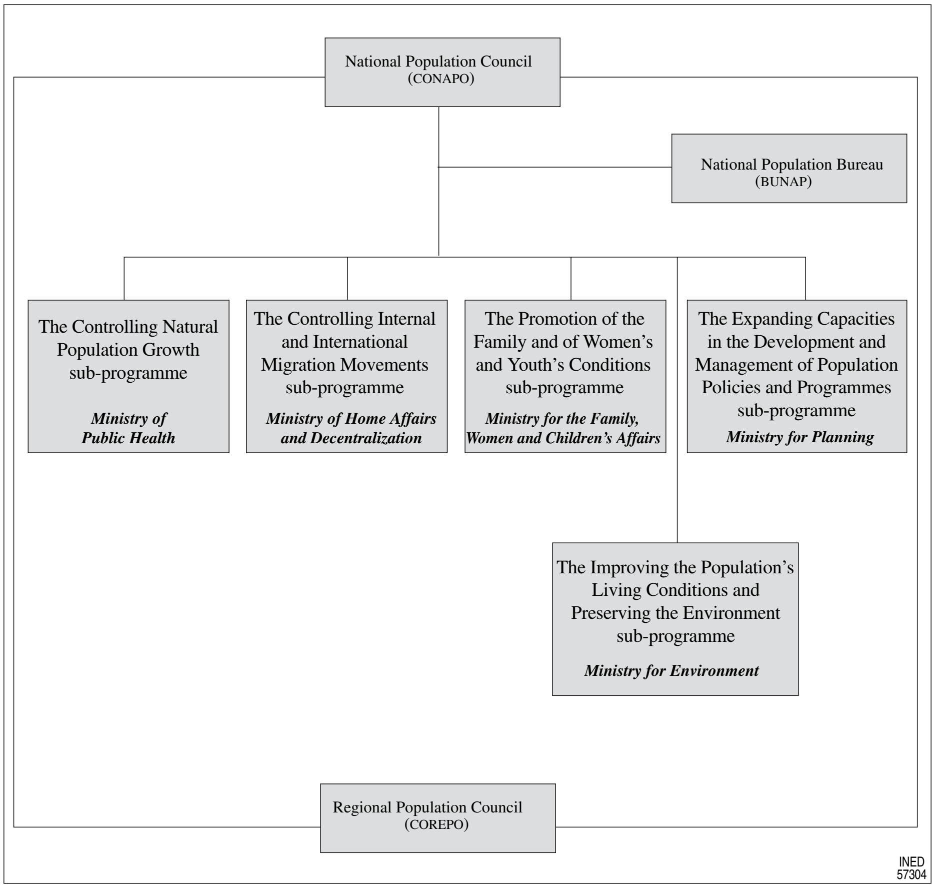

FIGURE 116–9 The organization of the Population Program.

Decentralization (now renamed Ministry of National Administration).

Controlling the Natural Population Growth

The point on which the newly adopted population policy diverged from the former was primarily the question of fertility control. The subprogram on Control of the Natural Growth of the Population includes five PAIs, one of which is concerned with "improved supply, accessibility and use of reproductive health services (including the sexual and reproductive health of adolescents and youth)."

Seven immediate objectives are included, implying a number of activities the implementation of which requires the implication of the executive directions (EDs) of various programs, including the National Reproductive Health Program (NRHP). (There will be further discussion on the part played by the ED/NRHP as we analyze the reproductive health policy.) Technical government departments (the Ministry of Youth, of Defense, etc.) are also involved, as well as NGOs and associations.

By examining the operation plans of the various subprograms, it turns out that the immediate objectives are usually defined for the whole of the national territory. Does this mean that those objectives will be uniformly implemented in all the regions in the country? It is not mentioned, but considering that demographic behaviors are not homogeneous, the heterogeneousness should be taken into account.

The relations between the National Population Bureau (BUNAP) and the implementing structures must also be studied. At first BUNAP was no more than a minor department within the Prime Minister's office, but it has just been upgraded into a central department in the Ministry of Planning and Development. Such institutional position makes it easier for BUNAP to coordinate the activities of the other central departments involved in the national population policy. At the present stage of the process of developing and implementing the national population policy, it has been able to carry out its tasks without any major difficulties, probably thanks to the participatory approach being used, but there is no knowing how long such non-conflict collaboration can be continued between BUNAP, the technical government departments, and the NGOs working on population issues. The question is justified because, due to lack of any centralized planning, the government departments tend to develop their own individual sectoral development plans and compete in the search for funding.

A few examples can be mentioned: the 1996–2005 National Health Development Plan (NHDP); the 1996–2010 National Environment Action Plan (NEAP), the 1997–2010 National Plan for the Development of the Education and Training Sector (known as PNDEF), the 2002 National Action Plan for Women, and the 2002 Provisional Poverty Alleviation Strategy Document.

The armed conflict that broke out in Côte d'Ivoire on September 19, 2002 has slowed down the implementation of the National Action Plan, in that the development partners, who very actively participated in the implementation of the population policy, have redirected their support in favor of humanitarian aid, particularly assistance to displaced populations.

However, a number of PAIs are beginning to be implemented because they were defined based on actions that were already ongoing within sectoral programs conducted by government departments. For example, the PAIs for the Control of the Natural Growth of the Population subprogram are being implemented within the National Health Development Plan (NHDP), precisely within the National Program for Reproductive Health and Family Planning.

3. Immigration Control and Foreigners' Integration

The next major turnaround in Côte d'Ivoire's population policy concerns immigration. The ongoing changes include the three main components of migratory policies: the conditions for foreigners to enter and stay in the country, foreigners' integration, and international cooperation.

The law of May 29, 1990, under which the entry and stay of foreigners in Côte d'Ivoire are presently regulated, is more restrictive. Though, according to the law, any foreigner is supposed to have free access to the national territory, provided they produce official identity and health documents. The identity documents can be used to enter Côte d'Ivoire only if a visa has been delivered, and only the nationals of a few countries, namely those who are members of the Economic Community of West African States (ECOWAS), do not have to have a visa (Aggrey, 1999). Thus, incoming foreigners are now controlled as a rule. However, the law is not always wholly enforced because the borders can be easily crossed, and illegal situations can be perpetuated because the notion of residence is quite vague in Côte d'Ivoire, inasmuch as there is no precise system of residential address as in developed countries.

The migratory flows were first inverted during the latter half of the 1980s, due to the growing crisis in employment, as a result of scarcer investment and its consequences on the migratory exchange between Côte d'Ivoire and Burkina Faso (Vimard *et al*., 2002). President Felix Houphouet-Boigny had established a liberal system, in which immigrants had the same rights as nationals, particularly as far as access to land ownership and public offices and participation in various elections were concerned. Would the change have been so great, if that policy had not been called into question? Probably not—still, most of the arguments in favor of nationalism in Côte d'Ivoire, which is sometimes considered the impulse behind the principle of *Ivorianness*,[3] are built on the demographic weight of foreigners. However, there are not enough data available for us to distinguish with any accuracy, in the reversal of migratory flows, between what is related to policy change and what is due to the crisis in employment that resulted from the economic crisis.

As a matter of fact, though migration flows have been inverted, significant flows are continuing to come into Côte d'Ivoire, as discussed in a recent article in the daily newspaper *Fraternité Matin* (Zobo, 2003). Such flows are supported by networks established by the immigrants who have previously settled in the country.

Another important component of the migration policy is the set of measures taken to ensure better integration of immigrants in the country of residence. The issue is crucial because although immigrants keep close ties with their native countries, the majority of them have come to settle for good (Tapinos, 2002). According to the data from the 1998 national population census, the population pyramid is becoming more regular: the proportion of foreigners born in Côte d'Ivoire, of immigrant parents, was 47%, and the number of foreigners is bound to keep increasing because of its natural

[3] "Ivorianness" is quite vague a concept. Those who developed the concept say that it is related to culture, whereas those who oppose it think that it means exclusion and xenophobia (see, e.g., *Politique Africaine*, no. 78, June 2000).

dynamic. Integration, however, is a long-term process, and involves a number of mechanisms including education, employment, and nationality.

As far as education is concerned, the school enrollment rate among children of immigrants, though quite high, is lower than among the Côte d'Ivoire natives; this applies to both girls and boys. According to the 1993 Migration and Urbanization Survey (known as EIMU) (N'Cho *et al*., 2001), the school enrollment rate among the daughters of immigrant parents was 35.5%, compared with 51.7% among those of Côte d'Ivoire natives; among boys, the rates are 49.7% and 61.2%, respectively (N'Cho *et al*., 2001). And yet, all young people are supposed to have equal access to schooling and training in Côte d'Ivoire, whatever their nationalities. The variations observed between the various nationalities are thus due not so much to public policies as to the parents' assessment of the costs and benefits related to schooling. On the other hand, some immigrants' children return to their parents' native countries for further training because the cost of education is lower there than in Côte d'Ivoire (Zanou, 2001).

Virtually all foreigners of working age have an occupation. They are mostly in two sectors: the primary sector (agriculture, cattle breeding, fishing and forestry) and trade, though on a smaller scale. Such orientation in the foreigners' activity is determined by that of three communities: the natives of Burkina Faso, Mali, and Guinea, who represent approximately 82% of the foreign population. In the agricultural sector, the foreigners work as foremen, unskilled workers, or mothers' helpers; in trade and the craft industry, most immigrants are self-employed. It seems that foreigners have a monopoly over certain sectors, such as retailing. The foreigners' level of economic integration thus appears to be quite exceptional, or in fact unique in West Africa. Economic integration is achieved despite scarce use of the citizenship process, which is admittedly a means to facilitate or speed up the integration of immigrants in their country of residence.

In 1996 a Department for National Integration and Immigration was created within the Ministry of Home Affairs, which showed the authorities' intention to regulate migratory flows. The intention was reinforced in the Refoundation (the economic and social development program of the *Front populaire ivoirien* ([FPI], the People's Front), which came into office in October 2000), when Law 2002–03 was passed (on January 2, 2002) relating to the identification of persons and foreigners' visits in Côte d'Ivoire, a National Identification Office was created, and an operation was launched in June 2002 for new national identity cards and residents' permits to be delivered.[4] The operation was slowed down due to the armed conflict that broke out during the night of September 18, 2002. There are not enough data to assess the effect of such policy change on immigration. However, the effect is probably small, considering that the measures taken were only aimed at distinguishing among individuals, as in the developed countries. The operation is expected to make it possible for large numbers of people to obtain identity cards, though they had never had any because the registry offices system was inadequate.

The annual number of persons who applied for and were granted citizenship rose from 15,146 in 1988 to 88,714 in 1998, which implies an average annual increasing rate of 5.3% during the period between the two censuses. If such a rate were to continue, the number of people obtaining citizenship would increase twofold within 13 years. Based on the data from the latest population census, an estimated 1.3 million people are likely to apply for citizenship, in conformity with the Côte d'Ivoire Nationality Code (Law 72–852, dated December 21, 1972).

However, appropriate communication strategies should be implemented so that large numbers of that population, which is mostly illiterate, actually apply for citizenship (Anoh *et al*., 2002).

Though economic integration of foreigners is a reality in Cote d'Ivoire, political and cultural integration sets limits that remain difficult to overcome. The more obvious illustrations include withdrawal of voting rights for foreigners, after the death of President Felix Houphouet Boigny, and strict enforcement of regulations concerning access to public offices and posts. In principle, "political rights are exclusively reserved for nationals. This entails that foreigners cannot exercise any political rights in Côte d'Ivoire, nor participate in political elections, either as electors or candidates" (Aggrey, 1999). It should also be mentioned that in traditional societies in Côte d'Ivoire, foreigners have no right to leadership. It seems this is also true in the native countries of most of the immigrants in Côte d'Ivoire. This shows that in fact the turnaround in the policy is no more than reverting to standards that were prevalent in West African traditional societies and are still enforced today.

The third component of the migration policy includes the measures in international cooperation

[4] Foreign residents' documents include (1) a free movement permit for nationals of the ECOWAS, when their visit does not exceed 3 months and the person does not have a passport; (2) a resident's permit for visits over 3 months; (3) a provisional resident's permit or a refugee's card for asylum seekers (Article 9, Law 2002–03 dated January 2, 2002, on the identification of persons and foreigners' staying conditions).

taken at bilateral or regional level with a view to improving control of migratory flows and promoting development in the emigration countries. Efforts have been made in that respect. Among other things, an agreement was signed in 1979 concerning free movement of goods and people and, more recently, in May 2000, the Conference of Presidents decided to launch the ECOWAS passport.

The controversy over Ivorianness broke out in the mid-1990s, as a consequence of the rivalry between Prime Minister Allassane Dramane Ouattara and the constitutional heir apparent, Henri Konan Bédié. The notion of Ivorianness has been termed xenophobic and is loaded with high emotional charge, which accounts for the many various constructions around it. As a matter of fact, the notion implies national preference, but also breaking away from President Houphouet Boigny's ultraliberal immigration policy; however, those who invented it did not mean it to become an element of division. According to ethnologist Niangoran Bouah,

> [it is] all the social and historical, geographical and linguistic data through which an individual can be defined as a citizen of Côte d'Ivoire. Individuals who claim that they are citizens of Côte d'Ivoire are supposed to have Côte d'Ivoire for their country, to be born of parents who belong to one of the native ethnic groups of Côte d'Ivoire. (Jarret and Mahieu, 2002)

In a speech at the PDCI-RDA's 10th Ordinary Congress, on October 28–31, 1996 in Abidjan, President Henri Konan Bédié declared:

> Whatever our ethnic group, religion, region or race, Ivorianness is meant for all of us, even for foreigners, as long as they take up the national culture for their own, as many natives of Côte d'Ivoire do once they have settled for good in their country of residence abroad, for example in France. In other words, Ivorianness, as the distinctive culture of the natives of Côte d'Ivoire, of all of them, without any exclusion whatsoever, is the opposite altogether of tribalism, ethnocentrism or racism. (quoted by Adé Adiaffi, 1998)

To those who promoted it, Ivorianness thus means assertion of a cultural specificity. The notion later took on a political connotation, based on the fact that certain foreigners were blamed for making the most of their privileges as citizens of Cote d'Ivoire, while keeping their initial nationality. However things stand, the fact is that the concept has been used in a way that went far beyond the process of cultural and political integration of foreigners in Côte d'Ivoire, which it was supposed to respect.

4. Internal Migration

Population policies are also concerned with internal migration. Some of the objectives have begun to be implemented as part of the population redistribution policy that has been going on since the 1980s. As a result of the objective of reducing regional disparities, vast land development and regional development programs were implemented as part of development planning. Three examples can be mentioned: the Bandama Valley Development project, the Southwest Region Development project, and sectoral development projects such as those on palm, rubber, or coconut trees in the forest-covered South, or those on cotton and sugarcane in the savannah regions in the North. The aim of those programs is to slow down urban drift and redirect the migration flows from the forest-covered South to the North and Center of the country. Underlying the policy are decentralization and such measures as may encourage young people to work in agriculture (Brou and Charbit, 1994). The rotating national celebrations, which implied substantial investments, have contributed to the promotion of the inland towns by opening them up and modernizing them. This, however, did not hamper rapid expansion of the city of Abidjan, which benefited from substantial investment, as the main target of the hypermodernistic urban project of the authorities (Le Bris, 1998). Nevertheless, decentralization has been selected among the major components of Refoundation, which is likely to reinforce such population redistribution policy.

As an illustration, we now take a closer look at the Reproductive Health and Family Planning Program, the component that is most advanced in the implementation of Côte d'Ivoire's National Population Policy.

IV. THE CONSTITUTION OF THE REPRODUCTIVE HEALTH SUPPLY AND THE EVOLUTION OF FAMILY PLANNING

1. From the Human Resources Development Policy Statement to the Expansion of Family Planning Services

According to the Human Resources Development Policy Statement issued in June 1991, the public sector was to get more involved in family planning activities. A national seminar on family planning was held at Grand Bassam in April 1991, when the bases for a coherent framework for family planning activities in Côte d'Ivoire were first laid, and three major policy objectives were selected:

Promote maternal and child health through prevention of risky pregnancy and birth spacing

Prevent sterility by means of detection and treatment of sexually transmittable diseases (STDs) and infertility
Contribute to economic and social development through birth regulation (Bamsié and Kouamé, 1992)

Out of that basis a first pilot family planning program was initiated in 1992 in the département of Aboisso, in the Southwest, with support form UNFPA. The evolution, which had been initiated earlier in the decade, was accelerated when the program of action of the International Conference on Population and Development (Cairo, September 5–16, 1994) was adopted, and ratified by Côte d'Ivoire. A sign of the evolution was that a national symposium on reproductive health was held in June 1996, during which all stakeholders could agree over the components of the reproductive health concept and define the different segments of the target population. Four components or areas were thus established: mothers' and women's health, children's health, young people's health, and men's health. The method was in conformity with the widespread belief that the approach to reproductive health should take an individual's whole life cycle into account.

Each area has specific components. However, there are components that the different areas have in common: family planning, STDs and HIV/AIDS, and communication for behavior change program and project management. Moreover, related components were taken into account (education, nutrition, environment), which shows that social objectives were combined with purely health-related ones.

Besides the public sector, various private parties and multilateral and bilateral cooperation organizations were also mobilized. The predominant agent was AIBEF, which conducted its own activities at the same time as it provided technical assistance and supplies to some of the centers of the Ministry of Public Health (Bamsié and Kouamé, 1992). In 2002 it was working in 84 public sector service centers and 31 more in the private and semi-public sectors. Besides its Abidjan headquarters, it has seven branches inland (Bondoukou, Bouaké, Daloa, Man, San-Pedro, Korhogo, Boundiali), which are managed by regional volunteers. It also has nine clinics.

2. The 1999–2003 National Reproductive Health and Family Planning Program

Since 1999 Côte d'Ivoire has had a reproductive health and family planning policy document, in conformity with which the various service-providing organizations are supposed to work, whether they are public, semi-public, or private. The document is used as a reference, because in it are "defined the objectives, strategies and complementary activities to be developed in order to reach the objectives in the larger framework of the National Reproductive Health Policy" (République de Côte d'Ivoire, 1999, p. 8).

A National Program for the period 1999 to 2003 was first developed. The implementation of that policy was slow, due to instability in its institutional framework (Anoh *et al*., 2002).

The Reproductive Health Policy includes four programs: the National Program for the Control of AIDS, STDs, and Tuberculosis; the National Child Health Program; the Expanded Immunization Program; and the National Reproductive Health and Family Planning Program.

The latter is focused on reproductive health care; other important dimensions, such as reproductive rights or women's empowerment, are not taken into account. Nevertheless, these have not been overlooked. A National Committee on Violence against Women was created in 2000. The committee, in which several Ministries are members, is intended to assist the Minister for the Family, Women and Children's Affairs in defining the programs and actions to be conducted with a view to reducing social inequality. Although there are no specific programs, improvement has been observed in the areas of reproductive rights and women's empowerment (Table 116–4).

Thanks to the changes brought to matrimonial rules, which were adopted in 1964, and the broadened access to reversible contraceptive methods in 1982, the autonomy of women has been improved. However, the laws on abortion and sterilization have remained extremely restrictive, and conflicting views are now being expressed about relaxing them.

Besides, for 10 years now, all forms of exclusion against women have been legally banned, since Côte d'Ivoire has ratified the United Nations Convention on the elimination of discrimination. Certain reproductive rights are even mentioned in the new Constitution: the government must ensure that all citizens have equal access to health, education, culture, information, vocational training, and employment (Article 7); mutilations and all forms of degradation of human beings are prohibited and punished by the law (Article 3); and gender equality is affirmed (Article 17): "Every person has a right freely to choose his/her occupation or employment. Access to public or private positions is equal for all. Any discrimination in access to or exercise of a position, based on sex, political, religious or philosophical opinions, is prohibited."

The increasing popularity of women's NGOs in the last decade is likely to boost enforcement of reproductive rights and observance of women's new powers.

TABLE 116–4 Some of the Achievements in Terms of Reproductive Rights

Areas	Improvements
Matrimonial system	According to Law 64–375 concerning marriage, the legal minimum age at first marriage is 18 for women and 20 for men; the personal consent of each of the prospective spouses is mandatory, and polygamy and bride price are prohibited, 1964.
Access to contraception	Article 11 in Law 81–640, dated July 31, 1981, authorizes free access to the more common contraceptive methods.
Access to sterilization	Article 343 in the 1982 Penal Code stipulates that whoever is guilty of sterilization shall be sentenced to death.[a]
Access to abortion	Abortion is regulated by Articles 366–369 in the 1982 Penal Code. Therapeutic abortion is permitted, provided that it is meant to save the life of a pregnant woman. In all other circumstances, abortion is a crime, and so are advertising and sales of abortive substances.
Sexual violence	Rape is punished under Article 354 in the 1982 Penal Code. Sexual mutilation, as a form of violence against women, is punished under Law 98–757, dated December 23, 1998. Sexual harassment, forced labor and early or forced union are punished under Law 98–756, dated November 23, 1998.
Exclusion	The United Nations Convention on the Elimination of all kinds of Discrimination Against Women (CEDAW) was ratified in 1995.

[a] However, in the new Constitution, which was adopted by referendum in 2000, the death penalty was abolished.

Such efforts to actualize legislation are crucial in countries such as Côte d'Ivoire, where, as in many other developing countries, there is a wide gap between the law and actual practices.

The objectives of the National Reproductive Health and Family Planning Program are liable to some criticism. A major one is that not all of those objectives are realistic (Table 116–5). For example, a 25% reduction in the maternal mortality rate meant that the rate should drop down to 450 for every 100,000 live births in 2003. This would have been possible only if an extremely strong program had been enforced. Another example is that the desired 20% reduction in the rate of infertility prevalence among women seemed exceedingly ambitious, considering the poor health infrastructure available and the behavior of the populations.

According to a recent study conducted in the region of Aboisso (Anoh, 2001), few women go to health centers for infertility reasons, and the few cases identified were referred to health centers that have a gynecologist, particularly to the regional hospital of Aboisso. The fact that few people go to a health center does not mean that few people are affected with this problem; the fact is that infertility is negatively perceived by society and that those persons who have this problem prefer to go to traditional healers for help. Moreover, the notion of a "sexuality-related mortality rate" (Executive Direction/ National Reproductive Health and Family Planning Program, 1999) is not usually used, and measures of it are not available often enough for any precise value of the desired reduction to be given. Those remarks show that the process of objectives development was not built on any in-depth knowledge of the facts on which the program was to focus.

The strategy for the implementation of the program was based on three lines for action: increased availability and accessibility of services, stimulated demand, and improved quality of services.

As far as availability is concerned, in 2002 the program was managing 250 reproductive health/ family planning centers, which meant a coverage rate of 33%. Pilot programs were implemented in the health districts of Bondoukou, Bouaflé, and Tanda. A Reproductive Health in the Armed Forces project is being developed, and awareness campaigns for youth are being organized by the Network for the Promotion of Sexual Health among youth and adolescents (known as RIPS/AJ).

Accessibility of services is increased by means of integration of activities into primary health care; the activities are served by the strategy of the minimum package of activities (MPA). A study of the situation in the districts of Bondoukou and Bouaflé has shown that

> the MPA as defined by the Ministry of Health is not available in the health centers, nor it is open on all working days. Geographical accessibility is limited and infrastructure is insufficient. Reproductive health services are not always available, due to products stock shortages; except for the poor quality of reception, the patients were satisfied with the quality of the care they received. (Ministry for Planning and Development, 2002)

The government's commitment to reproductive health and family planning has been proved through

TABLE 116–5 Specific Impact and Result Objectives for the 1999–2003 NRHFPP (from January 1999 to late 2003)

Components	Impact objectives	Result objectives
Mothers' and women's health	Reduce the maternal mortality rate by 25%	Ensure that 60% of pregnant women go through at least three prenatal medical visits Raise the rate of deliveries attended by qualified health workers from the present 45% to 55% Ensure that 30% of women who have just had a child go for a postnatal visit Raise the present 5.7% contraceptive prevalence among women of procreating age up to 14% Bring the present 50% proportion of men in favor of family planning practice up to 80%
	Reduce the sexuality-related maternal mortality rate by 50%	Contribute to ensuring that 50% of women who go to a health center for asexually transmitted infection (STI) are examined and treated appropriately Contribute to keeping down HIV prevalence among women at the present rate of 12% Reduce the prevalence of infertility among women by 20%
Adolescents' and young people's health	Reduce the sexuality-related mortality rate among adolescents and young people by 15% Reduce the sexuality-related morbidity rate among adolescents and young people by 30%	Bring the rate of early pregnancy among girls aged under 18 from 37% down to 20% Reduce the rate of induced abortion among adolescent girls and young women by 25% Contribute to ensuring that 25% of young people who come to a health center for an STI are examined and treated appropriately Reduce the practice of female genital mutilation among adolescent girls and young women by 10%
Men's health	Reduce the sexuality-related mortality rate among men by 10%	Bring the proportion of men who know about the different means of preventing STI/AIDS up to 95% Bring the proportion of men who use condoms for sexual intercourse with occasional partners up to 25%
	Reduce the sexuality-related morbidity rate among men by 40%	Increase the rate of treatment of infertility cases among men by 25% Contribute to ensure that 25% of the men who come to a health center for an STI are examined and treated appropriately

changed parameters concerning family planning supply and use of contraceptive methods.

3. The Evolution of Contraceptive Practice and Choice of Methods

People must know about the methods and how to have access to them before they can use them. It is therefore necessary to deal with such knowledge before assessing the progress and evolution of choices.

a. Contraceptive Knowledge

Even though the level of contraceptive knowledge is usually higher among nonmarried people, it is the knowledge among married individuals that matters most as far as fertility control is concerned. Three categories of methods can be distinguished with respect to how familiar they are to the population.

The first category, that of the best known methods, includes male condoms, the pill, injections, and periodic abstinence. Already in 1994 male condoms were well known (to 61% of married women and 82% of married men), but by 1998–1999 virtually everybody knew about them (83% and 93% respectively). Such a result is directly related to the social marketing strategy implemented by Population Services International (PSI) and Economie et Développement (ECODEV) as part of the program on AIDS control. PSI is currently developing such social marketing activities in collaboration with a recently created NGO, the Côte d'Ivoire Agency for Social Marketing (AIMAS). The pill, injections, and periodic abstinence were also fairly well known in 1994, and knowledge of those methods has expanded since then: the proportion of women who have heard about them rose from 58% to 74% (pill), from 53% to 67% (injections), and from 40% to 58% (abstinence) between 1994 and 1998–1999. Among men, the proportion rose from 56% to 66%, from 52% to 61%, and from 61% to 62% respectively.

The second category, that of not so well known methods, includes female sterilization and male withdrawal. From 1994 to 1998–1999 the proportion of those who had heard about female sterilization rose from 37% to 44% among women; the proportion of men who knew about withdrawal rose from 46% to 53%.

The third category includes those methods that are definitely less familiar: intrauterine devices (IUDs), traditional methods, and, still less familiar, vaginal methods, male sterilization, and Norplant. In 1998–1999 the proportion of people who knew about those methods ranged from 4% (Norplant) to 34% (vaginal methods) among married women, and from 6% (Norplant) to 34% (IUDs) among men.

The fact that some of the methods are persistently unfamiliar is partly due to the policy itself. There are gaps where such methods as sterilization are restricted by law, or others, such as IUDs and Norplant, require qualified staff to prescribe them. Moreover, such methods as withdrawal or traditional methods are not included in the range of methods suggested in the program.

b. The Progress of Contraceptive Practice

The use of contraceptive methods has been progressing at a variable pace since the early 1980s. Among married women, the proportion of women who were using a modern method was under 1% in 1980–1981, but rose to 4.3% in 1994 and 7.3% in 1998–1999 (Table 116–6). Since the early 1980s, contraceptive prevalence among married women has then risen by 6.8% (in absolute terms), which means an average annual growth rate of 16%.

Considering all women, regardless of their marital status, the growth pace has been only slightly faster: 16.8% compared with 16.1% per year over the period from 1980–1981 to 1994, and 12.8% compared with 12.5% per year during the more recent period from 1994 to 1998–1999. However, there is one similarity: in both cases, the progress in modern methods use has been slower since 1994 than it used to be. The average annual growth rate dropped from 18.1% between 1980–1981 and 1994 to 12.8% between 1994 and 1998–1999 for all women, and from 17.3% down to 12.5% respectively among married women.

Observations made at Aboisso, the seat for a pilot family planning program, show that the level of contraceptive methods use there has risen faster than at the national level. For all women at Aboisso, the proportion of those who use any method rose from 19.1% in 1993 to 27.5% in 1999—an average annual growth rate of 6.3%—whereas the proportion of those who were using a modern method rose from 6.8% to 14.7%—an average growth rate of 13.7%. At the national level, the average annual growth rate for the recent period 1994 to 1998–1999 was only 5.2% for all methods and 12.8% for modern ones. However, the

TABLE 116–6 The Progress of the Level of Contraceptive Methods Use since the Early 1980s in Côte d'Ivoire (in %)

Contraceptive methods	All women			Married women		
	CIFS 1980–1981	DHS 1994	DHS 1998–1999	CIFS 1980–1981	DHS 1994	DHS 1998–1999
Côte-d'Ivoire						
All modern methods	0.6	5.7	9.8	0.5	4.3	7.3
Average annual growth for the preceding period	—	18.1	12.8	—	17.3	12.5
All methods	1.5	16.5	20.7	2.9	11.4	15.0
Average annual growth for the preceding period	—	19.4	5.2	—	10.6	6.3
Aboisso						
Modern method	—	6.8	14.7	—	4.1	13.1
Average annual growth 1993–1999	—	—	13.7	—	—	21.4
Any method	—	19.1	27.5	—	14.0	21.5
Average annual growth 1993–1999	—	—	6.3	—	—	7.4

The annual growth rates were calculated over exactly 13.5 years for the period 1980–1981 to 1994, and 4.5 years for the period from 1994 to 1998–1999, i.e., a total 18 years for the periods under study.

CIFS = Côte d'Ivoire Fertility Survey; DHS = Demographic and Health Survey.

Sources: Direction de la statistique, 1984, p. 285; N'Cho *et al.*, 1995, p. 56; National Statistics Institute (INS) and Macro International, 2001, p. 9; National Research Council, 1993, p. 31; Koffi *et al.*, 2000; Anoh, 2001.

period under observation was slightly shorter, and the real difference was consequently rather small.

The situation shows a larger contrast when only married women are taken into consideration. At Aboisso, the average annual growth rate was 7.4% for all methods and 21.4% for modern methods during the period 1993–1999; at the national level, those rates were 6.3% and 12.5%, respectively, between the two Demographic and Health Surveys.

The various strata of the population of Côte d'Ivoire are at different levels of contraceptive practice. For all of them, the use of contraceptive methods, particularly modern ones, has grown more frequent. The progress, however, much depends on social and demographical characteristics. For example, the use of methods has increased faster among women with a primary education level than among others—from 20% up to 25% (+5%), as against 5% up to 8% (+3%) among illiterate women and from 39% to 40% (2%) among women of secondary education level and beyond; increased use of methods is to be observed among all the different generations (Anoh, 2001). Those differences between social classes suggest that the progress of contraceptive practice does not solely result from the effect of family planning programs.

c. Changes about Method Choice

Contraceptive practice has progressed, but it is still limited and mostly relies on natural and traditional methods. Over 50% of users use natural and traditional methods (Figure 116–10). However, the proportion of conceptive users of modern methods grew between 1994 and 1998–1999. The modern methods most used are the pill and condoms, and to a much lesser degree, injections. The latter involve high leaving rates and do not contribute much to increasing contraceptive prevalence, when compared with other methods such as IUDs or sterilization, for which a small number of new cases a year is enough to induce significant boost in the prevalence. The level of contraceptive prevalence results both from the history of

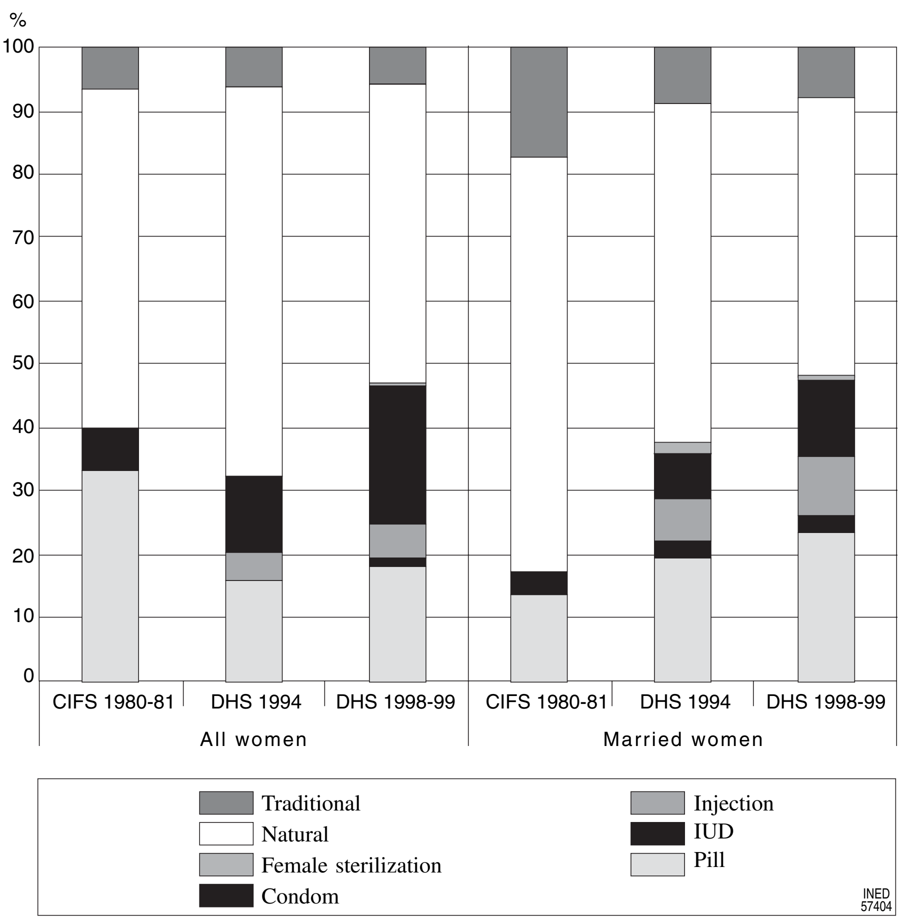

FIGURE 116–10 The evolution of the kinds of methods used. (Sources: Direction de la Statistique, 1984; N'Cho *et al*., 1995; INS and ORC Macro, 2001.)

how the methods were taken up and of their continued use, which in turn depends on the nature of the methods being used (Ross *et al*., 1999).

Suppliers for pills are very diversified in Côte d'Ivoire. In particular, small shopkeepers are playing an increasingly significant part (3% and 12% of women in 1994 and in 1998–1999 respectively), which shows that not all the pills in use require a medical prescription. This raises the question of compatibility between a woman's health condition and the method she is using, and also of the possible side effects that should be monitored.

Condoms, the second most used method, could be bought mostly from the nonmedical private sector in 1998–1999, as a direct consequence of the social marketing organized by PSI and ECODEV.

CONCLUSION

Côte d'Ivoire became aware at very early stages of the relations between population and development. The trend of its economic policy and certain ideological motivations, however, caused the country to seek to increase its population rather than slow down its growth. Such a populationist option was kept up until the late 1980s, implying an ultraliberal immigration policy and pronatalist measures. The change of position and the adoption of a National Population Policy in the 1990s are part of a regional dynamic that affected most African countries, particularly the Francophone ones, which had been reluctant up until then. The turnaround is the direct consequence of the economic constraints that resulted from the economic crisis and recession, on the one hand, and from the political constraints related to the structural adjustment programs, on the other hand.

The armed conflict that broke out in Côte d'Ivoire on September 19, 2002 has slowed down the implementation of the first program of action on population. However, certain priority actions and investments scheduled in the program have begun to be implemented because they had been defined out of operations already ongoing as part of programs that government departments were implementing in different sectors, due to the lack of centralized planning. In that respect, the reproductive health and family planning program, which can be considered part of the Control of Natural Growth subprogram, is somewhat more advanced than others.

This shows that, although the approach is one in which population programs are supposed to be integrated into social and economic development strategies, the population policy in Côte d'Ivoire, as is often the case, may very well focus on the family planning component at the expense of those components based on the economic, social, and environmental context, which in fact require much more effort in terms of investment.

Lastly, it must be emphasized how important political stability and sustained support from development partners are for population programs to be properly implemented. In addition, the process of implementing the programs must be based on in-depth analyses of demographic behaviors, so that the objectives that are set are not unrealistic.

CHAPTER

117

Population Policy in the United States

CARL HAUB

Population Reference Bureau, Washington, D.C., United States

Officially, the United States has no population policy. There have never been numerical goals or targets for a particular population size or rate of growth. Indeed, the country has always considered itself to be a "country of immigrants," a distinction that sometimes ignores that the populations of other developed countries of the "New World," such as Australia, Canada, and New Zealand are themselves largely products of immigrants from distant lands. There has never been any sort of demographic target or goal regarding birthrates, although concern has been raised in the past when birthrates declined to low levels, as happened in the 1930s. In responding to the United Nations Population Division's biennial survey on population policies, the United States stated that population growth was satisfactory and that no intervention to alter the rate was needed (United Nations, 2002).

As of this writing, U.S. population increases at about 3 million per year, 1.6 million through natural increase of births minus deaths and 1.2 million through net immigration, both legal and illegal (see Figure 117–1). This is the largest amount of growth in absolute terms in the country's history and is nearly the equivalent of adding the population of Sweden every 36 months.

The closest the country has come to considering some sort of national population policy was in the early 1970s at the urging of Republican President Richard Nixon with the establishment of the Commission on Population and the American Future, also known as the Rockefeller Commission. The Commission consisted of a large number of sociologists, demographers, and environmentalists, giving it by far the largest assembly of expertise ever focused on the population issue. At the time, population had begun an acceleration spurred by the period of high fertility during the baby boom and by rising immigration. Over 50 million had been added to U.S. population since 1950, partly due to the effects of the landmark immigration act of 1965. The sweeping 1965 immigration reform opened U.S. borders to immigration from the nontraditional regions of Africa, Asia, and Latin America, a part of Democratic President Lyndon Johnson's Great Society, itself an outgrowth of the civil rights movement of the 1960s. Prior to the 1960s, immigration had been at very low levels throughout the depression years of the 1930s through the 1950s as immigration from traditional European countries declined. Ironically, the Commission also began its work on the eve of the steepest decline in fertility in U.S. history, that of the 1970s.

The Commission's findings, presented in 1974, were a controversial departure from the "growth is good" mentality, to say the least. "The health of our country does not depend on population growth, nor does the vitality of business, nor the welfare of the average person" (Negative Population Growth website, *Footnotes*, March 1998, accessed May 14, 2003). The Commission, whose report filled six volumes, called for the decriminalization of abortion, removal of any remaining restrictions on contraceptives (the pill had been approved by the Food and Drug Administration in 1960, but individual states had their own laws), the wide availability of sex education, freezing immigration at 400,000 per year and stopping illegal

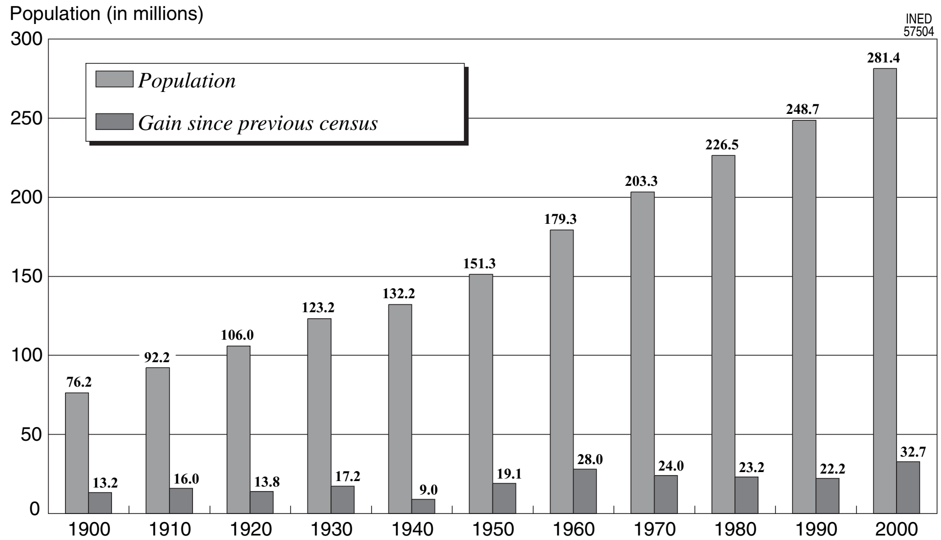

FIGURE 117–1 Population of the United States at each census and gain since previous census, 1900–2000. (Source: USCB, 2002.)

immigration, as well as support for bans on any type of sex discrimination. President Nixon ultimately rejected the report, possibly due to both the controversial nature of the recommendations and the distraction of the Watergate scandal, which led to Nixon's resignation in June 1974.

If population growth was one of the Commission's fears, then many of their concerns have come to pass. Population, numbering 203 million at the 1970 census, has grown to 291 million in 2003 and will reach the 300-million mark in 2006. Still, many of the Commission's wishes were realized without Presidential approval. In 1973, the historic *Roe v. Wade* Supreme Court decision legalized abortion on demand, families voluntarily chose the two-child family it sought (the total fertility rate [TFR] actually dropped to 1.7 in 1976, oddly the year of the country's Bicentennial celebrations), and there are now no legal restrictions on contraceptives whatsoever. The sole area where the Commission's goal has not been realized is immigration.

Although debate over population growth has waned since the 1970s, individual groups do keep the notion alive. Negative Population Growth in Alexandria, Virginia, Californians for Population Stabilization in Santa Barbara, California, the Center for Immigration Studies in Washington, DC, Population Environment Balance in Washington, DC, and Population Connection (formerly Zero Population Growth) in Washington, DC are just a few examples of organizations that lobby or otherwise promote slower population growth, primarily by advocating reduced immigration.

But, in some ways, all countries have a population policy, be it clearly stated or inferred indirectly. Still, by not having an expressly stated policy, the United States has implicitly stated that it has no position on population size. Significantly, while the 2000 census enumerated nearly 7 million more residents than anticipated, increasing the annual estimated rate of population growth, there has been no particular public concern or media attention generated as a result. The single area in which the United States does impose numerical limits to a component of demographic change is that of immigration law, yet even here there is no direct connection with any sort of population size or growth rate target.

For much of its history, immigration was not only uncontrolled but was openly encouraged. During the 19th century, immigrants were welcomed to help develop and occupy the largely empty continent, stretching over 4,000 kilometers from the Atlantic to the Pacific. Viewing the United States today, it is easy to ignore just how new the country really is. During the 1990s, many cities and towns in the central United States, or the "Midwest," celebrated just the 100th anniversary of their founding. New residents arrived by the millions and all were welcome, although arrivals from new areas, such as Eastern or Southern Europe were initially subjected to various forms of discrimination. But virtually all of these immigrants were from Europe, the traditional sending countries of new Americans.

Responding to the UN policy survey, the United States stated that immigration levels were satisfactory and that current immigration of permanent migrants,

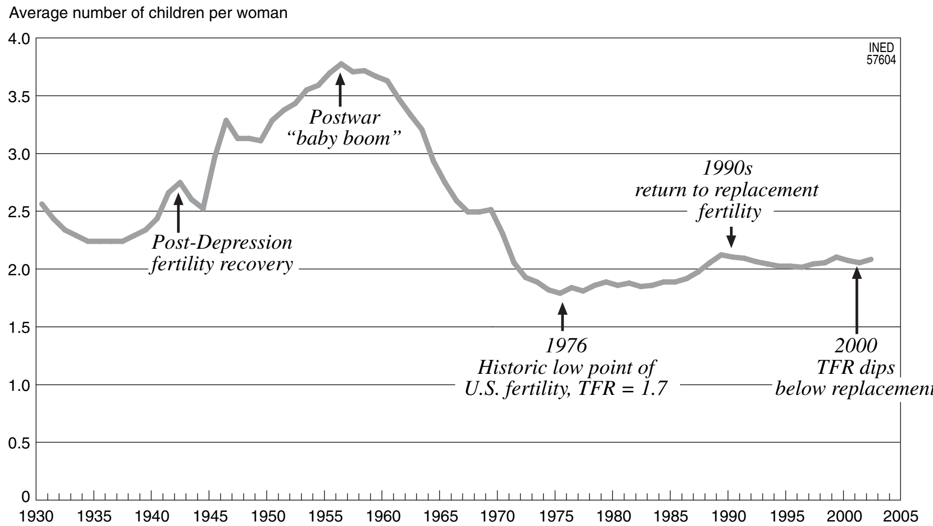

FIGURE 117–2 U.S. total fertility rate, 1931–2003. (Source: U.S. National Center for Health Statistics, Vital Statistics of the United States, Natality, various issues; National Vital Statistics Reports, various issues.)

migrant workers, and dependents should be maintained as well as the policy toward integration on non-nationals. U.S. policies on growth and migration can be compared to that of France, insofar as that country also said that current population growth was satisfactory, but indicated that the level of immigration was too high and that the official policy was to lower it. Similar sentiments were expressed by Germany and the United Kingdom, sharp contrasts to U.S. stated contentment with the level.

Fluctuations in fertility rates (see Figure 117–2) appear to be far more a product of the economic background than of any government action to provide support for families The United States today has the highest TFR of any industrialized country (*The Economist*, 2002). In the 20th century, there were two periods of significant decline in the total fertility rate, both of which reflected similar trends in Europe. The TFR declined to 2.1 during the global Depression years of the 1930s, recovering as World War II approached and then reached its modern zenith in 1957 at 3.8, the peak of the well-known and much-celebrated baby boom. A second plunge took place in the early 1970s, perhaps partly attributable to rising feminism, but quickly fueled by the oil crises of the same decade and resulting inflation as well as high unemployment. Fertility responded to a favorable economic outlook in the late 1980s, rising to the replacement level by 1990, a level generally maintained until the end of the decade. Following the larger than expected 2000 census count, there has been a downward revision in the U.S. TFR for both 2000 and 2001 of approximately 0.1, to 2.056 and 2.034, respectively. Replying to the United Nations, the U.S. considered that their fertility level was satisfactory and in no need of intervention, but labeled the adolescent fertility rate a "major concern" with policies and programs to influence it. While fertility has certainly fluctuated, it is quite difficult to identify any specific public policy that has had a measurable effect on the TFR.

In terms of mortality, the current level of expectation of life was reported as unacceptable to the United Nations. With respect to mortality, the United States does have an implicit policy to improve overall health conditions, although no specific targets for measures such as life expectancy are mentioned. This overall goal or policy can be contrasted with that France and Germany, who stated to the United Nations that current mortality levels were acceptable. The United States does have any number of programs to improve health conditions such as Medicare, Medicaid, and public health programs and clinics for low-income populations, which can certainly be seen as intended to improve medical care and overall health, ostensibly increasing life expectancy. Government programs as well as media attention focuses on racial differentials in rates such as infant mortality and the prevalence of specific diseases, but references to overall life expectancy are infrequent.

I. IMMIGRATION

Half of U.S. population growth now stems from immigration, despite the fact that the level of natural increase is quite high by industrialized country standards. Currently, there is little public debate on the level of immigration, although illegal immigration was widely discussed in the late 1980s and early 1990s. Since the terrorist attacks of September 11, 2001, public sentiment has changed insofar as steps to control the entrance of those who would do the country harm are generally accepted, albeit with some misgivings that such steps are now necessary. It is interesting to note that the issue of "urban sprawl," the rapid spread of suburbanization around cities into former farmland, receives much attention, but it is viewed more as an issue of population distribution policies, rather than as a result of the country's growth of 3 million per year.

As welcoming a country as the United States has been, its past immigration history has been filled with friction between more established immigrant groups and those arrivals from newer source countries. From the country's earliest days, there were concerns about immigrants from countries seen as nontraditional. Even Benjamin Franklin fussed about the arrival of Germans in Pennsylvania:

> Why should the Palatine boors be suffered to swarm into our settlements and, by herding together, establish their language and manners to the exclusion of ours? Why should Pennsylvania, founded by the English, become a colony of aliens, who will shortly be so numerous as to Germanize us, instead of our Anglifying them?' (Esmond, 1986; p. 83)

The "Know Nothing" political party worried about the arrival of Catholics from Ireland in the 1840s and were elected to Congress on sentiments of anti-immigration of such groups, but failed to sponsor any successful legislation.[1] Following the Civil War in the 1860s, some laws were passed prohibiting convicts, prostitutes, paupers, and "mental defectives." In 1882, the Chinese Exclusion Act was a landmark law aimed at barring a specific group. Many Chinese had been recruited to build the railroads across the West, but after the work was complete, fears of a flood of cheap Chinese labor prompted the ban, which continued in force as late as 1943. Subsequently, other laws tried to ensure that immigrants could read and write and were intended to limit immigration to countries of Northern and Western Europe, due to the perceived undesirable qualities of migrants from other areas. It was in 1921 that the first numerical limit was set on the number of immigrants, and, in 1924, a limit of 150,000 was imposed, with quotas favoring traditional countries. As a result, the vast majority of immigrants continued to be from Northern and Western Europe until well after World War II.

Following World War II, Presidents Truman and Kennedy favored eliminating national quotas, but it was not until the landmark amendments to the Immigration and Nationality Act, passed in 1965, that U.S. immigration was truly opened to all countries. The amendments of 1965 were, in all likelihood, the single most defining pieces of legislation in U.S. history, forever changing and defining the ethnic structure population of U.S population. After 1965, the countries of origin of immigrants shifted dramatically. Symbolically, the new legislation was signed by President Johnson at the base of the Statue of Liberty in New York harbor. During the 1950s, 53% of immigrants were from Europe; by the 1980s, only 17% were. The full impact of the 1965 law has been such that, by about the year 2050, the country will likely have no majority ethnic group at all. Such a development would most certainly have horrified Franklin, but seems to disturb most contemporary modern Americans little if at all.

United States' policy on immigration is not specified in any official statements but remains implicit in the laws that govern it. The U.S. population is composed of a large number of ethnic and national groups, each arriving in different waves over the course of history. The notion of a "country of immigrants" seems to be a well-accepted aspect of American social change, although such change is never without its frictions. Nonetheless, it is probably fair to say that significant restrictions, let alone a total ban on new immigrants would be seen by most as unthinkable. Concern over illegal immigrants surfaces from time to time, although even that may be viewed as beneficial in that many illegal immigrants take jobs that many Americans no longer want. During the 1980s, there was considerable debate over illegal immigration and the means that could be used to stop it. Most recently, concern has been universal over immigrants whose sole purpose is to do the country harm, with many feeling that some immigrant rights may be abused in the name of security. Beyond considerations of a certain perceived moral obligation toward immigrants, serious restrictions on immigration would cause a political firestorm, as individual national groups would raise a loud protest.

Nonetheless, it is a clear, if tacit, policy that immigration will continue although the United States reserves the right to regulate who and how many come to its shores, as does any sovereign nation. The policy is to favor immigrants who can benefit the country via needed occupational skills and special expertise, allow a generous program of family reunification, and accept a reasonable number of refugees and others seeking asylum.

II. CURRENT IMMIGRATION LAW

The laws defining who comes in and who does not are quite complex. Immigration is currently governed

[1] Much of this discussion is drawn from Martin and Midgely, 1999.

by the Immigration Act of 1990 (Public Law 101–649), although the law is often amended as Congress deems appropriate, typically to include new groups, such as special categories of refugees. This law, passed at the height of the debate over illegal immigrants, actually raised the amount of allowable immigration.

At present, over 30 million people are known to enter the United States each year. The vast majority of these are tourists or people on temporary business who leave in a short period of time. A restriction on those visitors is that they do not generally have the right to work, a right restricted to migrants who receive permanent resident visas or specific work-related visas under other provisions of law.

Current immigration law specifies two broad categories of immigration, permanent and temporary, but only the former are designated with the legal term of *immigrant*. Only immigrants receive permanent resident visas, popularly called "green cards," although the card itself is no longer green. When used in the discussion below, the word *immigrant* refers only to those granted lawful permanent residence and, subsequently, the right to apply for citizenship after 5 years of continuous residence. It is most important to take note that immigrants are not necessarily new residents in the demographic sense in that many have been living in the country for some time, possibly quite a long period. An example of the latter might be an employee of an international organization who reaches retirement age and only then applies for permanent residence.

III. IMMIGRANTS

The legal use of the term *immigrant* causes some confusion in interpretation of immigration data with some users naturally assuming that 1,064,318 immigrants physically arrived on U.S. shores for permanent residence in Fiscal Year (FY) 2001, as shown in the *2001 Statistical Yearbook of the Immigration and Naturalization Service*.[2] In FY 2001, there were 1,064,318 immigrants, but only 411,059 were new arrivals in that year; the balance were previous residents whose status was adjusted from temporary to permanent. A second caveat is the use of immigration data as a times series. Annual numbers fluctuate with the ability of the INS to process visa applications. In 1998, Congress transferred the processing of undocumented aliens from the State Department to the INS without increasing staff. As a result, processing fell behind. The high figure cited above of just over 1 million can be compared to the previous two fiscal years. In FY 1999, there were but 646,568 visas processed and, in FY 2000, 849,807. The apparent rise in numbers from FY 1999 to 2001 was a result of "catching up" the processing of forms. There is also a per-country limit on visa allocations for a particular year to 7% of the annual total.

An additional category of immigrants are the so-called diversity immigrants, a special group of 55,000 added under the 1990 law to encourage immigration adversely affected by the 1965 law. These are potential immigrants from "old-seed" sending countries before the 1965 law, chiefly those of European origins and especially those from Ireland. This addition was partly sponsored by Senator Edward Kennedy of Massachusetts.

IV. IMMIGRATION LIMITS PRESCRIBED BY LAW

As described in Table 117–1, different categories of immigrants are assigned numerical limits. There are two broad categories of immigrants, those granted permanent residence for employment purposes (employment-based preferences) and those admitted for the general purpose of family reunification. Employment-based preference immigrants are often those most often thought of as new immigrants to the United States in that they do not necessarily have any previous connection to the United States, but are admitted for needed job skills or may be investors who are likely to create new jobs. Their number is "capped" at 144,000 per year. Family-sponsored immigrants are relatives of legal residents who are admitted for family reunification. Their number is set at from 226,000 to 480,000, the exact limit being equal to the larger of 226,000 or a calculation of 480,000 minus the previous year's total of immediate relatives. There is also a per-country limit on visa allocations for a particular year to 7% of the annual total.

V. NONIMMIGRANTS

Temporary migrants, the vast bulk of whom are tourists and visitors for business purposes totaled 27.8 million in FY 2003, are actually referred to by law as "nonimmigrants," since they do not receive green cards for permanent residence. Significantly, this number was nearly 6 million less than in FY 2000, a

[2] The Immigration and Naturalization Service (INS), as such, ceased to exist with the establishment of the new Department of Homeland Security (DHS) in the wake of the terrorist attacks of September 11, 2001. A new agency, the U.S. Citizenship and Naturalization Services (UCIS), has been created as its replacement.

TABLE 117–1 Immigrant Categories Included in Worldwide Annual Limit Specified in Section 201 of the Immigration and Nationality Act: Fiscal Year 2003 Limits

Categories		
Total		**701,532**
Employment-based categories		**171,532**
First preference	Priority workers	49,058
Second preference	Professionals with advanced degrees or aliens of exceptional ability	49,058
Third preference	Skilled workers, professionals, needed unskilled workers	49,058
Fourth preference	Special immigrants (ministers, religious workers, etc.)	12,179
Fifth preference	Employment creation (“investors”)	12,179
Family-sponsored immigrants		**480,000**
Family-sponsored preference		**226,000**
First preference	Unmarried sons and daughters of U.S. citizens and their children	23,400
Second preference	Spouses, children, and unmarried sons and daughters of permanent resident aliens	114,200
Third preference	Married sons and daughters of U.S. citizens	23,400
Fourth preference	Brothers and sisters of U.S. citizens (at least 21 years of age)	65,000
Fifth preference	Immediate relatives of adult U.S. citizens (spouses, children, and parents) and children born abroad to alien residents	**Not limited**
Diversity immigrants		50,000

Note: The annual limits are adjusted based on visa usage in the previous year.
Source: UCIS, 2004.

result of the September 11 terrorist attacks. Beyond the 87% of this group arriving in FY 2001 who were simply tourists or businesspeople, 3.5 million were accommodated under a variety of programs, ranging from students to foreign ambassadors and their families. There is no ceiling on the total number of this group who may be admitted in any one year.

The largest group of nonimmigrants, outside of visitors for business or pleasure, are temporary workers and trainees who, along with their spouses and children totaled 726,613. This group contains two visa classifications that are numerically limited, H1B and H2B visas. H1B visas are issued to specialty workers who must have a university degree or the equivalent and a license to practice their profession, if one is required. The typical H1B recipient is, as the INS describes it, a 29-year-old Indian working in the computer field and earning $55,000 per year. The next largest group, 624,917, was composed of students.

Temporary workers who are employer-sponsored employees may remain in the country a maximum of 6 years (the H1-B program). They may, of course, apply for permanent residence at some point. In FY 2001, there were 331,206 such nonimmigrants, about half of whom were from India. The provisions of the various nonimmigrant programs specify persons with college degrees and specific training and are almost always in some type of professional occupation or needed occupation. Other categories include people performing services not available in the United States, athletes and entertainers, religious workers, and the spouses and children of such workers.

There are additional groups such as refugees and asylees, and special agricultural workers to fill labor force needs, particularly in the Southwest. An additional group comprises “diversity” immigrants, a special provision to reverse what was seen as disadvantages to immigrant countries from “traditional” sending countries, particularly Europe. This group numbered 42,015 and did receive green cards.

Are limits imposed on the annual number of immigrants? While there are numerical limits imposed on many categories, in actual practice, application of the law is rather complex.

VI. FERTILITY

It is probably true that no program of family support has ever been enacted in the United States with the intent of directly influencing the level of the TFR. Rather they have been designed to ensure that Americans can have the number of children they wish to have, more as a right than as a demographic goal. Increasingly, the provision of equal rights for women in employment has emerged as a primary concern.

The TFR in the United States stands at 2.0, a level that has remained relatively constant since about 1990. It is often thought that higher fertility among ethnic groups accounts for this comparatively high rate, given that Hispanic women, for example, have a TFR just below three children. But the TFR of “majority” women, defined as White non-Hispanic, stands at 1.9, well above most countries of Europe and Australia, Canada, and Japan. Why is American fertility so high? While it is not possible to quantify an answer, it is reasonable to speculate that U.S. society is simply more oriented to the expectation to have children, particularly in certain geographic areas. Church attendance is still relatively common and the expectation that one will raise a family is almost certainly more persistent. Or, perhaps such a perception is misplaced, that U.S. fertility in the 1990s is more a result of a robust, optimistic economy. Perhaps U.S. fertility is not truly "high," but only appears to be in comparison to very low European fertility. It is still true, however, that, in the 1995 National Survey of Family Growth, 14.8% of women interviewed said that their last birth was mistimed and 6.5% said that it was unwanted (NCHS, 1997).

While programs benefiting parents of children may have had an unplanned effect on fertility, the intent of those programs has always been to provide financial relief to families and to help support the two-earner family, thus facilitating careers for women. The latter has been a response to the rapid entry of women into the full-time career labor force as well as a genuine need for two earners as the cost of living rose substantially from the 1970s. High living costs can be illustrated by some examples. In the early 1970s, a single-family house in the Washington, DC area cost about $25,000 or less, but by even the 1980s, the cost had risen to $250,000 and continues to increase. Families with two full-time earners have also served to make the expense of the two-car family commonplace, particularly given the great geographic expansion of the suburbs and the lack of practical public transportation. Such economic factors could certainly be seen as having a depressing effect on fertility, as has arguably happened in Europe, but it is likely that support for families with children has played some role in maintain the two-child family, however inadvertent.

Along with Australia, the United States is alone among industrialized countries in that there is no government-funded program for maternity leave, placing the burden of providing such leave on employers. In many ways, this is in keeping with the general national attitude that individuals, and not the government, are responsible for arranging and financing their own affairs. It should be kept in mind that Americans do not look to the government as the ultimate form of socialized support and even find "government meddling" unattractive. At the same time, income taxes are considerably lower than the social taxes paid by many Europeans. Americans, much more so than in Europe, are expected to provide for themselves.

In the 1960s, pregnancy often meant that a working woman would leave her job to become a full-time mother, and an employer who granted any sort of maternity leave was rare indeed (USCB, 2001). Since that time, however, women have entered the world of work in increasing numbers. In 1970, 43.8% of women 16 years of age and over were in the labor force (79.7% of men) but, by 2001 the proportion had risen to 60.1% (74.4 of men). In 1978, the Pregnancy Discrimination Act was passed by Congress, forbidding discrimination in employment for pregnancy and childbirth. Along with this development, families were able to take an income tax credit for child care expenses from 1976. Subsequently, the ability to work flexible hours, child care centers at the workplace, and a general notion that working women must be accommodated became frequently debated national issues. These began to be offered by employers as incentives to obtain and keep trained workers.

For those parents who must pay out-of-pocket fees for daytime child care while the parents work, the income tax credit allowed by federal law amounts to a significant subsidy. Expenses up to $2,400 for one child or $4,800 for two or more children up to age 13 may be claimed, and 20% to 30% of the claimed amount may be taken as credit against the amount of income tax, not simply deducted from taxable income. The percentage that may be taken as a credit varies with income, with lower income parents eligible for the full 30% credit.

In 1993, the Family and Medical Leave Act mandated up to 12 weeks of unpaid leave for employees of companies of 50 or more employees and who worked at least 1,250 hours in the past year for their current employer. There is, however, no provision for *paid* leave in the federal law. Paid leave remains an option for an employer, although in some states, such as New Jersey, women receive 75% of their weekly salary up to a maximum of $364 (National Center for Policy Analysis, accessed April 4, 2003, from www.ncpa.org).

While the rise in maternity leave has certainly been dramatic, paid leave of some type is still enjoyed by barely half of all women (see Table 117–2). "Paid leave" also refers to a combination of different options that may or may not be available to a women, such as the use of accumulated sick and vacation time in addition to actual paid maternity leave that may or may not be available. Thus, maternity leave remains something of an ingenious assembly of available options to a family, not a matter of public policy. Overall, about three-fourths of all women who worked during pregnancy in 1991–1994 returned to work in the first year, 42% returning within 3 months.

TABLE 117–2 Leave Arrangements Used by Women Who Worked during Pregnancy: 1961–1965 and 1991–1995 (Percentage)

Type of leave	Year of first birth	
	1961–1965	1991–1995
Total	100.0	100.0
Quit job	62.8	26.9
Paid leave[a]	16.0	42.7
Unpaid leave	14.1	40.3
Disability leave	(—)	11.2
Dismissed from job	4.2	5.0

(—) not applicable.
[a] includes paid maternity, use of sick and vacation leave, and other paid leave.
Source: USCB, 2001.

While any effects that maternity/paternity leave may have had on keeping the United States TFR at a modestly high level cannot be directly quantified, there has been a clear effort on the part of government and the private sector to accommodate working mothers and fathers. Day care centers at the workplace have become commonplace, the use of sick leave to care for a sick child is widely accepted, and some mothers even bring their young infants to work. In addition to programs and benefits, it is almost certainly a major factor that attitudes toward work and motherhood have undergone a sea change in the United States. Certainly, this has arisen as a result of the movement for equal rights for women, but it can also be seen as pragmatic in that employers are less likely to lose trained, valuable employees.

In 1996, the first significant change in public assistance to poverty populations, popularly referred to as "welfare reform," was passed in the form of the Personal Responsibility and Work Opportunity Reconciliation Act (PRWORA). This act placed new limits on the length of time public assistance benefits could be received and encouraged disadvantaged mothers with children to seek gainful employment. Due to the latter provision, the act is popularly referred to as "workfare." Prior to the passage of PRWORA, there had been much public debate on welfare payments discouraging women from remaining on the rolls at public expense. PRWORA, then, is a landmark experiment and a major restructuring of public assistance programs and the philosophy behind them, a shift from long-term support to a program that helps poor mothers adjust to the need for self-support. And, it can certainly be argued that welfare reform was a matter of public policy, designed to encourage those on welfare to seek gainful employment as well as discouraging out-of-wedlock childbearing supported by public funds.

Will PRWORA affect fertility levels among poor women? This question takes on added significance when we consider that 22% of the 35.5 million mothers in 1996 received some form of public assistance (USCB, 2002a).[3] Overall, mothers who participated in one or more public assistance programs had given birth to 2.361 children in their lifetime, compared to 2.071 who did receive benefits. Of the mothers who received benefits, the first birth of 58.5% was outside of marriage, compared to 24.7% of mothers not receiving benefits. Clearly, the question is: does welfare encourage childbearing among poor women, particularly out of wedlock births?

During the 1990s, the only significant change in the TFR by ethnic group was that of Black women, who recorded nearly a 12% decrease. The decrease in the birthrate for the 15–19 age group was particularly sharp, leading to speculation that welfare reform was the cause. However, it is evident that fertility decline was under way well before the 1996 act became law. While it is possible that pre-passage publicity may have had an effect, the timing of age-specific fertility decline in the 1990s suggests that there were a multiplicity of causes, such as antipregnancy publicity campaigns in the schools.

Looking at birthrates for unmarried young women (see Figure 117–3), a primary target group for welfare reform, the effect of PRWORA may be somewhat more evident. The decline in birthrates for unmarried Black women appears to have accelerated in the years leading up to passage and then continued in a clear downward path. For Hispanic women, the increasing trend reversed itself, leveling off in the second half of the 1990s. For White women, there is no apparent trend, although poor mothers receiving public assistance are a small minority of White women overall.

Support for parents is available from a variety of other sources, notably financial aid for university attendance. In the United States, even state-sponsored colleges and universities are not free, with tuition, room, and board expenses falling to the parents. Many parents aspire for their children to attend college, which has become a virtual necessity for a well-paying position. The cost of even the less expensive state schools easily runs $10,000 per year and that of the highly desired private institutions at least two times that figure. Saving for tuition is something young parents strive to do early on, and parents may even wish to space births so as not to have two or more

[3] The cohort for these data are women ages 15–44 who had had at least one birth.

TABLE 117–3 Age-specific Birthrates and Total Fertility Rate, White non-Hispanic, Black non-Hispanic, and Hispanic Women, 1990, 1996, and 2003

Categories	Rate by age group (per 1,000)						TFR
	15–19	20–24	25–29	30–34	35–39	40–44	
White non-Hispanic							
1990	42.5	97.5	115.3	79.4	30.0	4.7	1.851
1996	37.6	90.1	104.9	82.8	33.9	6.2	1.781
2003	27.5	83.5	110.9	97.7	43.2	8.1	1.858
Percentage change 1990–2003	–35.3	–14.4	–3.8	23.0	44.0	72.3	0.4
Black non-Hispanic

children in college at the same time, depending on how strong their motivation for college educations might be. In part, parents are assisted in their dilemma by a variety of state and federal student aid programs (for which a full financial statement must be completed) and scholarships that provide some relief, particularly for low-income families, although the chief burden is borne by the parents.

VII. DISTRIBUTION

While there may be no national policy on population growth, many local governments have taken steps to limit growth, particularly in the vicinity of cities, a development now receiving wide media publicity as urban sprawl. Urban sprawl refers to the rapid expansion of suburban settlement circling cities into areas once considered rural. A typical scenario is a county near a city that has historically been lightly populated and with an attractive, bucolic setting. At some point, housing developers begin construction of new units, which often attract younger families due to the lower cost compared to expensive houses "in town." The nature of the rural setting is itself an attraction, but newcomers soon find themselves joined by increasing numbers of even newer arrivals and soon the bucolic nature of the area disappears. A result is heavier traffic and a common expression is that one left the city but "the city followed me here." A major contributor to sprawl is the fact that many jobs leave the city and relocate to suburban areas, allowing commuters to live further and further from the city itself.

Generally, sprawl itself is seen as a result of *distribution*, not overall national population growth itself. This tends to ignore the fact that the country grows by 3 million per year and that those new residents must clearly live and work somewhere. As a result, population growth tends to be concentrated in two general areas: the large suburban areas of larger, established cities, such as Atlanta and Washington, DC, and smaller cities and their suburbs which have gained attractiveness in recent decades, such as Charlotte, North Carolina and Boise, Idaho.

The geographic spread of settlement has often been exacerbated by what has been called "the American dream," a single-family house on a tract of land ranging from one-quarter acre to an acre in size. Local jurisdictions often attempt to limit growth with moratoriums on sewer hookups, limits on how many houses may be built on lots, and the requirement that developers provide funds for needed roads before housing permits are issued. There are often, however, conflicting goals between those who wish to limit growth and county officials who may wish to attract more tax dollars.

VIII. MORTALITY

Particularly since the 1960s, there has been a concerted effort on the part of local, state, and the federal governments to become involved in providing greater access to full health care to those unable to afford it. In fact, few Americans could afford to pay for health care. Employed persons nearly always benefit from some type of group insurance plan, but those without regular employment and the elderly were typically left to their own resources, which often meant little or no health care at all. In a very real sense, public policy has become interventionist in health care, following a largely laissez-faire policy for most of the country's history. This was in part due to the rising cost of health care which, in turn, resulted from an explosion of diagnostic methods and the expensive equipment they require. Health care shifted from home visits by a local doctor to a vast array of costly in-patient and out-patient services. In short, the nature of health care itself underwent a sea change after the 1950s.

1. Medicare and Medicaid

Medicare, established in 1965 along with Medicaid as Title XIX of the Social Security Act, is a government program that covers Americans age 65 and over as well as some persons below age 65 with disabilities. The law was a reaction to the fact that rapidly rising medical costs were increasing much faster than the cost of living. About 1960, it became evident that private insurance companies could no longer provide coverage to senior citizens and pensioners at premiums they would be able to pay. It was estimated that only one in four had adequate medical coverage (considered to be insurance that would pay 75% of a hospital bill).

Premiums for Medicare are normally paid throughout one's working life through payroll deduction. Upon reaching age 65, full hospital coverage is provided under Part A. Medical insurance, covering doctor's fees, out-patient services, and the like are included in Part B, but the beneficiary must pay a monthly fee of $58.70, an amount that can also rise. Individual states vary in how procedures are judged to be medically necessary, what procedures are covered, and the amount they pay, but there is nearly always a deductible or percentage that must be paid by the patient. In 1997, Congress passed the Medicare+Choice legislation, a move championed by those who wish to "privatize" government programs, transferring more cost to the consumer. This program gives more options in that patients are free to choose private Health Maintenance Organizations (HMOs), often at a higher cost. About 15% of Americans have opted for the new plan.

Medicare does not cover prescription medicines, an issue of debate at present. The elderly are particularly hard hit, given their disproportionate use of such medications. Television ads promoting prescription insurance show Americans driving to Canada to buy drugs at lower prices. A proposal submitted in 2003 by President Bush would extend drug insurance to participants in new Medicare, and discount cards as well as an unspecified cap on annual drug expense. For many, particularly Democratic lawmakers who generally favor the expansion of government programs, the proposal does not go far enough and it appears to be

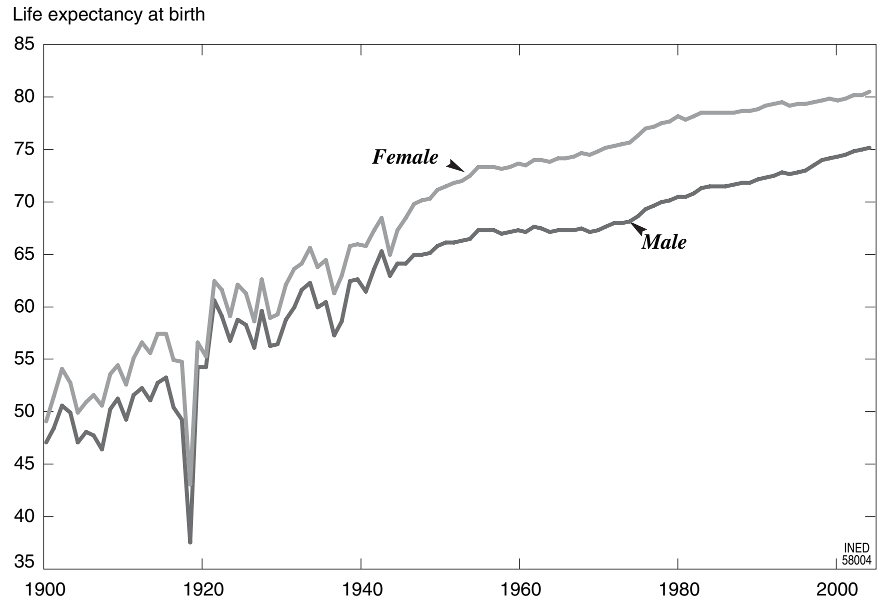

FIGURE 117–4 Life expectancy at birth, United States, 1900–2003. (Source: USCB, 1976; NCHS, 2004a, 2004b).

crafted to satisfy both sides of Congress. It is likely some version of the proposal will become law given that drug expense today has risen in much the same way hospital expense did in the 1960s.

Given that Medicare is the largest government health program in the nation's history, it is logical to inquire if there was an improvement in a possible outcome, such as life expectancy (see Figure 117–4). In 1954, life expectancy at birth was 66.7 and 72.8 for men and women, respectively. In 1965, the year Medicare was passed, life expectancy for men was unchanged and that of women had increased only one year, to 73.8. Twenty years after passage, life expectancy for men had jumped to 71.1 and, for women, to 78.2. The gain has, however, been much less since 1985, rising to 74.4 for men and 79.8 for women. A 1997 paper by Morris Davis at the University of Pennsylvania estimated that the elimination of Medicare and near elimination of Medicaid would reduce the life expectancy of 70-year-olds by .37 years but not affect that of wealthier people. It may be that these life expectancy figures indicate that any improvement that Medicare might have contributed may have run its course. It will be interesting to see if a comprehensive prescription drug plan causes a second burst.

Medicaid generally provides health care benefits for low-income persons. Originally, eligibility was extended only to those who were eligible for Aid to families with Dependent Children (AFDC) (recently modified as Temporary Assistance for Needy Families in line with the current policy to limit the time spent receiving welfare payments). The program is a federal-state matching program, with each state setting an income limit on who can receive benefits, with great variation among the states. The primary beneficiaries are poor families headed by a single parent. Since its inception, Medicaid has been expanded to cover uninsured pregnant women, low-income families not receiving welfare, the elderly and disabled, and other groups. Medicaid also funds full-time nursing home care after determining that the individual is unable to pay, as most are, greatly relieving the expense and time involvement of caring for the infirm elderly on their children.

Any effect of these programs, which primarily benefit the poor, can be evaluated by examining life expectancy at birth trends among minorities. In 1955, life expectancy for the non-White population was 61.4 for males and 66.1 for females. Ten years later, that of males actually declined slightly to 61.1, while that of females rose to 67.4. By 1996, life expectancy for non-White males has risen to 68.9 and, for females, to 76.1.

2. Health Insurance

Given the high cost of medical care and prescriptions and the lack of a system of socialized medicine, Americans depend heavily on health insurance to defray costs, particularly catastrophic costs. In 2001, 41.2 million Americans, 14.6% of the population, were without health insurance of any kind, including government health insurance for the elderly and those below the poverty line (USCB, 2002b). Minorities are the hardest hit by the lack of coverage, with 19.0% of Blacks and 33.2% of Hispanics without coverage.

The largest source of coverage is that provided by an employer through a group plan in which the cost is shared by the employer and the employee. In 2001, this represented 62.6% of the population, although there was a 1% drop from the previous year. Government insurance, through Medicare, Medicaid, and military health care, covered an additional 25.3%.

CONCLUSION

While the United States has no population policy to directly affect the size of the population or influence the growth rate, its many laws and programs do affect its demographic parameters. Legislation controlling immigration is hardly unique to the United States, and it can probably be said that the United States is among the more liberal countries in the area, particularly since most recent legislation has only served to increase the amount. Certain changes in visa processing policies since September 11, 2001 are reducing the number of visas issued to a degree, but, again, the goal here is not demographic but security related.

Policies toward the family have given assistance to families with children, but the motivation has been one of equality for working and poor women, certainly not demographic. The many provisions for health care for the poor and elderly have had an undisputed effect on life expectancy and perhaps that was an unspoken goal. But, in terms of numbers, the U.S. attitude has always been "come what may."

Population Policy in Russia

SERGUEY IVANOV,* ANATOLY VICHNEVSKY, AND SERGEI ZAKHAROV

*Population Division, United Nations, New York, United States

Center of Demography and Human Ecology, Russian Academy of Sciences, Moscow, Russia

During the Soviet era (1917–1991), the State was much more actively involved in all spheres of society in Russia than in countries with more liberal regimes. Demographic processes were no exception and were strongly influenced by the State. This is no way implies, however, that the State aimed to meet specifically demographic goals. Quite the reverse—it was unable to appreciate demographic reality as a phenomenon in itself, relatively independent of the life of Soviet society, and any influence it had had on the issue was incidental, the consequence of government decisions concerning economic and social policy, the regime's foundations, or even external affairs, and the like.

At the start of the 20th century, Russia was still a high-fertility country. Its population, in expansion within an immense territory, was growing relatively rapidly, offering no serious reason to intervene in demographic processes. The very high level of mortality was the only population problem the authorities were aware of at that time; consequently, shortly after the revolution, great efforts were made to reduce mortality through the development of a real public health policy whose main objectives and results will be mentioned here.

The internal migration created by the country's commitment to forced industrialization became the second demographic problem soon facing the regime. In very little time, tens of millions of peasants left the country for cities or went to exploit the new regions, and the State quickly recognized the need to control the massive migration flows it had itself instigated. As early as this era, it is possible to talk of setting up a migration policy, although the expression was never officially used.

Half a century later, at the start of the 1970s, Russians became aware of a third major population issue, low fertility—a topic that was completely new at that time. The question aroused animated discussions about the relevance of pronatalist family policy, and led to the creation of the first measures to this end.

Finally, in the 1990s, after the break-up of the USSR and with the natural population balance in Russia showing signs of growing increasingly negative, Russian society had to face yet another new problem, that of external migration: strong immigration from other republics of the ex-USSR at first, followed by a substantial wave of emigration. Policies to meet this new challenge needed to be developed.

These four main population policy themes do not completely exhaust the topic. Soviet and post-Soviet policies also affected many other aspects of demographic behavior. Apart from these four broad areas, however, policies were rarely elaborated according to strictly demographic objectives. While not responding to any demographic logic, for example, the *iron curtain* ideology and policy, characterizing almost the entire Soviet era, involved severe restrictions on external migration. The same is true for many of the often-contradictory family policy measures. Loosening or tightening laws on marriage, divorce and the family, permitting or forbidding abortion and such like, these waves undoubtedly influenced the course of demographic processes; however, they were more a reflection of fluctuations in internal politics, one minute permitting greater freedom and the next tightening the

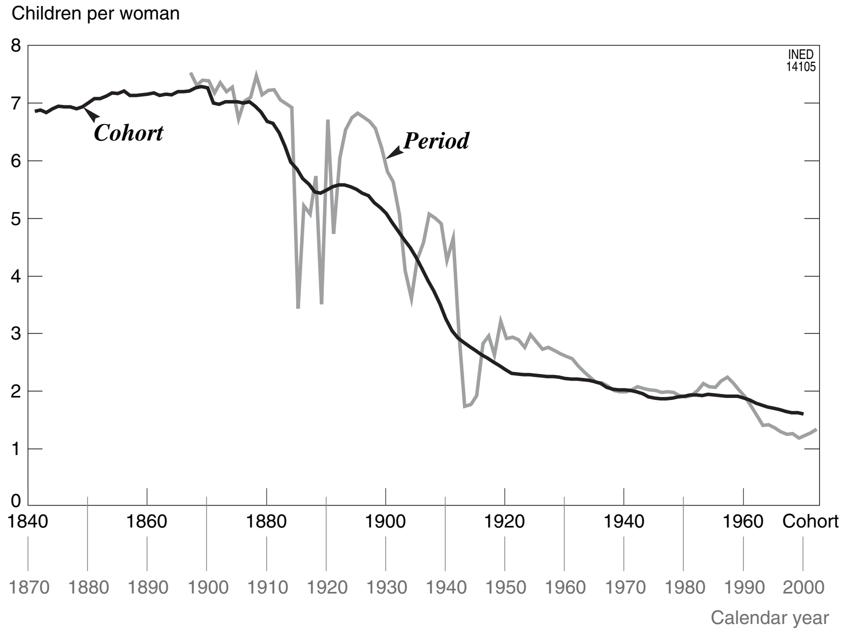

FIGURE 118–1 Completed fertility for the 1841–1970 cohorts and total fertility rates from 1897–2002 (children per woman). (Source: Vishnevsky, forthcoming.)

screws, and vice versa, than of the desire to meet demographic challenges, however real.

I. FAMILY POLICY

Today, Russia is among the countries most affected by low fertility. During the first half of the 20th century, the rapid and often brutal modernization of an essentially peasant society transformed reproductive behavior patterns. Starting much later than in Western nations, and from a higher level, Russia's fertility transition was also much faster. Completed fertility declined regularly from one cohort to the next, despite the many catastrophes (World Wars I and II, the 1918–1920 civil war, massive repressions during the 1930s, famines in 1932–1933 and 1947), which triggered sudden interruptions in fertility timing and strong swings in total fertility rates around the general downward trend; these fluctuations were mainly ironed out during the second half of the 20th century (Figure 118–1).

The completed fertility of all generations born after 1931 is below replacement level; the total fertility rate (TFR) crossed this threshold in 1966. In the two following decades, the TFR remained close to the threshold, oscillating between 1.9 and 2.0 children per woman; then, a brief and gentle rebound in the mid-1980s was followed by an abrupt drop during the 1990s. At 1.2 to 1.3 children per woman, Russia now has one of the lowest TFRs in the world. Despite similarities with Western countries in the level and tendencies of these summary fertility indicators, reproductive behavior in Russia had retained several distinctive features, an earlier entry into reproductive life among them. A change in fertility timing during the 1990s sent the TFR (period indicator) below completed fertility (cohort indicator).

1. From the October Revolution of 1917 to World War II

Within communist doctrine, family policy was viewed in turn as a means to found the new social order, a lever for economic projects, an instrument to reduce social inequalities or, finally, as a tool to reach demographic objectives, depending on the different perspectives taken. Despite these various viewpoints, family policy always occurred within a general context of massive invasion of privacy with the aim of creating an original socialist lifestyle conforming to the superior interests of society as a whole.

According to communist doctrine, society should help women exercise their right to motherhood. Among the first measures taken after the 1917 Revolution, the Soviet regime instituted maternity leave,[1]

[1] Decrees and the Labor Code of 1918–1922 instituted prenatal and postnatal leave at full pay. During this period, work was forbidden and there were legal sanctions that could be applied to employers who contravened these clauses.

introduced family allowances,[2] and started the free distribution of food to children. Female emancipation was also a priority on the political agenda. A decree of December 1917 made divorce easier to obtain—from then on granted on request of one or other spouse, which broke completely with the prohibitive laws of Imperial Russia—and created equality in the rights of children, irrespective of whether they were born within or outside marriage. A 1927 law allowed tribunals to recognize legal rights for cohabiting couples. Abortion on demand, forbidden until then, was legalized in 1920.

At the same time, the attitude toward the family as an institution was ambivalent. In the 1920s, the debates centered on the acceptability of various union types and on individual reproductive rights. According to classic Marxism, the *bourgeois family* and the patriarchal rural household were incompatible with socialism. However, the Bolsheviks were hesitant about implementing such principles as abolishing the institution of marriage or socialization of children. Instead, the regime ventured into less radical experiments, introducing pilot housing projects where individual apartments had no kitchens and in which residents were supposed to take turns preparing meals for everybody, and where children were cared for in nurseries or kindergartens.

The public debate on new union types and collective households quickly lost relevance. During the 1930s, the aim to build a solid socialist fatherland gradually replaced the doctrine of the disappearance of the nation-state under socialism, and the State embraced the precommunist principle within which the family is the basic unit of society. At the same time, mass industrialization provided a practical reason for public family-assistance programs. Vast numbers of women entering the labor force flew into industry, construction, and offices. Work was proclaimed women's duty and basic right. This led to conflict between women's dual role as mother and homemaker and as worker. This tension appeared quite independently of fertility levels, even if it emerged at a time of fairly rapid fertility decline. This decrease was not as yet perceived as a threat for State objectives.

Simultaneously, the idea that population growth would benefit the communist cause emerged. Since population was indeed expanding at that point, the Communist Party stated that high fertility and rapid population growth were inherent to socialism—a myth that prevented discussion about population issues for several decades. At the end of the 1930s, population growth slowed. The regime preferred to blame declining fertility than to accept responsibility for massive losses during the Great Famine of 1932–1933 and the results of repressions during the 1930s. In keeping with its predilection for coercion, its main response took the form of prohibitions. In 1936, abortion was banned (except when the mother's health was directly threatened). In 1944, the liberal law on marriage introduced in 1927 was repealed, and divorce became more complicated and beyond the reach of most couples.

The State also introduced economic support for motherhood. In 1936–1937, it doubled the expenditures for maternity wards and preschool child care. The government introduced monthly allowances for mothers with seven children or more (1936); however, this covered only a small fraction (6% on average) of children's consumption needs (Kharaeva, 2001). The allowance for single mothers of children under 16 years (introduced in 1944) was higher, equal to 15% of the average wage. In addition, allowances for third or higher order births, and for children aged 1 to 4 years, were created. Funding for these new financial awards was met by reducing payments on state bonds. Maternity leave was increased from 9 to 11 weeks. A series of six medals was created (1944), going from the first level, the "Medal for Motherhood" to the title of "Mother-Heroine" (10 children, all living at the last child's first birthday). These medals conferred certain material advantages on their holders, such as preferential positions on waiting lists for kindergartens, summer camps, and housing, as well as priority in queues for shops.

2. The 1950s to the End of the Soviet Regime

During the 1950s, official interest given to demographic aspects of motherhood was low, mainly because, although falling, fertility remained comfortably above replacement level (Figure 118–1). Abortion on demand was once again legalized in 1955, and the divorce procedure was steadily simplified in 1965–1969. The State's involvement in support for family well-being strengthened, notably at the turn of the decade. Huge housing construction enabled many families to move from tiny communal apartments and factory barracks into small individual apartments equipped with a minimum of modern amenities and virtually rent-free. Preschool services were improved and extended.

At the same time, in Russia as in the other USSR European republics, fertility dropped below replacement and population growth slowed considerably. The

[2] A birth allowance equal to the average wage, and a child-maintenance allowance equal to a quarter of the average wage for a period of nine months after the birth.

political climate at that time permitted relatively open debate on the determinants of the less-than-ideal population growth and on the ways to reverse the trend. Discussion was limited in two ways, however. First, of the three demographic components of population growth, only fertility was considered. Immigration from foreign countries, all perceived as too foreign or as plainly hostile, was not even mentioned. The authorities also preferred to maintain their taboo on the question of high mortality rather than look for ways of reducing its level. On the other hand, nobody dared question the assumption that the State had the ability to reshape any type of individual behavior.

In the late 1960s and during the 1970s, the theoretical foundations for fertility policy were formulated and a group of practical measures, aimed to encourage childbearing, were developed. They dealt as much with the obstacles to the satisfaction of fertility preferences as with the preferences themselves. Despite the obvious theoretical difference that ultimately separates the two approaches, in practice this difference mattered little, as most of the concrete recommendations were compatible with both.

The recommendations were widely debated at academic conferences, in professional journals, and in the press, and ended up reaching the ears of policy decision makers. The 24th Party Congress (1971) indirectly recognized that the demographic situation was unsatisfactory, and the 25th Congress (1976) called for the development of an "effective population policy," meaning a fertility policy. The 26th Congress (1981) identified specific areas for political intervention: financial and in-kind assistance to young married couples and families with children, improvements of housing conditions and preschool establishments, expansion of part-time and home-based employment for women, and introduction of partially paid child care leave. This policy canvas included no quantified demographic targets, however. This contrast with the well-established practice of matching a quantified goal to every political action, however illusory or distant it might be, reveals doubts about the real demographic effect of population policy.

These policy decisions were followed by legislation. Maternity leave on full pay was extended from 77 to 112 days (then to 126 days in 1990). The fringe benefits for pregnant women and mothers of young children in the workplace, in terms of shifts, overtime, or types of tasks, were reinforced and extended to lone fathers and legal guardians. Three new child care options were introduced: (1) 18 months of leave on full pay to take care of a sick child, (2) leave with 20% of the average wage between the end of maternity leave and the day the child reached 18 months, and (3) unpaid leave to raise a child from 18 months to 3 years. In 1989–1990, these options were offered to fathers, grandparents, and even to more distant relatives. Moreover, in addition to the relevant allowances, the caregiver was granted the right to part-time or home-based employment. Businesses were obliged to offer part-time or full-time work or, under certain conditions, flexible hours, to women with children under 14 years, if they requested it.

A monthly income-related allowance was introduced in 1974 for children under 12 years. Until 1991, a flat housing allowance of 12 rubles per month was paid for each child if the family's per capita income fell below the unofficial but implicitly used low-income threshold of 50 rubles per month. In 1991, both the condition of eligibility and the amount of this poverty allowance were linked to the minimum wage.

The government also imposed a special tax on men aged 20–50 years, and women aged 20–45 years who were either single or married, but with fewer than three children. The tax rate was 6% of income for childless individuals, 1% for families with one child, and 0.5% for families with two children. The money from this tax went toward financing the monthly allowances for single mothers or for women with large families.

In the early 1980s, the government once again reinforced its population policy. The proportion of all family allowances in the federal budget rose from 0.2% in 1980 to 0.3% in 1985, whereas, in the budgets of the constituent republics, this proportion increased from 0.1% to 0.2% (Kharaeva, 2001). Funding for child care establishments increased. The number of establishments rose from 75,000 in 1980 to 88,000 in 1990, and their staff increased from 638,000 to 994,000. The growth of enrolment ratio was accompanied by an improvement in the quality of services offered to children, as the number of children per employee fell from 13 to less than 9.

Family allowances were diversified and increased. Birth allowance for mothers who were working or studying was raised to 50 rubles (the equivalent of a quarter of the average monthly wage) for the first child, 100 rubles for the second, and the same for the third. The allowance for higher-parity births (introduced in 1944) was also increased. Also created was an allowance of 30 rubles for working fathers with a wife at home. In 1990, these allowances were merged into a single allowance independent of parity, and indexed on the minimum wage.

Although the allowance for single mothers of a child under 16 years quadrupled relative to its starting level, this still did not restore its value relative to the average income. Certain categories of parents became eligible for similar, or even larger, benefits, such as widowed or single mothers who had themselves been orphans, widows not receiving reversion pensions, conscripted soldiers, and ex-spouses of persons not paying child support or paying only at a level below a given threshold.

The number of children a woman needed to quality for the special status of "mother of many children" (*mnogodetnaya*, which literally means "having many children"), which gave access to certain additional benefits, was reduced from seven to five, four or three, depending on the benefit. For instance, a woman who reared five or more children to the age of 8 years became eligible for a pension at 55, as long as she had worked at least 5 years, or at 50, if she had worked for 15 years. For parents with four or more children, the fee in preschool establishments was reduced by half in 1990. Mothers with three or more children received free summer camp vouchers. Probably, these multiple definitions of *mnogodetnayat* not only resulted from budgetary constraints, but they also reflected the confusion reigning around what could have been reasonable policy goals with respect to fertility.

On the surface, this new set of policy measures seemed to have some degree of success, as the total fertility rate rose from 1.9 in the late 1970s to 2.1–2.2 in the mid-1980s. The authorities congratulated themselves on the "positive sociodemographic impact" of strengthening their family support policy (Ryzhkov, 1986). However, this increase in TFR resulted essentially from a tempo effect; many women gave birth to their first child earlier than they would have done without the population policy effort of the early 1980s, but did not increase their completed fertility. The impact of these new measures on period fertility indicators thus disappeared rapidly (Zakharov and Ivanova, 1996), and the new trend reversed from 1988 onward.

Fundamentally, the government was extremely suspicious of family planning, which it saw as a direct cause of low fertility. In 20th-century Russia, abortion was by far the most common birth control method. Although the incidence of abortions fell during the 1960s, it was still among the highest in the world in 1970, with a rate of 135 abortions per 1,000 women aged 15–49 years; two-thirds of pregnancies ended in an abortion (Vichnevski, 1994). Although officially abortion was condemned, no theoretical or practical alternative was offered. Very few contraceptives were available, not even the condom. Abortion, on the other hand, was virtually free of charge and on demand, and the number of clinics and doctors specializing exclusively in abortion increased constantly throughout the period.

As the 1970s drew to a close, a new policy approach was adopted, aiming to replace abortion with modern contraceptives. A few years later, the Ministry of Health purchased huge quantities of intrauterine devices (IUDs) and birth control pills, and launched a vast information campaign. However, although it constituted an important ideological shift, practically speaking, this turnaround only inspired an increase in traditional contraceptive methods, in the early days, and a modest decline in abortion (Avdeev, 1994).

Only in the late 1980s and early 1990s did the authorities begin to encourage the development of networks of family planning centers and authorize the creation of the National Association for Family Planning. The new policy's positive effect on abortion thus expanded. In 1995, the abortion rate fell to 73 per 1,000 women aged 15–49 years, and then to 50 in 2002. However, plummeting fertility levels mean that, today, almost four out of five pregnancies end in abortion, and age-specific abortion rates put the total abortion rate at two per woman (Visnevsky, 2004). The abortion rate is estimated in the same way as the TFR, that is, by adding period age-specific rates. This means that at the current abortion rate, a woman will have an average of two abortions in the course of her reproductive life.

3. The Transition Years

The TFR fell to 1.75 children per woman in 1991 and, since 1996, has plunged to 1.3. The demographic situation thus became the subject of bitter debate. Since 1993, the government's official line on fertility is that it is "too low" and, since 1998, it has been proclaiming its desire to raise the level (United Nations, forthcoming). Given that this fall coincided with the country's political and economic disruptions, a popular explanation holds the abruptness of the transition responsible for the demographic crisis (Caldwell and Schindlmayr, 2003). Although the new deprivations may well have amplified the reduction in fertility intentions, the evidence is inconclusive. Another explanation focuses on the similarity between most developed countries, in terms of the recent evolution of fertility, and on the behavioral changes underlying this evolution (Ivanov, 2000; United Nations, 2004; Vishnevski, forthcoming). These two approaches, however, are not mutually exclusive.

Contrary to widespread assertions, family support policies have often survived the disruption in the country's economic system and political regime. The government approved a National Plan of Action for Children (1995) and a Family Policy Framework (1996), which focus on both family autonomy (as opposed to the Soviet era's subordination to the

State) and the principle of partnership with social institutions.

The swift and radical drop in the number of preschool establishments, personnel, and enrollment (Figure 118–2) is often interpreted as the destruction of an essential social service. The majority of nurseries and kindergartens did indeed undergo severe local budget cuts. At the same time, however, the number of preschool-aged children fell even more quickly than the number of children registered in these establishments (Figure 118–2); thus, the staff-to-child ratio increased, and the deficit in number of places available became a surplus. This evolution should be interpreted as the rational adaptation of the means to the real needs of the population rather than as a breakdown of the system.

This does not mean that the transition went without a hitch. The enrollment ratio fell by 17 percentage points during the first half of the 1990s, due to the combined effect of two factors. First, the evolution of property rights and budgetary constraints disrupted normal functioning of many nurseries and kindergartens and obliged their managers to collect registration fees. Although these fees were often optional, paid only by those who wished, in 1992 the State limited the proportion of costs for which parents were responsible to 20%, or 10% in the case of parents with at least three children. Second, the huge reduction in employment transformed many working mothers into housewives who no longer needed daily child care services. At the end of the 1990s, the recovery of the job market reversed the trend in enrollment ratio. The development of private nurseries for the middle and privileged classes also contributed to this growth.

The State rightly attempted to maintain the system of monetary allowances for children, notably in the mid-1990s, when the national economy and government finances were at their lowest. No benefit was abolished, and some were, on the contrary, even expanded. Thus, paid maternity leave, at 100% of the lost wage, was increased to 140 days (in 1992), and applied to the period during pregnancy after stopping work (1993). The monthly allowance for children aged 1.5 to 5 years was extended to younger children (in 1994), and a monthly allowance for children aged 6–16 years was also created. In 1996, these two types of child allowance were merged into a single allocation for children under 16 years. In the same way, parents on parental leave became eligible both for child care allowances and for child allowances. In the attempt to alleviate the massive rise in poverty, the income criterion for child allowance was abolished in 1992. The proportion of combined expenses from different sources (consolidated State Budget and social insurance funds) allocated to family allowances rose from 1.6% in 1993 to 3.1% in 1996, before falling to 1.3% in 2000, gaining 0.1% in 2001, and increasing again in 2002.

The family allowance system had only a mitigated effect, however. It was effective neither in redistributing income to those in need, nor in easing the financial burden of motherhood for all income groups. Short-term and one-time benefits largely predominated to the detriment of long-term allowances. Benefits were not adequately indexed to inflation. The budgets allo-

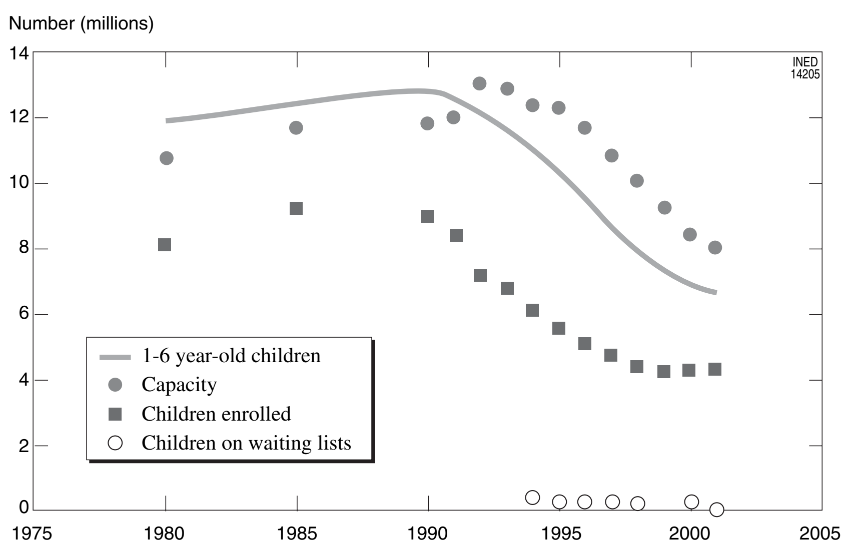

FIGURE 118–2 Children of preschool age and enrollment in preschool establishments, 1980–2001 (in millions). (Sources: estimated from data published in Goskomstat, 1994–2002).

cated were lower than the entitlements they were supposed to fund.

The indexing mechanism did not stop depreciation in the real value of allowances. The minimum salary instituted in 1990 as a base for indexation was not itself indexed to the cost of living. Consequently, the ratio of the minimum wage to the subsistence level fell to 7% in 2000. The multiplier for allowances was increased several times to counterbalance the gap between the cost of living and the minimum wage. For example, the birth allowance was raised from three times the minimum wage in 1990–1992 to 15 times the minimum wage in 1996–2000; in 1995, child care allowance increased from an amount equal to the minimum wage to twice the minimum wage. Nonetheless, the ratio of family allowances to the level of subsistence, or to the average wage, fluctuated enormously (Figure 118–3).

In fact, the birth allowance was the only substantial amount given. The child care allowance was at only 13% of the subsistence level. Child allowance (less than 5% of the average wage) represented a negligible amount, whatever the income level, and many parents did not even go to the trouble of applying for it. Despite continuing economic hardships, the proportion of actual applicants for child allowance among those eligible for it fell from 82% to 70% in 2000.

Other changes made to the system during the 1990s contradicted one another. Discarding the link between birth order and birth allowance reflected pronatalist leanings. At the same time, repealing the income criterion of eligibility weakened the redistribution role played by family support. The child allowance (the most costly element for the State budget) was not large enough to make any significant difference to its beneficiaries. The federal government transferred the responsibility for funding family allowances to the local level, without providing them with the necessary resources.

Funding for family allowances comes from two sources. Maternity, birth, and child care (for children aged under 1.5 years) allowances are financed by the Social Insurance Fund and employer contributions. The consolidated State budget (federal, regional, and municipal funds, to be more precise) finances child allowances (for children under 16 years). The Social Insurance Fund has generally met its obligations. In contrast, child benefits weighed heavily on the State budget, and the different funds were often insufficient to meet the obligations. Furthermore, the federal budget withdrew from funding monthly child allowances in 1994. The difficult economic conditions in many regions strongly affected the availability of the funds (Elizarov *et al*., 1997), and regional budgets built up considerable delays in child allowance payments.

The prolonged fertility decline over the last 15 years has provoked heated debate. The most vociferous pro-

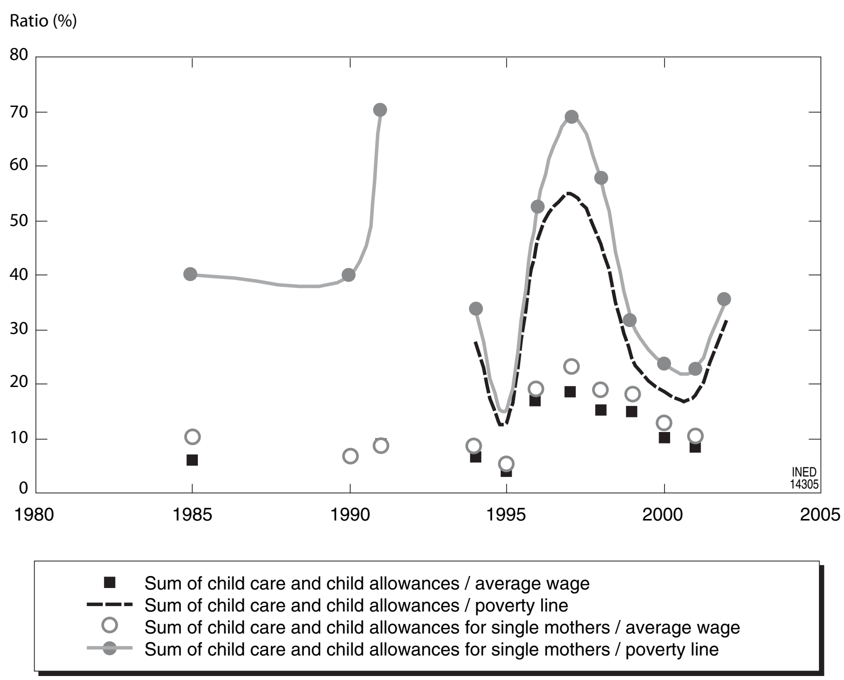

FIGURE 118–3 Trends in the ratios of family allowances to selected indicators, 1985–2002 (per 100). (Sources: estimated from data published in Goskomstat; 1996–2002; Valentei, 1985.)

tagonists are not simply demanding a return to replacement-level fertility. On the contrary, they readily endorse such policy goals as an average family size of "three or four children" (Russia, 2004). The government's white paper on the country's demographic situation (2001) repeats this visionary objective. Several participants in the debate suggested introducing generous birth allowances such as, for instance, an interest-free 20-year mortgage to reward a first birth (written off if the parents raise their child), a free car for a second birth, and a plot of land for a third (Popov, 2004). Others recommended that only biological parents should obtain public housing, but added, paradoxically but in keeping with the old Marxist doctrine, that the government and not parents were responsible for providing for children (Russia, 2004). Equally audible were calls for the return to the traditional family based on the father as breadwinner and mother as homemaker (Antonov and Arkhangelskii, 2002).

Few wealthy regions had the means and desire to establish their own family support programs with the stated intention of improving the region's demographic situation. Family allowances created by Moscow's municipal government in 2004 are several times higher than the payments offered at the national level. The city's residents aged under 25 years (27 for students and 30 if they are married) qualify for an allowance of 15,000 rubles (around 500 dollars) for a first birth, 21,000 for a second, and 30,000 for each higher-order birth. These payments are equivalent to 5, 7, and 10 times respectively the official subsistence level; this compares with 1.5 times for the federal allowance, which is independent of birth order. If no child was born within the first three years of marriage, the couple no longer qualified for these benefits. The official line on these measures is that their goal is to "improve significantly the city's demographic situation." The city of St. Petersburg created a similar program, although on a more modest scale.

Thus, raising fertility has become a high priority for a substantial part of Russian society. At the same time, little attention is given either to other options concerning demographic evolution, or to socioeconomic adaptations to the demographic situation. The pronatalist focus could undermine rather than reinforce the existing family support system. One danger is that even where ambitious programs have been adopted, they will not be sustainable; in other cases, the suggestion to introduce exotic benefits could jeopardize existing programs in the eyes of policy decision makers. Another weakness of this debate is that participants tend to move directly from the assumption that fertility is too low, to formulating solutions. Generally speaking, findings related to the effectiveness of government policy on reproductive behavior in low-fertility countries are weak and unconvincing. In any case, public debate on the issue in Russia scarcely refers to whatever knowledge has been gained from international experience. As a result, the solutions offered combine hyperambitious goals and instruments whose effectiveness has proved very weak, or remedies which might perhaps cure the illness but would certainly kill the patient.

This does not mean that it would be better to leave current family support policies in their present state. These policies, which form a major part of the social safety net and whose justification is therefore not limited to purely fertility objectives (Vishnevski, 1994), need to progress in order to better fulfill their role.

II. HEALTH POLICY

Russia entered the 20th century with very high mortality levels, characteristic of a backward rural country where traditional norms govern the natural movement of the huge majority of the population. Traditional mortality factors, especially the most dangerous infectious and parasitic diseases, were still far from eradicated; for instance, cholera epidemics were still frequent, notably those of the 1890s and of 1905–1911. Mortality rates from scarlet fever, typhoid, and smallpox were still double the maximum levels observed in other European countries (Brochaus and Efron 1898, 1898). At the local and even national levels, famine remained a threat and, over and above widespread chronic malnutrition, bad harvests, exacerbated by outbreaks of infectious diseases, lead from time to time to major crises with exceptional peaks in mortality (as in 1892, e.g.). Thus, life expectancy at birth in Russia was 10 to 12 years lower than in developed countries (Table 118–1). The infant mortality rate, over 300 per 1,000, was the main component of this high mortality. Deaths among children under 5 years accounted for 60% of all deaths; 52% of boys and 40% of girls died before the age of 15 years.

The life expectancies given in Table 118–1 come from recent reestimations based on data adjusted for underregistration of deaths among infants and among the very old from the 1950s onward (Meslé *et al.*, 2003), as well as on a more general correction for earlier periods (Andreev, 1998). Figure 118–4 illustrates the difference with Goskomstat's official estimates. It also shows in detail annual fluctuations in life expectancy for the periods where reconstitutions had been carried out (1927–1938 and since 1946).

TABLE 118–1 Life Expectancy at Birth in Russia Compared with the Average for a Group of Developed Countries, 1900–2000

Year	Russia		Average for 27 developed countries[a]		Difference	
	Men	Women	Men	Women	Men	Women
1900	29.4	31.4	42.4	43.4	13.0	12.0
1930	34.6	38.7	53.4	56.6	18.8	17.9
1938	35.7	41.9	58.1	61.8	22.4	19.9
1950	53.4	60.9	64.0	68.2	10.6	7.3
1960	62.9	70.6	67.4	72.5	4.5	1.9
1970	62.6	73.1	68.4	74.7	5.8	1.6
1980	60.9	72.5	69.9	76.8	9.0	4.3
1990	63.4	74.0	71.9	78.6	8.5	4.6
1995	57.9	71.4	73.1	79.5	15.2	8.1
2000	58.8	72.1	74.0	80.1	15.2	8.0

Mortality had undoubtedly started to decline by the end of the 19th century as a result of social, economic and political reforms undertaken since the early 1860s.

From then on, the history of Russian mortality was composed of extreme contrasts, with periods of progress interrupted by major crises. In reality, Russia experienced only three relatively short periods of genuine progress during the 20th century (before 1914, from 1923 to 1928, and from 1947 to 1964), separated by two disastrous episodes (World War I and the civil war, on the one hand, and the Great Famine and repressions of the 1930s, followed by World War II, on the other) and ending in a long period of slow deterioration of the situation, after 1965, notwithstanding the fluctuations of the 1980s and 1990s. Setting aside past crises and recent fluctuations, one could say that in the course of a century Russia, trying to make up lost ground first experienced a period of convergence with western countries; on the contrary, in the mid-1960s the country entered a phase of radical divergence due to a decline in life expectancy unconnected to any crisis and as such unprecedented in the history of developed countries. At the start of the 21st century, the gap between Russia and industrialized countries was 15 years for men and 8 years for women—as great, on average, as it had been 100 years earlier, at 13 and

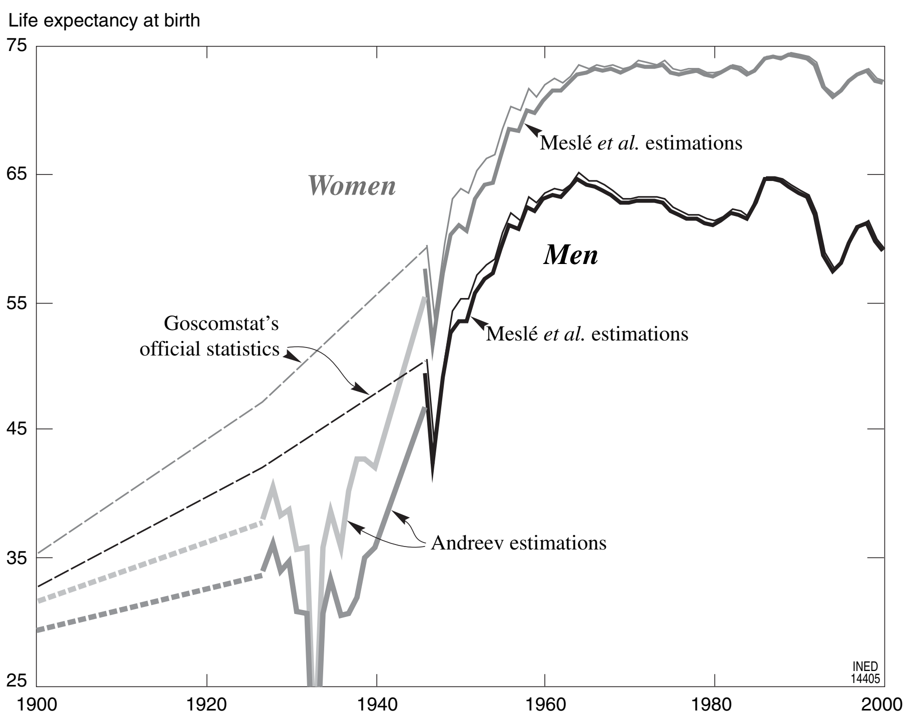

FIGURE 118–4 Trends in life expectancy in Russia since 1900. (Sources: Goscomstat, 1988; Andreev, 1998; 1900–1950, Meslé *et al*. 2003.)

12 years respectively (Table 118–1). This development is obviously not unrelated to health policy and, more generally, to the country's political, economic and social evolution. We will demonstrate this by focusing on four different issues, namely (1) the successes and contradictions of the state monopoly on health care (1918–1965), (2) the public health care crisis and the State's abortive attempts to check it (1965–1990), (3) the ups and downs of the campaign against alcohol, and (4) the return to negative trends.

1. State-Controlled Health Care: Achievements and Contradictions (1918–1965)

World War I, the 1917 Revolution, and the 1918–1920 civil war halted the process of modernization and the first reduction in mortality. However, the latter resumed in a while under new conditions and despite the catastrophes of the 1930s and 1940s, by the 1960s life expectancy attained its highest level ever. The main determinant of this chaotic evolution was State policy in all areas of social life, without significant modernization of health-related behaviors.

As early as 1919, health protection had been declared a priority for the new government. From the moment they took power, the Bolsheviks proclaimed their wish to provide the whole population with free access to high quality medical care, to create a more secure health environment, to establish scientific means to prevent the development and spread of infectious diseases, and especially to fight social diseases such as tuberculosis, sexually transmitted diseases, and alcoholism.

This statement of intent later became one basis for the myth of the unprecedented success of the Soviet socialist system in terms of health protection. Only a few decades later, however, it became apparent that this success was only relative. There may well have been significant positive changes, but they were not extraordinary ones. Mortality was falling in many countries, and the fall was often faster and more profound than in the USSR. Moreover, many of the medical achievements were built on pre-revolutionary developments, as a result, for instance, of the culture and actions of professors and physicians of the *zemstvo* (local assembly that functioned as a body of provincial self-government in Russia from 1864 to 1917). The Soviet regime's only real innovation was the principle of a State monopoly on health care (Mirsky, 1996).

The lack of resources was the first problem facing the founders of the Soviet health system (known in the West as the Semashko system). Having abolished the *zemstvo*, the State had to recreate a whole network to manage the prevention and treatment of diseases, and provide the necessary resources for its functioning, in terms of materials, technical instruments, medicine and personnel. To obtain the funds needed to fulfill its aspirations, the State had diverted into its own budget the profits generated in the commercial sector, and had artificially devalued wages. The substantial funds collected in this way were first invested in heavy industry and transportation, with particular attention given to the military-industrial complex. The social sector as a whole, including public health, received only the meager remnants. The acute lack of resources and the notorious depreciation of medical personnel's wages became the Soviet public health system's chronic ailment in all subsequent stages of its development.

During the early decades following the Revolution, mortality decline in Russia appears to have been fairly rapid (due to a general change in lifestyle, fast rising education levels and the spread of information, as well as to relatively cheap mass measures within health and hygiene, such as improvements in the urban sanitation, vaccination campaigns, quarantine measures, etc.). The many studies that found an association between these latter factors and morbidity or mortality reinforced the optimism.

Indeed, a substantial movement toward modernization was developing in the country. Education at all levels was spreading rapidly; science, including medicine, and mass culture were progressing. Significant investments were made in health education as part of the fight against illiteracy. At the same time, medical institutions were expanding, an accelerated training for medical personnel had been organized, and the pharmaceutical industry was developing (albeit too slowly), and so on.

On the other hand, during the entire period that followed, the Soviet government became obsessed with maintaining the growth of quantitative, formal health progress indicators (number of beds, doctors, medical check-ups, etc.) that had appeared in the 1920s and 1930s. Public health's centralized development entailed target-based budgeting. The priority given to such investment parameters as numbers of beds, doctors or hospital nurses, or the proportion of the population receiving medical check-ups, was certainly justified at the start. Later, however, by preventing the use of other parameters to track progress during the health transition, this approach ossified the system and blocked any new directions for investment (and thus advances in health).

In particular, too little attention was paid to qualitative parameters—the provision of modern equipment and decentralized services to hospitals, the introduction of new treatment methods, the development of new drugs and progress within the pharmaceutical and medical industries. Decades later, in the mid-1980s, 15% of hospitals were still without running water, 49% had no hot water on tap, 24% had no sewer systems, and 45% no baths or showers (Goskomstat of the USSR, 1990). Already problematic early on, health investment efficiency has become completely inadequate since the 1970s. In addition, the health authorities rarely took regional, economic and demographic particularities into account. The central administration gradually lost control over the functioning of the vast network of medical institutions, and management efficiency deteriorated; meanwhile, the inflexible rules and rigid hierarchies left regional authorities little room for maneuver in responding to evolving structures of population, its epidemiological profile, and medical and health needs.

Undoubtedly, partly because of these deficiencies of the health system put under the complete control of the Ministry of Health, alternative health institutions developed in parallel within other ministries or organizations, with their own standards, structures and personnel. Those in the highest echelons were not the only ones to have their own medical services; it was also the case for the Ministries of Defense, the Interior, the Defense Industry, Nuclear Industry, as well as the different Ministries responsible for transport. After the Ministry of Health, the Ministry of Railways had the largest network of medical services. In addition, establishments such as the Ministry of Culture or the Academy of Sciences also had their own dispensaries or clinics. All these alternative medical institutions were better equipped and had more highly qualified personnel than those controlled by the Ministry of Health. Evidently, the multiplication of these parallel, and often overlapping, institutions enabled many individuals to register themselves and their families with several medical establishments at the same time: at their place of residence, through employment in a particular sector of industry, owing to their privileged status. The Soviet system, supposed to provide all citizens with equal access to high-quality medical services, thus made this access closely dependent on profession or social status, to the detriment of the health of the great majority of the population.

Health statistics became more difficult to compile; the sector-related medical services did not divulge indicators of their activities and were not therefore taken into account by the Ministry of Health, making any objective evaluation of the situation difficult.

Despite high ratios of medical personnel and hospital beds per capita (Table 118–2), long waiting lists for consultations became one of the thorns in the side of the medical system, particularly in the network of territorial institutions managed by the Ministry of Health. The overload in the health services was not only due to high morbidity levels. The doctor providing the first line of care to patients also issued documents authorizing sick leave; in the post-Stalin period, such documents could be supplied on false pretences, often just at the patient's request, without any medical check-up. Real diagnoses and the appropriate care were virtually unobtainable outside hospitals, while prevention and primary health care became increasingly formal and ineffective.

Until the 1960s, infectious diseases were the main focus for public health policies. There is no denying the success of the battle against these diseases, that the hypercentralized health service fought, even though it was not total (Table 118–3). Starting in the period between the two world wars, the frequency of diseases such as diphtheria, typhoid, and especially smallpox

TABLE 118–2 Growth in Numbers of Hospital Beds and Doctors (per 100,000 persons), Russia, 1928–1990

Year	Number of beds	Number of doctors

declined significantly. However, in the late 1930s it was still too early to talk of a radical decrease of the incidence of malaria, dysentery, measles, scarlet fever, and rickets.

The contradictory nature of the Soviet type of modernization must be taken into consideration. Rapid industrialization had been accompanied by a formidable increase in population density around the main construction sites and new industrial centers, which were very often built out of nothing. In the old cities, the infrastructure was inadequate to accommodate the huge waves of immigrants. The forced collectivization of agriculture and its consequences, such as the great famine of 1932–1933, pushed millions to migrate, and provoked a resurgence of infectious diseases both in famine zones and where refugees and deportees congregated, and in what have been called "special settlements" (different categories of forced migrants within the context of the repressions: dispossessed peasants, ethnic groups, transgressors of the regime of interior passports, the unemployed, etc.) World War II and the massive evacuation of tens of millions of people led to the reemergence of infectious diseases exacerbated by malnutrition and famine.

Although the advantages of a centralized health care system were used to the full for anti-epidemics operations, it was not up to dealing with the challenge created by a continuous chain of social disruptions.

With the end of mass repressions, and with the country's economic and political climate relaxing a little, the mid-1960s marked a turning point with respect to morbidity and the structure of mortality by causes of death. Lifestyles improved somewhat. Mass urban housing construction enabled millions of families to leave the factory barracks, shantytowns, or overcrowded municipal dwellings. The quality of drinking water, the development of central heating, and, finally, medical progress made it possible to drive back many infectious diseases more quickly.

The planned large-scale introduction of essential medical supplies, such as sulpha drugs and antibiotics, played a key role in the general fall of mortality rates and in transforming their age structure. In the early 1950s, the USSR organized wide-scale production and dissemination of antibiotics, and for a decade and a half mortality plummeted. As in other countries, infant mortality and deaths from infectious and respiratory diseases declined most, enabling Russia to complete the first phase of its health transition (see Chapter 57). However, this was the Soviet regime's final victory in the health domain.

The state monopoly on health services lasted several decades longer (until the early 1990s), but with no significant positive outcomes and no fresh mortality reduction. Then the calcified Soviet health system had only a limited success in the area for which it had been created initially, that of controlling the main infectious and parasitic diseases, where the essential task had already been accomplished; in addition, it proved totally incapable of meeting the challenge of modern ailments, such as cardiovascular diseases, chronic old age-related diseases, accidents and injuries of all sorts. In contrast with Western countries, it failed to enter the second phase of the health transition (see Chapters 57, Volume II, and 69, Volume III, as well as Chapter 108, Volume IV).

2. Crisis in Health and Ineffective Remedies (1965–1990)

During the second half of the 1960s and the 1970s life expectancy declined throughout the USSR, but the deterioration was most serious in Russia. Infant mortality slightly fell and old-age mortality stood still; their respective levels had not yet fully caught up with those of developed countries. At the same time, working-age mortality rose substantially. Moreover, Russia's exceptionally large gap in life expectancy between men and women grew even wider (Meslé and Vallin, 1998; see also Chapter 54, Volume II). In addition, the differentials between rural and urban populations deepened. In 1977–1978, the life expectancy of rural men was only 57.7 years, whereas that of urban women reached 73.3 years. In this period, the "northeastern" mortality gradient became prominent: the further north and east one moved through the country, the more the population's health status degenerated (Vasin and Costello, 1997).

One of the most glaring aspects of the mortality crisis is the spectacular rise in violent deaths: accidents, accidental poisonings, injuries, homicides, and suicides. The crisis, nonetheless, resulted just as much from premature deaths through cardiovascular disease. According to the life tables by causes of death, in 1965, the average age at death by cardiovascular disease was 74.3 years in Russia; by 1980 it declined to 70.7 years, and by 1995, to 67.5 years (compared with 77 years in Western countries at the start of the 1990s).

On the other hand, the crisis did not affect infectious, respiratory or digestive tract diseases, nor cancer. Deaths from tuberculosis, gastro-intestinal disease, and viral infections declined. Pneumonia, chronic bronchitis and influenza also evolved in the right direction, although more modestly. Apart from some Russian particularities, tumor-related deaths followed approximately the same evolution as that witnessed in Western countries (Meslé *et al.*, 1996).

The government and Communist Party leadership were informed of the unfavorable trends in health and mortality early on. Many major documents of the 1970s (minutes of the Communist Party meetings, Council of Ministers' decrees, etc.) reflect the authorities' concerns and generally identify correctly problems such as excess working-age mortality or excess male mortality. Civil society, however, had no complete information on what was happening in the USSR in this area.

In the first half of the 1970s, as in Stalin's time, the USSR once again banned the public use, publication and transfer to international organizations (such as the United Nations or the World Health Organization) of basic information on the evolution of health and mortality (life tables, morbidity indicators, data on causes of death). In particular, causes-of-death statistics were classified, and for certain causes access restrictions were even stricter. The publication of demographic and epidemiological research findings was strictly controlled. These severe limits on the dissemination of information lasted until the mid-1980s, when Mikhail Gorbachev's arrival in power opened the way for *glasnost*.

This embargo on information also prevented any serious reform that might improve the health system's efficiency. This does not mean that no effort at reform was made, however. During the 1970s, in particular, rural health services were reorganized as part and parcel of the restructuring of local rural communities. The aim was to increase the population's concentration in settlements "with a future," and gradually empty settlements "with no future"—those in which emigration had already significantly reduced the number of residents. As a result, most small hospitals, outpatient offices, primary health care centers, and obstetric clinics were closed. Instead, larger multifunction hospitals with outpatient services were created in district centers. The organization and management system for rural health was simplified, and the quality of diagnosis and treatment improved. However, this recentralization of medical services often made access more difficult because of low density in the means of transport and communication. The selective effects of migration that skimmed off the rural population's most active and healthy members, as well as the destruction of traditional rural social structures made major contributions to the deterioration of the demographic and health situation in the rural areas in the 1970s.

During this decade, the USSR Ministry of Health continued its policy of establishing a system of specialized polyclinics, hospitals, research centers, coupled with outpatient departments. Centers for cardiology, oncology, pediatrics, surgery, and other specialties also appeared, draining the best specialists, the best diagnostic equipment, and the best pharmaceutical and medical supplies. In the context of weak growth in public spending in the health and social spheres, however, this policy created a situation when the regional health services (the lowest level in the public health care structure) increasingly lagged behind. Thus, the basic level of medical intervention (where mass prevention programs are implemented) started to deteriorate not only in rural areas but also in the large cities.

This structural imbalance in the health system should have been corrected by a population-wide program of "general mandatory medical check-ups" aiming to improve early diagnosis. The vast territorial network of polyclinics and the number of doctors per person (higher than anywhere else in the world) should have made it possible to achieve this goal. However, the program's implementation was blocked by financial constraints, lack of medical, technical and computer equipment, and the medical personnel's insufficient training in screening methods and in the use of diagnostic equipment. People themselves did not see the point in attending competent services without a serious health problem. The attempt to introduce a "medical passport," required when entering employment, also failed. Generally speaking, this was the weakest and most ineffective health policy and attempt at health system reform in the country's entire history. No positive results were gained during this period; on the contrary, mortality trends were unfavorable, particularly in the area of cardiovascular and chronic diseases, the policy's principal targets.

3. Ups and Downs of the Anti-Alcohol Campaign

In May 1985, the USSR launched a campaign against alcohol. From the start, it was presented as a means to reduce violent deaths. At the same time, Soviet specialists had gathered sufficient proof that excessive and expanding alcohol consumption was largely the cause of increasing working-age mortality, excess male mortality, large rural-urban mortality differentials, and regional disparities in mortality. It was just as evident that alcoholism was not only responsible for heavy demographic losses but also was at the root of many social and economic problems, whether at the macrosocial or family level.

The campaign was implemented with the aim of limiting the production, sale and consumption of alcohol. It was incisive and involved all possible political, administrative and economic levers. As a result, in the space of a few years, per capita alcohol consumption dropped. The effect on mortality curves was immediate: according to official statistics, in only 2 years, life expectancy at birth rose by 2.6 years for men and 1.2 years for women. The fall in mortality rates was even greater in republics of the ex-USSR and regions of the Russian Federation that had experienced the steepest rises in mortality during the previous period. Working-age groups benefited from maximum changes. This unique social experiment fully confirmed the importance of alcohol consumption's impact on Russian mortality (Shkolnikov and Nemtsov, 1997). The anti-alcohol campaign not only reduced deaths from external causes, but it also helped reduce cardiovascular mortality (Meslé *et al*., 1996).

This campaign did not produce durable results, however; rather than providing the means to eradicate the cause of alcoholism, the authorities only introduced prohibitions and restrictions on the production and sale of spirits. Once the surprise effect had worn off, these measures rapidly elicited a return to a soon-thriving domestic production of traditional alcohols, the consumption of nonalimentary alcohol products (medicinal tinctures, *eaux de Cologne*, etc.) and other substitutes (solvents, industrial alcohol, etc.), not to mention the growth in drug consumption and the dependency phenomena that accompanied it. From 1988 onward, mortality stopped falling and soon afterward started to climb again to pre-1985 levels. The losses are thus in complete symmetry with the gains produced by the campaign (Meslé *et al*., 1998). Mortality regained ground essentially in working-age population groups; violent deaths (homicides, accidents, suicides) and deaths form accidental poisoning (which, in the Russian classification of causes of death, includes alcoholism) played the dominant role, with cardiovascular diseases in distant second place. The most affected regions were those that had benefited the most from the anti-alcohol campaign's positive effects. The evolution of cancer-related mortality, in contrast, was scarcely affected either by the drop in mortality at the start of the campaign, or by its subsequent rise. Similarly, mortality among children, the elderly and the highly educated adults proved less sensitive to the fluctuations. Like certain cohort analyses, these facts suggest that those spared during the campaign against alcohol did in fact die a few years later. In all cohorts affected by this fluctuation, the excess deaths observed in the late 1980s and early 1990s correspond almost exactly to deaths avoided during the preceding years thanks to the campaign against alcohol; in the end, the campaign had virtually no effect on the number of years lived by these cohorts (Avdeev *et al*., 1997; Zakharov, 1999; Andreev, 2000).

Nevertheless, mortality increased even more rapidly between 1992 and 1994, this time as a result of the economic and social crisis following the brutal transition to the market economy. In 3 years, men's life expectancy fell by 6 years, and women's by 3 years. Life expectancy was thus lower than before the campaign against alcohol in both rural and urban areas—even lower than the level that might have been predicted from a simple return to past long-term negative trends (Meslé *et al*., 1998; Vallin and Meslé, 2001). Violent deaths and cardiovascular diseases certainly continued to play a particularly important role in exacerbating this decline, but all the other causes also contributed to it; even though working-age groups remained central to the problem, mortality among children and the elderly was also affected. When the initial shock was over, mortality fell again and in 1996–1998 reached the level it would have been at had it followed the long-term negative trend uninterrupted by those specific events.

Thus, responsibility for the first fluctuation (1985–1991) can be assigned to the disruptions of the alcohol market which affected behavior, first by reducing consumption, then by directing consumers toward alternative sources of supplies (Leon *et al*., 1997). The general economic crisis brought on by political reforms, with its huge decline in living standards for the majority, and, in particular, the deterioration of health services, is responsible for the second, inverse fluctuation, in 1992–1998. Very probably, the sociocultural shock was accompanied by a collective psychological stress, related to the transition to the new model of society, which also helped aggravate mortality's resurgence in 1992–1994 that brought life expectancy to an unimaginably low level in 1993–1994 (Shapiro, 1995; Cornia and Paniccià, 2000).

4. Return to Long-Term Negative Trends and Problems with Reform

With the fall of the communist regime, the very principles on which the Soviet system of funding and management in the social sphere rested were obviously questioned, including in matters of health. The fundamental principle of free access to medical care was among the first issues to be dealt with in the context of transition to a market economy.

At the same time, it was impossible to ignore the fact that the principle of free access to medical services had already been significantly eroded during the period of "advanced socialism" (official label introduced by Brejnevian ideologues), that is in the 1970s and 1980s. For the great majority of people, the supposed ease of access to medical services was already largely vitiated by the mediocre quality of the services actually provided. For rapid, high quality medical assistance, it was normally necessary to call on parallel informal services paid in kind or in cash, unless one had access to special services reserved for certain social categories. For instance, highly qualified gynecologists were very wealthy but they owed it to the bonuses, monetary or in kind, received illegally from their patients. Corruption developed very quickly in the health sector.

In the final years of the Soviet regime, the principles of fee-free and easily accessible medical services, as well as the preventive orientation of health policies, were thus undermined by the deterioration of the quality and efficiency of the services provided, and became the mere echo of an ideological rhetoric unrelated to reality (Krichagin, 1989). These problems, more or less concealed under the socialist guise of the Soviet regime, came explosively to light when the regime fell.

Fifteen years after the reforms began, however, health policy goals are still undefined, and priorities remain vague. In the post-Soviet period, health policies have often changed course, reflecting the instability in the balances of power in the public health sector. Russian society is clearly far from ready to face the struggle needed to reverse the unfavorable trends plaguing the population's health.

At the present moment, the main problem affecting public health in Russia is the rift separating the State's guarantee of broad access to free medical care from the inadequate funds allocated to it (for a detailed analysis of the situation, see Bogatova *et al.*, 2002). The health sector was already chronically underfinanced during the Soviet era, but budgetary constraints reached a new dramatic threshold in the early years of the transition to the market economy. Employees in the social sectors, medical practitioners included, were no longer paid their salary. For months, the maintenance of medical buildings and equipment which escaped looting was neglected.

It appeared that the target-oriented approach for public financing of priority goals was partly justified by the fact that no investment mechanism had been set up that could combine the principles of territorial-industrial funding with those of target-oriented funding. Consequently, the federal target programs adopted over the years (Prevention through Vaccination, Insulin-Dependent Diabetes, Children of Russia, Family Planning, Motherhood without Risks, Urgent Measures against Tuberculosis, Anti-AIDS) were constantly underfinanced.

The attempts made to transform the state health system to one based on insurance (Law on the Medical Insurance of the Citizens of the Russian Federation adopted in 1991) were largely formal, and have failed on the whole. The financing of medical institutions hardly differs from the budgetary system set up during the Soviet regime. In reality, the funds generated by the new compulsory insurance merely redistribute tax revenue and fulfill none of the functions of insurance institutions that should evaluate the amount, type, quality, and validity of services offered to people. The compulsory medical insurance premiums paid by the employed persons, defined as a percentage of the salary received (3.6% in 1993), bear no relationship to the real financial needs of medical care. Those insured are excluded from the negotiation process and cannot influence either the timing or the quality of the medical services made available.

Since 1998, the Government has examined many proposals for a free health care program guaranteed by the State based on providing a minimum of well-defined benefits limited by allocated resources. However, none of these numerous proposals was ever adopted. The management of public health institutions operates on the basis of temporary, and constantly changing, standards. Their financing depends directly on the region's economic conditions (efficiency of its businesses, governor's political influence, and so on). As a consequence, basic medical services offered to the population differ enormously throughout the country in terms of both quantity and quality.

Alongside free medical services, the state medical institutions also provide paying services. Regional authorities and autonomous local institutions establish the list, the order and, in some cases, the price list of paid medical services provided in public medical institutions (belonging to State or to municipalities). Furthermore, since the mid-1980s a private market of medical services grew rapidly. Next to institutions providing medical services as such, a large number of businesses have surfaced in the last two decades, offering traditional or alternative medical treatments and paying services for diagnosis, prevention, and treatment for the whole range of known diseases. Simultaneously, optional medical insurance has emerged. As a consequence, the population's global medical bill has soared.

From 1994 to 1999, health expenses (including payments for medical care and drugs) from non-state sources as a proportion of total health expenditure thus climbed from 13% to 36.5% (Belyaeva, 2001). During the decade starting in 1993, private expenses for paid medical services and optional insurance premiums increased several times, by a factor of 100 in constant prices. Experts have concluded that in the late 1990s the ratio of the State's global expenses on health to those of the population was 55 to 45 (Bogatova *et al*., 2002, p. 15–16). According to *Russia's Longitudinal Monitoring Survey* (RLMS), the proportion of the average Russian family's total expenditure allocated for health care and drugs rose from 0.9 to 4.6% between 1992 and 2001. In 2001, 10% of patients paid for outpatient treatment, and 15% of patients paid for hospital inpatient treatment. Among those who paid for health services, approximately half did so officially, at the medical establishment's cashier office, whereas the others paid under the table (Bogatova *et al*., 2002), p. 17).

The extent of "informal" payments varies considerably from one region to the next; it also differs according to the type of medical institution and the nature of the services provided (Shishkin *et al*., 2004). Even in the same regional hospital, the proportion of patients paying on the side varies from 10% to 70% depending on service and treatment. It is practically impossible to be operated free of charge in such fields as neurosurgery or vascular and thoracic surgery (Shishkin, 2003). Among families of modest means, official and non-official medical expenses for theoretically fee-free services represent a higher proportion of income than among wealthier families. In poor regions, this social discrimination is stronger than in the richer ones (Shishkin *et al*., 2004). Informal payments are higher and more frequent in the poorest regions, implying that, in fact, people alleviate through these payments the regional disparities in state financing.

Thus, the black market is thriving alongside the official market for paid services. In 1990–2001, this informal health care market pocketed 600 million dollars per year (Satarov, 2002), whereas the State's total expenses on health barely reached 7 billion dollars.

Thus, the Russian health care system appears as a patchwork of state activities (managed by the Ministry of Health), sector activities (independent of the Ministry of Health) and private activities providing services legally, semi-legally or illegally; services are provided either completely or partially free of charge (funded at the federal or local level, or through compulsory health insurance funds), or fully payable (with the possibility of subscribing to voluntary insurance programs). Having lost its monopoly on health care planning, the Russian Federation's Ministry of Health no longer has the power to make substantial improvements. The main group of reformers for the health services (and for the social sector in general) is made up of health professionals representing the government's macro-economic bloc (the members of which are constantly replaced) and of experts from various research centers with government instructions to work on particular programs. Federal and regional legislative authorities then slightly edit government proposals and programs, often in an unprofessional manner, with the clear aim of satisfying the political and ideological preferences of the majority of deputies.

During the 1990s, the international agencies that financed the research projects on how best to reform the health system were very active. Thus, the project *Zdravreform* (Public Health Reform) was set up with the help of the World Bank. Within the TASIS program, the European Union sponsored the following projects: Program of Health System Development, System of Prophylactic Measures and Population's Health, Reform of Health Care Financing, and Insurance-based Health Care. It is difficult to assess the effectiveness of these and other lesser known projects. At the same time, they unquestionably played an educational role with respect to health system organizers and in terms of international experience in solving similar problems and setting up modern health systems.

The current Governmental Health Development Plan up to the year 2010 (see http://www.med-pravo.ru/common/conception/concepmed-1.htm) proposes a new transformation in the supply structure of medical care by reducing the range of treatments requiring hospitalization, transferring them to the outpatient sector. At present, financial resources are distributed in the following manner: hospitalization 60%, outpatient consultations 30%, emergency services 10%. The plan intends to invert these proportions, thereby reducing the number of hospital beds needed (by 17% between 1991 and 2002). The newly created service of family doctors (currently comprising less than 3,000 of the 2 million doctors working in the health system) would occupy the central position in the primary health care system. Improving the efficiency of emergency services has also been given priority.

The main objectives toward which the Ministry of Health is channeling most of its energies include the following (in the order in which they appear, and as formulated, in The Concept of Public Health Development) (see http://www.med-pravo.ru/common/conception/concmz2001-1.htm): (1) to reduce the level of premature mortality (from cardiovascular diseases, accidents, poisoning, traumas, and cancers); (2) to fight diseases that are particularly relevant for the country's demographic situation (diseases threatening reproductive health, mother's and child's health, and middle-age and old-age diseases); (3) to wage war on diseases posing a particular threat for the whole nation's health (tuberculosis, AIDS, alcoholism, sexually transmitted diseases); (4) to set up specific mechanisms giving people access to the resources necessary to achieve these targets; (5) to develop preventive measures, and set up ways of maintaining and rehabilitating people in good health; (6) to become involved in activities designed to give people a better understanding of the value of good health and encourage them to adopt behaviors to help safeguard it; (7) to develop medical sciences and advanced medical technologies, in every way possible, including information technologies; (8) to meet the population's need for medications and other medical products; (9) to set up a system of sociomedical insurance; (10) to fix a price policy in the market for medical services; (11) to introduce professional liability insurance, and improve the social protection for health sector personnel; (12) to create a system of medical rehabilitation, and develop preventoriums and sanatoriums; (13) to extend the organizational and legal framework of public health institutions, and optimize the nomenclature of medical specialties.

On the whole, this document reads more like an ideological text, in the manner of numerous writings of the Soviet period, than a practical guide for action. It reflects the ideas and interests of the Ministry of Health's main leaders before its reorganization in 2004; with little danger of being proved wrong, it can be said that this document will go through major adjustments in the coming years.

It is not surprising that the transition period's blurred policy did not lead to any major success. Apart from a reduction in the number of abortions, declines in maternal and child mortality, and gaining control over a certain number of infectious diseases, such as diphtheria, whooping cough, hepatitis A, typhoid, brucellosis, rabies, or malaria, the population's health status has shown no positive change, nor any promising tendency. Incredible as this may sound, Russians have a lower life expectancy at birth at the start of the 21st century than they had 40 years ago.

It was easy to identify the key heath challenges, and certain policies could have met these challenges. Looking first at the rapid worsening of various infectious diseases (tuberculosis, STDs, AIDS); for all these diseases, morbidity rates increased at an unprecedented rate in the last decade. Although the rising incidence has slowed down in the last two or three years, the future evolution of the situation remains uncertain and worrying. Second, exogenous mortality (accidents, accidental poisoning, homicides) shows no sign of letting up. On the contrary, it has begun to rise again, probably as a result of increasing alcohol consumption. Third, the risks of premature death, essentially through cardiovascular and chronic diseases, have grown substantially. In the current state of affairs, it is impossible to foresee how society and the State could curb a trend that started more than 40 years ago.

III. MIGRATION POLICY

1. Internal Migrations

During the Soviet period, the size and nature of internal migratory flows were essentially determined by two State-driven processes: forced industrialization, which accelerated the process of urbanization, and the development of peripheral regions, which triggered off massive flows toward the east and north of the country. The aim was to transform an agrarian country into an industrial power as quickly as possible by transferring resources, human and others, from the countryside to the cities, or toward regions to be developed. The immense population movements engendered by urbanization and regional development were completely consistent with the policy of the State. In so doing, however, the authorities rightly feared losing control over massive migrations that risked ruining the system, a danger they sought to avoid.

Deep regional inequalities in living conditions were present throughout the entire Soviet era. An immense urban-industrial periphery living in poverty existed alongside small enclaves where living standards were relatively high and artificially maintained (capital cities, several regional centers, or privileged industrial centers). Residents of the periphery were constantly on the lookout for the slightest opportunity to move toward more prosperous areas, thereby undermining the very idea of privileged enclaves. The authorities also feared too swift an exodus from the countryside, which played the role of an internal colony whose exploitation had for a long time made it possible for them to achieve their ambitious plans. In a word, massive migrations were necessary for development, but their strict control was just as necessary to anchor and maintain the totalitarian political regime then asserting itself. These contradictory aims spawned a hypocritical and paradoxical migratory policy. On the one hand, the State did its utmost to bolster the factors forcing people to leave the countryside and small towns, and to ensure an uninterrupted flow of undemanding human resources toward industry and other urban sectors, the army, and remote regions. On the other hand, however, the State implemented a system of restrictions and barriers to ensure its total power over migration by submitting every individual move to bureaucratic controls.

The key instrument of this policy was the internal passport system. Making it possible to control all citizens' movements, this system had been widely used in Western Europe in the 19th century but had more or less disappeared everywhere by the beginning of the

20th century. It had been kept in place in Russia (at least for those who left their permanent place of residence), however, providing Lenin with the opportunity of declaring, in 1903:

> Social-democrats demand complete freedom of movement and enterprise for the people. But what does "freedom of movement" mean? [. . .] It means that passports must also be eliminated in Russia (in other states, passports have long since disappeared) [. . .] that no policemen, no zemstvo civil servant will have the power to stop people from living and working wherever they see fit. [. . .] Isn't this a case of feudal serfdom? Isn't it insulting people? (Lenin, [1966]).

Once in power the Bolsheviks eliminated the internal passport and, despite the fact that serious obstacles to the movement of citizens resurfaced in the years following the revolution, the general policy of abolishing "feudal serfdom" remained in force for some time. In 1922–1923, a whole series of legislative documents were adopted to abolish the system of internal passports and all institutions related to it, as well as all other constraints on the right of Russian Federation citizens to move or reside anywhere on the Russian territory, by demanding that they have a residence permit or other such document. Thus, *The Small Soviet Encyclopedia* could write that "Soviet law does not recognize the system of internal passports [which] had been an important tool of police intervention and fiscal policy in a so-called police State" (*Encyclopedia*, 1930).

Less than 10 years later, however, a new article in *The Great Soviet Encyclopedia* tells of the Bolshevik State's sudden policy turnaround:

> Passport system: rules of administrative registration, of control and regulations over population movement through the introduction of passports for the said population. The Soviet legislation [. . .] never concealed that its passport system was class-based, using it according to the conditions of class struggle and the aims of the working class's dictatorship at different stages in the construction of socialism. (*Encyclopedia*, 1939)

These words referred to the new system of internal passports already established by a decree of the Central Executive Committee and the Council of People's Commissars on December 27, 1932. According to this decree, all people living in cities, industrial towns, sovkhozes, and new cities had to have an internal passport stamped by the authorities testifying to their place of domicile (the *propiska*). Ipso facto, this inhibited the right to move since the choice of residence depended on the possibility of obtaining the *propiska*. Very quickly, in cities such as Moscow, Leningrad, the federal republic capitals, and other important cities, the *propiska* was restricted, and even citizens with a passport could obtain the *propiska* only with special authorization. As for the peasants—the majority of the country's population—without passports, they were unable to move to the city and were effectively prevented from leaving their village or kolkhoze.

Admittedly, the State did not intend to ban all migrations by introducing such restrictions. On the contrary, its economic policy demanded a radical upheaval in the population's geographical distribution and, as a consequence, vast migration. The aim was to define and control these flows from the center, regardless of its citizens' individual aspirations. As Stalin declared in 1939, "at present it is only a matter of proposing to the kholkozes to accept our request and allow at least one and a half million young members of kholkozes to depart each year to satisfy industry's increasing needs" (Stalin, 1952). Although rather hypocritical, Stalin's formulation clearly reveals the cynical order thus created: the individual could only move if "he was allowed to leave" by being granted a passport authorizing him to go and live elsewhere. From this point on, migration flows were thus strictly regulated.

By the late 1930s, the already severe controls placed on population movement proved insufficient. As a result, in 1940, a new law added penal sanctions against any individual leaving his work or changing his place of work without authorization. Conversely, engineers, technicians and qualified workers who refused to accept a change of residence dictated by the State could be penalized. Although this law was at first followed to the letter, it was undoubtedly applied less rigidly over the years; nonetheless, the 1940 law was abrogated only in 1956.

These regulations aimed at controlling spontaneous migrations, or those considered as such, even though the desire to migrate often resulted from very pressing economic or political constraints. In counterpoint, forced migration also existed, involving mass displacements and even repressive population transfers.

The Soviet regime frequently resorted to political repression to solve the most diverse problems, with economic issues first, or almost first, among them. As early as 1929, on the basis of a proposal put forth by a special commission of the *Politburo*, the Sovnarkom adopted a secret decree on "the use of prisoners' labor," which specified that people condemned to 3 years or more of "deprivation of freedom" by common law tribunals had to serve their sentence in labor camps by working for OGPU. And, to welcome those deprived of their freedom, the OGPU had in turn to enlarge or build new labor camps in remote areas "in order to colonize them and exploit their natural resources by using the labor of those deprived of freedom" (Materik, 2000, p. 64).

Very quickly, deprivation of freedom for criminal or political offences became an important instrument for the "colonization of outlying regions." These regions soon became the sites of a vast network of camps, colonies, and special settlements (*spetsposelenie*) where millions of people newly deprived of their freedom were sent: *dekoulakised* peasants, Gulag prisoners, ethnic deportees, and so on. In 1953, the total number of prisoners and *specposelency* rose to 5.4 million people, while Siberia, the Far-East and Kazakhstan combined, where most of these prisoners were concentrated, barely numbered 30 million inhabitants in total.

Stalin's death ended these massive deportations, but the system of migration regulation initiated under Stalin did not die with him.

The discrimination imposed by the system of internal passports went on for a long time. It took more than 20 years before new passport regulations in the USSR were introduced by a USSR's Council of Ministers Decree on August 28, 1974; according to this new decree, passports had to be issued to all USSR citizens aged 16 years and over. For the first time, this decree created the same system for rural and urban dwellers. "The passport campaign began on the first of January 1976 and was completed on 31st December 1981. In 6 years, 50 million passports were delivered in rural localities." (Lioubarski Kronid, *Régime de passeport et régime de propiska en Russie*, http://www.hrights.ru/text/b2/Chapter5.htm).

The *propiska* lasted even longer, until the USSR collapsed, and has still not completely disappeared. In principle, any citizen holding a passport could move freely throughout the entire country; in reality, however, he could not settle in any place where the *propiska* was restricted as, without it, he had access to neither work nor housing. As the demand for labor was in general very high in these regions, the State's need for labor in key economic sectors (industry, science, etc.) was in constant contradiction with a migration policy that paralyzed the labor market. In practice, the creation of non-viable artificial social statuses made it possible to bypass these contradictions. Thus appeared millions of *limitchik*—people whom businesses and state organizations were entitled to employ by issuing them with a temporary *propiska* for the duration of their contract of employment. This authorization to live in large cities was precarious and did not extend to other members of the family (even marriage to a *limitchik* did not entitle them to a provisional *propiska*).

Only on October 26, 1990, did the USSR's Supreme Soviet Committee for Constitutional Supervision acknowledge that the *propiska*'s authorization procedure in force for so many years "prevents citizens from enjoying their fundamental right to freedom of movement, work, and education"; legally, this paved the way for abolishing the *propiska*. Furthermore, on June 25, 1993, President Boris Yeltsin approved the law on "the right of citizens of the Russian Federation to freedom of movement and to the choice of their place of residence within the limits of the Russian Federation," which should have put a term to the *propiska*. In reality, this did not happen. In many places, the attempt to eradicate the *propiska*'s authorization procedure met with resistance from local authorities, and it still survives today. Moreover, many bureaucrats at all levels still openly favor a return to the *propiska*.

Although prohibitive and repressive measures were the main tool of Soviet migration policy, this was seldom referred to. Instead, the focus was constantly placed on the incentives that had also always existed. A whole system of privileges had been created at the time the State needed to increase flows of migrants toward certain cities or regions. A most typical example is the priority accorded to regions of the extreme North, rich in natural resources but suffering from harsh climatic conditions. The list and particular status of these territories were defined in 1967 by a decree of the Soviet government. In 1990, the list was extended to 70% of Russia's territory (11.9 million sq. km.), without any real reason according to some authors. Those volunteering to come and work in these regions enjoyed a higher salary, more days off, subsidies for temporary work stoppage, higher pensions, and so on. These measures met with relative success. The benefits attracted many people to the northern regions; in 20 years, from 1970 to 1989, the population in the far eastern regions increased noticeably, from 7.2% to 8.6% of Russia's total population (12.6 million people). In subsequent years, these regions lost some of their economic attraction and their population size, in absolute terms and as the percentage of the country's total population, has started decreasing.

Another type of incentive was used to encourage migrations toward developing regions. It consisted of combining economic interests with young people's enthusiasm referred to as the "*komsomol* appeals." In the decades following World War II and until the mid-1980s, it was common practice to call on volunteers to work on the large sites of natural resource development, construction of railways, power stations, and so on. In this way was ensured, for instance, a flow of young people to Kazakhstan in the 1950s, to exploit virgin lands or build the Baikal-Amour railroad during the 1970s.

During World War II, people and industries were evacuated from the occupied territories, which played a considerable role in increasing the population and developing the economy of the Asian part of Russia.

The population census of 1989 makes it possible to assess the results of internal migration during the post-war period and, as a consequence, the effect of Soviet migration policy.

According to the first Soviet census of 1926, 82% of the population within the borders of the USSR as well as those of Russia were rural (Goskomstat, 1988, p. 8). At the end of the 1920s, right from the start of forced industrialization, a rural exodus took place on an unprecedented scale. Between the 1926 and 1939 censuses, the urban population of the USSR (within the pre-1939 frontiers) increased by 30 million people (from 26.3 to 56.1 million) and its share of the total population rose from 18 to 33% (Goskomstat, 1988). Over the next 50 years, the USSR's total population (within its new borders) increased by 94.5 million but, during the same period, the urban population grew by 127.5 million whereas the rural population fell by 33 million despite its fertility being higher than that of the urban population. Between 1950 and 1990, the USSR's urban population increased, on average, by around 30 million people every 10 years (Goskomstat, 1997, p. 7). At the end of the 1980s, the urban population represented two-thirds of the USSR's total population and close to three-quarters of Russia's population. Of the 29.8 million–strong increase in the urban population of the USSR between 1926 and 1939, 18.7 million, or 63%, were migrants from rural areas. Between 1939 and 1969, within the USSR's post-1939 borders, the urban population rose by 75.6 million people, 61 million of whom were migrants (Urlanis, Borisov, 1984, p. 414).

The migrations taking place during the Soviet period also modified the regional distribution of Russia's population. These changes, however, were less important than those brought about by urbanization. The USSR had inherited from the Russian empire an immense territory far from uniformly populated and developed. During several decades after the end of the 1920s, occurred a substantial shift of population eastwards, as a result of migrations from the European to the Asian parts of Russia. The total population east of the Ural increased from 13 to 22 million people between 1926 and 1939 and reached 32.1 million in 1989 (thus multiplied by a factor of 2.5, whereas Russia's total population increased only 1.7 times). However, population movements toward the East hardly changed the overall picture (Figure 118–5). As in the past, Siberia and the Far East have remained very sparsely populated and the concentration of population in the Central region that includes Moscow, has only slightly decreased (Figure 118–6).

During the period following the USSR's collapse, former restrictions on freedom of movement were either abolished or considerably weakened, and the State's once active policy in the realm of internal migrations disappeared. Migrations then took place against a backdrop of depopulation, economic crisis, and political conflicts (especially in the Caucasus), and have often flowed in directions contrary to those imposed for decades by previous policies. Noticeable since the late 1980s, this migratory ebb has gathered momentum, mostly from the eastern and northern regions that the State once sought to populate.

This is not really because the State, with its more liberal political regime, no longer allows itself to resort to methods used during the Soviet regime. More fundamentally, this occurs because the potential of internal migration became severely limited by the level of urbanization already reached and by the trend toward depopulation. In Russia, internal migration can no longer play the role it enjoyed from 1930 to 1980. Today, the migration issues are related much more to external migration, and more precisely to immigration, which completely alters the objectives that policies may be aiming at.

2. External Migration

a. Emigration

The Russian empire contributed much less than other European countries to the trans-Atlantic migrations of the late 19th and early 20th centuries. This can be explained by Siberia's vast and vacant lands, and by the enormous potential for internal agrarian colonization, encouraged by the government. Nevertheless, the country produced emigration flows, mostly consisting of non-Russians. Estimates put the number of people who emigrated from Russia in the period 1861–1915 at 4.3 million, of whom 2.6 million left during the first fifteen years of the 20th century. Two-thirds went to the United States (close to 80% during this period) (Obolensky-Ossinsky, 1928). Among those who left, predominated the Jews (approximately 2 million between 1881 and 1914), and other non-Russians. From 1860 until the beginning of World War I, the majority of migrants to North and South America were non-Russians: Jews (44%), Poles (25%), Lithuanians (8%), Finns (7%), and Germans (6%) (Obolenski, 1928, p. 24).

Although World War I abruptly halted these emigration flows, the Revolution and the civil war generated new, and very different, streams. In fact, these political upheavals incited a massive and definitive emigration. Although estimates vary greatly from one author to the next, it is now estimated that the USSR,

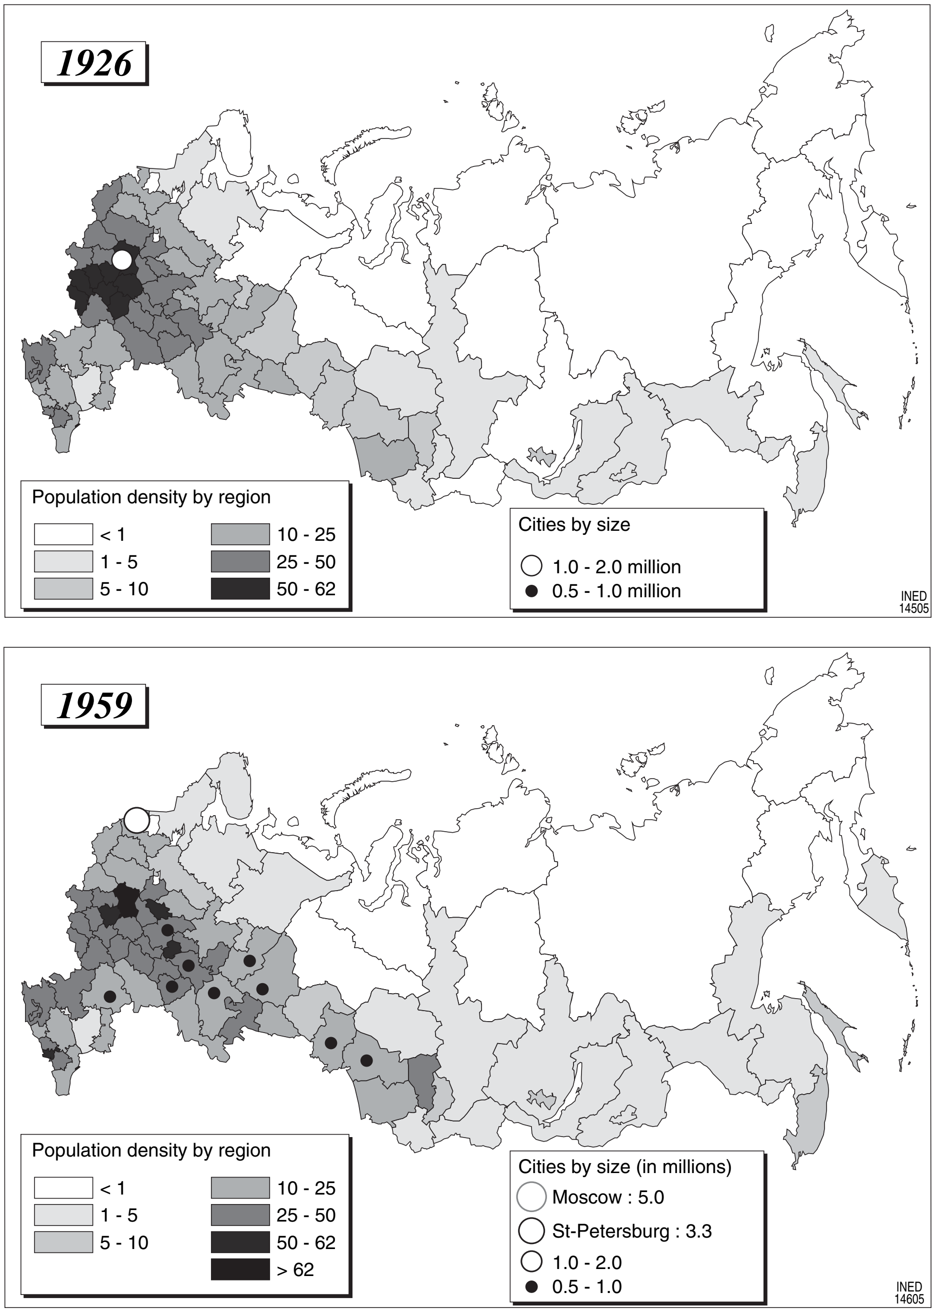

FIGURE 118–5 Maps showing the evolution of the Russian population's geographical distribution during the 20th century.

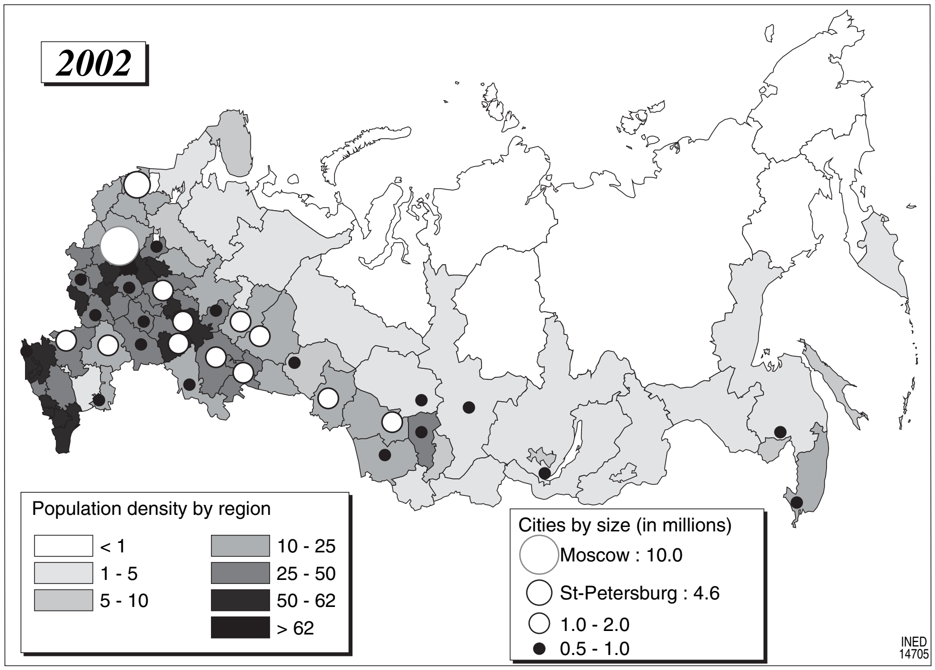

FIGURE 118–5 (*Continued*)

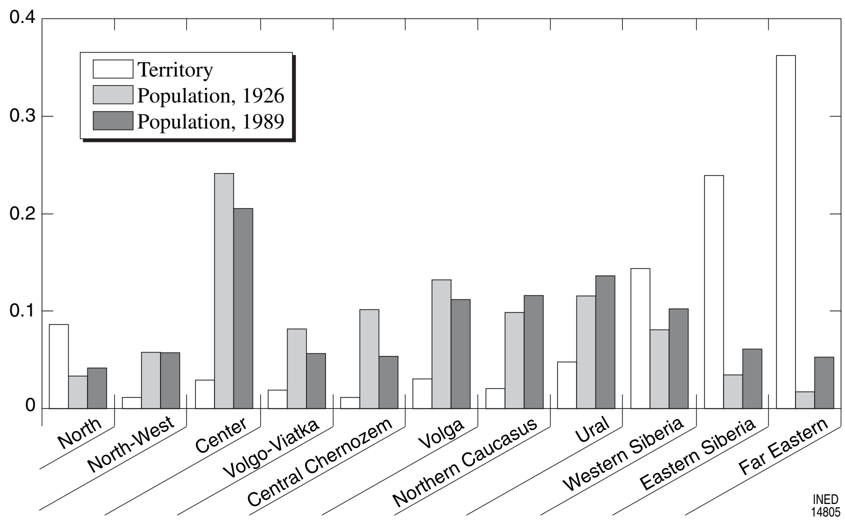

FIGURE 118–6 Large economic regions as a percentage of the entire Russian territory and total population. (Source: Goskomstat, 1998, p. 50–53.)

within its 1922 borders, established at the time of its foundation, lost then approximately 2 million inhabitants (Jiromskaia, 2000, p. 134–139; Adamets, 2003, p. 284–285).

When the civil war ended and the Soviet regime imposed its power over the entire country free emigration outside the USSR stopped. It became exceptionally rare for individuals to receive authorization to leave the country (an exit visa), except for official duties abroad. A few waves of uncontrolled emigration took place nonetheless. In 1931–1933, according to some estimates, some 200,000 Kazakhs definitely left for China, Mongolia, Afghanistan, Iran, or Turkey, to escape from a raging famine (Kozybaev *et al*., 1991, p. 226).

World War II spurred new, and very substantial, waves of emigration, some more or less uncontrolled and others, on the contrary, forced and severely controlled by the authorities. On the one hand, a vast number of refugees and displaced persons refused to return to the USSR, despite the fact that the Soviet authorities did their utmost to get them back. Various estimates have been made of their numbers. According to official sources, on January 1, 1951, 452,000 Soviet citizens remained abroad (Polian, 2002, p. 573). However, some of those who refused repatriation after 1945 had died by 1951, so that the total number of permanent departures was greater. Other estimates provide much higher figures: 1.2 to 1.5 millions, or even 2 million (Heitman, 1987, p. 10), a figure considered exaggerated, however (Polian, 2002, p. 576). On the other hand, the State decided to expel nearly 900,000 Germans (approximately 400,000 in accordance with the 1939 Soviet-German Pact, and 500,000 after Russia annexed Eastern Prussia) from the USSR territory within the borders established after the war. In addition, close to 1.5 million Poles from Western Ukraine, Western Bielorussia, Lithuania, and other regions of the USSR were moved to Poland, and nearly 400,000 Finns were moved from Karelia to Finland, and so on (Heitman, 1987; Piesowicz, 1988).

Once the waves of migration prompted by World War II were over, the iron curtain fell again, putting a sudden end to all emigration from of the USSR.

During the 1960s, departures out of the USSR were minimal, and were more than counterbalanced by arrivals, themselves very few (Armenians returning to their historical homeland, refugees from China or students from Asian or African countries); as a result, before 1970, net migration was slightly positive.

In the two following decades, the number of entries fell and, despite the rarity of departures, net migration was negative. In the 1970s, net emigration fluctuated between 10,000 and 15,000 people, only exceptionally reaching 30,000 to 40,000. During the 1980s, emigration had slowed even further.

A major change took place in 1988, as Jews, Germans and Greeks were allowed to emigrate with relative ease, and trips abroad on personal invitation were authorized. The reaction to this breath of freedom was immediate. Departures from the USSR almost trebled from 1987 to 1988 (108,000, as opposed to 39,000), and doubled again in 1989 (235,000), and once again in 1990 (452,000). As immigration remained a rare event, net emigration skyrocketed.

In May 1991, the USSR adopted a new law on the entry and exit modalities, guaranteeing that international law in matters of freedom of movement would be respected; this law was supposed to be implemented throughout the whole USSR territory from January 1st, 1993. The USSR ceased to exist at the end of 1991, but the law was nonetheless implemented in the Russian Federation and remained in force until a federal law was adopted, on August 15, 1996, on "the modalities of entry to and exit from the Federation of Russia." This law stated: "Every citizen of the Russian Federation can freely circulate outside the borders of the Russian Federation and freely return to the Russian Federation." Thus the final restrictions on leaving the country, in place for decades, disappeared; as a result, emigration increased substantially.

According to published government statistics, Russia's net emigration from the ex-USSR's borders rose to 1,071,000 people during the years 1990–2000 (Goskomstat, 1997, 2001).

b. Immigration

Whether taking its present frontiers, those of the Russian empire or those of the USSR, Russia never experienced large-scale immigration waves in the past, despite the fact that the government occasionally accepted relatively numerous groups of migrants belonging to specific categories. Thus, for instance, German settlers were made welcome in the 18th century, and Armenians in the 19th and 20th centuries. On the whole, however, within its present borders, Russia has been a sending rather than a receiving country. This is even more the case in the European part of Russia, which for a long time was an important source of migration toward the Asian part of Russia as such or toward other republics of the USSR which became independent states after the USSR's collapse.

In the days of the Empire and under the Soviet regime, these migrations were always considered internal and, fitting neatly in its strategy to develop peripheral regions, were encouraged by the central government. However, for demographic or sociopolitical reasons, migration gradually lost its role and Russia became host country to in-migrants as early as the second half of the 1970s (Figure 118–7). In addition, the USSR and RSFSR (Russian Soviet Federal Socialist Republic) leaders became aware of the need to open their doors to immigrants. Experts and policymakers hotly debated the question of how to supplement a scanty demographic tank of Russia with the help of migration from regions with excess manpower, such as the central Asian republics; their attempt at measures of this nature met with no great success.

As the USSR was dismantled and the Russian Federation became an independent state, the migration context and interpretations have radically changed. On the one hand migrations between republics, hitherto considered internal, became international migrations overnight. On the other hand, the population's natural increase became negative since 1992 and immigration suddenly became an important counterbalanc-

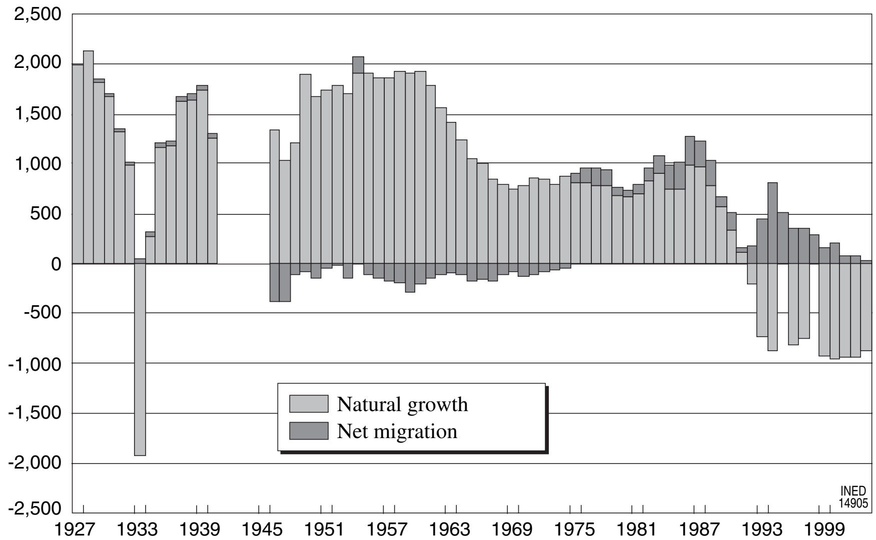

FIGURE 118–7 Components of population growth in Russia, 1927–2003 (per thousand). (Source: Vichnevski, 2004, p. 18).

ing factor: even if it is not sufficient to offset the population's natural decrease, it nonetheless considerably curbs the population decline.

In the early 1990s, Russia, which, at its level, had no experience managing migration flows, created institutions and legislation essential for this management. In 1992 the Federal Migration Service was established as an independent federal agency that subsequently was reshuffled many times. In 2002, this service lost its independence and its functions were passed on to the Ministry for Matters of the Federation, Nationalities and Migration Policy. This Ministry was in turn dismantled and migrations became the responsibility of the Ministry of the Interior where, the Federal Migration Service was reconstituted in 2002 as a ministerial department.

Present laws concerning the treatment of refugees and displaced persons were adopted in 1993, together with a presidential decree aiming to introduce migration controls. However, more general federal laws on Russian Federation citizenship and on the status of foreigners, replacing regulations dating back to the Soviet regime, were only passed in 2002. Without going into detail on the content of these documents, it is nonetheless worth noting that they aroused strong criticisms within society. Recognizing its weaknesses, even the President of the Russian Federation criticized the law on citizenship and, in 2003, some amendments were made.

The unfairly restrictive nature of these two laws does indeed open them up to criticism. They create too rigid a boundary between Russian Federation citizens and those of former constituent republics of the USSR who shared, until recently, the same citizenship as the inhabitants of Russia. By putting the inhabitants of Ukraine, Armenia, or Kazakhstan on the same legal footing as those from China, Vietnam, or an African country, they groundlessly sever kinship ties, prevent the return to Russia of persons of Russian culture, who either have Russian as their mother tongue or are fluent in Russian, and thereby deprives Russia of an extremely valuable source of immigrants.

Despite these unfair restrictions, it is not true that Russian migration laws completely close the door to immigrants. They acknowledge that foreigners can legitimately remain on Russian soil provided they have a residence permit, temporary residence permit, visa, or any other type of document accepted by federal law or international agreements confirming the right of foreign citizens to stay or reside on Russian Federation territory.

A 5-year residence permit can be issued to any foreigner residing in Russia and in possession of a temporary visa; it can also be extended many times. Anyone holding such a residence permit is considered a permanent resident of Russia, whereas all other legal immigrants are defined as temporary residents (the temporary residence permit is issued either according to quotas defined yearly by the government of the Russian Federation or, in certain legally defined cases, outside quota), or as persons staying temporarily in the Federation of Russia (with visa, or without visa when they come from countries for which the visa is not required). Every foreigner who has resided in Russia for more than 5 years can apply for Russian citizenship.

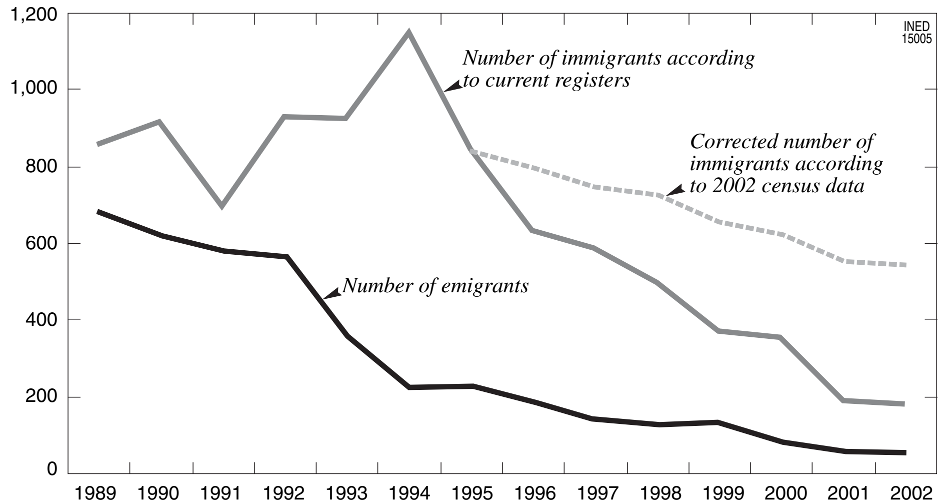

FIGURE 118–8 Trends in external migration in Russia, 1989–2002, in thousands of persons. (Source: Vichnevski, 2004, p. 140.)

Therefore, the current legislation provides a legal framework that is relatively favorable for immigration and for gradual integration of immigrants into Russian society. Nonetheless, the presence of a large number of illegal immigrants, often mentioned by the authorities and the media, shows that the system provided by this legislation functions poorly, that it was created without taking into consideration actual operative policies, and that it fails to regulate spontaneous, weakly controlled migration flows about which no reliable information exists.

The official statistics only provide data on registered migrants. According to these statistics, the exchange of migrants between the ex-republics of USSR changed radically with the Union's collapse. Entries into Russia suddenly outnumbered departures, resulting in an abrupt increase in Russia's net migration. This increase was short-lived and by the end of the 1990s, net migration had greatly diminished. However, it is quite possible that the real evolution of immigration flows was different, as a result of increasing illegal immigration.

This may to some extent stem from a change in the nature of migration movements. In the early years following the USSR's demise, repatriated Russians, returning to live permanently in Russia, made up the bulk of immigrants; with time, however, immigration has increasingly included migrants in search of temporary work. Mounting difficulties in obtaining permits for work, residence, or temporary stay, were soon felt.

After the 2002 population census, Russia's Goskomstat (which became the Federal Service of State Statistics in 2004) adjusted the data provided by current migration registration after 1995, raising immigration estimates (Figure 118–8). This correction is supposed to include illegal immigration as well, but this is questionable because census data on illegal immigrants are probably incomplete.

In the absence of reliable information, public opinion tends to overestimate the number of illegal immigrants, and increasingly resents it, which explains the government's ambivalent attitude and migration policy. On the one hand, the authorities are starting to appreciate immigration's new role as the main means to counterbalance natural depopulation and shortage of manpower. On the other hand, central authorities are more preoccupied by public opinion than by the active development of migration policy. They prefer to leave the responsibility of organizing and implementing this policy to the lower (departmental) echelons and regional authorities; the latter, however, tend to manage migratory processes according to their own interests, which are sometimes at odds with those of the country as a whole.

As a result, the President of the Russian Federation declares, "What we need [. . .] are not prohibitions and obstacles, but an efficient migration policy that can benefit the country while being acceptable to people" (message from Russia's President to the Federal Assembly, dated May 16, 2003). At the same time, the President acknowledges that "we [. . .] have not yet succeeded in developing a civilized mechanism to recruit manpower from other countries" (comment made by Russia's President on the radio, on December 18, 2003). A migration policy tailored to Russia's present needs remains to be invented.

Acknowlegment

CHAPTER

119

Population Policy in France, 1896–2003

JEAN-CLAUDE CHESNAIS

Institut national d'études démographiques (INED), Paris, France

INTRODUCTION: AN UNUSUAL DEMOGRAPHIC DESTINY

France, a country of smallholders, has for a long time been highly populated, and was even readily compared in the 18th century to the Chinese world (Braudel, 1986). It was here, from 1760 onward, that revolutionary ideals, such as emancipation from divine authority, abolition of royalty, and a quest for liberty and equality, were born.

The secular decline in fertility was in keeping with this context and reinforced by the reform of the civil code, which abolished primogeniture in relation to succession and introduced equality of treatment among the siblings of the same family by partition of inheritance in equal shares. It was from this that arose the risk of fragmenting plots of land, which was later highly disliked for its direct contribution to impoverishment.

It was in this way, with a good century in advance of its neighbors in Western Europe, that France started on its secular decline in fertility. In certain regions, such as the Southwest, Normandy, and the mountainous areas, the movement arose even earlier and was more marked. It was therefore a rural society that was the first to initiate this movement. As early as 1850, before the change in fertility had arisen in the other countries of Western Europe, the fertility rate in France was no more than an average of 3.5 children per woman, and had indeed already covered half the distance separating tradition (5 or more children) and modern times (2 children or less). Associated with the rural exodus, this weakness in fertility (well below the replacement threshold on account of the high early death rate of the period) did not take long to create pockets of depopulation and even global depopulation by the end of the 19th century.

An overview of the long-term tendencies supports this diagnosis. Finally, the reconstitution of the completed fertilities of the cohorts shows that, since the Napoleonic era and with the exception of the 1919–1946 cohorts that participated in the post-war baby boom, all of the female cohorts have had (taking into account the mortality of their epoch), a fertility below the replacement level. Consequently, ever since the mid-19th century, the economy has been undermanned, in both agriculture and industry, and has had to call on foreign immigration. Here again, the situation was contrary to that prevailing in the neighboring countries, which were still in a phase of high fertility and decreasing mortality, and sending an ever-greater demographic surplus toward the New Worlds. Napoleon wanted soldiers, irrespective of their nationality. A half-century later it was workers who were to arrive. Immigration to France was to become a structural feature. In spite of the intensity of the naturalization policy adopted in 1851 and reinforced at the end of the 19th century, foreigners numbered 7% of the total population by 1931. Because of the low fertility situation, France only participated marginally in the great wave of population that peopled the Americas.

There was another lesser-known but important feature specific to France: its relative excess mortality (reflection of a poorer state of health), which was to endure until the 1950s. Disturbed by the losses in

World War I, frightened at the prospect of a German revenge, demoralized by its economic backwardness, subject to immobility (lack of construction, rigidity of institutions and regulations), crushed by the sugar beet growers and drink salespeople, France remained a victim of the serious social scourges of tuberculosis and alcoholism. Most of the dwelling places were old, dilapidated, devoid of comfort, and particularly lacking in sanitary installations. The smallest village could count several taverns. The numerous and powerful home distillers were not only protected, but privileged. This health situation contributed to obstructing the population momentum of the country, and to increasing absenteeism from work and lowering the productivity of the labor force. It recovered in a spectacular way after the 1950s, when France became one of the countries where average life expectancy was the highest.

Until the 1940s, subfertility, immigration, and excess mortality made France a special case. The turnaround linked to the reconstruction and family policy of the war period lent its baby boom a more powerful and durable character. As for the phase of subfertility introduced into the industrial world of the 1960s, it has, up to the present, affected France less than its chief partners (except for the United States), and this preservation appears to be linked both to a collective mentality (see the Euro barometer reviews on the ideal family), and to a population policy that, although admittedly inadequate, is better adapted than that within the neighboring countries. This historic reversal is clearly insufficient to curb the decline in the French share of the world population: 3.4% in 1750; 2.5% in 1900; 1.7% in 1950; 1.0% in 2000. Recent decades have certainly been marked by an acceleration in population growth in the less developed countries (see Chapter 69), but it is on the European scale that the results are most significant. Estimated at 28 million inhabitants in 1800, the French population on the present territory occupied second place in Europe after Russia (40 million), and represented just over 15% of that of the continent (180 million). In 1939, with its 42 million inhabitants on the eve of the war, the weight of France halved (7.9%). Due to the early decline in fertility (a good century before other Western countries) and the fall in mortality, the population increased by only 50%, whereas it doubled or tripled in the neighboring countries of the North. It must also be stressed that from 1870 to 1940, in the absence of foreign immigration, the French population would have diminished. It is appropriate therefore to analyze here the three large components of the policy that provoked this distinctive drive toward lesser growth (until 1945), and then the stronger growth than other European countries since 1945, with its policies relating to childhood, fertility, public health, and internal and international migration.

I. THE POLICY OF ENCOURAGING FERTILITY

1. Demographic Movement Compared

The singularity of the French fertility policy can only be understood by reference to the historical context of a relative decline in France and an increase in the power of France's larger neighbors, at a time of tension when the number of men still played a strategic role in military confrontations.

Between 1850 and 1950, with a stable territory, the population of France increased by only 16%. This was despite the fall in the death rate, the relative initial youthfulness of the population pyramid, and the migratory contribution that Alfred Sauvy (1945) estimated at 5 million people around 1940. The relative growth in a century had been two times lower than during the following period of scarcely 40 years (1950–1988). All the other great countries in the industrial world had evolved in the opposite direction. Between 1850 and 1950, the other European countries (except Russia), taken as a whole, saw their overall population growth exceed 100%, whereas, between 1891 and 1946, France experienced a long stagnation in its total numbers, because, within the framework of its present borders, although it had turned 40 million since 1891, the population in the 1946 census was still 40 million! France had therefore experienced a cessation of population growth just at the time when it was at its peak in most of the other European countries. As a result, the changes in ranking have been profound and irremediable. It should be recalled that in 1850, France was more highly populated than Japan or the United States.

In 1945, France was in the forefront of demographic stagnation and aging, and in its secular decline in fertility a good century in advance (Figure 119–1). The death rate was higher than that of England. This was abnormal for adults, especially for males , and was due to two main causes: tuberculosis and alcoholism. Compared with other countries at the same level of socioeconomic development, food in France was satisfactory, but living accommodations were frankly insufficient and drinking was excessive. The number of insane people in asylums had risen due to alcohol dependence, and yet 2 years of restrictions on alcohol during the war sufficed to halve the number of confinements. The reduction in the numbers of internees in psychi-

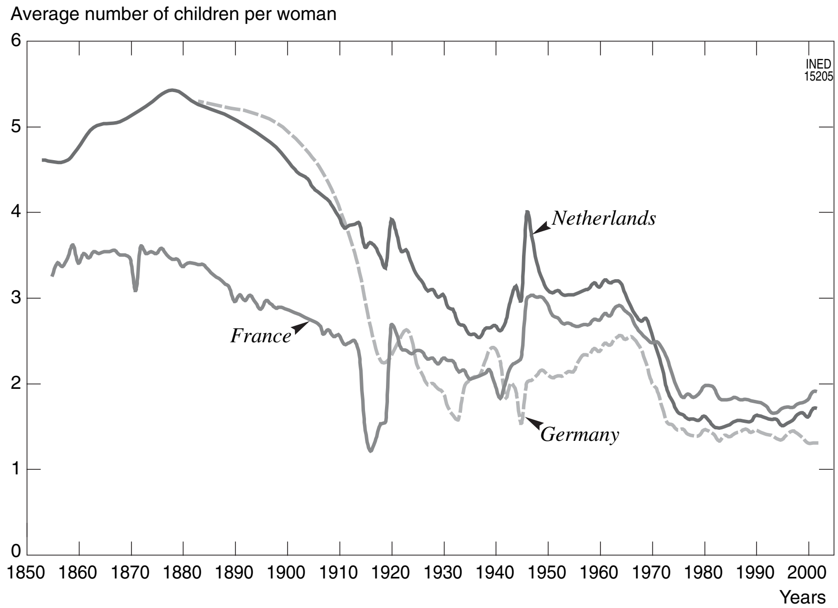

FIGURE 119–1 Total fertility rates in France, Germany, and the Netherlands, 1855–2002.

atric hospitals was not solely due, however, to the war restrictions. The policy of the Vichy government with regard to the insane also largely contributed to it (Meslé and Vallin, 1981). Although, as shown by the recent study by Isabelle Bueltzingsloewen, the charge of genocide is doubtlessly exaggerated (Guyotat, 2003), there was certainly, as written by Max Lafont (1987), a policy of "soft extermination." In Paris, where the alcohol restrictions were better observed than elsewhere, the decrease in the number of people confined to asylums was 90% (Sauvy, 1945).

TABLE 119–1 Birthrates in France and Germany (per 1,000 Inhabitants)

Period	France	Germany
1841–1850	27.4	36.1
1851–1860	26.3	35.3
1861–1870	26.3	37.2
1871–1880	25.4	39.1
1881–1890	23.9	36.8
1891–1900	22.2	36.1

a. The German Eruption

The contrast between France and Germany, and the known military consequences, are clearly visible in the birthrates of the two countries during the period 1841–1900 (Table 119–1).

Already weak during the 1840s, the French birthrate continued to fall until the end of the century (–20%), moving toward a previously never observed value of 20. It was quite the reverse in Germany where the birthrate was maintained at a clearly higher level to the order of 35 to 40 per thousand. This difference was for a long time to be an influence in the power struggle. The German age structure still remained young for many decades, and only fell after 1900. This fall was drastic, however, and the total fertility rate decreased by two-thirds in 33 years, passing from an average of 5 children per woman in 1900 to 1.6 in 1933. But in 1913, disequilibria in the mobilizable forces (to the order of 2 to 1) was such that the National Assembly had to lengthen the period of military service.

b. The English Takeoff

In pre-revolutionary France, fertility was hesitant and relatively high, with on average more than five children per woman. The revolutionary period and the first half of the 19th century (1790–1850) marked a profound change, in that the total fertility rate fell from 5 to 3.5, and the change in fertility was therefore halfway between the pretransitional and the cohort replacement levels. The epoch of the Second Empire (industrialization and the birth of modern capitalism) was characterized by a halt in the fall, and even a slight rise. The decline resumed at the end of the 19th century to the point where the total fertility rate became less than an average of 3 children per woman—a level without parallel (and at a time it should be recalled when fer-

TABLE 119–2 Total Fertility Rates (Average Number of Children per Woman) in France and England, 1760–1900

Period	France	England	Difference	Period	France	England	Difference
1760–1769	5.21	4.88	+0.33	1830–1839	3.76	5.25	–1.49
1770–1779	5.06	5.21	–0.15	1840–1849	3.57	5.00	–1.43
1780–1789	5.13	5.24	–0.11	1851–1860	3.43	4.97	–1.54
1790–1799	4.91	5.67	–0.76	1861–1870	3.50	5.22	–1.72
1800–1809	4.43	5.76	–1.33	1871–1880	3.43	4.91	–1.48
1810–1819	4.37	6.07	–1.70	1881–1890	3.25	4.35	–1.10
1820–1829	4.18	5.98	–1.80	1891–1900	2.93	3.76	–0.83

tility in Germany was still more than 5 children per woman).

English development was quite different. The earlier industrial revolution created thousands of jobs and people found employment at early ages. They were then able to get married more easily and earlier, and have larger families (Kindleberger, 1964; Deane and Cole, 1967). An extraordinary growth in fertility resulted, which attained its historical maximum toward 1820 with an average of 6 children per woman, whereas the long-term tendency before the industrial revolution had only been between 4 and 4.5 (see also Chapter 68).

Table 119–2 compares the course of total fertility rates (the average number of children per woman) in France and England, in 10-year periods between 1760 and 1900.

The effect of this long swell in English fertility was impressive, accounting for a fivefold increase in the English population between 1750 and 1900, and for the massive emigration and supremacy of the English language, especially in the new worlds growing in population. At the end of the 19th century, 440 million people altogether, that is, almost one-third of the world's population, had English as their official language. For 80 years (1800–1880), as is shown in Table 119–2, the difference in fertility to the advantage of England relative to France was of the average order of 1.5 to 1.8 children per woman. It was the combination of an exceptionally high English fertility rate (5 to 6 children per woman) and an abnormally low French fertility rate that produced the contrast in their destinies—rise of the Anglo-Saxon world and rapid relative decline of France and its language (see also Chapter 4, Volume I for a comparative analysis of the evolution of the French and English population pyramids). Because England, having turned exclusively toward the high seas, no longer had any continental ambition in Europe, its demographic domination had only indirect and negligible implications for the continent. But the repercussions of this excess fertility soon became universal, above all thanks to the supremacy of the United States.

2. Birth of a Consensus

The situation was quite different in Germany, the military rival with continental ambitions, where nationalism had become virulent and where, according to the geopoliticians such as Friedrich Ratzel and especially Karl Haushofer[1], there had to be a conquest of the living space (*Lebensraum*) that the German people required. This was to be at the expense of Denmark, and later of France, with the loss of Alsace-Lorraine at the close of the Franco-Prussian war of 1870. In his desire to build a "thousand-year Reich," Adolf Hitler was to carry the application of this doctrine to its final conclusion, when in 1942–1943, his troops occupied almost all of Europe. In only 70 years, the French territory was invaded on three occasions: 1870–1871, 1914–1918, and 1940–1945. Long accustomed to dominating the European continent, France was living with the nostalgia of its super power. From then on, France was weakened (in the 1930s, France was at the forefront of demographic stagnation and aging), and had lost confidence. Meanwhile, in 1940 France did not rearm and refused to fight—it was the "phony war." During the years of occupation France was to favor collaboration with Germany rather than with the Resistance.

But the Anglo-Saxon allies and the "resistants" were able to galvanize the awareness of national unity and to create the feeling of a victory and of entry into a new era. It was essentially during the period at the end of the war that a whole series of institutions such as Social Security and the *Commissariat Général au Plan* (National Planning Body) came into being. A contem-

[1] Heir to this tradition, general and professor of geopolitics in Munich, Karl Haushofer initiated the journal *Zeitschrift für Geopolitik* in 1924. One of his leading ideas was to move borders (by war). He was to be an adviser to Adolf Hitler.

porary or retrospective consensus existed among the ruling elite, between such different individuals as Philippe Pétain, Charles de Gaulle, and François Mitterrand, which held that the defeat and occupation were linked to demographic weakness, and that national reconstruction had to come about through a revival of fertility. In the polls subsequent to the war, public opinion was unanimous in attributing the recovery of fertility to the payment of family allowances, and it is true that at that time they constituted a novelty and their relative amount was high.

The shock of the defeat in 1940 was present in all minds. Henceforth, the linkage to demographic anemia, stressed by the military general staff, was recognized by all classes of the population.

The first indicator of the actual demographic state of the country came with the unexpected defeat by Prussia in 1870. This reverse (that followed the Prussian victory against the Austro-Hungarian Empire at Sadowa in 1866) was seen as a humiliation. One of the reasons put forward by contemporaries—apart from the deficiencies in training of the French troops—was mainly the greater numerical superiority of the enemy.

This type of analysis was then shared abroad, both by English specialists and their German counterparts; demographic differences were everywhere perceived as the main factor in changing the military equation. Population development was primarily viewed according to its external implications, in terms of shifting strategic equilibria. From this point of view, France was described as the seriously sick man (or woman) of Europe.

Nevertheless, right up to the German occupation, save for certain restricted circles, there were relatively few among the civil population who were aware of the real factors in the relative decline of the country. An association, however, was to play a leading role in the evolution of minds: the *Alliance nationale pour l'accroissement de la population française* (National Alliance for the Growth of the French Population). Founded in 1896 on the initiative of Jacques Bertillon, doctor and statistician, its aim was to alert the population and the public authorities to the risks that "depopulation" involved for French society. Its most celebrated recruit was the writer Émile Zola (1899) who, at the time when the Dreyfus affair was in full swing, wrote the famous novel *Fécondité* (*Fertility*), in which he vaunted the delights of family life. (During the Dreyfus affair, Émile Zola introduced a manifesto in the *L'Aurore* newspaper titled "J'accuse"[(I accuse], undertaking the defense of Captain Dreyfus the condemned person, a Jewish army officer accused in 1894 of having delivered some military documents to foreigners. Dreyfus was stripped of his rank and sentenced to transportation, but was in fact a victim of intrigue. His belated rehabilitation, after some 15 years of violent controversy concerning the Jewish question, generated a state of deep division.) Supporters of a pronatalist policy included influential Ministers, such as Adolphe Landry, author of *La Révolution démographique* (1934) and Paul Reynaud, inspirer of the CDF (*Code de la famille* [statutory family law] of July 29, 1939). The CDF, which is seen as the originator of the new fertility policy, laid the foundations for a coherent and pronatalist family legislation.

But in 1940, it was too late. Aware of their weakness and traumatized by the blood bath of 1914–1918 (almost every family had lost a relative), the French people and its leaders were in fear of a well-trained and fanatic Germany. This was the "phony war." Invaded and occupied, France was subjugated, stripped, and robbed of its freedom. Yet 20 years or so earlier, Georges Clémenceau had already issued a warning by declaring that the first of the clauses that should have figured in the *Treaty of Versailles*, was the "need to have more children." Otherwise, whatever the clauses in the Treaty, "France will have lost, since there will no longer be any French people" (Ceccaldi, 1957).

The best expression of national consensus occurred in late 1945, when the dependants' allowance, the taxation principle based on ability to pay and faithful to Article 13 of the *Declaration of the Rights of Man and of the Citizen*,[2] was adopted unanimously by Parliament. Despite some misunderstandings, this taxation device marrying concern for vertical equity (progressive tax rates according to income level) with concern for horizontal equity (taking into consideration the number of children in the household) has been maintained up to present times. This taxation principle is called "quotient familial" (family splitting); it has a moderating influence on the rate of contribution for families with dependent children; it arose from the demands of the Revolution.

3. Reason of State, Social Motivations, and Individualistic Ideals

The population policy adopted in the developed countries of Europe from the 1930s onward has for long been confused with that of the dictators of the extreme right: Nazi (Hitler) and fascist (Mussolini and Franco). Often tainted with racism (especially in

[2] Article 13 of the *Declaration of the Rights of Man and of the Citizen* (1789) stipulates, "The maintenance of the police force and administration expenses require public contributions. These contributions are to be borne by the citizens equally according to their 'contributive capacity' " (combination of income and household size).

Germany), this policy carried out a veritable policing of bodies and considered the individual as being an instrument to serve the requirements of the State (the "thousand-year Aryan Reich" of Adolf Hitler, the reconstruction of the Roman Empire by Benito Mussolini, the conscience control by allying Church and State under Franco). After the war, it was the dictatorships of the extreme left that were to follow, with the deplorable precedent set by Stalin in 1936 (brutal prohibition of abortion, legalized in 1920). The most tragic case was that of Romania under the iron rule of Ceaucescu (1966), where abortion—the main regulator of births—was suddenly prohibited, provoking a wave of births of unwanted, and frequently abandoned, children. There, yet again, the aim was that of power and completely unrealistic. The dictator wanted a population of 30 million people by the year 2000; the figure actually achieved was 22 million.

There is a tendency, nevertheless, to forget that present-day family policies were initiated by the pluralist democracies from the 1930s onward, as a response to fertility deficiency. Thus, the *Beveridge Report* (Beveridge, 1943) in England, although primarily concerned with the struggle against poverty and unemployment, eventually reached conclusions similar to those of Adolphe Landry (1934) in France: that since family size, alongside unemployment, is the greatest generator of inequalities, it is necessary, in order to overcome the dangers of depopulation, to introduce a system that compensates for dependants.

It was, however, the work by Alva Myrdal, *Nation and Family* (1945), that formed the focal point in the reasoning of advanced urban societies. Alva Myrdal and Gunnar Myrdal (1934) raised the question of freedom of choice: to have children (monetary allowances, equipment) or not to have children (freedom of contraception and abortion); and pondered about the need to reconcile family and professional life. Alva Myrdal was to become Minister of Social Affairs and a Nobel Prize winner. Already, in 1934, she and her husband had considered the challenge to freedom within a democracy facing a demographic crisis (Myrdal and Myrdal, 1934), and more particularly within a social democracy.

Many ideas are common to England, France, and Sweden. The French policy, often considered exemplary for the degree of protection it ensures for mother and child, is not solely the outcome of demographic preoccupations (number, continuity of institutions, and reason of State). It is based primarily on social motivations, in particular the concern for equality that consists in guaranteeing a satisfactory level of well-being for all households, irrespective of size. It must be conceded, however, that the full exercise of freedom to choose the number of children is not independent of the conditions of daily life of the families (the cost of a child has become very high, and the contribution to this by public financing is only partial, thus causing budgetary problems for large families). Under these conditions, the two possibilities of choice are unequal—it is easier to defer the setting up of a family than to extend it.

Nevertheless, for some 50 years (discovery of the contraceptive pill, which only became legal in France with the *Neuwirth Law* of December 28, 1967, and abortion, which was only authorized in 1975 by the *Weil Law*), the family policy in France has complied with a new ethical principle that requires the exercise of a new freedom, quickly to become fundamental: that of having only the children you want and having them when you want them. It is probably because it associates some complex individualistic and sometimes contradictory ideals (such as the emancipation of women) with collective requirements for historical continuity and social solidarity that this policy has successfully resisted the hazards of political life and found itself consolidated under the Vichy regime, as well as under the presidencies of Charles de Gaulle and François Mitterrand.

Thus, since the 1960s, a new dimension of individual freedom has gradually asserted itself: the freedom to control the number of one's children and their moment of arrival. This happening concerns the couple, and even more the woman, especially where she has the possibility of contraception, abortion, or sterilization. The right of a woman to prevent pregnancy has materialized with the perfection of safe antinatal techniques that operate durably, if not permanently. Thanks to this medical progress, women have seen a thousand-year dream become reality—that of having access to sex that is free from the fear of an unwanted pregnancy. Sexual pleasure has become an explicit component of individual happiness; it has opened the way to hedonism. The contraceptive revolution has ultimately been the matrix of the sexual revolution.

4. The Important Dates

The first conspicuous measure aimed at encouraging fertility was one that favored the families of public servants, SFT (*Supplément Familial de Traitement* [Family Supplementary Income]), adopted during World War I. Up until that time, there had only been selective and local measures linked to the private initiative of company directors, but these varied considerably from one branch or province to another.

a. 1920: Repressive Law against Contraception and Abortion

At the close of the war and in spite of the reduction in population, State intervention only expressed itself by adopting repressive legislation.

The intention was to remedy the hemorrhage of the war years, when almost 1.5 million were killed, all about 20 years old (Huber, 1931; Vallin, 1973), and the number of men mobilized rose to 8 million, thus causing a serious shortage of births and having the cumulative effect of provoking an increased aging of the population. But the law of July 31, 1920, which suppressed incitement to abortion and forbade antinatalist propaganda and the distribution of contraceptives, was without appreciable effect on the birth curve. This, following a short recovery in 1920 and 1921 linked to the regrouping of families, resumed its downward slope, and from 1926–1928 the total fertility rate was appreciably lower than its pre-war level (an average of 2.3 per woman, instead of 2.5 as in 1910–1913). Abortion had already been assimilated to a crime since 1791 and forbidden by the penal code since 1808. The 1920 law did no more than reiterate and confirm these penal provisions. It was to be reinforced in 1923 by the so-called *Barthou Law* of March 23, which sent cases of abortion before a court of summary jurisdiction, in order to avoid the habitual indulgence of assize court juries. What had previously been a crime became an offense, but the number of adjudged cases doubled.

The failure of the 1920 law (whose objective had been to check the decline in fertility) could be understood in the following way: (1) the confidence of the population had not been restored, and remained in a state of shock; (2) French people have a secular know-how concerning the limitation of births, such as coitus interruptus, clandestine abortion, adoption of separate beds by couples, and condoms. (Bergues *et al*., 1960; Himes, 1963).

b. 1932: Extension of Family Allowances to Wage Earners in the Private Sector

In 1932, there was an important breakthrough in the initiative for social compensation for dependants. It was in that year that the State took over from the private initiative by making membership of family allowance funds for wage earners in industry and commerce compulsory for businesses. Family allowances came about mainly through an initiative by Christian employers. Observing the living conditions of their workers, they noted that those who were single lived comfortably, those who were married without children were uncomfortable, those with one child had some difficulty in living, and those with two children had to appeal for help (often in kind) from their parents who had remained in the countryside. As for families with three or more children, these sank into poverty, since the same wages had to provide for a growing number of mouths. From this arose the idea of paying a supplementary wage to compensate for the cumulative decline in living standards (Ceccaldi, 1957).

But such a measure incurred the risk of distorting competition. Employers paying family allowances then found themselves penalized by higher labor costs. Thus, the 1932 law made the compulsive power of the State available to progressive employers by enabling the contribution to dependants' compensation to be extended to all employers. It should be noted, however, that universal coverage was only attained after the war, with the extension of the system to farmers and independent workers. On the other hand, from then on family allowances could no longer be viewed as employer generosity, but as an absolute right for the wage earner and a legal addition to the salary. Frequently perceived, until then, as a paternalist measure, and also denounced as a method of preventing wage rises, they saw their image transformed and soon to figure (retrospectively) under the headings of social progress and legitimate claims of the working class. In 1936, family allowance benefits were extended to agricultural wage earners. At the end of 1938, more than 90% of the families from the business, industrial, and liberal professions envisaged by the law were effectively receiving family allowances. As for those in the public sector, they continued to benefit from a special indemnity regime for dependants that was more favorable than the general regime of family allowances.

Large families, who most frequently lived in poverty or even destitution, were those, however, who ensured the major responsibility for the reproduction of the society (Vincent, 1946).

The above-mentioned proposals, intended to improve the lot of families with children, were insufficient to prevent the fall in fertility during the Great Depression; at most they were able to limit its extent. The scales of family allowances at that time still varied considerably from one fund to another, but the amount paid out remained small and without a common measure of the needs arising from the dependants. At the end of the 1930s, deaths again exceeded births, and in 1938 the deficit reached 35,000.

c. 1938–1945: The Turning Point (Statutory Order of November 12, 1938, Adoption of the Code de la Famille [Family Law], Improvement in the Family Allowance Scales, Inception of the Social Security Plan)

It was in 1938 precisely, on the eve of the new invasion, that everybody felt that positive (incitement) measures of considerable extent should be taken to counter depopulation. The statutory order of November 12, 1938 included, within a succession of statutory orders, some provisions relative to the compensation for dependent children. Prepared by Alfred Sauvy, then a member of Paul Reynaud's (Minister of Finance) cabinet, it was this order that gave the benefits paid up to then the true nature of family allowances and conferred on them a daring demographic character. The benefits could no longer be identified as a supplementary wage allied to the trade carried on and the uncertainties of wage negotiations. They became independent of the salary and of the company. Their amount, on the other hand, varied according to the ranking among the siblings (it was progressive in order to take account of the additive nature of the upkeep costs of children). Paid monthly, their rate was fixed according to the average salary of the legislative department. It was established at 5% of this salary for the first child, 10% for the second, and 15% for each of the following dependent children, with a guarantee of annual revision (updating), according to the change in wages noted in the interval.

At the same time as it achieved an important uniformity of the rates, the 1938 reform immediately caused a substantial increase, in the order of 50%, in the amount of benefits paid out. It envisaged, moreover, an increase to compensate for the loss of salary suffered by the mother in giving up a professional activity in order to devote herself to her family (this was the future Single Salary Allowance, adopted in 1941). This increase corresponded to 2% of the total payroll and increased the overall cost of this reform by 3% or 4% of it. In 2 years, between the beginning of 1937 and the beginning of 1939, family allowances increased two or three times more than they had done over the preceding 20 years.

By the end of 1938, the broad outlines of the CDF, which marked another major innovation, had already been drawn. This statutory law was the work of the HCP (*Haut comité de la population* [High Committee of the Population], where Adolphe Landry was based), created some months earlier. It was adopted by a Chamber stemming from the Popular Front. The text of the law sought to discourage voluntary infertility—frequent in France in the period 1890–1939—and to encourage more particularly those families whose composition would contribute to an increase in population, that is, families with at least three children (Sauvy, 1954). In practice, however, the rate of family allowances was scarcely restructured except for very large families (for families with three children, the rate remained unchanged at 30% of the reference salary). For the family with two dependant children, the rate was revised downward (10% instead of 15%), and the allowance for one child was abolished. It was replaced by a high birth premium designed to encourage newlyweds to have their first child quickly. In 1941, under the Vichy government, the allowance for the mother in the home was increased by the single salary allowance, which quickly occupied a dominant position in the system for mitigating the cost of dependants—since 1943, indeed, the payment of this allowance has accounted for more than one-half of the total allowances paid out. It is appropriate to resituate the context of the period, at a time when most of the mothers did not have salaried employment and devoted themselves to raising their children. The payment of the single salary allowance came about after marriage.

5. Priority of the Child and Peak of Family Policy

The war crystallized demographic awareness at the same time as it gave rise to a new, less individualistic and calculating state of mind. After the poverty, trials, privations, and food rationing, the merits of solidarity were recognized by all as being evident. The family was in fashion, and it increasingly personified the symbol of happiness—the privileged place for personal development. Against a background of destruction and ruins, history was being refashioned. It was the atmosphere of reconstruction, the pioneer spirit.

With the 1945–1946 decrees, family allowances became part of the general system of Social Security managed by Pierre Laroque, himself a former member of the Adolphe Landry cabinet. The principle of compensation for dependants was established:"Family allowance is justified for the same reason as retirement; it represents in short a salary advance that society grants to the apprentice, who will in turn repay it" (Sauvy, 1954).

Sickness and maternity insurance was also set up, and development of family policy continued with an improvement in the contributions and alignment of rates in the provinces with those of the capital.

But the contribution rates deducted from the salary (subject to a ceiling) for the benefit of the family branch increased from 5% in 1938 to 12%–13% in 1947–1948, and was soon to culminate in the 1950s at around 16%–17%. The 1947 *Charte des prestations familiales* (Law on Family Benefits), which envisaged an indexation of productivity increases, was not applied. The amount of the family allowances was to follow the simple progress of the consumer price index, but the frequent delays in so doing were to account for the enormous gap that arose in the course of the decades between the volume of benefits contributed to young parents by the family branch and the amount of retirement and sickness insurance expenditures.

6. Implications

The real recovery in fertility did not begin (as is frequently written) in 1942—it was then only the matter of a minor change (+10%), linked partly to the movement of returning prisoners—but rather took place at the end of the conflict (+30%), after the return of the soldiers and the sudden increase in the rate of family benefits.[3] This baby boom was not limited to France, but affected all of the countries of the Western allies. It was not experienced, however, in Germany, Italy, or Spain, or in the countries of Central and Eastern Europe that had fallen under the Soviet yoke. This baby boom, however, had certain features that were peculiar to France.

1. The recovery there of the post-war years was more sudden and powerful than in the homologous countries. The relative position of France in the international natality hierarchy between the pre- and post-war periods was inverted. From 1945 to 2002, the average rate of growth of the French population was higher than that of Germany, Italy, and the United Kingdom.
2. The demographic characteristics of the baby boom corresponded to the raising of the family allowance rate. Actually, it was with the emphasis on the second child that the expenditure effort was by far the most marked (sixfold). With two dependent children, a family received almost the equivalent of a second wage (in the aftermath of the war, three-quarters of the mothers with two children remained in the home and received a single salary allowance). This change in the rate created a very strong incentive to abandon the family model so widespread in the pre-war France, that is, that of the single child. It was in agreement, moreover, with the wishes of the legislator. There was thus a concordance between the variations in the legislation scale (differential incitements) and the increase in fertility following the pre- and post-war birthrates—couples without children or with a single child became rarer, to the advantage of limited or average families (those with two children especially, and a few with three), who were the main beneficiaries of the single salary allowance).

   It is also appropriate to bear in mind that, at that time, the payment of monetary benefits was a complete innovation in a country that was coming out of a barter economy.
3. The revival assumed greater importance than elsewhere because it generated 28 cohorts (1946–1973) with numbers that were one-third higher than those of the previous cohorts. It was the weighting factor of these cohorts, moreover, that was to cushion the fall in the number of births from the 1980s onward, and it was this momentum that made it evident that the country would be immunized against a further fall in fertility.

   Under the influence of Georges Pompidou, family policy became of secondary importance. At the time when productivity took off (this was the heart of the "Trente Glorieuses" ["Glorious Thirty," i.e., the 30-year period from 1945 to 1975], according to the Jean Fourastié formula, 1979), financial transfers for the benefit of young parents scarcely followed prices (disindexing had in fact started before 1950, in violation of the CDF). Above all, there came about a distortion in family policy. Its essential purpose had been to correct horizontal inequalities of income, that is, between families whose only difference was the number of children, whereas there was a gradual increase in benefits conditional on resources that henceforth transformed horizontal transfers into vertical transfers, thus adopting the form of redistribution from rich to poor. The application of the same reasoning to sickness insurance or state pension schemes was to arouse fierce opposition, but properly speaking there was no existing family lobby, and even less for children. Owing to the increasing numbers of exclusion thresholds, family policy declined in importance (it is easy to lower inflation-adjusted ceilings) and especially in universality. It became opaque, incomprehensible,

[3] Many analysts, among them Gérard Calot (see his Chapter 105 in this volume) date the recovery to 1942, but with 2.1 children per woman, fertility was then appreciably lower than what it had been in the previous period (on average 2.18 for 1927–1939). In 1946, on the other hand, there was a phenomenon without precedent since 1890–1893, when fertility reached 3 children per woman and maintained this for the following four years (1947–1950) and subsequently remained above 2.5 until 1969.

> and remote from the initial concern about demographic equilibrium. Family policy therefore became an aid policy for specific groups—the attribution rates vary from one case to another, and the number of benefit categories in 2002 reached 26 or 28, instead of only 6 in 1946.

This decline in family policy is illustrated by the evolution of contribution rates (deducted from earnings) intended for family allowances. First of all there was an increase, especially during the wartime, expressed by a rise of more than double (5% in 1938, 12% in 1947), followed by a new increase (16.75% in 1951–1958). The following period has been one of decline, as the rate has now returned to 8%, its level during the war.

7. Financial Drift of Social Regimes in the European Union

What happened in France has often taken place in an even more marked fashion among other European Union (EU) countries. Controlling social services (retirement, health) is an old sea serpent. The fall in fertility and disappearance of large families enabled substantial economies to be made with reference to the family sector, and was therefore redeployed in disguised intergenerational transfers from the rising generations (children) to the retiring generations of aged people. This applies to all EU member States, whose budgetary preferences clearly favor the old rather than the young.

Although France has achieved highly effective results in the retirement area by combining the contradictory qualities of early retirement and generosity and universality of pensions (occupying 6th position among the 15 EU members in terms of average pension measured according to purchasing power), in 1999 the country devoted 13.4% of its gross national product (GNP) to the payment of retirement pensions. This is one of the highest values in the world, and actually exceeds that of Germany, and even of Sweden. Only Italy attains a higher level of expenditure, due to the exceptional frequency of very early retirement and the rates of salary replacement by the pensions.

If the benefits paid in the form of pensions and health care are added together, we now come to countries such as Sweden, Germany, Italy, or France, where it is nearly 25% of the GNP. Taking into consideration the inversion of the population pyramid, which is often only at a halfway point, the viability of such devices in the long term can be questioned, and the tax burden and increase in public debt are regularly invoked by international financial institutions for their effects in terms of the loss of competitiveness in highly aging populations.

There is a striking contrast in the expenses allocated to young parents and their children, for the observed maximum reaches only 3.8% and 3.5% of the GNP (Denmark and Sweden respectively). France, where child policy is reputedly pronatalist, no longer merits this qualifier (at least on the financial level), as it occupies a similar position to that of Germany (3%). But it is especially the position of countries most sparing in public expenses in favor of their children that merit the most attention. There are, in fact, two EU countries where the financial distribution in favor of children is less than 1% of the GNP: these are Spain and Italy, countries where the fascist dictatorships (Franco and Mussolini) had set up family allowances, but where these have suffered a continual monetary erosion to the point of becoming derisory and no longer of benefit to even the most humble households. It should be noted in passing that these countries are precisely those where fertility is lowest (Eurostat, 2002, 2003).

Even in France, it is a long time since family allowances occupied the forefront of social expenses. The negative correlation between the erosion of allowances and the decline in fertility is shown by the spectacular case of the Saar (French, then German) in the immediate post-war period.

8. Balance of Family Policy: Strong and Weak Points

a. Strong Points

France's fertility policy has the unique advantage (that it shares only with Belgium) of pre-elementary schooling that is both public and early: from the age of 2 years, almost 50% of French children are already attending nursery school. At the following ages (3, 4, and 5 years), all children are enrolled. The generalization and nonpayment for nursery schooling are the envy of neighboring countries, where parents have to undertake the care of their children up to the age of 5, 6, or even 7 years. From the age of 2–3 years, the network of nursery schools is well thought out and available to the greatest number of children. It fulfils the needs of both parents and children and is a powerful socializing instrument.

It only remains to close the gap between the end of maternity leave and entry into the nursery school, which involves the need for the development of solutions, such as recourse to maternal assistants, parental leave, or day-care centers.

Another original French feature is the system of direct taxation, which is, in fact, a moderator of progression adjusted according to the number of dependent children. The system was set up at the time of the Liberation, following centuries of debate. It is based on an idea of fiscal justice. Instead of applying the taxation rate to the income itself, but by income share, taxation is applied to the living standard of the household. This idea of family support, which is nowadays sometimes incorrectly interpreted and considered to originate from the right, dates back in fact to the period of Enlightenment in the 18th century. It fulfills a republican and revolutionary ideal inscribed in the *Declaration of the Rights of Man and of the Citizen*. Whenever taxation is evoked in this fundamental text, there is mention of the need to take into account the contributive ability of the person paying (i.e., the number of dependants).

b. Weak Points

Since the accumulation of benefits conditional on resources (late 1960s), an increasing number of beneficiaries have been excluded from benefits under family policy, thus marginalizing it. The family policy was clearly of high priority in 1946 (concern was for national reconstruction based on the revival of fertility) with more than 40% of the national social budget (instead of hardly 10% at present). Even more symptomatic is its wretched aspect, which has appeared and grown over recent decades. It is the Family Allowance Funds that manage the allowances for adult handicapped persons, and above all carry out the payment of the RMI (*Revenu minimum d'insertion* [income support: unemployment pay]). Children are thus relegated to the same ranking as the poor, infirm, and unemployed. Here, there is clearly a diversion of aim. Just as the policy of sickness insurance aims to ensure a financial transfer between the healthy and the sick, and the retirement policy to pay replacement incomes from the present active population to the former active members, the function of the family policy is to ensure compensation between small families and those without children and those of greater size. But this principle has often been ignored to the benefit of a more visible and political consideration, such as the struggle against poverty, which itself entails employing fiscal means.

The underindexing of family allowances also goes a long way to explaining the fall in the share of benefits within the GNP. It has enabled the appearance of the famous CNAF (*Caisse nationale des allocations familiales* [National Agency for Family Benefits]) surpluses, which, regardless of the principle of separating various branches of social protection from the budget, have regularly been employed to make good (without repayment) the deficits from other sectors. Families with dependent children have found themselves impoverished through this, and all the more seriously as the number of their children is greater.

Although other countries also have child support mechanisms in mind, it does nevertheless appear that in France the strong points appreciably outweigh the weak. The family policy, however, still presents many shortcomings. The most serious concern early childhood and post-adolescence (children around 18–20 years-of-age enter a period of maximum cost, whereas the family allowances cease all payment).

II. PUBLIC HEALTH POLICY

Defining the role of health policy in lowering mortality requires much greater subtlety, for the determinants of the main causes of death are multiple and intertwined.

1. Initial Delay

Toward 1930, life expectancy in France was 10 years lower than in the Netherlands (54 and 64 years, respectively), and France occupied the place in Western Europe, with a net disadvantage for men.

But after having long occupied a mediocre ranking in terms of the struggle against death, France now finds itself well placed among the advanced countries. Although the leading position has been occupied by Japan since the 1970s (a model of individual and collective providence), the second place is held, almost equally, by the large countries of Western Europe (France, Germany, Italy, Spain, and the United Kingdom) (Figure 119–2). The convergence of the health performances contrasts with the differences in fertility. Thus, toward the year 2000, Spain and Italy presented total stabilized fertility rates to the order of 1.1 to 1.2 children per woman; Germany around 1.3; the United Kingdom, in slight regression, around 1.6–1.7: and lastly France around 1.8–1.9. These relative divergences in fertility are important and may be due to differences in collective psychology, early childhood institutions, territorial and national policies (explicit or not), and fertility support. Progress concerning the struggle against death form a consensus and may be related to the general socioeconomic level of development and to technical means (vaccines, medicaments, equipment, etc.), which are more easily transferable from one country to another. This development is the result of voluntarist actions carried out

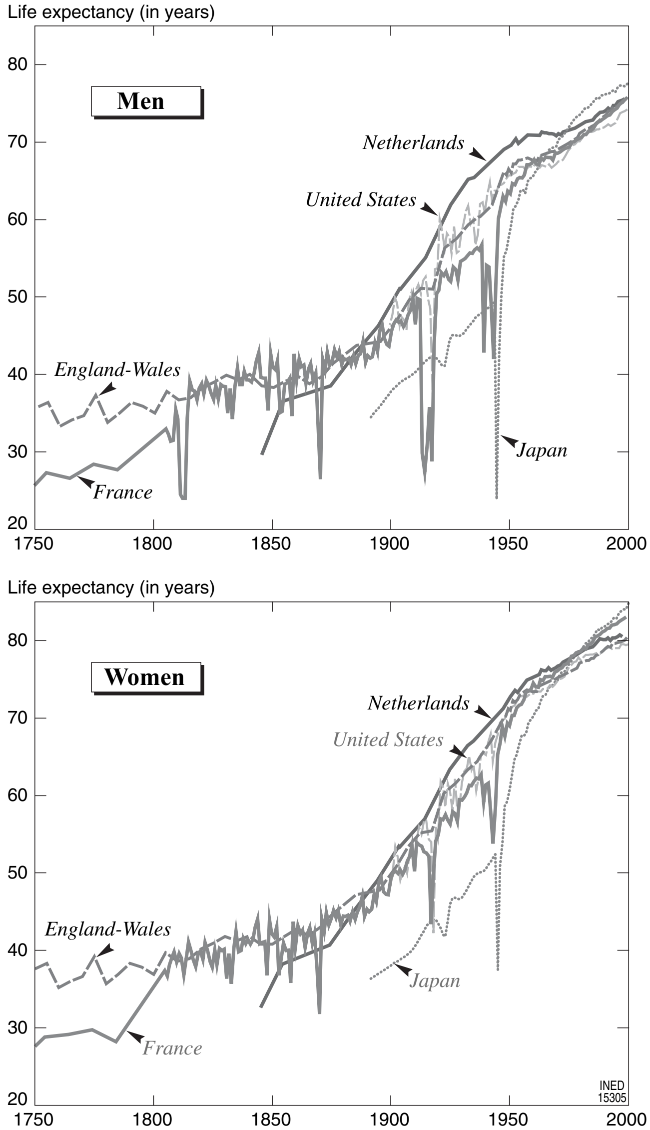

FIGURE 119–2 Trends in life expectancy at birth in France and in other selected industrial countries, since 1800. (Sources: Vallin and Meslé, 2001, 2004.)

by public authorities. In the first place, there was the effort to eliminate tuberculosis, which was strengthened by the extraordinary revival (construction and renovation) of the housing policy in the 1950s.

Although alcoholism, the traditional scourge of France, has reduced under the IVth Republic phase of society modernization and urbanization, the success has been relative. Admittedly, the number of deaths from this cause has fallen since the 1940s due to prevention, but excess mortality allied to alcoholic poisoning among men sets France apart from other EU countries and even the OECD (Organization for Economic Cooperation and Development). Alcohol consumption has certainly diminished among the young generations, but the struggle against alcoholism remains insufficient in relation to that prevailing in the northern countries.

2. A Prevention Model: Road Accidents

Road deaths increased up until the first oil crisis, placing France in the worst international rank category. Annual deaths rose from 3,354 in 1950 to 16,617 in 1972, not because roads were becoming more dangerous (the number killed per kilometer traveled was, on the contrary, already greatly decreasing[4]) but because the expansion of motor vehicle traffic had been very rapid. Arising from ecological awareness, it was at this time in the seventies that thought was given to the cost and advantages of choosing the motorcar. The oil crisis had had a major psychological effect on the way the automobile was viewed in relation to collective transport or the bicycle. A discussion arose about the damage caused to the urban atmosphere, to congestion, environment, and road insecurity. In successive stages, the government adopted stern measures, such as mandating the wearing of a seat belt, limiting speeds, reducing and monitoring drinking and driving, technical checking of vehicles, and so forth. Above all, the public became aware of the annual toll of the roads, carrying off thousands of human lives in the prime of life, and even more slyly leaving tens of thousands of young people handicapped for life.

France formed a group apart, with an atypical road death rate double of that of England, for example (or of Japan). Over recent years, the scourge has been designated by the name "road rage," and has become the object of priority action by the government. The results are impressive: death on the road is declining regularly. By 2002, road deaths were half as many as in 1973 in absolute figures, and the rate reduction was even more marked, for the population had in the meantime increased. Sanctions are becoming ever more severe against reckless or drunk drivers, and these people are now brought before the courts and frequently awarded severe terms of compulsory imprisonment.

The same cannot be said for death from cancer, which continues to worsen (about 150,000 deaths per year, or 28% of the total mortality). It is highly resistant, doubtlessly linked in part to the aging of the population and also to the delay in prevention. It is in France that the frequency of deaths from cancer is highest, due especially to the importance of lung cancer among both women and men (more women

[4] In fact, the number killed per 100 million passengers/km fell from 10.9 in 1953 to 5.4 in 1968, and to 3.5 in 1976 (Vallin and Chesnais, 1975; Chesnais and Vallin, 1977).

smoke than men, especially at young ages). Nevertheless, the decline in deaths from lung cancer among men has started.

3. Resistance to Alcohol and Nicotine Addiction

The *Évin Law of* January 10, 1991 marked a first in the struggle against nicotine addiction. Although the law aims to combat alcohol and nicotine addiction, public opinion has only remembered the basically more innovative effort to fight against nicotine. It involves the prohibition of smoking in public places (except those specially reserved for it), in order to protect both smokers and non-smokers from inhaling toxic substances. France is thus in line with the Anglo-Saxon countries (United States and England), which were the first to undertake a firm and effective struggle against the ravages of tobacco. The results are still inadequate.

4. Records of Infant Mortality

Through the total number of institutional and socioeconomic factors that it depends on, infant mortality is one of the most robust indicators of development. It is no surprise that Japan heads the world classification, followed quite closely by the advanced Western countries such as Germany, Italy, France and the United Kingdom, which present fairly similar values. The setting up of maternal and infant protection (post-war), followed by the program for preventing prenatal mortality (1970s), comprising regular monitoring of the pregnancy and of the infant's development, and lastly the systematic application of vaccinations have had the effect of provoking a spectacular fall in infant mortality and eliminating the French lag. Between 1930 and 1932, the French infant mortality rate reached 77 deaths per 1,000 live births, thus largely exceeding that of Norway (46), the Netherlands (48), Switzerland (50), Sweden (54), and England (64), among others. Between 2000 and 2002, with a rate close to 4 deaths per 1,000 births, France had, for some 20 years, descended beneath the 10 per thousand floor, long considered to be impassable. It has become one of the front-runners among the countries with the best health record (Figure 119–3).

Premature death has fallen, but not only just before the age of 1 year; death before 5 years has in fact almost disappeared, and reference is now increasingly made to death before 60 years. For the newborn, this is increasingly due to technical progress (especially in the area of neonatology) and to prevention (medicalization of childbirth, generalization of prenatal medical visits, struggle against prematurity, echography, electronic monitoring of childbirths, etc.).

Although clearly declining in the long term, however, the regional disparities are far from disappearing. This indicates that differences in mortality are rooted in lifestyles, eating habits, differences in industrial pollution, and in the consumption of alcohol and tobacco.

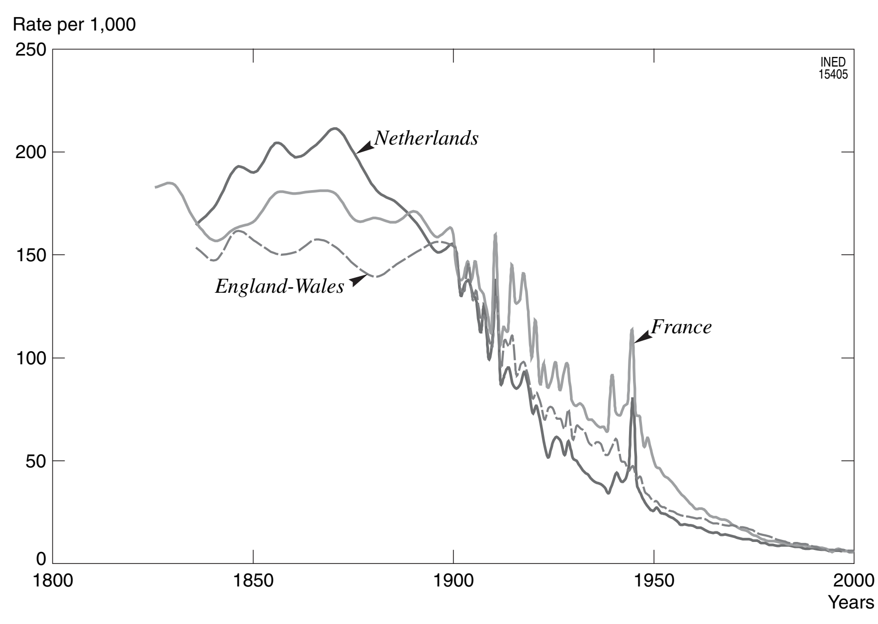

FIGURE 119–3 Trends in infant mortality rates in France, England-Wales, and the Netherlands, 1830–2000.

5. Disappearance of Infectious and Parasitic Diseases

The most striking feature of 20th-century mortality is the collapse of infectious and parasitic diseases (Vallin, 1988; Vallin and Meslé, 1988), and that henceforth it is the progress in chronic diseases (principally cardiovascular diseases, but also cancer) that dominates pathology (Meslé and Vallin, 1988). Following the law of October 30, 1935, the reporting of contagious diseases by families became obligatory in France (obligatory for doctors and midwives since the end of the 19th century). In a few years, between 1938 and 1950, the requirement for vaccination was extended against diphtheria, tetanus, typhoid and paratyphoid, and tuberculosis (1950), and also in 1964 for poliomyelitis. This generalization of vaccinations was to cause a fall in infectious diseases. It should be borne in mind that in 1950, tuberculosis accounted for the deaths of 24,364 persons (i.e., 4.6% of total deaths).

6. A Constellation of Progress Factors

But among the factors in the victory over death (fully described in Section I of Volume II), it is important to recall here the progress in hygiene, disinfection, and asepsis; advances in surgery made during World War I; the birth of laboratories; the availability of drinking water and elimination of waste; the modernization of hospitals; perfection of effective medication; globalization of medical research; discovery of the first sulphamides in 1935 (providing treatment for those with bacterial, pulmonary, and digestive infections); and finally, the decline in a certain millennial fatalism with regard to disease and death (Biraben, 1988), and the post-war discovery of antibiotics that accelerated the eradication of infectious diseases.

A turning point appeared to have been reached, but it was only a stage. The advances against death by infectious diseases appeared to be partly nullified by the increase in the so-called diseases of civilization (transport accidents, pollution, drug abuse, alcoholism, tobacco addiction, etc.). Sometimes, this resistance was also imputed to the powerlessness of struggling against diseases due to the biological aging processes. Increase in the average length of life has therefore proceeded in stages that were sometimes rapid and sometimes slow, according to the advances in medicine.

7. Institution of Social Security (1945)

But the most fundamental factor in the French recovery took place without doubt in 1945 with the introduction of social security, which very soon facilitated access to medical coverage. Although the French post-war population growth exceeded that of neighboring countries, it was not solely due to an advantage in fertility but also to a more rapid mortality reduction than most of the European countries, especially among females. France made up its delay, and then even moved ahead. This fact is related to the extension of social security coverage (health and retirement), restricted until the 1930s to the limited category of salaried workers. Since 1970, the faster progress in the means and personnel of the health sector (induced by the soaring health insurance expenses) is probably the reason for the renewed fall in mortality. Similarly, the important decline in deaths among elderly people (60 years and over) during the same period is probably attributable to the intense effort in redeploying social finances in their favor (massive increase of the minimum old age pension, high adjustment of purchasing power relative to retirement pensions), added to strong income growth and improvement in living conditions. At the beginning of the 21st century, the female life expectancy at birth was 83 years, only 2 years from the world record of 85 years held by Japan. The male excess mortality, continually increasing since the 18th century, had begun to diminish—the average life expectancy of men exceeded 75 years.

It is indeed possible that due to a number of new factors (emergence of new diseases, increase in obesity, environmental neglect), we are moving toward a slowing down of the recent progress, obtained moreover at an ever higher cost (growing deficit of sickness insurance), but up to the present, the pessimistic forecasts have been denied by the facts.

Added to the economic anxieties concerning health are those relating to territory and to difficulties, in times of high unemployment, of integrating foreign populations. The latter largely condition migration policies both through national and regional development and through immigration policy.

III. NATIONAL AND REGIONAL DEVELOPMENT

1. National and Regional Development Policy

a. Paris, a "Primaspatial"[5] City

The Parisian agglomeration occupies a disproportionate place in relation to the other large French towns

[5] According to the expression used by Denise Pumain and Daniel Courgeau (1988).

in that its population has always remained six or seven times higher than the second city, Lyons or Marseilles according to the epoch.

France is a macrocephalic country, with a hypertrophic center, congested and with many aged provinces that are often suffering depopulation. Considerable disparities (demographic among others) characterize the national area and hence the necessity for national and regional development.

Already invoked after the post-war period by Jean-François Gravier in the founding work *Paris et le désert français* (*Paris and the French Desert*, 1947), the wish for decentralization in the service of national and regional development has been ignored since the 1970s (decline in planning and the DATAR[6]), but has now become a major preoccupation with a central ecological dimension—rural people are no longer considered simply as farmers, but henceforth as guardians of the environment. In addition, the principle of equality of access to the public services (post offices, schools, hospitals, and infrastructure), which was for a time called into question, has been preserved. Guidelines for action are regional balance, the creation of employment, and correct utilization of European structural funds.

The integration of Europe and its expansion toward central Europe have redrawn a vision that is directed eastward.

Despite a lower polarization of internal migrations, however, serious disequilibria remain to be reduced between the overpopulation of the Ile-de-France and the desertification of the disadvantaged rural zones: the differences in density and potential are extreme. Tourism and mobility (secondary residences) can only change these marginally, for in the end it is only the presence of employment that dictates the setting up of new households. Different formulae have been attempted, such as the creation of regional centers and establishment of new towns, a law on decentralization, and even the setting up of high-speed trains (TGV), but the Parisian region, situated at the heart of the country, continues to drain manpower and wealth. Lastly, as in the United States, in a context of deficit State expenditure, the question arises as to whether decentralization does not also pursue the aim of transferring expenditures to the regions and municipalities.

b. Space and Demographic Transition

The secular fall in fertility began in the countryside, thus accounting for the relatively low migration toward the cities and delay in urbanization. The long period of demographic atony contributed to the disequilibria between Paris and the provinces. This migratory movement took place to the detriment of the rest, and rural preponderance was also allied to the low agricultural productivity and the predominance of small concerns. On the eve of World War I, more than half the French population was still living in the country, in rural districts of less than 2000 inhabitants clustered around the chief town. It was not until 1982 that France became three-quarters urban, and it was only after World War II, with the end of the demographic freeze, that urbanization became explosive. The population abandoned its lethargic state of secular quasi-stagnation in order to grow until the 1970s at a rate of about 1% per annum, accompanied by a rapid industrialization of the economy and attraction of its labor force from the country districts.

The expansion of the urban system frequently took on two forms: the birth of new towns and the extension of the existing fabric (see Chapter 61). There was then periurbanization rather than disurbanization (Pumain and Courgeau, 1988). Many rural districts belonged to the ZPIU (Zones de peuplement industriel et urbain [Industrial and Urban Population Zones]). The secular reversal of the migration between country and towns succeeded in giving rise to talk about "the end of towns" (Chombart de Lauwe, 1982); the faltering of the industrialization and urbanization process at the end of the 1960s gave way to tertiarization during the 1970s. The industrial crisis then reached the North and East, creating gigantic zones of temporarily inactive industry and unemployment, and inducing the developers to act without delay by reconversion aid and the setting up of new businesses. A large number of départements (akin to counties) were continuing to lose population through net emigration, but the essentially industrial and urban areas (Paris basin, Mediterranean South, Lyons, and Marseilles) continued to grow.

Departures from or nonentry into the agricultural world, however, led to considerable migration to the towns, where the possibilities of industrial or tertiary employment were concentrated. Nevertheless, mobility away from the rural communities was largely intraregional: two-thirds of the migrants remained within the same region.

In the early 1980s, there was a reversal in the migratory current. Up until then, industrial and urban centralization functioned as a suction pump that emptied most of the peripheral regions of the country to the advantage of a small number of regions. In the 21st century, a movement in the opposite direction is taking place, where old industrial and urban regions are being emptied to the advantage of other regions, previously considered to be disadvantaged but

[6] Delegation à l'Aménagement du territoire et de l'action régionale (Agency for Land Planning and Regional Development).

better equipped for the implantation of services and for attracting the working population of the tertiary sector. England is still a more striking case, in that the industrial sector has almost disappeared, following privatizations that quickly led to delocalizations.

c. Centralizing Tradition

Its central position in the heart of the country gives Paris a natural geographical advantage. But this asset has been reinforced by some political choices according to a very ancient centralizing tradition. Since 1842, the choice of railway plan put Paris in the center of the network, thus favoring the administrative conception of a network radiating from a center in Paris. The servicing of the industrial regions was not considered to be a priority, and the command functions were therefore concentrated in Paris, which monopolized the centers of political, economic, and financial decisions, and even that of research (Figure 119–4). The power of Paris has, however, been gradually relativized by the reversal of the above-mentioned migratory flows, especially those between Paris and the provincial areas.

d. Some Success in National and Regional Development

The DATAR was created in 1963 by the interministerial structure allied to the planning entrusted to the *Commissariat général du plan* (General Planning Commission). It was provided with ample means and played, at least until the 1970s industrial crisis, an important voluntary role. It constituted an essential piloting instrument, which weakened with the mythical rallying call for the correction of regional inequalities. It succeeded, however, in opening up certain poor regions, with the 1968 *breton plan*, the Massif Central development program in 1975, and the restructuring of the urban web. Less successfully, it set up *métropoles d'équilibre* (regional centers) and important development schemes. Lastly, it created nine new towns: five in the Paris region and four in the provinces.

IV. IMMIGRATION POLICY

1. 1945: The Desire to Integrate Immigration into the Population Policy

In the aftermath of the war, the planners aimed to include immigration among the objectives for relaunching the population of the country. It was the time when Alfred Sauvy (1946) evaluated the immigration needs of France, but the avowed aims were never to be followed, for employers adopted various channels, legal or otherwise, and sometimes even went to recruit workers from abroad. In addition, the robustness of the baby boom lessened the preoccupation with population, creating, however, deficiencies of labor force in certain sectors.

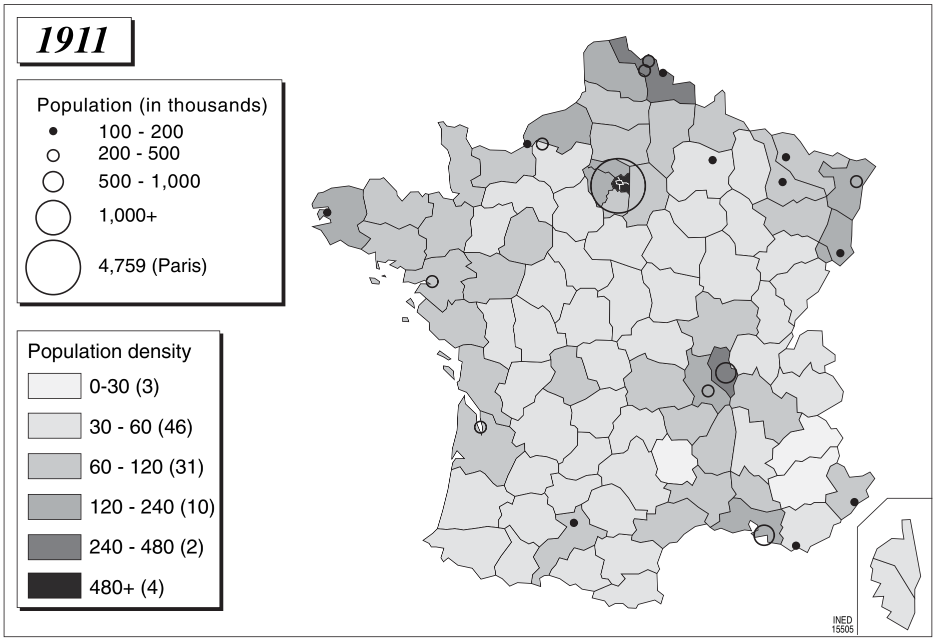
With the first oil crisis in 1973, the government altered its position and aligned itself with most of the European OECD members in closing the borders to the inflow of new workers, encouraging return, and integrating the numbers of the foreign population legally installed within the territory. It was the so-called policy of zero immigration. We now know that this policy failed everywhere (in Germany, Switzerland, France, etc.). By its very nature, foreign immigration is a life project that does not concern just a single individual, and the granting of a bonus is therefore without effect as an incentive to return. (Zero illegal immigration is mentioned later in the chapter.) There again, this is to disregard a powerful reality that imposes itself on all rulers: international disequilibria, political crises, massive poverty in the countries of the South, the role of families already in place on arrival, activities of smuggling rings, corruption around the borders (illicit payments, falsification of documents etc.), everything that combines to sustain migratory pressures.

In addition, from the internal point of view and despite the persistence of a high rate of unemployment, there were indeed important sectoral needs among the workforce (domestic services, construction, hospitals, and personal assistance, etc.). In France, as elsewhere, unemployment was no longer experienced as an indignity or social shame, and an increasing number of jobs were considered to be degrading by reason of what had to be endured (excessive working hours, low salary, dirty work).

This distortion, in fact, between rhetoric (cessation of immigration) and reality (sustaining entry flows) is at the origin of misunderstandings, and to a large extent doubtlessly of pressure from the extreme right.

2. Freedom of Movement (19th Century)

France is traditionally an immigration country. According to the 1851 census, there were already 379,000 foreigners (more than 1% of its total population). This is the threshold statistic of 1% that for European countries corresponds to the end of secular emigration and beginning of the contemporary era of immigration. Thus France had a good century of advance over its European partners with regard to immigration: Among its neighbors in Western Europe, this threshold was only crossed between the 1960s and



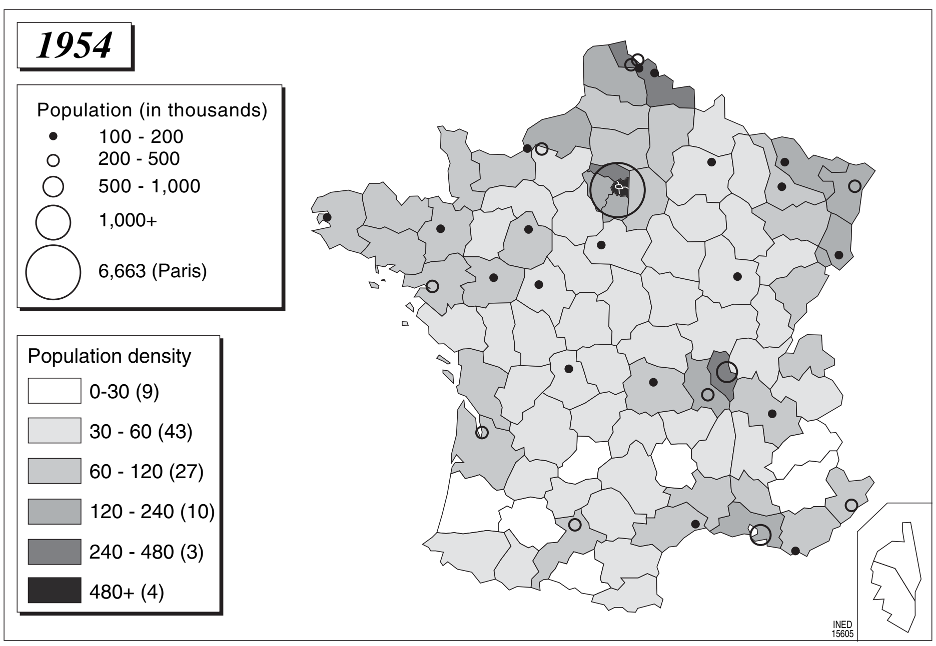


FIGURE 119–4 Population densities by département in 1876 and 1990, and population of the urban agglomerations of more than 50,000 inhabitants within the present French territorial limits. (Sources: Brunet and Aurillac, 1995; Noin and Chauviré, 2002, p. 447.)

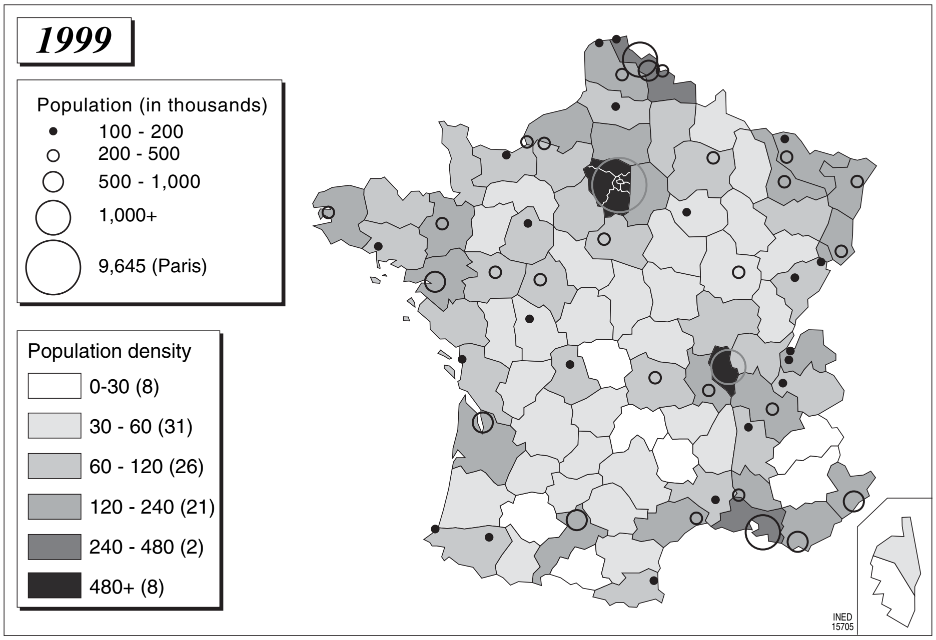

FIGURE 119–4 (*Continued*)

1980s. This fact is just a reflection of the century of advance in the secular decline of fertility, and the lack of fertility was not long in finding its expression in the sectoral shortages of the labor force.

Immigration into France was completely free until the end of the 19th century. The settlement of immigrants has subsequently been progressively controlled, and their employment was limited in 1932, following the economic crisis (discussed later).

From the mid-19th century, foreign immigration increased in importance. In the 1886 census there were more than 1 million foreigners (i.e., 3% of the population). The gross contribution of this immigration to population movement, even if limited solely to the migratory balance in the total population increase, was decisive. Thus, during the whole 1851–1896 period, the arrival of foreigners contributed to 35% of the total growth in the French population, and the direct contribution was even greater in a period of demographic stagnation (such as between 1881 and 1911) when foreign immigration then accounted for half the population growth.

The number of foreign nationals acquiring French citizenship served to mask the slowing down or even decline in the national population. The law of June 26, 1889 eased the acquisition of French nationality to the extent that, in spite of the inflow of immigrants, the number of foreigners remained stationary almost until 1911, thus largely compensating for the decline in French population.

3. Interwar Period: From the Peak of Immigration to Rejection

After the blood bath of World War I, France lacked a young labor force, and immigration increased to the extent of placing France in the front rank of immigration countries. It is also true that the United States had, by their restrictive laws in 1921 and 1924, dried up the flow to their country. In 10 years, despite the many naturalizations following the 1927 law on nationality, the number of foreign nationals in France increased by more than 1.2 million (in addition to Poles and Belgians, this wave included colonial workers), thus reaching the figure of 2.7 million in the 1931 census (i.e., 6.6% of the French population). If the population born outside France is considered (which excludes naturalized neo-French), the situation is even clearer. The number thus increased from 866,000 in 1891 to 2,942,000 in 1931—an increase of more than 2 million.

It is well-known that the Great Depression and unemployment led to xenophobic tensions, and the government decided to limit the employment of foreigners and encourage their return to their countries of origin; this affected arrivals. The law of August 10, 1931 aimed at protecting the national work force by a decree that fixed the proportion of foreign nationals having the right to employment. The war also stopped immigration and motivated return to such an extent that in 1946 the number of foreigners did not exceed 1.7 million, and was therefore below its 1931 peak.

All in all, the interwar epoch was most marked as a time of high immigration (1918–1931), allied to the replacement of those killed in combat. Between 1920 and 1939 the influx of foreigners accounted greatly for the growth in French population—a most important migratory contribution was added to natural growth.

4. Post-war: From Opening to Restriction

In the aftermath of World War II, the national leaders felt the necessity for massive foreign immigration in response to both demographic needs and reconstruction requirements. The legally regulated ordinance of November 2, 1945 laid down the conditions for entry and residence of foreigners in France. The award of a residence permit was subject to obtaining a work permit, and bilateral agreements were signed with the countries of origin. Family regrouping was seen as a demographic aim, and was encouraged. The new *Code de la nationalité* (Nationality Law), promulgated by the Ordinance of October 19, 1945, was relaxed for the youngest generations. The child became French if either of the parents were French or if it was born in France of foreign parents, and lastly the foreign bride of a Frenchman also became French (the reverse case was to be adopted in 1973).

Labor immigration became more frequent after 1955 and quickly found itself swollen by the return of repatriates from the former colonies (1.3 million as a whole, 710,000 in 1962 alone).

Three waves of permanent workers followed during 1955–1973 period: Italians, Spanish, and Portuguese. Their entry took place under the control of the ONI (*Office national d'immigration* [National Immigration Office]), since renamed OMI (*Office des migrations internationales* [International Immigration Office]). As for Algerian immigration (the oldest), this came about according to an evaluation by the Ministry of the Interior (*Direction des renseignements généraux* [Central Department for General Information]).

Similarly to the Great Depression of the 1930s, the oil crisis was to close down the entry of workers and encourage their return to their countries of origin. But the anticipated effects did not come about. There was a rise in family regroupings (from North Africa for the most part) and a development of requests for asylum and clandestine entries (and the precariousness with which they were associated).

TABLE 119–3 Absorption Indicator of Foreign Population

Country	Indicator
Australia	319
Canada	249
Switzerland	170
United States	138
Germany	119
Sweden	94
France	89

5. A Statistical Balance: France within the Main Currents of World Immigration, 1950–2000

In the absence of adequate statistics, especially on the population born abroad, one can assume as a first approximation that the difference between the total increase in population and the natural balance will measure the flow in migration that is applied to a sole national population. In accordance with this rule, the migratory balance of the main Western countries over the whole period of 1950–2000 can be evaluated. As total population is very different from one case to another (285 million in the United States, 7 million in Switzerland, e.g.), we have divided the volume of net immigration obtained by the corresponding population of each country in the middle of the period (1975).

The result provides an absorption indicator of the foreign population. Table 119–3 shows the indices obtained for the seven main Western immigration countries, per 1,000 inhabitants:

The gross data are thus relativized. Despite having a migratory balance of 30 million people, the United States is situated far behind Australia and Canada. As for France, it is in last position.

CONCLUSION

Comparisons within the EU (CEC, 1990; Testa, 2003) regarding the ideal family bring out the unique quality of the French situation. As everywhere else (except in the German-speaking countries in 2001), the family size preferred by young couples is two children, but the second choice is for three children, and this accounts for almost one-quarter of the answers, and is clearly more than in other countries. Doubtlessly, it is also appropriate to attribute the lesser fertility deficit in France to this attitude. For some 30 years, fertility has, according to the situation, been from 10% to 20% below the cohort replacement threshold. A recentering of family policy in favor of the third child could therefore be envisaged, and all the more so since the demographic effectiveness of public transfers to families has proved its effectiveness on the European scale (Chesnais, 1982).

The room for maneuver of the public authorities with regard to population has been largely underestimated. This also applies to fertility, mortality, and international migration. Although very probable, the European population implosion is not entirely inevitable.

Every population wishes to ensure its own replacement (United Nations, 1999). There is nothing to be ashamed of in this objective, and it is even praiseworthy in the name of social equilibrium and biodiversity. In France, it has been regularly repeated by the Supervisory Ministers in prefaces of the reports from the Institut national d'études démographiques (INED) (National Institute of Demographic Studies) to Parliament. It is, moreover, by no means beyond the reach of countries that devote adequate means for preserving the relative position of young couples and their children in society.

As for immigration, it is not only inescapable but also necessary (IFRI, 2003). Where, however, fertility has not collapsed, the gaps to be filled will be minimal and more easily managed. France has a century and a half of, often tentative, immigration policy behind it and two-thirds of a century of political support for fertility (admittedly declining). Public opinion is receptive to population concerns, and a return to cohort replacement is not impossible if unemployment among young people falls and if the government slackens the pressure on pension expenditures and redeploys it to the young people. This time, France could avoid the pitfall of depopulation, which henceforth threatens, often in the short term, most European countries.

In France, indeed, as elsewhere, the philosophy implicit in the redistribution system has been split in two: a universal and comfortable sector for the sick and retired and a partial and weak sector for the poor and the children. Everything takes place as if it is a matter of insurance for the former and assistance for the latter, thus recalling the fate reserved in other times to the destitute. We are far indeed from social investment.

CHAPTER

120

World Population Growth and the International Community from 1950 to the Present Day

JEAN-CLAUDE CHASTELAND

Institut national d'études démographiques (INED), Paris, France

INTRODUCTION

Without a benign "invisible hand" to guide individual demographic behavior toward the interests of the group, there was little option but to adopt a voluntarist approach that few accepted, or even envisaged, at the end of World War II, as much because of the religious interdictions still controlling the private life of many societies as because of the era's cold war ideological and political context. Today, this voluntarism has become quasi-consensual, as is all the more apparent given the extraordinary convergence of behavioral norms observed in the last few years, concerning population, perhaps, more than any other field. Five decades, however, is a short time for global attitudes toward an issue as sensitive as population to evolve. In 1959, the Belgian delegate, a conservative Catholic, could still declare that the United Nations Population Commission "should not attempt to propose a solution to what was a serious problem, and least of all suggest that it advocated curbing or stopping demographic expansion" (Symonds and Carder, 1973; p. 87). As for the USSR delegate at the same Population Commission session, he was opposed to "any suggestion that the Commission should recommend action which would lower birth rates" (Symonds and Carder, 1973; p. 88).

To reach this point, during the 1940s influential American researchers like Frank Notestein had first to undergo a type of intellectual *aggiornamento* which led them to conclude that the demographic transition's natural mechanisms were not sufficient in themselves to trigger fertility decline in time and that it would be necessary to intervene in the process (Szreter, 1993). The original small group of researchers and decision makers who had joined them had subsequently to show great persistence and persuasiveness in order to mobilize around this project their country's resources, and later those of the international community within which the United Nations played a central role.[1] Americans for the most part, but also Scandinavians, these were the pioneers of the Population Movement. This group of scientific and political figures was to have a decisive influence on the international stage. Throughout the period, they were to be found in different halls of power: the foundations, American universities and government, the United Nations, international NGOs, and the like. Among those creating this *Population Movement*, or holding influential positions within it, however, the same small set of sociologists, demographers, physicians, and other scien-

[1] The international community refers here to a collection of players on the world stage, grouped within and around the United Nations and its member states, and includes academic institutions, nongovernmental organizations (NGOs), foundations and the media, whose respective influence can vary over time.

tists are particularly noticeable. A shared conviction brought them together: to place their expertise at the service of a political endeavor. They constituted what is referred to by Anglo-Saxon political scientists as "epistemic communities," meaning, "a network of professionals with recognized expertise and competence in a particular domain and an authoritative claim to policy-relevant knowledge within that domain or issue area" (Haas, 1992, p. 3). These networks tended to develop rapidly into transnational networks, as was certainly the case in the field of population.

Attitudes toward this issue have not followed a linear evolution; as discussions in Mexico in 1984, and even in Cairo in 1994, have shown, an about-turn is always possible. These difficulties come as no surprise when the population and resources (or development, to use today's term) debate is placed within a historical perspective that extends back far beyond the last decades of the 20th century. The first World Population Plan of Action adopted at Bucharest echoes concerns rooted in the 18th century, when the appearance of what Michel Foucault (1976) termed "bio-politics" made possible the better administration of the human resources necessary for the development of Europe's future industrial states.

Today, the population and development debate continues its arduous course, still associated nowadays as it was during the 18th and 19th centuries with three frequently irreconcilable elements: ethics, ideology, and science. This uneasy combination has not succeeded in holding back voluntarism, as the adoption of three successive world population action plans has shown; it contains within it, nonetheless, sources of tension that can either stimulate voluntarism or, on the contrary, paralyze it, according to the circumstances.

This chapter is organized around five foundational events that marked the period between the end of World War II and today. The creation of the Population Movement in the United States after World War II is the first; the second, the adoption by the United Nations in 1966 of a resolution authorizing the United Nations to support family planning programs in countries requesting them. Next is the organization of a series of three large intergovernmental meetings that were crucial, as we will see, to legitimize and generalize antinatalist policies in the Third World. The Bucharest Conference opened a decennial cycle of world population conferences; the Mexico conference followed in 1984; Cairo, in 1994, was the last in the series. A final prospective section explores the future of population policy at the international level.

I. 1946–1965: CREATION OF THE POPULATION MOVEMENT IN THE UNITED STATES AND THE EARLY MOBILIZATION OF THE INTERNATIONAL COMMUNITY

From the late 1940s to late 1960s, the *Population Movement* in the United States developed primarily around researchers and representatives of the large foundations and NGOs. These individuals later created links with the American administration, which did not itself become involved until the mid-1960s (Donaldson, 1990).

Two concerns awakened people to the problems raised by present and future Third World population growth: one was geopolitical in nature, and stemmed from the discovery, as early as the 1940s, of very rapid population increase in Latin America and Asia, two regions constituting a crucial part of the United States' strategic horizon. This growth was seen as a threat to political stability in regions that were considered essential for United States' security and for world peace, whose main guarantor this country perceived itself to be. William Vogt's book, *Road to Survival* (1948), in which the author describes the apocalyptic situation in which humanity would find itself if it did not take rapid steps to limit population growth, perfectly illustrates the fear this issue instilled in public opinion as soon as it was recognized. The book created quite a stir in the United States and in the rest of the world. The other concern was a humanitarian one. It focused on the well-being of the populations involved, and on their access to family planning, considered to be a universal right. With policy as a principle thus justified at the strategic and humanitarian levels, only an economic rationalization needed to be found in order to gain the support of Congress and the administration. It was here that American researchers, whose studies had the advantage of being highly oriented toward world problems, played a significant role. In the late 1940s they were already alerting funding agencies and government officials to the speed of population growth; all that remained was to demonstrate that such an increase was a major obstacle to development, and that development would, in fact, be impossible unless they got it under control.

At that time, economic theories of growth were dominated almost exclusively by considerations regarding the formation of physical capital, believed to be the unique key to development. Ansley Coale and Edgar Hoover's (1958) work, largely inspired by India's experience but with a more general application, established a rigid and negative association between population growth and the creation of savings and investment. Falling easily within the framework of this issue, it provided the economic argument to justify the adoption of birth control policies. The same line of reasoning reappeared later from the lips of the Democratic President, Lyndon Johnson, when he declared before the United Nations in 1965, "*Five dollars invested in population control is worth 100 dollars invested in economic growth*" (Green, 1993).

Demographers supplied additional arguments in favor of family planning (thanks particularly to findings from the KAP [Knowledge, Attitude, and Practice] surveys). By demonstrating that demands in this sphere were not met and that one could therefore legitimately respond to them, on the one hand, and by clarifying the determinants of fertility, on the other, they had cleared the way for possible intervention on these determinants (Davis and Blake, 1956).

Nothing could have been achieved, however, without key developments within biomedical research. Certainly, militants within the Population Movement believed that the diffusion of birth control practices depended essentially on making effective and cheap contraceptives available. In 1954, therefore, the discovery of the contraceptive pill by physicians Gregory Picus, John Rock, and Min Cheuh Chang was viewed as a major breakthrough; their work, on the initiative of Margaret Sanger, had been funded up to $150,000 by Mrs. MacCormick, the wealthy heiress of the company International Harvester. Several years later, the development of a much-improved version of the Population Council's intrauterine device (IUD), followed by that of Norplant, was another important step in extending access to contraceptive methods in terms of their efficacy and ease of use in poor countries (McLaren, 1990). Later still, even more effective contraceptives appeared, not to mention improved sterilization and abortion techniques.

The American administration was not particularly enthusiastic at first. In 1959, with reference to family planning, the republican president Dwight Eisenhower stated, "Birth control is not our business. [. . .] I cannot imagine anything more emphatically a subject that is not a proper political or governmental activity or function or responsibility" (Green, 1993). He later came to regret the statement and had to admit that he had been mistaken at the time. In the meantime, the foundations and American NGOs were left to spread the word and finance the first programs, and especially research developing efficient contraceptives. Personalities like John D. Rockefeller III, one of the Population Movement's outstanding figures, General William H. Draper Jr., a frequent participant in negotiations with the United Nations, Dr. Clarence Gamble, very wealthy heir of the pharmaceutical firm Procter & Gamble, Frederick Osborne, former vice president of the American Eugenic Society, President of the PAA (1949–1950) and of the Population Council (1957–1959) as well as the Ford, Mellon, MacArthur, and other foundations, all had prominent roles in creating or financing such organizations as the Milbank Memorial Fund (1944), the Population Council (1952), the Pathfinder Fund (1957), and the like. A special mention should be made of John D. Rockefeller III, who devoted to population issues an important part of his considerable political influence within the American administration and United Nations, of his financial power, and of his prestige among scientists (among other things, the Population Council in 1952 was his creation) (Harr and Johnson, 1991).

The US Agency for International Development (USAID), whose expertise also included population programs, only really got going later on. In 1965, it provided no more than 2 million dollars of aid compared with the Ford Foundation's 11-million-dollar contribution. It was only after the first private initiatives, encouraged mainly by Democrat presidents like Lyndon Johnson (Richard Nixon, through his support, was an exception among the Republicans) that the USAID Population Bureau (responsible to the State Department) became one of the main funding sources for population programs in many Third World countries and at the United Nations. From its creation in 1966, the Bureau was directed by a family planning militant, Dr. Reinert T. Ravenholt, whose extreme activism ended up alienating not only the academic world but also the administration, who demanded his resignation in 1979. During the 1960s, private and public American funds accounted for almost all international funding destined for Third World family planning projects; during the 1970s, it still represented three-quarters of it. Only after 1981, under Reagan's administration, did the relative weight of this funding drop significantly, due to the arrival of other donor countries (Germany, Norway, the Netherlands, Japan, etc.); its contribution remained substantial nonetheless, representing 40% to 50% of all international financing in the 1990s (Donaldson, 1990). Also since 1981, the administration's policy position on family planning program funding has been challenged on several occasions, due to growing disagreement between Democrats and Republicans about contraception and abortion, with the Republican Party's right wing dominated by Christian fundamentalists for close to 15 years.

Outside the United States, countries like Sweden had made a commitment to support for Third World family planning programs early on. This was the case for Sri Lanka from 1958 and Pakistan in 1961, and personalities like Alva Myrdal, ambassador to India at the time, played key roles (Wahren, 1986). A pioneer in many fields, Sweden was quickly joined by other Nordic countries, such as Denmark, Norway, and, more hesitantly, Finland. Owing to their moral authority and dynamism, these countries formed a highly influential pressure group on all questions relating to population at the United Nations, as well as in other organizations or international NGOs, like the Organization for Economic Cooperation and Development (OECD) or the International Planned Parenthood Federation (IPPF). What was lacking, perhaps, was a certain autonomy in relation to the American scientific domination. Furthermore, their bilateral aid strategy, structured around public aid organizations in the Third World (DANIDA for Denmark, NORAD for Norway, and SIDA for Sweden) and well endowed financially through their government's strong commitment to public assistance for development, proved to be of high quality.

Some developing countries also did not remain idle, however. In 1952, at the close of a conference organized in Bombay on the Family Planning Association of India's (founded in 1949) initiative, the participants decided to create the IPPF. Twelve years later, in 1964, this association finally obtained consultative status at the United Nations Economic and Social Council (ECOSOC). At that time, the IPPF already brought together several dozen national associations. Today it unites 141 associations in 180 countries and its donations reached 59 million dollars in 2001 (www.ippf.com). The scope of its activities has also diversified considerably; in addition to its traditional family planning interests, the IPPF has adopted most of the Cairo conference's vast array of reproductive health objectives, to be examined further on.

It is not by chance that the IPPF was created in postwar India. This developing country was, in fact, the first to officially declare its resolve to take control of population growth. The roots of this commitment go even further back, however: as early as 1937, the Indian Congress Party had examined the prerequisites for establishing a family planning policy. In 1952, India launched a family planning program as part of its first five-year plan (see Chapter 113, this volume, by S. Irudaya Rajan and Jacques Véron). From its English administrators, the country had inherited a solid statistical tradition and, from its researchers, a strongly Malthusian view of the role of population. Its experience would therefore have a great influence on the whole Indian subcontinent (Caldwell, 1998). In 1965, it became the first country to ask the United Nations for technical assistance to develop such a program. As early as 1956, on China's behalf, Chou En Lai had also expressed the need to develop a family planning program, but without asking for outside help. We know that this political direction would be challenged several times, particularly on President Mao's initiative, until the one-child objective was adopted at the end of the 1970s, an objective maintained up to the present day (see Chapter 112, this volume, by Isabelle Attané).

The growing number of countries adhering to the general aim of population growth control, however, should not make us forget the formidable opposition aroused by this endeavor. This opposition grouped a coalition of highly disparate countries. First, the communist bloc (including China, until the Bucharest Conference) perceived family planning policy as a manifestation of a false conception of the relationship between demographic increase and economic development (in their view, population growth stimulated economic growth); it was also seen as a convenient way for the West to protect the advantageous geopolitical status quo, by preventing expansion among populations who were the most deprived and potentially, therefore, the greatest threat to world order. Numerous so-called nonaligned countries of that era (who formed the Group of 77 soon afterward at the United Nations) shared this last point of view. Their hostility was reinforced through reading not only the American media or polemical works like that of William Vogt, but also by the writings of eminent scientific Population Movement members, such as Frank Notestein (who was later called successively to the direction of three organizations that played a crucial role on the international scene: the Office of Population Research at Princeton University, the United Nations Population Division, and the Population Council). By 1944, inspired by the purest geopolitical realism, he unhesitatingly stated, "By launching a program of modernization, the now dominant powers would in effect be creating a future world in which their own peoples would become progressively smaller minorities, and possess a progressively smaller proportion of the world's wealth and power" (Notestein, 1944; p. 156). In 1968, at the Vatican, Pope Paul VI had just published the encyclical *Humanae Vitae*, a virulent condemnation of any form of "artificial" contraception, and several Latin American and European countries joined the opposition as much for religious as geopolitical reasons (as in the case of Brazil, e.g.). France, along with other French-speaking countries, perceived these American endeavors as reflecting their desire for hegemony, though couched at times in humanitarian terms, as illustrated by this quotation from another influential demographer of the period, Dudley Kirk: "We will probably be serving our own political ultimate interests by speeding the social evolution that will bring about slower population growth. Most important of all, we shall have led all humanity to new possibilities of life" (Kirk, 1944; p. 35).

The double talk of the American position, notably at the Population Commission, was an easy target for criticism from the French representatives who defended an opposite agenda. During the 1960s, the French position corresponded to what could be termed a sort of "demographic Gaullism," whose objective was to maintain or if possible to increase the weight of the French speaking countries in the world. France had only adopted the Neuwirth law on contraception in 1967, and the Weil law on abortion in 1975. This delay in the much-needed evolution of its national legislation handicapped France in international debates. It also blocked progress in the legislature of its ex-colonies, who modeled themselves closely on it. In taking a critical stance toward the *Population Movement*, France often played a useful role, but by remaining in this position, was also marginalized. A kind of natural division arose between the intellectual importance of French demographic research and France's weak political influence on the international scene.

In 1946, the Population Division was created at the United Nations, a step that facilitated the process of reflection on world population problems; this body, mandated to carry out studies for the Population Commission (a subsidiary body of ECOSOC), was composed of government representatives chosen from different regions of the world (27 at the present time). The creation of an organization exclusively concerned with world population questions was far from evident as, at the time, population issues were viewed as falling naturally within the sphere of national governments. The Population Commission was to provide governments and the United Nations Secretariat with opinions and recommendations on population questions bearing on the international community. The United Nations, it should be noted, took over and considerably extended activities initiated on a modest scale at the time of the Society of Nations in Geneva.

The Population Division applied itself to the task without delay, under the authority of its director, Frank Notestein, who had also worked for the Society of Nations, notably in the sphere of population projections. From 1951 onward, its publications started to appear, with the first population projections (United Nations, 1951) and, among others, an important report titled: *The Determinants and Consequences of Population Trends* (United Nations, 1953). The discussions surrounding the planning of this report in 1951 provided the opportunity for a thorough review of the different positions held by the Population Commission's member states on the population and development question. Rereading the report today, it is impossible not to notice how painstakingly and carefully it was argued. It concludes by suggesting very cautiously that rapid demographic growth could create difficulties. The report was nonetheless violently attacked by the USSR representative and, to a lesser extent, by the French one, Alfred Sauvy, director of Institut national études démographiques (INED) at the time. A new version had to be drawn up, and this was the one finally published in 1953 (United Nations, 1953). As for the population projections, regularly revised from 1951 onward, they had a significant influence in raising awareness within the international community. Their remarkable reliability over time made their impact all the greater (see Chapter 77).

As this is not the place for a detailed description of the Population Division's achievements, we will mention only that in the early years they had a huge influence on demographic research in developing countries, particularly with the publication of model life tables, manuals for indirect analysis of incomplete data, and stable population studies. In addition, five training centers were created: in the Middle East (Cairo), Africa (Accra and Yaounde), Latin America (Santiago, Chile), and Asia (Bombay); their impact was critical for the education of several generations of Third World demographers. Later, it became more oriented toward the comparative analysis of the growing quantities of available data, from censuses or World Fertility Surveys (WFSs) during the 1980s, and later from Demographic and Health Surveys (DHSs), one of the most massive undertakings for the scientific exploration of human behavior worldwide. The Population Division also pioneered population policy surveys among its member states, and is the holder of the largest comparative data bank on these policies and on international migration. In its many publications, it has always taken care to be open to as broad a demographic field as possible, especially avoiding any extreme polarization on questions of fertility, while endeavoring simultaneously to remain neutral at the politico-ideological level.

During this period, in collaboration with the International Union for the Scientific Study of Population (IUSSP), the Population Division directed preparations for the first world population conference in Rome in 1954, which brought together 455 participants from 74 countries. A conference of specialists with no government mandate to adopt any recommendations, however, its aims were purely scientific. Nonetheless, the organizers hoped that the work it achieved would enlighten government actions. As Milos Macura observed, it helped spread the idea that "all populations of the world should be properly studied and their problems understood in the context of their particular economic, social and cultural conditions" (Macura, 1986). This was a way of responding in advance to criticisms concerning the global population concept.

In Asia, which found itself up against substantial population problems early on, and where American influence on the political, economic, and intellectual elites was strong, the reaction was rapid. Japan, defeated and facing the return of its settlers from countries within the defunct Grand Asia project, passed the so-called Eugenics law in 1948, which made it possible for an ambitious population control program to be set up. India, Sri Lanka, and Pakistan followed suit. When the United Nations Economic and Social Commission for Asia and the Pacific (ESCAP) organized a regional conference at the governmental level in New Delhi in 1963, therefore, no one in the region was surprised that the final document supported recommendations regarding the creation of family planning programs. This initiative had been seriously criticized by certain Population Commission members, however, who had no wish to have their hand forced (Symonds and Carder, 1973).

The climate was still not ripe, therefore, to set up a governmental level world conference. When the second world population conference was organized, yet again by the IUSSP, in Belgrade in 1965, its objectives were once more restricted to a scientific analysis, by close to 1,400 experts from 118 countries, of the population problems confronting the international community. Nevertheless, in his opening speech, the Frenchman, Philippe de Seynes, Deputy General Secretary at the United Nations and head of the Department responsible for the Population Division, had the courage and lucidity to declare that "at the opening of this Congress whose declared objectives are technical, why do we have the feeling to be participating in an exceptional event which is taking on a political dimension?" (United Nations, 1965; p. 29). At Belgrade, fertility issues were abundantly debated (more than 100 of the 487 presentations focused on fertility and family planning). For the first time at a conference organized by the United Nations, family planning and the problems of program implementation were discussed, giving them a type of implicit recognition. The evolution since the Rome conference was thus very clear, and reflected the evolution of the countries most involved. Whereas only three countries had family planning programs in 1954, the number had already risen to 23 by 1965.

The collaboration between the Population Division and the IUSSP needs to be briefly touched on as it was a key ingredient of developments in the study of problems raised by global population trends during the two decades following the end of World War II. The experience acquired in jointly organizing the Rome and Belgrade Conferences, in preparing the *Multilingual Demographic Dictionary*, in sharing the preparation of several reference manuals particularly on the subject of fertility, and their participation in the various IUSSP scientific committees in their official capacity as Division members, produced a close collaboration right up to the early 1980s. After that, two developments altered the nature of this collaboration. First, Division members gradually became less involved in these committees, as the need for multidisciplinary expertise had somewhat reduced the importance of demography, and that of the Division with it. Second, the Division's role in the union's general conference preparation and organization dwindled, while, simultaneously, the role of the United Nations Fund for Population Activities (UNFPA) within these same conferences, and in financing its activities, expanded (IUSSP, 1988). Like the IPPF, the IUSSP has developed significantly in the last 50 years and today includes more than 1,900 members from 127 nations.

In 1966, a year after Belgrade and following arduous discussions, the United Nations General Assembly took a decisive step in adopting its famous GA Resolution 2211 authorizing the United Nations to support family planning initiatives in any country expressly requesting it. Sponsored by 15 countries, this resolution was proposed by Sweden, Norway, and Denmark, with the backing of 11 Third World countries and of Yugoslavia, a nonaligned country. The central, though relatively unknown, part played by Philippe de Seynes during preliminary discussions about the adoption of this resolution at the General Assembly's second commission is once again worthy of note. After integrating numerous amendments, it was adopted by consensus on December 17, 1966. The ground had already been prepared by the World Health Organization's (WHO) adoption, on May 20, 1966, of WHA Resolution 19–43, authorizing the organization to "lend its technical support to the development of family planning activities in countries requesting it".

Having gained international legitimacy, from then on the *Population Movement* grew progressively stronger.

II. 1966–1973: THE UNITED NATIONS' GROWING INFLUENCE

Although the United States enjoyed almost total control of the *Population Movement* at all levels—ideological, political, intellectual, and financial—during the period from 1950 to 1966, this position gradually evolved as the Movement grew more international following the United Nations' strong entry into its field of action. Well aware of their problem with direct intervention in numerous Third World countries with relatively hostile governments, the U.S. administration had actually encouraged this internationalism. It entered into a new collaborative relationship with the United Nations, not unlike the one it had experienced and continued to experience with NGOs and American foundations. During this period, the role of the foundations and NGOs remained important, but they encountered an increasingly powerful United Nations' presence in territory they had occupied alone for many years. Some institutions, very active ones, were still being set up at the end of the 1960s, such as the Alan Guttmacher Institute (1968) or the Population Crisis Committee (1968).

The United States' intellectual supremacy scarcely changed during this period. Stimulated by an abundance of funding, numerous studies even helped consolidate their intellectual hegemony. Among those attracting the attention of the era's decision makers, the National Academy of Science's (NAS) 1971 report should be cited, with its pessimistic conclusion on the consequences of population increase for Third World countries (NAS, 1971). Paul Erlich's (1968) work and Garrett Hardin's (1968) article also made waves, and achieved lasting influence by introducing the ecological dimension into the population and development debate. This new line of argument, which in fact resuscitated the old idea of physical limits, had the success it is known to have had and arrived at exactly the right moment, namely when theories of economic growth were beginning to free themselves from considerations related exclusively to the creation of physical capital. Furthermore, empirical observations were becoming available that show the impact of demographic growth on the formation of savings and investment to be less negative than previously expected.

Although American population policy in the Third World was based on an abundant neo-Malthusian literature, there was also a highly dynamic body of literature contesting their arguments, but which the Administration ignored (Hirschman, 1958; Kuznets, 1967); within the American academic community, individuals such as Colin Clark (1967) and Dame Esther Boserup (1965) were also very influential. The strongest critiques of American political involvement did indeed hail from the academic world. The conservative and religious political wings had not yet managed to organize a counter-offensive comparable to the one they succeeded in setting up in the early 1980s.

Outside the United States, the opposition was made up of the same heterogeneous coalition as in the early 1960s. Rubbing shoulders with the Vatican were communist countries (soon to lose one of their influential allies, China), nonaligned countries like Algeria, then at the forefront of the Third World struggle (these countries formed the Group of 77 at the United Nations in 1964), as well as the Catholic countries of Africa, Latin America, and Europe. Still taking the same critical stance held from the start, a French representative at the United Nations Economic and Social Council suggested making a distinction between family planning, on the one hand, and birth control, on the other.

> That process whereby the population unbalance resulting from the fall in the death rate was to be corrected by deliberately reducing the birth rate was called "family planning" although, in fact, it implied birth control measures resulting not from the free decisions of individuals or families, but from the application of a veritable national policy (Symonds and Carder, 1973; p. 179).

He warned the international community of the danger of attempting to encourage birth control on the pretext of supporting family planning. This warning was something of a premonition; the campaigns for sterilization and forced abortions in China, India, and elsewhere, and the not-always equitable methods of dissuasion and encouragement used, proved it to be well founded.

At the United Nations, a number of factors contributed to the rapid creation of technical assistance programs in the area of family planning, forbidden until then: the General Assembly's adoption of Resolution 2211 in 1966; the publication by U Thant, the United Nations Secretary General, of a Declaration in favor of family planning, signed by 12 Heads of State in September of the same year, at John D. Rockefeller III's suggestion; and, in 1968 at Tehran, another publication on human rights containing a paragraph on the right of couples to decide freely the number and spacing of children. These programs developed not only at the United Nations itself, in the New York Secretariat, and in UN regional commissions at Bangkok, Addis Ababa, Beirut and Geneva, but also in the United Nations' large specialized agencies: first at the United Nations Education, Sciences, and Culture Organization (UNESCO), no doubt due to the involvement and personality of it director at the time, Julian Huxley; then at the International Labor Office, executive body of the International Labor Organization (ILO), and the Food and Agriculture Organization (FAO).

On account of its mandate, the WHO had started discussing the possibility of giving support to family planning initiatives very early on, but there was also an effective opposition until 1965, the year preceding the adoption of the WHA Resolution 19–43 which, as mentioned, had opened the way to United Nations involvement.

The International Bank for Reconstruction and Development (IBRD), known today as the World Bank, enjoyed a special status within the United Nations system, as one of the so-called Bretton-Woods institutions, where communist bloc countries were not represented. At first, it was satisfied simply with showing certain countries, like Thailand in 1958, that rapid population increase was leading them into an economic impasse and with helping fund Ansley Coale and Edgar Hoover's celebrated work on India in 1966, within the context of studies on population growth in developing countries (Kasun, 1981). Up to this time, however, the Bank had no wish to be directly involved in financing family planning programs. GA Resolution 2211 and Robert MacNamara's nomination as President in 1968 accelerated considerably its involvement in this issue, all the more so that Robert MacNamara rapidly became simultaneously one of the Population Movement's leaders and the inspiration for the World Bank's antipoverty programs. In Robert MacNamara's mind, however, geopolitical considerations needed to remain at the forefront. Thus, in 1969, in a famous speech at Notre-Dame University, he declared, "population growth creates stress in the body politic which in the end can bring on conflicts among nations" (Crane and Finkle, 1981). Since then, the World Bank has continued to play a decisive role in the population arena, no longer only at a financial level where the volume of its low-interest loans exceeds the volume of grants from UNFPA (more than 500 million dollars in 2003) but also at an ideological and political one, using its political weight widely to influence vacillating governments. At the same time, it broadened its field of action to encompass such varied activities as providing financial support for health, education, and the improvement of women's status programs, and even the promotion of "methods of good governance" for local authorities.

Still at the United Nations, the General Secretary had decided to set up a trust fund in 1967 to collect voluntary contributions from donor countries. This was in response to the many countries opposed to the United Nations using its regular budget to finance family planning programs. Administered for 2 years by the Population Division, and with the United States as the first contributor (a sum of 1 million dollars), in 1969 this fund became the UNFPA, mentioned earlier. Its administrative and especially political management was entrusted to the United Nations Development Program (UNDP), a decision fraught with consequences. It had been instigated by the United States and its representative at the Population Commission, General William H. Draper Jr., who opposed the management of this new program going to the Population Division on the pretext that it would give too academic a twist to future programs. This decision was contrary to the advice of Philippe de Seynes, who complained to the United States' representative at the United Nations, none other that George Bush, future United States president, that the Secretariat had been pressured by General Draper and his assistants (Symonds and Carder, 1973). In fact, the motive was essentially political: the United States has always had great influence at the UNDP, whose director, right up to the present day, has consistently been an American. Their influence is more modest, on the other hand, at the United Nations Secretariat, to whom the Population Division is responsible. Alfred Sauvy, together with the USSR representative, had no difficulty, therefore, calling attention to the fact that this new fund's political management had in fact fallen to an advisory board operating within the UNDP, with neither political representativity nor legitimacy, whereas, legally, this function was among the Population Commission's responsibilities, whose mandate clearly included monitoring population policy and programs. This decision particularly reflected the weakening of ECOSOC, the Population Commission's regulating body, mistrusted by the United States since the Group of 77 and the Soviet Bloc had come to dominate it. This decision would have a durable influence on the fund's operation as, unlike the Population Division, it never attempted to appear politically neutral and took a decidedly Malthusian line throughout.

The first Fund director was nominated by the Secretary General in 1969. He was a high-ranking Philippine official, Rafael Salas, former Secretary General of the President of the Republic during President Ferdinand Marcos' time. Rafael Salas and his successors developed the fund in a remarkable way; starting out as a handful of collaborators, some of whom came from the Population Division, the fund has since opened offices in 112 countries and finances projects in 141 countries. In 2003, it received 398 million dollars entirely from voluntary contributions; the cumulative total since the fund's creation in 1969 has risen to almost 6 billion dollars. It has played an important and often unrecognized advisory role among Third World countries, which were mostly complete novices with respect to the organization and management of family planning programs. The often-archaic national administrations could certainly not serve as models. In fact, the newly created family planning services have often been the only modern sector of their government.

While family planning program funding continues to be central, UNFPA's activities have broadened considerably; in addition to promoting reproductive health, they include financial support for programs against violence to women, the AIDS epidemic, or the promotion of sustained development, for example (www.UNFPA.org).

Since the Belgrade Conference in 1965, an increasing number of nations—more than 30 in 1973—had adopted population policies aiming to reduce their level of fertility. Within the international community, the idea of a conference devoted uniquely to population policy problems had taken root. A small group of five experts, Jean Bourgeois-Pichat among them, was set up in 1969 under the aegis of the Population Division to explore the possible options concerning the organization of the next world population conference. This group recommended that this conference focus uniquely on policy questions, particularly those concerning population programs. The year chosen for the conference, 1974, was also designated World Population Year.

III. 1974–1983 BUCHAREST: THE VOICE OF THE THIRD WORLD

1. The Political and Institutional Context

The decision to organize a governmental level conference on population was neither an unexpected nor an isolated event in United Nations' history. It was not unexpected because it fell in line with the goals the *Population Movement*, very influential at the United Nations Secretariat, had been struggling to achieve. Neither was it an isolated event in the United Nations system. On the contrary, organizing this and other similar conferences during the 1970s fell directly within the context, from the late 1960s onward, of a deliberate UN strategy to regain, at the economic and social level, territory lost at the political one. Cold war clashes meant, effectively, that none of the era's great conflicts (Vietnam, Palestine etc.) could be resolved within the system. The idea of constructing a universal society with shared political values had to be abandoned in favor of identifying common interests in areas such as the environment, energy, oceans, and the like, or in promoting individual rights such as women's status, childhood, health, living conditions, nutrition, and, of course, population. The United Nations was still the only forum in which conflicts arising from positions taken by national governments, in areas where States were interdependent, could be arbitrated globally (Smouts, 1983).

Another interesting question is why the United Nations resorted increasingly to large specialized conferences for the preparation and adoption of policy documents on subjects as varied as nutrition, employment, the environment, women or population, and not, for example, to ad hoc sessions of its permanent deliberative bodies like the General Assembly, ECOSOC, or, in this case, the Population Commission. First, this choice demonstrates the declining status of these political bodies, where even debates on purely technical issues were, in the eyes of the developed world, at risk of being disturbed by the intrusion of political problems (e.g., the Palestine question in a discussion on women's status or population, etc.); it also shows a growing preference among industrialized nations for purely technical, temporary conferences which they can control all the more easily since they have often paid for their organization. Until recently, the 1989 UN Convention on the Rights of the Child (adopted nonetheless in 1990 at a one-day World Summit of Heads of States), and that of 1990 on the Rights of Migrants and their families, were among the rare instruments prepared and adopted outside a large conference. The adoption of the latter, incidentally, passed completely unnoticed by international opinion. Yet, it is precisely this awareness and mobilization of international opinion that are sought increasingly nowadays in areas such as the environment, women's status, population, and so forth. Large conferences, and the accompanying media coverage, are considered the best way to achieve these objectives. The United Nations deserve credit for recognizing early on that these conferences, on relatively well-demarcated issues, offer some kind of catharsis for international problems; by unblocking situations from which there appeared to be no way, it helps contributes to their speedier resolution. More recently, they have also provided public opinion, the media, civil society, and NGOs with opportunities to gather information, voice their opinions, and put pressure on governments (Chasteland, 1994). Finally, they are a stake in the power game for members of the epistemic communities, mentioned above, and of the UN bureaucracy. A successful conference improves the position of its instigators and organizers in terms of obtaining a broader mandate for their institution and the greater resources that go with it. This is a compelling and rarely mentioned motive, which nonetheless has a considerable influence on the decision to organize a conference, and in its preparation.

2. The Players

The UN Secretary General appointed Antonio Carillo-Flores, a former Mexican Foreign Affairs Minister, as the conference's general secretary. Two deputy secretaries assisted him, one of whom was Leon Tabah, director of the Population Division. No UNFPA representative was among this group of three whose role would be a decisive one. The UNFPA's only responsibility was organizing the Population Year.

The conference objectives were ambitious: to explore world population trends, the relationship between development and these trends, and the measures necessary to improve population welfare. In fact, the main aim was to discuss and adopt a World Plan of Action whose application would help reduce fertility and improve well-being particularly among developing nations. Aided by a group of five experts, the Population Division prepared a project for the Plan of Action and submitted it to the Population Commission. The resolution authorizing the conference stipulated, furthermore, that prior to the conference itself, five regional conferences (in Africa, Asia, Latin America, Europe, and the Arab countries) and four expert groups (in population and family; population and development; population, resources and environment; and population and human rights) should be set up, thereby separating scientific discussions and policy deliberations. The conclusions reached by the expert groups were intended to clarify the policy decisions taken during the conference. Rather a vain hope. The next two conferences, at Mexico in 1984 and Cairo in 1994, were organized in a similar way, the main difference concerning the preparation process for the final document: the Plan or Program of Action. By 1984, the Division, whose principal partner at Rome in 1954 and Belgrade in 1965 was the IUSSP, would also have a new partner, the UNFPA. At the Mexico conference, the latter even took over the political and administrative direction of world population conferences.

With the help of its expert group, the Population Division prepared a project for the Plan of Action containing approximately 100 paragraphs and submitted it to Population Commission members, who accepted it without major modifications. It was also presented for comment at the five preparatory regional conferences, and no particular opposition was visible on this occasion. As already mentioned, however, conference participants gave it a highly critical reception, and revisions were made to almost three-quarters of the original document.

One explanation put forward for these numerous alterations was the conference Secretariat's lack of attention to the current international political context, and the ensuing poor communication with the principal players on the international political stage in the early 1970s (Finkle and Crane, 1975). In retrospect, the late 1960s and early 1970s do indeed appear as the apogee of the Third World school of thought that perceived the unequal distribution of global resources as the principal obstacle to development which was, according to this line of thinking, the indispensable condition for subsequent fertility reduction. This was the position skillfully defended by Algerian leaders at the time and supported by Latin American countries such as Argentina, Brazil, Peru, and Cuba. China, which had not yet experienced its ideological *aggiornamento* on population, put its whole weight behind this group of countries. During this era, these nations, members of the Group of 77, had a quasi-hegemonic influence over the international organization. Some were ideologically close to countries from the socialist bloc, and many were crowned with the glory of their anticolonial struggles. At the United Nations they obtained what appears in retrospect to be a short-lived victory: a special session was organized at the General Assembly that adopted a Declaration on the Establishment of a New International Economic Order in May 1974. Accepted just before the Bucharest Conference, this declaration contained no reference to population issues.

In many Western nations, however, the tone was resolutely Malthusian. Public opinion was disturbed by the strongly pessimistic conclusions reached in the Club of Rome's report, published in 1972 (Meadows *et al.*, 1972). The report reintroduced the old obsession with physical limits to economic and population growth. Western, and especially American, demographers continued to be extremely uneasy about the world population's rate of growth. Since 1950, this rhythm had never stopped accelerating and, in the early 1970s, the fact that it was finally starting to slow down was as yet unknown. Based on data that could not take this changing trend into account, the United Nations population projections published on the eve of the conference overestimated population increase (United Nations, 1973).

The small group of experts who helped the Division prepare the Plan of Action project were relatively unaware of the deep ideological currents stirring the United Nations. The same was true for the Population Commission, which was largely composed of specialists of population questions. At that point, also, NGOs still had only a minor role in conference preparations, and in discussions taking place within the Population Commission. The power of American NGOs was undisputable, but at that time it was exercised more over the U.S. Administration than over United Nations organs. From the 1980s onward and with the Republicans' arrival in power, as we will see, they would increasingly exert their influence within the United Nations, which had become unavoidable in matters of population. Once completed, the project would reflect the main preoccupation of most Anglo-Saxon demographers: how, rapidly, to bring about a demographic transition which, left to its own devices, would develop too slowly. While not excluding the role played by economic factors in the process, the project only assigned them a function that might be described as contextual. Finally, the project makes two references to quantitative objectives concerning population growth. These references so much reflect the acceptance of constraint in this ultrasensitive area at that time that they have gained a symbolic value. India, with its sudden conversion to a coercive population policy in the late 1970s, is a typical example. It would be almost 20 years, after the downfall of Indira Gandhi's regime and the end of coercive measures, before India solemnly proclaimed that it was discarding quantitative objectives in the area of population. A more coherent vision of family planning was thus restored, legitimated above all by its voluntary nature.

The conference was to be held in Rumania, at Bucharest. Then a socialist nation, independent in its foreign policy but highly orthodox in its internal politics, Rumania was politically a fascinating country in which to organize the first world conference whose sole aim was to analyze policy issues. Its choice shows that a socialist country could give its backing in a way to the conference's main aim—legitimizing population policy within the international community—but with the inverse objective: to increase the birthrate.

3. The Outcomes

Conference participation was a success. One hundred and thirty-six of the member states were represented, out of the Organization's total membership at that time of 138. Of the NGOs invited to take part in the conference, 109 were present at Bucharest. A gallery had been reserved for them where John D. Rockefeller, president and founder of the Population Council, gave a much talked-about speech in which he admitted holding for too long the belief that family planning programs alone could solve the problems raised by demographic increase. "I now strongly believe," he said, "that the only viable course is to place population policy solidly within the context of general economic and social development" (Rockefeller, 1974). It was virtually a paraphrase of the famous Plan of Action formula on the need to integrate demographic policy into development (United Nations, 1975b, para. 1). Made by one of the era's eminent figures, this statement marked a withdrawal from the most orthodox American positions within the Population Movement. It corresponded relatively well, however, to what American researchers like Bernard Berelson were calling for, in the light of the ineffectiveness of early family planning programs essentially organized around the free supply of contraceptive methods. They were demanding an approach to family planning more oriented toward stimulating the demand for these techniques; an approach that, in addition to access to contraception, included direct measures of persuasion and dissuasion as well as indirect measures, such as improving education, health, women's status, and the like, which could encourage a change in ideal family size (Berelson, 1969).

As with all the large United Nations conferences, the media (more than 100 journalists had been invited) helped turn the conference into a real "happening" by rallying a budding international public opinion on the issue for several days. Although important at the time, this number of journalists would soon appear very modest compared with what would happen at future conferences.

Before examining the key results of the conference, a few words need to be said about a procedure commonly employed within the United Nations, but little understood outside it, regarding policy paper adoption: that of *consensus*. Remember that, after considerable modifications and ten days of heated discussions, the Plan of Action was adopted by consensus—by the 136 participating States with the exception of the Vatican. So why is the rule of consensus so important at the United Nations, compared with straightforward majority rule, for instance? Quite simply because most policy papers accepted by the United Nations are only recommendations and cannot therefore be enforced. In order for these recommendations to have an influence, they need to be universal in nature, hence the rule of consensus. Only under these circumstances will they be able to define new behavioral norms, applicable among others to the governments accepting them. Ignoring them can place these governments in a difficult position in relation to the international community as a whole, especially that these norms, as in the case of population, are promoted and defended by powerful transnational networks; besides scientists from the epistemic communities, these networks include leaders of powerful nations and international NGOs, and influential individuals on the international stage—the so-called transnational moral entrepreneurs, of whom John D. Rockefeller III was one of the most conspicuous representatives (Nadelman, 1990). Much more uncommon at the United Nations are documents, known as conventions, which are compulsory for the countries signing them. The United Nations wields substantial resources for activities in the population sector; allocated only to countries respecting the spirit, if not the letter, of the recommendations, this raises the chances of them being followed through.

To reach consensus, governments negotiate compromises. This was the case at Bucharest, where certain compromises were crucial to the conference's success. First among them was the famous compromise allowing those who believed that development alone could reduce population growth to reach agreement with their opponents, who viewed family planning as the sole route to controlling this increase. The idea of incorporating population programs into development planning was born of the conciliation between these two positions. It proved extremely useful, despite being difficult to put into practice. This first compromise allowed a type of ideological reconciliation between two long-conflicting parties. The second important compromise falls within the political sphere. The Plan of Action recognized national sovereignty in population policy decisions, while simultaneously defining the general orientation of what the international community needed to do in this area. The third compromise was an ethical one. The Plan stated that couples and individuals had the right to choose freely, but in a responsible fashion, the number of their children. It accepted individual liberty as long as it was part of a perspective of moral responsibility toward the community and, thus, did not contradict the sovereign right of nations to determine demographic policy.

Besides these compromises that brought reconciliation between opposing positions, the Plan had the immense merit of legitimizing the vocabulary and action of population policy at a national and international level. It also contained an impressive number of useful recommendations, although they failed to rank in terms of priority. Admittedly, defining priorities is extremely tricky in a world conference where too many different interests are at stake.

The Plan's value lies not only in these compromises, however fertile; at the ideological and political levels, it was also undeniably innovative in character. A number of recommendations concerning women's status and fertility (six paragraphs) are clearly ahead of their time. They even anticipate certain recommendations adopted at the first United Nations Conference on Women that did not take place until 1975. Also ahead of its time is the wording of the principle of right to free choice over family size of couples and *of individuals,* as became clear in Cairo when the same topic came under discussion. Likewise, the insertion of paragraphs regarding both legal abortion and maternal mortality in an international document is, in itself, a first. The Swedish delegation certainly had reservations about the abortion paragraph being placed in the plan of action's mortality section; they would have wished the issue to be debated during discussions on the question of reproduction and the family.

Moreover, the Plan displayed a solid economic realism, particularly in the attention given to the economic and social consequences of population inertia. Whatever the effect of population policy, it pointed out, world population would continue to increase, and this expansion would require the international community's economic mobilization (United Nations, 1975b, para. 13). The Bucharest conference benefited from publications from the United Nations' First Conference on the Environment, held at Stockholm in 1972, and from the population and environment expert group. Taking into account the fact that the topic was new, the policy content of recommendations on the environment was relatively weak, but they nonetheless had the merit of raising the issue 20 years before the Rio de Janeiro conference.

Finally, as would be the case with subsequent plans (or programs), except possibly Mexico, which was adopted during a period of radical ideological and economic mutation, the Bucharest Plan is a faithful enough reflection of the balance of power existing at the United Nations at the time of its adoption. Rereading it nowadays, it is hardly astonishing that it seems a little outdated in its excessive celebration of the virtues of planned development and the pre-eminent role of the State. The document remains, nonetheless, the first universal population policy document that the human race has ever agreed to discuss, accept, and implement.

IV. 1984–1993 MEXICO: THE UNITED STATES AND THE THIRD WORLD AT ODDS

1. The Political and Institutional Context

In the early 1980s, the United Nations envisaged organizing another world population conference. Discussions were tight. In 1981, the United States, who had led and inspired the *Population Movement* until then, elected a Republican president on a highly conservative platform that diverged from that of the *Population Movement* on many points. Associations demonstrating against abortion, sometimes violently, had a great deal of influence over the new Republican Administration. They expressed a wish to return to a moral order that excluded, or barely tolerated, abortion and even contraception. The prevailing spirit was also one of cuts in public expenditure, nationally and internationally. Ideologically, those who believed in state intervention in the social and economic sphere were on the defensive. Previously ignored by the administration, the works of the so-called revisionist economists or demographers, who rejected the neo-Malthusian vulgate, at last found a favorable echo in influential political circles. Their research findings fuelled the case of a Republican Administration reluctant to fund family planning programs for diverse ideological reasons (Simon, 1981; NRC, 1986; Kelley, 1991). The welfare state had become the scapegoat for all the developed world's problems, in the same way as planning had in the Third World, given the scope of its spread. The success of East Asian countries, where capitalism alone ruled, contrasted with the repeated failure of countries with a planned economy, of which Africa offered a sad example. The stagnation in Socialist bloc countries could no longer be concealed, at the same time as the Third World abandoned claims for a reformulation of international North–South economic relations. The Declaration on the Establishment of a New International Economic Order was well and truly buried.

The situation in Third World countries diverged increasingly. Whereas some East Asian countries had entered the world economy with outstanding success, others, especially in Africa and Latin America, were living an unprecedented crisis which, among other things, manifested itself in levels of indebtedness that appeared out of control at this point. These were also the final years of the East–West conflict, which did nothing to ease international cooperation, particularly since the United States suspected the United Nations of a systematic bias in favor of socialist and Third World countries.

In terms of demographics, the old polarization between developed and developing countries was now giving way to a new one, this time between developing nations. Of the 4.4 billion people on the planet in the early 1980s, only 900 million still remained outside the general movement toward fertility decline, which accelerated and spread between the early 1970s and the early 1980s. As mentioned earlier, although at the time of preparations for the Bucharest conference in the early 1970s everyone was still unaware that population growth rate had finally peaked, by the early 1980s the downward trend was no longer in doubt.

At the same time as the slowdown in population growth rates was becoming clear, the perception Third World governments had of their demographic situation was also evolving. In their 1973 government survey, the United Nations observed that 28% of governments, representing 57% of the world population, deemed their country's fertility level too high. In 1983, these proportions stood at 37% and 61% respectively. Furthermore, in 1983, 29% of governments stated that they were implementing fertility reduction policies, compared with 26% in 1973. Sub-Saharan African countries were bringing up the rear in this evolution (United Nations, 1975; United Nations, 1995c).

During the same period, empirical observations and theoretical research led to advances in thinking on the question of economic growth and its determinants. Thus, economic growth theories had cleared new ground, like that relating to the role of human capital in economic growth processes. Just before the Mexico conference in 1984, the World Bank, never slow to adhere to the dominant intellectual models, published its annual report on world development, and devoted it to the relationship between population and development. The report's content has been described as harboring a kind of "retreating" Malthusianism; if so, it is because the classic theme that highlights the negative relationship between population growth and physical capital formation has been replaced by one underlining population growth's same negative role but, this time, on the formation of human capital (World Bank, 1984).

2. The Players

These changes in the international context occurred at a time when one of its principal actors, the new U.S. government, was radically altering many of its predecessor's political choices. The new Republican Administration was quick to demonstrate that its position on abortion at the international level would be no different from the one taken internally. It suppressed all grants to UNFPA, on the pretext that the organization was financing pro-abortion measures as part of family planning programs, notably in China.

Public funding for family planning programs grew rapidly more international as the United States stopped funding a United Nations program to whose creation and promotion it had made such an important contribution (as it had also to the IPPF). This evolution also reflected the rising power within the United Nations, as in other areas, of Asian countries like Japan, and of European ones, like Germany, the Netherlands, Norway, and the United Kingdom, as well as that of the European Union itself, whose financial contributions partly compensated for those of the United States.

Finally, an intense lobbying organized mainly by countries receiving UN assistance (India, Pakistan, Mexico, Egypt, etc.), a few donor countries (the

Netherlands, Scandinavian countries, Japan, etc.), and UNFPA's executive director, won the day. China, who had experienced a remarkable about-turn in the field of birth control since 1974, also offered its support, but more discretely in order not to upset certain Group of 77 countries. In 1981, ECOSOC authorized the organization of a conference, this time named the International Population Conference. Its objectives were as follows: to evaluate the implementation of the Plan of Action adopted 10 years earlier at Bucharest, on the one hand, and, on the other, to make recommendations to improve the conditions of its implementation. Evidently, there were also power objectives surrounding the conference within the United Nations itself. In response to criticisms about waste made to the organization by donor countries, the General Secretary decided that they should economize in its preparation by using the existing personnel resources as far as possible. Thus, he nominated Rafael Salas, Executive Director of UNFPA, as the conference's General Secretary, and Sankar Menon, Director of the Population Division, as deputy. The UNFPA was to take responsibility for the political and financial aspects of conference preparations, the Population Division, for its scientific aspects, for the project to revise the plan and for the organization of four expert groups to meet prior to the conference (fertility and family; mortality and health policy; population distribution, migration and development; population, resources, environment and development). The United Nations' regional commissions were responsible for organizing five regional conferences.

In reality, the Director of UNFPA exercised absolute power throughout the conference preparations. The UNFPA took advantage of its strategic position, as it would do with even greater success at Cairo, to try and press its case for transforming UNFPA into a specialized United Nation agency, totally independent from the UNDP and its governing board (like the FAO, the WHO etc.), with certain member states. The fund was not supported by the majority of member states, some of whom, like France, could not accept a change in the organization's status quo, which would have implied the UNFPA absorbing the Population Division, and probably leading to dismantling the Department of International Economic and Social Affairs on which the Division was dependent and which was itself an integral part of the United Nations Secretariat. Unlike the UNDP, the Secretariat was accountable to all member states and not principally to donor countries, as was the case for the UNPD's board of directors.

Although the conference preparation was similar to Bucharest's, there were some important innovations in addition to the decisive role given to UNFPA. The preparation process for revising the Plan was one of the major changes. Bucharest's experience had shown that the process needed to be opened to the various political influences then dominating the United Nations if the conference Secretariat wished to avoid Bucharest's unpleasant political bombshells and the significant alterations that had to be made to the Plan project. The decision was made, therefore, to submit the Plan revision project to a Population Commission extended from the usual 27 members to include all members of the organization. Although it did not avert all the surprises, this decision made it possible to take better account of the views of all member states and helped reduce considerably the number of amendments made during the conference, whose duration had been reduced to 6 days (from 10 at Bucharest).

3. The Outcomes

Once again there was an excellent level of participation, with 147 countries out of 157 member states represented at the conference, held in a developing country, Mexico. In 1973, on the eve of the conference, this country had adopted a demographic policy that subsequently proved to be relatively effective. Besides the official delegates, 154 NGOs were also present. Finally, over 300 journalists helped enormously to arouse international public opinion. As at Bucharest, scientific activities were separated from policy ones, with the former concentrated in the period before the conference around the four expert groups already mentioned. The conference focused exclusively on discussing and adopting the revised Plan of Action project.

Despite all the precautions taken by the organizers, elements external to the conference disrupted it as they had in Bucharest. First, there were interminable discussions about peace and security, which, in retrospect, appear as the final manifestations of the East–West conflict. Two other external issues also complicated the deliberations, one with regard to the formulation of recommendations concerning Third World debt (a North–South confrontation), and the other, the question of Israeli settlers on the West Bank (involving Arab countries, the United States and Israel).

The debates were disrupted most of all, however, by the United States' change of position before the conference and the attitude of an American Administration that was more interested in gaining support from the Republican electorate (just one year before presidential elections) than from Third World countries (Finkle and Crane, 1985). Thus, the American delegation in Mexico declared that population growth was unrelated to economic development. It sufficed to free market forces, end state intervention, and, stimulated in this way, economic growth would make it possible to meet the needs raised by population growth. The Administration paid lip service to the idea of supporting family planning to the extent that it contributed to family well-being and was voluntary. Evidently, this line of reasoning removed any economic justification for family planning programs. Paul Demeny (1994) described the U.S. Administration's about-turn as a temporary setback. As the U.S. government has still not returned to its pre-1980s position since this "temporary setback," the expression was perhaps a little over-optimistic. As our analysis of the Cairo conference results will show, there definitely appears to exist in this country an enduring opposition toward government intervention in issues of population policy. This was certainly the message passed on by the U.S. Congress, Republican in majority, contradicting that of President Clinton's Democratic Administration, and recently taken up again by the current president, George W. Bush.

To return to the Mexico conference, the 88 recommendations in the Plan of Action's revised project were adopted, as was a declaration, thanks to the skill of its organizers and the unqualified support of Third World countries. Any modifications, it should be noted, left intact the principles and objectives accepted at Bucharest (United Nations, 1984). Given the restrictions put on the organizers, no radical initiatives could be expected from the revised Plan. Many of the recommendations replicated, with clarifications, those adopted at Bucharest. The conference did innovate, however, by extending the number and importance of recommendations related to the environment and, in particular, to women's status, which were treated in a section of their own. This progress was due partly to pressure exerted on the spot by American feminist NGOs, who were well represented in Mexico because of its proximity; it signified their strong entry into the population debate. At the international level, the same remark could be made about environmental questions. The debate on abortion made a public confrontation on the issue possible. As at Bucharest, the problem of abortion was raised in the section on mortality. Sweden once again expressed reservations, as it would have preferred a more liberal presentation of abortion issues. All its attempts were blocked, among others by the American delegation, concerned not to upset an electorate opposed, in majority, to abortion. As a whole, the Mexico program stayed carefully within the lines drawn in Bucharest's Plan of Action, even though, as we have seen, the politico-ideological context within which it was adopted had undergone rapid changes.

Finally in Mexico, as mentioned, through its opposition to the Population Movement's traditional theses, to whose formulation it had nonetheless so powerfully contributed, the American administration freed the Movement, and UNFPA, from its control and accelerated their internationalization (Finkle and Crane, 1985). Experience would show, however, that American NGOs filled the gap this created to some extent, until the return to power of a new Democratic Administration.

V. FROM 1994 TO THE PRESENT DAY: CAIRO, AN ANGLO-SAXON VICTORY

1. The Political and Institutional Context

In the early 1990s, neo-liberalism became the dominant ideology and only a few isolated countries, such as North Korea, Cuba, and Vietnam still proclaimed themselves socialists, China standing alone as a particular case. With the collapse of the Socialist bloc, the Group of 77, whose Third World ideology, as mentioned earlier, often drew its inspiration from the same Marxist sources as the Eastern bloc countries, was reduced to a group without clear political direction. Asian countries in full expansion, Latin American nations emerging from an economic quagmire, and African countries on the verge of economic disaster coexisted within it with ever-increasing difficulty.

The one-time objectives of transforming the economy and giving priority to the struggle against social inequality gave way to new objectives of State disengagement. Leaving market forces to stimulate economic growth, the state withdrew to the role of umpire for the protagonists involved, while at the same time reinforcing its stately functions. In this context, the traditional struggle for collective rights to be recognized in the economic and social spheres, in which the State and unions had a decisive role to play, has shifted toward new demands bearing on rights related more to individuals or group identity, where other players from the civil society (e.g., NGOs) play a key role. The struggle against social inequality was thus somewhat demoted to second place, in favor of the struggle against status inequalities. This was the context within which the Cairo Program of Action was conceived and which, symbolically, ceased to be a plan as at Bucharest.

In practice, it quickly became obvious that creating an open market could marginalize whole groups of the population in many Third World countries; this was soon echoed in international documents, in which were multiplied the number of recommendations aimed at protecting the most vulnerable groups, such as children, the elderly, women, rural populations, or those termed outcasts, and in which, more generally, the theme of the struggle against poverty received systematic treatment. In this struggle, however, when the State was called in to help, any interventions were viewed as humanitarian measures rather than as a return to a global policy of social justice.

At this point in time, most developing countries certainly had no wish to resolve their economic, social, and, evidently, demographic problems on such terms. It was only later that they came round to the neo-liberal policies omnipresent today.

The debt crisis, which surfaced in the late 1970s and continued into the years preceding the conference, provides a striking illustration of the gulf still existing at this time between the Group of 77's point of view and that of the rich countries. For the 77, this crisis blocked any chance of development and thus the ability to solve their population problems. The wealthy nations, headed by the United States, perceived the use of this argument in international debate, particularly when discussing population issues, as a way of avoiding the real demographic problems and, more particularly, of challenging the new global economic order that was emerging. A theme that united the poor countries, these debates can be seen as the weakened Group of 77's final attempt to recover their influence, lost after their short-lived victory with the adoption of the Declaration on a New International Economic Order. The way in which this crisis was resolved, notably by very strict economic restructuration measures imposed by the International Monetary Fund (IMF), confirmed their waning influence on the international stage. The 77's failure also marked the United Nations' ideological alignment with the neo-liberal ideas of the IMF or the World Bank, dominated as they were by wealthy Western nations; until the 1980s, strengthened by its representation of the Third World, the United Nations had asserted its ideological difference.

Worries about the environment added to those raised by the persistence of the 1980s economic crisis. The Bruntland report (United Nations, 1987) crystallized these concerns and succeeded in mobilizing both public opinion and governments, resulting in the adoption, at the 1992 Rio de Janeiro conference, of a program of action, Agenda 21, whose aim was to make it possible to bequeath a preserved environment to future generations. Concepts such as "durable development" and "sustained growth" today appear inescapable for political and economic decision makers, and mark the strong return of a concept at the very roots of Malthusianism—that of physical limits to growth. Cited in abundance in the Program of Action adopted in Cairo, they are also the expression of a new alliance between ecologists and family planning enthusiasts. We will return to this later. This alliance was all the more necessary that, in the United States especially, economists and demographers, charged with revisionism, undermined the very foundations of the economic justification for fertility reduction. This questioning did not pass unnoticed by a Republican Administration, little inclined to support these programs for diverse ideological reasons, as we saw at Mexico. The United States were in any case against funding public assistance programs, believing that this approach was ineffective and that only the free play of market forces would make economic take-off possible in developing countries.

The demographic situation at the start of the 1990s accentuated still further the trend toward greater polarization among Third World countries, already in evidence in the early 1980s. Government leaders and public opinion would take all the longer to become aware of this radical change because, although widespread, fertility decline was still not universal, and especially because the timing of entry into the demographic transition between 1970 and 1990 varied greatly (see Chapter 69, Volume III). This polarization made for an ambivalent interpretation of the observed evolution. For the optimists, the evolution between the early 1980s and early 1990s was extremely encouraging. The proportion of the world population with a total fertility rate (TFR) at replacement level (2.1 children per woman) rose from 1.2 billion to 2.7 billion during the period. The percentage whose fertility was declining significantly (between 2.5 and 4.5 children per woman) reached 2.3 billion in 1990, compared with 2.8 billion in the early 1980s. Finally, although numbers had fallen from 900 million to 750 million in 10 years, at this time there nonetheless remained a sizeable proportion of the world population still delaying their entry into the second phase of the demographic transition, the phase in which fertility starts to fall. A growing proportion of the population in developing areas, therefore, were showing a certain convergence toward an evolution close to that experienced by developed countries. For their part, the pessimists emphasized the fact that countries where fertility had not yet started to fall were among the poorest on the planet, located for the most part in sub-Saharan Africa, a region which had faced enormous problems during the previous two or three decades, or in South Asia, an equally underprivileged region. They added that the United Nations projections medium scenario indicated that fertility in most African countries would not reached cohort replacement level until after 2025, by which time their population would have doubled, reaching 1.1 billion, compared with 500 million in 1990. This growth constituted a considerable challenge, given their present and future economic potential, not to mention their political situation. Furthermore, countries in transition, which included the most populous in the world, still had considerable potential for population growth; this potential was all the greater given that fertility decline was slow in some countries, or had scarcely begun (as in Nigeria, e.g.). Finally, basing themselves on the medium scenario of the United Nations long-term projections, the pessimists added that the level at which the world population would stabilize moved from 10.2 billion to 11.6 billion in 2100, depending on whether the projections referred to were estimated in 1981 or in 1991 (United Nations, 1991). With the United Nations long-term projection cycle before last (1998) putting the probable level of stabilization once again at 10 billion, it seems today that the pessimists were mistaken (United Nations, 2000b). Ecologists added further to the demo-economists' pessimism by stressing that those yet to be born in developing countries, whether or not they had completed the transition, would be additional producers and consumers whose improved living standards would help destabilize further the broad ecological balance. Paradoxically, the march toward progress of ever-growing populations thus became a new source of concern.

Evolving attitudes toward population growth issues among Third World governments further reinforced this pessimistic trend. In 1993, before the Cairo conference, the last survey that the United Nations carried out on government attitudes toward their country's demographic trends, and on measures taken to respond to problems raised by these trends, revealed a significant evolution during the previous decade. Compared with 37% in 1983, 45% of governments then thought that fertility levels in their country were too high. Moreover, in 1993, 41% of governments interviewed stated that they had adopted a fertility reduction policy, up from 32% in 1983 (United Nations, 1995c).

With growing governmental support for population policy, one might question the need to organize a third conference, extremely expensive in both money and manpower. The Bucharest conference was a response to fears raised by two decades of rapid population growth. Any decision to intervene in this required global legitimacy, and the ethical and political rules of this unprecedented intervention needed to be specified. In Mexico, the situation had already changed: the legitimacy of these programs was no longer in question, especially in the Third World. On the other hand, it was once again necessary to overcome reservations surfacing in donor countries about funding programs whose macro-economic justification was beginning to be replaced by a humanitarian one. On this justification also depended the funding of many other programs that thus entered into competition with family planning programs.

The early 1990s brought an end to the cycle opened by the Bucharest conference. Some believed that it was virtually impossible to update further the Plan of Action that already contained, in its two versions, close to 200 recommendations whose innumerable directives were no longer very convincing. Problems with funding surfaced once more, as the United States republican administration continued to refuse funding to the UNFPA; at the same time, it also started to reduce its bilateral aid. Other countries had taken over (notably Norway, Germany, the Netherlands, and Japan), it is true, but some sponsors, such as Canada, Finland, Italy, and Australia, had also reduced their contribution or stopped it altogether. Third World aid was no longer a winner, and population programs had lost their former priority. As in 1984, it was necessary to try and find ideas that could rouse international opinion and stir it into action. One such idea had already been used with some success by the Population Movement: to link population problems to environmental ones. The second idea was to associate population problems with those of improving women's status (McIntosh and Finkle, 1995).

2. The Players

The same bureaucratic forces at work within the United Nations during preparations for the Mexico conference once again intervened in a decisive way to convince member states of the need to organize this conference. For the UNFPA—directed since Rafael Salas' death by Nafis Sadiq, a woman physician of Pakistani nationality—the conference also opened up the possibility of finally changing the institutional status quo in its favor, enabling it to gain independence from the UNDP and be promoted to the rank of specialized United Nations agency. This was not an unrealistic perspective, given on the one hand the weakening of the United Nations Secretariat, funded by compulsory contributions that were paid ever more unwillingly by some member states, such as the United States and, on the other hand, given the opposite trend, namely the rising power of United Nations programs like UNFPA, which were funded by voluntary contributions. For the first time in the history of plans of action concerning population issues, a paragraph was included concerning the reorganization of this sector of activity (United Nations, 1995b, para.

16–26). The growing strength of UNFPA's position emanates from the expansion of its activities and financial power (its resources grew from several tens of millions of dollars in 1973 to more than 370 million in 2001). Consequently, it is also linked to the fact that donor countries, members of the Population Commission, increasingly turned their interest toward the UNDP's governing body, which managed programs financed by voluntary contributions like those of UNFPA, and where their political control could be freely exercised. This was where the true power games were played out in the early 1990s. More symbolically, the *World Population Situation Report,* submitted regularly by the Population Division to the Population Commission, went completely unnoticed, while the *State of the World Population Report,* submitted by UNFPA to the UNPD governing body, drew the attention of the media, and thus of international opinion, thanks to a huge public relations drive.

In 1989, ECOSOC authorized the organization of a population conference for 1994. Other resolutions later defined the modalities of the organization, its objectives, and the conference location, namely Cairo. Its objectives were the following: to evaluate progress made since the preceding conferences; to heighten awareness in the international community of population problems arising in relation to development; to provide guidelines for the way in which population issues should be broached at the national and international levels; and to adopt the new recommendations. The General Secretary nominated Nafis Sadiq, Director of UNFPA, as conference general secretary, and the director of the Population Division as her deputy general secretary.

Responsibilities were divided, and the preparation organized, much as they had been in Mexico. UNFPA kept its political and financial duties, while responsibility for the scientific content fell to the Population Division. The latter consisted essentially of organizing six meetings of experts before the conference on: population, environment and development; population policy and programs; population and women; family planning, health, and family well-being; population growth and demographic structures; and, finally, population distribution and migration (no expert group was to deal with mortality). It also included preparing the project for the Program of Action (the word *plan,* used for the final conference documents in 1974 and 1984, was dropped). Moreover, five regional conferences were to be held before the Cairo conference. The conference itself, titled the *International Conference on Population and Development* (ICPD), was to discuss and adopt the project for the Program of Action. As before, the most important modification in the preparation process concerned the drawing up phase for the project of the final document. In addition to extending the Population Commission to all UN member states, as it had in 1984, the decision was made to open it equally to NGOs, and to organize numerous meetings with individuals and representatives of the most diverse groups, in order to gather as many reactions to the project as possible before the conference (more than 30 meetings in all).

Opening the Population Commission to NGOs other than those generally associated with it, and inviting these same NGOs into the national delegations, was a decisive element in the orientation the conference would take. It effectively meant saying goodbye to the closed circle of government delegations and welcoming civil society and its preoccupations. Increasingly solicited by government leaders who delegated all or part of their responsibilities to them, these NGOs became inescapable players at the national level (Haas, 1992). It remained to establish whether these NGOs truly represented civil society, itself far from a homogeneous entity, and to ascertain from which countries they originated. The influence of some NGOs in international organizations was comparable, relatively speaking, to that enjoyed by large multinationals (Keck and Sikkink, 1998). With regard to American NGOs, who played a decisive role in this conference, two points can be made. In the United States, NGOs within the population sector were, and still are, financed primarily by public funding (United Nations, 1994, 2002). This was not the case for NGOs working to promote women's status or the protection of the environment, and they thus had more room for maneuver.

A substantial discrepancy has always existed in the United States between the progressive position on population issues held by the majority of NGOs and that of the essentially conservative so-called moral majority (representing the broad mass of mid-America). The progressive discourse of the former nonetheless differs markedly from the Third World or Marxist ideological perspective: little concerned with questions of social injustice, Third World debt, or unequal development, it essentially focuses on inequalities whose origins stem from biological differences (e.g., sex), ethnic identity, or sexual preferences. Within international bodies, this is the most strongly represented group and, until now, it has exerted most of its influence outside the United States, although this situation may well change given the country's current political context. Like NGOs dedicated to population questions, feminist NGOs, primarily North American (especially the New Organization for Women [NOW], which played a critical role during the preparation of the Program of Action and during the Cairo conference), seized the long-awaited occasion to present their viewpoint on population policy. Their influence can be analyzed as follows: on the one hand, they criticize the macro-demographic approach of traditional family planning programs that do not adequately take into account the right of women to control their own sexual health, including, if necessary, their right to abortion in suitable conditions; on the other hand, they are also critical of development strategies that do not take environmental constraints into account, particularly for women in the Third World (Dixon-Mueller, 1993; Germain, 1987; Sen and Grown, 1987; Sen and Chen, 1994). This was the crossroads where the two ideological trends dominating the conference—the feminist and ecological ones—could meet (McIntosh and Finkle, 1995). This coalition could have been created at the expense of the traditional family planning trend, represented by the IPPF, had not the latter already associated itself with it at the end of the 1980s. It was not by chance, therefore, that the IPPF adopted objectives similar to those of the Cairo conference.

These feminist and ecological trends emerged from the Anglo-Saxon world, in power for the last half-century, and bear a strong Protestant imprint which, in the face of society's great problems, places individual responsibility above all other, and has absolute faith in instrumental rationality to resolve them (Finnemore, 1996). Islam and the Latin world remain outside this ideological canvas, and of its conception, for instance, of what the relationship between man and nature ought to be, and of women's place in society (Lassonde, 1996). This Protestant imprint is just as strong in the economic domain, especially in the perception of relations, on the one hand, between the individual and the economic laws of the market, and, on the other, between the individual and the State. To find this essentially American hegemony reflected in many spheres is an important aspect of globalization.

The Program of Action project, drawn up by the Population Division under UNFPA's rigorous supervision, was presented to the Population Commission for adoption. Difficult discussions ensued. The document's very conception, the emphasis placed on "reproductive health" and what this implied in terms of individual freedom in sexual matters, especially that of adolescents and women, as well as the importance given to the abortion problem and to new family forms, provoked a severe reaction from the Vatican and from both Catholic and Muslim countries who viewed it as challenging the values at the heart of their vision of society. Recent studies have shown that the adhesion to, or rejection of, these values constitute one of the most important cultural splits existing between Islam and Western nations today (Inglehart and Norris, 2003). For the first time, a religious divide emerged during preparations for an international population conference. This new split replaced the earlier secular ideological divisions (Marx vs. Malthus), which pitted the East and the West, or the North and the South, against each other at the United Nations. The project document, more than 100 pages long (a record compared with the Bucharest and Mexico texts of around 30 pages each), of which more than 80% had been approved within the Commission, went to Cairo with the most contested paragraphs still without approval.

3. The Outcomes

Conference participation reached record numbers: of the 190 United Nations member states, 182 national delegations were present, bringing together 3,500 delegates. Particularly unprecedented, however, was the importance given to NGOs and the media: 1,257 NGOs attended (of which 23% were American and 15% European), as well as 3,800 media representatives—over 40 times more than at Bucharest. This civilian presence played a significant role, constantly exposing the delegations' deliberations to the gaze of an international public opinion largely won over to the Population Group's perspective, reinforced on this occasion by the ecologist and feminist movements. As at the conference on the environment at Rio de Janeiro in 1992, the conference on women in Beijing in 1995, and at Seattle's trade conference in 2000, the forceful arrival on the international stage of those representing global public opinion resulted in a sort of marginalization of governments in the discussions, and it led to a questioning of, if not the principle, at least the current architecture of these large international conferences. The 1996 Social Summit at Copenhagen, a modest attempt by the United Nations to restore their lost priority to social questions, was a semi-failure, despite adopting such innovative programs as the Program 20/20 (20% of donor countries' aid, and 20% of receiving countries' budget to go toward social programs). A semi-failure with regard to the unwillingness of some industrialized nations to put social questions back at the center of economic debates, the conference was also a semi-failure for the United Nations, who had seen it as an opportunity to recover the ideological initiative, in relation to the IMF and the World Bank.

In one sense, the conference discussion held few surprises compared with what had already surfaced during the preparations. The Vatican, certain Latin American and African Catholic countries, and the

Islamic States were still among the nations most opposed to certain of the Program's paragraphs, particularly those concerned with reproductive health, the family, and women's status. The industrialized nations, Asian countries, and a good number of Latin American and African countries were in favor. The views of the former Eastern bloc as such were obviously no longer voiced, and the Group of 77, presided over by Algeria, kept a low profile.

The project was finally accepted after very lengthy discussions around the controversial paragraphs. This was the case in particular for paragraph 8.25 on abortion and paragraph 5.9 on family forms; a compromise in the document made it possible to unlock the situation in both cases (United Nations, 1995b). The wording of paragraph 8.25 provides an excellent example of the application of what Louise Lassonde termed the "principle of juxtaposition," which consists of juxtaposing rather than synthesizing the most antithetical positions. It is hardly astonishing that the phrasing of recommendations drawn up following this principle is rather obscure!

To general surprise, the Program was adopted by consensus, including the Vatican's. This consensus was accompanied by so many qualifications on the part of the Vatican and other member states, however, that one might wonder whether it was not an entirely new form of consensus. The final document, 100 pages long, contained 11 pages of provisos, a record compared with Bucharest and Mexico. More worrisome, however, was the introduction of a new principle making the application of the Program of Action conditional on the civil and religious laws existing in each country; this principle existed only in its secular form in the Bucharest and Mexico documents, and considerably weakened the Program of Action's field of application.

Comparing the Bucharest Plan and the Cairo Program highlights the degree of innovation in the areas of action envisaged, and especially in the conception of the document as a whole. First, as already mentioned, the Cairo document is extremely voluminous: 100 pages compared with 30 at Bucharest. The conference secretariat registered 243 recommended actions (without taking subdivisions into account) as opposed to 108 in Bucharest. Consequently, the first impression given by the Cairo document is one of great depth and detail in its recommendations, whereas the Bucharest text remained at a more general level. Given the above-mentioned references to the context in which the Program of Action was prepared and adopted, it would have been astonishing if it had been no more than a simple update of the preceding plan. At the purely formal level, a report from the conference secretariat identified approximately only 60 recommendations arising directly from the Bucharest plan, the others dealing either with new problems or broaching old ones in a new way (United Nations, 1995a). Just as when Agenda 21 was drawn up during the Rio de Janeiro conference, the desire to produce a self-sufficient document, with all the recommendations justified by a contextual analysis and a detailed presentation of the objectives, also accounts for the document's large size.

At a more fundamental level, the perspective selected to surmount the population problem was very different from that of Bucharest. This time, it involved encouraging the realization of individual aspirations for improved well-being; promoting reproductive health constituted an essential but not unique element of this well-being, as improvements in reproductive health should also lead to a control of fertility that would benefit the whole group. In implementing this policy, women were the strategic group; the main efforts would, therefore, be directed toward them, not only in the reproductive health sphere but also in terms of education and, more generally, with regard to everything involved in improving their situation. Incidentally, although the French representatives remained rather marginal in these discussions, it should be noted that they could have claimed the intellectual paternity of this female-oriented strategy, as the Marquis de Condorcet advocated it as early as 1792 in his *Sketch of the Progress of the Human Spirit*. On the international scene, the concept of reproductive health somehow sanctioned the fact that women were now taking control of the reproductive sphere, as a result of efforts made by feminist movements for a radical redefinition of the traditional family planning perspective. At Bucharest, fertility reduction was expected to ensue both from the diffusion of family planning in its traditional sense and from the beneficial effects of planned economic growth; at Cairo, however, fertility control appeared essentially as a consequence of specific measures promoting individual rights, in particular those of women. No longer central, as in Bucharest, the role of economics had moved to the periphery of the Program of Action.

In the Program of Action adopted in Cairo, however, elements brought to the forefront in Bucharest were reaffirmed, such as the fact that family planning programs will only be effective if integrated into other broader programs, and if, within this context, individual freedom and responsibility are respected. Most noticeably, new elements entered the picture, such as reproductive health, evidently, a concept that encompasses family planning in its traditional sense, as well as other aspects of sexual life; the essential role given to the promotion and education of women as decisive factors in the evolution of fertility; recognizing free access to contraception for all individuals, even adolescents; problems linked to abortion; the existence of diverse family types; men's responsibilities; on quite another level, environmental problems; and, finally, the need to establish quantitative objectives in the realm of aid for population programs. In the panoply of measures adopted, no reference at all was made to measures of persuasion or dissuasion, so popular in the 1970s.

Although these are certainly positive and innovative elements, the perspective taken led necessarily to important omissions. It is impossible not to be struck by the absolute precedence given to individual considerations at the expense of macro-demographic ones, or to purely demographic issues at the expense of those in which population and economy are closely linked, as was the case at Bucharest. Thus, the economic and social consequences of population growth associated with population inertia are scarcely mentioned. Even though deliberations for a detailed program of economic or social measures could not be expected in a conference devoted to population policy, one might have hoped that the conference would at least provide an opportunity to raise awareness of the considerable problems created by consequences of spontaneous or controlled demographic evolutions (Vallin, 1994). In a conference on population and development, never has the necessity of economic mobilization received so little attention, nor poverty so much, with so little discussion about social inequalities, one of poverty's principal causes. Is this the consequence, already mentioned, of giving priority to the fight against group inequalities at the expense of the struggle against social inequalities? Finally, among the other subjects scarcely touched upon, or even evaded, were questions of bioethics (abusive use of prenatal diagnosis of sex, human cloning, etc.), adult mortality (except AIDS), internal migration (primacy of urban lifestyle, growth of megacities), or international migration (multiplication of the number of countries involved), as well as those linked to population aging (including in the so-called developing countries). More generally, it could be said that the conference missed a perfect opportunity to examine the demographic problems of developing and developed countries jointly; this synthesis could have brought their positions closer and underscored future convergences, persisting differences, and the interdependencies and their consequences, especially in matters of international migration. Once again, the global population problem was addressed almost uniquely through that of developing countries, as though developed countries were in no way involved. In any case, it becomes increasingly difficult to justify this approach given the growing homogeneity of demographic situations, and the increasing irrelevance, in this respect, of the "developed countries" and "developing countries" categories.

Finally, as Alison McIntosh and Jason Finkle (1995) noticed, the participants at this conference, as at other conferences of this type, tended to follow the current political trend, to be "politically correct," and therefore focus on themes popular with public opinion. This convergence is not surprising, and, as already mentioned, it reflects the diverse conference players' ever-growing participation in a global/worldwide society that establishes universal behavioral norms in areas such as population, as well as in the environment, women's status, childhood, and so forth (Meyer *et al.*, 1997). Alongside the United Nations and other international organizations where, traditionally, consensual norms have been drawn up, particularly during the last 20 years, NGOs have had a growing and sometimes competing role in the creation and diffusion of these same norms at the national and international levels. As might be expected, the norms promoted by NGOs are not neutral in relation to their countries of origin. They often reflect their country's ideologico-political choices, and the NGOs influence depends directly on the power (at times termed *soft power* in opposition to military or political power, known as *hard power*) and influence enjoyed by these same countries in the international arena (Boli and Thomas, 1997). The media and experts, often selected because they adhere to these norms, then disseminate or elaborate these very norms, each in their own way.

4. After the Cairo Conference: A Preliminary Assessment

It is, of course, impossible to appraise in a definitive way a still unfinished Program of Action; such an evaluation would, in any case, be delicate for a number of reasons. One stems from the qualitative nature of many recommended objectives. It is difficult to assess whether these objectives have been reached entirely, partially or, even, not at all. As for the quantitative objectives, in the absence of evaluation methods like those used for family planning programs, for example, it is impossible to distinguish the effect specific to Cairo programs from that of other measures which would have been taken in any case, even without this program, not to mention the intersecting influence of different recommendations. Moreover, all countries do not define the content of their population programs in the same way. By adopting the concept of reproductive health, which broadens considerably traditional area of application for population programs, it has become even more difficult to obtain a precise and comparable definition of population program content from the different players involved. Generally speaking, the examination and evaluation process was devised more to verify the extent to which the accepted recommendations had or had not been implemented than to assess their intrinsic effectiveness (United Nations, 1999). During the Examination and Evaluation of Bucharest's Plan of Action in Cairo, it was clear that government delegations, little used to the problems of evaluation, were only superficially interested in the exercise (United Nations, 1995c). Finally, the extent to which these international programs were implemented depended on how implicated the political leaders of the countries involved were, and thus on how committed they were to the norms defined in the Cairo program. On this topic, in-depth surveys were carried out in some countries (Bangladesh, Ghana, Jordan, and Senegal); none could clearly indicate whether the commitment displayed by these countries' political leaders stemmed from their own voluntary adhesion to the program, or whether it reflected a pragmatic attitude toward a program whose implementation would imply substantial financing (Luke and Watkins, 2002).

As we have seen, one objective of large international conferences is to convince governments and the other players involved to make additional resources available; evaluating the financial resources unlocked by these conferences, therefore, is one criteria of their success or failure. It is possible to track the financial resources allocated to population programs in the years preceding and following the Cairo conference. From 1993 to 2003, the amount of aid provided by donor countries rose from 1.3 to 3.7 billion dollars (loans not included). As with previous conferences, however, it seems that the mobilization it stimulated may not last. Some authors write of "cycles of attention" toward specific problems that determine the degree to which public opinion and governments' involvement are awakened, and thus the level of financial contributions (Schindlmayr, 2001). Also, the rising anxiety among a growing number of donor countries about a potential decline in their own population seems to weaken their commitment by obliging them to take an almost schizophrenic position at home and abroad, and helps explain their decreasing interest. Whatever the case, the figure of 5.7 billion dollars in 2000 is far from the one the Cairo conference was looking for. It is nonetheless possible that more funding has, in fact, been allocated to population programs as defined at Cairo, given variations in the definition of such programs among the donor countries. In this connection, it can be said that the allocation of funds by type of activity has significantly evolved. Family planning activities received only 461 million dollars in 2003 against 723 in 1995. In contrast, activities related to reproductive health have increased during the same period by 275% and those related to the fight against AIDS by 1300% (United Nations, 2005). Until the Monterrey International Conference on Financing for Development in 2002, a stagnation or a downward trend of Official Development Assistance (ODA) was observed. It seems that this conference and the adoption in 2000 by the Members States of the United Nations of the Objectives of Development for the Millenium have reversed this trend. Thanks to the commitment of a handful of donor countries, assistance in the field of population has passed the threshold of 2% of ODA to reach 4% in 2003. As a final point, it is worth noting that contributions made by private foundations and NGOs rose from 240 million dollars in 1999 to 324 million dollars in 2003, and, in contrast with ODA before Monterrey, was steadily growing (United Nations, 2002). These contributions come principally from well-established American foundations, as well as from more recent ones, such as the MacArthur, William and Flora Hewlett, David and Lucile Packard, Warren Buffett, William Gates (76 million dollars in 2001), and Ted Turner (one billion dollars between 1997 and 2007) foundations. In addition to these contributions, donations made to a new United Nations Fund for International Partners (UNFIP) are partly committed to population programs (United Nations, 2000a).

An assessment of population program funding needs to underline the fact that more than two-thirds of these programs receive funding from the national budgets of developing countries. A recent United Nations study estimated at 11 billion dollars the internal resources allocated by governments of developing countries to population programs in 2003 (United Nations, 2005). To this figure should be added 1.1 billion dollars contributed by private individuals, bringing the total to 8.9 billion (United Nations, 2000a). The majority of these funds are nonetheless concentrated in a few large countries, like India and China, whereas other countries are not involved at all (e.g., countries of sub-Saharan Africa). Finally, public funding predominates at the international and national levels.

Beating all records in terms of its size and cost, the Cairo conference appears to be the last in the decennial cycle of large world population conferences started at Bucharest in 1974. Faithfully reflecting the power struggles and contradictions of their times, these conferences also acted as midwives, at times unexpectedly, for programs that would influence population policy throughout the world. In 2004, a modest cycle of conferences organized by United Nations regional commissions, whose results will be analyzed by the Population Commission (renamed the Population and Development Commission since 1994), ECOSOC, and, lastly, the United Nations General Assembly, was all that was on offer. These activities are only commemorative, rather than seeking to create a new order, as was the case in Cairo in 1994.

Reflecting current priorities, a Global Commission for International Migration was recently created, jointly presided by a Swedish public figure and a South African. This Commission will be modeled on the World Commission on Environment and Development whose efforts were published in 1987 as the *Bruntland Report*. The majority of governments asked about the direction this commission's work should take, and who responded to a United Nations Secretary General questionnaire on the question, do not appear to wish it to work on policy problems as such, and to have resolutions accepted that could put constraints on member states (United Nations, 2003a). This dual movement toward regionalization and sectorization undoubtedly signals the waning influence on the international stage of the Population Movement, whose global political project had somewhat served the interests of environmental and feminist groups; it is also an adaptation, however, to a new demographic reality characterized by an extreme disparity in circumstances between countries with fertility levels that are still very high, and the growing number of countries in which fertility has plummeted.

VI. THE FUTURE OF GLOBAL POPULATION POLICY

One thing is almost certain about the place of population questions on the national and international political stage in the future: they are not about to disappear. The growth, composition, and movement of populations will always raise policy questions, but two fundamental changes will make it compulsory, among others things, to create new solutions. The first concerns the political, economic, and cultural context, transformed by a globalization whose effects we are only just beginning to see. Extending far beyond its most visible economic, technical, and cultural consequences, the latter "from then on inserts social facts [and thus demographic ones] in a causal chain whose point of departure is global, not local"[2] (Laidi, 1998; p. 95). It would be astonishing if globalization did not elicit, nationally or regionally, the same contradictory reaction in the realm of population as has been observed in other areas. The second change involves the complete transformation of demographic perspective offered at the dawn of the 21st century. After decades spent mobilizing national and international forces in the attempt to curb a population growth feared out of control and thus prepare for a population explosion, the international community now finds itself facing a radically different demographic evolution, dominated by the extraordinary prospect, in the not too distant future, of a stable, or even declining, world population and, in particular, by the uncertainties of what the post-transition period may bring (see Chapter 69).

We will distinguish between two time horizons: the near future of a single generation and the more distant one of two generations (2025–2050).

1. A Single Generation's Time Horizon (2000–2025)

Although fertility levels as a whole continue to converge toward ever lower levels more quickly than expected, the period is nonetheless one of enormous variability, where populations whose fertility has not yet fallen or has just begun to, such as some West African countries, will survive for some time alongside a rising number of populations with a TFR close to 2.1 children per woman, and even populations where it barely reaches 1.2 children per woman (like Italy and Russia). Over the last few years a new element of variability has emerged, one which remains a constant source of astonishment: the evolution of mortality. In a growing percentage of world population, mortality has stopped decreasing, or is actually rising (see Chapter 69). This turnabout in a tendency that we believed achieved is all the more paradoxical in that it is occurring during a period of peace, and in countries as diverse as Russia and Botswana.

It is also the ultimate period of enormous growth in absolute numbers, however: according to the United Nations projections' medium scenario, the population will still grow by 2.8 billion between 2000 and 2050 (United Nations 2003b). Increasingly concentrated in part of the Third World, nonetheless, this growth diminishes rapidly, with an increase of 1.7 billion predicted for the first quarter of the century compared

[2] "... enserre désormais les faits sociaux [et donc démographiques] dans une chaîne de causalité dont le point de départ est global et non plus local" (Laidi, 1998).

with 1.1 billion in the second quarter. Future population growth in the former Third World is characterized not only by its changing rhythm, but especially by changes in the growth components which have policy implications.

First, given the future distribution of populations in the process of transition, the relative weight of different growth components (fertility and mortality evolution, inertial effects from age structure) will not be identical to that of the previous century. With the exception of sub-Saharan Africa, where fertility is still very high, the age structure of the population of reproductive age will be the principal component of future Third World growth. Mortality and fertility decline will be in second and third place, respectively.

Among countries where the transition has barely begun, where the TFR still hovers around 5 or 6 children per woman (24% of the global population), the task will inevitably be to jumpstart it, or speed it up. In the 49 least developed countries, most of which are found in sub-Saharan Africa, the medium scenario of the most recent United Nations projections indicates that the TFR of 5.5 children per women in 1995–2000 will still be at 3.7 in 2020–2025, and 2.5 in 2045–2050 (United Nations, 2003b). Together with a few South Asian countries, sub-Saharan Africa is thus family planning's *final frontier* (Caldwell, 2002). For this subcontinent, the question is to know whether the Cairo strategy, with its call for a coherent and dynamic civil society and a State capable of providing a panoply of social services, is well adapted to the region's circumstances, where family planning programs have still not been systematically implemented or, where they have been, have not met with great success. Geoffrey McNicoll (1995) stresses that part of Asia's success with demographic policy can be put down to the presence of strong governments in the region; this is not the case in Africa. Furthermore, even supposing that international aid is available, it cannot totally replace national involvement, as the experience of other countries has shown. It should also not be forgotten that the AIDS epidemic is particularly violent in the region and that it is unlikely it will be curbed within the given time horizon.

In countries where the TFR is midway (23% of world population), the task remains to bring fertility decline to completion. International aid and continuing attention given to their problems may play a decisive role in making it possible for them to reach the reproduction replacement level of 2.1 children per woman toward 2030–2035, as the United Nations projections' medium scenario suggests. As we have seen, however, this aid is more uncertain than in the past.

Third World countries in which the TFR is already close to 2.1 children per woman will continue to grow, given the growth potential accumulated within the age structures in the course of the decades following the end of World War II. In countries viewing this growth as excessive, it will no doubt be interesting to experiment, at the practical level, with measures aiming to restrict growth linked to the structure of their population of reproductive age, such as incentives to increase the average age at motherhood (Bongaarts, 1994). Furthermore, as the example of countries like South Korea shows, we will undoubtedly witness the gradual withdrawal of the State from support for family planning programs, with contraception increasingly entering into the private sphere.

The final growth wave of almost 3 billion will be a population qualitatively very different from that of the previous century. Restructuring certain population characteristics, such as education levels, labor force involvement, type of employment, and place of residence will trigger radical changes, in addition to the evolution of population numbers between 2000 and 2050. The new generations will be composed of individuals who are mostly literate or even more (especially women), living primarily in the city, some in gigantic urban sprawls. Most are likely to have swapped their ancestral rural values for new urban ones. This new population wave will therefore display very different characteristics from those of the earlier waves that swelled world population during the second half of the 20th century, and which included a high percentage of uneducated rural dwellers. In all probability, the demographic behavior of this new wave will reflect that of a population exposed to modern information systems, more open to the world and more likely to accept new norms concerning family and women's status.

A tendency to worry about population decline is gradually resurfacing among wealthy nations today, as we have seen. The medium scenario of the United Nations projections suggests that the European population (including the Eastern European countries and Russia) should decline by only 4% between 2000 and 2025 and by 9% between 2000 and 2050. These estimations may result from the excessively optimistic fertility hypothesis selected, one assuming an increase to 1.85 children per woman by 2050. Skilled observers of European demography like Thomas Frejka and Ron Lestaeghe believe, on the contrary, that fertility decline is neither temporary nor merely the result of a timing effect (Lesthaeghe and Willems, 1999; Ross and Frejka, 2001). Unworried by their own population, the perception of donor countries had been dominated by anxiety over too rapid population growth in the Third

World. Little by little this perception has changed radically; the rich countries are now reassured about Third World demographic evolution but starting to be concerned about their own. The prospect of seeing populations like that of Italy declining by 20% by 2050, or that of Russia by 50%, could not but spur their governments into action. (Incidentally, corresponding to the United Nations medium variant, these estimates are on the optimistic side for these countries.)

To tackle their declining population, three types of intervention can be envisaged. First, actions designed to act on fertility levels are likely to be inspired by the Swedish model's cocktail of measures, with the emphasis placed on taking collective responsibility for a more or less substantial part of women's tasks; also included will be institutional reforms affecting intergenerational relationships, such as taking more account of the number of children in pension calculations than is done at present. It is interesting to note that, both in developed countries where fertility has plummeted and in Third World countries where it is still high, women are at the centre of political strategies for fertility regulation. Liberated from certain economic and social constraints by policies designed to meet a variety of ends, women seem to be expected to bring their reproductive behavior in line with the collective good. In a certain way, they have become the "invisible hand" of the 21st century.

The second type of intervention concerns international migration. While migrations that help regulate the labour force are tolerated relatively well, this is not the case for what is known as replacement migration, even if its only aim is to slow down population decline. The type of migration that could be envisaged as a remedy for population aging is unlikely to be implemented given the size of population flows needed. Effective or not at the demographic level, international migration holds a privileged place on the international political agenda because of the tensions it arouses within and between countries. The Global Commission on International Migration, mentioned above, can play an influential role in waking the international community up to the size of the problems international migrations are already creating and, especially, those they will create with a globalization movement that cannot be limited to the circulation of material or immaterial goods alone.

Finally, in third place, there exists a type of political route to reach desired population size, a kind of "collective demographic insurance system." By this is meant the constitution of large population clusters through the union of independent countries. Forming these supranational entities makes it possible to transcend the demographic shrinkage of national boundaries. With demographic giants like Brazil and China catching up economically and technically, population size confers an advantage equivalent to that offered by strategic depth. This "demographic depth" thus becomes today an indispensable factor in the race for economic and geopolitical power. The current period, with globalisation as its dominant theme, has witnessed the birth of the European Union, whose population, in its present form of 25 countries, ranked below that of China and India but above that of the United States and even above that of NAFTA (the North American Free Trade Association, which includes the United States, Mexico, and Canada). In the long run, the community institution specialists are already working with the vision of a European Union expanded to include 30 members. It would be naïve nevertheless to assume that this changing geography could remain unilateral: NAFTA has the possibility to expand into South America.

For the first time, however, anxiety surrounding population decline is no longer confined to European countries. In former Third World countries like Singapore, we have witnessed an extraordinarily rapid turnabout in the government's position compared with the delayed reaction of European nations who found themselves in the same situation: within the space of a few years, from being antinatalist, the country became pronatalist (see Chapter 103, this volume). A reaction typical of countries in which fertility is considered too low, the growing role of international migration has started to seriously preoccupy countries like South Korea or Malaysia. Japan, the country with the famous Eugenic Protection Law of 1948, is reflecting on the consequences of its aging and future demographic decline. We can thus expect to see these countries take political action similar to that taken by European governments who had to deal with the problems associated with plunging fertility levels some time before them.

Population aging is among the problems linked to the rapid evolution of fertility and, to a lesser degree, mortality (see Chapters 68 and 69). The abrupt drop in fertility (instances of a transition from 6 to 2 children in the space of a single generation are not uncommon among developing countries, whereas the same evolution required two to five generations in industrialized nations) will bring about a structurally different population aging process (primarily through contraction at the base of the pyramid and, second, by extending life expectancy at advanced ages); more particularly, the process will be much faster than in European countries, leaving the economic and social structures of these countries without the time to adapt to it, and their economies unable to release the necessary resources. This evolution will especially affect East Asian countries, the first to enter the transition, especially giants like China, and then the Latin America countries that followed, and contrary to what is indicated in the Cairo Programme of Action (par. 6–16), the population aged 60 and over in these countries is not composed in its great majority of women since, in 2000, men represented 46% of this age group (Knodel and Oldestal, 2003). Aging is a truly universal phenomenon, and we should not forget that it will continue in industrialized countries. The North and South will experience its consequences very unequally, however, because of differences in economic wealth and variations in the speed of demographic change. According to the United Nations, the proportion of the population over the age of 65 years in developing countries will exceed that of children under 5 years in 2020 (United Nation, 2003b; see also Chapter 77). This inversion of the population pyramid's profile in an exceptionally short space of time will have many consequences for Third World societies, for example, with respect to health policy. Among causes of death in Third World countries, the tendency today is still to assign the greatest weight to infectious diseases although, except in Africa, degenerative diseases have already become the most important cause of death. Their weight will increase further as populations age. In countries with few financial and human resources, the battle against these diseases will encounter considerable difficulties. This means that all international aid policies in the spheres of health and population, up to now centred on early child mortality and high maternal fertility, need to be rethought (Raymond, 2003).

2. A Two-Generation Time Horizon

At the 2025 time horizon, predicted demographic events involve a global population, the vast majority of whom are already born today; this is evidently not the case for 2050, however, and wider margins of error need to be taken account of with the extension of projection period (see Chapter 77).

According to the United Nations projections' medium scenario, the global demographic transition should be complete toward the middle of the century, when the average level of fertility equal to that strictly necessary for generation replacement–2.1 children per woman—will be reached (United Nations, 2003b). This average figure, however, is obtained by combining the fertility of 16% of the population with a TFR still superior to 2.1 (mostly that of least developed countries) with that of the 84% of countries with below replacement level fertility. It is unlikely that governments of these countries, or at least those where fertility had dropped the most or for the longest, will resign themselves to see their population disappear without making any attempt to prevent it. In such circumstances, the population question may once again become a cause of international tension. Pronatal policies implemented unilaterally, and not only in today's industrialized nations, could jeopardize the perspective of world population stabilization, which most governments undoubtedly find acceptable.

It is easy to foresee enormous difficulties with the coordination, at the international level, of new probirth policies that are national, or at best regional, in nature (Harbinson and Robinson, 2002). No existing international power has the legal and fiscal power necessary to implement probirth policies, and it is obviously impossible to say whether such a power will exist in the future. Consequently, an essential task for the international community will be to reach a new consensus about a demographic objective acceptable to all, such as that of a world population stabilized at the level reached at the end of this century. A programmed decline would not attract much support because of the contradictory interests it would put at stake. An international laissez-faire, on the other hand, could lead to demographic fluctuations resulting from an anarchic, or inopportune implementation of population policies, or quite simply from fashionable demographic behaviors.

CONCLUSION

Over the last 50 years, demographic evolution has been a part of the broad movement toward global modernization. What differentiates it from other areas also undergoing this modernization process, such as education or health, where from the start there was consensus about their aim of improving services, is that during the two decades following World War II much effort had to be put into creating consensus around a major objective of population policy: fertility reduction. This search for consensus was not obvious, given the mixed memories left by pronatal population policies that were implemented in several countries during the period between the two wars and sometimes smacked of eugenics (see Chapter 100, this volume). Furthermore, during the next three decades, it required great persistence and ingenuity to elaborate family planning programmes, a field in which little or no previous experience existed.

There was, and still is, no shortage of criticisms and doubts about the effectiveness of these programs, whatever form they have taken through time. A substantial literature on the topic exists. Suffice it to say, at this point, that intervention from the United

Nations, then from governments, NGOs, and the media, have aroused an influential current of international opinion that has greatly contributed not only to legitimizing new norms of reproductive behavior, but also to making them desirable.

As already noted, two main actors took the initiative in mobilising the international community in a unique way; first, the Population Movement (born and nourished in the United States and, to a lesser extent, in Scandinavia), and second, the United Nations. To the former goes the credit for conceptualising the need for action, for raising awareness, and for initiating the first programs; to the second, for legitimising it in the eyes of the international community, as both a human right and a condition for development, and for contributing substantially to its implementation, both financially and technically. The United Nations could be criticised, however, for not taking a harder line with countries implementing policies whose coercive nature violated the very principles and rights the United Nations were supposed to be promoting. The organization could also be pulled up for ceding too often to pressure from the Population Movement, who viewed the global population problem as an exclusively Third World issue, ignoring that posed by populations in industrialized countries. Thus was destroyed a unique opportunity to prepare the international community for the truly universal and prospective vision on population questions that would be needed in subsequent decades.

Between Bucharest and Cairo—the greatest period of mobilization within the international community—the ideological, economic, and demographic context changed radically. It was only natural, therefore, that the Cairo document reflect these changes and suggest new strategies. In 20 years, one of the most important changes on the international stage, and one which may be the most influential in the area of population given its secular association with the State, was the challenge to the State's role as sole player in development, particularly in the Third World. The State of today has ceased to enjoy its privileged position and, as in Cairo, has to compete with new actors, individuals, civil society, and the NGOs that represent it, as well as with representatives of religious forces, something it finds more difficult to allow. Part of the social and economic responsibilities of a strong state, as understood during the last decades—to guide society toward economic development and the demographic transition with a firm hand—had been transferred to representatives of civil society (NGOs, local authorities, etc.) or entrusted to market forces. Paradoxically, however, this reduced state continues to be seen as an inescapable provider of social services in the most diverse spheres, with reproductive health, education, promotion of women, and the like among the most important.

The second change, evidently linked to this contraction of the state's role, is the emergence or reinforcement of transnational players, such as international NGOs. Their influence was highlighted especially in the section dealing with the Cairo conference and its preparation. This is only the most visible aspect of their role at the United Nations, however. In fact, by gaining the status of observers within UN deliberative bodies, they are in a position to circulate their own proposals, and intervene in the debates under certain conditions: in a word, to lobby in order to advance their programs, their ideas, and the norms and values they stand for. Their lobbying is all the more effective given that, recently, some government delegations have decided to include representatives of these NGOs. Finally, NGOs possess their own transnational networks, making their presence felt almost everywhere.

The third change bears on the way in which population policy has been justified. Neo-liberal ideology triumphed, as mentioned, just as new players were appearing on the international stage, with different objectives from those at the forefront in the 1970s. As a result of these transformations, earlier macro-economic justifications were more speedily abandoned in favour of humanitarian ones, among which reproductive health is a good example. As it is impossible to bypass macro-economic rationalisations entirely in the political sphere, an attempt was made to replace the old macro-economic justifications with new environmental ones; arising out of thinking on the conditions for durable development or sustained growth, they were not always obvious to operationalise, as we have seen. Despite these efforts, the new programs adopted in Cairo are, above all, humanitarian ones that clearly differentiate them from those adopted at previous conferences. As programs with an essentially humanitarian calling, however, they risk having to compete with numerous other humanitarian programs which, in some cases, could have demographic effects. Unfortunately, this reorientation is occurring at a time when the slowdown in global population growth, and, in particular, the prospect of population decline in a growing number of countries—often donor countries—may modify their priorities with respect to family planning program funding.

As we have seen, the fourth change concerns the increasing speed at which universal social and demographic norms are diffused and adopted. In recent years, countries as different politically, economically, and culturally (especially with regard to women's status) as Brazil, Turkey, and Vietnam, for example, embraced the reduced family size norm (two children) in a remarkably short space of time compared with the experience in Europe; this duration continues to shrink in the most recent countries to enter the demographic transition. The demographic transition seems to have freed itself from certain of the initial model's constraints. It is drawn along by the vast modernization movement within societies, itself accelerated by the recent globalisation phenomenon that fuels the diffusion of types of behavior until then limited to the most developed countries.

This is the new context within which future demographic evolution, and the inevitable political reactions it arouses, will take place. With the end of the transition toward the middle of the century, and world population potentially stabilized by 2075, we will witness a vast demographic transformation that will radically alter the international demographic scene and, more generally, our perception of population issues. Only 10 years ago, such a rapid evolution would have appeared utopian. In 1992, as mentioned, the United Nations did not predict stabilization before 2100 (United Nations, 1992). The transition may end sooner than expected, however, and may also spell the entry into unknown territories that will have to be explored without the precious guide provided by the transition's theoretical schema (see Chapter 69). The post-transition era opens up all kinds of possibilities, such as global population stability at the level achieved before the end of this century, gradual decline, or fluctuations around a point of equilibrium constantly pushed forward (see Chapter 78).

Before reaching that point, the international community is likely to have to manage extremely diverse demographic situations, characterised by fast growth in a minority of countries and by population decline in an increasing number of them. Like any period of rapid change, this may also prove to be a time of great tension, and a return to state intervention in countries concerned by an uncertain demographic future is probable. It will also be a crucial period, allowing the international community to prepare for the post-transition period. As happened in the 1960s and 1970s, a new consensus needs to be created around a universally acceptable demographic goal, and international institutional mechanisms must be designed to reach it. Whether or not this new consensus will be instigated through the efforts of a new *Population Movement*, only the future will tell.

Acknowledgments

This chapter is a revised and extended version of a chapter on the same theme in a collection published by INED (Chasteland, 2003).

This chapter was translated from the French by Heather Juby.

The author would like to thank Jean-Claude Chesnais and Jacques Vallin for their careful rereading of this chapter and for their stimulating comments.

SECTION

II

OBSERVATION, AUXILIARY METHODS, TEACHING AND RESEARCH

Introduction

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

This is the final section of Demography: Analysis and Synthesis. Volume I, Section I looked at the central study of the discipline—the in-built mechanisms of population dynamics. Volumes I, Section II, and Volume II went on to address the determinants of the three big forces of population change—fertility, mortality and migration. Volume III, Section I drew on all this groundwork to paint a broad panorama of the historical and geographical forces behind population processes and sketch out prospective future medium and long term trends. Volume III, Section II then examined the biological, economic, social and political consequences of demographic changes and, more generally, the big issues facing society on the cusp of these changes. Volume IV, Section I, on population thought and policies, considered whether society ought to and can act to shape the course of demographic processes, and with what likelihood of success.

While all the big issues of population dynamics had arguably been touched on over those seven volumes, there was nevertheless thought to be a useful purpose in adding an eighth volume given over to a number of matters which either did not fit into or had been broached only to a very small extent or in passing within the closely-ordered framework of the previous seven.

This section in fact does three quite different things. It first sets out to give a more systematic overview of an overarching issue in demographic research: data sources and quality, and how to maximize the use of defective sources. It was thought that this key topic was best placed at the end of the work where readers might find a greater relevance in it after having explored the issues involved through those of the analyses done in the first 3 volumes. Then, some explanation was also needed of a number of analytical tools borrowed from other disciplines that are either extensively used in demography, or have become sufficiently specific to it to warrant inclusion in a treatise on demography. Nor, obviously, could the final word be said without some specific consideration of the discipline itself: its history, how it is taught, and trends in current research. Although each of these merited a separate small volume to itself, the choice was made to consolidate them in a single volume since, to some extent, they work across boundaries in the discipline, from three different angles: sources, the methodological input of other disciplines, and the historical dynamic of the discipline from the very beginnings to the issues for the 21st century.

Part One, Observation Systems and Indirect Estimation Methods, gives the necessary overviews of two aspects that recurred in each preceding volume, but only ever tangentially and never fully, in relation to discussion of whether a particular analysis could be done using available data, or whether specific data needed to be collected, or indirect estimation techniques used, without ever touching on demographic data collection as such, or the processing of imperfect data. Six chapters are devoted to data collection: the first gives an ordered overview of the different data sources, while the other five each address a more specific aspect that seemed to require a more particular focus here. A further three chapters look at the analysis of imperfect data, with particular reference to the specific requirements of historical demography in one case, and those of developing countries in another.

Part Two, Statistical Analyses, Specific Tools and Qualitative Approaches, brings together a number of methods that are auxiliary or supplementary to demography and are either simply borrowed from other disciplines, or the result of recent developments in particular methods which, while not entirely unconnected with demography, evolved out of (or are being developed from) exposure to approaches prompted by other disciplines. They cover a wide range of different standpoints from the philosophy of science to the most practical statistical methods. There are three main focal points to this section: qualitative approaches, statistical tools and the outputs of individual data analysis.

Part Three, History of Demographic Science, Teaching and Research, offers a panorama of the history of demographic science, from the pioneers who invented it up to those who much later named it and gave it structure. It will also give thought to developments in how the discipline is taught, and in the production of teaching aids, from treatises on demography through learning materials up to computer programs. It concludes with a review of recent and current research, and the small community of demographers as it prepares to confront the scientific challenges of the 21st century.

I

OBSERVATION SYSTEMS AND INDIRECT ESTIMATION METHODS

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

As stated in the introduction to this section, this first part aims to give a more systematic overview of an issue that is of overarching importance to demographic research, but tends to deter readers not motivated by having a basic knowledge of how significant the outcomes of an analysis of adequate data can be. Investigating existing sources or having to contrive and develop a complete set of new data presupposes having a research purpose in mind, whence the decision to leave the topic until the very end. The issue of data that can be used or needs to be collected has certainly been touched on in the previous volumes, in particular when it dictated the kind of analysis proposed or could bias the results, but never more than to a minor extent and in passing, dealing only with what was strictly necessary for the purpose of the specific chapter topic, without ever discussing demographic data collection proper. It is now dealt with in six general and specific chapters in this volume. Furthermore, a substantial proportion of demographic data may be incomplete or defective, and this raises particular and often awkward issues for analysts. This is considered in the remaining three chapters.

The section on demographic data collection opens with chapter 121, in which Dominique Tabutin gives an overview of demographic data collection tools, whether from mainly administrative sources, where demographers tend to have little direct involvement in their production, the two most traditional sets being vital registration and population census statistics, or data that more or less directly address demographic research issues, usually obtained through specific surveys, not forgetting all the other forms of collection ranging from simple administrative files to the most complex continuous recording systems, and to the possible linkage of data sources.

The following five chapters then focus on particular aspects of demographic data collection, which may be specific either to the research topic, or to the methods of collection. When evaluating Volume II in Section II, on the determinants of migration, the INED publications editorial committee pressed for a specific, in-depth discussion on data collection for the analysis of migration to be included in this treatise. This valid idea is therefore addressed here in two chapters on observation and concepts in internal migration (chapter 122, by Brigitte Baccaïni) and in international migration (chapter 123, by Corrado Bonifazi and Salvatore Strozza).

Chapter 124 deals with a very specific method of collection devised purely in response to prompting from researchers (demographers, epidemiologists and public health specialists) in a bid to remedy the lack or serious failings of more traditional sources, through the long-term systematic and continuous collection of all the data essential to gaining a knowledge of a comprehensively-observed small population. Gilles Pison examines the specific benefits and limitations of demographic surveillance sites, which, on the restricted and, of course, non-representative, territory that they cover, in fact go well beyond simply making good the gaps in vital registration records and censuses.

Finally, in chapter 125, Viviana Egidi and Patrick Festy address the many facets of comparability of international demographic statistics, the desirable harmonization of which faces problems that may be insurmountable without a compromise between comparability and data quality.

Part One concludes with three other chapters dealing with methods that demographers often need to use as a "get-around" to extract meaningful, not overly-biased, conclusions from data that are incomplete, insufficient or of doubtful quality. Two areas in which specific demographic formulae have been applied—historical demography and the indirect estimation of basic demographic indicators for populations (initially in developing countries) for which only imperfect data are available—have expanded remarkably in recent decades, and their value is not set to decline anytime soon.

In Chapter 126, Lorenzo Del Panta, Rosella Rettaroli and Paul-André Rosental look at specific methods in historical demography where direct investigation of now-defunct populations is impossible, and so any means available must be used to try and reconstruct population statistics from a very wide range of often fairly deficient sources. Some, like the old parish registers of Europe, are not far-removed from our present-day systems of vital registration (although sometimes very incomplete), but were only very seldom or partially investigated in their time as a source of demographic data. Their statistical exploitation must therefore be done ex post, usually by sampling to limit costs. But this kind of source is far from historically or geographically universal. The historical demographer has therefore to take into account the paucity of data and the many pitfalls of all kinds from other entirely discrete sources. Consider, then, the plight of the pre-historical demographer!

The indirect estimation of demographic indicators proper ranges, at least in theory, across a field even wider than that of historical demographers, who may at times be able to make as valid use of it as the specialists in developing country demography, by and for whom it was developed, and may also prove useful in the context of countries with highly developed statistical records to address certain particular issues. On the other hand, it is technically far more specific to a particular problem: can indirect observations be used as basis for making any (or more reliable) estimations of demographic indicators that cannot be calculated at all, or with sufficient reliability, due to the lack or inadequacy of direct observations? Kenneth Hill considers this in chapter 127.

Finally, in chapter 128, Josianne Duchêne looks at the history of model life tables, and examines the different means of constructing model life table networks. This specific tool of demography, which is equally essential to the development of indirect estimation methods and the specific reconstructions of historical demography, has its own more general scope, not least of which is framing population projections.

Information Systems in Demography

DOMINIQUE TABUTIN

Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

Every science is based on observation, on collecting new data or assembling available data. Demography is no exception to this rule: there is no demography without data, nor are there data without information systems, data sources or data collection methods.

After some brief general remarks on observation in demography (history, position, role), each of the major existing systems will be presented here: continuous registration (civil registration data, population registers and laboratories), censuses (of which there are currently various types), surveys (of varying natures and procedures), without forgetting to include remote sensing, administrative information systems, and qualitative approaches. The advantages and limitations of each system will be discussed and the latest methodological developments will be mentioned, both in developed countries and developing countries.

However, this chapter will only discuss the observation of population phenomena (structure, fertility and nuptiality, mortality and morbidity, and migration), thus excluding, due to lack of space, purely health and socioeconomic information systems. Moreover, the diversity of methods and the variety of problems are so considerable that we will simplify and summarize them as much as possible in order to make the synthesis as readable as possible.[1]

I. FROM OBSERVATION TO ANALYSIS

At the beginning of any research, researchers find themselves faced with a vague reality, especially if the subject or issue under consideration is new. They perceive it subjectively through a prism of varying degrees of deformity, depending on their *a priori*, culture, ideology, and experience, even though, as privileged and well-informed observers, they try to understand and measure in as objective and neutral a way as possible (Fig. 121–1). To define it, they should gather new data or make a selection from the observations already made by others. The data collection strategy should be well thought out before being operationalized according to precise objectives and according to the hypotheses to be verified. The hypotheses may be imagined or result from the existing theoretical corpus.

These three major phases of collecting raw data, producing and monitoring the indicators (rates, etc.), as well as modeling and causal research, are interdependent within the scientific process, even if they follow one another chronologically at the operational level. Data collection precedes analysis, analysis depends on collected material and it is therefore essential that the information system is set up (a survey for example) or that the selection of existing data be organized according to the hypotheses or types of analysis clearly stated at the beginning.[2] In other

[1] For further detail, readers can easily refer to one of the numerous publications devoted to the subjects discussed here or listed in the bibliography.

[2] Without, of course, forgetting common problems encountered by researchers such as lengthy waiting time for results and financial or human resources.

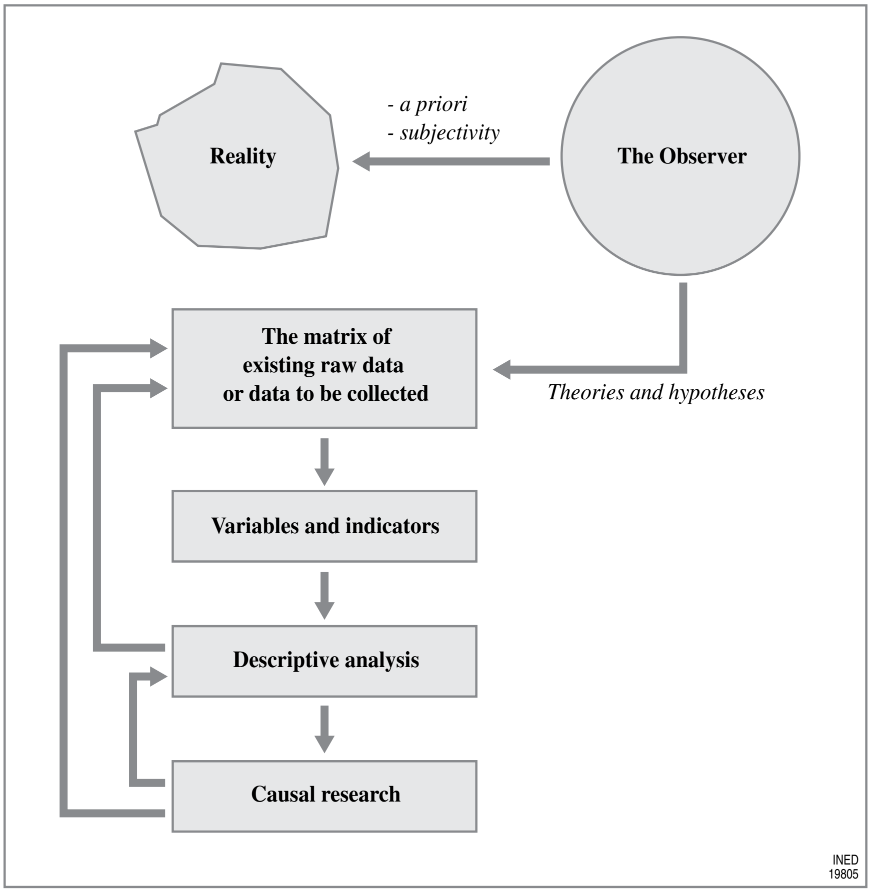

FIGURE 121–1 From reality to observation and analysis.

words, *strategies for the collection of data and analyses should be well thought out and integrated at the beginning of any study*.

II. HISTORY AND ROLE OF OBSERVATION IN DEMOGRAPHY

1. A Brief History

More so than statistics in the general sense, scientific observation in demography has only a brief history, even though before the appearance of the term demography (Guillard, 1855), and the constitution of a real technical corpus (20th century), a number of sources and collection operations useful to the subject had come into being. The majority of these were of an administrative nature, with frequently fiscal objectives and limited geographic coverage.

The first population *enumerations* go back to Early Antiquity (Mesopotamia, China, India, etc.), and the era of the first large centralizing empires (Tabutin, 1984b; Hecht, 1977; Vilquin, 1983; Dupaquier *et al*., 1985). In Europe, the Middle Ages was a period of eclipse, but it was with the mercantile system and the formation of states and centralized governments that the need to measure the population reappeared: surveys and censuses increased from the middle of the 17th century with mainly fiscal objectives. It was only at the end of the 18th and the beginning of the 19th century that we moved "*from administrative observation to scientific observation*" according to Louis Henry (1963). In Europe, the first real national censuses were mostly carried out during the 19th century[3] and their history is even more recent in the rest of the world. Apart from some countries under English rule, where censuses were organized from the end of the 19th century (1872 in India, 1881 in Pakistan), in most Latin American countries the first censuses were carried out

[3] With some countries like Sweden being in advance (1749), and others like Italy (1861) and Canada (1871) being delayed.

in 1900, 1910, or 1920. In the remaining Latin American countries and in Asia this only occurred after World War II, and in a considerable number of sub-Saharan African countries it did not happen until the 1970s.

In Christian Europe, parish registers were the origin of modern *civil registration data*. From the middle of the 16th century,[4] parish priests were to some extent obliged to keep records of baptisms, marriages, and burials, for accounting purposes and as legal proof (of religion and affiliations). Seldom exhaustive before the 18th century, these records are nevertheless the basis for many reconstructions of local population history. However, as was the case for censuses, modern civil registration systems did not cover the whole of Europe or leave the hands of the Church for those of the state[5] until the end of the 18th century. In parallel, the Netherlands (in 1829) and Belgium (in 1856) set up the first *population registers*. In developing countries, the history of civil registration data is entirely different: even though the obligation to register sometimes dates back to the 19th century (1884 in Brazil, 1882 in Algeria), it was rarely aimed, in the beginning, at the whole population, and in many countries the system did not really begin to be developed until the 1950s or 1960s, while to date the coverage rate for civil registration data records remains very poor in a considerable number of cases (notably in sub-Saharan Africa and South Asia).

Although the theoretical foundations of the *demographic survey* of representative samples of the population was established during the 18th century, resulting from the development of the theory of probability, there were hardly any concrete applications to social science before 1910.[6] In demography, this method was only really adopted after the World War II, initially in developed countries, to supplement data taken from civil registration, followed quite rapidly by developing countries to make up for the shortcomings of the civil registration data or instead of censuses, but also as an independent source of information—in particular on practices and attitudes regarding fertility. Today, it has become a major source of information in population research, and in many developing countries is even the main source.

2. Status of Observation in Population Science

Demography has a historical specificity: for a long time, observation was mainly carried out by administrative bodies (statistical offices, ministries) without any particular relationship to universities or research. These bodies had a near monopoly on observation, while in other scientific areas, as Louis Henry (1963) wrote: "*theoretical considerations, observation, analysis, and education are closely linked, if only because the same person considers, observes, analyses, and educates.*" In demography, teaching and research are, as a result of this, developed in universities,[7] cut off from observation, or, in any case, with little influence on it. The situation has obviously changed and the separation is less distinct than it was at one time: because of their main objectives, censuses, civil registration systems, and population registers still depend on the administration (they are even sometimes called *administrative sources*), but the relationship between those who produce the data and those who analyze them has become closer and has improved: statistical monopoly (or the idea of a monopoly) has lessened and cooperation between administration, research, and education has developed considerably, both at the level of dialogue on concepts and methods, and with regard to access to data and circulation of results. Not only does this trend fulfill the increasing needs of the administration and the government for information to be as objective as possible, which only a rigorous scientific approach can provide, but it has been significantly strengthened by the growing importance of survey methods which, while being more complex, are also lighter and less expensive than the traditional sources and the nearly endless growth in the analytical capabilities provided by the computer revolution. These developments certainly do not occur at the same time or at the same rhythm, but the trend is a general one.

Despite all this, researchers in demography retain less control over their observation sources, and the problems associated with data collection methods is not their main concern. To achieve the scientific recognition of their peers in demography it is better to be an analyst or a theorist than a specialist in data collection. This is verified by the low number of articles on observation published in international journals and the near

[4] 1539 in France, 1538 in England, 1563 in Belgium. See, among others, for the history of parish registers: Guillaume and Poussou, 1970.

[5] Here again, the Scandinavian countries (Finland, Norway, Sweden and Denmark) were pioneers, as their national systems were constituted around 1730. In France, parish registers were replaced by civil registers in 1792. In the United States, the system was implemented in the whole of the Federation in 1841.

[6] Arthur L. Bowley in 1913 was the first to use the survey method for a sociological study on the condition of the working class in five English towns.

[7] Except, for example, in France where it is mainly carried out at the Institut national d'études démographiques (INED).

absence of this issue in international conferences.[8] This is particularly true in developed countries where researcher-demographers frequently remain far from the field.[9] The problem is represented differently in developing countries, where administrative sources are rare and sometimes poor and where surveys are all the more numerous as researchers must frequently create their own collection tool: designing questionnaires, checking the quality of information, and adjusting incomplete data are all part of their daily work. Here the risk for the researcher is to be monopolized by data collection and not concerned enough with detailed analyses.

3. The Dependence of Developing Countries with Regard to Information Systems

Each developed country controls its population information system, determines its budget, priorities, the periodicity of activities, etc. There is a certain heterogeneity within a region such as Europe. In developing countries, even though the situations vary, few countries, particularly among the poorest ones, have the means to carry out large-scale data collection with their own funds. The majority depend largely (and sometimes completely) on international donors or bilateral partners, international data collection programmes (such as the World Fertility Survey of the 1970s, or the Demographic and Health Surveys of the 1980s and 1990s). This financial dependence, which in itself results in considerable scientific dependence, increases with the cost of operations and economic inequalities. In these conditions, how is it possible to establish a national medium- and long-term collection strategy?

III. A TYPOLOGY OF DEMOGRAPHIC OBSERVATION SYSTEMS

Table 121–1 provides a general overview of the different data collection sources and methods currently used all over the world, and indicates the importance of each one for each region (developed or developing), the observation unit that it uses, and the main objective assigned to it (movement or structure). It highlights six very different large systems, and the largest ones (continuous recording, censuses, and surveys) are accompanied by a certain number of subsystems or specific methods.

1. **Continuous registration systems**, of which the best known are *civil registration*, the *population register*, and the *demographic surveillance system* or *population laboratory*, i.e., a kind of permanent observatory of population dynamics covering a small geographic area, instantaneously (or almost instantaneously) measure basic demographic events.[10]
2. The main objective of **censuses** is to enumerate the population and obtain a cross-sectional knowledge on its demographic, social, and economic structures, etc., at a given time, even though they nearly always include questions regarding migration, and quite frequently in developing countries (direct or indirect) questions regarding fertility and mortality. The basic principle of the census is to exhaustively cover the target population, even though a census survey carried out on a relatively high percentage of the population in question is sometimes incorrectly called a *microcensus*. Censuses remain common practice, even though recently some European countries are attempting to replace it with population estimates supplied by information from registers.
3. **Demographic sample surveys** are extremely diverse both in their objectives and in the size of the samples used, the observation methods implemented, and naturally the cost of the activity. Six large categories can be distinguished according to the method used to observe the events: the *retrospective survey* over a short period, collecting events which occur over a short period, generally 12 months preceding the interview; the *biographical survey*, collecting all target events which have occurred over the life course of each respondent; the *multiround survey*, collecting events at a given round which have modified the observations made during the preceding round;

[8] Of a total of 269 sessions organized during seven conferences of the International Union for the Scientific Study of Population (IUSSP) from Mexico in 1977 to Salvador de Bahia in 2001, only 12 dealt specifically with data collection or information systems. Of the 88 sessions of the Salvador de Bahia conference, only 3 dealt with this subject. The themes were "The collection of demographic statistics," "Qualitative methods in demography," and "Census data in the 21st century," respectively.

[9] Even though today, in the increasing number of studies on international comparisons, they are more concerned with the problems of information systems, which could hamper the comparability of definitions, concepts, indicators, and therefore the results.

[10] It must however be noted that, generally, civil registration data do not cover migration, which in a few countries is subject to systematic obligatory declaration, as is the case in Italy, for example. On the other hand, contrary to the two other sub-systems, civil registration data do not provide population estimates that can be used as denominators to the rates.

TABLE 121–1 Typology of Information Systems According to Their Frequency, Observation Unit and Main Objective in Both Developed and Developing Countries

System	Developed Countries	Developing Countries	Unit of Observation	Main Objective
Continuous registration systems				
Civil registration data	xxx	xx	Individuals	Movement
Population registers	x	–	Individuals/Households	Movement /Structure
Demographic surveillance/ Population laboratory	–	x	Households/Individuals	Movement
Medical registers of births	x	–	Individuals	Movement
Censuses				
Traditional censuses	xxx	xxx	Households	Structures
Censuses based on registers	x	–	Households/Individuals	Structures
Microcensuses	x	x	Households	Structures
Surveys				
Short reference period survey	–	xx	Households	Structures/Movement
Retrospective or biographical surveys (births, marriage, child mortality, migration histories, etc.)	x	xxx	Individuals/Households	Movement
Multiround household surveys	–	xx	Households	Structures/Movement
Longitudinal prospective surveys monitoring births or individuals	x	xx	Individuals	Movement
Repeated or trend surveys	–	x	Households/Villages	Movement
Dual record system	–	x	Individuals	Movement
Medical and administrative registers	xx	–	Individuals	Movement
Aerial photography/Remote sensing	x	x	Districts/Villages	Movement
Qualitative surveys	x	x	Communities, households, and individuals	Understanding/Explanation

xxx = very frequent; xx = quite frequent; x = infrequent; – = never

cohort studies, a form of *longitudinal prospective studies*, where events in the lives of individuals born in the same year or who fulfill certain criteria are monitored over a number of years; *repeated* or *trend surveys*, which are much less widespread and which consist of repeating, after a relatively long period, a survey which is more or less identical to the preceding one; and finally the *dual record system*, the coupling of observations made during two independent surveys (or other information systems) carried out on the same population, in the same time period.

4. **Aerial photography and remote sensing** are geographers' methods that are useful for studying urban or rural populations and drawing up samples.
5. **Administrative registers** of schools, medical establishments, social security, and companies, etc., are also an additional data source, up-to-date but rarely exhaustive.
6. **Qualitative surveys** are more anthropological in nature and their objective is not measurement, but understanding, and are generally carried out on small samples.

The following sections will be particularly devoted to civil registration, population registers, censuses, and surveys. The other approaches will be the subject of a more succinct discussion, while the final section will deal with the problems of protecting privacy and some general comments.

IV. CONTINUOUS REGISTRATION SYSTEMS

Civil registration data, population registers and demographic surveillance systems aim above all to record events and, to ensure that the recording is as comprehensive as possible, they are designed in a way that minimizes the time period between the event and the recording of the event.

1. Civil Registration Data

Civil registration can be defined as a *continuous, permanent, and obligatory recording system of the events which establish or change an individual's civil status* (birth, death, marriage, divorce, separation, annulment, adoption, etc.) (Tabutin, 1984b, p. 63–64; United Nations, 1973, p. 155–172). It is a national and legal tool everywhere, under the responsibility of the public authorities. Civil registration is a precious resource for population studies but it also has its own limitations, while its spread to developing countries is far from generalized.[11]

a. Advantages and General Limitations

In addition to its primary function of providing legal proof (of an event, an identity, kinship ties, etc.), civil registration has a statistical function and this, of course, is what interests the population scientist. It is the only source that regularly provides[12] the numbers and main characteristics of births, deaths, stillbirths (i.e., late fetal deaths), marriages, and divorces at every geographical level (from the ward to the entire country). It also makes it possible to follow population trends (size and structure) and, notably, to undertake period and cohort analyses of fertility and mortality in all the more depth due to its secular nature. Most frequently however, the system ignores migration, and therefore limits the analysis of population dynamics to natural increase. Furthermore, it only records official marriages and divorces and excludes other unions (consensual and traditional), which are common in many developing countries and increasingly so in Europe and North America.

Almost everywhere in the world, civil registration is nevertheless the essential knowledge base for population change, causes of mortality (here it is irreplaceable), general characteristics of childbirth and children at birth (sex, legitimacy, weight, gestation period, type of childbirth, birth order, etc.,), and those of the parents (age, occupation, level of education, etc.). The types and number of variables selected in the statistical reports obviously vary considerably from one country to another but they make it possible to carry out numerous analyses, differential studies, and measure biological or social risk factors.

This source of abundant information does not however fulfill the growing needs of population research, which looks increasingly towards the explanation of phenomena. This requires numerous economic and social variables regarding the individual, his/her spouse, family, and environment, both with regard to the current situation and the past, which cannot appear on a simple statistical civil registration form.

Moreover, the requirement of exhaustiveness is not always compatible with the collection of detailed, good-quality data. For example, the recorded cause of death is frequently imprecise,[13] with confusion between primary and immediate causes, while changes in nomenclature cause comparability problems over time (Vallin and Meslé, 1988, 1998). Another example, weight at birth, which is available in many European certificates, is often only approximate and, again, the declared occupation (that of the parents for a birth, or that of the deceased for a death) is frequently too vague. The quality of data collected of course varies over time and space. It depends on the practices and diagnoses of the medical profession, the competence of the staff in civil registration offices, coding rules, and data management, but also frequently on the quality of the administrative or medical documents on the basis of which the statistical forms are filled.

Another problem that is crucial for comparison over time or space is the variability in the legal definitions of events, particularly regarding stillbirths and live births. In Europe alone, despite World Health Organization's (WHO's) recommendations and efforts at statistical homogenization in the region, registration criteria still vary considerably (Gourbin and Masuy-Stroobant, 1995). For example, although WHO has for a long time recommended that each birth where the child has shown any sign of life should be recorded as a live birth, in 1998, 5 out of 22 European countries still restricted the criteria by limiting the type of sign of life required or by requiring a minimum life span (Czech Republic). This has resulted in five different definitions. In the same year, only four countries followed WHO's 1975 recommendations on stillbirths[14] and, in

[11] For further information beyond these two points developed here, notably on the diversity of the operating methods and content of civil registration data, the reader can refer to specialized publications (United Nations, 1973, 1985; Tabutin 1984b, Chapt. 3; Linder and Moryama, 1984; Lohlé-Tart and Clairin, 1988).

[12] The results are generally published by year, and less frequently by quarter. Publication most often occurs within a relatively long time scale: from 1 to 2 years, and sometimes even more in some developed countries, such as Belgium.

[13] In Europe, for example, badly defined causes of death varied according to country—from 1% to 12% in 1990 (Meslé, 1995).

[14] According to these recommendations, a miscarriage should be considered a stillbirth (or late fetal death) if the gestation period lasts for at least 22 weeks or if the child weighs more than 500 g. Only Finland, Portugal, Belgium, and Poland adhere to these recommendations.

2003, there were still seven different definitions of stillbirth in Europe. This results in problems and requires the greatest prudence in international comparisons, notably when relating to rare phenomena that are sensitive to changes in definition, such as the rate of stillbirths, perinatal mortality, or infant mortality in developed countries. Depending on which definitions are used it is even possible to obtain different classifications of the countries (Masuy-Stroobant, 1994; Höhn, 1981).

b. The Situation in Developing Countries

These few problems that are inherent to every civil registration system are however negligible compared to those faced by the majority of developing countries. Without going into too much detail here,[15] let us say that there are problems of variable intensity according to region in the level of coverage, the type of data collected, and their use.

The coverage of events by the system is frequently incomplete and sometimes even unknown, and is rarely above 90%.[16] The situation is particularly bad in South Asia and sub-Saharan Africa where, in some cases, civil registration only really functions in urban zones. Generally, the coverage rate is always lower in rural areas than in towns. It is frequently lower for deaths (15% to 60% in sub-Saharan Africa) than for births (30% to 80%) and it is lower again for marriages. In a certain number of countries, the coverage has improved over time (in North Africa and Latin America, for example), while in others it is stagnant or has even regressed.

The data collected varies from one country to another. However, it is often limited to the minimum of information, sex, date of event (or of registration), place of the event, age of the mother (for a birth) or the deceased (for a death). Sometimes marital status is also included (of the mother or the deceased), or the father's nationality or profession. It is much rarer to find variables such as parity or education of the mother (or the father), the length of the gestation period, and the weight of the child at birth (United Nations, 1985, p. 41).

The processing, publication, and analysis of civil registration data is generally only very partial and incomplete, in the best of cases only resulting in the publication of some basic data such as the annual number of events or distribution according to sex or age group (of the mother or the deceased). Much of the information is not processed, and when it is used it is frequently with considerable delay (2 to 5 years).

The weaknesses and shortcomings of civil registration systems in developing countries are due to a large number of combined factors, such as the system itself (lack of infrastructure, resources, competent staff in the area of registration and analysis), the population (ignorance or lack of motivation), or the authorities (who give low priority to the problem). Numerous projects, whether stimulated from outside or not, have tried to improve the system, notably in sub-Saharan Africa, but the majority has had little effect. In reality, the civil registration system cannot function correctly without a strong and well-organized territorial administration, without any real legal obligation and sanction, without the population becoming aware. What can be done in the meantime? We can use and analyze existing data (data from towns, for example), motivate statistical institutes, train population scientists to specialize in the area, rehabilitate as much as possible the image of this information system. But in many countries it will take a long time before the civil registration system becomes a reliable source of national population measures and before it will be able to provide information for proper population registers.

2. Population Registers

From the 19th century, population registers were set up in some European countries with wider objectives than those of the civil registration system. The population register can be defined as *a permanent and continuous system of demographic and social information on each individual and household in a given territory*. Initially local, now frequently national (it is now called a National Register), it is progressively becoming a paramount and promising source of administrative and scientific information that obviously has its advantages and its limitations.[17]

[15] For further information, please refer to specialized publications that either provide an overview of the world situation (United Nations, 1985) or perspectives by major regions, like Africa (François, 1988; Gendreau, 1993; Garenne and Zanou, 1995).

[16] According to an already old survey carried out on 112 countries, the United Nations (1978) estimated that of 93 developing countries, only 28 for births, 25 for deaths, and 19 for marriages had a coverage rate of over 90%. This rate is unknown for 10 others (United Nations, 1985, p. 37). There is no precise recent data available, but generally, it would seem that the situation has changed little since then.

[17] For some publications regarding population registers, see United Nations (1969), Verhoef and van de Kaa (1987) or Poulain *et al.* (1991), for example.

a. Local Population Registers: Philosophy and Content

The local register system is not new. It dates back to 1749 in Sweden, 1847 in Belgium,[18] 1850 in the Netherlands, and 1924 in Denmark. In 2003, 9 of the then 15 member-states of the European Union had registers,[19] along with 6 Central and Eastern European countries.

The principle of registers is to gather certain information on each individual living in a community. The content varies from one country to another. Generally, names and given names, sex, date and place of birth, address, marital status, nationality, or profession, date and place of death are included in the register; the marriage date, the previous address, and the relation to the household head are also sometimes included. All changes in situations are recorded there through a mandatory declaration or through linkage with other forms: births, deaths, changes of address, marriages, divorces, or changes in occupation. For each migration, for example, the Belgian register records the date of arrival in the area and the previous place of residence as well as the date of departure and the destination.

Their principle of operation is relatively simple. The register is created from an initial census of the *de jure* population: selected information on each individual is recorded. It is organized by household and housing unit. Thereafter, the register (which was previously manual, but is now computerized) is regularly and rapidly updated by the recording of observed changes, either continuously with information collected in the civil registration system and by the authorities responsible for recording changes in address, or periodically (every 10 years in Belgium from 1866 to 1981) during each successive census.

In addition to the various administrative uses (identification of individuals, updating of electoral rolls, taxation, files linked to social schemes), the register is also of obvious interest for statistics and demography.

1. It can provide at any time an estimate of the population of each community and its composition according to various characteristics, as well as population dynamics (natality, mortality, and migration, internal and international).
2. It is a monitored observation, a kind of biographical surveillance system, as it collects and preserves information on each individual (and household) on the various demographic events that take place over the course of the life span. It makes it possible to combine period and cohort approaches.
3. It facilitates the preparation and evaluation of population censuses, and it is a good sample frame for surveys. Some countries that continuously record migration have even stopped carrying out censuses, as they consider that their system for recording events is sufficient to correctly update the population register.

But there is often a wide difference between the principle and reality.

Approximately 30 countries have population registers at present. The basic principles are the same everywhere, but the content, the organization, and the quality vary. It is possible to simplify by comparing the very reliable and well-organized systems of the Scandinavian countries, Belgium and the Netherlands, to the less-rigorous systems of countries such as Germany and Italy, where the updating (sometimes still manual) of data is carried out with delay and suffers from omissions and where definitively the register is not yet the central axis of the local system of information and management.

In this respect, it is advisable to distinguish the *centralized systems* at the level of the whole of the country (the Benelux and Scandinavian countries) from *local systems*, whether computerized or not, where information only exists at a local level (Poulain, 1995). Centralization, which leads to a kind of superregister covering the whole of the country, invariably favors the quality of the information (i.e., removes double counts, promotes more effective verification). It also facilitates linking the central population register to other administrative registers (Housing, Social Security). Under certain conditions, it even makes it possible to replace the traditional census. In Belgium, extending the communal register to a national one took 17 years between the adoption of the idea (1966) and its legal and practical implementation (1983). All information declared in the *Local Population Register* (*Registre Communal de Population*) is now transferred electronically to the *National Register* (*Registre National*), which instantaneously modifies its corresponding individual file and sends an acknowledgment of delivery with the new individual file. This system is reliable and quick.

b. Limitations and Dangers

Although it is a very valuable resource for population scientists, the population register also has its

[18] Shortly after independence (1830), Belgium followed an old regulation from the French Revolution (of 1791) of keeping *nominal lists of inhabitants* by municipality, a regulation which was practically never adhered to in France.

[19] Only Austria, Greece, France, Ireland, Portugal, and the United Kingdom do not have such a system.

limitations (notably with regard to the nature and quality of the data) and can even constitute a danger (risks of infringing on respect of privacy).

The nature of the data. A register naturally contains, above all, information which is of interest to local (and central) administration. It includes demographic variables but very little economic, social, medical, or cultural data (for example, in Belgium stillbirths are not included). The register alone therefore is not comprehensive enough to enable real differential demographic analysis to be made.

The quality of data. The quality of the information collected depends on resources, the competence of local staff, and on the motivation of staff and that of informants. Emigration (particularly beyond national borders) is generally badly recorded. It is indeed quite common for departures not to be declared, while the reasons for declaring an arrival are more binding. If the register is centralized, some of the gaps regarding departures can be filled by the recording of the arrival in another area, but this procedure is nearly impossible to implement for departures abroad. Changes in occupation also frequently suffer from underregistration.

Access to information. Access to the register data should obviously be strictly regulated and limited, in order to respect privacy.[20] On the one hand, in places where a register exists, legislation is strict and access to the data is generally difficult. On the other hand, when there is no register, such as in France for example, this is partly due to concerns regarding the capacity of the legislation to effectively preserve the confidentiality of the data.

Ultimately, a good population register is an incomparable source of information on local or national population dynamics and on internal migration. It can even sometimes call into question the usefulness of censuses. On the other hand, it will doubtless never remove the need for surveys.

3. Demographic Surveillance Systems or Population Laboratories

A *population surveillance system* means different things to different people, as well as to the reality covered by them.[21] In any case, the *demographic surveillance system* or *population laboratory* can be defined as *a method of continuous and long-term observation of a small area or a specifically defined society, the objectives of which are both the measurement and understanding of sociodemographic changes and health changes*. This will be discussed in more detail by Gilles Pison in chapter 124, which is devoted to this very particular and original method of collecting demographic data. Initially, in the absence of a reliable civil registration system, the idea is simply to place the entire population of a given geographic zone under constant, or at least very regular, observation. These geographic zones are generally small rural zones, as is the case of the demographic surveillance sites in Gambia and Senegal,[22] more rarely larger zones such as Matlab in Bangladesh.[23]

Even the methods of observation can vary enormously, from frequent multiround surveys (every 3 or 6 months) to permanent recording systems combined with periodic censuses. Moreover, multiple surveys on extremely varied themes are generally added to this basic observation. The interest and the value of these demographic surveillance sites depend largely on their durability, which makes it possible to trace changes over a long period: 10, 20, 30 years, or even more. The numbers concerned are, on the other hand, low (3,000 to 8,000 households, with Matlab being an exceptional case), and nonrepresentative.

Let us look at some examples. In Burkina Faso, in the context of a research project on levels, trends, and factors of child mortality and health, three quite different rural zones from economic, ethnic, and health points of view, made up of a total of 37 villages, approximately 3,800 households, and 34,000 individuals were monitored from 1986 to 1994. After the initial census, visits took place regularly every 6 months (multiround surveys), while in parallel, more specific operations were carried out at household (on migration in 1994 to 1995) and village level (on social, agricultural, and land characteristics).

Another example is when Institut national d'études démographiques (INED) set up a new population laboratory in Mlomp (Casamanca) in 1985, which supplements the older sites of Niakhar and Bandafasi (Pison *et al*., 2001; see also Chapter 124). The objective, which was initially mainly demographic, was to measure levels and trends in fertility, mortality (including causes of death), nuptiality, and migration (permanent or seasonal) of this small rural population

[20] Even more so as in the most advanced countries, such as Belgium, each individual has only one national identity number which enables the various administrative systems to communicate among themselves. In 1995, the European Union officially drew attention to the risks to individual freedom that are presented by these possibilities of linking individual data files.

[21] The term *Prospective Community Studies* is also found in English language publications (for a good summary, see Das Gupta *et al*., 1997).

[22] The first was established in 1963 by ORSTOM (which has now become Institut de Recherche pour le Developpement; IRD) in Niakhar in a zone of 30 villages with a total of 25,000 inhabitants.

[23] Some 200 villages with a total of 200,000 inhabitants that have been monitored for over thirty years.

of 11 villages (6,220 people in 1985, 7,600 in 2000). After an initial census carried out at the end of 1984, the data collected on the population was regularly updated by an annual survey, while in parallel, more specifically targeted surveys were carried out on very diverse subjects: conditions of childbirth, the feeding and growth of children, contraception, acquired immune deficiency syndrome (AIDS), etc.

The usefulness of these demographic surveillance systems no longer need to be demonstrated: they provide very valuable demographic data that enable longitudinal analyses to be made from individual and collective data (households, villages)—to which numerous economic, social, and health observations can be added, thus making explanatory analyses possible. They are particularly useful for studying changes over the long-term. The information collected is generally of good quality.

The limitations are nevertheless just as obvious. The main one is the very local nature of the information which, although perfectly representative as ideal for the area studied, does not go beyond the borders of the examined zone. In no case can the results obtained be extrapolated to the national level, or even the regional level. On the other hand, if there are several population laboratories, as is the case in Senegal, the information obtained can give an idea of the scale of the geographic variations. But the main advantage of the demographic surveillance system is found in its contribution to the understanding of phenomena and its evolution, rather than in the measurement of intensity levels. Furthermore, the duration, the cost, the delicate procedures of matching surveys, the complicated nature of data management, the problems associated with small numbers, and the complexity of the analyses (not always carried through to their conclusion) confine this technique to a rather experimental approach (hence the name *population laboratory*), preliminary or complementary to more basic procedures but can claim to be representative.

In spite of their limitations, demographic surveillance systems are an essential tool for research and studies in the developing countries. Of course they require competence, stability, motivation of scientific staff, financial resources, and time (an aspect which is not sufficiently taken into consideration by funders). But, in many contexts, it is only at this cost that we can (or could) improve our understanding of reality and changes.

V. CENSUSES

The census is doubtless the oldest tool for collecting demographic data (Hecht, 1977; Tabutin, 1984b), the best known by the general public today, and also the most debated from several points of view (i.e., cost, social usefulness, respect of privacy). Following a brief reminder of some general points, it is useful to examine in more detail the reasons for its existence, issues of quality, and the need to adapt the collection of information to the realities of the modern world, which naturally leads to the search for possible alternatives to the traditional census.

1. A Definition and Some General Points

The United Nations (1992b, p. 3) define population censuses[24] as "*a group of operations which consist of collecting, grouping, evaluating, analyzing, publishing, and disseminating demographic, economic, and social data relating to all the inhabitants of a country, or of a specific part of a country, at a given time*. This definition is essentially a reiteration of previous ones (United Nations, 1958, 1970), apart from the fact that it now includes the concept of disseminating information. This may appear banal, but it is revealing of the scale of the proportion of information never used and often definitively lost even though collected at great cost and with the support of the United Nations or other donors. Above all, a census aims at obtaining a kind of snapshot of the population: it makes it possible to know, at a given time, the size, geographic distribution, as well as distribution according to a certain number of socioeconomic and demographic characteristics. Furthermore, it is quite frequently used to obtain certain information regarding population movement. It nearly always includes questions on migration as, in the absence of a continuous registration system, it is the most effective tool available for collecting data on internal migration at the lowest geographical level. In developing countries, censuses are also frequently used to collect information on fertility and mortality. In the cases of migration and fertility, they can simply be status data (place of birth or residence at the previous census, number of children already born, etc.) of the same nature as other traditional census questions, although direct questions on events that have occurred during a recent period (generally the last 12 months) are also sometimes included.

The four main principles of the census are: *exhaustiveness* (it should cover all the inhabitants of a given territory), *individual enumeration* (it gathers informa-

[24] There are also other terms, such as census, general population census, population and housing census (all censuses include questions on housing, the basic statistical unit).

TABLE 121–2 Dates and Types of the Three Most Recent Enumeration Operations in Europe

Country	Mode of Operation (Most Recent)	Dates (Month/Year)		
Traditional censuses				
Austria	Delivery—collection of questionnaire	05/81	05/91	05/01
Belgium	Sending—return of the questionnaire by post	03/81	03/91	10/01
France	Delivery—collection of questionnaire	03/82	03/90	03/99
Germany	Delivery—collection of questionnaire	05/87		
Great Britain	Delivery of questionnaire, return by post	03/81	04/91	04/01
Greece	Interview by census taker	04/81	03/91	04/01
Ireland	Delivery—collection of questionnaire	04/81	04/91	04/02
Italy	Delivery—collection of questionnaire	10/81	10/91	10/01
Luxembourg	Delivery—collection of questionnaire	03/81	03/91	02/01
Portugal	Delivery—collection of questionnaire	03/81	03/91	03/01
Spain	Delivery—collection of questionnaire	03/81	03/91	11/01
Enumeration from registers or surveys				
Denmark	From registers	01/81	01/91	01/01
Finland	From registers	11/80	12/90	12/00
Germany	From surveys		04/91	
Netherlands	From registers and surveys	04/81	04/91	01/01
Sweden	From registers	09/80	11/90	

tion on each individual),[25] *simultaneity* (the information collected refers to the situation at the same single date and in order to carry out this exercise should be completed in a few days) and, lastly, *periodicity* (the census should be repeated at regular intervals). Let us add to this that, in contrast to surveys, a census can only be carried out by the government, not only because of the enormous human, technical, and financial resources that it requires, but also because it is closely associated with major administrative and political stakes.

Today, *censuses are conducted universally* with two exceptions. On the one hand, some developed countries such as Denmark, Finland, the Netherlands, and Sweden estimate their population using their population registers and no longer carry out censuses. On the other hand, certain developing countries have not been able, for various reasons, to carry out censuses. Between 1975 and 1984, 191 countries, of a total of 213, carried out a census; therefore 95% of the world population were subjected to a census during that decade.[26] Since 1990, with the exception of countries at war (i.e., Democratic Republic of the Congo, Angola, Afghanistan) or countries where the census is a political taboo (Lebanon), nearly every country has carried out a census. The African countries, which for a long time were very late in this field, have by now carried out at least two censuses.[27] North Africa has had four or five since the 1950s. The time interval between censuses is usually 10 years in America (North and South), in the Lusophone countries, and frequently in the former English colonies. Elsewhere, it is more variable, currently between 11 and 12 years in Africa, and 8 to 10 years in Europe during the 1980s and 1990s (Table 121–2). Only Japan and Ireland enumerate their population every 5 years.

The content of census questionnaires and therefore the wealth of information varies enormously from one region or country to another. Besides the essential variables of age, sex, and marital status, questions on nationality, level of education, and occupation can frequently be found. The quantity and nature of questions posed are very variable. It is also necessary to take into account this significant variability and the changes in definition, which sometimes make comparisons in space and time difficult. Weighty censuses (household questionnaires and individual questionnaires with 50 to 70 questions) can be distinguished from light censuses (a collective form with approximately 20 questions, as is the case in Africa and South Asia).

2. Advantages and Disadvantages of the Traditional Census

Although the traditional census, as it has just been described, remains the most common method of

[25] It is *inter alia* that distinguishes it from the *administrative census*, a practice inherited from colonization and still sometimes used in Africa, which consists of collecting some aggregated information from each household (number of persons by sex, number of children and adults, number of foreigners).

[26] For a world view, see United Nations, 1991; for Europe, see Eggerickx and Begeot, 1993; Redfern, 1987.

[27] Only Djibouti, Ethiopia, Chad and Congo R.D. have still carried out only one census.

observing a population and has become nearly universal due to the huge efforts made in developing countries over the last few decades, its fate is under debate in the most advanced countries due to the evolution of requirements and the appearance of alternative methods.

The *advantages* of the census are considerable. Its exhaustiveness enables it to provide total statistical coverage, from the broadest level (the country), to the most local which is the parish, district, or even zone of enumeration, and finally, the household[28] (or house unit). It makes it possible to study all kinds of ethnic, social, or occupational subgroups at the finest level. It is also the only source for analyzing internal migrations up to local level. It is an essential sample frame for any population survey, which only the few European countries that possess population registers can do without. Definitively, and perhaps especially, it is, far beyond the needs of demographic research, an essential tool for regional planning and management (both public and private) of national and local economic and social affairs.

But the census no longer enjoys unanimous consensus: it is increasingly being questioned both by the producers of data as well as by the users and even sometimes by the population itself. Indeed, despite its advantages it also has *weaknesses and disadvantages*, of a technical, methodological, and ethical nature. We will refer briefly to the most important points.[29]

1. **Periodicity.** The time interval between two censuses, which is generally approximately 10 years, is too long for taking into account ongoing changes rapidly enough.
2. **Publication intervals.** Too frequently, the time interval between analyses and particularly publication is very long; often 5 years and sometimes more.[30] When the results are published (notably at a local level), they are often completely out of date.
3. **Cost.** The traditional census is the most expensive collection operation of all, at least in internal budget.[31] Of course, the cost varies greatly from one country to another.[32] The current trend in Europe (and elsewhere no doubt) is to try and reduce it as much as possible by shortening the questionnaire, by reducing the frequency or, even more radically, by finding alternatives. This financial problem is particularly acute in the poorest countries, precisely where the census remains the main source of demographic information.
4. **Content.** Because of the scale of the operation, the questionnaire of a traditional census should be as simple as possible. There should be few questions. They should be easy to ask and the responses should be easy to provide. Complex questionnaires and delicate questions such as those concerning income or certain aspects of personal life, reproductive history, migratory history, and occupational history of individuals are excluded from it. It is essentially a diachronic tool.
5. **Quality.** The census is not perfect, no more than any other information system. Its objective of exhaustiveness is always confronted by coverage problems (over- or underestimates of some subpopulations), while the responses do not always strictly reflect reality.

To these technical and organizational problems is increasingly added an obstacle which is specific to modern democratic societies: the *respect of privacy*. The census is certainly useful and confidential,[33] but it is increasingly difficult to convince the population of this. The growing fear of intrusion into private life leads to the census being seen as an additional bureaucratic hold that, furthermore, is expensive to the taxpayer. Numerous pressure groups and anticensus organizations were established in Europe during the 1980s and 1990s (in Germany, the Netherlands, Switzerland, Belgium, etc.). This dispute, while never leading to the total abandon of the census (except perhaps in the Netherlands), has sometimes seriously affected its quality (failure to respond, falsification of responses).

Faced with all these problems, more or less radical alternatives are being sought.

[28] For example in this respect, see the work of Françoise Bartiaux (1991) on the households of elderly persons using the American, Australian, and Italian censuses.

[29] For more details, see notably the analysis of Philip Redfern (1987) on the problems and the future of censuses in Europe.

[30] In spite of the very widespread practice of percentage sample analyses (25% sample, to 5% sample, etc.) and of the undeniable progress in data-processing (acceleration of data capture and verification, optical character recognition, etc.).

[31] If it were necessary to take into account the total cost of the continuous registration of events for a population register, this statement would certainly need to be reviewed.

[32] From $2 to $5 per inhabitant in Europe, from $5 in Canada and the United States in the 1980s (Redfern, 1987). In Belgium, they increased from 12.4 million Euros in 1981 to 25 million Euros in 1991, in the United States they increased from $1 billion dollars in 1980 to $2.6 billion in 1990 ($10 per inhabitant). The cost of censuses increases considerably in developing countries.

[33] It was nevertheless used in Belgium to update the population registers.

3. The Alternatives to the Traditional Census

On a worldwide scale, the traditional census certainly continues to hold first place and it will remain for a long time essential in the majority of developing countries, although its content might need to be revised occasionally. However, some countries, often amongst the richest and most advanced in the area of statistics (registers, coupling of files, etc.), during the 1980s started to implement other data collection methods that could replace the census due to economic and effectiveness concerns (time, nature, and quality of data).

1. **The microcensus.** Some countries have attempted from time to time to replace a traditional census with a microcensus, which in fact is nothing more than a demographic sample survey on a varying scale. For example, in Germany in 1981 and 1991 a national survey on 1% of the population was carried out either side of the traditional general census of 1987. A microcensus was also carried out in Russia in 1994, as a general population census was not possible soon enough after the collapse of the USSR to be able to detect the demographic upheavals that followed it. The term microcensus leads to confusion as, due to its lack of exhaustiveness, it obviously cannot replace a census. It would be more appropriate to call it an intercensus survey as its objective is basically to reduce the disadvantage of the long time interval between two censuses whose cost prevents the periodicity from being increased. This pseudoalternative should therefore be classified among surveys.

2. **The light census accompanied by an extensive survey.** The population as a whole only receives a short questionnaire limited to a few basic questions on population and housing, but for a significant percentage of the population (from 10% to 25%), the questionnaire is much more comprehensive and deals with numerous variables concerning education, employment, migration, fertility, etc. This is the system that has been adopted in North America, in some Latin American countries (Brazil, Venezuela), and in Hungary and Russia. It accelerates the procedure for analysis and makes it possible to look deeper into some areas with a large sample.[34] This method has been proposed to reduce the cost and improve the performance of African censuses (Gubry *et al*., 1996), but it continues to be confronted by resistance from statistical offices that are accustomed to rely on the financial bonanza provided by the traditional census.

3. **The reduced census combined with administrative registers.** In the same spirit, some countries, like the Nordic countries (Sweden, Finland, and Norway) only carry out very light censuses that are immediately enriched by being matched with information from different administrative registers (education, housing, income) that are interconnected. One could even go as far as to say that these minicensuses are only *ad hoc* operations that are aimed at periodically verifying the exhaustiveness of the population estimates based on registers. In any case, this system is faster and the marginal cost is relatively low.

4. **Enumeration operations based exclusively on registers and surveys.** Two countries, Denmark since 1980 and the Netherlands since 1981, no longer carry out a general population census in the traditional meaning of the term (Eggerickx and Begeot, 1993; Redfern, 1987). In Denmark, the census has been replaced by the combined use of the data from seven different registers (population, housing, companies, salaries, employment, income, and education). In the Netherlands, the same is done using three sources: population register, a survey on employment, and a survey on housing. Following the 2001 census (its last), Belgium will change to a similar system based on the population register and three data bases (housing, education, socioeconomic characteristics) that will be created using information from the 2001 census.

The advantages of the two alternatives above are clear: variety and wealth of information, speed of execution, lower cost, possibly greater frequency of the operations, and no direct participation of the population. But this is only possible in the few countries that have a well-established tradition of high-quality centralized registers and can link files while guaranteeing the confidentiality of information.

5. **The French attempt at a "renovated census."** In France, the ongoing renovation of the census method is due to the paramount concern of adapting public statistics to the expectations of the users, with, notably, the need for a faster update of information (Institut National de la Statistique et des Etudes, INSEE; 2000). Instead of a traditional census every 8 or 9 years, since 2004, the renovated census is based on an annual collection of information that only affects a part of the population each time. The procedure used differs according to the size of the area. In areas with fewer than 10,000 inhabitants a traditional census must be carried out every 5 years, at a rate of annual operations dealing each time with a different fifth of the area. Areas with more than 10,000 inhabitants are each divided into five large groups of buildings. Each year,

[34] In Hungary in 1990, 20% of households received a long questionnaire (63 questions instead of the 29 in the short questionnaire); in the United States in 1990, this was the case for 17% of households (with 59 questions instead of 14 in the short questionnaire).

the housing units of a group are enumerated and a census conducted in 40% of the housing units. Therefore, in 5 years, all the housing units in the area will have been enumerated but only 40% of the population will have taken a census. The supporters of this new system believe it will make it possible to gain 3 to 4 years on the provision of results, with a better distribution of cost over time, and possibly improved quality (INSEE, 2000).

4. Quality and Comparability

The general public, users, and sometimes even demographers forget that every census includes errors, gaps, and shortcomings: regardless of the method used, the operation is of scale and should be completed in a short time. The scale of errors varies considerably from one country to another, from one census to another, according to the past experiences of the authorities in charge, the care taken in the preparation of the operation, the concern with verifying and correcting the data, and also according to the abilities of the census takers, and the population's education level. Didactically, these errors can be classified into two large categories: those which stem from the responses to the questions asked (observation errors), and those stemming from the census coverage (enumeration errors). Here we will only discuss the case of the traditional census.

1. **Observation errors.** Some examples are inaccuracy (whether voluntary or not), confusion, false declarations, nonresponses, etc.—of course anything is possible (even declaring fictional persons or children born after the census date[35] or persons who died before this date). There are of course variables that, for various reasons (technical, psychological, political) are more prone to error than others: economic activity (occupation, status, qualification), nationality, sometimes marital status, residency status (when asked in terms of present/absent/visitor), migratory status (date of arrival for example), and mortality (during the previous 12 months in the developing countries).

2. **Enumeration errors.** All users should be able to know their scale and nature. No census is completely exempt from omissions and double counts, with omissions generally being more numerous than double counts. What is the rate of net omissions? Who has been omitted or counted in error? How are the results rectified? Measuring these errors is the objective of *postcensus verification surveys* that consist of carrying out the census again on a sample of districts and comparing the results with those of the general census.[36] Unfortunately, not all countries carry out this type of verification. Table 121–3 presents some results for Europe. The omissions are between 0.5% and 6%, while the duplications (less well-known) are between 0.5% and 5%.

TABLE 121–3 Omissions and Double Counts in the Traditional Censuses of Some European Countries Circa 1991[1]

Country	Omissions	Duplications
Austria (1991)	0.5%–0.8%	0.5%–0.8%
Belgium (1991)	3.4%	ε
Spain (1991)	2.9%	3.0%
France (1990)	1.8%	0.7%
Ireland (1991)	ε	ε
Luxembourg (1991)	ε	ε
Portugal (1991)	6.3%	5.3%
FRG (1991)	<1.0%	?
United Kingdom (1991)	2.0%	?
Switzerland (1990)	1.1%	ε

Source: Eggerickx and Begeot (1993)
ε = very low; ? = data not available
[1] Data per official of corresponding country.

The coverage rate of censuses varies greatly according to the population category or the living environment. In Belgium in 1991, for example, the omissions varied from 2% among Belgians to 12% among foreigners, from 9% in Brussels to 4% in other cities, and to 2% in the rest of the country. In the United States in 1991, the omissions varied from 2% among whites to 5% among blacks and hispanics. In developing countries, there are generally no precise measures, but where they exist the omission rate is between 5% and 10% and is particularly high among very young children, men aged 15 to 30, and elderly women.

Certain population categories can also almost completely be omitted by censuses: people with no fixed address, illegal immigrants, the homeless, nomads, etc. These groups should be the subject, and sometimes are, of specific enumerations or estimates.[37]

3. **Comparability problems.** The diversity of these errors, as well as other factors of discordance, cause a

[35] These were estimated to be around 16,000 in the French census in 1990.

[36] For further detail on the procedure and the results obtained, see Hogan, 1993, and Pauti, 1992, for the United States; Coëffic, 1993, for France; Boudreau, 1989, for Canada; Redfern, 1987, for 12 European countries.

[37] In some countries, attempts are made to enumerate the homeless in nocturnal operations. Nearly 250,000 were enumerated in this way in the United States during the night of March 20–21, 1991. In some countries such as Mauritania, for example, the nomads are the subject of specific operations (a survey of a sample of wells for example, during a period of regrouping herds and households).

certain number of problems in the comparability of census data both in time (for the same country) and in space (between countries). Differential errors but also differences or changes in the definition of concepts used (occupation, living environment, etc.) or variations in the composition of the questionnaire and the formulation of questions (addition, removal, new formulation) may introduce a bias in comparisons. In their study of European censuses, Thierry Eggerickx and François Begeot (1993) conclude "*that apart from variables relating to structures* (*age*, *sex*, *marital status*, *and nationality*), *the comparison of results in time frequently seems impossible to achieve with the other demographic topics.*" International comparisons are even more delicate.

5. What is the Future for Censuses?

The future of the census is frequently evoked and discussed, both in the Northern and Southern regions, but in different contexts and for different reasons. The majority of demographers and many other users recognize *a priori* the importance of censuses: it is necessary from time to time for every country to have a detailed image (geographic or social) of its population, its structure, and sociodemographic characteristics, its housing stock, etc. There is however debate on the best means of achieving this objective.

In developed countries, the debate is centred, on the one hand, on the durability of the traditional census compared to other sources likely to satisfy the same needs at a lower cost, and on the other hand, on the adequacy of responses, which it can provide on major concerns, and its social usefulness. Abandoning the traditional census can, in effect, be envisaged in countries that have excellent population registers, and this step has already been taken in some Nordic countries and will also doubtless be taken shortly by some other countries (Belgium, Luxembourg). But the censuses based entirely or partly on registers themselves do not only have advantages: they are less flexible (changes or adaptation of questions), rather rudimentary (for employment or education, for example), and not always of excellent quality. In addition, they can clash as much, and maybe even more, with the sensitivity of a population that feels observed without really knowing why or how.

While the traditional census remains essential in other countries (the vast majority), some would like its content to be better adapted to the major concerns of our time (unemployment, youth, elderly people, part-time employment, situations of precariousness and poverty, etc.). But this is asking too much of a census. Every subject cannot be addressed in a census whose main objective is exhaustiveness. This is what enables a census to provide a complete and precise sample frame for every type of survey that is better able to approach these same questions in more depth than the census itself.

The problems raised by the census in *developing countries* are of a different nature: they are variable from one region to another (the statistical situation in Brazil or Mexico cannot be compared with that of Burkina Faso or Nepal). But the census remains essential everywhere and it would be out of the question to abolish it. In the statistically poorest regions, on the contrary, it is necessary to increase the frequency, decrease the time delays in analysis and publication, and improve the analyses and the dissemination of the results. The most serious impediment remains the increasingly high cost of the operation, which very few countries can meet. For example, in Africa it has certainly become time to use light censuses, which are more rapid from all points of view and doubtless of better quality, together with a solid program of detailed surveys in the context of a national strategy of coherent data collection (Gubry *et al*., 1996).

VI. SAMPLE SURVEYS

The survey is a more recent tradition (in demography, the method became generalized from the 1950s) and is, for various reasons, a preferred and ideal tool for collecting data in demography, and more generally in social science. It exists in developed countries and in developing countries, but with different objectives, which relate to the performance of other information systems. Basically, in Europe and North America the survey is a supplement to qualitative and quantitative information (i.e., behavior, opinion, individual life courses) compared to the source data provided by censuses and permanent registration systems; elsewhere it is still frequently a palliative to the lack of basic sources and its main aim is to measure levels and trends of components of demographic change, but it must also fulfill the needs of explanatory analysis.

The problems of population surveys[38] are vast and diverse.[39] After a brief reminder of their advantages and limitations, and an attempt at creating a typology, I will then focus particularly on two major types of

[38] Here I will not discuss specific surveys on health, budget, and household consumption, or the workforce and employment, even though they are sometimes indirect sources of demographic information.

[39] For more details, see, for example, Tabutin, 1984b, Chapter 5; Committee on Population and Demography, 1981; United Nations, 1992a; Lohlé-Tart *et al*., 1988.

survey: the retrospective survey and the multiround survey.

1. Definitions, Advantages, and Limitations

The sample survey estimates certain characteristics of a population through observing only a fraction of that population.[40] This is a completely general definition, which applies to population surveys as well as to other social science and health surveys. Basically, it is the fact of using a sample that distinguishes a sample survey from a census, which is an exhaustive survey. But because of this, its objectives can also be different from those of a census.

Its main *advantage* is the fact that it is far less costly, which leaves a large margin to invest in other directions, which, in turn, contribute to the advantages of the method. Firstly, the data quality can be improved (the very small number of interviewers allows for high-level recruitment and a more comprehensive *ad hoc* training), the room for maneuver provided to the researcher with regard to the definition of concepts is nearly limitless (in any case incomparable to the rigidity of statistical administrative systems), the quantity of possible variables (frequently between 100 and 200) is high, and the nature of the questions asked (sometimes specific or delicate) is very open. Far from being merely a process of replacement or a substitute to the gaps in administrative statistics, the sample survey is above all an essential tool for advancing knowledge: it makes it possible to reconstitute the past; establish family or individual biographies; and study the interference between events, phenomena, or the interrelations (individual or aggregated) between population and social, economic, or cultural factors, to provide quantitative (unions outside marriage, contraceptive prevalence, etc.), and qualitative (opinions, practices, motivation) information that would otherwise be impossible to obtain.

Of course, on the other hand, it has its *limitations* and poses some problems. The level of geographical analysis can only be fairly rough: the majority of national surveys, at least in developing countries, are only representative at the level of two or three living environments, or of four or five large regions. Let us not forget that every estimate through a sample survey is affected by a sampling error,[41] which is greater when the sample size is small. The latter must obviously be in connection to the statistical frequency of the events studied (rather low in demography) and the precision required. But furthermore, the greater the sample, the higher the cost of the operation and the greater the risk of observation errors. Finally, a problem sometimes difficult to solve, in particular in the developing countries, is the precise, complete and up-to-date sample frame required for the constitution of the sample. The census, which is the natural basis for this, is sometimes too remote to be effective enough. Sample surveys are not without their cost, or delays in completion, or problems of quality, and all these aspects vary significantly according to the type of survey and the strategies of observation.

[40] A similar definition to that of the 1981 Multilingual Demographic Dictionary (IUSSP, 1981).

[41] Sampling errors (or sample errors) add on to observation errors (Desabie, 1965; Tabutin, 1984b, Chapter 5; Clairin and Brion, 1996). Demographers have an annoying tendency to only seldom clarify it in their publication of results.

2. Objectives and Typology

But *what do we understand exactly by population or demographic survey?* Let us say that it is a survey whose main objective could be measurement of population composition and changes, or the understanding and explanation of levels and trends of the demographic phenomena (fertility, nuptiality, mortality, migration). Considered in this way, the line between demography, sociology, and health is sometimes narrow. We could for example include family surveys or health surveys, at least when they relate to individuals or households and seek (among other things) to quantify. On the other hand, we should doubtless exclude operations specific to employment, education, living conditions, nutrition, and consumption from the demographic field, even if they can indirectly contribute to sociodemographic knowledge.[42]

Thus defined, we can classify population surveys into a few large categories according to their main objective:

1. **Measurement surveys.** Many surveys carried out in developing countries aim above to compensate for the shortcomings of the civil registration system. They therefore measure one or all of the phenomena that contribute to population growth.
2. **Opinion or behavioral surveys.** Other surveys have a main objective of knowing and understanding the motivations, aspirations, and practices of individuals or couples, who condition the evolution of demographic phenomena.
3. **Mixed surveys.** However, the most common case today is that of surveys with two simultaneous objectives. For example, we wish to measure not only

[42] However, some authors prefer to classify surveys on employment or schooling within the field of demography (Desabie, 1965, p. 30–31).

fertility and its intermediate variables, but also to discover why or how some practices (breast-feeding, postpartum sexual abstinence, contraception, for example) exist and evolve, or to discover the fertility plans and aspirations of couples or women. They are particularly interested in the interaction between factors, in social inequality, and in geographic disparities. In short, the objective is focused greatly on explanatory research.

The term *population survey* consequently covers extremely diverse operations both at a technical level and at a thematic level. First of all, with regard to objectives, Table 121–4 proposes a general typology of the most common surveys, with the main characteristics of each category, i.e. the method of observation, geographic coverage, and sample size.

Having given the population survey a rather broad definition, I use the term *household surveys* here for what many demographers call *population surveys*. Common in developing countries, these are often surveys with multiple objectives: measuring the sociodemographic composition of the population and its dynamics (fertility, mortality, migration). In the past, their aim was to replace both the civil registration system and the census. Nowadays, they are mainly carried out in the middle of the intercensus period. They require large samples (often around 30,000 households).

4. **Fertility** was, by far, the most studied phenomenon (due to greater funding), notably in the context of large international programs: the Knowledge, Attitude and Practice (KAP) program of the 1960s, the World Fertility Survey (WFS) program of the 1970s, the Demographic and Health Surveys (DHS) program of the 1980s, 1990s, and 2000s, for developing countries, or the American program of contraceptive prevalence surveys of the 1980s. These surveys obviously vary from one program to another, but they are all national and are all based on samples of 3,000 to 8,000 women with a predominant objective: fertility and family

TABLE 121–4 Typology of the Most Common Population Surveys

Survey Category	Observation Method[1]	Geographic Coverage	Sample Size
Multiple objectives household surveys (numerous developing countries since the 1960s)	1 round or 3 rounds (over 1 year)	National	20,000 to 40,000 households
Fertility/child health surveys (WFS program of the 1970s, DHS program of the 1980s, 1990s, and 2000s; and the GCHS for the Gulf countries; ±210 in total)	1 round	National	4,000 to 8,000 women (1,500 to 3,000 men sometimes)
Fertility/family surveys (FFS program; 24 developed countries, from 1990 to 1999)	1 round	Most frequently national	3,000 to 6,000 women; 1,000 to 4,000 men
Contraceptive prevalence surveys (e.g., CDC program; 30 in total since 1985)	1 round	National	2,000 to 3,000 women (and men sometimes)
Migration/rural migration/urbanization survey (e.g., REMUAO Project in West Africa, 1990)	1 round	National or regional	Varies
Child mortality survey (e.g. IFORD Project in Africa, 1980s)	Multiround (over a period of 1 to 3 years)	Local (frequently cities)	10,000 to 15,000 births
Pregnancy and Childhood survey (WHO-Europe ELSPAC Project, 1990s)[2]	Multiround (from birth up to age 3 or 7 years)	Regional	±5,000 pregnancies
Survey on birth (e.g., INSERM-France)	1 round	National	5,000 to 6,000 births
Biographical surveys (migratory, occupational, and family itineraries; e.g., INED's 3-B survey, RIVASS Project in the Sahel)	1 round	National or cities	3,000 to 6,000 individual adults

DHS = Demographic and Health Surveys; ELSPAC = European Longitudinal Study of Pregnancy and Childhood; FFS = Fertility and Family Survey; GCHS = Gulf Child Health Survey; INSERM = Institut national de la santé et de la recherche médicale; REMUAO = Network of Migration and Urbanization in West Africa; RIVASS = Research on Integration into Cities in Africa South of the Sahara; WFS = World Fertility Survey.

[1] The characteristics presented are those most frequently encountered. They do not exclude other alternatives.

[2] The ELSPAC surveys from the beginning of the 1990s are at the limits of demography as their objectives are broader: the health and the development of the child.

planning—even through the most recent project (the DHS survey) is also interested in child health. The European Fertility and Family Surveys (FFS) project of the 1990s (on 24 countries) also deals with fertility but is mainly focused on the family.

Neither *migration* nor *mortality* was the object of such attention. They were the subject of only purely national operations, or at best, some regional programs, such as those on migration in West Africa (REMUAO Project of the beginning of the 1980s). The majority of these operations are only concerned with one region of a country, or often even one city (the capital); very few countries, such as Tunisia in 1989, have carried out a national survey on infant mortality.

Although it is a major factor of fertility, *nuptiality* is the poor relation in demography, in developed countries as well as in developing countries. It is the subject of very few specific surveys. We can certainly approach it in fertility surveys through the reconstitution of the marital life of each woman. The questionnaire must enable this, as was the case of the WFS, but not, unfortunately, that of the DHS.

5. **Biographical or life course surveys**, a more recent and innovative approach, have a specific category in Table 121–4 because they integrate, in the full meaning of the word, migratory, residential, family (fertility and nuptiality included), and occupational histories. Some good examples of these are the 3B (triple biography), a pioneering survey carried out by INED in 1981,[43] the urban insertion surveys in Africa (Dakar 1991, Bamako 1992, Yaoundé 1996, and Antananarivo 1998),[44] and finally, the survey carried out in 2000 in Burkina Faso (the first at a national level) on migration, urban insertion, and the environment. All these surveys aim to understand and measure the interactions between the various aspects of the family, migratory, and occupational lives of the respondents.[45]

[43] *Family, occupational, and migratory biography* survey on a national sample of 4,602 persons aged from 45 to 69 years (Courgeau and Leliévre, 1989, 1990). The length of each interview was between one and two hours (one hour and ten minutes on average).

[44] The Dakar survey was carried out by Institut Fondamental d'Afrique Noire (IFAN) and ORSTOM, that of Bamako by Centre d'Etudes et de Recherche sur la Population pour le Développement (CERPOD) and the Department of Demography of the University of Montreal. The procedures were similar and the results were relatively comparable. The Bamako survey consisted of three questionnaires: household, biography, and health. The biographical questionnaire was made up of no less than 6 modules: "family origin and childhood," "migratory and occupational life in Bamako," "residence of more than six months in Bamako," "active life in Bamako," "married life," and "live-born children." It covered 2,141 individuals aged 25 to 54 years.

[45] Concerning the advantage of these surveys with regard to analyzing the interaction between phenomena in Africa, see: Antoine, 2003; Antoine and Dial, 2003.

3. Observation Methods and Types of Survey

In any collection of information on demographic events (births, deaths, migration, marriages, illnesses, etc.), on practices (vaccinations, attendance of health centres, contraception, etc.), or on the evolution of certain individual characteristics (marital status, occupational situation, level of education), the observation method can be retrospective or prospective and the operation can be specific or permanent.

1. **Retrospective or prospective survey.** In a *retrospective* survey, individuals are questioned on what they have experienced over the last weeks, the last year (short reference period, Fig. 121–2a), or throughout their lives since a given age or a given event (Fig. 121–2b). They are generally single-round surveys. In a *prospective* survey, the same population sample (individuals, households, or geographic zone) is monitored over a period of varying duration by visiting them[46] at regular intervals to record changes that have occurred since the last visit (Figs. 121–2c and 2d). The latter are called *multiround surveys* (or sometimes *panel surveys* when individuals are the observation units).

2. **Ad hoc or permanent survey.** A survey is called *ad hoc*, even if it is repeated (in that case, it can be called a *trend survey*), when each observation is disassociated from the others and no individual monitoring is possible. It is only at the aggregate level that evolution from one point to another can be observed (Fig. 2e). For example, this is what occurs when the results of surveys of the same nature that were carried out successively are compared, e.g., the two or three DHSs of a given country. On the contrary, the survey is called *permanent* if a population (frequently a group of villages or districts) is regularly monitored (through a multiround survey or even continuous observation) for a long period (up to several dozen years). This is the basic principle of demographic surveillance systems or population laboratories discussed earlier.

Let us now look more closely at the retrospective single-round survey and the multiround survey to discuss their advantages and disadvantages.

4. The Single-round Retrospective Survey

When visiting the sample only once, we should necessarily ask questions concerning the past if we wish to observe changes in the population and its compo-

[46] Or, as is the case now in most developed countries, by post or by telephone.

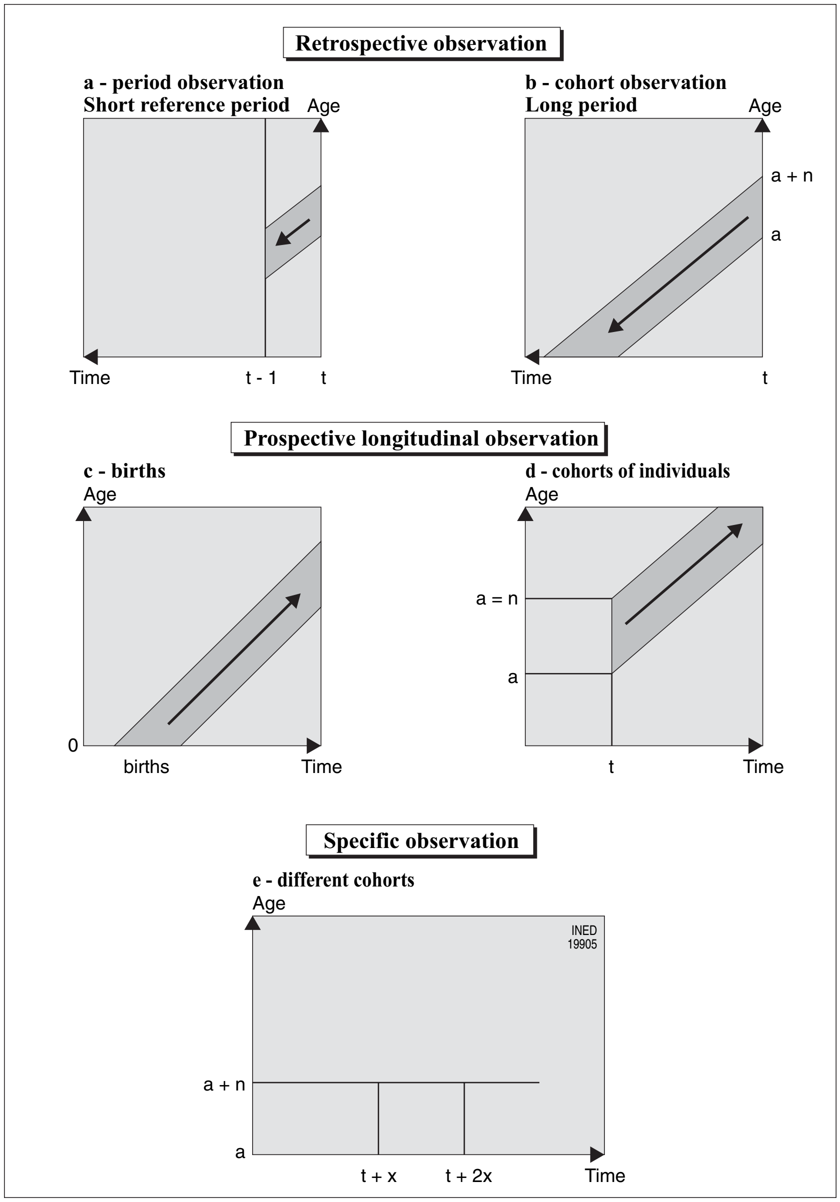

FIGURE 121–2 Schematization of the different types of observation.

nents. But we should distinguish two possible strategies with different results according to whether one short and recent reference period is sufficient, or whether we wish to trace all the demographic events experienced by the respondents.

a. Retrospective Surveys over Short Reference Periods

To grasp events such as births, deaths, marriages, and illnesses through a retrospective survey,[47] we should question individuals on what occurred during a reference period. Here, it is a short and recent period. Regarding births and deaths, for different reasons (annual rates, suitable numbers, eliminating seasonal effects), it is most common to ask about events in the 12 months preceding the interview; regarding illnesses, this can be, according to the case, between a few days to a few weeks or months. The method of the last 12 months, frequently used in household surveys (and censuses) in developing countries, is *simple* at the conceptual and analytical levels (it leads to calculations of the period indicators, rates, or incidence), and *relatively inexpensive* (it only requires a few questions),

[47] Let us recall that the last 12 months are also much used in censuses in developing countries for estimating fertility and mortality.

but, as has been demonstrated many times (Vallin, 1969; Tabutin, 1984b, 1984a; Arretx, 1984), poses many problems. First of all, the method requires large samples (from 20,000 to 40,000 households, Table 121–4) to counteract the scarcity of demographic events. Furthermore, it is then susceptible to considerable sources of bias, whether from a *telescoping* effect, due to errors in localizing events in time (the respondent wrongly includes or excludes an event in the period), or that of omissions (conscious or not). These errors, which are sometimes modest for natality, are frequently enormous for mortality, sometimes making the results unusable.[48] I have been asking myself for a long time why, in spite of such problems, such a method is still being used, notably for mortality and for censuses! Attempts have been made to reduce the errors of the last-12-months method, notably those which are due to the memory of the respondents, e.g., by using a fixed, easily identified date (a memorable and popular festival, for example) as a starting point for the reference period, but this has not totally solved the problem (Tabutin, 1984a).

b. Retrospective Surveys over Long Reference Periods

These errors are much easier to manage in long retrospective surveys and make it possible to better ensure the coherence of the information collected on the same individual. All the respondents are questioned on their experiences since a given change in status (marriage, motherhood, residence in a community, unemployment, for example), since reaching a given age, or since birth. In other words, from an event or a starting age, respondents entirely reconstitute their reproductive lives, matrimonial course, or migratory, residential, educational, occupational experiences, and sometimes even several of these components or all at the same time, as is the case in biographical surveys. For example, this is the strategy used for the majority of fertility surveys (women are interviewed on their reproductive and marital lives from the age 15 or from their first union formation) or in migration surveys (for example, men aged 40 to 65 are interviewed on their history since their first migration or since leaving school). It is a *demanding* process both for the respondent and the interviewer (many dates, durations, causes), but *rich in information*. For example, the complete reproductive histories of women aged 15 to 49 years (including questions on the survival of each child, or on the duration and result of every pregnancy) makes it possible to reconstitute the fertility trend over 15 years or infant and child mortality over the 20 or 25 years preceding the survey. The results can obviously be analyzed by period, but they lend themselves quite naturally to longitudinal analysis, even if the duration of individual observation varies from one respondent to another according to age at the time of the survey.[49]

This approach also has its *disadvantages and risks of error*. Retrospective observation by definition operates a selection in the cohorts: we can only interview individuals who are still alive and who have not emigrated (we must therefore make a hypothesis of independence between the phenomenon studied and other events excluding the individual from the population). The long retrospective survey also calls upon the *memory* and recollection of an event that is sometimes far in the past. Inaccuracies (in the dating of events, notably) and omissions are likely to increase with the amount of time past of the event. The method therefore may distort the observed trends, for example, underestimating the scale of a reduction in fertility or infant mortality. These recall lapses arise differently according to values and perception of time but they exist in every social context, in both developed and developing countries (Courgeau and Leliévre, 1989, p. 17–19). Finally, the *duration of the interview* is long, particularly in multiple biographical surveys (1 to 2 hours).

5. Multiround Surveys

These were developed during the 1960s, particularly in Francophone countries, in response to problems (omissions and inaccuracies) in retrospective observation, notably over the last 12 months. They very rapidly attracted supporters and opponents due to the fact that, while they certainly have many advantages, they also pose significant problems. A multiround survey[50] is *a survey where following an initial complete observation, the same population sample is interviewed again several times and at short time intervals*. As in the other demographic surveys, it can involve a sample of individuals, households, dwellings, or geographic zones, but also, in some cases, a sample of events (pregnancies, births, marriages).

[48] There are of course correction methods, but they have their limitations. They are notably based on considerable hypotheses (constancy of omissions according to age or social group, for example).

[49] On the *truncation effects*, see Tabutin, 1984b, p. 120–124; Courgeau and Lelièvre, 1989, p. 21–22. In fact, there is generally double truncation: on the *left* as the account only begins at a given moment in the life cycle and we have no information on the preceding period, and on the *right* with the interview date.

[50] Which is also sometimes called prospective survey or follow-up survey.

a. Monitoring Households

Multiround household surveys carried out since 1965, particularly in Africa or Asia (20 in total, most of them national),[51] aim above all to correctly measure population change and avoid the disadvantages of the last-12-months method mentioned earlier. The reference period is determined by the time passed between the first and last interview. In this case, the area sample (based on districts of around 500 inhabitants, for example) is preferable (to better manage the problem of sample ageing), but samples of dwellings (households) have also been used. Most frequently, the sample is visited 3 or sometimes 4 times a year. At the first visit, a census provides an initial inventory on the basis of which any changes that occurred since the last visit can be observed, notably arrivals (births, immigrations) and departures (deaths and emigrations). The area sample makes possible the observation of collective migration (entire households), not only at departure but also on arrival (Tabutin, 1984b; United Nations, 1992a). Indeed, this method considerably reduces the risk of omissions[52] and significantly increases the precision of the observation. However, unless the period of reference and therefore the number of visits (and the cost) are increased, the samples should be as large as they are for retrospective surveys over a short reference period (between 20,000 and 40,000 households). The cost is high due to the number of visits. The duration of the operation is relatively long (at least 18 months of collection, if 6 months on the ground for each of the three visits are counted). Preparation of data and analysis are complex. The risk of total failure (when fieldwork is stopped) or partial failure (when the analyses that enable full advantage to be taken of data is abandoned) is not negligible. In a period when resources are increasingly rare and in view of certain failures in developing countries, the number of skeptics has increased and includes the author of this chapter who was however formerly in favor of this technique, which is full of potential.

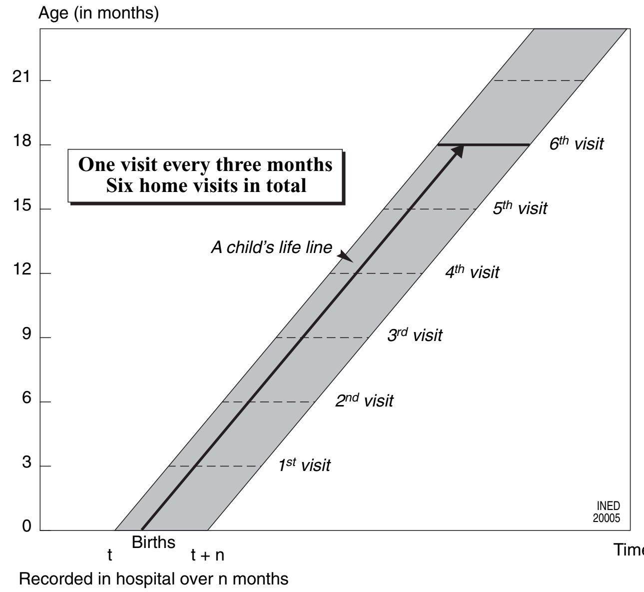

FIGURE 121–3 Monitored observation of a sample of births over 18 months of age.

b. Monitoring Individuals or Births

Multiround surveys can have more specific objectives and resort to monitoring individuals, either since their age of arrival to the population exposed to the risk (e.g., 18 years, if we wish to study marriage, or 1 to 4 years for the study of child morbidity and health) or since an original event (i.e., school entry, first visit to a family planning, Figs. 121–2c and 2d; or since their birth, Fig. 121–3).

After a first visit, when the interview pertains to a fundamental event, the past, or on the family or social environment, the individuals concerned are visited at regular intervals. Comparison of the situation at various visits and questions on what has occurred between two interviews[53] makes it possible to measure and understand the changes. The total duration of observation, the number of visits, and the interval between visits are all variable from one survey to another, according to the objective (from a few weeks for perinatal mortality, to 5 or 10 years for monitoring the health and nutrition of children, or conditions of access to marriage) and, of course, according to the human and financial resources available.

[51] To my knowledge, the most recent was that of Morocco in 1987–1989 (two years of observation, five rounds at six month intervals).

[52] There is certainly a risk of omission for two contrary events that are monitored over a very short interval, e.g. an entry followed rapidly by a departure by migration, or a birth followed by a death at a very young age. The individual could not be identified during the preceding visit and is no longer there during the current visit. For migration, the issue can be resolved by defining the permanent residence according to a duration of presence longer than the interval between visits. For death at a young age, the situation is greatly improved if the pregnancy was declared during the previous visit. More generally, it is also possible for the initial itinerary to be incorrect (omission or under-enumeration) but the later visits often make it possible to identify and correct them.

[53] In developing countries, the method always used is that of the interview, while in developed countries questionnaires sent by post can be used as well as interviews over the telephone.

The most common example in demography, at least in developing countries, is monitoring a *sample of births* in order to study childbirth, characteristics at birth, mortality, morbidity, and maternal behavior with regard to health and nutrition (vaccination, breast-feeding). For example, a sample of childbirths or newborn infants (recorded in maternity wards or in the civil registration system, where it works efficiently) are regularly visited at home. In the *Les enquêtes sur la mortalité infantile et juvénile* (EMIJ) program (surveys on infant and child mortality) carried out by Regional Institute for Demography Training and Research (IFORD) in the 1980s in five African capitals (Courbage, 1979), samples of around 12,000 births were selected in maternity wards and then observed during seven home visits over 2 years. A similar scheme was adopted for the EMIS programme (surveys on infant mortality in the Sahel). Numerous similar surveys, although generally less ambitious, were carried out in Latin America and Asia.

Theoretically perfect, the prospective observation method, which indeed generally leads to better results than the retrospective short-period method, is however not without its methodological and operational problems.

c. The Limitations and Problems of Prospective Surveys

Without going into detail here, there are two different types of problems (Tabutin 1984a, 1984b; Riandey, 1988; van de Walle, 1988): some are inherent to the procedure, others are linked to the field and to analysis.

The major problem of any multiround monitoring of individuals (or households) is *loss to observation* through migration[54] and refusal to respond. These sample losses can introduce bias and affect individuals (and households) whose behavior differs from that of the population of respondents. They also lead to the attrition of the observed population, which can affect the precision of the final measurements. This phenomenon of *sample slippage*, towards more sedentary individuals and towards more favored social classes, through the progressive exclusion of the most mobile populations, the poorest, the most marginal, increases with the duration of monitoring. Moreover, the multiplication of observations during successive visits causes *increased problems* at the operational level of the survey (duration of collection, fatigue of respondents and interviewers, cost of the operation), and also at the level of analyzing the results, which is much more complex.

6. Retrospective/Prospective: An Outdated Debate?

During the 1970s and 1980s, supporters and opponents of the prospective survey clashed, with the former stressing the advantages of multiround surveys[55] and the latter stressing its constraints compared to the flexibility and the rapidity of single-round surveys.[56] The major aim was to improve collection, which was then in full expansion in Third World countries.

The debate gradually died out, partly due to lack of combatants and the fact that the problems and methods of collection were no longer of great interest to many, but also because, for financial reasons, retrospective observation was imposed on the large international programs (United Nations and United States). The developing countries are following the movement because they do not have sufficient resources to explore alternatives. Indeed, very few of them have the financial and human resources to carry out a national multiround survey. A good retrospective survey is better than a bad multiround survey.[57] Nevertheless, the retrospective survey cannot be a replacement for a multiround survey: the correct measurement of mortality at different ages, collective migration, and spatial or social inequalities require prospective observation. But this procedure is more costly, longer, and riskier, at least when used at a national level. The retrospective survey is fashionable, financial resources are rare, international pressure is strong, and prudence and security are required (often rightly so). However, the debate should not be considered definitively closed.

VII. EXTRA TOOLS: AERIAL PHOTOGRAPHY AND REMOTE SENSING

For a long time limited to military strategy and disciplines such as geography, geology, and agronomy,

[54] For examples on France, see Riandey 1988; for an example on Africa, see van de Walle, 1988.

[55] Whether at the theoretical level or because of some clear successes in this period, such as the National Statistical Population Study (ENSP) in Algeria in 1970–1971, based on a three-round survey (Vallin, 1975; Tabutin, 1984b).

[56] Indeed, one of the great misunderstandings of this debate was that the supporters of the multi-round survey were fighting against the proven ineffectiveness of retrospective surveys of the last 12 months, while those of the retrospective survey were relying on the wealth of biographical surveys to safeguard the last 12 months.

[57] By this we mean the common under-use of this type of operation.

aerial photography and remote sensing recently entered into the panoply of tools for demographic data collection, notably in the context of urban observation systems and developing countries.[58]

Aerial photography, an old technique which is very common today, can only correctly record, notably due to the curvature of the earth, microsurfaces. Therefore, a large number of photos must be combined in order to obtain comprehensive aerial coverage of a small territory or a city, but it provides many details, and this is one of its advantages. When it is well executed, it makes possible the selection of districts, compounds, and even buildings, and it clearly provides useful reference points (wells, schools, etc.).

Remote sensing by satellite is much more recent[59] and makes it possible to observe much larger zones (a whole city, a region, even a country), to rapidly obtain the required satellite image (in 20 days, for example, with the SPOT system (Satellite Probatoire d'Observation de la Terre) or even to order it for a specific date, and with classification techniques,[60] to rapidly carry out an initial stratification of the city according to the type of vegetation, densification, the type of habitat, or soil. On the other hand, the satellite image does not yet have the precision of an aerial photograph. For example, it is still often difficult to distinguish the limits, function, and nature of buildings, to distinguish a building from a street, or a large market from a residential zone if the roofs resemble each other.

Remote sensing can be of great benefit to demography in the establishment or implementation of a sample frame, in other words, the constitution of a sample of households, which is a thorny and expensive problem in many countries. The satellite image today makes it possible to quickly and cheaply define[61] an aerial sample frame of a city,[62] by proceeding successively to a stratification according to the density of the frame, then to a selection of small enumeration areas (1st degree) and finally on the ground to a selection of households in these small enumeration areas (2nd degree). Research by ORSTOM[63] (now IRD) on Marseille, Quito, and other towns have demonstrated, since the beginning of the 1990s, the effectiveness of this approach (Dureau, 1995b). In addition to the rapidity of implementation of a sampling frame in cities that do not have a traditional frame, "*the selection of a sample by satellite imagery also favors the description of the internal differences of a city and the analysis of the dynamics of the city's subpopulations*" (Dureau, 1995b, p. 284).

Remote sensing is also very useful in studying urban planning and management, for which censuses and traditional surveys are, and will no doubt remain, unsuitable. They make it possible to continuously and precisely observe the morphology of a city: occupation of the ground, vegetation, densification, buildings, etc., even if all the technical problems have not as yet been solved and that there are non-negligible margins of error (Baudot, 1994). The approach needs to be developed for studying rural settlements, at least in nonarboreus zones.

Going even further, researchers in remote sensing are now attempting to indirectly estimate (on the sole basis of data from the images) the number of households and population, and even the size of families, population density, and sometimes even certain socioeconomic characteristics. Will it be possible one day to dispense of all the other collection methods and notably of censuses for obtaining this type of information? This would truly be revolutionary, but it is still far in the future. The few studies that have compared satellite estimates, with results from the ground, show that the margin of error is still very wide (Baudot, 1994).

Remote sensing is no doubt a tool for the future due to the availability of images, the rapidity of their treatment, and their relatively low cost.[64] They increasingly fulfill certain needs for geographic and spatial analysis. In demography, we can expect it to become an essential tool in the construction of samples and the study of settlements (urban and also rural), at least in countries where the landscape, the climate, and the vegetation allow it, but it will not supplant the essential collection of individual data, which is increasingly varied and numerous and which only the traditional sources of demographic information can provide. This goes without mentioning the technology and the competence necessary to interpret and analyze the images from which many developing countries will suffer.[65]

[58] For more information on this subject, see Dureau *et al*., 1989; Dureau and Weber, 1995; Baudot and Wilmet, 1992.

[59] Use of remote sensing by satellite in town planning began with the appearance of the first high-resolution satellites at the beginning of the 1980s.

[60] Complex techniques which relieve specialists of the interpretation of satellite images.

[61] At least with regard to traditional cartography of the terrain.

[62] So far, this has mainly been done in urban zones.

[63] *Office national de recherche scientifique et technique outre-mer*, recently renamed *Institut de recherche pour le développement* (IRD).

[64] A standard satellite image with spatial high resolution (20 m × 20 m) is far less costly ($1,900 for this type of SPOT image in 2003) than complete aerial coverage of a territory (a city, for example).

[65] Technology which, if it were essential, would once more reinforce the scientific dependency of the poorest countries.

VIII. NEGLECTED SOURCES: ADMINISTRATIVE INFORMATION

By administrative system, we refer to *every source of statistical information currently used by an administration (public or private) in a management objective*. The sources that are of interest to us here are obviously those which contain individual data relating to children in schools, mothers or children monitored by health centres, women giving birth in maternity wards, subscribers to pension funds, those paying social security contributions, patients in hospitals, etc. Of the multitude of administrative registers and files, here are some examples:

- school registers
- hospital registers, maternity clinic registers, and registers of maternal and infant health centers
- social security files
- social insurance fund files, pension fund files
- military, police, and judiciary files

Each of these registers, whether managed at a central or local level, computerized or not, contains information (of variable number) on each individual concerned and sometimes on his/her family environment. They can also be an additional source for studying sociodemographic issues, as long as they are up-to-date and of good quality. They are rarely representative of an entire population and it is sometimes difficult to access them (due to statistical confidentiality, for example). These administrative sources are still rarely sought out by demographers.

IX. A FEW WORDS ON QUALITATIVE APPROACHES[66]

Demography, as a social science based on measurement from the beginning, moving more or less towards comprehension, explanation, interaction between factors, cannot avoid the need for more qualitative approaches. In other words, they are observation methods whose main objective is not measurement, but understanding a phenomenon, a process, or a mechanism by placing it in its social context.[67] As Hubert Gérard (1988) writes, "*the qualitative approach appears as a process of questioning and seeking a response, in the same way as the quantitative approach; it can at the same time therefore be autonomous and sufficient, and consequently it must meet the same demands in rigour and quality as the latter, even if, for this, it must necessarily approach it differently.*"

Generally in demography, qualitative observation is considered as a complementary approach to quantitative observation, and takes one of the following three forms.

1. **Structured or semistructured interviews** are practiced on a few dozen target individuals (generally thirty or so), selected logically, with no concern for a strict statistical representation. During these interviews (there can be two or three), freely or semi-freely (if there is an interview guide), the people speak about their vision of the problem under consideration, of themselves, and of their environment. The content of these interviews, which often last several hours, is then analysed.
2. **Interviews of resource persons** which can be individual or collective (focus-group); the individuals are chosen according to their role, experiences, and their competence with regard to the subject under consideration. For example, with regard to fertility, these would be doctors, midwives, traditional midwives, and welfare officers.
3. **Participant or direct observation** is rarely used in demography. By residing somewhere for varying periods of time (from a few months to several years), the observer integrates as much as possible into the district, the village, or community which is the object of the study and notes all the daily events (both individual and collective) likely to clarify the issue under consideration. This type of work and approach relates more to anthropology than demography.

Different qualitative methods can obviously be combined, notably the first two: life histories or semi-structured interviews can indeed be carried out in parallel with focus groups.

Demographers still seldom use the qualitative approach. Some (generally sociologists) take the risk but the majority do not consider it to be of interest or are unaware of it, if they do not challenge it.[68] It does however have a role in our discipline, either as a preliminary to a quantitative survey (identification of issues, problems, variables, or key factors), or as a complement to quantitative analyses for which they provide an explanation for certain facts or certain statistically established relationships. But it is true that

[66] This aspect will be discussed in greater depth in Chapter 136 by Michel Bozon.

[67] For a broader view on qualitative problems and methods in social science and in demography, see *Chaire Quetelet 1985* (Gérard and Loriaux, 1988). See also Chapter 136 hereafter.

[68] Moreover, this is not surprising when we consider the content of numerous training programs in demography, that are essentially if not entirely focused on quantification, number worshipping.

one cannot just suddenly become a qualitative expert. The collection as well as the (complex) analysis of results require a specific and well established methodological arsenal.

X. PRIVACY AND DATA COLLECTION

The deontological issue of protecting privacy is currently in the headlines in North America and Europe, particularly in countries where computerization and the coupling of information systems is very advanced, where individual freedom is of primary importance, and where private (and frequently commercial) statistics meet public statistics. The problem is not a new one (in a number of countries, the first legislation for regulating surveys dates back to the 1950s and 1960s), but it is accentuated by the multiplication of data collection organizations, the increasing number of operations, the diversification of subjects of study, the opening of borders, the power of new information technologies, and the increasing sensitivity of public opinion (Eurostat, 1986; Riandey, 1996; Moreau, 2001).

In addition to the chapter already dedicated to ethics in demography in Volume 7 (Chapter 99, by François Héran), let us return here to the three main elements composing the problem of relations between statistical collection[69] and privacy: the obligation to respond, confidentiality (or statistical confidentiality), and the content of information requested. It will become particularly clear that the seriousness of the problem varies according to the type of survey, but also that every survey is inevitably an intrusion of privacy.

1. The Obligation to Respond

During surveys and even currently during censuses, some people refuse to respond in the name of respecting their privacy, or that of their household, sometimes through fear of future use of the information provided, other times by the simple refusal of an intrusion into their personal lives. The more sensitive the subject (income, sexuality, marginal behavior . . .), the greater the likelihood of refusal. Should a survey be obligatory? Can it even be so, to the extent that a forced consent necessary leads to bias in the information collected? "*The freedom to refuse and the information provided by the respondent are high priorities in the legal texts, the French Law of 1978 (Informatique et Libertés), and the 1981 Convention (of the Council of Europe in relation to protecting privacy)*" (Riandey, 1996, p. 451).

[69] These problems obviously go well beyond demography.

2. Confidentiality or Statistical Confidentiality

Confidentiality and secrecy are practically always guaranteed in a survey, to the individual participating in a census, or the informant in an administrative register. No personal information is provided to third parties (whether commercial or not), to organizations other than the one to which the declaration was made. But the concept of confidentiality today goes well beyond this simple preliminary guarantee. It includes (or should include) the power for every individual to know, control, and, in the extreme, to refuse any future use of the information provided. The scientific surveys, and those on public (or parapublic) funds mentioned here, and traditional censuses do not cause any major problems from this point of view. In Europe and in North America, research organizations assure anonymity and the protection of computerized files. The case of registers is *a priori* a little more complex: how can the use of population registers be controlled at a local level? How can the fusion of administrative files be controlled in countries where there is only one single national identity number? Who can have access, and under which conditions, to the statistical wealth that is a computerized national register? Northern Europe and Canada completely protect their files and there is complete confidence in their statistical organizations (Eurostat, 1986), while "*French jurisprudence tends to divide the identifiers into sectors in a way that prevents the communication of data between administrations*" (Riandey, 1996, p. 444). In 1995 the European Commission adopted a directive relative to "*the protection of persons with regard to the processing of personal data and the free circulation of these data*", which came into force in October 1998. It states the rights of individuals and the duty of those responsible for the files, but it also includes many exemptions. The risk of personal data being transferred to the commercial private sector, "*the business of population data*" (Moreau, 2001), is more than ever an issue in a world of free exchange, of excess marketing, and fierce competition between large commercial companies.

3. The Type of Information

The protection of privacy includes the types of questions included or excluded in questionnaires. The most typical example in demography concerns variables of cultural identity (ethnic group, language, religion), and variables of behavior (sexual life, relation between spouses, etc.). The sensitivity of these questions, which varies greatly according to situation and country, can lead to the self-censorship of researchers in their topics of study and in their questions.

"*All citizens have the right to be protected against any excesses, including the carelessness or incompetence of researchers*" (Leridon, 1993, p. 399). Ultimately, the problem is finding a balance, a working arrangement between the collective and essential protection of individual rights and the need for reliable and varied statistical information. Exceeding the national context, Europe (now including 25 countries), is committing itself little by little,[70] and is trying to harmonize national legislations (that are still very diverse), while at the same time ensuring the free movement of data, two objectives that are difficult to reconcile. Statistical collection and scientific research can only gain from working within a legislative context which is both clear and adapted to the knowledge needs of contemporary societies.

XI. SOME FINAL THOUGHTS

Everyone will agree that observation is a crucial phase of every study, in demography as in all the other social sciences. The results of analysis, descriptive and causal, depend on the nature and quality of data available (administrative registers, civil registration system), or data collected (censuses, surveys). But societies evolve, mentalities change, new issues emerge, technology progresses, and financial constraints are considerable. Are the current information systems still adapted, appropriate, and relevant?

1. New Demands and Needs of Society

For a long time, too long a time undoubtedly, demography was confined to observing and measuring the traditional demographic events of births, deaths, marriages, and internal migration, measuring growth, and making projections on population dynamics. Today it is obliged to widen its field of observation and research, to assure its social credibility and its role in the system of scientific production. It faces the challenge of "*impossible issues*" (Leridon, 1993, p. 390), that are often burning issues, both politically and socially: illegal induced abortion, illegal immigrants, international migration, omissions in censuses, population ageing, etc. It must also deal with the increasing diversification and complexity of individual life courses, notably of family structures and residences. It must become more committed to the interactions between professional activity, migration, and family life. In short, *it must increasingly deal with the new problems of society* and here it is obvious that the old, traditional demographic information systems are inadequate or totally outmoded, without forgetting that social demands are becoming more diverse, from stakeholders (users) that are more numerous now than in the past (public and private sectors, associations, NGOs, local managers, mass media, other sectors of social science research).

2. Technology and Cost of Information: Progress, But . . . ?

In a few years (the 1970s and particularly the 1980s), the spread and progress of computerization has transformed demographic data collection, regardless of method: acceleration of data entry, data management and processing, increase in record linkage, direct linking of one level (e.g. a town) with another (the region, the country). We can even foresee little by little tools for portable and direct data entry on the ground, which will even change the nature of the interviewer's work. But paradoxically, apart from some rich countries, this has not resulted in the hoped for revolution in the waiting period for scientific production, whether it be in the context of civil registration, censuses, or surveys. Progress is being made but we still depend on cumbersome and slow machinery.

The technological progress has not led to a drastic reduction in cost either. In the best cases, the unit cost falls, but not the total cost, which sometimes even increases. The collection of population data remains expensive, as it requires increasingly detailed questionnaires and the samples must be relatively large in order to be representative. With regard to the census, it may soon be considered as a luxury that very few developing countries can afford, without mentioning recent technologies, such as remote sensing which is promising but financially and technically difficult to access for many. A large number of developing countries, notably the poorest ones, are already in total or near total financial dependence.

3. International Recommendations and Programs—Warning: Danger!

One cannot *a priori* deny the usefulness of *international recommendations* in the field of demographic information. Generally proposed by the various specialized organizations of the United Nations, or by regional organizations such as the European Union,

[70] See notably the directive on privacy and the movement of data voted by the European Parliament in July 1995.

they vary from the definitions of concepts to the issues and variables to include within observation systems. The praiseworthy objective is to succeed in generating demographic statistics that are comparable between countries. But by standardizing too much, and by imposing too much (willingly or not), the diversity of local or regional initiatives is reduced, the freedom of choice in each country is restricted, scientific knowledge is definitively impoverished. Without mentioning the fact that reference models and expertise come mainly from developed countries. Regional recommendations do not fundamentally change anything.

One cannot either deny the usefulness for countries, or for the international scientific community, of *large international survey programs*, such as DHS and FFS. Due to the DHS programme notably, in sub-Saharan Africa alone, 69 national surveys in 33 countries (many of them amongst the poorest in the world) were carried out between 1986 and 2003. Without them, knowledge of fertility and child mortality/health in Africa would be lacunary. But every coin has its flip side. Concepts, procedures, measurement, reports: everything is standardized (or almost) at an international level. As Thérèse Locoh (1995) writes about Africa: "*the standardized drafting of reports only leaves a little room for understanding the specificities of a society and makes it possible to standardize the interpretations that are proposed with a view to orienting the actions with regard to population. The necessity for rapid production and of providing a clear message (the need for family planning) results in simplifications that can frequently be criticized.*" Under no circumstances should these programs supplant national operations and research, but the risk is very real in the increasingly numerous countries that are stripped of resources.

4. And the Quality?

Much is discussed in terms of the quantity of information: increasing and diversifying the number of surveys, carrying out censuses more frequently, developing civil registration systems. There is no lack of recommendations, plans, and ideas. And on this aspect some progress has been made all over the world during the last two decades. On the other hand, much less is spoken of the quality of data, notably for example, problems on the ground, the pertinence of questionnaires, the degree of reliability of the results, the margins of error, the procedures for verifying and correcting data, the nonresponses. This is due to the lack of methodological research on data collection, as much in developed countries as in developing countries. Studies of quality and methodology should once again become priority.

5. The Future of Training and Imagination?

In conclusion, it seems to me that the area of information in demography suffers from a lack of imagination and new ideas. It is not a coincidence but a consequence of the fact, already mentioned at the beginning of this chapter, that data collection is the poor relative in demography, due as much to the procedures in force for evaluating research and researchers, as to the directing of programs by funders. Strengthening training in this field seems to me essential if we wish to introduce methodology, a critical attitude, and imagination within the new generation of demographers. In other words, in order to make progress and to be innovative *it is necessary ultimately to restore data collection to the position it held at the beginning of our discipline*.

Internal Migration: Observation and Concepts

BRIGITTE BACCAÏNI

Institut national d'études démographiques (INED), Paris, France

Migration is undoubtedly the demographic event that poses the most challenges for observation and conceptualization. It assumes a double reference, both spatial and temporal: a residential migration is a move between two places situated a certain distance apart and in which the duration of residence has been long enough for the move not to be considered temporary. These criteria are not entirely clear, nor are they unanimously accepted (see Chapter 22 of Volume I). Short-distance residential mobility, as between two dwellings in the same municipal district or same city, for example, is not always considered migration. Use of the term *residential migration* assumes also that a place of residence or successive places of residence are clearly identifiable, which can be problematic for certain population categories or in the case of multiple residence.

The sources of observation are disparate and rarely free of defects, and are themselves at the origin of assorted concepts and measures, often of poor comparability. Measures of mobility can vary even within the same country, depending on the source of observation used. At the international level, the harmonization of sources and of measurement methods for internal mobility remains an as-yet unrealized goal.

For several decades, however, migratory movement, rather than natural change, has been responsible for the differentials in population growth between subnational areas, especially at finer spatial scales and for this reason deserves particular attention. The contrasts in growth between rural and urban areas, between city centers and suburbs, between economically dynamic and declining regions, result primarily from migration exchanges. More importantly, the internal contrasts of the natural balance are themselves often merely a consequence of migration. With levels of fertility and life expectancy tending to uniformity at the national level, the disparities observed in birth and death rates arise primarily from differences in age structure. Now the contrasts in age structure between regions or between different neighborhoods of a conurbation originate in the age composition of the migration flows, which vary widely according to the zones of origin and destination. A region such as the Ile-de-France, attractive for young people who come to study or to look for a first job, but strongly propulsive for other age groups, enjoys a strongly positive natural balance thanks to migration. Somewhat paradoxically, therefore, the relatively fast growth of the Ile-de-France population is driven by the migration flows affecting the region despite its own balance being negative (Baccaïni, 2001).

Migration not only contributes to changing the spatial distribution of the population inside a national territory, it modifies the sociodemographic structures of the spatial subdivisions that make up this territory.

An initial definition of *internal migration* is a permanent change of residence inside the boundaries of a country. It is therefore a fundamentally spatial event, one that is observed at a variety of scales, stretching from a simple change of address within the same municipal district or *commune* (the smallest administrative unit in France), to a long-distance move to another region. These movements are very different in nature, and so necessarily are the concepts associated with them.

Concepts evolve also in response to social change and changing lifestyles. New concepts develop when new kinds of migration flows emerge, like those involved in the processes of suburbanization (periurbanization) or of counter-urbanization, for example.

Section 1 of this Chapter shows how the conceptualization of internal migration is related to different modes of approach and research questions, still largely bound to disciplinary divides. The question of the shortcomings in sources for internal migration, and hence in its observation, is addressed in Section 2.

I. DIVERSITY IN APPROACHES AND CONCEPTS

From the start of this discussion, we exclude the various journeys undertaken daily or less frequently but that are not associated with changes of residence—journeys by commuters and holiday makers, for example—and confine attention to residential migration. Two main approaches are then possible. According to whether the focus of study is the territory (spatial analysis of migration) or the individual (demographic or sociological analysis of migration), the concepts employed are different. In the economic analysis of migration, the main emphasis can be on the territory (spatial economics) or on the individual (microeconomics), depending on the case.

1. Internal Migration as a Revealing Factor in Spatial Interaction

Spatial analysis of migration approaches the migratory phenomenon in terms of flows that create interactions between distinct places. Attention focuses not on the individual migrant but on the territory and on the spatial interaction that migration can help to create or reveal. The term "flow" here denotes the "*measurement of spatial interaction obtained by summing the individual moves or the material or immaterial quantities exchanged between two geographical zones for a given length of time*" (Pumain and Saint-Julien, 2001). Geographers and planners study the distribution of flows of migrants between the geographical subdivisions of a country, the migration balance of the units under analysis and their net migration rate (obtained by dividing this balance by the population of the zone). The phenomena brought to light include specific flows, barrier effects, poles of attraction and places of repulsion.

This line of research led to the introduction of spatial interaction models, usually based on the gravity model and in which distance plays a key role. This model was first proposed in the late 19th century by many authors who observed a pattern in the organization of migrant flows: the closer together the zones and the larger their populations, the greater the flows between them. In this model, F_{ij} the number of interactions between geographical zones i and j is proportional to the product of the masses M_i and M_j of each region and inversely proportional to the distance between them:

$$F_{ij} = kM_iM_jd_{ij}^{-a}$$

Parameter a in this equation represents the frictional effect of distance. Other things being equal, the higher the value of this parameter, the fewer exchanges there are at a given distance. Parameter k, which controls the relationship between the volume of flows and that of the masses, depends on the rate of mobility, i.e., the proportion of migrants in the population.

The gravity model often gives a good account of migration flow patterns, but "*the theoretical framework underlying this model* [. . .] *is still weak*" (Pumain and Saint-Julien, 2001).

In fact, this model is valuable—less for showing the effects of distance and of the populations at risk, often regarded as trivial, than for permitting through examination of the residual flows an analysis of the migration flows that eliminate these effects. The divergences between the empirical observations and the model may thus reveal less familiar explanatory factors for interregional flows and bring to light the existence of "barrier effects" or "preferred flows" (Pumain, 1986; Baccaïni, 1993).

Over the longer-term, the flows exchanged between the regions of a country result in a spatial redistribution of the population. However, it is possible for two regions to exchange large numbers of migrants without these movements having any major impact on their populations if both flows are of similar size. Conversely, migration at a low intensity can have a relatively large impact on the population of the regions concerned if the two flows are highly unbalanced. The concept of migration "efficiency" expresses the proportion of the flows between two areas that have a real effect on the spatial redistribution of the population. It is measured as the ratio between net migration (the difference between in- and out-flows for an area) and gross migration (the sum of in- and out-flows). The closer this indicator is in absolute values to 1, the more *efficient* the migration movements have been in terms of redistributing the population.

It is frequently observed that population movements are in large part simple substitution movements. For example, in France between 1990 and 1999, only one quarter of the migration between the 137 urban areas with over 50,000 inhabitants qualified as efficient. Put another way, three quarters of the migrants who left one town or city for another had no effect on the population profiles of these towns and cities, in strictly numerical terms, even though they may have altered the sociodemographic composition of their populations, as when a 10-year-old child replaces an economically active 45-year-old, for example (Baccaïni, 2003).

2. Varied Processes Contribute to Population Redistribution

Processes of various kinds contribute to the redistribution of the population within a country, processes that often succeed each other over time and in this way lead to the introduction of new concepts. We shall draw on the case of France to illustrate these concepts.

In the industrialized countries, the evolution of migration flows is closely bound up with changes in town-country relations broadly defined. The concept of "urban transition" developed to parallel that of the demographic transition, summarizes the general pattern observed in most western countries since the industrial revolution (Baccaïni *et al.*, 2000). In this pattern, a population distribution dispersed between numerous small rural localities has given way to one concentrated in urban centers that are larger and more differentiated in size. At the level of cities, after a period of concentration, the population distribution began to decentralize, through a reduction in inner-city densities and an extension of urbanization in the suburbs and semirural periphery from the 1970s. In Europe, these stages have appeared at different times in different countries: earlier in the United Kingdom and the countries of northwestern Europe, later in those of southern, central and eastern Europe.

In western countries, the period comprising the 19th century and the first half of the 20th century was characterized by rural depopulation or "rural exodus." In many countries of the developing world, this process is still under way. Rural depopulation occurs when the population of zones in which agriculture is the main economic activity migrates to towns and cities. Because of its selective nature, this out-migration produces distortions in the age and sex structure of the population. Those leaving are primarily young, economically active people, and frequently include more females than males. The rural zones thus have to contend with both an ageing population and with a rise in the proportion of men never marrying. For France, this phenomenon has been analyzed in detail by Pierre Merlin (1971). He found that 30% of the rural population, or around 7.5 million persons, left the countryside between 1872 and 1931.

The rural communes of France had a negative migration balance, i.e., departures outnumbered arrivals, until the early 1970s (the annual rate of change due to net migration still stood at –0.8% between 1962 and 1968, and at –0.2% between 1968 and 1975). It was only from this date that the direction of migration reversed and rural communes taken as a whole became attractive, acquiring a positive migration balance. The rural communes are defined by Institut National de la Statistique et des Etudes (INSEE) as communes that do not belong to any urban unit. An urban unit is a commune or group of communes in which is located a built-up area of at least 2,000 inhabitants where no dwelling is more than 200 m away from its nearest neighbor. Other definitions of "rural," based on more functional criteria, exist—in particular the one which stems from the classification of zones as urban areas (Bessy-Pietri and Sicamois, 2001).

Urbanization is a corollary of rural exodus and corresponds to the concentration of population in urban settlements of varying sizes. Usually it is accompanied by growth of the urban population in absolute terms. Depending on the stage of the process, different levels in the urban hierarchy are affected. In France during the 1960s, a decade of rapid urban growth, the larger the size of the cities, the greater their "pulling" power. Between 1962 and 1968, the annual rate of change due to net migration rose steadily from the smallest urban units (+0.4% for those with under 5,000 inhabitants) to the largest (1.3% for those with over 200,000 inhabitants, except the Paris urban area, which grew more slowly). At the start of the 1970s, urban units except Paris still had a positive migration balance, but the smallest among them had become the most attractive. Since 1975, the medium- and large-sized urban units of over 20,000 inhabitants have been losing population in aggregate terms due to migration (though they continue to grow because of a net natural increase), and only the smallest retain a positive migration balance, though lower than in the rural communes.

Does this justify use of the term *counterurbanization* for the case of France? The concept of counterurbanization was introduced in the United States in the 1960s. It denotes a systematic loss of population from urban centers, especially the largest ones, that contrasts with gains for the population of smaller towns and cities and rural areas. The only countries in Europe for which this process is confirmed are the United Kingdom and, to a lesser degree, the Netherlands (Fielding, 1986). For France, such a hypothesis is poorly established, since the least accessible rural areas and some small towns continue to lose population. Furthermore, analysis of migration rates by city size shows that the highest net losses are not from the major cities (over 200,000 inhabitants, excluding the Paris urban area), which have seen a substantial reduction in their migratory deficit over the last decade, but from the intermediate cities with between 50,000 and 200,000 inhabitants. The medium-sized cities, with populations between 20,000 and 50,000, also record heavier losses from migration than the very large cities.

At the scale of urban areas, the phenomenon that has prevailed in most of the industrialized countries since the end of the 1960s (slightly earlier in the United States and United Kingdom) is a process of urban deconcentration that sometimes goes under the name of "periurbanization." This process is also observed, albeit in different forms, in the countries of the developing world (Dupuy and Sajous, 2000).

Periurbanization (or suburbanization) can be defined as the relocation of population within an urban area away from zones in or near the center, to zones on or beyond the periphery. In many cases, the members of this "periurban" population continue to work in the city center zones, thus causing an increase in both the volume and length of home-workplace commuting journeys (Baccaïni, 1997). In France, the peak of periurbanization occurred between 1968 and 1975 for Paris, and between 1975 and 1982 for most of the other urban centers (Le Jeannic, 1997). During this period, the annual rate of net migration gain in the periurban rings was 2.4%, whereas the core zones or "urban poles" experienced negative net balances (–0.43% per year). This process has since slowed, with the periurban rings recording a relative annual gain from migration of 0.6% between 1990 and 1999; however, urban sprawl is affecting zones further and further from the city centers. Most urban poles and their periurban rings have thus registered a migration deficit since the period of 1975 to 1982.

3. The Migrating Population Perspective

When attention focuses more on the population itself than on the territory, the question of internal migration leads to the different concepts of, first, the level of mobility, and second, the selectivity of migration.

By *level of mobility* one means the proportion of the population in a zone undertaking a move during a specified period. The mobility in question can therefore concern every residential move or, on the contrary, be limited to moves from one administrative unit to

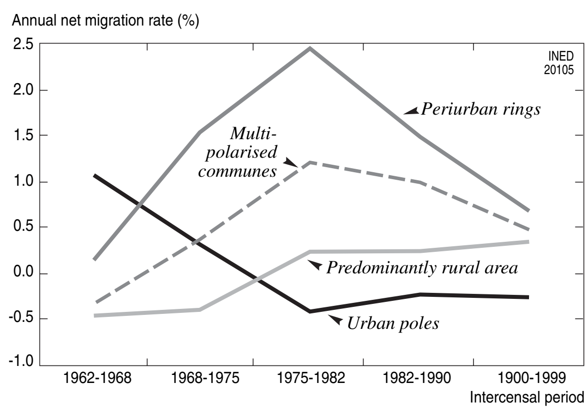

FIGURE 122–1 Trend in migration balances by type of spatial unit, France. (Source: INSEE, Population censuses).

TABLE 122–1 Net Migration Balance by Size of Urban and Rural Units, France

Rate of Annual Variation due to Migration Balance (%)	Intercensal Periods 1962–1968	1968–1975	1975–1982	1982–1990	1990–1999
Rural communes	–0.79	–0.22	0.95	0.73	0.48
Urban units <5,000 inhabitants	0.44	0.70	0.84	0.49	0.45
Urban units 5,000–10,000	0.81	0.75	0.54	0.36	0.30
Urban units 10,000–20,000	0.87	0.76	0.20	0.14	0.06
Urban units 20,000–50,000	1.12	0.45	–0.22	–0.19	–0.13
Urban units 50,000–100,000	1.27	0.64	–0.35	–0.27	–0.36
Urban units 100,000–200,000	1.20	0.40	–0.58	–0.47	–0.17
Urban units 200,000–2,000,000	1.29	0.43	–0.37	–0.16	–0.08
Paris urban area	0.63	–0.11	–0.60	–0.27	–0.64

another. The degree of mobility of the population will thus vary considerably. In France, for example, the annual rates in the period from 1990 to 1999 were 8.1% for changes of residence, 5.3% for between-commune moves, 2.5% for between-department moves, and 1.6% for changes of region (Baccaïni, 2001).

The sensitivity of mobility measurement to the form and/or scale of the geographical or administrative division creates problems for international comparisons in particular. Having shown that the rate of mobility varies as a logarithmic function of the number of units in the division used, Daniel Courgeau in 1973 proposed an index for quantitative evaluation of internal migration that is independent of the geographical unit of measurement (Chapter 22, Volume I).This index has recently been used to compare mobility levels in ten European countries, showing that mobility is higher in northwestern Europe and lower in eastern Europe (Rees and Kupiszewski, 1999b).

Migration motivations affect individuals to varying degrees. As it does for other demographic phenomena, selection operates on the basis of age, sex, marital status, educational level and occupational status. The concept of differential migration expresses this unequal propensity of populations to migrate according to their sociodemographic characteristics. Most research in this domain shows relatively high mobility between ages 20 and 30, a greater mobility among men than among women, and among highly qualified individuals compared with those who are not. But while selectivity by age follows the same pattern in most settings, it is harder to generalize about the role of selection by sex (in the developing countries, for example, women are often more mobile than men) or by educational level (the higher mobility of qualified individuals is mainly for long distance migration, far less for short-distance moves).

To capture the qualitative effects of migration into and out of a particular zone independently of the overall attractiveness of the zone, a coefficient of differential migration can be used. For a subpopulation x, this coefficient is defined as follows: If I_x is the number of arrivals in the zone belonging to subpopulation x, and E_x the number of departures from the zone belonging to subpopulation x, then I and E the total number of arrivals and departures, respectively, for the zone:

$$c_x = \frac{I_x/E_x}{I/E}$$

We say that the zone is selective for subpopulation x when this coefficient is greater than unity, and conversely that it has a repulsive effect for the subpopulation when the coefficient is less than unity.

4. Analysis of Individual-level Migration Behavior

If we adopt the standpoint of the individual, for the study of individual behavior, other concepts, both temporal and spatial, have to be employed. Here we discuss those of life cycle, residential strategy, residential trajectory, and change of life space.

Demographers and sociologists are devoting a growing proportion of their research to studying spatial mobility, for the most part explaining it by reference to the motivations and attributes of individuals. The objective is to understand and explain why the propensity of individuals to migrate varies with their sociodemographic characteristics, and to identify the reasons for their migration. This approach has been enriched by the concept of the life cycle, introduced into demographic and sociological research 20 years ago (Courgeau, 1984). This substitutes criteria of social age (the position of the individual in relation to family and labor market careers) for the traditional considerations of variations in mobility by age, thus improving the interpretation of migration at the individual level. Residential migration by individuals is examined in relation to their complete life histories, in a longitudinal perspective. Attention focuses on the interactions between the different events of the life cycle (Baccaïni, 1991). A better understanding of residential mobility has been gained through the development of new methods of analysis with the capacity to handle individual (micro) longitudinal data and to allow for the interactions between events occurring over the life course of individuals (Courgeau and Lelièvre, 1989; Baccaïni and Courgeau, 1996). The *residential strategies* research theme first emerged in the mid-1980s. It was the subject of a seminar held in October 1988, organized by Institut National d'E'tudes De'mographiques (INED) and the Plan Construction et Architecture (PCA). As Jacques Brun (1993) has pointed out, "use of this concept is based on the assumption that the bulk of individual actors have the possibility of expressing a minimum of independence in managing their residential life." Thus, some authors reject use of the term for the practices of individuals, arguing that institutional and macroeconomic actors alone have the possibility of implementing genuine strategies. Residential strategies can be considered from three angles: (1) strategy related to housing occupancy status and in particular home ownership (Cribier *et al.,* 1990); (2) strategies related to certain periods in the life cycle (nest leaving, divorce, retirement, etc.); (3) and strategies related to locational choices (Brun, 1990). Using the notion of strategy is not to deny that migrants face constraints, notably economic ones, or to credit them with unlimited freedom in their residential decisions; the objective is to capture the social and cultural determinants of these decisions in their full diversity; more attention is given to the aspirations of individuals and to residential behavior.

The concept of *residential trajectory* represents a direct continuation of the two previous concepts of life cycle and residential strategy. Use of the term trajectory implies envisaging residential migration in a life history perspective, as a succession of residential choices, of places occupied, and with linkages to family and labor market trajectories. This notion thus takes into account the spatial and temporal dimensions of the phenomenon. *Residence* is defined as the place where the individual usually lives. The *life space* is defined, then, as that part of space in which the individual carries out all his or her activities (Courgeau, 1980; Courgeau, 1988). A simplified life space may correspond to the individual's home and place of work or education, but it can also be made to include his or her relational network, thereby delineating a more complex life space. Conceptualizing migration as a change of life space considerably enriches the notion of residential migration, since the life space of an individual can evolve in several ways: extension to new points of spatial attachment, spatial relocation or transplantation, or contraction.

5. The Economist's Perspective and Concepts

In the macroeconomic perspective, migration is an indicator of disequilibrium. Migration balances are interpreted as measures of spatial economic disequilibrium, hence migration acts as an adjustment mechanism, particularly for income and employment levels between regions, helping to bring about an optimal economic equilibrium.

This theory is the basis upon which are constructed most aggregate-level econometric models of migration. These models proceed by estimating a migration function in which the dependent variable is the flow of migrants (or migration rate) from origin zone i to destination zone j, with the explanatory variables most often introduced being the income differentials between the zones (Greenwood, 1975), levels of unemployment, occupational structure, level of job skills, etc. If the wages- (or income level–)migration relationship often yields significant results, that between unemployment and migration is less certain. As Michael Greenwood (1975) notes, many studies into the effect of the unemployment rate on migration have produced results that do not conform to expectations. The relationship between unemployment and migration is complex and cannot be reduced to a direct correlation, as is shown by the example of the French regions at the present time. In the northern regions where the negative migration balance goes with high levels of unemployment, one might be tempted to attribute the strong out-migration and weak in-migration to unemployment and lack of job opportunities. But in the regions of southern France (Languedoc-Roussillon in particular), a high level of unemployment coexists with a strongly positive migration balance. In these regions, it is as if migrants move in independently of labor market opportunities, bringing new demand, but also, with their savings, a capacity for expenditure or investment favorable to growth on an appreciable scale, albeit insufficient to provide jobs for everyone. Unemployment thus appears to be at once a cause (in the declining regions) and a consequence (in the growing regions) of migration (Aydalot, 1985, Chapter 5).

The microeconomic approach to migration is based on the idea that for individuals the decision to migrate is the consequence of a comparison between their present situation (employment, income, etc.) and the situation they hope to achieve by changing place of residence. The notion of migration for the pursuit of well-being has been given theoretical form by Larry Sjaastad (1960, 1962) with the so-called "human capital" models. Individuals migrate to improve their human capital, i.e., their lifetime capacity to create the conditions for achieving higher income. In other words, individuals will migrate if they believe that the benefits will exceed the costs. Human capital models take into account economic costs and benefits, but also introduce nonmonetary measures (psychological costs like that of leaving one's friends, the benefits to be derived from a better climate, moving closer to friends, etc.). The costs and benefits of the migration become apparent not immediately but over a period of time, so the migration can be seen as an investment made by the individual. By formalizing this approach, one can define a value for the investment associated with migration from i to j and, therefore, suppose that an individual will migrate from i to j only if this value is positive. Moreover, the individual will tend to select a destination j for which this value is highest. These models thus take the form of a subtraction: the hoped-for gain from migrating from i to j is a function of the difference between the expected utility at j and that existing at i, minus the costs of migrating.

William Milne (1991) has produced a good synthesis of these human capital models. He formalizes the individual decision to move to live in a region

j as an indirect utility function (v), in the following way:

$$v(P_j, W_jOY_j, A_{ij}) > v(P_i, W_iOY_i, A_{ij}),\ i \neq j$$

where:

P_i = a vector of prices of goods in region i.
W_i = individual wages in region i.
OY_i = individual benefits (other than wages) in region i.
A_{ij} = a vector of other variables (climate, job opportunities, etc.) characterizing region j from the perspective of an individual residing in region i.

The general formulation of the human capital model, used in empirical studies, considering that the flow of migrants from i to j can be written:

$$M_{ij} = f_{ij}\ (X_i, Y_j, c_{ij})$$

where:

X_i = a vector of variables in origin region i that influence the decision to migrate.
Y_j = a vector of variables in the destination region j that influence the decision to migrate.
c_{ij} = the cost of migrating from i to j
f_{ij} = a functional form (for example, linear or log linear).

These models have been extended for interpreting family migration. In this case, the move is viewed as a family investment in human capital (Mincer, 1978).

II. MULTIPLE BUT DEFECTIVE SOURCES

In contrast to the other demographic phenomena (births, marriages, divorces, deaths), migration is not the subject of recording by civil registration systems.

Four sources of information can be used to measure and analyze the residential migrations of populations. They fall into two main groups (Poulain, 1994). First, censuses and surveys, whose purpose is essentially statistical. Second, population registers and other administrative documents for which statistical analysis, particularly the study of mobility, is not the principal objective. Data from censuses and registers may have the advantage of giving complete coverage of the population of a country, but they often prove inadequate for a satisfactory analysis of residential mobility, particularly when one wishes to examine individual behavior. Surveys alone can capture the stages of the process that leads an individual to move.

1. Censuses

In the past, the bulk of information on the residential mobility of individuals came from censuses and was obtained by cross-tabulating the question on place of birth with that on place of residence. Over the last 50 years, new questions have been included in censuses: the date of the last move, the place of residence prior to this last move, and the place of residence at a particular date in the past.

A simple method for estimating the migration balance of a geographical area between two censuses is often used, since it is based on a minimum of information.

If the natural balance of a zone (B_{t1}–$D_{t1,t2}$) is subtracted from the total population change (P_{t2}–P_{t1}), we obtain an estimate of net migration:

$$I–E = P_{t2}–P_{t1}–B_{t1,t2}–D_{t1,t2}.$$

This estimate has the disadvantage of lumping together domestic and international migration, as well as making measurement dependent on the uneven quality of the censuses conducted at t_1 and t_2, and on the possibly defective recording of births and deaths by the civil registration system (Baccaïni, 1999).

However, this method does also permit estimation of migration balances by groups of cohorts (for example, the migration balance for persons born between 1960 and 1970), births not then being included in the equation.

The question on place of birth presents the advantage of supplying a basic statistic of high spatial and temporal availability, having long been included in most census questionnaires. Over time, however, a falling off has been observed in the use of this question for measuring residential migration, probably due to the introduction of questions that permit a more refined approach.

This question can be used in a given territory to identify the persons whose current place of residence is different from their place of birth, referred to as *lifetime migrants*, but it raises several types of problem. The results are hard to interpret because they amalgamate the moves that have occurred at any age in a long and ill-defined period extending from the birth of the persons enumerated up to the date of the census.

Nothing is known about multiple intervening moves between birth and the census, or about return moves away from and back to the place of birth. Thus, individuals counted as residing at their birthplace could in fact have made many moves in their lifetime but have returned to the birthplace by the date of the census.

Identifying the place of birth of elderly people can be difficult because of changes to territorial divisions that may have occurred since their birth. Moreover, it seems that a nonnegligible proportion of the population, even in the industrialized countries, is unaware or has only hazy knowledge of its place of birth.

Nowadays, births in the industrialized countries usually occur in clinics and hospitals, most of which are situated in towns and cities. Consequently, the place of birth question is of limited value for studying migration, in particular between rural and urban zones. A question on the place of residence of the mother at the birth of the enumerated individual would be more useful.

Despite these limitations, however, the place of birth question can supply valuable information on residential mobility. Thus, when working on age groups not yet at retirement (for which returns to place of birth are assumed not to be on a significant scale), comparison of the place of residence with the place of birth gives a good idea of the trend in the mobility of the population. In France, the percentage of people aged 45 living outside the *département* in which they were born has risen from 20% in cohorts born at the start of the 19th century, to 25% in those born mid-century, to 35% in those born at the start of the 20th century, and to nearly 50% in cohorts aged 45 at the end of the 20th century (INED, 1989).

The question on birthplace can also be valuable when used in conjunction with the question on place of residence at a fixed date in the past. In this way, the spatial location of the individuals is known at three dates, and although any multiple moves that occurred during the two periods are not observed, examination of these data is richer than when using a single question (Courgeau, 1982).

In some countries (though rarely those of Europe), a question is asked on previous place of residence, often in association with a question on duration of residence at the address occupied at the time of the census. These questions thus provide geographical and temporal information on the last move of the individuals. Analysis of internal migration using these questions faces numerous pitfalls. The last moves of individuals may have occurred at very different times: for some individuals the last move may have been very recent, for others many years ago. This aggregate of last moves can thus provide no information about the volume of migratory movements in a country at a particular point in time. Furthermore, individuals who have been in the same place of residence for long periods may give incorrect answers, due to recall failure. Frequently, therefore, attention is limited to last moves that occurred in the year prior to the census, by considering only the individuals who reported a length of stay of less than 1 year at their present address. A spatial analysis of internal mobility in the course of the year is then possible.

An increasingly common practice is for national censuses to include a question on the place of residence at some fixed date in the past. The date selected in the past is usually 1 or 5 years before the census, which is the basis recommended by the United Nations. In some countries, a reference date is chosen that has connection with a major event in national history, so as to limit memory recall errors. In France, since the 1962 Census, individuals are asked about their place of residence on January 1st of the year of the previous census. In 1999, therefore, the question concerned the place of residence on January 1, 1990.

However this question is formulated, it allows identification of migrants (individuals who have changed residence in the course of a fixed period), not of moves (events occurring at specific points in time).

The number of migrants is underestimated due to the omission of any individuals who, in the course of the period, have gone abroad, or died, or made a return move between two zones. For children born in the period, the United Nations (1988) recommends that they be assigned "*migration characteristics derived, preferably, from data for the migration characteristics of the mother*." These children will thus be considered migrants if their mother is, even if they were born after their mother's move. It may be preferable to exclude these children from published migration statistics, as is done by some countries (including United States, Canada, and Australia).

Because of multiple moves, the number of migrants is less than the number of moves. The underestimation of mobility using this question is especially large for short-distance moves, which are more frequent than long-distance moves. In addition, the real direction of the migration flows is poorly identified. What we obtain by comparing the place of residence of individuals at two dates separated by a relatively long interval is the result of all the moves made by individuals during that period. In an extreme case one could count the migrants between i and j without any real move ever having occurred between these two places, if all the migrants had in fact merely made one or several intermediate stages. When the reference period is 1 year, the number of migrants is close to the number of moves, since multiple moves are fewer the shorter the period. Note also that migration balances *are* well measured, if we overlook however the impact of mortality.

It can also be noted that for understanding the role of migration in the process of spatial population redistribution, information on migrants between two dates is probably more useful than information on moves. If the objective is to compare the spatial distribution of the population at two dates, by revealing the relative contributions of migration movement and natural increase to the observed changes, information on the resultant moves and on migration balances is quite adequate. On the other hand, using this information on the migrants is more problematic when the objective is to analyze the mobility (frequency of moves) of individuals. Recourse to migration behavior models then becomes necessary (Chapter 22, Volume I).

2. Surveys

Among the many surveys used for analysis of residential mobility, we must distinguish between those in which migration is the central focus and those whose objective is quite different but include questions on mobility.

Among the specific surveys that seek to give a full account of residential migration, two main types can be identified: retrospective surveys and prospective surveys.

a. Retrospective Surveys

Retrospective surveys are the most widely used and the easiest to conduct. The French *Triple Biography* (or "*3-B*") survey, a retrospective survey conducted by INED in 1981 and directed by Daniel Courgeau, probably represents the best approach in this domain. This retrospective survey had objectives going well beyond the study of mobility, though this came within its scope. It recorded the main lifetime events of respondents in the areas of family, employment and migration. The many analyses based on this survey have increased the understanding of the frequently complex interactions between moves by individuals and family and labor market events (Courgeau, 1984; Courgeau, 1985a; Baccaïni, 1991). The "*3-B*" survey marks a direct extension of surveys conducted by INED from the early 1960s. Mention can be made of Guy Pourcher's 1961 survey, entitled *Le peuplement de Paris. Origine régionale. Composition sociale. Attitudes et motivations* ["The Population of Paris. Regional origins. Social composition. Attitudes and motivations"], or the survey conducted in 1972 by Alain Girard and Henri Bastide called *Mobilité de la population et motivations des personnes* ["Population mobility and personal motivations"]. The *Peuplement et dépeuplement de Paris* ["Population and depopulation of Paris"] survey conducted by Catherine Bonvalet in 1986 was modelled on the "*3-B*" survey, though it put the emphasis more clearly on the links between family and housing. The "*3-B*" survey has provided the model for numerous surveys conducted in other countries.

These retrospective surveys raise a number of problems that are often hard to overcome. The most intractable is certainly that of misreporting by individuals, who have to rely on their memory, resulting in omitted events, errors on dates of moves or places of residence. Also, to the extent that a survey can only reach the individuals who have survived and are present in the country, the sample is never representative of the cohorts studied.

b. Prospective Surveys

Prospective surveys are widely used in the developing countries, little so in the industrialized countries. This type of survey overcomes the problem of recall failure. A distinction needs to be made between multiple-round surveys, which do not really track individuals spatially but at best question people who have not moved to obtain information on those who have, and surveys which do follow the initial population. These surveys, though they yield extremely rich information on mobility, are costly to execute, and the risk of being unable to trace the majority of migrants is high.

In France, surveys on residential mobility have been conducted using the records of the French electricity distribution company (EDF) on its account holders. The methodology for these surveys was developed by Observatoire des loyers de l'Agglomération parisienne (Observatory of Rents in the Paris region; OLAP) in 1995, in response to a request from the Direction générale de l'urbanisme, de l'habitat et de la construction (DGUHC) of the *Ministère de l'équipement, des transports et du logement*. A national survey and six local surveys have been conducted using this method. The main disadvantages with these surveys, besides their high cost, are that they cannot be used to calculate mobility rates, compare the population studied with the total population, or carry out detailed cross-tabulations.

c. Other Surveys

Other surveys not primarily intended for analysis of residential mobility are nonetheless suitable for this purpose. Here we will mention two such surveys.

The labor force surveys conducted in most European countries provide valuable information on spatial mobility. The French version of the labor force survey, the *Enquête emploi*, is conducted by INSEE. It is an annual survey, conducted on a continuous basis since 2003 (interviewing is spread over the whole year), on a sample of some 60,000 households in which all individuals aged 15 or more are interviewed. One third of the sample is replaced each year. The survey includes a question on the place of residence 1 year ago. Few individuals change address more than once a year, so this measure of movers in 1 year corresponds closely to the number of moves. In addition, a parallel can be established between residential change and occupational change, since a series of questions describes the main activity of the respondent 1 year before the survey date.

These data cannot be used for studying migration flows at a detailed geographical scale (though the survey is representative at the regional level). However, they do permit monitoring of the phenomenon on a yearly basis and are helpful for detecting the most recent trends in mobility.

The *Enquête logement* (Housing Survey) is one of the main surveys conducted by INSEE both by the length of time it has been running (since1955) and its periodicity (conducted, on average, every 4 years), and by the size of its sample (roughly 40,000 households). It is the main statistical source in France for describing the housing stock and the occupancy conditions of households in their main residence. Several items from this survey can be used for analysis of residential mobility, in particular the question on place of residence 4 years ago. For households that have moved, the survey records the main characteristics of the housing occupied 4 years ago and the occupancy status at that date. Households that have moved more than once in the last 4 years are also asked about their occupancy status prior to the last change of address and about the reasons for this last move. The survey also asks respondents about their mobility intentions (Baccaïni, 2000). This survey can thus be used to analyze mobility and mobility intentions, and to bring out the connections between past mobility and intended mobility. Residential histories, in particular, can be studied in detail (Bessy and Tabard, 1996). On the other hand, unless regional or local extensions of the survey are set up, it is not possible to study mobility across a territory.

3. Population Registers

Population registers are administrative records whose purpose is to provide an up-to-date record of the population in the various administrative units that make up a country. Births, deaths, arrivals and departures of population are recorded. Population registers do not exist in all countries; 20 countries in Europe operate them. Furthermore, where they do exist, these registers are not always used as a source of data on internal migration.

The comprehensive review conducted by Philip Rees and Marek Kupiszewski for the Council of Europe (1996) shows that of the 28 member-countries of the Council of Europe, 14 use their population register as the main source on migration.

Population registers supply information on changes of residence and thus on movement, and in this way provide a dynamic picture of the population. The data on internal migration contained in the registers allow two kinds of approach to the phenomenon: (1) an overview of migration trends within the country from year to year and (2) a tracking of individuals from place to place over their entire lives.

TABLE 122–2 Main Sources of Migration Data in Council of Europe Countries

Population Registers	Censuses	Registers and Censuses	Migration Surveys	Censuses and Migration Surveys

By combining the information present in these registers it is possible to produce matrices of annual interregional migration, disaggregated by subpopulations (by age, sex, etc.). In some countries, the information is available every 3 months or even monthly (in Lithuania). So for these countries where population registers are in use, we have long series on interregional exchanges at a detailed geographical scale.

The possibility of tracking individuals over their entire lives is one of the main advantages of population registers. Their chief drawback comes from the limited amount of information they contain on the individual characteristics of migrants. The Norwegian register is one that lends itself most to this type of longitudinal analysis. This central computerized register has been combined with individual-level data collected in the 1960, 1970 and 1980 censuses (an operation no longer possible today, as the census has been abolished in Norway). The result is a rich statistical database containing individuals' successive changes of address and births, plus a large variety of sociodemographic information collected at the date of the census (educational level, occupation, marital status, income, etc.). Methods of longitudinal analysis are particularly well suited here, notably for revealing the effects of individual characteristics on the probabilities of making specific kinds of residential relocation, for example, from a rural area to an urban center (Baccaïni and Courgeau, 1996).

In Europe, centralized and computerized registers on these lines exist in the Nordic countries, Belgium, Poland, the Czech and Slovak Republics, Hungary, Slovenia and in Liechtenstein (Poulain, 1994). These population registers are maintained by means of two procedures. One involves updating civil registration records at the place of legal residence; the other is the compulsory declaration and registration of changes of address in the localities of origin and of destination.

Data from the registers are not free from measurement problems. As Michel Poulain (1994) stresses, some changes of address are not recorded (for example those occurring within a single smallest administrative unit). Also, what movers report may be at variance with the facts, influenced perhaps by the existence of advantages or disadvantages attached to declaration. Finally, the collection of information may introduce errors, particularly when the system is not centralized.

In many countries, moreover, legislation regulating access to the registers has made them hard to use. In some countries where there is no population register, census and civil registration data have been used to set up panels. In France, the *Echantillon démographique permanent* (Demographic Longitudinal Sample; EDP) can be used to construct the family, labor market and migration histories of individuals. The EDP is a longitudinal base of individual microdata maintained by INSEE for the last 30 years, and contains data on nearly 900,000 individuals who are or have been residents of metropolitan France. Information recorded in successive census forms (since 1968) is stocked and matched to civil registration records, to compile a vast panel. The study base currently contains 886,458 individual records, of which 617,195 concern persons in the 1999 population census. In contrast to population registers, the EDP does not supply all the successive addresses of where individuals have lived: "*The dates observed precede and follow the migration event one wishes to study, which in effect means that one has a fragmentary life history*" (Courgeau *et al.*, 1998). It does, however, constitute an extremely rich resource for the study of mobility and residential histories. The same kind of data set exists in the United Kingdom, the Longitudinal Study (LS), which was started the same time as the EDP in France.

4. Administrative Records

In every country, the records kept by various official departments and organizations can be a source of valuable, though rarely flawless, information on residential migration.

In the United Kingdom, the central register of the National Health Service (NHS) is an important source of information on the redistribution of the population between administrative units (the unit used is specific to the NHS), which has been used since the 1950s (Stillwell *et al.*, 1994). When patients who have moved home register with a doctor in their new area of residence, their previous area of residence is recorded. The main problem with this source is an underrecording of short-distance moves.

In France, a number of administrative records, access to which is often restricted, provide information on residential migration. Similar records are available in most industrialized countries. The records of the French electricity company (EDF) on new accounts and those of the telephone company, France Télécom, are extremely rich sources since they contain the household's previous address. These sources provide information on current locational trends, but the information is poor in qualitative terms. EDF also has a source on household mobility that supplies longitudinal information.

The fiscal records relative to income tax and local taxes can also be used. With these it should be possible to produce crosstabulations at the level of individual communes between the housing and sociodemographic characteristics of households, and the date of moving to the address.

The annual data returns *Déclarations annuelles de données sociales* (DADS) are the official documents by which employers notify the tax authorities and social security organizations, individually for each of their employees, of the amount of wages paid yearly. Except for people employing domestic staff, any employer, whether a physical person or a business, based in France and who pays salaries or wages is required to fill in an annual DADS-type return. INSEE, which administers this register, currently excludes farm employees and public sector employees, whose returns relate to special social security schemes and are specific, from processing for statistical purposes. Since 1998, the French data protection agency National Council for Data Processing and Civil Liberties (*Commission national informatique et liberté*; CNIL) has authorized INSEE to reconstitute a register of salaried workers using the national identification number, so as to group together the different positions an individual has held. Hence, it is possible to monitor all the changes of address and employment by salaried workers. Because the geographical reference unit is the commune, only intercommunal mobility is counted.

Research conducted at INSEE by Cédric Blum in 2000 pointed up the value of using the DADS for studying residential migration. This source offers a number of new elements compared with the population census, especially regarding the link between residential mobility and occupational mobility. The periodicity (annual) of the DADS register is also a serious advantage.

Electoral registers can be used for residential migration study, but with caution. They only cover the population old enough and eligible to vote, thus there is no coverage of foreigners and individuals who have lost their right to vote. Furthermore, even if registration is compulsory, a nonnegligible proportion of the population is not in fact inscribed on the register. Lastly, in France individuals are not required to register to vote in their commune of destination and can remain registered in another commune, where, for example, they own a weekend or holiday home.

CONCLUSION

At the end of this nonexhaustive review of the principal concepts and sources of observation relative to internal migration, two questions arise.

Could it be possible to bring together or reconcile the different approaches to internal migration, with the aim of constructing a migration theory (or theories) of a universal nature? The purely spatial approach that deals with geographical entities would clearly gain from including the preoccupations of demographers and sociologists, focused on populations and individual behavior. Vice versa, analysis centered on the individual, by ignoring that individual behavior, is always spatially defined and thus largely dependent on contextual effects, if only because an individual lives in one place rather than another, would be enriched by inclusion of the geographical environment.

From a methodological point of view, the approach based on multilevel models contributes to bridging the gap between these different levels of analysis, that of the individual and that of geographical entities, or indeed intermediate levels such as the family or the individual's relational network (Chapter 24, Volume I). From a more theoretical point of view, however, much remains to be done to disentangle the extremely complex linkages between the different levels of aggregation, in order to produce a coherent theory for these models and for human behavior in general.

A second question that demands attention concerns the reliability of the measurements of internal migration that can be achieved through the various sources currently available. On this point it must be recognized that, although the trend is toward improvement, the data suitable for characterizing spatial mobility within a country are often of poor quality. As a consequence, the available data are hard to compare across countries. Very often, comparison can apply only to processes and trends but not to levels of mobility and measured flows. On the other hand, increasingly complex surveys and improved analytical methods offer the prospect of a better understanding of individual mobility behavior.

Conceptual Framework and Data Collection in International Migration

CORRADO BONIFAZI AND SALVATORE STROZZA

Istituto di Ricerche sulla Popolazione e le Politiche Sociali-Consiglio Nazionale delle Ricerche, Rome, Italy

Università degli Studi di Napoli Federico II, Napoli, Italy

"Migration is a fuzzy concept with many definitional problems" (Willekens, 1984, p. 2–3). *"Trying to piece together a coherent statistical picture of any of the five key groups*[1] *(of migrant workers) is similar to trying to put together a large puzzle based on photographs of a rapidly changing reality, with important pieces missing and many of the available pieces out of focus"* (Hoffmann and Lawrence, 1996, p. 2). Expressions like *fuzzy concept* and *puzzle* are not often encountered in scientific literature, and their use therefore strongly underlines the difficulties facing those attempting to conceptualize, define, and measure migratory processes.

The issues are well known. Competent international organizations and the scientific community have been working on them for more than a century and searching for adequate answers (Krali and Gnanasekaran, 1987). In recent years, efforts in this direction have increased, under pressure from the political resonance of the phenomenon and the increasing concern of governments and public opinion in the face of the dynamics and consequences of international migration. The results have been really important.

The United Nations has made new recommendations for the production of statistics on international migration (United Nations, 1998b). The International Labour Office (ILO) has also stimulated research aimed at improving the data collection processes for migration in general and, more particularly, on employment-based movements (Bilsborrow *et al.*, 1997; Hoffmann and Lawrence, 1996). To the classic report of the Systeme d'Observation Permanente sur les Migrations (SOPEMI) (continuous observation system for migration) set up by the Organisation for Economic Co-operation and Development (OECD) have been added the *International Migration Report* of the United Nations Population Division, the first edition of which was published in 2002, and the *World Migration Report* of the International Organization for Migration (IOM), published for the first time in 2000 and the second time in 2003. Publications and databases are currently produced by Eurostat, the statistical office of the European Community, while the Council of Europe has considerably increased the space reserved for international migration in its yearbook. In many cases, the geographical coverage of information gathered by these international organizations has increased. The information is no longer limited to traditional immigration countries within or outside Europe, but now offers a more complete view on essential aspects of the international migration panorama. Beyond this reminder, it is of course impossible to review the entire catalogue of more specific work undertaken at national, bilateral, and multilateral levels, but many of them focused on or are still based on the comparability of data and statistical cooperation to improve the quality of data produced in the countries of immigration and emigration (Poulain, 1991, 1993 and 2001; Salt *et al.*, 1994).

[1] Immigration of foreign workers, emigration of national workers, return migration of migrant workers, stock of foreign workers, and stock of national workers abroad.

Ultimately, never has Hania Zlotnik's statement (1987, p. v–vi) that *"Although the charge of inadequacy may be appropriate, scarcity is not necessarily a trait of international migration data. Indeed, statistical information potentially relevant to the measurement of international flows of migrants is more commonly available than one would expect"* been more applicable to the current situation. Indeed, despite the positive results of the growth in available data, we are still far from having satisfactory and definitive answers to all the problems related to the statistical measurement of international migration. However, current scientific research seems to have modified its own strategy and opted for a more pragmatic approach aimed at using and developing what already exists today by placing it in a conceptual framework that enables the understanding of the articulation of different types of migratory flows rather than looking for definitive answers to issues of definition or theoretical framework of the measurement of the phenomenon (Bilsborrow *et al.*, 1997).

This approach nevertheless takes some fundamental characteristics of the migratory process as a given. First of all, we must recognize its complexity and hence the corresponding difficulty at arriving at a definition and precise and univocal measure, because of the spatial and temporal variety and variability of its forms, its characteristics, its causes, its consequences, and the contexts in which it develops. Secondly, the existence of a strong tie between statistical records and the political dimension of the migratory phenomenon should be noted. On the other hand, if the complexity of the phenomenon and political interest work together to make the measurement of mobility and the comparison of data difficult, there are elements which promote the coexistence of a plurality of statistics and which make it possible to highlight the various aspects of migration (Costanzo *et al.*, 2002). This situation may produce a statistical picture of the phenomenon as fuzzy and ill-defined, but this may prove itself useful for constructing another, more articulate, and, finally, more realistic and interesting one. Especially in the current period (marked by great changes in the intensity, characteristics, and even the direction of the flows), the availability of many measurements of the same phenomenon, taken from different perspectives and different angles, is a favorable factor for the study and analysis of international mobility (Willekens, 1994). It is therefore judicious, at a practical level, to assemble the different statistics available, as elements of a mosaic or pieces of a puzzle to be built, on the condition that one starts by recognizing the real significance and the explanatory power of each piece.

The user, and before that the producer, of international migration statistics must first of all clarify the meaning of the data by taking into account the concepts and definitions used, as well as the procedures put in place for collecting information. In this regard, we wish to offer to the reader a series of elements to note for the correct usage of the major migration statistics. Both the United Nations and the ILO (Bilsborrow *et al.*, 1997; United Nations, 1998b), at the heart of the two major in-depth analysis projects in the last decade, have themselves given up on the exhaustive reconstruction of the characteristics of the sources used for measuring the phenomenon. They prefer to consolidate our knowledge on regional entities or explore in depth the pathways already traced by publications of the *Demographic Yearbook* of 1977 (United Nations, 1978) and of 1989 (United Nations, 1991), whose *special topics* focused on international migration.

The first section of this chapter therefore focuses on an overview of the problem. We will recall the principal definitions used at the international level while distinguishing between data of flow and data of stock. In the second section, we will study, separately for flow and for stock, the issue of identification of the major categories of migrants and of immigrant populations. In the third section, dealing with data collection modalities, we have chosen, for practical reasons, to work according to the sources of statistics rather than to the type of data. We will therefore successively study censuses, population and foreigners registers, statistics of border movements, other administrative sources and finally, sample surveys. Specific flows, like that of the movement of refugees or that of migrant workers, have not been isolated as such, for most of the general remarks apply also to these particular cases.

I. THE OVERALL FRAMEWORK

The starting point of the problems of measuring mobility is in the concept of migration itself, whose definition is far from obvious. The definition of the phenomenon requires taking into account the relationship linking man with space and time and thus supposes that one has conceptual instruments capable of distinguishing among all space-time movements—those that are migrations and those that are not (Courgeau, 1980). We are confronted here with a type of problem that the analysis of a population's natural dynamics does not generally encounter, because it is based on events (births and deaths) that are much simpler to define and identify and necessarily occur in the life of each individual once and only once. First, an individual, on the contrary, may never migrate, or may migrate many times. There is therefore no univocal relationship between these events (migrations) and the individuals to whom they occur (migrants). Secondly, migration implies a relationship between one geographic space and another. Consequently, its observation always has a precise territorial dimension, which must be defined at the moment of data collection and made known when published. And this complicates demographic research when territorial reality is often disregarded within the framework of the conceptualization and theoretical formalizations.

Because of the complexity of the phenomenon, quantitative analysis is forced to simplify. The first distinction to make is obviously the separation of internal migration from international migration, according to whether an international border has been crossed or not. In a way, this distinction may appear superfluous as the context, the causes, effects, and mechanisms of the two phenomena show similar characteristics. However, because of its very high dependence on political factors, international migration dynamics are really a different phenomenon from internal migration. Better still, it is precisely the control exerted by each state on its borders that defines international migration and makes it a social process independent of other movements (Zolberg, 1989). And consequently, as we shall see, the different international migration data collection operations are articulated around this state control.

Efforts to conceptualize migratory processes on which to base data collection procedures seem to have followed two directions. First, especially among international organizations, attempts were made to reach a consensus on a definition that would serve as a reference point for various producers of statistics. Secondly, efforts were made to construct typologies capable of describing the main aspects of the phenomenon. These two perspectives have crossed on more than one occasion in recent years in an attempt to find effective operational solutions to issues raised.

One could say that the first international recommendations for the improvement of migration statistics were made in 1932 with the International Conference of Migration Statisticians, organized by the ILO (Bilsborrow *et al*., 1997; Krali and Gnanasekaran, 1987). According to these recommendations, *"In principle, every act of removal from one country to another for a certain length of time should be included in the statistics of migration, with the exception of tourist traffic"* (United Nations, 1949, p. 3–4, cited by Bilsborrow *et al*., 1997, p. 1). From this statement, the United Nations then later developed a first set of recommendations, adopted in 1953, centered on the definition of *permanent immigrants* as *"non-resident (both nationals and aliens) arriving with the intention to remain for a period exceeding a year"* and of *permanent emigrants* as *"resident (nationals and aliens) intending to remain abroad for a period exceeding one year"* (United Nations, 1998b, p. 5). The inaccuracy of the concept of residence and especially of its temporal dimension proved to be the weak point of this definition. Consequently, in the 1976 review of these recommendations, a *long-term immigrant* was characterized as *a person who has entered a country with the intention of remaining for more than one year and who either must never have been in that country continuously for more than one year or, having been in the country at least once continuously for more than one year, must have been away continuously for more than one year since the last stay of more than one year"* (United Nations, 1998b, p. 5).

The coherence of this last definition was not enough to assure its effective usage in the production of migration statistics, so much that the United Nations had to again revise their recommendations in 1998. The major objective of this revision was to simplify the definitions and admit that *"An international migrant is* [. . .] *any person who changes his or her country of usual residence"* (United Nations, 1998b, p. 9). The country of usual residence is, according to the definition used in the census, one *"In which a person lives, that is to say, the country in which he or she has a place to live where he or she normally spends the daily period of rest."* Trips abroad, *"for purposes of recreation, holiday, visits to friends and relatives, business, medical treatment or religious pilgrimage"* (United Nations, 1998b, p. 10) are not regarded as a change in the country of usual residence. The duration of stay abroad, based on a 1-year threshold, determines the distinction between *long-term* and *short-term migrants*.

Beyond the changes in definitions, which, moreover, are far from covering all the real problems of migration statistics, the last recommendations of the United Nations are especially remarkable for their application modalities. Indeed, based on the premise that it would be difficult to obtain from states a change in their definitions and an adoption of those of the United Nations, it has proposed a two-stage approach. In the first, the available statistics are supplied with instructions explaining the differences and similarities between the different sources of the same country. In the second, each country is expected to define specific strategies for improving the quality and comparability of its data. Fundamentally, this two-stage process is founded on establishing a well thought out taxonomy of international mobility (not only migration) on the basis of the legal status established by the country of arrival. The typology is established with regard to four occurrences (two relating to nationals and two to foreigners): departure from a given country, arrival in a destination country, departure from a destination country, and return to the country of origin. To simplify, the United Nations assumes that the flows always start from the country of nationality of the migrant and are directed towards the country of destination; migrants are classified into different categories that do not change during their stay in the host country. These four occurrences are combined with 18 categories of persons, which thus has lead to a definition of 72 types of mobility. However, among these categories of travelers, some are not relevant for international migration (inhabitants of border zones or transit passengers), others are important for international tourism, and some (diplomatic staff, the military, and nomads) are generally excluded from migration statistics. Lastly, there are only eight relevant categories for migration statistics (students, trainees, workers, staff of international organizations, free establishment migrants, settlers, family reunion migrants, refugees), whereas for two other categories (asylum seekers and illegal migrants), the duration of stay is uncertain.

In the same perspective, to classify international migration with regard to real situations, the ILO has also prepared *Guidelines for Improving Data Collection Systems*) (Bilsborrow *et al*., 1997). By tabulating nationality (nationals and foreigners) across the legal basis of entry, the ILO has defined 10 types of international migrants and 16 subcategories:

1. return migrants
2. returning ethnics
3. free circulation migrants
4. foreigners admitted for special reasons (students, trainees, retirees)
5. settlers
6. workers (seasonal, project, contract, temporary, permanent, highly qualified)
7. economic migrants (business travelers, investors)
8. refugees and asylum seekers (refugees, persons admitted for humanitarian reasons, persons granted a temporary protected status or a stay of deportation)
9. irregular migrants
10. family reunion migrants (ILO has defined specific categories for this group).

These two examples show the complexity of the migratory process and the difficulties in establishing a typology for adequate collection of data on its various components. This was already made evident in previous attempts at classifying migratory flows, from that of William Petersen in 1958 to the more recent work of Antonio Golini (1987). The latter, working from causes (grouped into three different types of mobility: migratory, semi- or pseudomigratory, and nonmigratory mobility)—taking into account the spatial dimension (distance or the crossing of administrative or political borders), temporal dimension (periodicity and duration), and the legitimacy of movement—identified 55 types of population movement.

Definitions and ordering criteria can therefore take into consideration different elements: nationality, residence, duration of stay, reasons for stay, place of birth, the spatial dimension, the cause of the move, legal status, etc. The first five factors are generally considered the most important (Zlotnik, 1987b). In different combinations, they contribute to defining migration statistics. In the next paragraph, we shall discuss in detail the limitations and characteristics of some of the elements, but before then, it is useful to make a comment on the reasons why, despite all previous efforts, there is a major gap between international recommendations and national practice.

First of all, it must be stressed that apart from the difficulties mentioned earlier, there is also the question of scale. The ease, speed, and low cost of movement from one point of the globe to another today, have led to an unprecedented rise in the mass of international movement, especially of what is not migration in the sense indicated earlier. It only makes it more difficult to put in place, at an acceptable cost, statistical data collection instruments, which will enable migrants to be identified among the set of individuals who cross borders daily.

But the major reason for this gap is because the modalities for the collection of international migration data have a specific political dimension, resulting from complex processes determining the role given to immigration within each nation state (Bonifazi, 1998). From then on, one cannot but be surprised at the preponderance of administrative sources, not only for the more than obvious economic reasons, but for the greater possibilities offered for the study of the different categories defined in migratory policies (Birindelli and Gesano, 1991) and the measurement of the effectiveness of policy. This also explains the medium and long-term instability of the systems of data collection, which undergo the changes in the characterization of the phenomena and the influence of the political and cultural debate. In addition, it should not be forgotten that statistical data on migration are a central element of the process (including migratory history, perception of the phenomenon, migratory policy) with which each state builds its own relationship with immigration (Kritz, 1987). In this sense, *"nomenclatures and categories continue to interact with the entities which they* *represent. As 'convention', they produce reality by the frames of reference which they place at the disposal of the public debate. Reciprocally, they are in tune with the social world and record its evolution"* (Simon, 1998, p. 541).

From a strictly demographic point of view, one must be interested in all migratory flows, whether it is of foreign citizens or citizens of the country in question, precisely because each one of these two movements contributes to the variations in the size and structure of the various aggregates forming the population. As we have shown, the United Nations's definitions have always towed this line. In practice however, national definitions are, on the contrary, often very different (Kujisten, 1995). The principal concern of statistical offices is to measure the presence and the movements, in particular that of the arrival of foreigners, for the simple reason that—especially in these times of strict control of immigration—the demands of the policies and governments go in this direction without considering that it is even sometimes easier statistically to measure the movement of foreigners than that of nationals because of the many administrative traces that foreigners, at least those who move legally, are obliged to leave in their wake (Bonifazi and Strozza, 2002).

It is obviously important to distinguish between the data on flows and the data on stock. The former enable the study of migration in a continuous manner in time, the latter are useful for measuring the result of this in an arrival zone. Indeed, as with the other demographic phenomena, and as with the majority of economic and social phenomena, the first thing to look for in the area of migration is the number of events that occurred during a given time interval. In fact, the principal objective should thus be to know the extent and the nature of entry and exit flows; an adequate accounting of this would also provide an information base on the size of the immigrant population at a given time. However, from a theoretical and practical point of view, the observation of migratory flows requires a well-organized and structured statistical system which is always very difficult to set up. This situation has led to the use of migratory statistics of stock, not only jointly (as one would have wished) but sometimes in an alternative manner, because of the impossibility of direct access to statistics of flow.

In reality, it is not only a question of two different measures of the same phenomenon but of two radically different phenomena. The second, the immigrant population, depends not only on the past dynamics of the other, but also on the effects of mortality. In addition, stock data rarely cover the concept of migration alone because of the very different status accorded to different categories of migrants. Thus, in the United Kingdom and in countries of permanent immigration (North America and Oceania) primary emphasis is on the population born in a foreign country and, possibly, their descendants. In continental Europe, on the other hand, the stress is laid on the foreign population, with a vast range of criteria arising from the various legislative frameworks governing entry and the conditions of residence of foreigners as well as access to naturalization. In France for example, because of the greater ease with which immigrants were able to obtain nationality, the data on the foreign population was not very representative of the extent of the migratory phenomenon. This obliged statistical research to take stock of the concepts used and to consider the direct and indirect effects of immigration (Tribalat *et al*., 1991; Tribalat, 1994). In Germany, on the contrary, the almost insurmountable obstacles erected to prevent naturalization, even for the children of immigrants born in Germany, created the opposite situation, by inflating the foreign population with people born in Germany and thus nonimmigrant. Thus, the more the stock depends on old immigration flows the greater the difference between what is administratively regarded as the immigrant population and the real stock of immigrants in the demographic sense of the term.

II. IDENTIFICATION CRITERIA FOR THE DIFFERENT COMPONENTS OF MIGRATION

Before examining the different systems of observation of international migrant flow and stock, it is useful to introduce some further clarification. First of all, much more than for internal migration, the study of international migration is confronted with the problem of hidden flows, qualified as irregular, illegal migration. But, generally, the various types of migration are perceived differently from one country to another, or even in the same country from one period to another, and the systems and data collection criteria adopted depend on these (Zlotnik, 1987b; Krekels and Poulain, 1996).

At first, in a very schematic way, a country's international migration can be distinguished according to the direction of the move (entry or exit) and the *relationship* of the migrant to the country, defining four components. Table 123–1 illustrates this framework in cases where nationality is taken as the criterion of membership (Natale and Strozza, 1997). For entries, one can for example compare nationals to foreigners or persons from the host country (repatriates, for example) to individuals from other countries. The dis-

TABLE 123–1 Direction of Migration and Relationship of Migrants with Host Country Determined by Nationality

Relationship	Direction of Movement	
	Entry	Exit
Nationals	Immigration of nationals	Emigration of nationals
Foreigners	Immigration of foreigners	Emigration of foreigners

tinction can thus be made on different criteria such as country of birth, nationality or place of residence, each one preferring a different notion of membership of the host country. The nationality criterion is perhaps that which, at least in theory, makes the most useful distinction possible, not only because of its legal and objective nature (at least when it is recorded on the basis of passports or other official documents) but because of its clear limits. On the contrary, the country of birth can be fortuitous and the home country, even when residence is the subject of a legal definition, depends on very different definitions from one country to another, resulting in annoying confusion (Zlotnik, 1987b). Especially for countries with a recent history of emigration abroad, the criterion of nationality appears to be more coherent and more interesting in distinguishing migration flows according to the migrants' relationship to the host country.

The following pages will demonstrate several times that emigration and immigration flows pose different measurement problems. Let us add that each country tends to focus its attention on the most significant migratory component at the time of data collection. Lastly, this results in a better quality of the entire immigration statistics for several reasons. First of all, countries have historically been more concerned about measuring the arrivals and the presence of foreigners on their territory than their departure or the stay of their nationals abroad. Secondly, the principal immigration zones are the more developed countries where statistical systems are more effective. Thus, the criteria for measuring migration flows of arrival have been the object of the greatest care, on the one hand because they attract the attention of the authorities more, and on the other hand because the arrivals occur more in the countries best equipped to observe them. The statistical information available in this area is thus more abundant and of better quality.

The identification of the stock of immigrants during a general data collection exercise (for example, a population census) is not a simple problem to solve. Indeed, it depends as much on the definition of the target population as on the availability of necessary identification information (Strozza *et al*., 2002). The United Nations has many times recommended the definition of the *immigrant population* as people born abroad and residing for more than 1 year in the considered country. More recently, based on the definition of *long-term international migrant*, the United Nations indicated it as the *"stock of international migrants present in a country . . . the set of persons who have ever changed their country of usual residence, that is to say, persons who have spent at least one year of their lives in a country other than the one in which they live at the time the data are gathered"* (United Nations, 1998b, p. 83). As foreigners are almost never accorded the same social, economic and political benefits as nationals, it is important to count the number of persons who do not have the nationality of their country of residence, and even the number of those who, although they have acquired the nationality of the country of residence, did not have it from birth. On the basis of these considerations, the United Nations defined two subpopulations: (1) *"foreigners living in a country . . . [that] includes all persons who have that country as country of usual residence and who are citizens of another country"*; and (2) *"persons born in a country other than the one in which they live . . . [that] includes all persons who have that country as country of usual residence and whose place of birth is located in another country"* (United Nations, 1998b, p. 83).

The definition based on the *criterion of country of birth* makes it possible to take into account all immigrants, irrespective of whether or not they have obtained the nationality of the host country. It excludes, of course, the children of immigrants born in the host country (the "second-generation immigrants," who, contrary to the impression given by this term, are not at all immigrants), whereas it naturally includes the nationals of the host country born abroad, a category which, in a country that has undergone a high level of emigration in the past, could constitute a large group (Strozza *et al*., 2002). This definition makes it possible to identify the population born abroad from one year to the next with the following equation:

$$^{n}P_{t} = {}^{n}P_{t-1} - {}^{n}D_{\Delta t} + {}^{n}I_{\Delta t} - {}^{n}E_{\Delta t},$$

where ($^{n}P_{t}$), the number of persons born in a foreign country present at the end of year t, is equal to the same number ($^{n}P_{t-1}$) present at the end of year ($t - 1$) reduced by the number of deaths ($^{n}D_{\Delta t}$) or emigrations ($^{n}E_{\Delta t}$) and increased by the immigrations ($^{n}I_{\Delta t}$) during year t of persons born in a foreign country.

In the same way, the definition based on the *nationality criterion* makes it possible to identify a foreign population made up of persons who do not have the nationality of the country where they live, irrespective of their place of birth. This population is thus made up of foreigners born abroad and those born in the national territory. It excludes, on the contrary, persons born in a foreign country who have since acquired the nationality of the host country, as well as nationals born abroad. The nationality criterion thus identifies a group made of two components: the first, generally the larger one, is made up of first generation immigrants (immigrant foreigners not yet naturalized), while the second is made up of immigrants of the second or subsequent generations (foreigners born in the host country and not yet naturalized). The portion of descendants of immigrants born and who remain foreigners depends obviously on the national legislation regarding nationality and naturalization: it is minimal when *ius soli*, which enables children of foreigners born in the host country to automatically acquire the nationality of the country, is applied and it is maximal where *ius sanguinis*, which attributes nationality only by filial relation, prevails. Besides acquisition of nationality (${}^{s}A_{\Delta t}$), the size of the population depends also, of course, on births (${}^{s}B_{\Delta t}$) and, in the absence of cases of loss of the country's nationality, one can write:

$$P_t = {}^{s}P_{t-1} + {}^{s}B_{\Delta t} - {}^{s}D_{\Delta t} + {}^{s}I_{\Delta t} - {}^{s}E_{\Delta t} - {}^{s}A_{\Delta t}.$$

Thus, the nationality and the country of birth identifies very different subpopulations. Indeed, *immigrant foreigners*, who at the beginning of the migratory process made up practically the entire population (except in cases of major national repatriations), are reduced with time to a part of the total flanked by a second, that of the *naturalized immigrants*, and a third, that of the *descendants of immigrants* whose number grows with time. This is how in reality the mixing of simple concepts like *immigrant* or *foreigner*, which never coincide, moves them farther and farther away from one another over time and especially only covers one section of the population that one is interested in (Strozza *et al*., 2002).

Furthermore, in countries where a high level of emigration had occurred in the past, as was the case in Europe but especially in the recent past in southern Europe (Italy, Spain, Greece, and Portugal), the differences between the criteria of country of birth and those of current nationality are still very significant. Take the case of Italy. Recent censuses have recorded a considerable difference between the resident population born in a foreign country (almost 1,000,000 in 1981 and around 1,500,000 in 1991) and the foreign population (210,000 in 1981 and 360,000 in 1991). Among those born in a foreign country, there were in reality in those years a great majority of Italians and a minority of foreigners as naturalized persons were few.

Some European countries have decided to simultaneously use the nationality and the country of birth variables, thereby reducing some of the inconvenience related to the separate use of the two criteria.[2] The combination of the criterion of current nationality and that of place of birth is still not enough to identify the foreign population. Among nationals born abroad, it does not enable the distinction between those of foreign origin and those of the national origin.

This difficulty can be illustrated in a diagram in which current nationality is matched with previous nationality (or nationality at birth) with country of birth (Strozza *et al*., 2002). In this way, it is possible to identify eight different groups, four of which are related to the population of foreign origin (S) and four to that of the national origin (N). This diagram (Table 123–2) shows how the foreign population observed at a given time consists not only of foreigners of the first generation (SI) and the second generation (S2), but of emigrants of national origin (N3) or children of emigrants (N4) who have returned to their country of origin but who no longer have the nationality of that country. Furthermore, the national population is composed not only of people who have the nationality from birth, whether they were born in the country (N1) or not (N2), but of naturalized persons of the first generation (S3) and second generation (S4). Consequently, the two central columns of Table 123–2 form what can be called a "grey area" made up of persons who, according to the adopted criteria, can be considered as belonging to the country or not (Strozza *et al*., 2002).

At the European level, the concept of *population of foreign origin* has been proposed. The concrete determination of this should be *based on the combination of many criteria*, which should enable a real comparison between the data from various countries and at the same time make it possible to monitor the whole social process associated with immigration (Krekels and Poulain, 1996 and 1998). The observation of this target population is complex for technical and political reasons. In fact, it requires asking each person his/her nationality at birth or their previous nationality (that which they had in their country of origin), and children of immigrants born in the host country, the nationality or country of birth of their parents. Politically, it is increasingly difficult to ask this type of question, which citizens refuse to answer, as they consider it a statistical intrusion in their private life and an

[2] In particular it is possible to better identify the origin of migrants and thus the membership group especially in host countries which have an important colonial history that is reflected in the nationality of immigrants.

TABLE 123–2 Categories of the Resident Population of a Country: Data Obtained by Matching Current Nationality With Previous Nationality (or Nationality at Birth) with Country of Birth

Country of birth[1]	Previous Nationality or Nationality at Birth			
	Foreign Current Nationality		National Current Nationality	
	Foreign	National	Foreign	National
Foreign	S1 Immigrant foreigners	S3 Immigrant foreigners (first generation) who are naturalized	N4 Born of emigrated nationals (second generation) and have returned to the country with a foreign nationality	N2 Nationals born abroad or born of emigrated nationals (second generation) who have returned to the country
Country studied	S2 Foreigners born of immigrants (second generation)	S4 Born of immigrants (second generation) who are naturalized	N3 Emigrated nationals who have returned to the country after having lost their nationality of origin	N1 Resident nationals who did not migrate

[1] The variable country of birth can be likened to the *de facto* situation (country of actual birth) or to the *de jure* situation (the mother's country of residence at the person's birth).

exposure to the risk of being included in a national database, even if these concerns, widely shared, are in contradiction with the desire or demand by each minority for recognition of its specificity (Golini *et al*., 2001).

In the following section, we will focus on the possibilities of access, through the available sources, to the immigrant population understood as the population born abroad or the foreign population, without forgetting either the risks of incoherence in these criteria for international or temporal comparison or their limitations for the analysis of the process of integration of immigrant communities.

III. A CRITICAL ANALYSIS OF THE MAJOR DATA COLLECTION SYSTEMS

Before examining the possibilities offered by each of the available sources, we must emphasize the fact that most of them cover only one section of the flows and stocks of international migrants: that of legal migrants. The legal conditions of entry and residence thus form another criterion of classification of migratory flows and the immigrant population (foreign or born abroad) on the basis of the legitimacy of the immigration or residence according to the prevailing laws of the host country. In a diagrammatic way, two components can be distinguished at the level of flows and stocks: one legal and the other illegal. For the flows, the distinction is based on the *status* of migrants with regard to the rules of entry into the host country (with or without an entry visa or, more generally, with or without the necessary documents), and for the stock it is based on the norms regarding residence in the territory (with or without a valid resident permit).[3] Naturally, entry without the necessary documents (illegal entry) implies presence in the host country at least temporarily outside the limits of the prevailing laws (illegal presence), and a legal entry should normally, at least in theory, go hand in hand with residence within the limits of the existing norms (legal presence).[4] Statuses do not however remain fixed in their initial state (Briggs, 1984; Strozza, 1996). They can, on the contrary, change during residence in the host country. The longer the duration of stay, the weaker the link

[3] Naturally, the legal situation of immigrants is related to the legislation and even to the policy adopted by each host country with regard to international migration. These provisions can differ significantly from one country to another and can provide for exceptions or variations with regard to certain categories of immigrants or particular immigration zones.

[4] In the case of a given host country, effective ad hoc schematisations have been suggested (see for example, for France that of Yann Moulier-Boutang, Jean-Pierre Garson and Roxana Silberman (1986) in 23 categories and for Greece, that of Angeliki Grammatikopoulou (1998)) which also takes into account certain specific criteria of the prevailing legislation. In addition, Daniel Delaunay and Georges Tapinos (1998) have proposed a dynamic classification of the situation of foreigners based on entry, residence and work.

between entry conditions (legal or illegal) and the residence status: among illegal residents we also find immigrants who entered illegally and are residing outside the prevailing legislation as well as legal immigrants who, beyond the period of validity of their residence permits (initial or subsequent), have remained in the host country without renewing their authorization. On the other hand, a section of the immigrants who entered illegally, may obtain a residence permit, for example after a regularization law has been passed. There again, the situation is different according to whether we are looking at the flow of illegal migration during a given time interval or at the population illegally present in the territory at a given date. Many specific studies, particularly where the phenomenon of illegal residents is very common, have tried to estimate the stock using various methods depending on the available statistical material. In the following analysis, we will examine various sources and determine whether they permit the observation of the illegal component of migrant population flows and stocks.

1. The Census

Despite the improvements recorded in recent years in international migration data collection and dissemination, the census still remains the only source for the large-scale measurement of the intensity of the phenomenon at a global level and of its long-term trend.[5] The census especially makes it possible to highlight and to quantify the stock of immigrant population through questions on country of birth or place of residence at a given date prior to the observation.[6] The latter question, whose main objective is to measure internal migration, also makes it possible to quantify (at least generally) the flow of immigration in the considered time interval (generally 1, 5, or 10 years). Specific questions on nationality make it possible to identify the foreign population, and questions on the acquisition of the nationality of the host country often enable the identification of persons of foreign origin. In some countries, questions on the ethnic group of respondents are also asked. The census can be used to analyze particular flows such as that of return migrants, or to improve knowledge on languages, reasons for stay, etc. In certain cases, data on emigration have been collected (Bilsborrow *et al*., 1997). The latest recommendations of the United Nations (1988a) on censuses list among the obligatory questions useful for the collection of data on internal migration or demographic and social characteristics of the population the duration of presence at the current residence, the place of previous residence, the place of residence at a given date prior to nationality. The optional questions that could be useful in the analysis of migration include: language, national or ethnic group, and year or period of arrival.

These recommendations are not followed by all countries. In fact, it is mainly the developed countries who deviate from them the most by using questionnaires designed to meet the specific information needs of their countries and therefore coincide less with the United Nations recommendations. Besides, for obvious economic reasons, the number of questions must be limited. The census, compared to other sources, has the advantage of being a complete observation capable of collecting from the entire population demographic, economic, and social information that is not available in administrative statistics. These characteristics are particularly useful in the case of relatively rare phenomena like international migration. Admittedly, the census cannot provide all the information, and in-depth analysis of migration demands more specific observation tools. But the collection of certain information from sample surveys and the increasing use of representative samples of census data should, in the case of international migration analysis, be evaluated according to the level of reliability of the data and the extent of information lost in the passage from the total population to a sample. We should also remember that very often the distribution of the immigrant population, according to elementary variables like sex, age, marital status, family composition, level of education, occupation, etc., are only available through the census or, at least, with greater detail than other sources can provide. Furthermore, the census is probably the only official source that enables the collection of information on illegal immigration. Lastly, we must remember that the detailed territorial level of analysis provided by the census makes it a rare instrument for the study of the geographic distribution of immigrant populations, a particularly important point in the study of large metropolitan areas (Champion, 2002).

This instrument, however has well-known limits. They include underenumeration, which for immigrants may be particularly high, especially in the case of illegal immigrants, and have many potential errors, especially relating to the more difficult questions because of the enormity of the task of administering a questionnaire to all the inhabitants of a country. Think

[5] We must not forget that with data from two successive censuses and an estimation of the intercensal natural increase we can obtain an evaluation of the balance of migration, which in its great simplicity often remains the only or the best estimate possible.

[6] In certain cases, questions on previous place of residence and date of arrival at current residence have been used.

of recall lapses, of the difficulties in countries that have had border changes for the determination of place of birth (for older persons especially, for example). Furthermore, repeated migration is not taken into consideration. Whereas, the persons who return to their country before the observation are not counted, as is the case for migrants who die before the census. In the case of the question on residence at a date before the census, we know nothing of the possible migration of the children born in the considered interval. The analysis should be adapted to the duration of the reference period: with the question on the place of birth, it depends for each individual on his/her age, but at the level of the entire population, it yields a measure of immigration over a period of around 100 years.

In conclusion, according to the United Nations, the census is *"the most comprehensive source of data on the types of population stock that are most relevant for both the measurement and the study of international migration. In countries that are major receivers of international migrants, census information provides the basis for many types of in-depth analysis of the economic and social aspects of international migration."* [. . .] *Census data have provided the basis for the most comprehensive set of estimates of the "total migrant stock" in countries of the world"* (United Nations, 1998b, p. 87).

2. Population Registers

Population registers,[7] in the broadest sense of the word, may be defined as systems of continuous observation of demographic and social information on every person resident in a given country or territory (United Nations, 1969). Even if the aim of the observations is administrative, these sources make statistical information available on the dimension and characteristics of the recorded population, as well as on a certain number of events (essentially births, deaths, migration). It is important to stress the fact that the registered population is the resident (*de jure*) population made up of nationals and foreigners. Thus, population registers make it possible, in theory, to measure internal migration. They should also make it possible to measure international migration. Records deleted because of departures abroad, as well as those entered as arrivals from abroad, could indeed be assimilated to international emigrations and immigrations, and in both cases one can separate the national and foreign components. These flows can also be distinguished according to source country in the case of immigration, or destination country in the case of emigration. In addition, it is also possible in many cases to obtain a measure of the stock of foreign population (or immigrants) resident in the territory by using place of birth and nationality as the identification criteria.

However, it must be noted that the countries that have population registers are few[8] and that among these various elements of differentiation make comparability of data difficult and raises questions about their depth and reliability. The few countries with population registers capable of providing information on international migration are also all European. The comparability of recorded information depends on the degree of homogeneity of the provisions adopted in the various countries to determine who is resident and who must be entered into or deleted from the register. The minimum duration of residence required for registration or erasure[9] varies. It could be the effective duration or the programmed duration, depending on whether reference is made to actual permanent residence in the territory or merely declared intentions. At the end of the careful analysis of information gathered by Michel Poulain, Marc Debuisson, and Thierry Eggerickx (1990) on European countries with data on international migration from population registers, *"A problem that is immediately evident is that there are a number of cases where persons moving between country A and country B may be considered emigrants according to A but not immigrants according to B and vice versa"* (Bilsborrow *et al.*, 1997, p. 87). This situation has already been highlighted by other authors (Poulain and Wattelar, 1983; Zlotnik, 1987b). In addition, the elements required for registration are often different not only from one country to another but within the same country, from one population category to another (Poulain *et al.*, 1990). In many cases, apart from the difference between nationals and foreigners, there is also diversity in the treatment of the latter, especially in the case of countries that are members of the same free circulation zone, like the European Union (United Nations, 1998b). Consequently, the categories of migrants (for example, nationals and foreigners) are often problematic because of the differences in registration modalities and the definition of migrants adopted in the population registers (OECD, 2002). The United Nations has proposed that *long-term immigrants*

[7] We are grateful to Alessio Cangiano for collaboration in writing this paragraph.

[8] According to the United Nations, during the 1960s, 65 countries had population registers, 35 of which used them to produce statistics of which only 13 contained information on international migration (Bilsborrow *et al.*, 1997).

[9] This duration varies in general from 3 months to one year. Certain countries distinguish *between short-term* and *long-term migrants*, precisely on the basis of this period, as suggested by the new recommendations of the United Nations on international migration statistics (United Nations, 1998b).

be considered as persons registered in a given year who are still in the register the following year, and *long-term emigrants* as those who have been deleted from the register in a given year and not reregistered the following year (United Nations, 1998b).

It is essential to measure the degree of reliability of available information so as to avoid making very serious mistakes. Indeed, the nature of these sources is inevitably reflected in the typology and quality of the data provided, as well as the major problems associated with the utilization of this type of statistical material need to be recalled. As has been rightly noted (Salt *et al*., 1994), emigration is more difficult to study than immigration, because, in general, recording an arrival in a given territory confers on the immigrant a series of rights and benefits, whereas there is no comparable incentive to inform the authorities of a departure. In addition, it is possible that people remain in the records long after they have left the country, either because they initially had the intention of returning after a short while and then postponed their return, or in the case of foreigners, it is in their interest to remain registered to ensure their readmission after a period of absence (United Nations, 1998b). Thus, because of lack of effectiveness of control procedures, the underestimation of exit flows results in an obvious overestimation of the stock of resident immigrants.

It is also essential to underline the consequences of the very nature of the existing population registers for the quality of information: in certain cases, the system is centralized (Nordic countries, Iceland, Belgium and Luxembourg); in others, it consists *of local systems that are not completely computerized* (Poulain, 1995). While in the latter the archives are managed by local administrators, in the centralized systems information is collected in a national archival center, thereby improving the quality of data available through greater internal controls (for example, in identifying and removing double counts) and matching with other administrative archives (such as tax, medical, social security, etc.). These record-linking procedures were made possible by the attribution of a personal identification number, or PIN, to each individual to be included on every administrative document concerning the person, sometimes along with other codes of more restricted use. The effectiveness of the population registers of northern European countries in estimating the effective migratory flows of nationals and foreigners is also dependent on the considerable efforts made by the national statistical institutions to counter the problem of noncancellation through periodic archival review operations carried out in collaboration with various public organizations and through specific verification surveys on "suspected" cases (Statistics Norway, 2000). In addition, the adoption of a single certificate of a change of residence for movement between the Nordic countries makes further verification of this particular component of migratory movement possible (Poulain, 1995; Kruijsten, 1995). In various countries, the population registers, whether centralized or not, are updated at each population census by linking archived data with those of the census. The ensuing automatic cancellations are obviously not linked to a date in the past, but they make it possible to obtain an estimate of the number of immigrant residents corresponding to the real situation. Furthermore, data on foreign immigration often undergo a time lapse between the moment of arrival in the country and the moment of registration in the population register, sometimes postponed for a few years until the effective stabilization of their presence in the territory or the regularization of their legal situation after a special regularization program has provided illegal immigrants with first temporary then permanent residence permits (Natale and Strozza, 1997).

Lastly, a word must be said regarding the registers of foreigners in certain countries. These registers operate in the same manner as population registers (through a continuous update of the stock of residents on the basis of recorded demographic events), but they perhaps have the advantage of focusing more on the aim of observation. In addition, registers of foreigners also record information on the legal situation of each person (for example, information on the type and duration of the residence permit), which at least should potentially enable an analytical distinction between different categories of international migrants. They also make it possible to more easily observe international migration of foreigners for short periods, which is rarely the case for population registers (except when the period of residence required for registration is less than 3 months). In Germany in particular, the register of foreigners, the *Ausländerzentralregister* (AZR), and in Switzerland the *Zentrales Ausländerregister* (ZAR), are usually used as sources of statistics on the foreign population (Salt *et al*., 1994).

Population registers and registers of foreigners are therefore great sources for the continuous measurement of (long-term) international migration, and it is recommended that countries like those of central and eastern Europe, which inherited this instrument from the past, should try to take these out of their historic role as instruments of population control and into that of providing quality data on external migration. An improvement of the information on the categories of immigrants, which varies from country to country (for example, that of asylum seekers), and the adoption of standardized tabulations among the given countries are simple objectives that can guarantee better comparability of data from the registers, even if doubts persist as to the heterogeneity associated with the different prevailing norms.

3. Visas, Residence Permits,[10] and Other Administrative Sources

Other international migration statistics result from administrative operations intended to control migratory flow (entries and exits) and the presence of immigrants in the national territory. *"Clearly, there is a wide variety of possible administrative sources which differ considerably in terms of modes of operation and types of statistics produced. However, all of them share a common trait: statistics derived therefrom usually reflect administrative procedures rather than people"* (United Nations, 1998, p. 20). Contrary to population registers or registers of foreigners, the statistical unit of observation for the other administrative sources is not the individual but the administrative procedure. In other words, the statistics produced refer to authorizations or other control documents but not directly to individuals concerned. This is one of the key problems of meaning and of reliability associated with data from such archives.

The major administrative records relate to the delivery of passports or exit authorizations from the country, which provide information on the emigration of nationals. The reliability of this depends on the respect of the rules imposed by the country and the category of moves considered. In host countries, the focus is on entry visas and on temporary or permanent residence permits.

Entry visas delivered to foreigners by diplomatic representations of the host country abroad are permission (*nihil obstat*) to cross the border, which must be obtained before migration. Consequently, it is possible to find a difference between the moment the visa is delivered and that of its effective use, just as it is possible for the visa to remain unused. It must also be noted that nationals of countries belonging to the same free circulation zone do not need a visa for their movement in the countries within the zone, and this is also the case between countries with bilateral agreements with a waiver on the visa obligation. Inversely, a visa, the most important limit, is required for a whole series of moves that are not considered migration (in particular, tourist or business moves, etc.). It is often very difficult to use these sources of information because of the complexity of separating migrants from nonmigrants, and in addition, international comparison is impossible because of the variability in the provisions made by the different countries.

Chronologically, after the entry visa comes the temporary or permanent residence permit for foreigners intending to remain in the territory of a host country for a period greater than a given number of months (this duration differs from one country to another; in certain cases, it is limited to 1 month). It must be stressed that the temporary residence permit, contrary to the entry visa, is most often required even for nationals of countries belonging to the same free circulation zone as the host country. Nationals of member countries of the European Union for example, do not need an entry visa for movement within the community, but they need to request a residence permit for a stay of over 3 months. The statistics of residence permits therefore constitutes a useful information base for measuring the flow of immigrant foreigners and, under certain conditions, give information on the size of legal foreign immigration in the country. Information on the type of the permits granted and on their length gives the opportunity to single out specific categories of immigrants and, sometimes, of estimating long-term and short-term flows.

As has been stressed earlier, the main limitation of administrative statistics and, in fact, that of the residence permit, is in terms of the procedures adopted for the management of the archives, and these are different from those used for population registers. There is no continuous update of the status of each foreigner with a residence permit. It is possible for the same person to have several residence permits delivered successively during a period between which no link is made (double counts are possible). It is rare to find procedures for checking that foreigners with valid residence permits are still present in the territory. Finally, even when foreigners leaving the country are required to return their residence permit, this obligation is often not fulfilled. Consequently, the total number of valid residence permits at a given moment[11] generally overestimates the real number of foreigners legally present in the country, at least, those whose legal presence require a residence permit. Indeed, people above a certain age, of variable threshold from

[10] The type and names of permits granted to foreigners vary considerably between countries; we use the general expression *residence permits* to indicate all these kinds of permits.

[11] Naturally, it is not possible to deduce the stock of foreigners legally present in cases where information on the date of expiry of the residence permit is not recorded. Even when this information exists, in certain cases, published national and international data include residence permits showing considerable overestimation of the phenomenon. This is the case for example, of Italy which, before the ISTAT revision of the archives of the Ministry of internal affairs, used to publish data with 20% to 40% expired residence permits (ISTAT, 1998).

one country to the other but generally between 14 and 18 years, are rarely given their own residence permit but depend on that of their parents. This population is thus almost always underestimated, as was indicated earlier, because only persons with documents are taken into account. For these reasons, only a few countries use data on stock of residence permits: in particular, in the SOPEMI report (OECD, various years) data on foreign population were treated from residence permits only from the new host countries of Mediterranean Europe (Italy, Spain, Portugal, and, at least in the past, Greece).

In addition, there are many interpretation problems associated with the use of residence permits to measure the flow of legal foreign immigration. In various cases, the available data on flows covers not only new permits delivered during the year to foreigners who have just arrived in the country, but includes permits delivered to foreigners already present in the territory as renewal or as change of status (change of type of residence permit). We must not forget that the number of permits delivered in one year is not equivalent to the number of persons admitted in that year either, as one person can receive more than one permit in the course of the same year, just as inversely, the permit delivered to the head of family can be used by other members of the family.

When information on the outflow of foreigners is inadequate or nonexistent it has consequences for the reliability of measures of stock. In fact, it is the entry flows that we try to match with the number of new permits and the renewals of permits, or a combination of both. In general, the countries that publish statistics on the number of residence permits delivered in a year do not provide enough information on the exact significance of the published data. The available statistics are often difficult to interpret and in any case are less able to represent the reality of the flow of persons than those of change of status of holders of residence permits (United Nations, 1998b). In some countries, however, information derived from residence permits or other documents regulating entry and residence of foreigners are the only available source of continuous observation of international migration and the estimation of the stock of legal foreigners.

"There is considerable heterogeneity in the statistics derived from residence permits, visas or other equivalent documents. [. . .] Because residence permit statistics are administrative in nature, they are closely related to the application of laws and regulations relative to the admission and stay of foreigners and reflect the idiosyncrasies of such regulations. A full understanding of the statistics available usually demands some knowledge of how those laws and regulations operate. [. . .] Statistics derived from the issuance of residence permits can be used to provide two type of measures: those relative to stocks, which usually reflect the number of valid residence permits at a given point in time, and those relative to the different flows that bring about changes in the stock issuance" (Bilsborrow *et al*., 1997, p. 128).

4. Statistics of Border Flows

The control of border movements is the most direct source of information on a country's international entries and exits. For a long time, it was also the focus of United Nations recommendations concerning international migration statistics. The major limitation of this type of observation resides in the difficulty in identifying migrants among all the international movements of persons including movements for other reasons. This problem has become more difficult to resolve as movements of persons have become more intense and the crossing of borders have increased in size. Data collection operations are even more complex along land borders, where the intensity of movements is often higher and the customs formalities are reduced to a minimum or are virtually nonexistent and can therefore be easily circumvented. The solutions used to adapt the source to the growth in volume of border crossings are a combination of administrative procedures, selective checks, or the use of samples as is the case with the *International Passengers Survey* of the United Kingdom. The first case consists of a mixed system of observation, which at the same time as border controls, uses data produced by different administrative procedures. In the case of Canada and the United States, this second element seems to take precedence over the first, as neither of the two countries produces statistics on the emigration and immigration of its own nationals or of foreigners. On the contrary, Australia and New Zealand *"gather border statistics that reflect the full range of possible movements, including those of citizens and former settlers, and those of foreigners admitted on a temporary basis"* (Bilsborrow *et al*., 1987, p. 121).

The main problem is identifying migrants among all travelers who cross borders. The usual criterion is based on length of stay, actual or assumed, in order to distinguish short- or long-term migrants from other travelers. In practice however, the purpose of the stay is often taken into account, especially for foreigners on the basis of their type of visa or entry permit. An efficient system for collecting data is based on a form to be filled in, in two steps: the first time at entry and the second time at departure. A problem here is the possibility of counting several times migrants who cross the border multiple times during the same year.

The countries without land borders have obvious advantages in the use of this system of observation, since the concentration of flows at ports and airports can be checked more easily. The collection of information can be based on administrative or statistical criteria. In the first case, the characteristics of migrants are recorded from documents (passports, visas, residence permits, etc.). In the second case, the information is derived from forms filled by the person at entry. The data collected at border checks reflect precisely the moment when the migration event took place. It is improbable that they can guarantee the same precision in the measurement of the intensity of flows, especially exit flows. *"In practice, statistics derived from border collection rarely provide the best measures of international migration flows because of the difficulties involved in gathering reliable information from a large volume of people subject to different degrees of control depending on their citizenship, mode of transport and port of entry"* (United Nations, 1998b, p. 23). Let us add that these statistics tend in any case to reflect only the legal situation and those migrants who cross the border at authorized points. It is highly improbable that at a border crossing one declares a status different from that established by the entry or exit documents.

The strict dependence on legal conditions is at the same time the price and the limitation of this type of statistical observation. On the one hand, it does indeed enable the collection of precise and detailed information on legal migration, on the other hand it is hardly possible to draw a credible conclusion on the exact extent of the real migration flows. In particular, entry flows are generally underestimated in statistics of border crossings, thereby giving low reliability to the estimation of the migratory balance, whereas the typology used for the data collection tends to reflect almost exclusively the targeted categories of migration policies. Besides, these categories are not always easy to define on the basis of the vocabulary used in official statistical publications, where the same word can relate to different categories. The result is a false impression of comparability between countries and of continuity within the same country where this type of observation is in use, as has been shown, for example, by a study of passenger cards in Australia and New Zealand (Carmichael, 1993).

5. Sample Surveys

Very detailed information on migrants' characteristics and, in certain cases, the causes and consequences of international migration, can be collected through sample surveys. Actually, in countries with a high immigrant population, it is possible to isolate within large family surveys the subpopulation of persons born abroad or who are foreigners. The most significant example is certainly that of the *Current Population Survey* (CPS), executed monthly in the United States. This survey enables the estimation, among other things, of the size of the population born abroad, including its illegal component, and even allows identification of the various countries of birth. Labor force sample surveys standardized in the European Union should make it possible to obtain representative data on foreigners, at least in countries where this population constitutes a large part of the total population.[12] In general, although these routine observations facilitate comparison on the dimension and characteristics of migrant and nonmigrant populations, they do not however allow covering very specific aspects of the migratory process. *"Thus, although it is common to use census or survey data to compare the status of international migrants with that of non migrants in terms of occupation, income, unemployment level, fertility, etc., and to interpret similarities between the two groups as indicative of the migrants' success, in reality such similarities reflect, at best, only the process of integration"* (Bilsborrow *et al*., 1997, p. 240). For a more detailed analysis of the related processes of international migration, it is necessary to have access to information on the situation prior to the migratory event in order to compare with the situation at the moment of observation. This information can hardly be derived from a general data collection operation aimed above all at representing the entire population. In addition, only in a few countries is the population of immigrants sufficiently large enough for a credible representation to be drawn from a general sample, and rarer still are the cases where it is possible to collect detail on the country of origin and the nationality of immigrants.

For further analyses, *ad hoc* surveys are necessary and some examples of operations of this type conducted either in the migrant's country of origin or the host country will be given here. Let us examine three specific surveys, which, in a certain manner, illustrate three different approaches. The first is the *Encuesta sobre migración en la frontiera norte de México,* initiated in 1993 within the context of a collaboration between Mexico and the United States (STPS, 2001). The objective of this survey is to study the dynamics of population movements between Mexico and the United States with a particular focus on temporary migration and return migration. Within the framework of a complex

[12] The situation is different when the proportion of foreigners is small. In Italy, for example, ISTAT collects information on resident foreigners from labour force surveys, but these data are not published as their level of significance is too low.

sampling method, specific weights were applied to observations made in each of the principal border crossing points between the two countries in proportion to the passage flows. A control group, which would have captured the specificity of the characteristics of the migrant populations, is however missing in this case. This reference population would have by comparison made it possible to draw some conclusions on the determinants of migration and the conditions of evolution of migrant populations.

The second example is provided by a system of sample surveys funded by Eurostat and coordinated by the *Netherlands Interdisciplinary Demographic Institute* (NIDI). It was carried out among migrants in some countries of origin (Egypt, Ghana, Morocco, Senegal, and Turkey) and some host countries (Italy and Spain) with the aim of analyzing the causes of international migration (Schoorl *et al*., 2000; Birindelli *et al*., 2000). Each survey employed a specific technique. In particular, the survey on Ghanaian and Egyptian immigrants carried out in Italy used the technique of centers and points of aggregation that will be discussed later.

The third example is that of the *Geographic Mobility and Integration* sample survey, carried out in France in 1992 by Institut national d'études démographiques (INED) in collaboration with Institut National de la Statistique et des Etudes Économiques (INSEE) on the living conditions of immigrants and their children. Three categories were considered: foreign immigrants (from seven zones: Algeria, Spain, Portugal, Morocco, Tunisia, Black Africa, and Southeast Asia), the children of immigrants born in France (persons below 30 years of Algerian, Spanish, or Portuguese origin), and a control sample of French people. The detailed questionnaires were built around a series of retrospective questions aimed at reconstructing the migratory, residential, marital, reproductive, and professional biographies of each respondent (Tribalat, 1995).

In recent years, especially in traditional European host countries, there has been a growing interest in designing and carrying out longitudinal (multiround) surveys on immigrants (Bilsborrow *et al*., 1997). In this sense, the *New Immigrant Survey* (NIS) set up in 2003 in the United States is particularly interesting (Jasso *et al*., 2003). It is a nationally representative longitudinal survey of immigrants who have obtained a permanent residence permit during the years of observation. The sample is extracted from the administrative archives of the *Immigration and Naturalization Service* (INS), and in 2003 consisted of around 11,000 persons interviewed immediately after obtaining their permanent residence permit and then re-interviewed periodically. This survey was aimed at collecting information on the multiple aspects of migration and measuring the process of integration of new arrivals. The use of the longitudinal approach is meant to control for the problems of selection posed by emigration outside the United States by some of the immigrants (Jasso *et al*., 2000).

In the new European host countries of international migration, many field surveys limited to specific contexts or particular foreign communities have been conducted in the past 15 years. In particular, in many countries like Italy, the extent of the presence of illegal immigrants has led to the testing of innovative sampling techniques aimed at observing rare populations or populations that are normally difficult to access. From sampling frames already adopted in other circumstances,[13] a new technique called *"sampling by centers and points of aggregation"* has been developed which, based on identification of the major points of passage of immigrants, makes it possible to allocate weights on respondents depending on their presence at these passage points (Blangiardo, 1996, and 2000). This technique has enabled the quantitative estimation of illegal migration and improved knowledge on its characteristics, and specific dynamism by comparison with legal migration. Nevertheless, the question regarding whether the data will make it possible to compare these characteristics and behaviors with those of the general population still remains.

CONCLUSION

A fully satisfactory solution is yet to be found to the problems of conceptualization and observation of international migration statistics, even in statistically advanced countries. Here, we have focused our observations mainly on the latter, although some conclusions are more general. The reason is that for the study of international migration, these statistically more advanced countries are also generally host countries, where it is not only possible to observe the greatest flows and have access to the most reliable sources, but it is also possible to do so on at least one of the two angles under which migration can be measured.

We have tried to provide a panorama of the problems encountered, but we are far from covering all the details of the various sources of statistical information available on different aspects of the phenomenon. Official sources provide measures of the extent and the characteristics of the migratory flows and of the immigrant population, but the level of detail, the quality,

[13] Like the *snowball sampling* for illegal Mexicans present in the United States (Cornelius, 1982).

and the degree of reliability, although generally quite low, varies reliability. Negative factors are many and varied. A major aspect comes from the very nature of the sources of information (statistics or administrative) and the prevailing norms regarding immigration and the presence of new arrivals in the national territory. It is rare, for example, that administrative sources enable access to illegal immigrants, who can be accessed, albeit at an unsatisfactory coverage, by censuses or certain types of sample surveys.

We have highlighted the existence of many grey areas around statistical information on international migration. The definitions and concepts are far from being stable in time and space. Obviously, this fluidity does not facilitate the task of the user and makes the use of statistics built on slipping concepts (migrant or migration, stock or flow, native or foreigner, etc.) of variable definitions unavoidable. This state of affairs inevitably reduces the degree of comparability of data and, in the absence of a careful evaluation of these difficulties, makes them unsuitable or even incorrect for use.

It is essential to undertake a meticulous evaluation of the real information from each source according to the categories of migrants (or of migration) and its adequacy to the studied phenomenon. Administrative records hardly allow anything beyond a descriptive analysis of the phenomenon, making it possible, at best, to follow certain dimensions of the migratory process more or less regularly. Only *ad hoc* surveys make it possible to contemplate looking further into the analysis of the migration and going from the purely descriptive dimension to research on causal relations and functional linkages. We must however not forget the usefulness of traditional sources for the construction of indicators capable of providing a general description of the phenomenon and an evaluation of basic trends. This information does not definitively allow for a full understanding of the causes and effects of the phenomenon, but that notwithstanding, it retains its importance especially if we succeed in using it within a conceptual framework capable of developing its specificities and synergies.

In the future, it will be possible to check if the new recommendations of the United Nations have had greater success than previous ones. In any case, we can expect a growing interest in problems of measurement of international migration. Indeed, at the national level, migratory movements play an increasing role next to natural increase within the total dynamics of population. Without it, many countries that would have been undergoing population decline continue to witness population growth due to the arrival of foreigners, while others are witnessing a reduction in their population growth due to emigration. More generally, the contribution of migration is that of a greater selection of the population compared to the population of origin or the host population. Migrants are different in their demographic, social, and economic structure, factors that encourage us to pay more attention to migratory phenomena.

Demographic Surveillance Sites: A Tool for Studying Demographic and Health Trends in Developing Countries

GILLES PISON

Institut national d'études démographiques (INED), Paris, France

As explained in Chapter 121, a demographic surveillance site is a system for gathering population data on a town or set of villages over a period of several years or decades by regularly gathering information on the life events—births, deaths, marriages and migration—that take place there. A demographic surveillance site differs from a cohort study in that the entire population of the area is monitored rather than a fraction of it.

A growing number of demographic surveillance sites have been established in developing countries since the late 1980s, in response to two requirements.

In many countries, precise data on population dynamics are lacking because public record systems are inadequate. Surveys, particularly demographic and health surveys (DHSs), partly fill the gap by indicating trends, especially where several successive observations are available. But these surveys only provide observations from two or three time points at best, and provide little information about factors underlying the trends. An in-depth study of a small area over a long period, although it gives only local information, can provide better measurement and understanding of the causes underlying major demographic trends.

Secondly, many developing countries have no reliable health statistics, and research based on hospital data gives a biased picture of the health situation since part of the population never, or only exceptionally, go to a hospital. Demographic surveillance improves knowledge of a population's health, as it allows studies of a whole population that can provide more accurate data on health issues. Demographic surveillance maintained for several years or decades can serve as a watchdog mechanism for the public health system. It is also an excellent context for testing and assessing new vaccines, therapies or healthcare strategies.

Following the brief presentation in Chapter 121, this chapter examines this innovative data gathering method in greater detail, with the kinds of results it can produce and its usefulness for health development and for studying demographic change. However, every demographic surveillance site has its own system and these systems vary widely. The first part of this chapter therefore reviews the demographic surveillance sites in developing countries, examining some of their particular methodological features in greater detail. The second part presents two specific examples, at Bandafassi and Mlomp, in Senegal.

I. A GROWING NUMBER OF DEMOGRAPHIC SURVEILLANCE SITES IN DEVELOPING COUNTRIES

There were several tens of demographic surveillance sites in operation in developing countries in

2003. Table 124–1 lists 22 of them, with their main characteristics (size of monitored population, start date and duration of monitoring, frequency of visits, etc.) and two mortality indicators: mortality in children under 5 years of age (per thousand) and life expectancy at birth for males and females. All sites in the list are members of the International Network of field sites with continuous Demographic Evaluation of Populations and Their Health (INDEPTH) network, which was formed in 1998 and had 31 member sites in 2003 (INDEPTH network, 2002). Table 124–1 is therefore by no means exhaustive, especially as not all monitoring studies are members of INDEPTH. However, the dividing line between a demographic surveillance site proper and a simple epidemiological surveillance system is not always clear, and the list in Table 124–1 gives a good idea of the characteristics of systems that can definitely be classed as demographic surveillance sites.

1. Renewed Interest in Demographic Surveillance Sites in the 1990s

Few existing demographic surveillance sites were established before 1990 (see Table 124–1). They were long regarded as relatively costly studies for the results they produced. They were particularly criticized for covering only subpopulations that were not represen-

tative at national or even regional level, at a time when basic demographic indicators for the population as a whole were lacking and the priority was to find reliable methods for estimating them. With very few exceptions, surveillance sites were established for only a few years, usually to study a particular disease or health problem, or to assess a control program. Surveillance stopped once these goals were attained. These numerous short-lived surveillance studies are not shown in Table 124–1, which includes only studies that were still in operation in 2003.

Of the 22 studies in the Table, only 6 began more than 20 years ago. These have been maintained beyond the period initially planned because it was found that there were advantages to be gained from a longer-term study. For example, the Matlab study in Bangladesh was originally set up to run vaccine trials, testing the effectiveness of different cholera vaccines in a drive to eliminate the disease from regions where it was endemic, particularly South Asia. A series of trials in the Matlab area began in 1963 and continued until the late 1980s (Aziz and Mosley, 1997).

In the early years, observation was limited to identifying all episodes of severe diarrhea by means of daily monitoring in a set of villages with a total population of several tens of thousands. Three years later, in 1966, it was clear that a demographic survey, periodically recording of births, deaths, marriages and migration, was needed to provide the study with up-to-date population data at all times. At the same time as the demographic surveillance was being organized, the study area was extended; by 1974, it covered a population of 277,000. As well as precisely identifying episodes of diarrhea in connection with the vaccine trials, the study also sought to improve knowledge of nutritional and diarrheal diseases in general. But it was hard to justify maintaining surveillance long-term for the cholera and diarrhea research alone, and in 1975 a major change was made to the goals of the work. A new research program was launched to assess the effectiveness of various birth control programs, including one project distributing oral contraceptives and another offering family planning services. In 1977, to reduce costs, surveillance coverage was reduced by nearly 40% (84 villages with a total population of 105,000 were excluded).

The seven surveillance sites in Table 124–1 that date from before 1985 are in Bangladesh (Matlab and Operations Research Project; ORP) and in the three countries at the westernmost tip of Africa—Senegal, The Gambia, and Guinea-Bissau. None of these early surveillance sites are in East Africa or southern Africa. The oldest was founded by Pierre Cantrelle in 1962, in Niakhar, Senegal (Cantrelle, 1969).

The mid-1980s marked a turning point, with many new surveillance sites established, particularly in East and southern Africa—a sign that the method was now recognized as a useful tool for monitoring demographic and health trends. Some surveillance sites were established specifically to measure mortality and causes of death and to supply healthcare policy makers with information, enabling them to monitor the situation. In some countries where several surveillance sites were established, such as Senegal and Tanzania, the locations were chosen so as to cover different regions or socioeconomic situations. Having a network of surveillance sites partly compensates for the fact that no individual site is representative. Another reason for the increasing number of surveillance sites during the 1980s and 1990s, especially in East and southern Africa, was the need to gather information on the general population regarding several emerging or re-emerging diseases, especially acquired immune deficiency syndrome (AIDS) and malaria, for which only partial and poorly reliable sources were available.

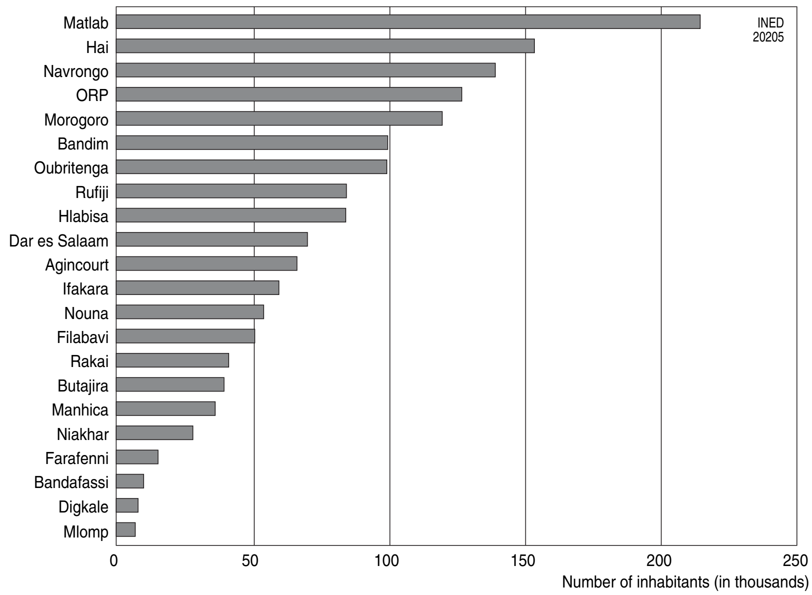
2. Characteristics of the Surveillance Studies

a. Population Size

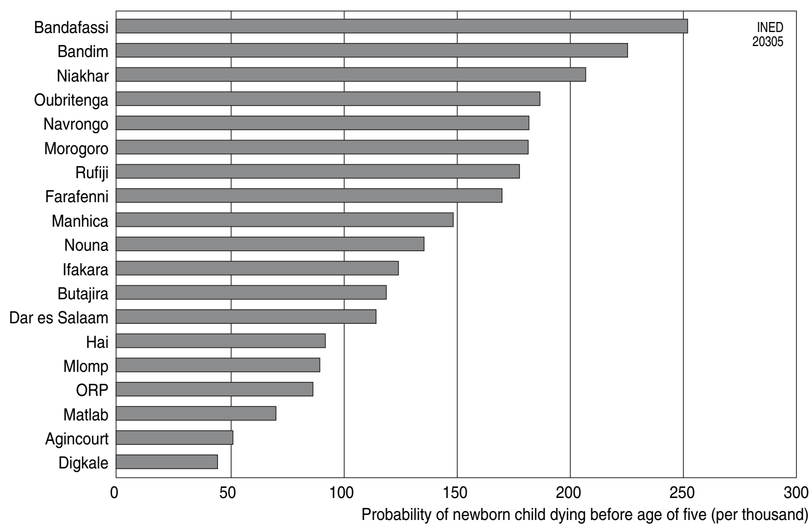
The studies in the INDEPTH network vary widely in the size of the population they monitor (Fig. 124–1a). The smallest, at Mlomp in Senegal, covers 7,500 people and the largest, Matlab in Bangladesh, 215,000. There are studies throughout the range between these two extremes, the median population size being just over 60,000. Surveillance sites set up in recent years tend to be large. For many of them, one purpose is to study mortality and causes of death among adults, including time trends, particularly in relation to the AIDS epidemic. And a population of at least 200,000 is needed to measure these correctly (Hayes *et al.*, 1989). Matlab, with a population slightly larger than this benchmark, is often regarded as a model.

The optimum size obviously depends on the purpose of the study and the resources available. But there is no guarantee that measurement precision will increase with population size; maintaining high-quality data gathering becomes more difficult as numbers of investigators and levels in the supervision hierarchy increase.

The examples of Mlomp and Bandafassi, examined in the second part of this chapter, show that studies covering only 10,000 residents each can reveal the main differences between the two sites for mortality and causes of death (children and adults).



A

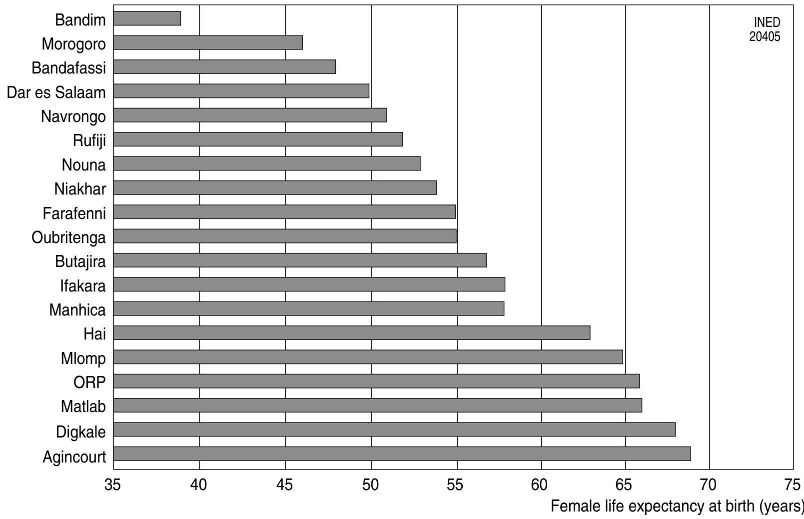


B

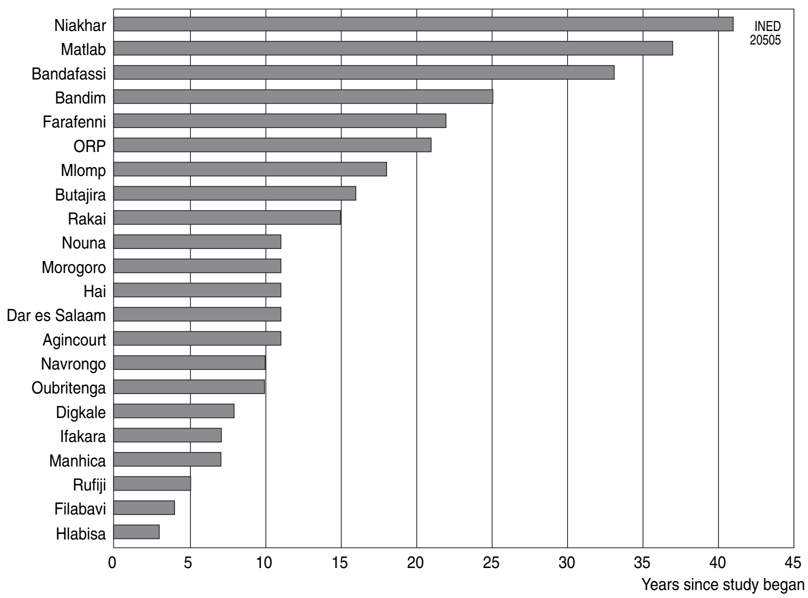
FIGURE 124–1 **(A)** Size of population monitored in 2000 (number of inhabitants). **(B)** Under-five mortality per thousand (5q0, probability of a newborn child dying before the age of 5 years of age), from 1995 to 1999.

b. The Health Situation

Table 124–1 gives two health indicators for each surveillance site: under-5 mortality rate (probability of a newborn child dying before the age of 5 years of age) (Fig. 124–1b) and female life expectancy at birth (Fig. 124–1c), both estimated for the period 1995 to 1999. The health situation seems very variable from site to site. In some populations, under-5 mortality rates are around 250 per thousand or more (Bandafassi in Senegal and Bandim in Guinea-Bissau); yet there are sites in South Africa where it is only one fifth that figure, at around 50 per thousand (Agincourt and Digkale). Figure 124–1b shows the contrasts between continents and regions, with child mortality markedly higher in Africa than in Asia and higher in West Africa than in East and southern Africa. However, exceptions can also be seen: the child mortality rate at Morogoro in Tanzania is close to those in West Africa; Morogoro is a poor, thinly populated rural area and was chosen precisely to analyze this type of exception. Conversely, Mlomp in Senegal has a particularly low child mortality rate for West Africa. As we shall see below, the population there has the benefit of



C



D

health programs and facilities that are rare in rural Africa.

The ranking order of the surveillance sites by female life expectancy at birth is much the same (Fig. 124–1c), since child mortality weighs heavily on life expectancy. The very short life expectancy in Bandim, Guinea-Bissau—39 years—is due to a combination of three factors: a low level of socioeconomic development, the AIDS epidemic, and the civil war that has ravaged the country since 1998. Several sites in Tanzania also have relatively low life expectancy, owing to low levels of socioeconomic development and the AIDS epidemic.

c. Age of the Surveillance Studies

Figure 124–1d ranks the surveillance sites in Table 124–1 by the age of the study. It illustrates what we already know: the majority are less than 10 years old and many of the recent ones are in East and southern Africa.

d. Frequency of Investigators' Rounds

At a rate of one surveillance site in three, the update rounds are annual; in just over half, they take place once every 3 or 4 months (Fig. 124–1e). It is generally recommended that the interval between visits be kept

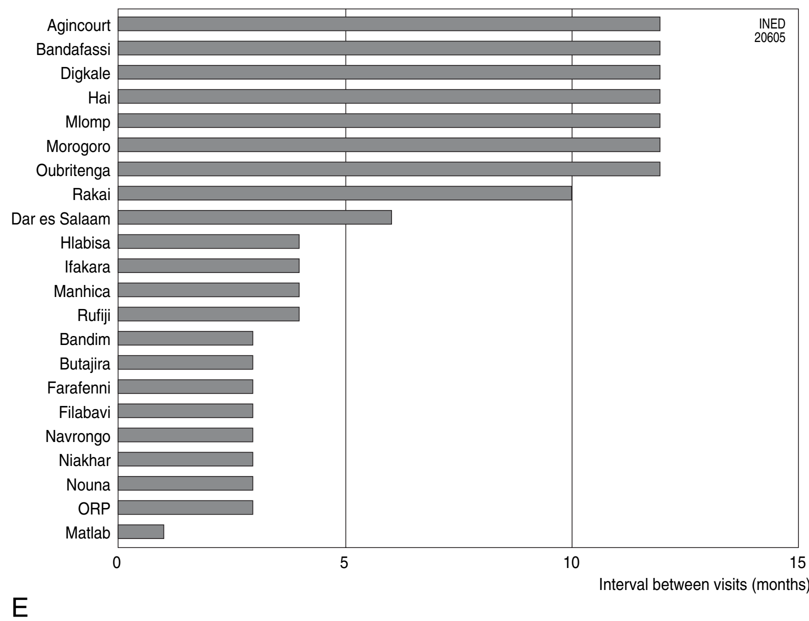

FIGURE 124–1 (*Continued*) **(E)** Interval between visits (months).

to about 3 months to make sure that such events as a birth quickly followed by death, or a brief outmigration and return, do not slip through the investigators' net. But here, again, actual practice is the result of a compromise between goals, resources and local limitations, and increasing the frequency of visits does not necessarily improve data gathering.

The data gathering method used at demographic surveillance sites, the types of finding they produce, and their usefulness for studying demographic and health trends in developing countries are illustrated later in the next section by detailed presentations of the studies at Bandafassi and Mlomp in Senegal.

II. THE DEMOGRAPHIC AND HEALTH SURVEILLANCE SITES AT BANDAFASSI AND MLOMP, SENEGAL

Bandafassi and Mlomp are rural districts of Senegal, with populations of about 10,000 and 8,000, respectively, in 2000. These populations have been monitored since 1970 and 1985,[1] respectively. Since the first year's baseline survey, both populations were visited annually without a break until 2003. At each visit, births, deaths, marriages, and migrations occurring since the previous annual visit were systematically recorded, cause of death being determined by a postmortem interview or *verbal autopsy.*[2]

1. The Bandafassi Demographic and Health Surveillance Site

Bandafassi is in the department of Kedougou, Tambacounda region, Senegal, near the border of Guinea (Fig. 124–2). On April 1, 2002, the population numbered 11,067. It is an entirely rural population, the main livelihoods being crop farming—sorghum, maize and rice, groundnuts and cotton—and cattle breeding.

The region is relatively disadvantaged compared to the average for rural parts of Senegal, owing to its remoteness from the main urban centers: it is 700 km from the national capital, Dakar, and 250 km from the regional capital, Tambacounda. The Tambacounda region itself is less well endowed with infrastructure and health programs than the rest of Senegal (Pison *et al.*, 1997b).

Bandafassi's population is comprised of three ethnic groups living in separate villages:

- Bedik (28% of the population)
- Malinke (16%)
- Fula (57%)

[1] Research program run by the National Institute of Demographic Studies (INED), Paris, in partnership with the Senegalese Ministry of Health.

[2] Before 1984, a brief information on cause of death was gathered. Thereafter, a structured questionnaire was introduced, as explained later in the chapter.

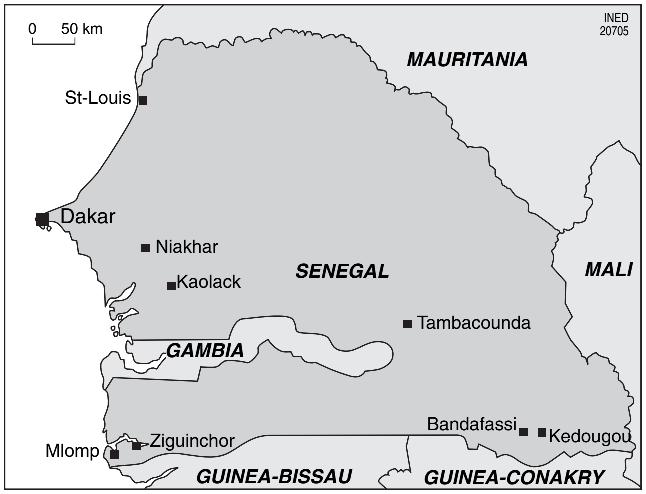

FIGURE 124–2 Map of Senegal showing locations of the Bandafassi, Mlomp and Niakhar demographic surveillance sites.

The baseline population survey and the monitoring were initially undertaken as preliminaries to a blood sampling campaign designed to study genetic diversity in the region's populations and measure differences in mortality rates in relation to individuals' genotypes. The study was intended to provide information about the mechanisms of genetic differentiation between population groups and the impact of differential mortality rates. Monitoring of the population, and particularly the recording of deaths, was designed to measure the variations of mortality rates according to individuals' genetic subgroups. However, that objective was soon abandoned, and the study's main objective now is to collect the necessary data for measuring demographic levels, trends and factors (Pison *et al.*, 1997; Guyavarch, 2003).

a. Demographic Monitoring

The gathering of demographic data began at Bandafassi in 1970. After the baseline survey, each village was visited yearly, usually between January and March. At each visit, the list of people present at the previous visit is checked and information is gathered on births, marriages, migration and deaths that have occurred since then (including causes of death). The information is usually given by the head of each compound or a few knowledgeable informants in the village.

At the start of the study in 1970, only the Malinke villages in the study area were covered. The study was extended to the Fula villages in 1975, and to the Bedik villages in 1980. The observation periods are thus different for the three groups of villages: 33 years (1970 to 2003) for the Malinke villages, 28 years (1975 to 2003) for the Fula villages, and 23 years (1980 to 2003) for the Bedik villages.

The documents used for the annual update survey include

- a list of households, updated at each annual visit
- a personalized questionnaire or nominative list of members of each household (see Box 1).

This list is also updated at each annual visit; thus, the list used for year N includes all the residents present in the household at the time of the visit in year N-1. All information required to identify each individual is included—first names, last names, parents' names, name of spouse, etc. (see Box 1).

The questions to be asked are also included. Some are the same for all residents (e.g., Is the person present or not?), while others are specific to each category, depending on sex, age, marital status and life history. For example, only women of childbearing age are asked whether any pregnancy or delivery has occurred since the last visit. In fact, the list mentions their last two deliveries, in order to make information gathering easier and avoid mistakes.

b. Determining Cause of Death by the Verbal Autopsy Method

The Bandafassi study aims to identify not only deaths but also their causes. But there are few cases where a doctor has certified the death and diagnosed its cause. During the early years of the study, cause of death was established by asking the deceased's close relatives what they died of. Since 1984, a verbal autopsy questionnaire has been used, asking the family questions about the illness or circumstances that preceded the death (Desgrées du Loû *et al.*, 1996). The verbal autopsy questionnaire covers a pre-established list of easily recognized symptoms such as fever, diarrhea, dehydration, vomiting, coughing, and convulsions. Each symptom is taken in turn, asking the family whether the person presented that symptom or not, and if so in what form; for this step, a second list of pre-established questions is used. By way of example, the questions asked in cases of diarrhea or dysentery are listed in Box 2.

Once the verbal autopsy questionnaire has been filled in it is read by two doctors who each give an independent diagnosis. In the event of disagreement between them, a third doctor reads the questionnaire and decides between them.

Diagnoses obtained in this way are more precise with some causes of death than with others. Neonatal tetanus, for example, is fairly readily identified; the signs are quite characteristic and mothers remember

Box 124–1 Example of Personalized Questionnaire, or Nominative List, Used in Bandafassi Annual Survey

This list gives the composition of the household—in this case at 1 March 2001—and was used as the questionnaire for the next annual survey in February–March 2002.

them clearly. So a diagnosis of neonatal tetanus can be made without much risk of error if the child died between the 5th and 28th days after birth and at least three of the following symptoms are identified at the interview:

- rigid body, legs stretched out and arms bent
- convulsive movements
- mouth clenched tight, child refused to suckle (sign of "trismus," contraction of mastication muscles causing mouth to close and clench)
- hypersalivation

Measles is also easily identified. Although the symptoms are less specific and less easily identified than with neonatal tetanus, the disease has a name in all the local languages and is well known to the people, who can identify it when an epidemic occurs. If a mother is asked whether her child died of measles (giving the name used in her own language), she is rarely mistaken. However, with the spread of immunization since the 1980s, measles epidemics have become less frequent and reduced familiarity has made self-diagnosis less reliable.

For some diseases, the verbal autopsy method does not give a very reliable diagnosis. Malaria is one example, as it is easily confused with other diseases involving fever.

c. *Other Data Collected*

Along with the routine annual collecting of basic demographic data, specific surveys are run on an *ad hoc* basis on subjects of particular interest concerning population, family or health. The population files act as a baseline survey for these studies. In Bandafassi, surveys have been conducted on

- Immunization (two surveys on vaccination coverage were conducted, in 1992 and 2001, to identify the proportion of children vaccinated and study variation factors)
- Breast-feeding and weaning (in 2000, a survey was conducted among a sample of women with small children, to provide new information about infant feeding practices)
- Sexual behavior and sexually transmitted diseases (in 1998, a survey was conducted among a sample of adult men and women to provide new information about sexual behavior, measure the prevalence of HIV, syphilis, gonorrhoea and other sexually transmitted infections, and analyze risk factors of getting infected. This survey combined a medical consultation, blood and urine tests and an interview on marital and reproductive history and sexual behavior. This was followed, between 2000 and 2003, by a survey among a network of informants on the effectiveness of prevention)
- Fertility (in 2000, a survey was conducted among a sample of adult men and women, gathering information on fertility and contraception. Combining this information with the local dispensary's family planning register and the demographic monitoring data, the year-by-year progress of contraception was tracked from the time it began, and the factors involved examined)
- Malaria (entomological, parasitological and pharmacological measurements were taken on several occasions, to improve knowledge of the epidemiology of malaria and monitor changes, particularly regarding the spread of drug resistance).

These quantitative surveys are often preceded (and sometimes followed) by more qualitative surveys on the same subjects, designed to prepare for data gathering or to examine particular issues in more detail.

2. The Mlomp Demographic Surveillance Site

In 1985, a new demographic and health surveillance site was established at Mlomp, in the Ziguinchor region of southern Senegal (Fig. 124–2). The aim was to complement the two existing rural demographic surveillance sites in Senegal (Bandafassi in the southeast and Niakhar in the center-west) with a third, in the southwest of the country (in the Casamance region) which has a different history, ethnic makeup and economic situation than the regions with existing surveillance sites. Data from the three surveillance sites should provide better coverage of the country's demographic and epidemiological diversity.

On January 1, 2000 the population of the Mlomp area numbered 7,591, divided among 11 villages. Population density was 108 persons/km^2. In ethnic terms, the population are Diola; the main religion is animist, with a strong Christian minority and some Moslems. Although educational levels are low (in 2000, 55% of women aged 15 to 49 had attended school for at least a year), they are significantly higher than at Bandafassi. The population also has much better health programs and facilities. Since 1961, there has been a private dispensary in the area run by French Catholic nurses and since 1968, there has been a village maternity clinic where most women go to give birth. Most children are fully immunized and are involved in a growth-monitoring program (Pison *et al.*, 1993, 2001).

Apart from a few points of detail, the Mlomp demographic surveillance study uses the same data gathering method as Bandafassi.

3. An Example of Findings: Child Mortality Trends

Findings on child mortality will serve to illustrate the potential of demographic surveillance sites for studying demographic and health trends.

a. Bandafassi: After Significant Improvements, Has Progress Ground to a Halt?

From the data gathered at Bandafassi, mortality rates and trends can be described, the main causes of death identified, and changes analyzed. For example, Figure 124–3 shows the trend in under-5 mortality rates ($_5q_0$). As not all villages had been monitored for

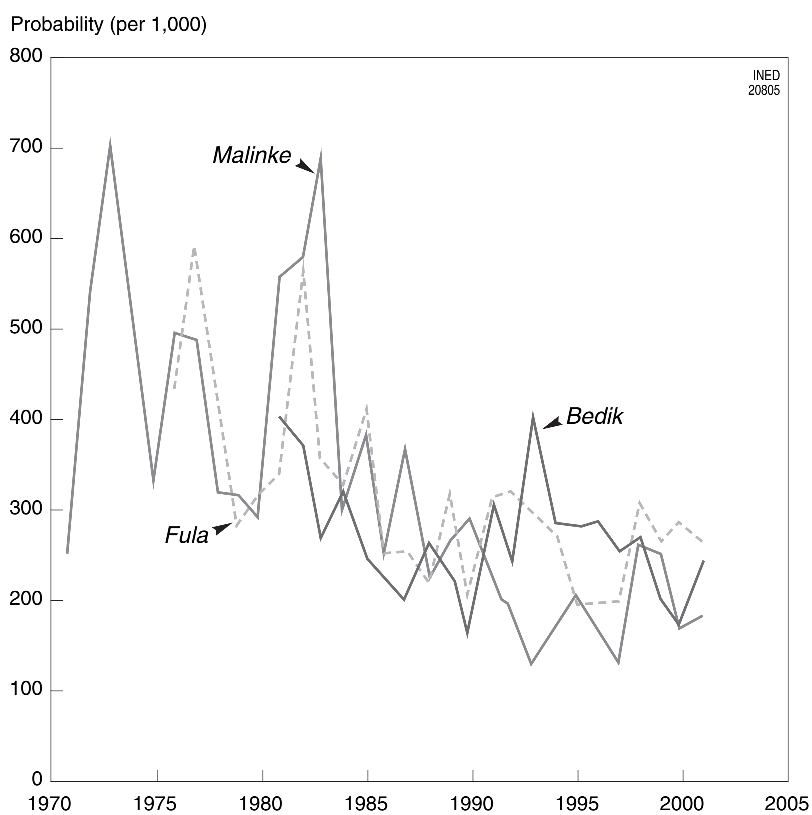

FIGURE 124–3 Trend in under-5 mortality rates ($_5q_0$, probability of a newborn child dying before the age of 5 years) in Bandafassi, by group of villages.

the same length of time, trends can be traced from 1971 for the Malinke, 1976 for the Fula, and 1981 for the Bedik. During the 1970s and the first half of the 1980s, 4 or 5 in every 10 children born died before the age of 5, though there were marked fluctuations from year to year. In the mid-1980s, mortality began to decline, until in the early 1990s the under-5 mortality rate was only 2 in 10, and year-to-year fluctuations became much sharper. Improvement ceased during the 1990s, and at the end of the decade there was even a slight increase in under-5 mortality.

The trend is similar, with slight differences for all three village groups. In the 1980s, under-5 mortality was slightly higher in Fula villages than in the other village groups, but during the 1990s it fell slightly below the others.

This pattern raises three questions. Why did under-5 mortality fluctuate so sharply before the mid-1980s? Why did it drop in the second half of the 1980s? What stopped that decline in the 1990s?

b. The Impact of Vaccination

Before 1987, the population of Bandafassi was not vaccinated on a regular basis. It was involved in a few national vaccination drives, such as smallpox vaccination as part of the global eradication of that disease, and the measles vaccination drives of 1967 and 1969. Apart from that, only some children of public servants—teachers and nurses—were vaccinated on a regular basis, and overall vaccination coverage was very low.

Vaccinations on a regular basis began in Bandafassi in 1987, with a national campaign to achieve country-wide coverage for the Extended Program of Immunization (EPI) that had been running in the cities since 1981. In the space of 3 months in the first quarter of 1987, vaccination coverage in Bandafassi rose to 48% (i.e., the percentage of children aged 12 to 35 months fully vaccinated, having received Bacillus Calmette-Guerin vaccine (BCG) and vaccination against measles, yellow fever, diphtheria, whooping cough, tetanus, and poliomyelitis) (Desgrées du Loû and Pison, 1994). The vaccination program was continued, with a view to gradually making it an integral part of the standard healthcare provided by the health services. The 1992 survey showed that although the vaccination drive continued after 1987, it varied from year to year with a downward trend overall: in 1992, 5 years after the start of the program, vaccination coverage was only 39%.

The population of Bandafassi entered the vaccination era abruptly. As the demographic surveillance system had already been in operation for several years when vaccination began in 1987, advantage was taken of this almost experimental situation to assess the possible impact of vaccination on under-5 mortality. Between the 6 years before the vaccination program began (1981 to 1986) and the 6 years after (1987 to 1992), under-5 mortality fell by 40%. The extent of the drop varied according to age group: 31% in the neonatal period (0 to 28 days), 20% between 1 month and 8 months, and 48% between 9 months and 59 months. As no other health change occurred during this period and the socioeconomic situation scarcely varied, vaccination clearly seemed to be the main explanation for under-5 mortality drop in the latter half of the 1980s.

A drop in under-5 deaths is hardly surprising, since the vaccinations gave protection against several common causes of death among children. But a detailed study of causes of death produced a surprising result: the drop was sharper than could be explained by even total elimination of deaths due to diseases covered by the vaccination program (Desgrées du Loû and Pison, 1996), and yet these diseases were still causing some deaths.

c. Measles: A Rapidly Declining Cause of Death

The decline in deaths due to measles was particularly dramatic. Because measles is a disease that the people of Bandafassi can identify easily, we have data on measles deaths from the start of the demographic monitoring in 1970, even before the verbal autopsy questionnaire was introduced in 1984. Table 124–2 compares deaths from measles between four periods, two prior to the start of vaccination in 1987 (1970 to 1979 and 1980 to 1986) and two after (1987 to 1989 and 1990 to 1993).

The change in 1987 is radical. Before that date, measles was responsible for about one death in seven (14% in 1970 to 1979 and 15% in 1980 to 1986) in children aged 1 to 20 months, and one in three (35% and 30%) in children aged 21 to 59 months. It was the foremost cause of death in these age groups. From 1987 on, measles accounted for only 3% and 5% of deaths in these age groups respectively.

Figure 124–4, which shows bimonthly variations in the 0- to 5-year age group's measles mortality rate gives a clear illustration of the epidemic nature of the disease. There were five epidemics between 1970 and 1995: in 1973, 1976 to 1977, 1981 to 1982, 1985, and 1992. Of the few children who died of measles between these epidemics, most were infected (and died) outside the study zone, when traveling with their mothers. Further, each epidemic affected only some villages. Before 1987, there were often intervals of over 10 years between epidemics in the same village. Because of the infrequency, when an epidemic did hit a village the

TABLE 124–2 Variations in Measles Mortality, by Age and Time Period

Period	Age group			
	1–20 months		21 months–59 months	
	Annual measles mortality rate (per 1,000)	Measles deaths as % of total deaths	Annual measles mortality rate (per 1,000)	Measles deaths as % of total deaths
1970–1979	21.0	15	25.3	35
1980–1986	14.6	14	14.9	30
1987–1989	0.0	0	0.0	0
1990–1993	2.9	4	2.6	8

Source: Bandafassi, 1970–1993.

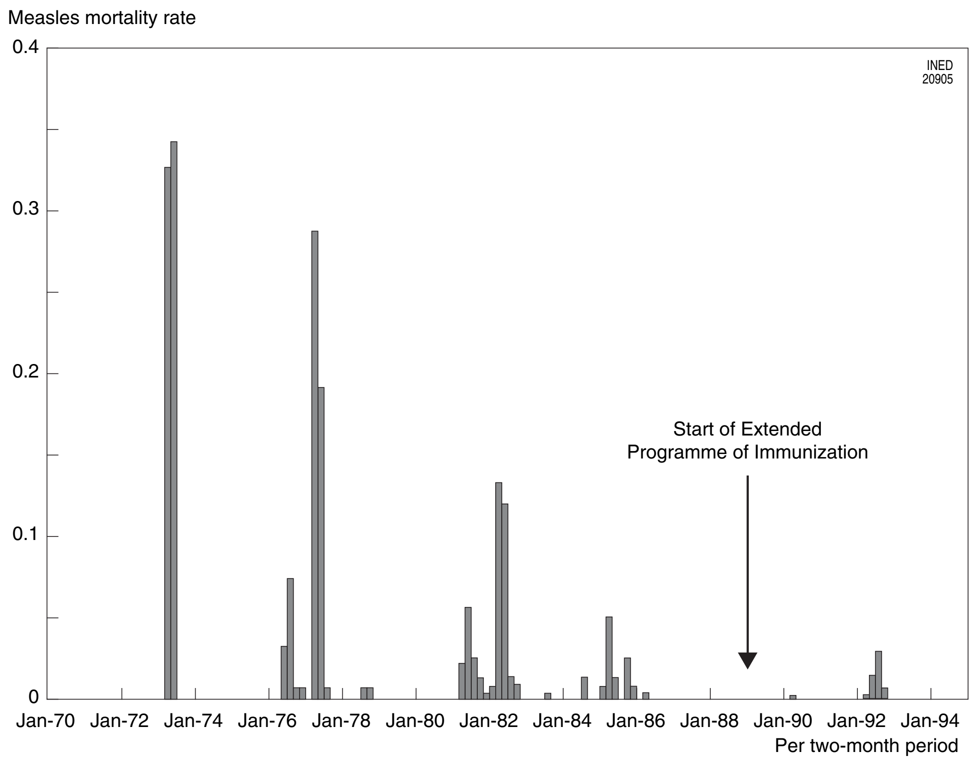

FIGURE 124–4 Bimonthly fluctuations in mortality due to measles in children under 5 years of age, Bandafassi, 1970 to 1994.

impact was severe: within a few weeks, nearly all children born since the last epidemic fell ill and the lethality rate was high—over 15% in the 1976 to 1977 and 1981 to 1982 epidemics.

From 1986, mortality due to measles plummeted. The virtual disappearance of one of the main causes of death in children is the most striking result of the introduction of vaccination in the study zone. But, as mentioned earlier, the decline in child mortality was greater than expected from the elimination of diseases covered by the vaccination program. This may be a sign that vaccines have a nonspecific beneficial effect, the measles vaccine in particular (Aaby *et al.*, 1995); like measles itself, the measles vaccine seems to stimulate the immune system in a nonspecific manner.

d. Mortality and Causes of Death at Mlomp Compared With Bandafassi

From an analysis of reproductive histories gathered during the baseline survey in 1985, child mortality trends in Mlomp can be traced back to the 1930s. Until the mid-1960s, the probability of death before age 5 was roughly stable, at 350 to 400 per thousand

(Fig. 124–5). It began to fall in the mid-1960s, and in the second half of the 1980s fell below 100 per thousand—far lower than that recorded in Bandafassi at that time. This very rapid decline is linked to the development of health programs and facilities in the 1960s and 1970s (Pison *et al.*, 1993).

From an analysis of the monitoring data for the two study zones, infant and child mortality per cause of death in Mlomp and in Bandafassi can be compared for the second half of the 1980s, distinguishing between neonatal mortality (Fig. 124–6a) and mortality between 1 month and 5 years (Fig. 124–6b). There are no data on cause of child deaths in Mlomp before 1970, when mortality rates were still high, but the causes recorded in Bandafassi in the recent period are likely to have been the predominant ones in Mlomp before 1970.

In the second half of the 1980s, neonatal mortality in Mlomp was less than half that of Bandafassi (36 per thousand compared to 87). This difference reflects differences in mortality rates for all major causes of death. For example, in Bandafassi neonatal tetanus was responsible for one neonatal death in 4 in that period, killing nearly 20 newborns per thousand compared to a mere 1 per thousand in Mlomp. Deaths due to premature birth or low birth weight show the same pattern: 2 per thousand in Mlomp compared to 21 per thousand in Bandafassi. For obstetric trauma, the figures are 3 per thousand and 12 per thousand.

After the neonatal period (Fig. 124–6b), the difference in overall mortality rates is even greater (45 per thousand compared to 277) and here too it is linked to differences in mortality for each of the main causes of death: diarrhea and malnutrition, pneumopathy, malaria, etc. In this period, measles was a declining though still significant cause of death in Bandafassi, but does not figure as a cause of death in Mlomp.

Assuming that mortality patterns in Bandafassi reflect those that were current in Mlomp until the 1960s, it appears that mortality in Mlomp too has waned because of a decline in each of the major causes of death.

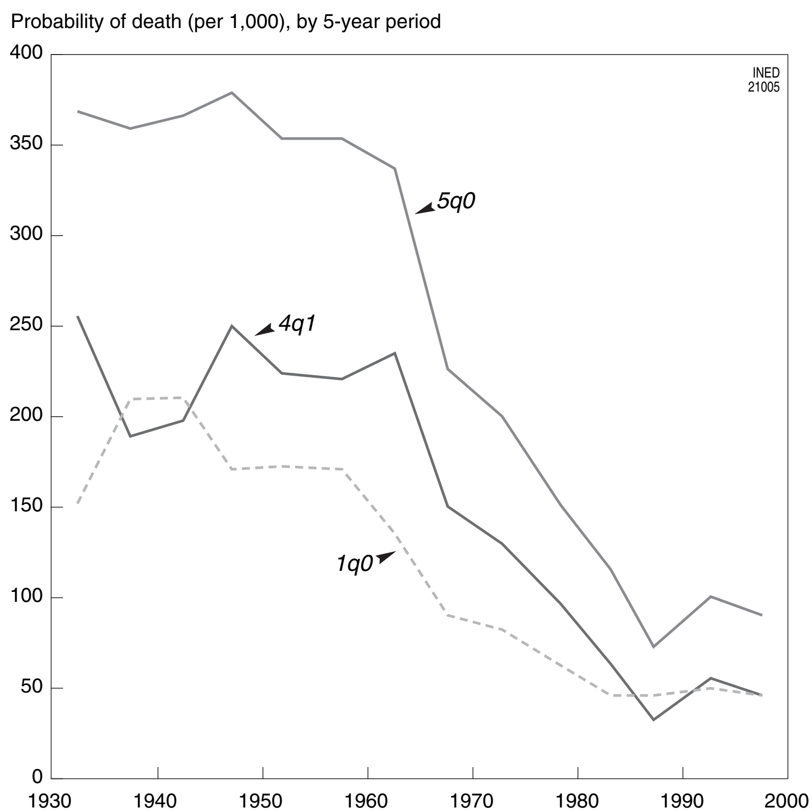

FIGURE 124–5 Child mortality rates in children age 0 to 5 years in Mlomp, since 1930. ${}_1q_0$: probability that a newborn child die before reaching the age of 1 year of age; ${}_4q_1$: probability that a 1-year-old child will die before the age of 5; ${}_5q_0$: probability that a newborn child die before the age of 5; *NB*: before 1985, measured by birth cohort (5-year age group) from reproductive histories gathered in 1985. From 1985 on, measured by 5-year period from demographic surveillance data.

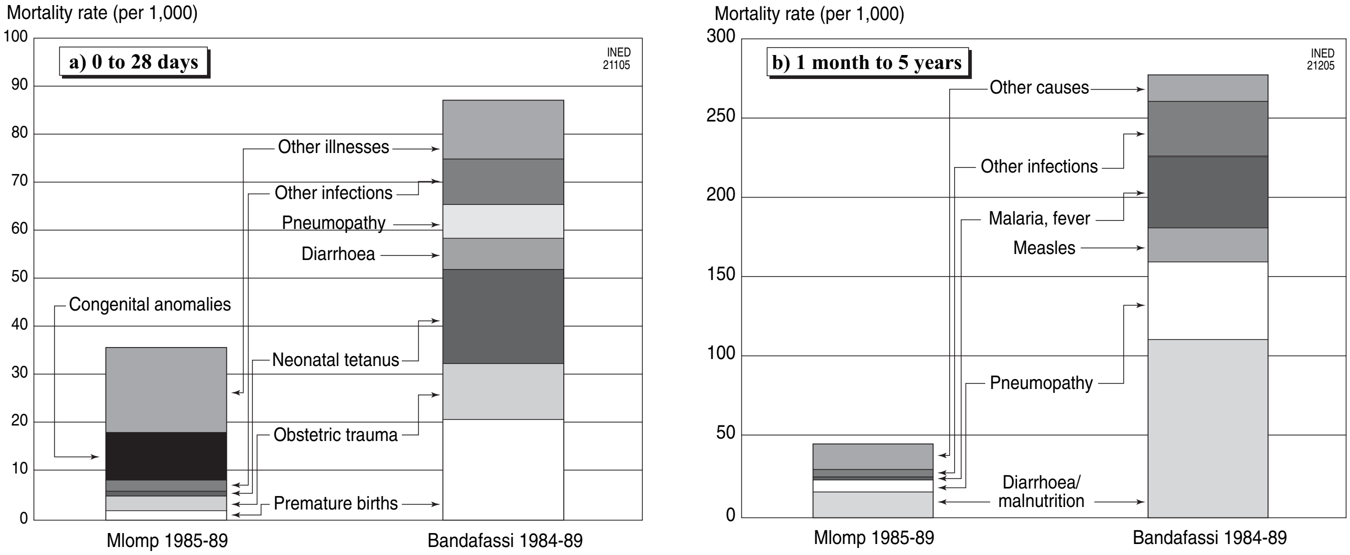

FIGURE 124–6 Child mortality: comparison between Mlomp and Bandafassi.

e. Malaria: A Cause of Death That is Regaining Ground

As shown earlier, child mortality ceased to decline in the early 1990s and even started to climb again at the end of the decade, in both Mlomp and Bandafassi. One reason is the considerable increase in deaths due to malaria (Fig. 124–7).

The verbal autopsy method is not efficient for identifying malaria as a cause of death because it is difficult to distinguish malaria from other illnesses involving fever. However, malaria mortality in Mlomp can be traced with some accuracy, as many children who died following a bout of fever had attended the local dispensary, where the malaria diagnosis was confirmed or invalidated by laboratory tests on thick blood films.

A sign of the success of the dispensary's antimalaria campaign in the 1970s and 1980s, malaria mortality was very low at Mlomp in 1985 and remained low until 1990. But it rose sharply between 1990 and 1992, and has remained quite high ever since. This is due to the arrival and spread of malaria strains resistant to chloroquine, the drug responsible for the earlier sharp reduction in malaria, mortality which is widely used by local people against fever attacks, both curatively and preventively (Trape *et al.*, 1998). Malaria mortality also increased again in Bandafassi and in Niakhar, Senegal's third demographic surveillance site (Fig. 124–7). This is one factor in the increase in overall child mortality rates in the 1990s.

Although many African countries have been hard hit by AIDS, Senegal has not yet been seriously affected and AIDS is not a major cause of death there. The recent increase in child mortality in the demographic surveillance sites is not AIDS-related.

CONCLUSION

As we have seen, demographic surveillance sites are a very effective way of monitoring changes in demography and health in countries with no reliable, routine data collection. In particular, they provide detailed information about mortality rates and causes of death in children under 5 years of age. At Mlomp, child mortality fell from the mid-1960s, in connection with the development of health programs and facilities. The demographic surveillance system has made it possible to measure the scale of the improvement and show that the rapid, dramatic reduction in mortality was due to significant reductions in mortality from every cause of death—a sign of good coordination and complementarity among the various health measures. The fact that the decline in mortality halted in the 1990s does not mean that change has ceased. Underlying the plateau in overall mortality there are contradictory trends, with some causes of death declining or disappearing and others gaining ground again.

While demographic surveillance sites are one of very few ways of monitoring mortality and causes of death in countries without health statistics, they are useful in other fields as well. For example, they can be used to monitor demographic and social change and study the processes involved. In this regard, they are a useful complement to demographic and health surveys. While DHSs provide estimated levels and

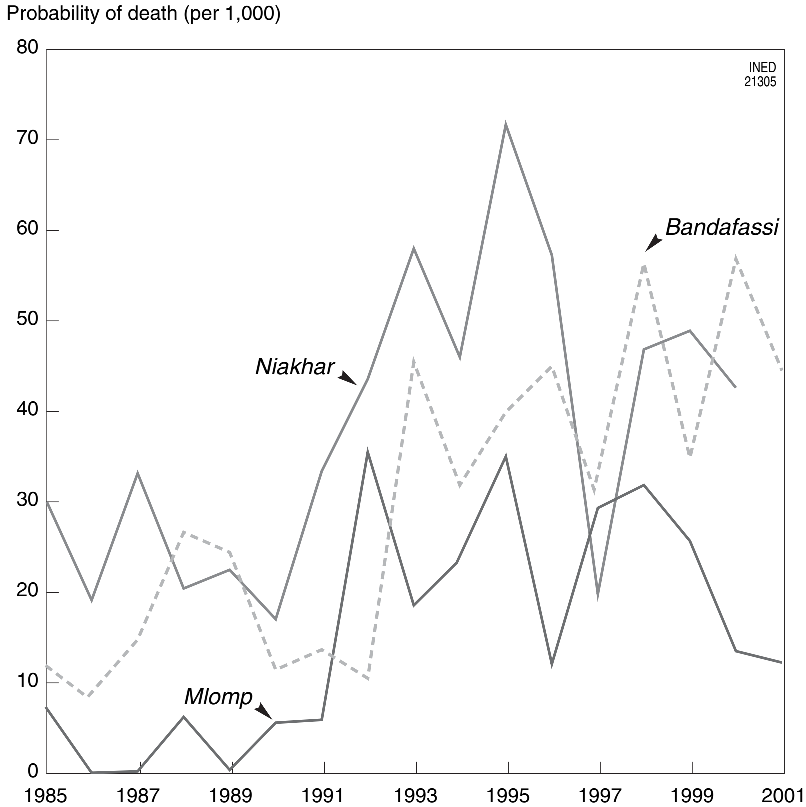

FIGURE 124–7 Malaria mortality in children under the age of 5 (${}_5q_0$) in Bandafassi, Mlomp and Niakhar, from 1985 to 2001.

trends that are representative at the national level, demographic surveillance sites supply detailed information about the mechanisms involved in those changes.

I. AGE AND DIVERSITY OF THE PRACTICE

Comparative analysis has always been an especially fertile branch of research—in demography as well as in the other social sciences. Demographers have always been concerned with comparing a population's demographic behavior with what is occurring in neighboring countries or countries that belong to the same cultural or economic zone. The main objective has varied according to era and demographic way of thinking: to expose the specificity in the characteristics and behavior within a country, or to find the universal factors or *laws* that may be hidden behind an observed heterogeneity. Comparison makes it possible to avoid the risk of giving specific and national interpretations to international phenomena, and to expose precursory signs indicating the direction that the population will take in the future.

In today's globalized world, regulated by increasingly uniform economic laws from one end of the planet to another, where countries associate to create vast common economic and social zones and where at the same time the concept of nationality is being defined at an increasingly detailed level, it is more imperative than ever to create a common language that will enable people to understand one another and communicate. The language adopted to this end is one that can, at a statistical level, make comparable information available and enable its analyses with methods capable of shedding light on similarities and differences. The aim is obviously not to construct comparable information by confining it to the limited field of demography or to the single level of societies and populations (macro level), as has been done for a long time. Following the development of studies aimed at the interpretation of and research into the determinants of demographic behavior, today's focus is on establishing the comparability of individual data (micro level) on an increasingly large number and range of descriptive demographic, social, economic, medical, and health variables, variables of individual behavior, and of the social and economic structure of different countries.

The definition of a common statistical language capable of ensuring comparability is faced with numerous obstacles, some of them are clearly legitimate, while others are linked to the varying quality of the information to be compared. The increasing demand for the development of comparable statistics necessitates approaching the issue with new tools, while attempting to identify the causes of differences and trying to reconcile the demands for quality at various levels, national (and increasingly infranational) and supranational, with the awareness that these demands can be conflicting as the objective of comparability can often contradict with the continuity of temporal series, which is another powerful knowledge tool.

Fortunately, the era of simplistic solutions (when attempts were made to solve the comparability problem through the rigid standardization of concepts, survey techniques and methods) underestimating the negative effect that such a strategy can sometimes have on the overall quality of information seems to have come to an end. We realize today that the solution is more complicated and that it requires a detailed knowledge of the concepts and structures of the various realities to be compared in order to represent of all of them. We have also realized that the construction of comparability, in the context of quality requirements, is a continuous process where each stage marks provisional progress towards better results, but where the objective of perfect comparability is only a theoretical aim.

II. THE CONDITIONS FOR COMPARISON: DATA COMPARABILITY

Comparative analysis should first of all be based on comparable data, i.e., data that can be compared to another in a common frame of reference: in other words, data that speak the same language. The harmonization process can be interpreted in light of the following objective: the development of a common language that makes it possible to obtain, for a determined variable, estimates that are not affected by the international diversity of concepts and social structure.

Data comparability thus requires, by its very nature, a compromise between the demand for the national specificity of information (which enables comparisons over time), and that of international comparability. It always has a cost in terms of informative capacity, insofar as losing specificity can imply that the information is less relevant for understanding local reality. This must be taken into consideration not only when the data are being produced but during the analysis and evaluation of the results.

Concern regarding data comparability and attempts at harmonization occurred very early in demography: the United Nations' recommendations for carrying out censuses and models for collecting and classifying information on causes of death are classic examples. Important progress has been made on the path to demographic data comparability but more remains to be done, in particular when comparative studies are based on data that are not strictly demographic. The process of harmonizing social variables, as well as socioeconomic variables, at the individual and family level, actually began much later: the first steps towards a common strategy were not taken until the second half of the 1990s. The *Siena Group* (one of the *City Groups* dedicated to social statistics launched by the United Nations), and in Europe, Eurostat (through various initiatives associating the managers of demographic and social statistics of various countries) concentrated their activities during this period on harmonizing demographic and social statistics, putting forward many propositions and tracing the course of a common path (Mejer, 2003).

1. The Notion of Harmonization

Harmonization is the search (never completed or definitive) for reasonable equivalences between concepts that translate the same idea into different social realities, the search for a common language that makes it possible to go beyond national specificities. All the elements of statistical language (concepts, definitions, classifications, collection methods, and methods for developing data) should be taken into consideration in the strategy for data harmonization, insofar as each element can facilitate or hinder comparability and thus influence the quality of the results.

a. Concepts and Definitions

When the objective is to compare demographic or socioeconomic variables measured in different cultural contexts, we should expect differences in the concepts used in diverse national realities, and consequently differences in the social and institutional structures that reflect these concepts (consider, for example, the concept of education and the educational structures set up in the different countries to fulfill the educational requirements of the population).

The divergences are particularly significant for certain complex concepts (such as well-being, poverty and social exclusion, health) that are based on theoretical structures deeply entrenched in the value system of each country and each era concerned.[1] In these cases, the construction of comparable measurements leads first of all to a search for the definition of the variable(s), which maximize(s) the similarities between the concepts (and/or between the national structures)—a sort of *greater common divisor*, which can become significantly removed from the most appropriate definition for each country. At the same time, it is necessary to protect the measurement as much as possible from all activities that can cause distortions in the comparison (collection, codification, correction, calculation).

[1] For example, after the adoption by the World Health Organization (WHO) of an international definition of health, the indicators used in studies on health have over time progressively replaced the traditional macro objective indicators (general mortality and by causes, child mortality), with clinical indicators (presence of diseases and clinically verified risk factors), and subjective indicators based on respondents' self-evaluation (perceived health).

The starting point of the harmonization process is therefore updating and going beyond the natural tendency towards ethnocentrism, through detailed knowledge of national concepts and the corresponding structures in order to develop a common definition of a compromise concept (an international or harmonized concept), which represents an agreement for comparisons between different countries (Ehling, 2003). This stage is simpler to carry out if it is possible to refer to a universal concept, or at least objective elements. Some of the variables most frequently used in demography are of this type: the concepts of *sex* and *age*, for example, are generally shared or they can at least be easily attached to international standards. Some recent developments should be carefully monitored to make sure that they do not distance us from this favorable situation. For example, the increasingly frequent use in demography of the *gender* concept, based on the social roles played by individuals, instead of the biological concept of *sex*, could cause progressive divergence in the operational definitions of different countries and loss of comparability.[2]

Concerning age, comparability problems are often linked to the recording method (age of the individual rather than the year or date of birth), but the distortion that can result from this is generally not likely to compromise possibilities for comparison, at least when the classification is detailed enough. Other concepts, also fundamental in demography, such as the vitality of a birth, parity, migration, nationality, and cause of death, pose more serious problems.

The problems are even greater for variables such as ethnic group, which, on the one hand, are more difficult to define, and which, on the other hand, are (in some countries more than in others) sensitive issues that cannot be broached with simple and direct questions (Hoffmeyer-Zlotnik, 2003). The same is true for variables that are more resolutely social (such as education, employment, or social condition) and that participate in demographic studies as possible determinants of the behavior of the individual or the family.

In these cases, the greater the difference between contexts, the greater the risk of the acceptable definition being too complex and too difficult to estimate with available tools (too many questions in the questionnaire, respondents' lack of understanding, lack of correspondence with administrative sources, etc.).

b. Definition of the Unit of Collection and Analysis: The Household

Some concepts and some definitions play a particularly important role, as they are attached to the units of analysis of the information collected, and, at the same time, to the units from which the samples and the information are taken. They should therefore be able to ensure complete coverage of the basic units. The household is an example of this type of unit: it is the unit of collection of numerous statistical surveys, as well as an active subject of demographic and social behavior, either autonomously, or as a framework within which individuals live their lives and make decisions in interaction with other members.

The household is a complex and dynamic unit, whose definition varies from one country to another (it can sometimes even refer to different concepts from one survey to another in the same country). Cohabitation (the concept of *household housing unit*) is the minimum condition, adopted by every country, for a group of individuals to constitute a household. Some countries, such as the United States, Canada, and France, adopt a definition of household based on this condition only, which guarantees complete coverage of the population, even if there are no population registers, and which enables samples to be selected on the basis of a list of addresses. But most frequently, the definition of household includes other conditions relative to the manner in which the members *live together*, and the way in which they use the resources available to them (*household budget* concept): if the household members pool all or part of their income regardless of their family ties, they have a common budget. These conditions can take various forms according to the habits and sensitivity of the population. In Australia, the household is a group of individuals who live and usually eat together, in the Philippines it is a group of people who sleep in the same residence and who prepare and eat their meals together, in New Zealand it is a group of people who usually live together and share the services of the residence (kitchen, bathroom, lounge), in Germany it is a group of people who live together and constitute an economic unit. In Great Britain, a group of individuals is considered to be a household if there is a combination of three elements: living together, eating together, and constituting an economic unit.

For censuses around the year 2000, the United Nations and its regional agencies recommended that

[2] "Although the above mentioned problems of distinguishing between men and women are real and may increase in the future, sex belongs to the variables most easily assessed. The reverse is true for gender and gender roles. Here researchers have still some way to go to yield fruitful clear-cut definitions and robust measures of these concepts that then can be adopted to cross-cultural studies." (Wolf and Hoffmeyer-Zlotnik, 2003). See also (Krieger, 2003).

countries use common housing and budget criteria[3] in information collecting operations. Working towards its objective of making European countries converge towards comparable demographic and social statistics, Eurostat suggests that the countries adopt the same conditions, not only for censuses, but also for social surveys from which statistical information useful to the European Community is extracted. Despite this, some countries continue, for internal consistency between the definitions used in their various national surveys, to use the single condition of co-residence (Mejer, 2003).

Of course, there is generally a nearly perfect correspondence between the households identified by the two definitions. The problem arises from particular situations such as that of domestic employees, subtenants, or lodgers, who live at the same address but who, generally, do not share their resources with other household members, or that of people living temporarily outside of the household for health reasons or study reasons. In the latter case, the recommendations suggest that a person's membership of the household should be judged according to length of stay (usually, at least 6 months out of the 12) and other information that makes it possible to understand the nature of his/her link with the household: for example, students who live far from their family and who do not receive any economic support should be excluded if their absence is longer than 6 months, but should be included, regardless of the length of absence, if the family is financially responsible for them.

The method of dealing with students living apart from their family is important, as numerous studies have been developed recently on this phase of the life cycle, on the methods and the rhythm of forming new family units, and on the consequences of the choice of autonomy on quality of life and well-being. Indeed, when units made up of young adults still in education are treated as autonomous households, there is a strong probability that they will be classified as poor. We will spend a little time on this example, as it clearly illustrates the complexity of choices that must be made in order to create comparability that goes beyond cultural specificities. The situation of students living away from their families and who have limited resources can correspond to very diverse situations in different countries, according to the way in which the parent-child link is experienced. In some contexts, leaving the parental home is experienced, by both the parents and the child, as the beginning of an autonomous life with all its advantages and disadvantages: independence but also economic fragility and the need for young people to find most of the resources that they need. In other contexts, in particular that of southern Europe, the departure of students is considered transitory, without the bonds of interdependence being distended. The children remain, in every way, members of their family and they share (from afar) the same level of well-being: the parents take direct responsibility for the majority of the cost while frequently providing the students with an income that enables them to pay their day-to-day expenses. In the first case, it is normal for households of students to be classified as being poor (according to their income and their expenses), but in the second case applying the same definition would lead to unduly overestimating the number of poor households.

Furthermore, the duration of absence from the parental home takes on a different meaning according to the tools available for choosing the sample. In many countries, the selection is made from lists of addresses and the criteria of duration of absence is necessary to avoid a person being selected twice. In other countries, there are population registers, particularly registers of the resident local population, from which the samples are selected. As a person cannot be recorded in several registers at the same time, individuals have the choice of defining their place of residence as the place where their interests lie, including emotional ones: children can maintain their place of residence at their parents' address even if they are away for longer than the 6 months recommended by the definition without changing their probability of being selected.

In general, therefore, in the European Union and more widely in Western countries, the adoption of a definition that only respects the condition of cohabitation does not create substantial differences in the structure of households (Bien and Quellenberg, 2003). Moreover, as the condition of a common budget is always combined with that of co-residence, the countries that adopt the most restrictive definition are able to aggregate their results according to the simpler criterion of cohabitation, while the reverse is impossible. This is why, for example, the comparative indicators and tables that the countries must provide the European Community based on their censuses only refer to the criterion of co-residence, although the *household budget* concept has been recommended (Eurostat, 1999a, p. 23). However, logical inconsistencies can

[3] "A household is classified as either: 1) A one-person household, defined as an arrangement in which one person makes provision for his or her own food or other essentials for living without combining with any other person to form part of a multi-person household, or 2) A multi-person household, defined as a group of two or more persons living together who make common provision for food or other essentials for living". (www.unstats.un.org/unsd/demographic/)

occur between the definition adopted for family and the type of phenomenon analyzed. For all the phenomena relative to the economic condition of households, their revenue, consumption, or poverty, for example (Bauman, 1997), it is important that the household be defined by the dual condition of common housing and budget, as the economic situation of a group is only meaningful if all members share it. In the *European Household Budget Survey*, which plays a key role in the comparative study of the living conditions of families, the definitions adopted by the countries are more or less restricted (Table 125–1) to the combination of the four criteria (Eurostat, 2003a):

1. co-residence
2. sharing expenditure
3. pooling income and resources
4. the existence of emotional ties

At the two extremes are France, which has adopted the least restrictive definition, and Italy, which combines all four criteria for defining a household.

In the *European Union Survey on Income and Living Conditions (EU-SILC),*[4] the new harmonized survey intended to gather statistical information on the economic situation of families and social exclusion in Europe, the definition of a household has been specified in a European regulation which, by being formally imposed on the countries, aims at creating conditions for improved comparability. The regulation makes the provision that a *private household* means "*a person living alone or a group of people who live together in the same private dwelling and share expenditures, including the joint provision of the essentials of living*" (Article 2)[5] and it specifies the conditions that make it possible to establish whether a person living at the address of the household (or is temporarily absent) is a member of the household.[6]

[5] Regulation (EC) No. 1177/2003 of the European Parliament of the Council of Europe, June 16, 2003.

[6] Commission Regulation (EC) No. 1980/2003, October 21, 2003.

The household is not only a unit of data collection, it is also a unit of analysis, either as an exclusive referent of behavior (in surveys on family budgets it is frequently impossible to attribute choices and practices to specific household members), or as an influential and often even determining context of the choices and behaviors of individuals. It is also fundamental, from this point of view, that common definitions delimit the borders of a household and determine the internal structure. Within a household, other complex units can also be used as analytical units: the *family* (group of co-residing individuals who are linked by affiliation, biological or adoptive, or by marriage (*de jure* or *de facto*), the *family nucleus* (limited to the relationships of couples and parents with unmarried children). The definitions of the family nucleus are generally shared by the countries, and the lack of comparability is mainly due to the tools for collecting information on the ties between individuals within a household, which enable the complete reconstitution of families or family units more or less effectively. There are two types of tools: those that collect information on family relationship, adoption, marriage, and cohabitation ties, relative to a single subject (reference person); and those that collect information on the ties of each person with all the others (relationship matrix). The second tool obviously collects more detailed information, which makes it possible, in theory, to more specifically define the relationship between the different individuals. The first tool is compelled to trace the entire network of relationships on the basis of those which attach each member to a single person. The method is an effective one when the reference person is at the center of the network (in some demographic surveys, it is advisable to choose a woman who belongs to the median generation).

The combination between the concept of household and that of family provides a hierarchical classification shared by many countries, who generally, in the presentation of results of their various surveys, adopt classifications at various levels of specificity according to the link between the phenomenon studied and the family structure.

c. Other Sources of Noncomparability

The differences between concepts and between definitions (of variables and units) only represent part of the problem to be solved in order to ensure comparability. Several other elements can prevent the comparison of estimates of the same phenomenon. Indeed, the construction of comparable statistical data (demographic, economic, and social) involves the whole process—from the appearance of the need for information, to making the data available. Harmonization should affect all the stages and all the tools for producing statistical information: instruments, nomenclatures, procedures, analytical methods, etc. In a demographic survey, for example, once the relevant variable has been defined, a set of questions must be decided upon, as well as the order in which they should be inserted and the whole of the questionnaire itself in order for this definition to be respected.

The questionnaire, its vocabulary, and its structure are key elements in constructing the comparability of variables collected in household surveys. Several efforts have been made to determine the best *translation* strategy in order to ensure better understanding on the part of respondents and to guarantee the highest possible equivalence of the measurements. Several methods are possible: the most common consists of adopting a questionnaire (or a module of a questionnaire) initially designed for a determined country, and then translating it into several languages. The implicit condition of this operation is that the national concepts that underlie the variables are similar to one another: in this case, the key element of the procedure is the quality of the translation, which should reproduce the precise meaning of the terms used in the original language and which suggest the same reactions in the respondent. Several methods were developed to improve translation quality and to overcome the tendency to place too much value on the formal equivalence of the questions in the different languages (precise equivalence of content) to the detriment of functional equivalence (the capacity that the question has of evoking the same concept to the respondent) (Brislin *et al.*, 1973). The most common method is that of back translation, in which the questions are first of all translated into the different languages (preferably several times by several translators) then translated once again into the original language (once more by different translators) in order to check for consistency.

In order to obtain good results, it is frequently necessary to forego strict adherence to the content of each question (Harkness, 2003; Harkness *et al.*, in press), but rather to take the meaning of a given word or expression in its everyday use and adapt it to different cultural and social contexts (Guyatt, 1993). The scale of responses is also sensitive to the context, insofar as the modes of response (whether they are numerical or verbal) can provoke reactions, and therefore produce different results. It would be useful to carry out experimental research on these themes, possibly resorting to psychometric tests and to the evaluation strategies that accompany them (WHOQOL Group, 1994, 1998), in order to reveal the communication mechanisms that regulate respondents' perceptions and reactions during the survey. These mechanisms are made up not only of questions, responses, structure, and sequence within a questionnaire, but also relations between interviewer and respondent and type of interview (face to face, *paper and pencil interview*, or *PAPI* type; *CAPI*, for *computer-assisted personal interviewing*; or *CATI*, for *computer-assisted telephone interviewing*). This methodological investment, common at the national level, has hitherto been missing from the development of comparative studies; its absence has in particular led to underestimating the importance of the period and the tools of the survey in the quality of statistical information, and therefore in comparability.

The circumstances that have just been described (adoption of a questionnaire for a single country, followed by translation) are undoubtedly not the most effective for obtaining comparable results. When the survey is designed from the start as an international project, it is undoubtedly preferable to carry out the design of the questionnaire (or of various thematic modules) in the different languages, with the participation of experts in statistical data collection to verify the similarities and record the differences between the national concepts and the social and institutional structures that correspond to these national concepts. The development of recommendations and standards for use during data collection can be a good strategy for reducing sources of incomparability, particularly when common tools result from a process of thorough dialogue. The *European Health Interview Survey* (EUROHIS) project provides a good example of a recommended procedure (Nosikov and Gudex, 2003a and 2003b). It was aimed at designing the necessary tools for the development of eight indicators essential for the *Health for All* program (chronic physical conditions, mental health, alcohol consumption, physical activity, recourse to curative medical services, consumption of medicine, prevention, quality of life), coordinated by the World Health Organization (WHO) European Office, with the cooperation of those in charge of statistical information on health in European countries. During the second half of the 1990s, a previous project had already led to the development of the tools necessary for producing six health indicators (perceived health, temporary incapacity, tobacco consumption, weight at birth, breast-feeding, body mass index) (de Bruin *et al.*, 1996). Thereafter, a *survey of surveys* on health carried out in Europe with the participation of 33 countries made it possible to select intervention zones for networking, with each network being responsible for developing a tool. The method adopted gave the project participants (each with specific responsibilities in their specialty) considerable co-responsibility, which enabled the emergence of a full consensus at every phase of the process, from the selection of indicators on which to intervene, the analysis of concepts used, and the development of operational definitions to field experimentation with the proposed tools (Nosikov and Gudex, 2003b).

Beyond the problems related to the questionnaire, a significant part of the lack of comparability between countries is due to the methods and modes of organization adopted for collecting and producing data. Let us list some of the most important ones (Egidi and Buratta, 1995; de Bruin *et al.*, 1996), by grouping them into four categories.

1. **Sampling factors**. The sample design and size are frequently very different from one country to another. The possibility of reliable comparison is often reduced when it is based on estimates taken from confidence intervals of unequal sizes. Even the reference population of surveys sometimes differs according to country, thus affecting the quality of comparisons: some surveys are representative of all the people living at a given time in a given territory in an ordinary household, with the exception of those living in institutions (hospitals, homes for the elderly, prisons, etc.), while others cover both groups. The sampling units can also differ according to country (individuals, families, households, housing units, etc.), the sampling frame can be constituted using nominative registers (population registers, electoral rolls, telephone directories, etc.) or it could follow a probabilistic strategy. We often underestimate the consequences of strategies for taking into account sample losses as much at the primary level (generally territorial units) as at that of secondary units (households, individuals, etc.). Some countries replace the missing units with substituted units, while others overestimate the initial sample so that the nonreplaced losses do not cause the sample to fall below the threshold necessary for statistical significance of estimates. Furthermore, in some countries, in the absence of the person who should have responded directly to the questionnaire, a *proxy* is interviewed, while in other countries this procedure is forbidden.

2. **Factors linked to the various data collection methods**. As discussed earlier, depending on the type of survey, the interview is carried out *face-to-face*, in direct interaction between the interviewer and the respondent, the questionnaire either being on paper (*Papi* method) or electronic format (*Capi* method); in other cases, the interview is carried out over the telephone (*Cati* method); lastly, the questionnaire can be self-administered (without any interaction with an interviewer). For some phenomena, the use of one method or another can cause variable reactions from respondents, either from one country to another, or from one subpopulation to another within the same country according to cultural specificities. When interviewers are used, the characteristics of their network can be determining factors: the best solution is obviously to use professional interviewers who have been specially trained and who are directly supervised by the person in charge of the survey; in many cases, at least one of these two elements is missing (interviewers who are not specialized or professionals, or monitoring fieldwork through a subcontracted company results in a screen being placed between the survey manager and the real conditions of data collection).

3. **Factors linked to time, to the distribution of interviews throughout the year, or as the reference period for the information collected**. For the same phenomenon, in some countries survey protocol requires interviews over different periods of the year (usually quarterly), and on one specific date in others. The reference period of some questions can also significantly influence estimates due to the effects of memory, which often acts differently in different cultural contexts.

4. **Factors associated with the procedures for collecting and analyzing data**. All the stages of the progress from raw collected data to statistical data are included in this group. The methods of identifying and correcting errors can differ considerably: countries use different consistency tests and different systems for correction based on deterministic or probabilistic models. Furthermore, the strategies develop over time with the introduction of innovations at both the conceptual and operational levels.

Tools, methodologies, and techniques can all encourage or impede comparability. In summary, comparative research should be able to rely on quality statistical information: precision, reliability, clarity and accessibility, consistency, and exhaustiveness are the conditions that, when they are respected in every country, result in good comparability (Eurostat, 1991).

Only one element of data quality can impede their comparability and that is the relevance of statistical information: the further the compromise concept adopted for comparative purposes moves away from the national concept and prevents satisfactory estimation, the more the information loses its relevance for knowledge of the phenomenon at national level conceptualization. It is necessary to take this into consideration in the design stage of the project as well as in the analysis of the results. This distancing has multiple negative effects: (1) in the current situation of limited resources available for statistical production, there is competition between statistical information that fulfills different requirements (national and international), (2) and the need for information at a higher level has suddenly been given priority (which could well occur under the effects of strong political pressure, such as that which is exerted today around the themes that are the subjects of community policies within the European Union). Information would lose consistency within its national context, at the risk of creating confusion among data users and reducing data validity, due to a reduced capacity to identify the errors. Where there is a valuable information heritage accumulated over time the conflict between comparability over time within a country and comparability in space with other countries is significant, and the reconstruction of chronological series making it possible to rehabilitate the previous heritage of information may be too onerous to be undertaken.

Thus, improvement in comparability is a costly process, both financially and in its effect on the overall quality of statistical information. The choice of a strategy of harmonization must take this into account and must resist the temptation of simplistic solutions that will inevitably lead to unsatisfactory results. Harmonization should always be considered a process that affects all of the stages of data production—from their definition, collection, and development to the construction of indicators—and a dynamic process that develops through successive stages respectful of the previous heritage.

2. Harmonization Strategies

The choice of a harmonization strategy depends on a number of elements, the first of which are the social, cultural, normative, and institutional distance between the national units to be compared.

The other elements to be taken into account are the characteristics of the object for comparison and the targeted objectives: comparison between indicators (macrocomparability or comparability of indicators), essentially with a descriptive goal or constructing integrated information bases from individual data in every country (microcomparability or comparability of individual data), leading to a microanalysis of the phenomena. Different levels of harmonization correspond to the two methods, imposing increasingly demanding conditions as we move from the aggregated level towards the individual level.

Traditionally two harmonization strategies are distinguished: that of *input* (or the harmonization of methods or sources), and that of *output* (or harmonization of results). Complex strategies have recently been developed, which borrow elements from both.

a. Input Harmonization

The input strategy requires that the different countries adopt the same definitions, and common methods and tools for collecting information (structure of the questionnaire and wording of questions, periodicity, sampling plan, sample size and rotation, form of interviews, methods of extrapolation, principles of checking and correcting data, coding methods, rules for imputing nonresponses, etc.; Grais, 1998, p. 12). This strategy makes it possible to eliminate or reduce as much as possible comparability problems related to the different methods of observation and the different procedures for the correction and analysis of data. It leads to good results if the social and cultural distance (and therefore the distance between the concepts and the structures) between countries is small and if it is possible to provide sufficiently clear and detailed definitions of the variables used. If this is not possible, the use of identical vocabulary (by way of an accurate translation) is often inadequate because of the diversity of institutional bases,[7] and the strategy leads to unsatisfactory results. Moreover, the operation can prove to be harmful insofar as it dissimulates the lack of comparability of the information that lies behind the apparent unity of the definitions, instruments, and methods.

Among the disadvantages of this approach is its considerable rigidity, which frequently imposes a choice between quality information for each country and information that is internationally comparable between the countries. Moreover, this is an expensive approach, as it generally results in the launching of new surveys, which can waste resources and frequently contradicts existing sources without necessarily improving the quality of the estimates.

But the method also has significant advantages, for when the quality is maintained, it guarantees comparability at the micro level and consequently makes it possible to create integrated information systems on individual data.

[7] This is the case, for example, of questions on income when taxation systems are different, or questions on the level of training and education when education systems are different.

The European Community Household Panel (ECHP) is an example of this type of approach: a socioeconomic longitudinal survey,[8] designed and coordinated by Eurostat and carried out between 1994 and 2001 in the majority of European countries (Eurostat, 1996a, 1996b). The experiment carried out on this occasion put into practice the strictest hypotheses of input harmonization, involving most of the factors according to a radical approach that was popular in the first years of the operation. Indeed, the strategy envisaged that countries adopt the same questionnaire or the same modules (translated into different languages), the same survey procedures, the same rules for monitoring households and individuals (then revised in some countries due to budgetary constraints), the same sample design, the same procedures for correction and imputation (further centralized by the services of Eurostat). Only certain aspects of the sampling could differ from one country to another (selection from registers or master samples compiled during censuses; the number of levels of sampling and stratification of the sample) (Peracchi, 2002). The experiment proved to be a positive one in many respects, but it also shed light on problems, which led to substantial modification of the strategy used thereafter in similar operations. First, the extreme complexity of the system implemented was quickly confronted by the impossibility, for the services of Eurostat, of ensuring effective and timely management and, consequently, in significant delays in the availability of the data. Second, aggregated indicators with a wide policy range were produced in significant contradiction to those taken from sources already available at national or European levels, which were frequently of far higher quality. More generally, the experiment revealed the excessive cost (and not only in financial terms) compared to the results that were frequently of inferior quality compared to those produced at the national level for the same variables and which, when they were the object of specific studies, revealed variations that were difficult to interpret without reference to persistent comparability problems (Robine *et al.*, 1998). An alternative policy for disseminating the information (obviously ensuring respect of statistical confidentiality) would have enabled useful investigation of these points, but the contractual rules and the high cost imposed by Eurostat on the researchers working on the ECHP data prevented the best use being made of the information collected, including of the comparative research.

[8] The survey covers a wide range of demographic variables and characteristics, employment behavior, income, health, level of education, housing conditions, migration, etc.

b. Output Harmonization

In the output strategy, only the final product (its definition and its characteristics) is precisely specified, but each country is free to choose the source(s) and methods of collection, correction, and analysis of the data they consider most appropriate.

There are in fact two strategies by which comparability can be constructed: *a priori*, when the output harmonization is designed at the same time the process data itself is produced; or at the end of the process, directly on the result. In the first case, called *ex-ante output harmonization*, the adaptation of the national concept to the international concept generally goes through definitions that make it possible to reconstruct the different aggregates in order to fulfill both national and international requirements. There are no constraints on the tools for collecting information and the countries are free to choose the source that provides the best quality information (statistical source, administrative source, combination of several sources). We thus reduce the risk of loss of relevance in the information at national level and we avoid breaking up temporal series, even if the disadvantage still persists of losing overall consistency of the information due to the possible dissemination of different estimates (corresponding to different definitions) of the same phenomenon. When it can be adopted, this strategy ensures the best comparability between the other requirements of quality, up to the micro level of data. The *European Household Budget Survey* (HBS) provides an example of this type of strategy: Eurostat puts forth strict and detailed recommendations on all aspects of the definition of analytical units, as well as the variables and classifications to be used (Eurostat, 2003a), and centralizes the individual data in order to create comparable aggregates and indicators.

Among the new operations, the harmonized EU-SILC adheres to this same strategy: strict and detailed rules are imposed on all the countries for the adoption of common definitions and classifications, while leaving them the possibility of choosing the best source (administrative source, statistical survey, combinations) from which to collect the required information. Moreover, the availability of microdata at the European level provides the possibility of carrying out *ex-post* harmonization on all that cannot be resolved during the collection phase (for example, the variables relative to gross and net income in countries with different taxation systems).

In the second case, *ex-post output harmonization*, intervention only affects the final result (micro or macro) of the production process. The quality of the result obtained depends largely on the degree of specificity of the national database and on its capacity to allow reconstruction of the information in the international definition. In the case of survey data, this strategy generally represents a transitory stage before an *ex-ante* intervention is possible. On the contrary, it is the most frequent method among those who do not have control over the production of information, and it is in general the only possibility for statistical data taken from administrative sources.

Classic examples of this strategy are provided by numerous compilations of demographic and social indicators published and disseminated by various international organizations. For example, the WHO's *Health for All* information systems or the Organization for the Economic Co-operation and Development's (OECD's) information system are valuable references for macrocomparative analysis, due to the range of the areas covered and the timeliness of their updates.

Output harmonization, whether it be *ex-ante* or *ex-post*, is far less costly than the input harmonization. The results, particularly those of the *ex-ante* variant are as good in terms of comparability as those obtained through input harmonization (for example, comparability is also possible at the micro level), while at the same time a good level of general quality of information is guaranteed.

c. Mixed Strategies and Targeted Strategies

Between the two extremes of input and output harmonization, numerous mixed solutions have been, and continue to be, tested, either on a purely transitory basis in a process that aims for complete harmonization of the input or possibly on a definitive basis.

An example of a mixed strategy is provided by the targeted harmonization of the new European survey on the workforce (*European Union Labour Force Survey*; *EU-LFS*), intended to provide information for Community policies on work and employment. Given the sensitivity of the theme, both at the national and community levels, a progressive advance towards better comparability has been planned, respecting as much as possible demands for the internal consistency of national information systems and the temporal continuity of the estimates (Mejer, 2003). To this end, strict rules have been established on the collection methods and characteristics of the survey, and a set of core variables of great importance at the community level have been defined, which must comply with the greatest comparability even for the short-term. The main objective of this survey is to subdivide the active-age population into three mutually exclusive groups (the employed, the unemployed, and the inactive) and to estimate the size and the main characteristics of these three groups. For these variables, the collection is totally standardized, to the extent that community law decides which questions to be asked and the order of the questions within the questionnaire. For the other variables, the definitions and characteristics of the quality required are fixed, but the countries are given the possibility of choosing the most appropriate source and method of collection. Little by little, taking advantage of the periodic reorganization of their surveys, the countries must ensure a progressive convergence towards the standards associated with every variable in terms of definitions and collection methods (Eurostat, 2003b).[9] For example, in 2002 a Commission regulation[10] considerably modified the concepts and measurements in the modules on school attendance and the level of educational attainment. In 2003, the survey in the different countries integrated the new modules, thus progressing further towards comparability. In the same year, the final phase in the progress—from an annual survey (quarterly in some countries) towards a continuous survey that provides quarterly estimates—was launched.

The level of comparability already reached by the harmonized survey EU-LFS is high and should continue to progress in the future. The most important aspect is the fact that, for the first time in the history of European statistics, the complexity of the comparability objective has been recognized, as well as the impossibility of attaining it through immediate and simplistic solutions, and the absolute necessity of simultaneously taking into account national and international requirements to ensure the statistical quality of the results. Harmonization through sharing and consensus is undoubtedly one of the main results of the experiment developed in Europe for creating an integrated and comparable information base on employment.

3. A Particular Problem: Statistics of Administrative Origin

In recent years, increasing economic constraints have moved the focus away from statistical sources towards administrative sources, in order to limit as much as possible the direct collection of data in fields in which sources of this type do not exist. Administrative sources have numerous advantages: apart from

[9] Council Regulation (EC) no.577/98; Regulation (EC) no.1991/2002; Regulation (EC) no.2257/2003; Commission Regulation (EC) no.1575/2000; Commission Regulation (EC) no.1897/2000; Commission Regulation (EC) no.1897/2000; Commission Regulation (EC) no.2104/2002.

[10] Commission Regulation (EC) no.2104/2002.

their low cost (at least when it is limited to the marginal cost of production), they generally provide universal data, which ensures detailed representation at various territorial levels, as well as population groups—even small ones; they do not require the good will of respondents, individuals, or families; they are continuously available and can, at least in theory, provide rapid results; when they are well used (for example if an individual identifier is available) they can make a longitudinal reconstitution of information possible.

However, there are also considerable disadvantages. The concepts used in the collection of the information respect administrative requirements and do not necessarily correspond to those that would be preferable for statistical aims or for definitions relevant to the international level. This poses problems at the national level, insofar as the relevance of statistical data is frequently limited, and more so when the aim is international comparability. Furthermore, data quality is largely dependent on the effectiveness of public administration and in the benefit of the data for the administration, the vigilance of the compilers being directly associated to the relevance of the data for their own activities. Moreover, even the goodwill of the individuals and families can affect the reliability of the information which they provide. This reflects the image which they wish to give to the public administration, which is sometimes far from reality (for example, statistics on income based on declarations made to tax services). Another disadvantage is the rigidity of administrative sources with regard to modifications and innovations, particularly in cases where the statistical authority does not have control over the forms used in administrative procedures.

a. Statistics on Causes of Death

Statistics on causes of death are often the only information available for comparing the health conditions of countries. They are exhaustive as they cover all the events recorded in a year, and their comparability is not affected by the problems related to sampling procedures. Moreover, as they are among the oldest statistics collected regularly by the countries, the collection procedures have become relatively homogenous over time: there is a standard model recommended by WHO, adopted nearly systematically by the different countries, there is a widely adopted nomenclature, the *International Classification of Diseases* (ICD) (WHO, 1995) which is in its tenth revision. Despite this favorable situation, problems persist with regard to the quality and comparability of data (EC and INSERM, 2001; Duchêne and Wunsch, 1995; Meslé, 1995; see also Chapter 42 of Volume III) and in many countries it would be necessary to update and modernize the collection procedures and tools.

Taking into account the considerable homogeneity of the concepts and definitions in this field, the comparability problems are mainly due to the differential quality of the data collected and analyzed in the countries. Two phases can prove to be critical: certification, i.e. the declaration made by the doctor of the series of causes that resulted in the death, and codification, i.e. the determination of the underlying cause and its translation into an ICD code (currently ICD-9 or ICD-10).

In 2001, the European project *Comparability and Quality Improvement of European Causes of Death Statistics* (CépicDc and Inserm, 2001) was concluded. It launched a detailed survey on certification practices and the quality and comparability of statistics on causes of death in Europe. The survey revealed the main problems for comparability (ISTAT, 2004; Pace *et al.*, 2004a). The first problem is due to the use of different death certificates: there are countries which still do not use the four lines advised by international recommendations (one for the initial cause, two for any intermediate causes, and one for the immediate cause). The second problem is the diversity of strategies for collecting information on infant mortality: many countries have adopted a special certificate (as recommended by WHO), while others, frequently those who have registers of births and deaths or hospital data that they can pair through the intermediary of an identifier, do not use different certificates for infant deaths but provide the information necessary to differentiate them in the registers. Furthermore, the definition of the infancy period is not the same everywhere: in some countries it is considered as the perinatal period (with some variants: between 154 and 196 days of gestation, up to 6 or 7 days after the birth), in others it is the neonatal period (27 to 28 days), and in others it is the first year of life (364–365 days). Moreover, the distinction between stillbirth and abortion has various definitions: in some countries stillbirths are determined by the gestation period, which can vary from 0 (Turkey) to 154 days (22 weeks) or 196 days (28 weeks); in others by the weight of the fetus, which can vary from 500 to 1000 grams.

The survey also revealed differences in procedure which can affect comparability: for example, differences in methods of diagnosis and an unequal proportion of autopsied deaths in different countries (in some countries, the autopsy of all violent deaths is obligatory, but not in others), from 7 to 38% (WHO, 1998; Pace *et al.*, 2004a and b), with the possibility of diverse consequences on death certificates. In cases of violent or suspicious deaths for which a specific procedure is adopted that includes the involvement of specialists (for example, the coroner in the United States and in Great Britain), the process is longer and more complex and can result in a deterioration in data quality that, as it cannot take into account the successive investigation of the information, results in a high number of deaths being attributed to an unknown cause, particularly for external causes and for young people.

Coverage problems can also occur. As a general rule, the resident population is the reference population for statistics on causes of death. But this is not always the case and most of the time it concerns the deaths of residents who die in their country of residence. The deaths of residents who die abroad does not generally include reference to the cause, thereby contributing to the number of deaths attributed to an unknown cause. Furthermore, it is not always clear if deaths of nonresident foreigners are counted. To overcome this type of problem, the creation of a centralized clearing house which would redistribute information on causes of death of residents dying abroad between the countries of residence is envisaged.

The coding phase can also have an effect on the quality of information and its comparability. The first problem appears when a new version of the ICD is published, which normally causes interruption in series (at least at the level of the detailed sections which have three or four numbers: Vallin and Nizard, 1978; Nizard and Vallin, 1980; Vallin and Meslé, 1988, 1998) and problems in comparability between the countries that use different versions of the nomenclature: these problems should become one of the main aspects that the WHO should take into account in its development of a new revision. The interruption of series considerably reduces the value of information on causes of death and this element should be explicitly included in the evaluation of costs and benefits when the best compromise between innovation and continuity of information is being sought.

An important contribution to the quality of data and to their harmonization can result from the introduction of new technology: automatic coding, particularly if it is designed in a coordinated manner during the initial introduction or in the continuous updating process of optical recognition and coding forms, limits errors and improves comparability. There is much to be done in the years to come in order to accelerate the conversion to automatic coding in the countries which have not yet adopted it and in order to facilitate the convergence towards homogeneous tools.

The European project devoted to comparability and the quality of statistics on causes of death formulated 39 recommendations which should serve as model principle for the countries which, in the next few years, are planning to modernize the collection of information through the introduction of new tools and procedures. The recommendations come in eight chapters devoted respectively to:

1. coverage
2. confidentiality
3. organization of services in charge of causes of death
4. certification of infant mortality
5. certification of mortality at other ages
6. complementary surveys
7. training
8. collecting information on mortality in Europe

Many recommendations relate to certification, and particularly to the training of certifiers, in faculties of medicine or in the context of the continuous training of medical personnel (Recommendations 30–36). Sessions in basic training (e-learning tools) adaptable to national specificities (Recommendation 33) have been developed and are currently being adapted (Pace *et al.*, 2004b) to facilitate training and to provide the certifiers with a common knowledge base. Furthermore, the importance is recognized, as much in terms of quality as comparability, of applying new technology to certification: the development of an electronic and harmonized death certificate is encouraged (Recommendation 22), as well as the creation of a common site for the networks of Eurostat and WHO on the certification of causes of death, destined for certifiers from every country (Recommendation 36).

The strategy of the European Union with regard to causes of death is therefore a long-term strategy and it takes into consideration the complexity of a task which largely eludes those in charge and the rules of statistics and often falls to personnel who are not frequently aware of the relevance of the task of certification. The full harmonization of input, through the progressive convergence of all the countries towards common procedures and tools will therefore take time. Even though the process could be accelerated through imposing a European Regulation on all countries, raising the level of awareness and training certifying doctors which is essential to solving some problems of data quality requires time. In the meantime, output harmonizing, on a minimum of information (abridged European list of 65 causes of death, age, concept of resident population), as well as the progressive introduction of various innovations in certification practices and tools as well as in the coding of information, should result in an improvement in the situation.

b. Administrative Registers and Statistical Sources: Problematic Harmonization

The creation of administrative registers is generally a long, complex, and costly process, but once the system is functioning correctly the production of statistics is relatively simple and economical. The countries of northern Europe in particular are showing increasing resistance to carrying out surveys on issues whose responses are already included in their administrative registers. These countries have long since harmonized their systems for recording the main demographic and social events, on the basis of a central population register and a single personal identification number (PIN) used in all contact with the administration. This number makes it possible to couple all kinds of information recorded on different public administration databases (civil registration, education, tax, health, social security, etc.).

Resistance to carrying out statistical surveys in countries with effective systems of administrative registers is often reinforced by laws prohibiting statistical authorities from asking questions which might not be strictly essential, in order to spare citizens innumerable demands from the public administration.

The position of these countries was clearly asserted within the group responsible for the *Generations and Gender Survey* (*GGS*) and a subgroup, Administrative Records Group (ARG), was created to study how some countries could extract some of the responses to the survey's questionnaire from existing information bases (Statistisk sentralbyrå, 2004). Indeed, it seems that in the northern European countries, a substantial part of the information (30% to 50% of the questions) can be obtained from existing registers, but using them requires a preliminary detailed analysis of the quality, validity, and coverage of the registers, as well as effective correspondence between the events included in the registers and the definitions used by GGS. A detailed analysis of the cost of extracting these data is also needed as, frequently, the marginal cost of administrative information is only low in theory and extraction can require complex and costly data processing procedures, as well as long administrative procedures to obtain the necessary authorizations.

4. Harmonization and Quality of the Information

The classification of statistical sources and the strategies for harmonization illustrated to date have above all a theoretical value. It is very rare for the distinctions to be so great in practice. The realities are multiple and complex between a step towards *ex-ante* harmonization of tools and methods (input harmonization) and the *ex-post* harmonization of output. They can go through all the intermediate combinations in the search for the difficult balance between cost, quality, and comparability.

Harmonization always has a cost, not only in economic terms but also in terms of the informative capacity and quality of the data. The adoption of concepts which decrease the relevance of national information, or which create inconsistencies in the data bases, can have negative effects on data quality while creating a dangerous illusion of comparability which can lead the most careful researcher to errors. Therefore, the problem lies in the level of comparability which should be aimed at in order to reconcile (at a given time, and for the targeted objective) comparative necessity, relevance of the information, and quality.

To progress towards more comparability, it is necessary to improve scientific knowledge of the obstacles to comparability between countries: nothing is obvious and everything should be verified and evaluated. Indeed, it is not always the case that the greatest comparability results from the adoption of strictly identical definitions and standardized procedures. As long as the institutional and normative characteristics of countries differ, without mentioning their social and cultural structures, the best comparability for all the phenomena influenced by these characteristics and structures will be obtained by the most flexible strategies for collecting and analyzing data. Such a strategy requires efforts in the area of theory and definitions which will make it possible to clarify the characteristics of the required result. Once the objective has been defined, strategies for improving comparability will generally coincide with those of improving the quality of statistical information. There is no shortcut to this aim, as numerous attempts at creating comparability through standardized procedures and tools have demonstrated. Total harmonization is only possible between countries whose economic, social, normative, cultural, and institutional contexts are similar.

More generally, the strategy that the United States has adhered to for a long time is the one which can lead to the most satisfactory results: a considerable effort at harmonizing the definitions and classifications is required, as well as improvements in and specification of the performance of the procedures in order to improve results and to reduce the risk of researchers mistaking the real possibilities of making good comparisons between countries.

III. METHODS OF COMPARISON

Quantitative demographic analysis, as we know it today, developed according to two streams, and at two distinct periods.

The first, and the oldest, is based on recording the volume and the characteristics of populations, as well as their transformations, by measuring the contribution of various phenomena (mortality, fertility, mobility) to these situations and their trends. It is based on aggregated data, taking the form of statistical tables. The indicators designed from these data reflect the frequency of the events or the prevalence of the situations and makes it possible to monitor their evolution and to model their dynamics. This way of thinking based on macrosocial aggregates was more or less exclusive from any other during the first half of the 20th century in demography but also in economics and sociology at the time of Alfred Lotka, John Maynard Keynes, and Emile Durkheim.

From the 1950's, focus shifted to a better understanding of the individual behavior at the source of the social situations and trends. The development of household surveys was an essential expression of this. This has resulted in a modification of the type of statistical analysis applied to the data collected. Focus was on the diversity of human behavior with regard to health, family, and a search for the reflection of the determinants affecting demographic phenomena. The base was thereafter constituted of individual data files rather than statistical tables: with the stress being placed on variability rather than on central values, on the individual rather than on social facts.

The difference between the two approaches is not in the nature of the information used. Statistical tables from censuses or civil registration data were based, at least from the middle of the 19th century, on collecting information on individuals, which does not fundamentally differ from sample survey procedures. But focusing on society in one case, and on the individual in the other, gives a very different position to the nation in global analysis. International comparisons are therefore approached very differently according to whether they use indicators based on aggregated data or the direct analysis of individual data. Therefore, at the time of analysis, there is a dichotomy already introduced when the various stages and strategies of the harmonization process are described.

1. The Comparative Analysis of Indicators

Demographic analysis aims at measuring behavior which contributes to the renewal of populations and understanding its influence on population growth and structure. It achieves this first by defining increasingly small *risk groups*, in order to find pure indicators, and by neutralizing the size of these groups by calculating rates or proportions. It then proceeds to synthesize elementary indicators by using models which combine, within various hypotheses, a series of rates or proportions (tables, comparative rates, etc.).

Because they eliminate size from the risk groups, these operations create the minimal conditions necessary for international comparison. If the absolute numbers of death are not comparable from one country to another due to different population sizes, the crude mortality rates are more comparable as they apply to the same number (generally 1,000 people). In the next phase, rates by age, as well as their synthesis in mortality tables are even more comparable as they overcome differences in age structure (see Chapters 5, 11, 14, and 15 of Volume I).

The indicators which lead to demographic analysis thus lend themselves directly to an international comparative analysis. But their use is not without some problems. For example, the complex indicators call upon hypotheses which need to be verified. In the calculation of comparative rates, the choice of standard population can influence the result when a country's age-specific rates are not systematically higher or lower than those of another country: for example, if two populations are distinguished from each other because one has a lower mortality rate before the age of 50 than the other, and that the opposite is true for later ages, the comparative rates will list the two countries in a different order according to whether the model population gives more weight to the young ages or the older ages. Moreover, syntheses which use a fictitious cohort can be affected, unequally according to country, by the effects of cohorts likely to distort the interpretation of the differences, from one country to another: later on we will see an example where the total fertility rate is affected both by the variations of mother's age at birth and the completed fertility of the cohorts, and the classification of countries can thus differ according to whether fertility is summarized by the total fertility rate or completed fertility.

a. Comparative Demographic Analysis is Descriptive

Demographic analysis reveals the effect that a specific group of factors has on demographic behavior and on the size and structure of the population. In addition to sex, they are mainly categories of temporality, whether they are the age of the individuals, their membership of a cohort, or the location of phenomena in history (duration, cohort, period). Although the web of these different scales of time can be extremely complex and its disentangling very informative with regard to the mechanisms of demographic behavior, this exercise and its results are often considered as descriptive, compared to that which the introduction of socioeconomic, cultural, or biological aspects contributes to the interpretation of behavior.

Comparative demographic analysis, by observing the diversity of behavior across international space is a step towards this interpretation. But it still remains descriptive and restricts itself to noting differences between countries before attempting to explain why demographic behavior varies in a given national context through socioeconomic, cultural, or other variables.

At the beginning of the 21st century, the population pyramids of the different countries of the European Union were thus compared (by bringing them to a standard of 100,000 inhabitants), to show their unequal levels of ageing, due to different fertility trends, to unequal progress in combating mortality at old ages, and to the differentiated consequences of international migration. "*The population pyramid of the twenty five Member States of the European Union provides an image of the secular history of these countries. The marks of the First World War are becoming blurred, but the deficit of births due to the 1939–1945 war is still visible in many countries where natality declined during the conflict. For the second half of the XXth century changes in natality have sculpted the pyramids in peaks and troughs, but these variations reflect national economic situations that no longer have the European dimension of the two World Wars. In addition, these variations cancel out and no longer appear on the pyramid for the whole of the European Union which is essentially distinguished by a major and general phenomenon: the fertility decline observed since the 1960's, at variable dates according to the countries*" (Monnier, 2004).

In this example, the comparison is static as it relates to populations characterized at the same time, but demography carries so many references to different dimensions of time that the analysis quickly becomes dynamic. In other cases, comparative analysis is dynamic from the start and covers chronological series rather than period data at a given date or a given period (for example, monitoring the current demographic situation).

The resources of demographic analysis are placed at the service of comparative observation in order to disentangle the role of demographic factors in the differences between countries. The evolution of the total fertility rate is thus distributed between what is due to the variation of completed fertility in different cohorts and what is due to changes in age at maternity to explain the role of one or the other in the differences between countries. "*The progressive reduction in age at maternity observed everywhere, and the provisional and identical reactions of women in all the countries of Europe to historical, economic, and social events leading them to more frequently reject or accept maternity at certain periods, are the source of the similarities in the evolution of annual rates. But this homogeneity of behavior, over the years, has not resulted in a correspondingly homogeneous evolution in the final number of children per woman in all the countries: the trend of completed fertility seems more linked to the starting level, declining in the countries where it was high, and increasing or stabilizing in countries where it was low*" (Blayo and Festy, 1975). The differences in life expectancy at birth from one country to another are also distributed between risks of death at various ages. "[From 1981 to 1996,] *most of the increases in life expectancy came as a result of decreasing mortality at older ages (ages over 60). This pattern was observed for males and for females, in East Germany as well as in West Germany. The pattern was more pronounced for females than for males, and it was more obvious in East than in West Germany*" (Gjonça *et al*., 2000, p. 8).

The compared countries are generally all the more numerous when the indicators are simple and their calculation easy. The differences finally exposed and measured by the demographic analysis are linked to an intuitive explanatory model which, at this stage, will not be subjected to a statistical verification in the real meaning of the term. The differences between eastern and western Europe have been a major subject during the decades following the Second World War, with the demographic patterns revealing the confrontation of the political regimes (Bourgeois-Pichat, 1985; Monnier and Rychtarikova, 1991; Meslé and Vallin, 2002). More recently fashionable, the difference in behavior between the countries of southern and northern Europe can lead to the suggestion, according to the case, of differences between Catholic and Protestant traditions, between systems of family and social interdependence, or between cooking with oil and cooking with butter (Ferrera, 1996). The measurement of differences used, whether relative or absolute, is based on descriptive statistics, not the modelling which would support a model of an *a priori* gap which reality would verify.

b. Comparative Analysis in Search of Universal Laws

A major objective of political arithmeticians, and of Adolphe Quetelet after them, was to search within the diversity of empirical observations for the set of *universal laws*, which were sometimes even conceived as revealing the *divine order* (Süssmilch, 1741). International comparison was one of the preferred methods for this. Many years after them, this state of mind is found in research into statistical regularities which reveals the action of underlying extrademographic variables.

During the 1950s, in order to establish the concept of natural fertility, Louis Henry (1961) grouped the curves of the age-specific legitimate fertility rate (number of legitimate births per married woman) established in very different countries; he showed their similar convex form at variable levels (an initially barely perceptible decline in rate when age increases between 20 and 30 years, then a progressive acceleration up to zero rates from 40 or 50 years); he deduced from this the role of physiological (fecundity, fecundability) and behavioral (breast-feeding) factors independent of the number of children already born, without being able to measure and specify the impact of each of these factors.[11] During the same period, the first *model life tables* were developed by compiling national tables in as diverse a group as possible of countries and periods and by exposing the relations between risk of mortality at successive ages which revealed a general trend of increase in mortality with age (beyond early childhood) and a typical rate of the progress in combating mortality over time. "*We had for a long time noticed that when mortality was high at certain ages, it was also high at other ages. In other words, knowledge of mortality at certain ages certainly does not make it possible to determine mortality at other ages, but it provides an idea of what it could be. To express the same idea differently, experts came to the conclusion that, for the same health situation, the model life tables observed were similar and their average could therefore be considered as a good means of spotting this health situation*" (Bourgeois-Pichat, 1994). That Jean Bourgeois-Pichat partly relied on international comparisons to demonstrate the rule of division of mortality in endogenous and exogenous components during the first year of life shows the importance of comparative reasoning during this period (Bourgeois-Pichat, 1951).

Here we will notice that, in particular in the example of model life tables, the empirical observations made on the various countries enter into a theoretical model of dispersion around central values, an expression of the law sought, which justifies the use of measurements and an analysis of variance, through the set of correlations within the group of points drawn by mortality rates at successive ages in the series of 150 national tables collected by Vasilios Valaoras for the United Nations (United Nations, 1955).[12] The same idea can be found today, although the search for universal laws has lost its appeal and has been replaced by the search for a possible convergence in demographic behavior in a group of temporarily diversified countries. The evolution over fifty years of the linkages between fertility, nuptiality, and fertility outside marriage, subjected to analysis of variance in sixteen countries in Western Europe by Alain Monnier, suggests waves of homogenization and heterogenicities which contradict the hypothesis of a movement towards a common stable and sustainable point. "*The main criticism that can be made of the concept of convergence is that beyond the 'point of convergence' nothing else happens. In reality, new behavior continually modifies the European family landscape and, while it spreads, introduces a differentiation factor. This is what occurred with the spread of modern contraception, induced abortion, births outside of marriage, and definitive voluntary infertility. Tomorrow, other elements of family life, which are still very marginal (for*

[11] "*The arithmetic mean of 13 series*

- 9 relative to European populations, 5 of which before 1800;
- 3 relative to populations in Asia (Formosa, India, Iran);
- 1 relative to a population in Africa (Guinea)

is the following:

[Indicators]	Woman's age					
	20–24 years	25–29 years	30–34 years	35–39 years	40–44 years	45–49 years
Legitimate fertility rate	0.435	0.407	0.371	0.298	0.152	0.022
Rate (base 100, average 20–24 and 25–29 years)	103.5	96.5	88.0	71.0	36.0	5.0

The shape of the curves, which represent the 13 series, obviously differs from this average but only very slightly; the average indicator for the 30- to 34-year and 35- to 39-year age groups is only from 67 to 89, 9 out of the 13 values are between 76 and 81; the average rate for the 40–44 and 45–49 age groups is more dispersed (14.5 to 28.5); but part of this dispersion is doubtless due to the influence, likely in these groups, of errors in age declaration" (Henry, 1961, p. 629–630).

[12] The validity of the statistical model used by Vasilios Valaoras (United Nations, 1955) to construct the United Nations' first model tables was seriously disputed thereafter, particularly by K.R. Gabriel and Ilana Ronen (1958, p. 164–169) then by Sully Ledermann (1969). The following model tables were created according to the same intellectual principle, but the statistical method had been vastly improved (Valaoras, 1973).

example couples who 'live apart together' as it is called by Catherine Villeneuve), will act as a new element of diversification. The history of the family is an endless story" (Monnier, 1998).

By building a single network of model life tables based on information contained in around 150 national tables, Vasilios Valaoras took advantage of the similarities revealed by comparisons between countries and periods to establish a reference, a norm which would make it possible to compensate for any shortcomings in statistical information on other populations. By supposing that the mortality model of these fits the form of reference, we can deduce the probable risks of mortality where it is not possible to calculate the actual risks.

Paradoxically, the reference can also be used for shedding light on the specificity of those countries for which good quality statistical information is available, and thus revealing their originality compared to the rest of the world. This type of comparative analysis is used as much for an improved understanding of the situation in each country as it is for questioning the norm on which the comparison is based.

For example, Ansley Coale and Paul Demeny (1966), took up the work of Vasilios Valaoras a few years later, systematically comparing each national life table to the corresponding model life table of the United Nations with the same life expectancy at birth and observed three typical ways of deviating from the reference. These three ways were dominated by the countries of southern, northern, and eastern Europe, respectively, they diversified the United Nations' single network of model tables by adding three others, denominated from the same three cardinal points, and giving the title of West to models for countries that could not be included in one of the other three groups. The single and universal norm was thus separated into four regional norms, through a new comparative analysis.

Furthermore, Jean Bourgeois-Pichat's adjustment, which places on to a line the points representing the cumulated number of deaths during the first twelve months of the life of infants, quickly revealed itself to be inappropriate for countries in which infant mortality is dominated by deaths due to respiratory causes (the deaths accumulated more quickly than is foreseen by the adjustment, at the beginning of the first year of life), or deaths due to digestive causes (the deaths accumulated more quickly than is foreseen by the adjustment, during the second semester of life). But by reversing the logic which initially dominated Bourgois-Pichat's research, a country's difference from the classic adjustment can be used to suggest a frequency of respiratory mortality (cold countries) or digestive mortality (hot countries) that is above the norm.[13] A country's distance from the reference becomes a means of revealing a country's specificity.

Lastly, the gap between the curve of the age-specific legitimate fertility rates in a country and the natural fertility curve drawn by Louis Henry for the populations where no Malthusian behavior reduces fertility after the birth of a certain number of children, was used by Ansley Coale and James Trussell (1974) in order to evaluate the impact of contraceptive behavior, without however measuring the latter's prevalence.

Thus, within the same intellectual context, comparative analysis is successively used to reveal the *laws of behavior*, which unite a large number of countries, as well as the obstacles to the universal adherence to these laws through a set of national specificities, like the many impediments to convergence towards a single model.

c. Identifying Explanatory Factors

Although the search for universal laws is no longer on its agenda, demographic research continues to wonder about the factors which are at the origin of changes in fertility, mortality and migration. Their association through ecological correlations taking the countries as a connection point is a common method here.

For example, when Jacques Vallin (1968) questions whether the decline in mortality is linked to economic development in Third World countries, he plots a graph for life expectancy at birth with the average income per inhabitant of those countries for which these rates are known. He states "*that the group of points fits entirely into the angle made by the y-axis with the first bisector. In other words, for an annual income per capita of 50 to 150 dollars there is a wide range of possible life expectancies ranging from 27 years (Guinea) to over 63 years (Formosa) and includes no fewer than 23 countries occupying the intermediate positions. On the other hand, when the income per capita increases, the likelihood of high mortality seems less. Beyond 300 dollars per capita per year, life expectancy does not fall below 55 years. Therefore, if there is a link between mortality and standard of living in Third World countries, this link seems to be one-way: a very low standard of living is not an insurmountable obstacle to an increase in lifespan but a relatively high income cannot be imagined without high longevity*" (Vallin, 1968).

[13] For example, "*The exceptions to the Bourgeois-Pichat Law, in many countries or regions in Southern Europe, North Africa, and no doubt the Middle East, come from excess mortality due to dietary risks, which only appears at the age of a few months and which mainly occurs during the hot season and increases the excess mortality that these countries may also have due to other causes*" (Biraben, 1957, p. 641–644).

Émile Durkheim, at the end of the 19th century, acted in the same manner when he established the existence of "*concomitant variations*" between the suicide rate and the proportion of Protestants in the thirteen Prussian provinces. "*The simple parallelism of values through which both phenomena pass, provided that it has been established on a sufficient number of sufficiently varied cases, is the proof that a relation exists between them. The method owes this privilege to the fact that it attains causal relations*" (Durkheim, 1937).

In any example, the interpretative model associates a demographic characteristic of a country (in Vallin's case, the survival conditions measured by life expectancy at birth, in Durkheim's case, the risk of suicide) with an economic or social characteristic of the same country (the level of economic development measured by income per capita in one case, the "*degree of integration into religious society*" measured by the proportion of Protestants in the other case). It is a holistic system of general explanation in which the whole of the interpretative model is situated at the macrosocial level.

The risk would be of transposing the interpretation to the individual level and deducing through the example of the relation established between the countries that individuals suffering from a low standard of living are barely affected in their health conditions (this could be either mediocre or medium) while those with a better income are not exposed to the risks of very bad health. This transposition can lead to an error known as *ecological*, when the measured relationship between macrosocial characteristics are not verified at the individual level. Daniel Courgeau (2004) thus demonstrated that migration from Norwegian regions is higher when the proportion of farmers is high, but that the mobility of farmers is lower than that of the rest of the population. Moreover, in Western Europe, current fertility is lower in countries which still have high proportions of practicing Catholics (Italy, Spain), while fertility remains higher among practicing Catholic couples than among those who are not. Furthermore, Daniel Courgeau emphasizes that the risk is more likely in comparative analyzes at the aggregated level when the initial hypotheses relate to the determinants of individual behavior rather than reasoning about social groups: "*Although the approach is macrogeographic, the characteristics selected in the models are according to our concept of individual migratory behavior . . . Moreover, the interpretation of the effects is often given in personal terms: it will be said that it is the attraction of a higher salary which encourages an individual to migrate, whereas the model only shows a relationship between the number of migrants and the average salary in the destination zone*" (Courgeau, 1994).

With this warning in mind, it is possible to introduce into the analysis of the differences in demographic behavior between countries a plurality of social interpretative factors, which progresses from a simple regression, for which Vallin and Durkheim provide illustrations, to multiple regressions. For example, in a recent article, Lee Budget (2003) links the recognition of homosexual couples by industrialized countries to the expression of social norms concerning marriage, religiosity, and tolerance with regard to male-female relationships on the one hand, and sexuality on the other hand. These norms are measured from the results of opinion polls with individual responses being aggregated to the national level. In order to guarantee the comparability of variables, she uses the single harmonized source of the *World Values Survey*, in which the 24 countries of the OECD (as well as South Africa) participated.

Two of the main problems of comparative analysis based on aggregated data are highlighted here. Data comparability, by using a group of social dimensions as explanatory variables causes problems which, as we mentioned earlier, have been tackled far more recently than the comparability of demographic events themselves. The field of comparison is thus restricted to those countries which have data taken from a single standardized source, resulting from a particularly delicate procedure as they concern questions on opinion and attitude which are always difficult to transpose from one culture to another. The issue of the number of statistical units therefore becomes a crucial one. In the most common case of a detailed analysis referring to such a relatively homogeneous group, at least in procedures for statistical production, there will be twenty or so countries at a given point in time which will oblige the analysis to be sparing in the number of predictive behavior variables studied (*parsimonious specification*).

In all cases, the geographic diversity of demographic facts is explained by other demographic, economic, or social facts, at the same level of aggregation. These were implicit in the previous section, they are explicit in this section. International comparisons play an important role in revealing these relations. Did Émile Durkheim (1937) not say that "*the comparative method is the only one that suits sociology*"?

2. Comparative Analysis of Individual Data

With the development of individual data we move away from explaining behavior indicators with social variables where both are at the same level. For interpreting individual behavior, we initially use the determinants, themselves individual, and the national dimension then has problems in defining its role.

In the lessons drawn from the *Fertility and Family Surveys* (FFS) which will serve as a common theme to illustrate the possibilities provided by individual data, Daniel Courgeau (2002) emphasizes "*The tendency is to consider individual behavior as being influenced only by individual characteristics. The danger here is of committing the atomic error, that is, of ignoring the context in which human behavior occurs. In reality of course, individual behavior is influenced by context, and it seems fallacious to consider individuals in isolation from the constraints imposed by the society and milieu in which they live*".

FFS was built on the biographical model, where complex life histories with marital, family, educational, occupational, and residential dimensions were collected with the aim of associating these through a methodology specific to individual data, such as the *event history technique* (see Chapters 23 and 24, as well as Chapter 134). But at the same time it is a comparative program which aims at placing the results within an international context through the introduction of a macrosocial dimension into the analyzes.

The research carried out based on the *FFS* provides numerous examples of the differences between countries in the use of individual data. These attempts differ significantly in their geographic coverage, their objectives, and their ambitions. This diversity clearly finds its place in the classification of three posts proposed by Anne Gauthier (2002), based on her experience of various comparative research programs:

- a descriptive analysis of the difference of situations in a large number of countries
- parallel analyses in several countries of the relationships between variables at the individual level, in order to test the generality of observations made in a country, referred to by John Hobcraft (1980, 2002) as *replicated models*
- the introduction of national level variables in relationships at the individual level, in order to explain the share of international variations which are not due to individual factors.

a. Descriptive Comparative Analysis

Descriptive studies generally cover a large number of countries spread all over Europe, so that the diversity of situations is automatically represented or constructed by a rational choice. Remaining at a descriptive level, these studies highlight the similarities which unite or separate the countries, most frequently on the basis of geographical vicinity (for example, Scandinavian and Mediterranean countries, eastern and western countries); in some cases an interpretation is put forward, based on common sense qualitative assertions, beyond geography but without a thorough demonstration (Scandinavian and Mediterranean countries become known as welfare and "familialistic" states; eastern and western countries become known for socialism and market economy).

For example, in order to observe all the countries of the European Union, Kathleen Kiernan (2002) uses the *Eurobarometer* of 1996 for simple indicators, before using the data of *FFS* for a more thorough analysis in thirteen countries (plus Great Britain, thanks to the *British Household Panel Survey*). Groups are formed *a priori*: "*the countries have been subdivided into four sets: the northern set includes Norway, Finland and Sweden; the western European set includes Austria, Switzerland, France, Great Britain and Germany (we further subdivide Germany into East and West given its different history for much of the postwar period); the southern European set includes Italy and Spain; and the eastern European set includes Poland, Hungary, Latvia and Lithuania*" (Kiernan, 2002, p. 59).

In most of the countries, some results are disaggregated into subgroups, according to three important individual characteristics: level of education, religious affiliation, and experience of their parents' separation.

Union formation is analyzed according to a sophisticated but traditional model: the proportion of individuals who have formed couples, type of union, age at first union and its duration, conversion of consensual unions into marriage, proportion of couples without coresidence. Then it is operated for the dissolution of unions, by duration since the formation of the couple, according to the type of union (with or without premarital cohabitation, with or without marriage).

Differences and similarities between countries are highlighted. The homogeneity and heterogeneity of geographic groups are stressed, but in no way does the text go beyond "*an overview and description of changes in union behavior*" (Kierman, 2002, p. 57).

The political aspects of the trends are the subject of a paragraph on the development of new legislation in the countries of northwestern Europe, concerning informal unions, including homosexual unions. The adoption of these laws is clearly presented as a political response to changes in families, and not as a possible factor of these transformations.

Here is a conclusion that is typical of this prudence: "*In this study, we have seen that in southern European and in some eastern European countries, marriage is still the pre-eminent marker for entry into first union. However, in most western and northern European countries,* *cohabitation has eclipsed marriage as the marker for first partnership, and in the northern countries and France there is evidence that long-term cohabitation has become more prevalent. But whether most countries are on the same trajectory to an ultimate destination where marriage and cohabitation are largely indistinguishable, or even where cohabitation overtakes marriage as the dominant form of union, awaits the future*" (Kierman, 2002, p. 75).

This type of analysis hardly differs from that which was traditionally carried out on civil registration data and censuses, based on aggregated data. It is revealing that several other studies have been based, not on survey data, but on the compilation of tables published in series of standardized national reports.[14] The specificity of *FFS* in this type of study is not so much the possibility of using data at the individual level, but rather that of providing information that other sources cannot. In Kathleen Kiernan's study, for example, marital status including informal unions and their dates of formation and dissolution can only be discovered by a survey, but its use is no different to that which is made of marital status limited to its legal categories in nuptiality analyses.

b. Replicated Models of Individual Data Analysis

It is a different matter in the second type of comparative study, where the individual characteristics of the respondents are preserved during analysis of the data. The diversity of behavior (for example in *FFS*, leaving the parental home, couple formation or fertility, etc.) is explained by the personal characteristics of the respondents through a regression-type modelization, in order to reveal the weight of these determinants on the heterogeneity of behavior. Replicated for several countries, the same operation makes it possible to show the international similarities or diversities of the explanatory capacities of different individual factors. Diversity includes national specificities which need to be explained by factors at national level.

A large number of comparative studies are based on this type of methodology. We will illustrate this with a study by Martine Corijn and Erik Klijzing (2001), who compiled ten national case studies built on the same methodology and placed the results into the context of international comparison. The study concludes with the observation of an international diversity in the action of certain individual factors and the necessity of developing an analytical framework which would make it possible to introduce the national dimension into the comparison of individual data.

Martine Corijn and Erik Klijzing studied the various stages of the transition to adulthood, particularly from school to the labour market, from the family home to the first union, and from this to fertility. They linked these stages to one another and to the characteristics of the individuals according to a well organized set of hypotheses on (1) the destandardization of pathways (which brings an end to the normative sequence of different events), (2) the role of school attendance, (3) the influence of level of education, (4) the effect of employment and unemployment, (5) the influence of religion. Each of these five points is detailed by age and sex, and each time a hypothesis deals with national specificities.

Ten countries took part, seven of which did so with FFS data. "*The countries that were selected in the end cover rather well the different parts of Europe and give a diversified, although necessarily incomplete, picture of the different pathways to adulthood in Europe. The data cover parts of northern Europe (Norway), Southern Europe (Spain, Italy), Eastern Europe (Poland), Central Europe (Austria, Germany), Western Europe (Belgium, The Netherlands, France) and noncontinental Europe (Britain). These countries present a wide array of social, economic and political systems*" (Corijn and Klijzing, 2001, p. 16).

The main conclusions on the role of individual factors go in several directions. In some cases, the influence of the factor on the stages of the transition to adulthood is the same in different countries, in other cases, it varies according to events, in yet other cases, it varies according to country.

As expected, school attendance delays the various stages of the transition to adulthood everywhere. "*An incompatibility between being enrolled in school and starting a union and/or family seems indeed to be the rule: the effect of enrollment is strongly negative in all countries (no appropriate data were available for Austria, France, Poland and Norway). The (longer) enrollment seems to discourage young adults from starting a first union: studying and living with a partner—even without a marriage and parenthood commitment—remains incompatible in terms of time, energy and money*" (Corijn and Klijzing, 2001, p. 330).

At the other extreme, the effect of employment and unemployment varies considerably, in particular among women, whose marriage is brought forward or delayed and whose fertility is favored or discouraged according to country. "*Female unemployment affects the marriage and parenthood transitions in two distinct ways. In West Germany,*[15] *Spain and Norway female unemployment leads to a postponement of marriage. In contrast, in*

[14] See, for example: Schoenmaeckers and Lodewijckx, 1999; Prioux, 2001.

[15] Martine Corijn and Erik Klijzing incorrectly named East Germany instead of West Germany (Hullen, 2001, p. 166).

Flanders and Italy female unemployment speeds up the marriage timing, although this effect changes across age. Female unemployment has no impact on the marriage timing in Poland (Fratczak and Liefbroer, 1996) and in East Germany (Hullen, this volume). In West and East Germany and in Poland female unemployment has no impact on the motherhood timing either. On the other hand, in Flanders, Italy and Spain unemployment has a strong positive impact on the motherhood timing: it doubles the rate" (Corijn and Klijzing, 2001, p. 335).

Halfway, the effect of the level of education is variable and depends on the stage of transition to adulthood. It is systematic on union formation and fertility, which are delayed by the most qualified individuals; it differs according to country with regard to departure from the parental home. "*In general, the educational level does have a negative effect on the union formation, marriage and parenthood timing. The only exception is among East German men. The more these events are disconnected from each other, the stronger the negative effect is for the parenthood timing. The impact of the educational attainment seems to be event-specific. The postulated positive effect of educational attainment on the timing of leaving the parental home was confirmed for the Netherlands, Britain, Austria, Spain, Poland, East Germany (both sexes), and for Norway and France (men only). The higher the educational level of young adults in these countries, the earlier they leave the parental home . . . In contrast, the effect of the educational level on the timing of leaving the parental home was negative at young ages in Flanders, Italy and among French women. The higher the educational level of young adults in these countries, the less inclined they are to leave the parental home before age 25*" (Corijn and Klijzing, 2001, p. 332–333).

One of the fundamental hypotheses was that the destandardization of the stages signified both the decline in the norms concerning the sequence of events from the departure from the parental home, and the increased influence of individual determinants of behavior. In a comparative perspective, it implies a reduction in the differences between countries, i.e. a convergence in trends all over Europe.

Certain facts do not confirm this implied hypothesis. There are considerable differences between countries in the action of various factors on different events, in particular (but not only) female unemployment on nuptiality and fertility. Beyond education, employment, or religion, the country remains an element of differentiation which must be taken into account. The authors and reviewers of the study have rightly emphasized this point. Explaining the differences between countries by introducing national level variables into a model based on individual data remains an unresolved problem.

"*The diversity in the results of some of the individual factors points to the importance of structural factors, including social policy factors. These factors are not investigated directly in this project, but they often surfaced as indirect explanatory factors: the institutionalization of the school-work transition, the unemployment rate, the housing market, the prevailing family model . . . Further specification of the theory must clarify the role of structural and social policy factors. Such a theory will need an appropriate data gathering design and appropriate multilevel analyzes. This could be one of the challenges of a possible second FFS round*" (Corijn and Klijzing, 2001, p. 338–339).[16]

Through this example, it appears that taking into account factors at the national level within an analytical framework focused on individual determinants should be explicit and requires a specific interpretative model. The repeated application of the same analytical model to individual data from different countries paves the way for hypotheses on the specific role of countries in the diversity of individual behavior. But in the absence of an appropriate analytical framework and a methodology which enables the variables at national level to be integrated in models based on individual data, comparative analysis remains rudimentary in the explanation of demographic phenomena.

c. Multilevel Comparative Analysis

Contrary to the first two types of analysis, which have both been illustrated by a study drawn from a large group of research based either on descriptive analysis or on replicated models, multilevel analysis has only a very limited number of examples. The idea of combining micro- and macrodata in the same model is still rare in the social sciences, with the possible exception of the educational sciences, and it is even more rare if it is a question of turning country into one of the macrolevels in order to undertake an international comparative analysis.

Alessandra De Rose and Filomena Racioppi (2001) started from the fact that individual behavior is not only explained by the relationships observed at the individual level, but also by the environment of which the individual is a part. The relationships are therefore defined in a contextual framework. The main question is therefore: how does the causal relationship between the variables studied (individual behavior, choices, attitudes, decisions, etc.) and their determinants vary according to the context? The analytical framework is unavoidably complex, as it must expose the importance of the environment (social, geographic, cultural,

[16] See also the review of the study published by Katrin Golsch (2002).

economic, political, etc.) and its effects on the attitudes, decision processes, and individual behavior.

The authors use a single statistical model which integrates the micro- and macrodeterminants of individual behavior into a multilevel regression. International comparative analysis appears to be a more inclusive method, which could include contextual dimensions other than the nation.

Alessandra De Rose and Filomena Racioppi studied the frequency of very low fertility in 13 European countries, using FFS data. They measured it from the proportion of women who are planning on having no children or one child only. The proportion is below 30% in German cohorts born in 1950–1954 and below 5% in the Norwegian and Swedish cohorts born in 1965–1969. In general the number of infertile or subfertile women declines over time.

The authors selected 13 countries on a technical criterion: they are those who have the greatest number of common comparable variables in the survey files.

National models were initially developed, taking into account selected individual determinants, among those that were revealed as being the most effective in explaining the frequency of voluntary infertility in the past. The general model is indeed replicated 13 times, according to the previously described methodology. The marital status, year of birth, employment status, education, number of brothers and sisters, religiosity, and the size of the place of residence are used as explanatory factors.

The majority of the variables, *when they exert a significant effect*, do so in the expected direction and in the same manner in the various countries of Europe. Low fertility is associated with the fact that women are unmarried, are employed, live in large cities, have no religious feelings, and are themselves only-children. The only unexpected and variable effect is that of educational level, which limits low fertility in the west and supports it in the east of the continent.

From one country to another, the main difference is not in the direction of the effect of the significant variables but in their number. This raises the question of the existence of "*a* [unique] *'European' model enabling us to identify a single typology of women who voluntarily decide to remain childless or stop at the first*" (De Rose and Racioppi, 2001, p. 23). The answer is negative: the application of a single model, which groups all women in all countries, highlights the same effects as previously, but with a mediocre adjustment quality, which implies a very weak explanatory capacity.

"*The bad performance of the 'European model' leads us to suspect that another dimension than the individual one plays an important role, probably the context. We can expect that contextual variables (i.e. characteristics of the environment) may affect individual behavior in terms of reproductive planning. Women with selected characteristics and belonging to one country have different fertility expectations from those with the same characteristics but belonging to another country, just because their respective countries differ as demographic, social, economic or cultural conditions, as well as gender system*" (De Rose and Racioppi, 2001, p. 24).

In order to characterize the countries, Alessandra De Rose and Filomena Racioppi collected a set of 15 demographic and socioeconomic indicators (four of which relate to the status of women) in each of the thirteen countries, and they defined the best combination of these statistics according to a small number of simple and relevant dimensions (through principal component analysis), thus retaining the majority of the information while simplifying it in anticipation of future stages in the research. They showed the differences, on an axis of economic and social development, between countries that are "*traditional*" and those that are "*innovative*" (countries of the east and countries of the north, respectively), and the differences between "*egalitarian*" and "*non-egalitarian*" countries (central and southern Europe, respectively), on an axis where the mechanism of the gender system is expressed. The position of the countries on these two axes represents national level information used in a multilevel analysis.

In the multilevel model, the individuals of each country are characterized by a small number of common variables (date of birth, marital status, and size of place of residence) and the same is true for the countries themselves which are characterized by their level of development and equality between men and women. The role of individual determinants is confirmed and that of the contextual factors is revealed: low fertility is more frequent in countries with a high level of traditionalism with regard to economic and social development, and in countries with a less egalitarian gender system. The first relation is barely significant, but the second one is entirely significant.

It is thanks to an astute innovation that the authors thus obtained a metrics of the national level effects on low fertility: the characterization of countries by their position on a continuous and supposed unidimensional stepladder, instead of a nonhierarchical typology like those of the regimes of welfare states, which group countries in small dispersed clusters.

On the other side of the coin, what is missing from this study is the analytical framework which would have postulated linkages between the individual and national levels and which would have guided their choice of factors and indicators at both levels: "*As to the definition of the context and its links with the* *individual dimension, there is still the problem of formulating a theoretical framework to provide a preliminary basis and to identify suitable indicators, and to clarify the various context roles*" (De Rose and Racioppi, 2001, p. 29). In the future, it would be good that the development of such a framework and its testing by the most appropriate quantitative methods associates sociologists and statisticians in an ambitious common adventure.

The scarcity of other examples in the field of demography where individual data are placed in an international comparative perspective in a tool which integrates the individual and national analytical levels underlines the exploratory and innovative nature of the work of Alessandra De Rose and Filomena Racioppi.[17] Despite the creation of very large comparative data bases that group individual data from coordinated international surveys (not only *FFS* but also the *European Community Household Panel*, the *Luxembourg Income Study*, etc.), the knowledge that enables these materials to be used is still being developed. The introduction of multilevel models in the field of comparative research is one of the most promising methods for the immediate future (Courgeau, 2004).

CONCLUSION

International comparisons have for a long time been the preferred method for making sense of statistical observations of human behavior, whether the observation is made from the point of view of the country or that of the individual. Let us take two emblematic examples.

Using censuses carried out all over Europe during the 1930s, John Hajnal notes that the proportion of people who marry during their lives and the age at which they do so are significantly different in the countries to the east and to the west of the Saint Petersburg to Trieste line: with marriage being more frequent and earlier in the east, less common and later in the west. He associates a second statement with it, that of a difference in household composition: in the east households are more complex, often combining several families, in particular families of successive generations (families of elderly parents and families of adult children); in the West, they are simpler and generally one-family. He concludes that in the east the family system envisages, facilitates, and organizes the coexistence of generations on the same piece of land for common cultivation which makes it possible to keep at least one son with his father and to encourage his marriage. In the same time in the West, the son only succeeds his father when the latter has left him his place; he only envisages marriage later, sometimes too late for a union to be concluded. Comparative analysis thus links nuptiality to the family system and to the system of agricultural cultivation, both of which differ in the east and the west of the continent: "*In [Western] Europe it has been necessary for a man to defer marriage until he could establish an independent livelihood adequate to support a family; in other societies [i.e. Eastern Europe] the young couple could be incorporated in a larger economic unit, such as a joint family*" (Hajnal, 1965).

Based on the first fertility surveys carried out in Europe during the second half of the 1960's, the team of demographers at the United Nations in Geneva showed that the completed fertility of couples is as low as their education level is high in eastern and southern European countries (Poland and Yugoslavia, for example), while the relation is more or less nonexistent and even the reverse in northern and western European countries (Denmark and France). The difference persists even after the inclusion of other individual variables likely to explain the diversity in the behavior of couples. The authors concluded that the level of economic development of countries is associated with the form of the individual relationship between educational level and fertility: "*If the countries were to be arranged by level of GNP per capita, the strength of the association between education and ultimate family size would show an inverse relation*" (United Nations, 1976).

There we have the two main types of comparative analysis, that which is based on indicators linked through the intermediary of the statistical unit of *country* for the first, while the second type associates individual behavior with their individual determinants before placing the relationships within a multinational comparative context.

The two categories of operation can only be carried out if statistical data speaking the same language are available for each country, despite the diversity of systems in which the data were developed. But this language itself can only be created by a series of compromises between national requirements which must satisfy the statistics of one country, and the similarity of concepts, definitions, tools, etc. necessary for international comparison.

The most natural path in this direction seems to be that which makes each stage of the process from the demonstration of the situation and behavior to their statistical interpretation as similar as possible: obviously not only using the same concepts and definitions but also the same questionnaires, sample designs, and collection procedures, etc. But the road is extremely

[17] See also, from *Fertility and Family Surveys* data: Dourlein and Liefbroer, 2004.

long as statistical production is a complex procedure, of which each element is essential in obtaining good quality results. And each stage is an opportunity for reflecting on similarities and differences. How is it possible to translate into two languages questions managing to give an equivalent stimulus for the respondents of two countries? What is the best way to take into account the availability of different sources in order to identify and reach the respondents? etc. Moreover, the result is uncertain, as similar tools are not always enough to guarantee equivalent results: for example, the use of a standard nomenclature of educational levels does not always make it possible to overcome the diversity of national education systems.

Also is it possible to prefer the harmonization of results to the harmonization of procedures by leaving the countries free to choose the best method to integrate the harmonized concepts into their statistical translation?

There is a certain correspondence between the type of harmonization to which the process of data production is submitted and the type of comparative analysis which would then be carried out on it. The census tables published by Eurostat for all the countries of the European Union adapt well to differences in collection methods (wording of questions, questionnaire administration), and even to the heterogeneity of sources (inclusion of results from population registers in some countries). Inversely, the most personal, and even intimate, information often used in the analysis of individual data (opinions and attitudes, religious or sexual orientation, ethnic origin, etc.) can be extremely sensitive to the method through which they are obtained and their comparability can only result from a process which is standardized from beginning to end. But there are intermediate situations and varied combinations between procedures that create comparability and the methods of comparative analysis.

The discussion of methods for international comparative analysis leads to a more general consideration on the evolution of statistical methods of analysis in the social sciences. In the initial phase, the community was in the forefront, research was built on aggregated data at this level and it found its method for explaining social behavior in comparisons of national communities. Today, the individual has come to the forefront and basic statistical data are at this level; analysis must therefore make an extra effort to also introduce a national level in order to supplement the study of individual determinants, as they are not enough to explain the diversity of behavior and situations.

Behind these developments are factors which are due to the transformation of societies, particularly Western societies, but it is not appropriate here to develop considerations on the trend of individualization. But there is also the effect of technical conditions such as the data processing and statistical resources now available to researchers to deal with large files of individual data. However, the vertiginous development of these means and the speed with which these files are created and then analyzed run the risk of making the analyst forget the length and the rigor of the process which leads to the production of data and which determines their quality. By placing problems of international comparability of data at the center of its reflection, comparative analysis has the great merit of refocusing attention on all the linkages of this chain, and on the primacy of the role of concepts, definitions, and tools, etc. in the significance which can be given to the result of analysis, regardless of its level of sophistication.

Methods of Historical Demography

LORENZO DEL PANTA, ROSELLA RETTAROLI, AND PAUL-ANDRÉ ROSENTAL*

I. DEMOGRAPHY AND HISTORICAL DEMOGRAPHY

Before attempting to examine the distinctive methods of historical demography and without imposing overly strict limits, let us try to define the discipline or, at least, its specific features within the field of demographic research. As common sense indicates, historical demography is in charge of studying past populations. However, it is almost equally obvious that the boundary between past and present is purely artificial or, at the very least, conventional. Admittedly, some key events in general history—for example, Italy's political and administrative unification in 1860—naturally influence the organization of statistical offices and the formation of demographic information sources; such events serve to draw the frontier between the domain of demographers scrutinizing the past and that of analysts examining the contemporary age. Likewise, the contrast between the "prestatistical" and "statistical" ages—in fact, between the periods before and after the introduction of national population censuses—arguably triggered the birth of modern historical demography after World War II. But it remains no less true that (1) demography, even of the contemporary variety, may be construed as a discipline that studies the changes in populations over time, as well as the determinants and effects of these changes, and (2) the study must be conducted over the *long duration*, on which it inherently *depends*.

Indeed, the time frame of demographic investigations is necessarily a long one, and the measurement of demographic processes often forces researchers to extend their gaze over several generations. Consequently, the statement that historical demography concerns *the study of past populations*, while acceptable in didactic terms, is not of much help in understanding the discipline's specific traits or the need for customized methods. It is surely more accurate to characterize historical demography by (1) emphasizing its links with (rather than distance from) many other social sciences (from economic and social history to human geography, from sociology to anthropology and population genetics) and (2) recalling the big questions that it tries to answer.

II. DATA ASSESSMENT AND CHECKING: THE CORNERSTONE OF RESEARCH IN HISTORICAL DEMOGRAPHY

This brief chapter is obviously not the place to discuss all the issues relating to the assessment of data quality and completeness. Nor can we provide a comprehensive account of the countless methods that historical demography uses to attempt to correct or integrate the imprecise or fragmentary data on which it must rely. More than in many other sectors of demography, researchers studying past populations need to exploit *basic data* that are often very rough. They cannot lose sight of the fact that their *results*, whatever the methods employed, are ultimately constrained by these limitations imposed at the outset.

In other words, one of the primary characteristics of historical demography is its forced reliance on documentary sources that are nearly always incomplete and imprecise. This has fostered among historical demographers a sensitivity and special attention to issues of *data assessment*; it has often stimulated the development of new error-assessment and error-correction methods, in regard to *coverage* as much as *precision*. Current practices now include the re-use of old statistical counts, which historical demography typically regarded with suspicion. Such approaches require a combination of historical demography and the history of social science, i.e., an understanding of the cognitive and social context in which the old data were produced, in order to exploit them for contemporary purposes.[1]

To focus on what long constituted the discipline's sole pursuit—namely, the production of fresh data—and to better understand the major burden that this research phase constantly imposes, suffice it to recall the two large-scale reconstitutions undertaken in recent decades by the *Cambridge Group for the History of Population and Social Structure* to describe changes in the English population. The first, in chronological order of completion, was obtained by means of a *back-projection*[2] based on a time series built up from a thorough statistical analysis of parish registers (Wrigley and Schofield, 1981). The second is based on the demographic analysis of individual biographies reconstructed thanks to the nominal processing of those sources[3] (Wrigley *et al*., 1997).

The first of the two operations—the trial reconstitution of aggregate data on the long-term change in the English population—uses birth and death series taken from the parish registers of a sample of 404 parishes, representative of England as a whole. Wrigley and Schofield (1981) devote five of their eleven chapters to the presentation of basic parish data, their critical assessment, and the methods used to identify biases and gaps so as to determine correct parish values—and, in the final stage, the estimation of national series. The basic technique adopted for defining potential periods of underrecording of events essentially relies on the analysis of monthly series[4] and was initially used on individual data (Wrigley *et al*., 1997). In this case, therefore, the monthly series analyzed are not the ones obtained directly from parish registers, but the series of events (arranged by month and year) concerning the families reconstituted from the family records. Previous efforts were directed at evaluating the completeness of the basic data. Now, the emphasis was on assessing the relevance of the reconstitution of individual and family life histories—hence the reliability of the conclusions subsequently drawn from this type of reconstitution. For this evaluation, the authors performed a series of *a posteriori* checks and *tests* that may usefully be recalled here, very briefly, as an example. This is also a way of acknowledging that the reconstitution of the characteristics of the English demographic system—based on the analysis of individual data from a sample of 26 parishes—is surely one of the most important historical demography investigations ever completed in recent years (its final results are now available[5]).

As source material, the Anglican parish registers pose special problems. In particular, a significant share of the population belonged to denominations other than the Anglican church, and that share grew over time. However, the reconstitution of individual biographies within the family histories somewhat attenuates this type of coverage error, given that non-Anglican families, as a rule, were not included in the reconstructed families.[6] Other types of checks were performed, particularly for the 19th century, a period for which the results[7] can be matched against infor-

[1] See Bourdelais (1993) on aging, Brian (2001) on birth rates under the Ancien Régime, Brian and Jaisson (2005) on the secondary sex ratio, and Szreter (1996) on the demographic transition.

[2] See section 4 for an overview of these special modeling techniques—developed by Jim Oeppen for the research project in question—as well as for some related methods.

[3] Using the method developed by Louis Henry, discussed in Section 3.

[4] Following a critical assessment of the reliability and completeness of the monthly data, based chiefly (but not only) on the results provided by the application of this technique, about a hundred of the 530 initial parishes for which the series had been recorded were eliminated from the final sample (Wrigley and Schofield, 1981, p. 16). This shows the value of modern techniques of statistical analysis of time series even at a preliminary stage of identification of underrecording phenomena, which a more cursory examination would not have revealed. The methods are also useful for filling gaps in incomplete series with estimates. This is especially true when the gaps—as is the case for the English parish series—concern only some of many series of demographic events recorded in the same sample to supply estimates of the components of population dynamics at the overall level (see, for example, Tonini, 1993a).

[5] Begun some thirty years ago in the wake of Louis Henry's studies, the reconstitution of family and individual histories was long passed over in favor of the parallel enterprise of aggregate reconstitution, completed in the early 1980s (Wrigley *et al*., 1997, p. 3ff.).

[6] The main concern will accordingly be to check whether the reconstituted families (presumably Anglican) can be regarded as representative of the total population (Wrigley *et al*., 1997, p. 89).

[7] This situation—with timing differences—is typically found in many European countries.

mation from independent sources. The most interesting feature is, no doubt, the checking of the *plausibility* and *internal consistency* of the results of family history reconstitution. In this field, many options are available. The most commonly adopted (even by British authors) is the identification and correction of recording errors, initiated by Louis Henry (1980). Significant examples include: (1) the procedure for estimating the underrecording of infant deaths based on the observation of baptismal names,[8] (2) the verification of the completeness of birth recordings based on the observation of birth intervals in the event of early child deaths (Wrigley *et al*., 1997, p. 108),[9] and (3) the measurement of the underrecording of baptisms (and therefore of births) due to the length of birth intervals and the underadministration of the sacraments.

We have dwelled on these examples drawn from the *Cambridge Group* surveys primarily for one purpose: to emphasize that these issues are one of the specific traits of historical demography research, as they feature very prominently at every research stage (however, we make no pretense of conducting a thorough assessment of problems and procedures concerning error evaluation and correction). Another emblematic example of the centrality of these issues is the reconstitution of the French population and the components of its dynamics in the 19th century published more recently by Noël Bonneuil (1997). Data quality and completeness are the dominant issues in Bonneuil's work (incidentally, the data are considerably richer and more varied than those used by Anthony Wrigley and Roger Schofield for their aggregate reconstitution of the English population). Bonneuil did not simply conduct a rigorous preliminary assessment of the quality of the basic data. He also proposed protocols for adjusting the biases observed in the population age structure in the censuses and for correcting the underrecording of statistics on population movement. These proposals come at the end of a research sequence involving the application of an original method of model-based reconstitution. Using data from Biraben's Institut national d'études démographiques (INED) survey, Bonneuil is currently undertaking an overall reconstitution of the population for a period that produced only fragmentary data: the sixteenth and seventeenth centuries. To this end, he is relying on several types of econometric comparison between partial time series (Bonneuil, 1998).

[8] We refer here to the custom of reassigning the name of a child who dies in infancy to the following child.

[9] After the end of breastfeeding, the death of a child actually stimulates the return of the menstrual cycle and makes a long interval far less likely.

Admittedly, it is often the preliminary assessment of data quality that guides the researchers' choice of the most suitable methodological instruments (sometimes even beyond what might have been their natural preference given the issues they wanted to address). We should therefore briefly draw attention to these initial choices before moving on to a more detailed discussion of the usefulness and limitations of some of the most common techniques in historical demography.

III. MICRO AND MACRO IN HISTORICAL DEMOGRAPHY: ANTITHETICAL OR COMPLEMENTARY APPROACHES?

The birth of historical demography as an autonomous discipline, even in methodological terms, coincided with Louis Henry's development of a technique known as *family reconstitution*, which relies on the statistical use of nominal sources—the most important being, of course, parish registers (Dupâquier, 1984; Rosental, 2003). Louis Henry's protocol has been used for many years without significant amendments to its original coding. As demographers know, it enables them to make measurements despite the lack of census data and the imprecision of some information items in registers of baptisms (or births), marriages, and burials (or deaths). The method involves *record linkage*, i.e., the collation of information from different sources on a single individual or family nucleus. This allows an accurate retrieval of some characteristics of an event that do not appear in the record for the event—in the case of a birth, for example, linkage may show the age of the mother at marriage and at the birth of her previous children. By grouping individual data and successive events on a *family reconstitution form*, demographers can reconstruct family histories and so measure the length of exposure to the risk of experiencing vital events. This approach ultimately yields precise, detailed measurements of fertility and mortality.

In recent decades, the *microdemographic* approach, linked to the collection of nominal data, has undergone major change. There has been very rapid progress in data estimation and the automation of archiving procedures. As a result, record linkage can now be applied to much larger databases than before. Above all, it has stimulated efforts to extend the scope of application of nominal surveys even to sources that are not strictly demographic. The accumulation of ever-expanding databases[10] has, in turn, driven historical demogra-

[10] See the thematic dossier entitled "Banques de données" (Databases) in *Annales de démographie historique*, no. 2, 1998.

phers to make efforts to implement an array of often fairly sophisticated statistical techniques.[11] These are capable of managing complex data systems and achieving substantial progress, at least in the description and measurement of demographic phenomena. In fact, this is a process that has affected—albeit in different ways—both historical demographers and demographers studying contemporary populations.[12] The main difference is, perhaps, the following. Among the second group, the collection and analysis of individual biographies—a means of going beyond the mere use of aggregate data—are undoubtedly much more recent phenomena. By contrast, in historical demography (as we shall see below), the evidence does not suggest an outright abandonment of the *microdemographic* approach. Instead, there has clearly been a strong impulse toward the parallel development of new analytical instruments—most notably, based on models—using aggregate data.

This design of new modeling instruments applicable to past populations relied only in part on the set of theories and instruments already available to demographers (in particular, Lotka's theory and its later versions) for analyzing incomplete or defective data. In fact, the new instruments took shape in a period, the early 1970s, when the enthusiasm for the opportunities afforded by nominal surveys may have begun to fade. It was not yet possible to foresee—at least realistically—the new momentum that the growth of information technology would impart to this field of historical demographic research. Without minimizing the major contribution of other researchers to the rise of model-based aggregate reconstitutions of past populations,[13] we can state that the most fertile methodological path was opened by Ronald Lee (1974), with what has become known as *inverse projection*. This procedure allows the reconstruction, from a series of hypotheses, of the main parameters of a population and their changes over time. Apart from the initial and final population size, the only data used are the annual time series of births and deaths. In one of the sections below, we use selected details to illustrate the later developments of this type of methodological approach. For the moment, it is interesting to note that the need for a fuller description of the mechanisms of a demographic system was not totally satisfied by the application of the nominal family reconstitution method. Setting aside the previously discussed issue of whether the results can encompass unreconstituted families as well as reconstituted ones, the method does not allow the construction of a *net maternity function*. There are two reasons for this. First, its analysis of fertility is confined to fertility within marriage; second, the method faces many obstacles in measuring adult mortality.

The techniques of model-based reconstitution range from Ronald Lee's *inverse projection* and its later variants and elaborations to Jim Oeppen's *back projection*, used in Anthony Wrigley and Roger Schofield's first reconstitution of the English population (1981), up to *generalized inverse projection*, in some ways a more flexible tool, developed later by Jim Oeppen (1993a and 1993b) himself (according to the information available, the third method might rely on one of the first two formulations). To ensure that the expected results are sufficiently consistent with the reality under study, all these techniques require the fulfillment of a large set of assumptions concerning the share of information about the demographic system that can be directly deduced from the data. In particular, users need to postulate the form of the age-specific fertility and mortality functions. Such information—often gathered from small samples—can hardly be obtained except by analyzing individual data.

There are several ways of viewing the *complementarity* between the different methods of historical demography—from those using individual data to those allowing aggregate reconstitutions by means of suitable models. Modeling techniques reveal the underlying trends and thus identify the distinctive phases of change in demographic regimes, the turning points, and possible splits along geographic lines; we can then investigate these in greater detail by analyzing individual data. In exchange, the latter may sometimes provide valuable indications about the choice of new *models* best suited to identifying the structural characteristics of the demographic system that might not have been initially spotted through reconstitutions based on aggregate data alone.[14]

Using partly different methods and benchmarks, the large-scale surveys by INED on the French popu-

[11] The difficulties were greater, no doubt, for the older members of the profession and for those who lacked an initial solid training in statistics.

[12] See, for example, on mortality studies, Caselli, 1995, p. 1532.

[13] We are thinking in particular of the reconstitution methods of Jean Bourgeois-Pichat (1951) and Étienne van de Walle (1974).

[14] In this respect, the most convincing example may be drawn from the recent publication of the results of the sample survey conducted in England on individual data (Wrigley *et al*., 1997, p. 515ff.). The results of nominal reconstitutions have actually highlighted major changes, over the long periods examined, both in the fertility tempo (variations in the mean age of childbearing) and in the age distribution of mortality. This has made it possible to revise and adapt the previous assumptions made in the application of *back projection* to the English population.

lation (of which the complete results are now available)[15] and by the *Cambridge Group* on the English population abundantly illustrate the value of a comprehensive, detailed vision of the demographic history of a country (France or England) that can be obtained by combining the results of vast aggregate reconstitutions and those of surveys that cover smaller samples but are based on the analysis of individual biographies.

In the following paragraphs, we shall therefore attempt a brief discussion—with no claim to exhaustiveness—about specific aspects of the techniques for analyzing individual data and aggregate reconstitution models. Our emphasis will be on some of the more interesting recent developments in both approaches. Concerning the analysis of individual data, we shall give a concise description of the introduction into historical demography of *event history analysis* (the analysis of biographies or life courses), which has been applied only recently to individual parish data.

For brevity's sake, however, we shall not address the many techniques of aggregate data analysis routinely employed by historical demographers. As a rule, they are simply adaptations of well-known analytical instruments—commonly used in other branches of demography[16]—to the sources specific to historical demography. They are abundantly discussed elsewhere in this manual.[17]

IV. ISSUES AND NEW DIRECTIONS IN THE ANALYSIS OF INDIVIDUAL DATA

There are several different sources in historical demography that can directly supply individual data. Depending on the context, *record linkage* itself can be applied in different ways, which cannot be fully described here. In our rapid summary, we shall therefore confine ourselves to emphasizing some issues in the application of the particular technique of nominal data analysis known as *nominal reconstitution of families*. As formulated by Louis Henry (Fleury and Henry, 1976; Henry and Blum, 1988),[18] it relies on the extraction of data from marriage, birth, and death registers, in the absence of status data. However, we should note that, in many countries (such as Italy, Sweden, and Belgium), the relative abundance of *status animarum* (literally, "state[s] of souls" or population registers) ought to entail a change in the reconstitution technique—as has actually happened in some cases: individual and family life courses have now been enhanced with status information deduced, at different moments, from nominal lists of inhabitants.

As the method proposed by Louis Henry is now familiar to all historical demographers, we shall not describe the entire procedure for reconstituting families and then obtaining fertility, marriage, and mortality indicators from family and individual histories. Instead, we shall dwell at greater length on some aspects that we find particularly interesting:

- the impossibility of reconstructing in identical detail the different components of the demographic system
- the problem of the representativeness of results and the possible alternatives for attempting to optimize the cost/benefit ratio of the reconstitutions
- the biases that can diminish the credibility of measures obtained from nominal reconstitutions, mainly due to the difficulty of continuously observing individual life courses

1. The Limits of Family Reconstitution

As regards the first point, the aspect worth noting is that the technique turns out to be far better suited to the analysis of fertility (for which it was actually designed) than to the study of mortality and nuptiality. Absent any status data, it is in fact almost impossible to extract reliable information on the never-married rate from family reconstitutions; likewise, it is very difficult to use nominal reconstitution to determine a *net reproduction* function—and thus a rough estimate of the intrinsic growth rate of the population studied. These shortcomings seem hard to overcome within the framework of Louis Henry's method. Often, however, we can add information (even of a sporadic nature) on population size and structure—generally, if the study is at the parish level, a few *status animarum* will suffice. We can then deduce, even with standard

[15] The results of the INED surveys, unlike those of the Cambridge Group on the English population, have never been collected in a single volume. For the nominal survey, see esp. Henry, 1972a and 1972b; Henry and Houdaille, 1973; Houdaille, 1976; Henry 1978. The results of the survey on aggregate data were published in 1975 in a special *Historical demography* issue of the journal *Population*. For a description of the data, see Séguy, 2001.

[16] For a fairly complete overview of these methods, see Del Panta and Rettaroli, 1994.

[17] Particularly in vol. 1 and the methodological chapters of vols. 2, 3, and 4.

[18] The first of these two publications (Fleury and Henry, 1976) is a small manual (1st ed. 1956) that provides a very precise and detailed description of the family-reconstitution protocol. The second (Henry and Blum, 1988) gives the methods for analyzing data from the reconstituted families.

aggregation techniques, a series of indicators that may help to fill out the demographic picture supplied by the nominal reconstitution.

2. Representativeness of Results

Perhaps the most acute problem concerns the representativeness of the results of nominal reconstitutions from parish data. First, it is well known that individual and family mobility—along with a broad set of causes intrinsic to the nature of the data and to the linkage procedures—is often responsible for a low yield on reconstitutions. Second, as a rule, there is no guarantee that the families whose complete life courses can be determined are representative of the socioeconomic conditions and demographic behaviors of the total population to be examined. In addition to this issue of representativeness in the parish or community, there is the problem of whether the communities or parishes analyzed are representative of all the communities or parishes in the region or country.

The large-scale surveys by INED in France and the Cambridge Group in England have been conducted, as we know, on samples of parishes or villages deemed to be potentially representative, to a certain degree, of the total (rural) population of the respective countries in different ways and hence, presumably, in demographic terms as well. Admittedly, we can raise the *yield* of reconstitutions and at least partly neutralize the mobility effect by working on large populations.[19] This approach was made possible by the computer, which has quickened data-archiving procedures and allowed the development of now well-tested *automatic linkage* procedures.[20] In any event, the reconstitution of families in a large demographic set—even if it consists simply of parishes or localities forming a representative sample—does offer a major advantage: the results can later be analyzed in greater detail, even from a *diachronic* standpoint, which is usually impossible when working on a handful of parishes.

Another approach, from a rather different research angle, offers unquestionable benefits at least in conceptual terms: the reconstitution of *genealogical lineages.* These enable demographers to track, from generation to generation, through the successive cohorts, all the demographic events occurring in a group of predefined family stocks.[21]

As a rule, genealogical studies are either descending or ascending. Descending genealogies are regarded as the more productive for historical demography, as their practical consequence is to supply family reconstitutions. Ascending genealogies are mainly used in genetics, for example to identify hereditary characteristics. They are less suitable for estimating demographic indicators because of the difficulty of locating all the individuals in the most distant generations—especially persons without offspring. In any event, methodological instruments have been developed to try to overcome the limitations due to the inadequacy of data sources in both approaches.

The aim is to try to follow each individual from birth to death even beyond the boundaries of his or her parish or community of origin and thus to analyze (1) *geographic mobility* and (2) *social mobility* over time by combining the demographic histories of successive generations. To some extent, the genealogical approach facilitates the identification of differential demographic behaviors (between family stocks, of course, but also between different social groups, as between successive generations). In certain conditions—most notably, when we can assume negligible information loss due to emigration—it also allows us to estimate the size of the observed population at different points in time (Rallu, 1992). This yields indicators that are totally unobtainable with classic nominal reconstitutions, such as empirical birth, marriage, and death rates. The linkage of these information items on genealogical lineages with nondemographic information also offers an interesting variety of applications—particularly, as one can easily imagine, in genetics and biomedical research (Chapter 96). By contrast, the evidence suggests we must be less optimistic about

[19] The leading example of an *exhaustive* nominal survey is undoubtedly the reconstitution of the Francophone population of Quebec by a University of Montreal research group (Charbonneau *et al*., 1987).

[20] Various programs are now available that even provide a complete, automated family reconstitution. The most notable is the one developed by the University of Montreal for reconstituting the Francophone population of Quebec (Charbonneau *et al*., 1987). Note, however, that these programs are generally not easy to adapt to sources whose characteristics differ from those for which they were initially designed. By far the most serious problem to solve is the *standardization* of nominal information (correction of reading and transcription errors, but also, and more important, the variants in name forms).

[21] The sample of 3,000 French families (Dupâquier, 1984, p. 128) is well known in the world of genealogical research. It seeks to reconstruct until the recent period the male genealogical lineages derived from original couples (early nineteenth century), with the aim of describing geographic and social mobility in nineteenth- and twentieth-century France. Many other interesting comments, on the implications of the genealogical approach in historical demography, are to be found in the monograph entitled *Démographie historique et généalogie* published by *Annales de démographie historique* in 1984. Lastly, we should recall the pioneering study by Andrea Schiaffino (1979, reprinted 1993) on fertility in Bologna in the late nineteenth century, based on the longitudinal analysis of the descendants of 532 first marriages registered in the city in 1871.

the real capability of the genealogical approach to solve—in terms of more strictly demographic results—the problems that cannot be solved via nominal reconstitutions covering a small number of parishes or communities. We shall return to these issues later on.

3. Tracking Life Courses

One example will suffice to illustrate the difficulty of fully tracking individual life histories: the obstacles encountered when seeking to measure the risk of dying in adulthood and the different alternatives that have been proposed to achieve this. Usually, the indicator cannot include the never married, except those who died in the parish studied. But, even for the ever married and widow(er)s, it will not do to restrict the risk-of-dying indicator to individuals belonging to the subset of "closed" families.[22] This would drive us toward an *overestimation* of mortality, as emigration introduces a selection in favor of individuals who have died at earlier ages.[23]

Louis Henry drew attention to the problem on several occasions, proposing increasingly refined solutions (Gautier and Henry, 1958; Henry, 1967; Henry, 1976); later, Jacques Dupâquier took up the subject (1978). In substance, we can try to retrieve the individuals—spouses or widow(er)s—whose dates of death are unknown by identifying the likely intervals within which the deaths occurred. However, depending on the type of information used to define the intervals, we may introduce biases, if the probability of observing an individual—and hence the probability of occurrence of a given event that would attest to the individual's presence—is not independent of the age at death (Blum, 1987, p. 40).

Alain Blum (1987) has explored a more "correct" method, at least in conceptual terms. In keeping with Louis Henry's suggestions, it involves the compilation of two different tables showing the upper and lower boundaries of *possible* mortality in the set of individuals studied. The novelty lies in the fact that the upper boundary of the interval in which the death should occur is estimated from information on fertility—more precisely, the mean birth intervals. For an individual who has had n children, the method basically consists in using the analysis of the fertility of the population studied to estimate the likely date at which (s)he would have had an $(n + 1)^{th}$ child.[24]

At the price of various methodological subterfuges, we can thus obtain information on adult mortality from nominal family reconstitutions. Nevertheless, it remains very incomplete. In particular, there will be no observations on older ages. Modeling (Blum and Bringé, 1992) therefore seems the logical path to follow in order to obtain plausible estimates of the total survival function by combining the probabilities of infant death—whose computation involves narrower risk margins—with the probabilities of adult death.

Naturally, when we can supplement the information on life histories gathered from family reconstitutions by information drawn from the nominal use of census sources, we can correspondingly reduce the adult mortality indicator's margins of approximation (Bideau and Brunet, 1993). The effect of exits from observation due to migration can then be estimated with a far smaller margin of error. Section VI of this chapter will deal precisely with how the application of sophisticated statistical techniques creates possibilities for the combined use of nominal status sources and movement sources.

V. DATA SERIES AND MODEL-BASED RECONSTITUTIONS

As noted earlier, there have been major advances, especially since the 1970s, in the methods for reconstituting the history of the main structure and movement indicators for past populations in the absence of full data. The development and application of new reconstitution methods have provided answers to a series of questions on the components of past-population dynamics hitherto visible only in theory. The pioneer in this field is unquestionably Ronald Lee (1974), with his earlier-mentioned formulation of an original reconstitution method subsequently known as *inverse projection* (*IP*).[25] At first, however, *IP* did not have the

[22] "Closed" families are defined as those for which the date of marriage and the dates of death of the spouses are known. To determine the exact ages at death, we also need to know the dates of birth of both spouses.

[23] In fact, it is obvious that the probability of leaving the observation field through migration and thus the frequency with which—for this reason—the family history cannot be "closed" increase as the individuals grow older. In a manner of speaking, the older the age at death, the greater the likelihood that the individual has migrated before dying. The deaths of younger persons are therefore overrepresented.

[24] The method proposed by Alain Blum has been criticized by Steven Ruggles (1992) who, using micro-simulation procedures, has found that it yields reasonably correct estimates of mortality when migration flows are intense, but can lead to significant overestimation of mortality when the migration flows are reduced. The limits of the method, Ruggles contends, stem from the fact that (unlike reality) it does not link the duration of intervals between successive events (used to estimate the upper boundary of the individuals' presence) to the probability of migration (Ruggles, 1992, p. 517).

[25] On the genesis of the method, see Ronald Lee's recent account (2004, esp. p. 1–4).

reception it deserved. Its application potential did not fully materialize until its author developed a second version (Lee, 1985) that made it possible to abandon the overrestrictive hypothesis of a zero net migration over the entire time interval examined. In any event, the debate over the use of models for reconstituting past populations was triggered by the publication of Anthony Wrigley and Roger Schofield's famous book (1981), based on a different method devised by Jim Oeppen: *back projection* (*BP*).[26] In some ways inspired by Ronald Lee's technique, *BP* enabled Wrigley and Schofield to paint a broad picture of demographic change in England spanning more than three centuries. Their work sparked a lively methodological discussion and stimulated other reconstitution projects in different geographic environments.

Space precludes our giving a full account of the lively, fertile debate fueled for many years by the inventors of *IP* and *BP*, and many other specialists in their wake (Lee, 1985; Wachter, 1986; Bonneuil, 1992). But it is this debate that has, among other things, led to the formulation, by Jim Oeppen (1993a) himself, of a new algorithm for reconstituting past populations: *generalized inverse projection* (*GIP*). Its advantage is high flexibility,[27] while enabling demographers to perform a more rigorous analysis using the same information required for *BP*. However, we shall confine ourselves to a few brief remarks on the potential and limitations of *IP*, especially as, in its various versions now available,[28] this reconstitution method has been by far the most commonly used in historical demography in recent years.

In its author's own words (Lee, 1993, p. 8), we can say that *IP* is a very simple demographic method for estimating the *levels* of a population's fertility, mortality, and age structure and their changes over time, from available time series of births and deaths and some data on population size. It is important to specify that the *inversion* is logical and not temporal, in the following sense: it does not project the sequences of births, deaths, and age structures on the basis of distributions of specific fertility and death rates as in normal projections; instead, it uses time series of births and deaths to compute sequences of rates and age structures.

Assuming, for simplicity's sake, zero migration flows, let us therefore try to summarize in a few words the idea underlying Ronald Lee's model. We assume that we know the initial population's size and age structure, and that the age distribution of mortality complies with that of a model (for example, one of Coale and Demeny's families of model life tables[29]). If so, there will be only one distribution of probabilities of dying (derived from the family chosen) that, applied to the population's initial age structure, will give the exact number of deaths recorded that year.[30] If we also know the total births in the first annual interval considered, and if we apply this distribution of probabilities of dying (which complies with the relationship indicated earlier) to the initial age structure, we can deduce the age structure at the start of the following year.

Having chosen a uniparametric family of life tables, we can estimate the probability $q_{x,t}$ of dying between ages x and $x + 1$ in the time interval t, $t + 1$ by means of the following formula:

$$q_{x,t} = {}^{1}q_x + k_t d_x \qquad [1]$$

where $d_x = {}^{2}q_x - {}^{1}q_x$, and ${}^{1}q_x$ and ${}^{2}q_x$ are the probabilities of dying between ages x and $x + 1$ obtained from two tables in that family (called table 1 and table 2, the first reflecting a higher mortality than the second). The two tables should be chosen so as to encompass, as fully as possible, the change in mortality of the population studied during the period examined.

The probabilities ${}^{1}q_x$ and ${}^{2}q_x$ (and hence d_x) depend only on age (meaning that they remain identical for each calendar year), while k_t depends only on time (its value, determined for each year, being identical at all ages).

Equation [1] can be resolved if we know k_t, whose value we can obatain by applying the following equation (demonstration not provided here):

[26] *Inverse projection* could not be applied to the English population for it requires a fairly accurate value for the initial population size—information unavailable for sixteenth-century England.

[27] Theoretically, *GIP* allows the model to incorporate all types of supplementary information. The fundamental difference between *IP* and *GIP* (Barbi and Rosina, 1997) lies in the treatment of migrations. In *IP*, migration rates are estimated from a net migration computed from empirical data (deduced from the comparison between movement data and census data); in *GIP*, by contrast, they are obtained with the reconstitution procedure (consistently with the same logic that informed *BP*). It would be interesting to test the application of *IP* and *GIP* to the same database. However, this is not possible for the moment, as Jim Oeppen's program is very sophisticated and hard to use (except for its author!).

[28] In this area, we can also mention—despite its being based on slightly different logical premises—a program developed by Salvatore Bertino and Eugenio Sonnino (1995): *stochastic inverse projection* (*SIP*). Although it is an original *micro-simulation* model, it basically uses the same *inputs* and produces the same *outputs* as the most common inverse-projection methods.

[29] Coale *et al*., 1983.

[30] The program actually uses two life tables, derived from the same model. They are uni-parametric tables, in the sense that they specify different levels of life expectancy at birth but have the same structure. Between the two tables, the model interpolates (or extrapolates beyond) a third table that belongs to the same family and that, once applied to the age distribution of the population, provides the number of deaths occurring in the year.

$$k_t = \frac{D_t - D_1}{D_2 - D_1}$$

where D_t is the (known) number of deaths recorded in year t, and D_1 and D_2 are respectively the deaths that we would have obtained by applying the probabilities of dying of tables 1 and 2 to the population's age structure in t.

Thus, once we have determined the value of k_t (which we may regard as a *mortality adjustment factor*) for the period $(t, t+1)$, we can use equation [1] to calculate the complete distribution of $q_{x,t}$ values for the same period, since k_t depends not on age but only on time.

Having thus obtained the distribution $(q_{x,t})$ of the probabilities of dying for period $(t, t+1)$, we can use them to project the population's age structure between t and $t + 1$. Simultaneously, we deduce an estimated life expectancy at birth (e_0) for each year.

We can repeat the procedure, in an altogether comparable manner, from year to year,[31] which will enable us to reconstruct not only an estimated life expectancy at birth but also an age distribution for each calendar year. If we further assume a model of age-specific fertility, we will be able to redistribute total births, year by year, as a function of the mother's age and hence determine an overall fertility indicator as well (total fertility rate or crude reproduction rate).

Our highly simplified description of the procedure enables us to emphasize the advantages, but also the limitations, of this reconstitution method. First, we should note that the method, now often tested (Lee, 1985; Breschi, 1990; McCaa and Vaupel, 1992), has displayed outstanding *robustness* with respect to the diversity of the mortality and fertility models used, as well as to the changes in the initial age structure, rather quickly "forgotten" during the projection (Wachter, 1986).

By contrast, *IP* is extremely sensitive to errors on the total size of the initial population—errors that grow over time for decreasing populations. In addition, systematic errors in birth and death series produce heavy estimation biases.

These phenomena confirm the need, even in the present context, of an accurate prior assessment of the reliability of the basic data. We should ponder the fact that the *IP* procedure merely translates the rather scanty information available on the changes in the population studied, these changes being expressed in terms of formally more refined indicators (the translation is achieved with the aid of fairly rigid assumptions, even if they are, at first glance, acceptable). Indeed, if the basic information is not sufficiently accurate, no method, however ingenious and sophisticated, can ever supply indicators—or, rather, estimates—closely reflecting a real situation that we cannot observe directly.

Nevertheless, having mentioned the robustness of the procedure with respect to the chosen model of mortality, we must admit that the hypothesis of a constant age distribution of mortality over time significantly restricts the power of *inverse projection*, as formulated by its inventor. The hypothesis is not very realistic if applied to historical periods characterized by frequent epidemics. Some of these often serious outbreaks could certainly strike all population strata indiscriminately and catastrophically. More commonly, however, they had a heavy selection effect by concentrating their effects on specific categories, most notably children. For the years marked by mortality spikes, we could obviously adopt (within the procedure) a different model for redistributing age-specific death rates, if we had at least summary indications on the nature of the event (typically, an epidemic) and hence on its possible differentiated effects. In dealing with catastrophic events such as the plague, historical demographers have sometimes assumed that mortality was neutral as far as age structure is concerned, impacting the entire population with a roughly identical force. Noël Bonneuil (1993) accordingly proposed to modify the procedure for distributing the age-specific death rates. He suggested adopting the standard model for deaths that would have been observed in the absence of a crisis and distributing the excess proportionally to the population age structure.[32]

In sum, there is ample room for amending and refining the procedure in this area. One alternative to the most commonly used mortality models (Coale *et al*., 1983; Ledermann, 1969) is William Brass's relationship system (1971), already applied by Jim Oeppen to *GIP* (Wrigley *et al*., 1997). The system might make it easier to incorporate any additional information, particularly from independent sources, on the characteristics of the mortality of the period[33] (doing this would also gradually modify the mortality structure over time, or in

[31] Applying an only slightly more complex procedure, we estimate annual net migration (using our knowledge of at least two population data items at the start and end of the reconstitution period) and therefore, by means of a subsequent model, its age distribution. The migrants distributed by age are then incorporated into the reconstitution, in a manner comparable to the procedure used in any ordinary projection.

[32] This implies identical ratios of crisis mortality at all ages. This idea was proposed by Robert McCaa (1993) and introduced into the most recent version of the "*Populate*" program.

[33] Brass's *logit* system is actually very useful when there exists an empirical life table for the population studied (or a table which, in any event, is assumed to be more consistent than a theoretical model with the age distribution of mortality in the population). In these cases, both tables used in the *IP* procedure to establish the death distribution, year after year, can be drawn, precisely, from the empirical table by keeping its structure (β parameter) constant and increasing or decreasing the α parameter, which determines the survival level.

specific years).

In cases where we have information on the age distribution of deaths in addition to the time series of deaths (a rather frequent occurrence, especially from the 19th century onward), another alternative is available: a modified version of *IP*, which its author describes (Rosina, 1994, 1996) as *differentiated inverse projection* or *DIP*. In many cases, *DIP* improves the estimate of survival levels and also yields indications on the typology of mortality.[34]

We have very little room here for a fuller discussion of this highly fertile and stimulating field of varied methodological proposals, although they do fall within the scope of reconstitution models operating on aggregate data. Earlier, we mentioned Noël Bonneuil's original method for reconstituting the 19th-century French population. Such a method appears, among other things, to have a structure closely tied to the data available in a particular historical and geographic context. It thus seems hard to generalize to other situations without some basic adjustments.[35]

For a diametrically opposite solution, let us take the case where our information is supposedly confined to a time series for births and our goal is to obtain an estimate of the population's size and, possibly, its age structure. We can cite two different methodological proposals. They are described in two publications: Noël Bonneuil's book (1993) and a paper by Massimo Livi Bacci and David Reher (1993). Despite their differences, both solutions involve (1) the reconstitution of cohort-specific mortality starting from birth (they therefore rely on vague general information on the characteristics of mortality in the period and geographic area studied) and (2) an assessment of the intensity and structure of net migration—a more difficult task. These situations seem, to us, representative of many others where data are almost totally lacking. Clearly, the priority here is to estimate the margins of approximation and to determine whether their size (usually rather large) is at least compatible with the research goals pursued.

Let us return to the most robust reconstitution techniques already described at length (chiefly *IP* and *GIP*) for one brief comment: the production of series of demographic indicators that we can easily obtain thanks to them has already made it possible, in many cases, to offer an extremely useful frame of reference for the characteristics and dynamics of past demographic systems.

Such results take on a special value when we can link the demographic series to comparable series of indicators reflecting economic or other conditions (for example, climatic) that may influence the demographic regime. In historical demography, as in the other branches of demography, the vast field of causal research is one of the most fascinating, but also one of the most arduous to explore—for two reasons: first, the chronic shortage of quantitative information needed; second, the difficulty of formulating and hence verifying the plausible models describing the relationships between the demographic system, the natural-environment system, and the socioeconomic system. The massive study by Anthony Wrigley and Roger Schofield on England is, in this respect as well, an essential benchmark;[36] however, it is also a model that may be hard to imitate, owing to the difficulty of obtaining the same quantity of historical economic data in other contexts.

The techniques most widely used today for analyzing the short-term relationships between economic (or meteorological) indicators and demographic indicators—but also to interlink demographic series—are common to econometric research and presuppose a consolidated theory on which we can rely to define the model's specifications (Tonini, 1993b, p. 16). In short, we need a very specific hypothesis on the meaning of the possible relationships between the variables studied. The most commonly used solutions are the *distributed-lags* models, applied by Ronald Lee (1985) in his study on English series, and by Patrick Galloway (1994) in a large-scale research project on the demographic system's responses to environmental and economic conditions, spanning four countries of northwestern Europe, between the mid-fifteenth and early 20th centuries. In distributed-lags models, the analysis rests on the following principle: the effects of a change in, say, the nutrition level (flagged by price observations) will not be confined to the demographic indicator examined (number of deaths, mortality rate, etc.) in the year in which the variation occurs; it may also influence a certain number of later years—or months, if the observation is monthly. The existence of such short-term relationships may therefore be effec-

[34] Taking, for example, two broad age groups (0 to 9 years and 10+ years), the program will follow the procedure that allows total deaths to be distributed into annual age classes separately for each group, by identifying for each group the survival level compatible with the total number of deaths. In the final stage, the complete results allow a comparative assessment of mortality trends in the two different age groups.

[35] The method in question, at least for the 1856–1906 period, is based on the age distribution of deaths and so requires data typically unavailable for the oldest periods (Bonneuil, 1997).

[36] The volume (Wrigley and Schofield, 1981) contains, among other things, an important study by Ronald Lee entitled "Short-term variation: vital rates, prices, weather." It is a fundamental contribution to the analysis of relationships between the demographic system, the natural environment, and the economic system.

tively identified by the models discussed above, which begin by eliminating the trend component, i.e., by reducing the series to stationarity conditions.

More recently, to study the short-term relationships between demographic and economic series, several researchers have used far more sophisticated statistical methods for analyzing time series, such as *Vector AutoRegressive Moving Average* (*VARMA*) models. Their main difference with econometric models based on distributed-lag regressions is that they are less structured (Tonini, 1993b): they posit a theory, at the most, for the choice of explanatory factors, and let the data suggest the form of the model. There is, for now, a fair amount of disagreement about whether these analytical methods can address the questions raised by historical demography research in a satisfactory manner and thus, ultimately, about whether they can clarify the mechanisms used by the demographic system to respond to stimuli from the economic and environmental system. Ronald Lee's highly critical verdict (1993) is particularly worth noting. He argues that structured econometric models remain a far more prudent means of attaining these objectives. In fact, all of the studies based on the use of modern statistical methods are rather explicitly informed by a different research philosophy that may be summed up as follows: we should not establish *a priori* the direction of relationships between the variables studied (see, for example, Entorf and Zimmermann, 1990); the set of potential linkages between the data should thus be determined on a purely empirical basis.

VI. STATISTICAL METHODOLOGY AND HISTORICAL DEMOGRAPHY

While historical demography has developed specific techniques for studying past populations—often needed to offset the chronic shortage of data—statistical methods have always been crucial to an understanding of past demographic dynamics.

Let us therefore review very briefly some of the statistical applications proposed in the literature and the new research approaches offered by available methods, most notably the analysis of individual data.

1. Analysis of Aggregate Data

Thanks to the results of observations and studies that have allowed the construction of demographic indicators at a fairly detailed level, the number of investigations of geographic variations—of mortality in particular—has been growing steadily since the 1970s. The approach known as *ecological* is chiefly based on factor analysis methods or, in their broadest sense, multidimensional analyses. The goal has been to link mortality indicators with contextual external variables, such as socioeconomic or health conditions, assumed to have a potential influence on the risk of death. Many valuable studies concentrate on this specific approach.[37] Researchers have also started to apply the ecological approach, albeit more belatedly, to historical periods, in particular the ones closest to us: the 19th and early 20th centuries. In addition to mortality, these studies cover fertility, marriage, and the identification of differential demographic regimes. The approach here is purely descriptive. It is largely focused on the identification of specific profiles, typologies or models of demographic behavior at the aggregate level.

This type of analysis, as noted earlier, rests primarily on the availability of aggregate statistics drawn from status data (such as censuses) and movement data or special surveys: in the 19th century, such material started to become available on a reasonably regular basis in many regions, in Italy and elsewhere in Europe. From these sources, we can often calculate or enumerate not only the standard demographic indicators, but also other variables in areas such as socioeconomic conditions, farming systems, occupational classification, some information on health status, educational attainment, and so on. While displayed as aggregate data, such inputs are well suited to multidimensional analysis. The basic scientific goal is always to determine geographic differences in behavior. Thanks to the links between variables that can be established with these multidimensional analyses, we can, to some extent, begin to examine the causal mechanisms underlying the differences observed.

The choice of the methods mentioned above is guided not only by technical criteria concerning the form of data availability—the data are aggregated, although the aggregation sometimes involves a very refined level of territorial division, even down to basic communities—but also by conceptual motives. The contextual indicators computable from status data, for example, are seen as measuring variables that influence the demographic parameter studied: death rate or probability of dying, total fertility rate, mean age at marriage, never-married rate, etc.

The ecological approach, however, has well-known limitations. While offering a rich and interesting description of phenomena, it does little to identify causal relationships. But its main shortcoming is inherent in the type of data employed and the time scale of the indicators. Because the approach uses aggregate

[37] For a selection, see: Castiglioni *et al*., 1991; Pozzi, 1990, 2000; Lesthaeghe, 1992.

data on entire populations or subgroups of individuals, the subject of the investigation is not the specific risk factors for a given behavior, but their *proxy* or, more precisely, an approximation of their proxy consisting of indicators of the group's average behavior (Caselli, 1995). Also recall that one of the major unresolved problems of ecological analysis is its inability to allow for the time that a context variable may require to influence the demographic process leading to the event studied.

Another area of methodological exploration that also concerns historical demography is the interpretation of time series for rates or probabilities in three dimensions: age, period, and cohort.

The reading of cohort indicators and their relationships with period measures have consistently interested historical demographers ever since Louis Henry stressed their potential via *nominal reconstitution*. Indeed, historical demography—most notably in the area of fertility analysis—was the first discipline to emphasize the importance of a combined reading of behavioral changes by cohort group and of period variations. This approach has long captured the attention of researchers seeking an overall interpretation of fertility trends but also, and above all, an identification of the start of the transition process for reproductive behaviors and their control.

The analysis of fertility through the family reconstitution technique thus clearly requires putting individual data in perspective. By contrast, the cohort analysis of aggregate data is a more recent development in historical demography.

The demographic use of specific statistical models to measure and identify the three different components of a matrix of rates or probabilities by age, period, and cohort (APC) is recent. In any event, the APC approach (see Volume I, Chapter 18) remains a descriptive approach that seeks to define a time frame of reference for the processes but cannot replace a causal analysis. As we know, demographers are applying APC models in an effort to distinguish the weights of the age, period, and cohort components in the explanation of the internal variability of a matrix of rates or probabilities.[38] An understanding of the different dimensions of the phenomenon analyzed can only help to move through the later stages of causal analysis.

The application of this type of statistical techniques can have highly stimulating effects in historical demography. If we are trying to reconstruct matrixes of probabilities of dying for sufficiently long periods, it is certainly worth describing the change in the age distribution of general mortality or of mortality in specific age groups by identifying the effects of periods or cohorts whose mortality diverges from the standard underlying level. We can thus specifically identify (1) period effects, due, for example, to epidemic crises or cycles, which were extremely frequent in the past, and (2) cohort effects, understood as the delayed consequences of events affecting particular cohorts, such as cohorts born in an unusually adverse period. With this technique, we can therefore begin to study the selection effect of a given epidemic—such as the plague—on certain cohorts by identifying its impact on the population's age structure (Rosina *et al*., 1999).

In this area, we should mention the application of the *age-period-cohort* approach to the life tables of Italian cohorts born between 1882 and 1953 (Caselli and Capocaccia, 1989). One of the study's main aims was to determine, by means of a log linear function, the relationship between child and adolescent mortality and adult mortality. The theoretical frame of reference is precisely the one just mentioned, i.e., the potential consequences, in survival terms, of unusually adverse conditions experienced by certain cohorts in childhood. Such conditions may exert a positive selection effect by eliminating the weakest individuals at early ages. As a result, they may increase the statistical weight of the most robust individuals and diminish the cohort's mean mortality at older ages. If, instead, the main consequence of the event is to weaken the survivors, the cohort's adult mortality will be higher. Without going into the details of the modeling results, when we can take account of age cohort interactions in the mortality variations, we can pinpoint the specific cohort effect by underlining the linkage between (1) the probability of dying in adulthood and (2) child and adolescent mortality. The model also allows a fairly specific analysis of intercohort differences in mortality by clearly identifying the most disadvantaged cohorts.

2. Analysis of Individual Data

Our knowledge of the differences between demographic regimes and of the changes in processes over time is steadily advancing. Hence it is ever more relevant and necessary to seek methods and forms of information analysis with which we can identify the true relationships underlying the data. To do this, we

[38] As we now know, APC models face identification problems (see vol. 1, chap. 18). In fact, it is impossible to estimate all the parameters simultaneously because of the linear dependence between the three variables involved. As a result, the models linking the dependent variables (rates or probabilities) to the three components (age, period, cohort) do not have a single solution, given that period = age + cohort. Therefore, we can obtain identical descriptions of data from different *sets* of parameter values; equally well, non-different groups of parameters may lead to very different interpretations. The only solution to the identification problem is to impose mathematical constraints on the model coefficients (Martelli, 1997).

must search for causes.

Such analysis makes it more vital than ever to take account of individual behaviors and the sequence of phases and choices that determine them. Concretely, this means that analysis, even in historical demography, now tends to reappraise the individual approach in terms of *life courses*.

The limits of the classic method of nominal family reconstitution have been recalled earlier; as we stressed, the yield of reconstitutions—measured by the numbers of individuals or couples under observation at different moments—can be significantly improved through the joint use of status data and movement data (Bideau and Brunet, 1993; Ge Rondi, 1988; Manfredini, 1996). This improvement is, as we know, perfectly feasible and rich with potential for many countries, thanks to the existence of records updated on an annual, multiannual, or even continuous basis: *status animarum* (nominal registers of religious origin) and *anagrafe* (civil registration) in Italy, "population books" in Belgium and Germany, parish registers tracking household changes in Scandinavia, and so on.

The aspect to stress here, however, is not so much the possibility of improving the yield from reconstitutions. The far more important task, taking Louis Henry's basic intuitions as a starting point, is to amplify the concepts underpinning such techniques in order to arrive at the statistical analysis of individual data.

As emphasized earlier, the powerful growth of information technology, especially since the 1980s, has had two consequences. First, it has allowed the collection of enormous databases and facilitated their management. Second, thanks to ever more effective algorithms, it has solved many of the problems involved in the *linkage* of documents pertaining to a single individual taken from different sources (status data, movement data, cadastral data, etc.). Today, it is far easier than in a still recent past to achieve a rapid reconstitution of life histories for a large number of persons who were active in a given period of variable length and were registered in nominal sources during that time.

Such possibilities may actually enable demographers to overcome many of the limitations specific to classic nominal reconstitutions by altering the perspective from which reconstituted event histories are viewed. We can thus switch from an often selective analysis—such as that of nominal reconstitution—to a study that treats individual histories as a sequence of transitions between different statuses. The transitions, which may involve different time intervals or durations, are marked by the events. In this approach, we can read a life course as a sequence of events and statuses along a time line (individual age or the time elapsed since a previous event), between a given instant that serves as the starting point and another that marks the exit from observation. To these reconstituted biographies, we can apply the many statistical techniques of regression analysis grouped under the name of *event-history analysis* (Alter, 1998).

Since our focus is on the advantages of moving from old forms of demographic analysis to new ones, it is interesting to note that we are not witnessing a conceptual break, particularly in historical demography: the fundamental principles of the statistical analysis of event histories were already present in Louis Henry's system and spelled out in the rules of family reconstitution. Indeed, in his famous monograph on the town of Crulai in Normandy, Henry had explicitly argued that the tracking of life histories would have been a valuable approach. The only reason that kept him from pursuing it was the lack of suitable statistical tools at the time.

In an interesting work on the links between *nominal reconstitution* of families and *event-history analysis*, Myron Gutmann and George Alter (1993) have stressed the resemblances and discontinuities between the two techniques by summing up the main limitations of the first in three points: rigidity of analytical rules for arriving at the computation of demographic indicators,[39] impossibility of conducting multivariate analysis, and difficulty of analyzing event sequences.

In reality, the notion that the understanding of individual demographic processes implies a continuous observation over time—already present in *nominal reconstitution*—is also the basic premise in *event-history analysis*.

In nominal reconstitutions, however, the rigidity of the rules for calculating demographic indicators entails a sizable loss of information by excluding all the data for which a truncation boundary cannot be determined. The analysis is thus confined to a subset of the universe analyzed—with all the problems this implies for assessing their representativeness. Actually, this limitation may be partly overcome, as noted earlier, by using supplementary sources of information, such as nominal status sources (e.g., censuses or tax lists), that may provide a clear end point for the observation.

Determining a specific moment in which the individual enters the observation field means that, if we know the starting point, we can identify with certainty the period of exposure to the risk of experiencing certain events. That said, if we know the sequence of events on the time scale, we can apply a series of statistical methods to analyze the durations and occur-

[39] This rigidity underlies the selectivity of the data used with respect to the data gathered initially.

rence rates of the events for all individuals exposed to the risk (Yamaguchi, 1991). Of course, there are different ways to describe the event histories: number of persons in a given status, mean time spent in a given status, rate of transition between statuses, distributions of durations between transitions, and so on (Gutmann and Alter, 1993).

The analysis of *event histories* also allows a fuller, multivariate analysis. Whether we choose continuous observation or discrete observations, regression techniques enable us to measure the extent to which certain individual or family characteristics can influence the likelihood of a transition between statuses, interstatus durations, or the rate of occurrence of a given event. Event-history analysis also allows us to take account of the succession of events in an individual life and of how yesterday's events can influence the likelihood of a later event (Courgeau and Lelièvre, 2001).

For historical demographers, *life histories* are certainly nothing new. However, the collection of ever more massive amounts of data and the enormous financial and labor costs needed to create event histories via *linkage* may find a practical justification if these data are then properly analyzed. The aim of the exercise must be to identify and describe the true relationships between the data. One can then move from the description and its attendant hypotheses to the confirmation and explanation of the relationships.

As noted earlier, the data from which we can reconstruct life courses may consist of movement data and status data from nominal lists or censuses. Movement data give us the dates of occurrence that tell us about the main stages in a person's life (birth, death, marriage, and, with greater difficulty, migration). Status data provide information on individual characteristics and attributes at a given instant or at successive moments.

When information abounds—for example, in Italy, where there are annual nominal status sources going back several centuries—we can reconstitute long portions of life histories in two steps. First, we establish a nominal link between successive lists. Second, we introduce the event dates from the continuous recordings into the life histories on an annual basis. In that case, the observation measurement unit is the year, and the biography naturally becomes a reconstitution in discrete durations. Where population registers (vital statistics) are available, the identification of attributes and the dating of events are very often combined in the same source; the life history is automatically generated by the reconstitutions performed on a routine basis. In both cases, the biographical reconstitutions are amenable to *event-history analysis* (Lagazio and Pagani, 1996).

The life histories thus identified are not always complete, however: they are beset by well-known *censoring* problems.[40] Both right-censoring and left-censoring are common in life histories reconstituted from historical sources. Observations often end before the analyzed event occurs (right-censoring). In certain cases, on the contrary, we can determine that an individual has already experienced the terminal event without our being able to date its occurrence (left-censoring).

Censoring must not be linked to the analyzed event, nor must the mechanism that causes the censoring enable us to predict the transition studied in any way. This essential notion was already explicit in Louis Henry's nominal reconstitution; Henry duly underscored its importance in his description of the possibility of "closing" families (Fleury and Henry, 1976). Both types of censoring can be resolved by applying suitable techniques of statistical analysis. Likewise, solutions have been proposed to overcome the difficulties involved in the use of fragmentary data, in particular the discontinuous data obtained by reconstituting life courses from civil registration records (Courgeau and Najim, 1995; Bonneuil *et al*., 2004).

Two other aspects of historical individual data should be emphasized (Diamond *et al*., 1993). Such data may be subject to recording errors that involve omission or to reporting and linkage errors. Such errors weigh on the computation of transition lengths and thus on the final estimate of the transition.

In addition, unobserved and hence unidentifiable factors may influence the processes studied. We will have to make allowance for these latent variables by looking out for them in the statistical analysis and inserting them into the models, so that we can accurately quantify the effect of the measurable variables.

In demography, the techniques of *event-history analysis* were first applied to the study of mortality (Hobcraft and Murphy, 1986). Today, demographers also tend to use them in the analysis of other demographic phenomena such as fertility, nuptiality, and migration. In historical demography, the first attempts at application concerned data from population registers, which are particularly well suited to the study of event histories (Gutmann and Watkins, 1990; Kertzer and Hogan, 1989).

The technique has now been rapidly disseminated via applications covering a wide range of biographical data. One of the most interesting applications concerns

[40] For a clear definition of censoring and truncation, see Trussell and Guinnane (1993); Yamaguchi, 1991.

the analysis of infant mortality, which has consistently played a leading role in the quest for a unifying theory of demographic transition (Lynch and Greenhouse, 1994; Lee *et al*., 1994; Breschi *et al*., 1997). Thanks to the methods suitable for aggregate data, our knowledge of the changes in infant mortality is making great progress; but the determination of the underlying conditions of such changes is important as well. For example, demographers have empirically observed massive variations in infant mortality levels between social classes, ethnic groups, and cultural groups. As we explore in ever greater detail the variables linked to infant mortality, it is interesting to study, for example, the potential influences of family factors on the risk of death, such as the family's general health conditions (which we can approximate, among other ways, via the infant and child mortality of the same mother's earlier children), its socio-occupational status, or its display of protective behavior toward children. To these variables operating at the family level we can add others concerning the environment and the community of residence, such as season of birth, crisis experience, and economic conditions.

If we have long-term data and can link them to the environment, we can also measure the lagged effect of childhood living conditions on adult mortality (Alter and Oris, 2002; Bengtsson and Lindstrom, 2000). This causal investigation even extends to the prenatal period. A recent study used multivariate regression analysis to track the birth cohorts of a sample of 16,000 European aristocrats born in the years 1800–1880. It found significantly shorter adult life expectancies among daughters conceived by fathers over 45. The method identified a strictly gender-specific effect: the authors found no evidence of a negative relationship between the father's age at conception and life expectancy for male children (Gavrilova *et al*., 2003).

Fertility studies are equally of interest in methodological terms (Mroz and Weir, 1990). We can use *event histories* to study if a woman is likely to give birth again and in what time frame the event may occur. The risk of giving birth and of parity progression can also be measured as a function not only of the woman's demographic characteristics (age, length of marriage, birth cohort, etc.), but also of factors directly linked to reproductive choices, such as the effect of replacing a child who died in infancy, or the physiological impossibility of conception due to breast-feeding. A number of the attributes included in the model will not remain fixed for the entire observation period but will vary over time, and their treatment will require the use of multivariate regression that will take proper account of time-dependent variables.

In conclusion, event-history analysis is a promising tool for causal research even regarding past populations. A final point concerns the great variety of relationships that can be analyzed with these methods. The occurrence exposure rate for a given event or the probability of its happening can be influenced by many independent factors. Let us assume that the dependent variable is adult mortality. An *event-history* regression model will enable us to establish relationships with equal ease between (1) the variables that pertain to the personal sphere (such as sex or year of birth) or identify family status (socio-occupational category, migration status, family composition) and (2) covariates acting at the community level (economic fluctuations proxied by prices, temperature, crises). Some of these factors may vary in the course of an individual life; we can then take such variations into account when determining exposure to the risk of dying. The new feature here is that the researcher can check the effect of macroscopic variations—such as economic or climatic fluctuations—at the individual level and the individual response to them, even on small populations. Such versatility makes the event-history method a key instrument for analyzing living conditions in pre-industrial societies by once again combining the *micro* and *macro* approaches into a single structure.

VII. KINSHIP AND ENVIRONMENT

Another significant feature of contemporary historical demography is the growth in studies based on genealogical data. To some extent, this development carries on an old tradition. In the early 1950s, Louis Henry began his quest for sources that might provide information on "natural" fertility levels. He first considered published genealogies. But he soon realized that using such sources could create social-selection effects that might bias the demographic conclusions. Henry soon opted instead for parish registers, to which he had been introduced by the Canadian Jacques Henripin, then an intern at INED.[41] Yet he did not entirely abandon the use of genealogical documents: they enabled him to produce his first major monograph (Henry, 1956), and he continued to explore their biases.

This early use of genealogies to supply basic information for demographic reconstitutions was hardly confined to France (Hollingsworth, 1957). In the past twenty years or so, it has enjoyed a revival thanks to the

[41] On the history of this trial-and-error process that led Louis Henry to "invent" historical demography, see Rosental (2003, p. 221ff).

powerful momentum of historical demographic studies on China. The country has a wealth of kinship data on descendants of a common ancestor, often spanning many generations (Lee and Campbell, 1997). They therefore constitute, if not the sole source, at least a major documentary series for reconstructing the main demographic variables of ancient China over the long term (Peng and Hou, 1996; Zhao 1997). However, there has been considerable debate over the risks of bias induced by this type of document. In a recent summary, Zhongwei Zhao (2001) focuses on the demographic-selection effect of the sources, whose presentation implies that the lineages under study were reproduced from generation to generation. The author concludes that the effect of this selection bias is concentrated in the initial generations, and that its intensity is inversely proportional to the genealogical depth available. Zhao relies on microsimulation, one of the techniques now commonly used to measure the potential biases entailed by the use of genealogies, whether preconstructed or reconstituted by the demographer: it allows to measure the gap between the observed data and the data that would presumably result from the interaction of what are regarded as plausible demographic variables (Smith and Oeppen, 1993).

A second use of genealogical data combines historical demography and genetics. It too has a long tradition, as it intersected the study of human settlement through the tracking of the spatial diffusion of genetic malformations (Jacquard, 1970). The compilation of large bases of nominal data by historical demographers has given a new impulse to this field of study, which can simultaneously (1) identify the immigrant couple(s) initially responsible for the spread of a genetic disease in their host country and (2) trace settlement processes at the regional level (Tremblay *et al*., 2003; Zeegers *et al*., 2004). Using its own specific sources, this approach thus bolsters geneticists' efforts (Cavalli-Sforza *et al*., 1994) to reconstitute the dissemination of human settlements across the planet. Another use of genealogical databases derived from historical demography is the analysis of potential demographic effects of consanguinity, particularly on infant mortality (Eberst Dorsten *et al*., 1999).

But, if we look in a totally different direction, the growth of genealogical databases also illustrates how studies on nominal data are providing historical demography with new approaches. At the outset, it will be recalled, Louis Henry's establishment of historical demography went hand in hand with a non-nominal use of parish register data. Family reconstitutions served to produce aggregate data, offsetting the lack of series comparable to those produced by administrative statistics beginning around 1800. Since the 1980s, the methods of life course statistical analysis have enhanced the potential for investigations, particularly of a causal nature. But the compilation of genealogical databases goes even further by calling into question the observation unit of reference. Between the population, defined as a macroscopic aggregate, and the individual, captured at the microscopic level, we are witnessing the emergence of a mesoscopic level that may radically reshape the priorities and explanatory frameworks of historical demography. Its observation unit is the interpersonal configuration in which each individual operates.

This shift has occurred gradually, starting with a question at the intersection between historical demography and family history: What was the actual availability of kinship in traditional societies? How did the number of kinship ties in the widest sense (mother and father, grandparents, siblings, etc.) change during a life cycle? This question, which, for a long time, could be addressed only via microsimulation (Le Bras, 1973), can now be tackled more directly—and more precisely—thanks to the advent of large databases with a family component. Post *et al.* (1997) do this for the Netherlands using information on 160,000 individuals for the period 1830 to 1990. But this wholly demographic approach to the issue is clearly incapable of transcending a purely formal vision of kinship, in which ties are defined by a degree of genealogical proximity, but not by their effective degree of activation or by their effects on ego. To sum up, we could say that the approach is useful for defining the widest boundaries of kinship in a given sociohistorical context, and that we can then measure the intensity of family mobilization actually observed against this theoretical denominator.

How can we break out of the confines of the household—a unit that long enjoyed the more or less explicit preference of historical demography—without overstating the importance of the extended family? How can we conceptualize a kinship network whose boundaries are intrinsically variable? To find the proper compromise and identify the boundaries of the family ties actually mobilized, many authors use indirect measures. In his study on the protective effect of the extended family on the mortality of illegitimate children, Anders Brändström (1997) looks at the geographic distance between related individuals. He relies on the database compiled in Umea on the Sundsvall region of Sweden in the mid-19th century: this involved a comprehensive enumeration and genealogical linkage of the population of several contiguous parishes. Brändström observes that an unmarried mother whose parents resided in the parish in which she gave birth was significantly more likely to see her children survive. In addition to Derosas (2002), a recent review study by Frans van Poppel (2000) suggests the degree of generality of this result at the European level for infant mortality in the aggregate.

The study of family proximity also enables us to reassess the relative influence of kinship networks on the geographic direction of migrations, as Bonneuil *et al*. (2004) show using the database of the "3,000 Families" survey (see footnote 22). The authors of the study have created individual files for each person in which the demographic, geographic, and social characteristics of ego are correlated with those of all the person's kin. We can thus observe the impact of each individual movement on the other kin: does it take ego away from, or bring ego closer to, his/her parents, siblings, aunts and uncles, etc.? The study breaks with the increasingly widespread notion that migration is chiefly determined by interpersonal networks, and in particular by kinship networks. The authors show that most family constellations (if we use the term for a given kinship tie) do not "explain" the destinations chosen by migrants. Migration does not bring related persons closer—or, if it does, the effect is weak. From a complementary viewpoint and using the same data, Kesztenbaum (2004) observes that, on the whole, internal migrants seldom choose as their destinations the localities in which their relatives resided. These counterintuitive results reveal the contribution of a genealogical unit of observation: it enables us to analyze a representative national sample, chosen independently of the phenomenon studied; by contrast, studies based on the observation of migrant populations may sometimes overrepresent networked individuals to the detriment of those who have dispersed toward seldom-chosen destinations.

These studies also show that extended kinship is not an intrinsically relevant unit for observing individual behavior (Plakans and Wetherell, 2003). To move out of the confines of the household, we must objectify the nature of the actual relations between members of a kinship group. With this aim in mind, historical demography is beginning to share the social sciences' growing interest in the study of interpersonal relationships (Lemercier, 2005). The practical result is a new approach to database design. It is no longer enough to collect biographical or intergenerational information (i.e., on individual life courses); we must now combine this with relational data, such as the choice of godparents at baptism and marriage witnesses.

This information can be used in different ways. One solution is to objectify it in the form of indicators—an approach well suited to samples of lineages that do not share the same environment, such as national samples. We can thus observe the extent to which members of a given lineage choose kin as marriage witnesses. This indicator arguably enables us to distinguish between *autocentric* lineages, in which the lineage and reference group coincide, and *exocentric* lineages, whose members do not share personal ties (Rosental, 1999). We can then incorporate the variable into logistic regressions measuring its relative power to explain sociodemographic behaviors, as against the classical attributes of ego such as age, gender, and social status (Bourdieu *et al*., 2000).

A second solution consists in the use of measuring instruments derived from *network analysis* (see Chapter 137, this volume). It is suitable for analyzing lineages that all function in the same social space. One example is the pioneering study by Cristina Munno (2005, 2006), which offers a genealogical and relational reconstruction of the entire population of a wool-producing town in Venetia in the 19th century. By combining event-history analysis and network analysis, the author seeks to determine the extent to which the integration of households into the social fabric of the parish determines their demographic characteristics, such as mortality and geographic mobility.

Besides their intrinsic contribution, studies of this kind are important because they clearly show that the analysis of genealogical databases calls for a sociohistorical approach—in the sense in which, for example, the nature of interpersonal networks depends on social position. This stands in contrast to the drift toward sociobiological approaches, which, through the use of contemporary statistical tools, revive the quest for a so-called genetic heredity of behavior. Geneticists are often the first to warn demographers and historical demographers against the simplistic nature of such determinism, and the interpretative reductionism that informs it. To take just one example, Westendorp and Kirkwood (2001), using a genealogical database on the English nobility for the period 740 to 1995, claim to demonstrate "influences" of parental longevity on offspring lifespan. But they follow this up immediately with an assertion that the result does not, in itself, imply a hereditary mechanism. To show the limits of the finding, the authors introduce an environmental variable easily available in their database: the age at death of ego's spouse. They see this as a convenient indicator of the influence of the environment on ego's mortality, and effectively illustrate its importance.

The scope of Westendorp and Kirkwood's study does not require them to define in greater detail what constitutes the "environment." But, as it happens, the notion is now under intense investigation. The development of historical demography in the 1950s was informed by an organic and broadly biological approach to population, which still permeates some contemporary work. However, the renewal of statistical methods coincided with a deeper change. Alongside historical demography—which, as its name indicates, is a demographic enclave in the land of history—we are witnessing the emergence of a social and political history that sees population as the product of social and political dynamics.[42] If we confine our analysis to the most quantitative aspects, we can observe this change in all the studies that examine the direct and indirect effects of social arrangements on demographic behaviors—instead of treating demographic dynamics as the outcome of more or less endogenous variables (such as fertility and mortality), or as the mechanical product of economic conditions. The link between population and social policies becomes the focus of the analysis.

The United Kingdom has proved a particularly fertile terrain for such explorations: a growing number of historians are combining the study of populations with that of the Poor Law system. Given the wide variations in poor relief from one parish to another, and the fact that it could involve a large share of the population, we may legitimately ask whether it might be an explanatory factor in accounting for local demographic differences. Andrew Blaikie (1998), for example, has studied the effects of local social protection (as well as the effects of family configurations) on infant mortality in two Scottish parishes. But the scholar who has unquestionably gone furthest in using the Poor Law system as the key to understanding all of 19th-century English demographics is Steve King. In addition to the classical sources of historical demography, he examines all the documentation produced by Poor Law administration—most notably the "pauper letters" sent to local authorities to request and justify relief. King uses these sources in two ways. First, the quantitative analysis of the content of these documents—of which tens of thousands survive—gives clues about the boundaries of kinship regarded by the "overseers" of poor relief as relevant and capable of being called upon. Admittedly, King is not the first to qualify the assumption, introduced by Peter Laslett, of "nuclear hardship"—i.e., that English households could not count on support from their kinship group.[43] Rather, King's originality is his incorporation of quasinarrative sources, far removed from the tradition of historical demography, into the social history of population.

A second use of these sources consists precisely in matching them against households' sociodemographic trajectories. King begins by noting the existence of demographic "sub-groups," i.e., households displaying a propensity for a specific behavior such as high infant mortality, illegitimacy, early marriage, or high fertility.[44] These concentration phenomena have been known for a long time, and not only in England. As they are often reproduced by successive generations, they are readily interpreted in genetic or culturalist terms.[45] True, they do not overlap conventional sociological variables such as occupation or land-tenure status. But King re-examines the issue in terms of the Poor Law criteria, distinguishing between the lineages that never require relief, those that fail to emancipate themselves from need, and those that seek relief either frequently or occasionally. These categories, drawn from sources that are unconventional in historical demography, turn out to provide far more effective explanations of behaviors. King attributes this to the different paths to marriage followed by the poor, and to the impact of these differences on their later life cycle.

On another scale, many demographic differences between parishes become easier to understand when we analyze the differences in the volume of poor relief distributed and in the procedures for doing so—such as cash payments, medical examinations, and handouts of food or clothing—whose practical effectiveness could vary. These differences, in turn, depend on the balance of power within the elites and between the elites and the rest of the population, as well as on pressure from neighboring parishes that did not want to see an influx of paupers ill-protected by their native villages or towns. In another area, the study by Frans van Poppel *et al.* (2005) on three provinces of the Netherlands reveals the contemporary spread of this type of approach, which is profoundly reshaping the picture of the population drawn by historical demographers. Using an excerpt of the "Historical Sample of the Population of the Netherlands," which seeks to document 76,700 life courses between 1812 and 1922, the authors show that the provincial environment—principally, health conditions—has an even stronger long-term effect on infant mortality than social status. Moreover, far from displaying a linear uptrend or downtrend, social inequality in the face of infant mortality fluctuates over time, precisely as a function of the environment. This finding has a major methodological implication: it demonstrates the low relevance of

[42] On this point, see Rosental (2006).

studies covering a brief time period.

In sum, contemporary demographic research no longer sees the population as an organic whole or as an entity automatically influenced by economic constraints. The approach that is gaining ground views the population as the product of sociopolitical power plays. In methodological terms, this vision requires demographers to widen the range of sources used, and to develop, if need be, statistical methods combining paths (intra- or intergenerational), social networks (both inside and outside the family), and environmental variables.[46] If these steps are taken, the demographic approach will help us to interpret, in a broader perspective, the ways in which societies are continuously shaping themselves.

Indirect Estimation Methods

KENNETH HILL

Department of Population and Family Health Sciences, Johns Hopkins University, Maryland, United States

Direct demographic measures are typically derived from counts of events and corresponding measures of exposure times. The resulting rates and their derivatives will be accurate as long as all events and exposures are reported and correctly classified, for example, by age. In many countries lacking fully developed administrative systems and with populations that include substantial proportions with limited education, accuracy of reporting and classification cannot be assumed. As a general rule, these countries come mainly from the ranks of developing countries, with developed countries enjoying accurate data. However, it should be remembered that being a developed country is neither a necessary nor a sufficient condition for accurate data: death registration in the United States has only been regarded as adequately complete for measurement purposes since the mid 1930s, and births were adjusted for underregistration until the late 1950s; similarly, data on international migration are of dubious quality almost everywhere, developed and developing alike, partly because administrative systems are not well developed in this area.

Indirect estimation techniques have been developed over the last 50 years to provide adequate measures of demographic processes in situations in which direct measures were too inaccurate to be informative. The basic philosophy underlying indirect estimation, conceived and largely developed by William Brass, was to take advantage of the most reliably reported portions of data, and discard the rest. The techniques can be divided into two broad groups. One group uses consistency checks between different measures of the same underlying phenomenon to explore likely accuracy, and then applies simple models of data errors to arrive at plausible corrections. The second group uses robust indicators of an underlying phenomenon, even though the indicator may be affected by other factors. An analytical method is then used to obtain an estimate of the underlying phenomenon itself by allowing for the effects of these other factors on the indicator.

A key characteristic of indirect techniques is the use of simple questions that can be included in data collection exercises conducted by interviewers with limited education and short training. In almost all cases it is possible to include the questions needed in population censuses. Several of the early methods were developed by Brass expressly to make use of information that was already often collected by demographic inquiries, but for which no systematic analytical methods existed for converting the information into standard demographic measures. In the last couple of decades, the need for indirect estimation methods for national measures of two key demographic phenomena, fertility and child mortality, has been greatly reduced by the development of standardized though complex event history questionnaires for use in sample surveys. Indirect estimation methods have remained important, however, in the measurement of adult mortality and international migration, and for small-area estimates of fertility and child mortality for which the small samples necessitated by complex data collection instruments cannot provide adequate disaggregation.

The two types of indirect estimation will be illustrated in the next section. Subsequent sections will then discuss the more widely used methods according to the demographic process measured: fertility, child mortality, adult mortality and migration. Within each section, one or more methods will be discussed and an application illustrated; modifications of the main methods will be discussed briefly.

I. TWO TYPES OF INDIRECT ESTIMATION

Estimation methods can be divided into two groups. An example of each group, both originally developed by Brass, will be given. The first group consists of those methods that can be literally called *indirect*. A data collection exercise collects information on a population characteristic that can be reported on reasonably accurately. The characteristic in question must be strongly influenced by the demographic process of interest, but will also be affected by other factors not of direct interest. Analytical methods are then used to transform the characteristic into a pure demographic measure, by allowing for the influences of other, extraneous factors. The second group of methods consists of those methods that are primarily *consistency checks*. Two (or more) different measures of the same demographic process are compared. Adjustment (if necessary) is made on the basis of prior knowledge of the error processes that would result in the inconsistencies observed. Reliance is placed on the portions of the alternative pieces of information that are expected to be most accurate.

The classic example of an *indirect* method is the procedure for estimating childhood mortality from summary birth history data, in which women report the number of children born alive and the number that were born alive but have since died. These data permit the calculation of the proportion of dead children according to the age group of mother. The proportion of dead children for women of a particular age group is primarily determined by the overall level of childhood mortality, but it is also affected by the age pattern of fertility. In an early-childbearing population, children of women of a particular age have been exposed to the risk of dying for longer than in a late-childbearing population. By allowing for the age pattern of childbearing (through ratios of average parities in successive age groups), proportions dead of children given birth by women classified by standard 5-year age groups can be used to estimate conventional probabilities of dying between birth and specified exact ages of childhood.

A good example of a *consistency check* is what is commonly referred to as the P/F ratio method for measuring fertility. Information is available on two indicators of the same process: the number of children ever born by women classified by age group, and the number of children born in a defined time period (usually 1 year) by age group of mother. These data permit the calculation of the average number of children ever born by women by age group and of age-specific fertility rates. If fertility is not changing and there are no selection effects at work, cumulated age-specific fertility rates will provide measures of lifetime fertility equivalents that can be compared to the recorded levels of lifetime fertility. The reported lifetime fertility is denoted by P for parity, the lifetime fertility equivalents obtained by cumulating age-specific fertility rates are denoted by F. The ratios of P to F, age group by age group, provide indicators of the consistency of the two types of information.

Once the comparison for consistency has been made, there is the possibility for adjustment. If the P and F values are consistent, there is no indication of error and no need for adjustment, but if they are not, a plausible adjustment can be made in some circumstances if there is some prior knowledge about the likely nature of data errors.

II. ESTIMATION METHODS FOR FERTILITY

1. Indirect Estimates

Indirect estimates of fertility are mostly based upon age distributions, and represent different systems of reverse projection. In a closed population, the number of children of a given age represents the survivors of the number of births that occurred that number of years earlier. The primary influence on the number of survivors is the earlier births, and the secondary influence is childhood mortality. If allowance can be made for the deaths, by reverse projection, for example, the number of births can be estimated. If the entire population can also be reverse-projected to the same time point, the birth rate can be estimated, and if the female population of childbearing age can be estimated, the general fertility rate (GFR) can be estimated. Reverse projection in this simple form requires only data on the age distribution of the population and knowledge of mortality rates over the preceding few years.

This approach to fertility estimation dates back many years. In practice, it is not very useful: it only provides estimates of (at best) the GFR, rather than estimates of more standard measures such as the Total Fertility Rate; age distributions are affected by typical age reporting errors (generally reducing the number of children reported as being under age 5 years), introducing a (downward) bias into fertility estimates for recent periods; child mortality (and especially trends in childhood mortality) may not be accurately known; and the age distribution may be affected by migration.

The *Own Children* method (Cho *et al*., 1986) is a variant of the reverse-projection methodology that provides standard age-specific fertility rates. Information within a data source (such as relationship to head of household) is used to match children in a particular household to a likely mother in the same household. The information on age of child provides information on when the births occurred, while information on age of mother minus age of child provides an indication of the age of the mother at the time of the birth, and thus a basis for estimating age-specific fertility. The method has been widely used with census data, particularly for East and South East Asia, where age distributions are of good quality.

The use of stable and quasistable population analysis techniques (Coale and Demeny, 1968) can also be thought of as a form of reverse projection. Standard age distributions reflecting known, fixed fertility and mortality schedules are used as reference patterns against which an observed age distribution is compared. Some single characteristic of the age distribution, such as the proportion under age 15, which is believed to be fairly accurately observed even in situations in which age reporting is of poor quality, is generally used as the starting point. Adjustment for mortality is then made either directly, if an estimate of child mortality is available, by matching the proportion under age 15 against stable populations which have the same childhood mortality as that of the population being studied, or indirectly, if no estimate of childhood mortality is available, by matching against stable populations with the same rate of growth as the population being studied.

The development of mathematical expressions to represent unstable age distributions gave rise to a method of reverse projection proposed by Preston (1983). This method is appealing because it does not require estimates of mortality *per se*, but rather an estimate of the general age pattern of mortality. It is also appealing because it makes use of the entire age distribution, and linear methods for fitting. In an unstable but closed population, the proportion of the population of a particular age, $c(a)$, is a function of the current birth rate, b, the current probability of surviving to age a, $p(a)$, and the sum of age-specific growth rates below a, $R(a)$. Thus

$$c(a) = b\ p(a)\ exp(-R(a))$$

where

$$R(a) = \int_0^a r(x)dx$$

Preston expressed the odds ratio of dying by age a as equal to a constant fraction of the odds ratio of dying by age a in a standard mortality schedule or model life table. Thus

$$(1 - p(a))/p(a) = g\ \{(1 - p^s(a))/p^s(a)\}$$

Substituting in for $p(a)$ and rearranging gives the relationship

$$1/\{c(a)\ exp(R(a))\} = 1/b + (g/b)\{(1 - p^s(a))/p^s(a)\}$$

Thus the reciprocal of the proportion age a adjusted for the sum of growth rates from age 0 to age a is linearly related to the odds ratio of dying by age a in the standard life table, with intercept equal to the reciprocal of the birth rate and slope equal to the ratio of the proportional factor linking the actual and model odds ratios to the birth rate. Even better, if child mortality is known, from some independent source, the expression can be rewritten

$$p(5)/\{c(a)\ exp(R(a))\} = 1/b + (g/b)\ \{(p^s(5) - p^s(a))/p^s(a)\}$$

where $p(5)$ and $p^s(5)$ are the actual and standard probabilities of surviving to age 5. This formulation is to be preferred because much of the variability between human mortality schedules and between different families of model life tables is the relationship between mortality before and after age 5.

Although the Preston method appears to make very effective use of both data and theory in a combination that should be robust to error, in practice the method has performed rather poorly. At best, the only fertility estimate it produces is of the birth rate, and this estimate turns out to be sensitive to selection of points to fit. Age misreporting is the most likely explanation of the problem.

2. Consistency Checks

The principal consistency check method in fertility estimation is the P/F method outlined earlier, whereby fertility rates for a recent period (for example from vital registration) are compared with lifetime fertility measures (for example from a census question on children ever born). Age-specific fertility rates cumulated across age groups provide cumulative fertility measures $F(a)$ that are equivalent to lifetime fertility measures at exact ages. For data tabulated by 5-year age groups, the cumulative fertility to the beginning of a given age group is just the sum of age-specific fertility rates for younger age groups multiplied by 5 (to allow for the fact that each woman spends 5 years in a 5-year age group). Lifetime fertility measures *P*(*i*), however, are averages for women within a 5-year age group. A method is therefore needed to interpolate between the cumulative fertility measures at exact ages to approximate lifetime fertility measures for an age group. Various ways of carrying out this interpolation have been developed. The original method, proposed by Brass (1975), used a very simple fertility model (a third degree polynomial) to interpolate between cumulative fertility to the beginning of an age group and cumulative fertility at the beginning of the next age group in order to arrive at an estimate of average cumulative fertility *F*(*i*) in the age group. The polynomial was fitted using either the ratio of fertility in the age group 15 to 19 years to that in the age group of 20 to 24 years, or the mean age of childbearing.

Once the *P* and *F* values for each age group have been calculated, *P*/*F* ratios can be calculated for each age group. The ratios indicate the consistency of the current and lifetime fertility information, but may, if certain assumptions about data errors can be made, also provide a basis for adjustment. Say that the data on children ever born come from a census question. Experience suggests that in some cultures older women may omit some of the children they have given birth to, if for example the children have died or moved away. In these circumstances, the P values for older women will be biased downwards, but those for younger women will be more accurate. If the data on births by age of mother come from a vital registration system that only covers 80% of the national population, there will be too few births registered, but the undercoverage of births may be roughly constant at all ages of mother. If so, the age-specific fertility rates and the *F* values derived from them will all be too small by a factor of 0.8. Under these circumstances, the *P*/*F* ratios for younger women should be an approximately constant 1.25, reflecting the underregistration of births and reasonable accuracy of the *P*s, but should drop for older women as the *P*s become biased downwards. An estimate of fertility better than either source on its own can then be obtained by adjusting the age-specific fertility rates by the *P*/*F* ratios for younger women. In practice, of course, the assumptions will only approximate reality, or may not even do that if fertility is changing rapidly, so adjustment may not be possible. The consistency check and the pattern of *P*/*F* ratios by age will always be informative, however.

The original method was slightly modified in the United Nations (Hill *et al*., 1983) *Manual X*. The interpolation procedure between successive cumulative fertility observations was based on a regression equation. Model fertility schedules were generated by the Coale-Trussell (1974) fertility model for a range of model parameters and combined with likely age distributions of women within 5-year age groups given different levels of fertility. Table 127–1 shows an application of the method to data from the 1992 census of Zimbabwe. The *P*/*F* ratios (column 5) rise steeply with age of mother, from below unity in the first two age groups to nearly 1.5 for the women over 40. Clearly, the two sources of fertility data are far from consistent, but as they are the ratios give little clue as to which source of data should be regarded as more accurate. Knowledge of the specific situation suggests that changing fertility may explain much of the pattern.

A further modification of the interpolation procedure is proposed by Brass (1981), making use of his Relational Gompertz fertility model, which is particu-

larly convenient for fitting to lifetime fertility data or their equivalents. The Relational Gompertz model can be fitted to the cumulated age-specific fertility rates to age a as a proportion of total fertility, $F(a)/TF$, or to ratios of successive cumulative values, $F(a)/F(a + 5)$, and the model parameters estimated. The model parameters can then be used with the standard average parity distribution values of the model, $P^s(i)/TF$, to estimate the expected average parity in each age group as a proportion of total fertility, $P^e(i)/TF$. An estimate of total fertility can then be obtained for each age group i as the ratio of observed parity, $P(i)$, to the expected proportion of total fertility represented by average parity at that age group, based on the model fitted to the *Fs*.

The exact method used to apply the *P/F* Ratio method makes little difference to the results obtained, since all that the methods are doing is using different ways of interpolating between observed cumulative fertility levels. The factors that do make a difference to the results are fertility trends and data errors that do not fit the very simple models specified. Results for women in the age group 15–19 are often unreliable, perhaps because of more complex error patterns affecting very young women. Fertility trends result in *P/F* ratios that deviate from unity, as noted above with regard to the Zimbabwe example, but a basis for adjustment can sometimes be obtained if data are available on children ever born from two successive surveys. If the two surveys are separated in time by approximately 5 years, the parity distribution for a hypothetical intersurvey cohort can be created by chaining together the parity increments for true cohorts aging from one survey to the next. This parity distribution for the hypothetical cohort, with an explicit time reference, can then be compared with the cumulated age-specific fertility rates from the second survey. Table 127–1 (columns 6 to 8) shows the application of this technique to the Zimbabwe data, combining the 1992 census data with data from a 1987 intercensus survey. The hypothetical cohort *P/F* ratios still start below unity for the youngest women, rise moderately to values slightly over 1.0 for the central ages, and then fall again. This application confirms that fertility trends were largely responsible for the pattern of *P/F* ratios in column 5, and also suggests that young women may underreport children ever born, while women over 40 may also omit some of their lifetime births (note that the average parity of 45- to 49-year-old women in 1992 is *lower* than that of 40- to 44-year-old women in 1987). The application suggests that an upward adjustment of about 5 percent to the reported age specific fertility rates would be appropriate.

The *P/F* ratio methodology can also be applied to data specific by birth order. For example, cumulated first birth rates can be compared with proportions of women who report having had at least one child. The assumptions about error are then that women are less likely to underreport ever having had a child than underreporting the number, and that first births are as well reported as all births. In practice, these assumptions about error are rather strong, and the order specific methodology has not been widely used.

3. Combined Indirect Estimates and Consistency Checks

Parity progression ratios are useful for studying long-term trends in family building behavior, and the techniques of indirect estimation and consistency check can be used in the process. Distributions of women after the end of childbearing by number of children ever born permit the calculation of parity progression ratios, and performing the calculations by age group provides an approximate time reference for the measures of fertility. Such ratios may be affected by age misreporting and omission of children from women's reports, but consistency checks of the measures for similar time points from successive surveys can demonstrate whether or not data errors are important (Feeney, 1988). Indirect estimation can then be invoked to fill in the incomplete fertility records of women who have not yet reached the end of childbearing in order to use these incomplete records as a basis for calculating parity progression ratios. Current age-parity–specific fertility rates are used to project future births of each parity for each age group of women, in order to fill in the truncated birth histories. This procedure will of course damp trends, because current levels are being assumed to apply to future childbearing of all cohorts.

III. ESTIMATION METHODS FOR CHILD MORTALITY

1. Indirect Estimates

Indirect estimates of child mortality, using data from population censuses and large-scale surveys, have contributed enormously to our knowledge of child mortality levels and trends in the developing world. The recent widespread use of birth history surveys, in programs such as the World Fertility Survey and the Demographic and Health Surveys, has provided alternative, direct estimates of child mortality at the national level in a large number of countries, and has also contributed to our knowledge of the factors associated with child mortality differentials. However, the indirect estimates included in censuses still provide the only viable way of examining small-area variations in child mortality in much of the developing world.

a. Method Based on Proportions of Children Dead

The method is based on proportions dead of children ever born by women, as classified by age. The basic questions are very simple: *How many children have you given birth to?* and *How many of them are still alive?* It is claimed that better results can be obtained by breaking the question down into three: children still alive and living at home, children still alive but living elsewhere, and children that have died. The questions can be further refined by asking about boys and girls separately. The analysis uses age of mother as a proxy for exposure to risk of the children. Other things being equal, older women have children exposed to the risk of dying for longer, and thus have higher proportions of dead children for a given level of childhood mortality, than do younger women. The proportion dead within a given age group is also affected by the age pattern of fertility. In an early childbearing population, average exposure time of the children of mothers of a given age group will be longer than in a late childbearing population, so the proportion dead will be higher for the same overall level of mortality. For simplicity, assume that women in a population bear all their children at one age. For women of exact age 30 who bore all their children at exact age 23 years, the proportion dead will measure (other things being equal) the probability of dying by age 7 years, ${}_7q_0$. For women of exact age 30 years who bore all their children at exact age 25 years, the proportion dead would measure the probability of dying by age 5, ${}_5q_0$.

Brass (1964) developed the first analytical method for such data by modelling proportions dead for standard 5-year age groups using a single model life table and a simple polynomial fertility model with varying age locations. He related the model proportions dead, age group by age group, to probabilities of dying by exact ages of childhood. A particular application used an indicator of the age location of childbearing, the ratio of the average numbers of children given birth to women in the age groups 20 to 24 years and 25 to 29 years, $P(2)/P(3)$, to select appropriate factors for converting proportion of dead children into probabilities of dying between birth and exact ages of childhood.

The method has been subject to a number of modifications over the years. Sullivan (1972) used a wider range of model life tables to model proportions dead, and proposed a regression-based method to obtain conversion factors based on observed values of $P(2)/P(3)$. Trussell (1975) proposed a set of regression equations based on a range of fertility models derived from the Coale-Trussell (1974) fertility model and a wide range of model life tables. Preston and Palloni (1977) proposed a method for using the ages of each mother's surviving children to infer the distribution of children by duration of exposure. The United Nations *Manual X* (Hill *et al*., 1983) presented a rather simplified version of the Trussell procedure.

The precise method of allowing for exposure time makes little difference to the results obtained relative to other data errors and to assumptions about another factor that affects the relationship between the proportion dead and probabilities of dying by exact ages of childhood, namely the age pattern of child mortality. Both model simulations and extensive experience have shown that that the probability of dying by age 5, ${}_5q_0$, is robustly estimated by the proportion dead among children given birth by women aged 30 to 34 years, over a wide range of age patterns of early child mortality. However, infant mortality (based on proportions dead among women aged 15 to 19 years) and the probability of dying by age 2 years (based on the proportion dead among children ever born by women aged 20 to 24 years) are not robustly estimated, partly because they are sensitive to the assumed pattern of childhood mortality and partly because of selection biases.

The second major breakthrough in the use of data on children ever born and surviving was the recognition that estimates of the time reference of the estimate based on each age group of women could be derived if the rate of change of mortality could be assumed to be approximately constant. Feeney (1980) developed a method for using the proportion dead for each age group of women to derive an estimate of the infant mortality rate and the years to which it referred. The basic idea is that both the average exposure time of children and the average time ago to which that exposure refers increase with age of mother. Under conditions of constant child mortality change, the pace of change does not materially affect the time to which each estimate refers. The United Nations *Manual X* provides conversion factors based on parity ratios for estimating the reference dates of successive estimates. One of the important results of being able to locate estimates in time is that results from different surveys can be compared for consistency. Each estimate of ${}_nq_0$ can be converted into a common indicator (${}_5q_0$ is normally

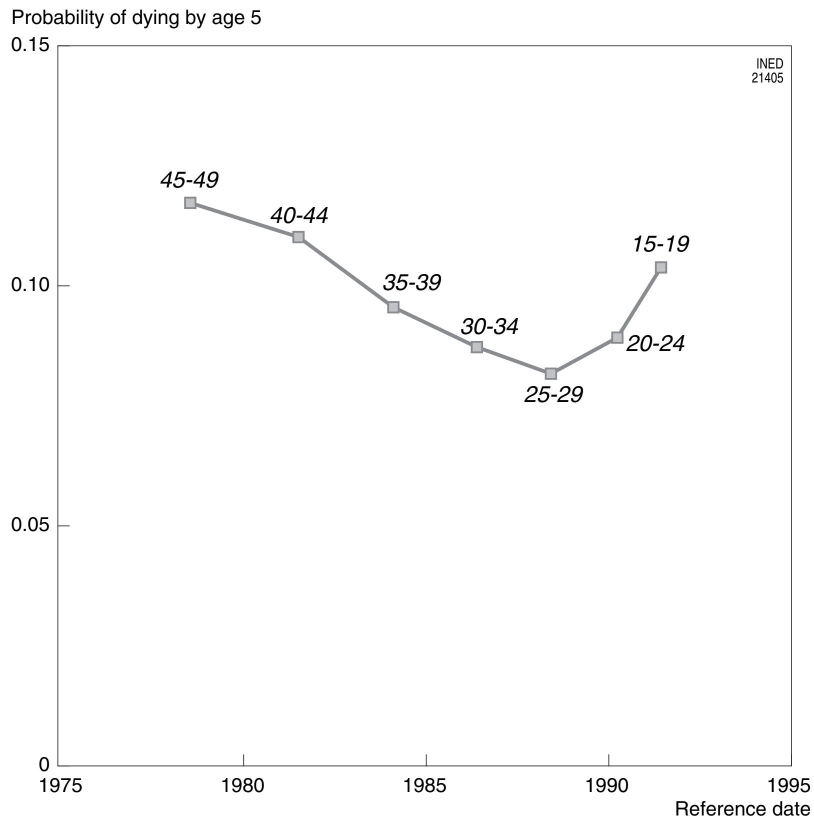

FIGURE 127–1 Indirect estimation of child mortality: Zimbabwe, 1992. Version applied: United Nations (Hill *et al*., 1983) *Manual X* using Coale-Demeny (1983) *West* Family model life tables.

used) using a system of model life tables. The estimates of $_5q_0$ can then be plotted against time and the consistency of successive surveys assessed. Results of the application of the *Manual X* method to data from the 1992 Zimbabwe census are shown graphically in Figure 127–1.

Further developments of the method have explored alternative controls for exposure to risk. One of the problems with the age based method is that early child bearers tend to be selected for low socioeconomic status and thus higher than average child mortality. This effect is clearly visible in Figure 127–1. Thus estimates based on proportions dead of women under age 25 tend to be above the population average. Sullivan (1972), Trussell (1975) and the United Nations *Manual X* provide factors for converting proportions dead by 5-year duration of marriage groups into standard risks of dying in childhood. The advantage of this approach is that the estimate for the first duration group, which gives an estimate with a reference period closest to the survey date, avoids the selection bias that affects the young age groups, since all socioeconomic groups are represented by children in the first duration of marriage group. The problem is that age at marriage may not be closely related to age at initiation of childbearing, particularly in populations with significant levels of premarital fertility. To avoid this problem, Hill and Figueroa (2001) have proposed a method based on time since first birth, but the method has not yet been tested widely enough to draw conclusions about its usefulness.

b. The Previous Birth Technique

A second indirect approach to the estimation of child mortality is the previous birth technique (Brass and Macrae, 1984). This approach is intended for application in settings in which registration or notification of births occurs, but recording of child deaths may be incomplete. At the time of a delivery, the mother-to-be is asked whether she has had a previous birth, and, if so, whether the previous birth is still alive. The proportion dead of the previous births closely approximates the probability of dying by age 2, $_2q_0$, approximately two years earlier. The simple questions can be added to a registration system (if a high proportion of births are registered) or to clinic record-keeping systems (if a high proportion of births occur in clinics). Even if proportions of births covered by the record-keeping system are not very high, it may still be argued that trends in ${}_2q_0$ will approximate population trends. However, concerns about selection bias or changing compositions of births recorded over time (particularly if the data are to be used for evaluating a program that aims to change that composition) may weaken possible interpretation.

2. Consistency Checks

Consistency checks have not played an important role in the development of measurement methods for child mortality (except for comparisons of consistency of alternative indirect estimates for similar time periods, noted above). Although in theory it is possible to compare a time sequence of births and child mortality estimates with the surviving population of young ages, in practice misreporting of ages of young children and uncertainties about true fertility levels make it impossible to draw conclusions about the child mortality element.

IV. ESTIMATION METHODS FOR ADULT MORTALITY

Large numbers of methods have been developed for measuring adult mortality, but the performance of the methods is often less satisfactory than in the areas of fertility and child mortality. As a result, firm information about current patterns, levels and trends of adult mortality is lacking for much of the developing world. One of the main reasons for the uncertain performance of the available methods is age misreporting. Exaggeration of age is an important error in many developing countries, and it affects all the available estimation methods to a greater or lesser extent.

1. Indirect Estimates

Indirect estimates are based on data on survival of relatives. Methods have been developed for three types of relative: parents, spouses and siblings. However, data on parental survival (and particularly survival of mother) are much more widely available than data on spouses or siblings, and more effort has been put into the development of analytical methods for parental survival than into methods for other types of relative. The presentation here therefore will focus mainly on parental survival methods.

a. Parental Survival Method

The basic questions needed to apply the parental survival methods are very simple: *Is your father alive?* and *Is your mother alive?*. Given that the respondent's mother must have been alive at the respondent's birth (and the father at the respondent's conception), the respondent's age provides a measure of the duration of exposure to risk of the parent. If all births occurred to mothers at exact age 25 years, the proportion of mothers alive among respondents aged exactly 20 years would approximate the probability of surviving between ages 25 and 45, $l(45)/l(25)$. If all fathers were exact age 30 years at the conception of their children, the proportion of fathers alive would approximate $l(50.75)/l(30)$, assuming the gestation period to be three quarters of a year. In practice, of course, women bear children at a range of ages from about 15 to 50 (and men beget children at an even wider range of ages). The proportion of those exact age 20 with a surviving mother (or father) is thus a weighted average of a range of 20-year survival probabilities.

The proportion of respondents in a given age group with a surviving parent depends primarily on the level of adult mortality, but also depends on the age pattern of childbearing. The analytical methods for parental survival data (Brass and Hill, 1973; Hill and Trussell, 1977; Timaeus, 1992) have all used model fertility and mortality schedules to model relationships between proportions with a surviving mother (or father) in a given age group and a standard life table conditional survivorship probability. The method is applied by using a standard indicator of the age location of childbearing (the average age of parent for a cohort of births) to control for differences in proportions with surviving parents that result from differences in age patterns of childbearing in order to convert each proportion into a life table survivorship probability. Thus in the United Nations *Manual X* version of the survival of mother method,

$$l^f(25 + N)/l^f(25) = a(N) + b(N)\,M + c(N)\,{}_5PSM_{N-5}$$

where $l^f(25 + N)/l^f(25)$ is the probability of female survival from age 25 to age 25 + N, M is the mean age of mother for a cohort of births (usually for data availability reasons a recent cohort, for example births occurring during the last 12 months), ${}_5PSM_{N-5}$ is the proportion of respondents in the age group (N – 5, N) with a surviving mother, and $a(N)$, $b(N)$ and $c(N)$ are constants estimated by regression analysis of model simulations.

The survivorship indicator estimated from parental survival is not a current estimate but rather an estimate of an average of mortality conditions over the exposure period (determined by the age group of respondents). Brass and Bamgboye (1981) have proposed a simple method for deriving an estimate of time location in the past of each estimate. Because mortality risks increase with age, the time reference is more recent than the midpoint of the exposure period, but it is still the case that estimates of female mortality based on survival of mother data for respondents aged between 15 and 50 years generally refer to time periods from 7 to 15 years before the interviews. As with indirect estimates of child mortality, the ability to locate adult mortality estimates in time makes it possible to compare consistency of estimates between surveys as well as track trends in mortality.

Parental survivorship methods have been widely applied, but with mixed results (for a review, see Timaeus, 1991a). There are some theoretical reasons for cautious interpretation. It is only persons with surviving children whose survival gets reported, and the survival is then reported in proportion to the number of surviving children; any correlation between survivorship and numbers of surviving children (whether through a fertility or mortality differential) will mean that parental survival proportions are not representative of the population at large. An attempt to limit responses to one per parent by restricting analysis to firstborn or eldest surviving children was not successful (Hill, 1977). There are also well-established data accuracy problems, most notably age misreporting (exaggeration of age of respondent increases apparent survival time and biases mortality estimates downwards) and what has been dubbed the *adoption* effect (young children with a dead parent appear to be reported as for a surviving adoptive parent, biasing upwards proportions with a surviving parent). The adoption effect is particularly important for respondents under 15, but age exaggeration may become a problem at almost any age thereafter. Finally, adults with high fertility are overrepresented.

A modification of the basic technique has been developed by Timaeus (1991b) to avoid problems with adoption. In some surveys, data have been collected on parental survival at the time of the survey as well as at some point in the past such as first marriage. The proportions with a surviving parent at first marriage whose parent has died by the time of the survey reflect parental mortality after the respondent has passed the stage of life during which adoption is possible, thus avoiding the adoption effect, and also reflect quite recent mortality risks, reducing the time ago of the reference periods of the estimates. Timaeus developed a method for analyzing such data using fertility, mortality and marriage models. Unfortunately, the necessary data have not been widely collected, so despite the method's promise, it cannot be widely applied. The only survey vehicles in which it has been applied are complex fertility surveys of the Demographic and Health Surveys program phase 1, so experience is lacking on how the method would perform in, say, a population census.

b. Spouse Survival Technique

Attempts have also been made to use information on survival of spouses as a basis for indirect estimates of adult mortality (Hill, 1977). In theory, such methods should work quite well: the problems with parental survival of adoption and multiple responses are removed, the spread of ages at marriage is narrow, and the mortality experience reflected is quite recent. However, in practice, the problems with data errors have been found to be formidable. To avoid effects of remarriage, it is necessary to specify a first spouse, but then misreporting current spouse as first spouse, or adopting a different standard of marriage for surviving partners versus those that may have died, become problems. Also, in populations affected by HIV/AIDS, correlations between spouse mortality may be quite high, resulting in selection biases leading to an underestimation of adult mortality.

c. Sibling Survival Technique

The third type of relative used for indirect estimates of adult mortality is siblings. On average, for respondents age 15 years or older, siblings born to the same mother are distributed by age approximately equally on either side of the respondent's age. Thus if mortality risk is constant with age or changes linearly with age, the proportion surviving of a respondent's siblings should closely approximate the probability of surviving to the age of the respondent. Hill and Trussell (1977) first suggested the use of sibling survival data for estimating mortality, and used fertility and mortality models to examine the relationship between proportions with surviving siblings and standard life table survivorship values. They confirmed that the relation between the proportion of surviving siblings and survivorship to the age of the respondent was extremely strong. Timaeus *et al*. (2001) have since modified Hill and Trussell's approach to reflect the fact that the dispersion of childbearing within families is smaller than the dispersion of fertility at the population level.

Despite its theoretical appeal, sibling survival in its indirect form has not been widely used to estimate mortality. The questions needed are not as simple as they at first appear: *How many brothers/sisters (siblings) did your mother give birth to in total?* and *How many brothers/sisters (siblings) born by your mother are still alive now?*. Note that asking separately about brothers and sisters provides estimates of mortality by sex. One problem with the questions is how to make clear that the respondent should not include him or her self. A second problem is that the respondent simply may not know about children born and died before the respondent reached an age to be aware of such matters.

A modification of the sibling method has been developed to measure maternal mortality (Graham *et al.*, 1989). The questions are changed to focus only on numbers of sisters who survived to reach some life milestone such as marriage or age 15, the number of those who have since died, and, for the dead sisters, whether she was pregnant, delivering a child, or had delivered within the 2 months before death. The risk of maternal death was modeled as a modified fertility function, and for each age group the relation between the proportion of sisters dead of maternal causes and the lifetime risk of maternal death was modeled. The approach has mainly been used in small surveys, and results across age groups have been pooled into a single estimate. Unfortunately, this single estimate has a reference date about 12 years before the survey, reducing the value of the method for monitoring purposes.

The development of the indirect sibling method for estimating maternal mortality led to the inclusion of full sibling histories in a number of DHS surveys (Stanton *et al.*, 1997). The data collection required is much more complex (for each sibling: name, sex, whether still alive, how old if still alive, and if not, year of death, age at death, and, for dead sisters, whether the death met a time of death criterion to be regarded as a maternal death). These data provide a basis for the direct calculation of mortality risks and maternal mortality risks, but initial assessments of data quality suggest substantial omissions of sibling deaths more than 6 years before interview (Stanton *et al.*, 1997).

2. Consistency Checks

Consistency checks in the estimation of adult mortality consist primarily of comparisons of the age pattern of deaths with the age pattern of the population. Brass (1975) was the first to propose the use of consistency checks to estimate death registration coverage. In a closed population, the birth (or entry) rate is equal to the sum of the death rate and the growth rate. Such a relation is necessarily true for any age segment of a population. Thus

$$b(a+) = r(a+) + d(a+)$$

where $b(a+)$ is the "birthday" rate (or entry rate) for the age segment a and over (equivalent to the birth rate for the total population), $r(a+)$ is the growth rate of the population over age a, and $d(a+)$ is the death rate over age a. In a stable population, the growth rate is constant at all ages. If the "birthday" rate (i.e., the rate of entries) is calculated only from the age distribution, but the death rate is calculated from recorded deaths of completeness c (constant at all ages) relative to the population coverage, the relationship then becomes

$$b(a+) = r + (1/c)d^o(a+)$$

where $d^o(a+)$ is the death rate based on reported deaths. Plotting the observed death rate against the observed entry rate for a range of ages a thus permits (if the assumptions of stability, and constant death coverage, hold) the estimation of both the stable growth rate r and the reciprocal of the coverage of the death records c.

If two successive population counts are available, the assumption of stability can be relaxed (Hill, 1987). Assuming that census coverage is constant by age, but may change from count to count, the relationship becomes

$$b(a+) - r^o(a+) = k + (1/c)d^o(a+)$$

where $r^o(a+)$ is the observed growth rate over age a, k is the natural logarithm of the change in coverage from the first to the second count divided by the length of the intercensus interval in years, and c is the coverage of death recording relative to the average coverage of the two counts. Figure 127–2 shows the application of this method to data for males from the 1982 and 1992 censuses of Zimbabwe, using deaths by age recorded in the form of household deaths by age and sex in the 12 months before the 1992 census.

Equations for stable and closed general populations have also been exploited for comparisons between age distributions and distributions of deaths by age. In a stable population, the population age a can be expressed in terms of the deaths over age a and the stable rate of growth (Preston *et al.*, 1980):

$$N(a) = \Sigma D(x)\ exp(r^*(x - a))$$

If deaths are reported with completeness c relative to the population count, the ratio of the population age a based on the above expansion of deaths at ages above a to the reported population age a estimates the value of c. If the stable growth rate is not known, the use of a range of growth rates can be used, with the one that gives the closest approximation to a consistent set of estimates of c across age groups being selected as the best single estimate.

Bennett and Horiuchi (1981) generalized the above relationship to apply to all closed populations, replacing the product of the stable growth rate and the age difference between the population and the deaths

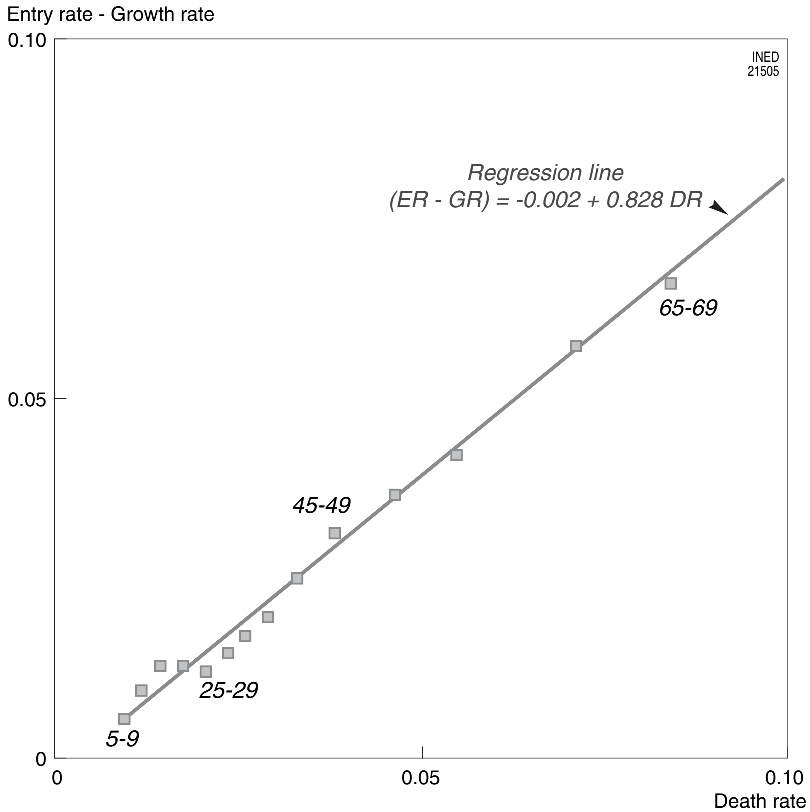

FIGURE 127–2 Application of consistency check to Zimbabwe males, 1982 to 1992.

$(x - a)$ in the above relationship by the sum of the observed growth rates between a and x.

These consistency checks between age distributions and age at death distributions can be thought of as extensions of conventional intercensus survival (whereby intercensus cohort mortality is estimated from cohort decrements between one census and the next) with the intercensus survival (or population age structure) estimates of adult mortality being compared with the estimates based on deaths by age. Assumptions about the nature of the errors (typically that errors are invariant with age) then permit adjustments of the original data and improved estimates of mortality.

These consistency checks have been very widely applied to death distributions obtained from registered deaths and from census or survey questions on recent household deaths. Experience suggests that the methods that assume stability are becoming increasingly inappropriate as populations in the developing world destabilize. The methods that do not assume stability appear to work very well in populations with good quality age reporting (Chinese populations, for example) as long as the coverage of deaths is high enough to be representative of the true age pattern of deaths; coverage less than 60% of those deaths that should be included is likely to give rise to selection bias and lead to unsatisfactory results. In populations with substantial amounts of age misreporting of a nonrandom nature, results can be disappointing.

V. ESTIMATION METHODS FOR MIGRATION

Direct measures of migration are often weak even in developed societies, so it might be expected that indirect estimation procedures would be well developed. In fact, however, the development of estimation procedures for migration has also lagged those for fertility and mortality. Even those methods that have been developed have not been widely applied: utilization of available data has been no faster than the development of methods.

1. Indirect Estimates

Indirect estimates have been largely limited to the use of information on residence of children or siblings to estimate emigration (Zaba, 1986). Mothers are asked how many surviving children they have, and how many of those live in the same country. For the sibling approach, respondents are asked how many surviving brothers and sisters (born of the same mother) they have, and how many live in the same country as the respondent and how many live elsewhere. Models of fertility and emigration are used to develop methods for deriving estimates of migration from the data, usually limiting analysis to the native-born population.

2. Consistency Checks

Consistency checks have followed lines similar to those used for adult mortality. For example, intercensus estimates of migration computed from cohort changes in numbers of migrants can be compared with direct measures of numbers of migrants available from administrative records (Hill, 1987). Use of an appropriate study population (for example, the nonnative population to study immigration) concentrates the numbers of events and improves robustness. As always, to use consistency checks as a basis for adjustment requires assumptions about patterns of data error. These assumptions (constant coverage by age, for example) may often be more problematic in the case of migrants than in the case of deaths or births.

CONCLUSIONS

Techniques for estimating fertility, mortality and migration in developing countries from less than optimal data have been developed over the last 40 years, and have contributed enormously to our knowledge of demographic conditions in the developing world. Over that same period, conventional data on event frequencies—registration of births and deaths—have not improved greatly, though population censuses have become much more an established part of routine and have in many cases improved in quality also. The other major change in demographic measurement has been the widespread use of complex data collection instruments, particularly birth histories, that permit direct estimation of a number of demographic processes. However, because these instruments are elaborate, they are typically only used for small samples, which in turn provide limited geographic or other detail. Indirect estimation procedures, including both indirect methods and consistency checks, remain important as ways of producing estimates for small population subgroups and for tracking trends. The procedures have become increasingly sophisticated and robust over time, but assumptions about true demographic patterns or error patterns still have to be made to interpret results. Purists sometimes find this indirectness distressing, whereas pragmatists accept what they can get.

Model Life Tables

JOSIANNE DUCHÊNE

Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

One alternative to the analytical approach based on mortality curves by age, sex and possibly cause, is to use the life tables produced in some countries to create what are known as model life tables—tables defined numerically, or by the analytical relationships between the "parameters" and other mortality functions, and intended to represent average mortality scenarios at different levels. Broadly speaking, model life tables are used whenever a life table calculated for a given period or place is applied to other populations, either in order to estimate missing data or to predict mortality.

I. MODEL LIFE TABLES BASED ON REGRESSION METHODS AND ON DATA FROM DEVELOPED COUNTRIES

The first attempt to construct a model life table summarizing the mortality patterns of several countries was published in 1944 by Frank Notestein *et al.*, in *The Future Population of Europe and the Soviet Union*, a study whose aim was to project the population of Europe and the Soviet Union. The authors calculated the regression coefficients relating ${}_5q_x$ and e_{10} for $5 \leq x \leq 85$ on the basis of European life tables used for the projections. Using regression techniques, values for e_{10} were obtained from the observed ${}_5q_x$ from $x = 5$ to $x = 20$, and these estimated average life expectancies at ten years were then used to correct the ${}_5q_x$ for $x \geq 25$.

1. The United Nations Tables

Most sets of model life tables were developed through applying regression methods to an array of life tables estimated from relatively reliable data. Vasilios Valaoras elaborated the first collection of such model tables for the United Nations in around 1955, using data from 158 tables essentially from developed countries; some of them had been smoothed using analytical or graphical techniques (United Nations, 1955, 1956; United Nations, 1956). A chain regression method of mortality probabilities (both sexes combined) linked successively ${}_5q_0$ to ${}_1q_0$, ${}_5q_x$ to ${}_5q_{x-5}$, etc., according to the quadratic relation:

$${}_5q_x = A + B\ {}_5q_{x-5} + C\ {}_5q^2_{x-5}$$

where the least squares method is used to estimate parameters A, B and C for each value (5, 10, . . . , 80) of x. These are called *one entry* tables (${}_1q_0$). Forty tables were created in this way for values of ${}_1q_0$ from 20‰ to 330‰ (‰ = per 1,000), corresponding to life expectancies at birth varying from 19 to 72 years. From these tables, model tables for each sex were then established for the total population, by applying standard (fixed) models of age differences in mortality by sex. Ruben Gabriel and Ilana Ronen (1958) criticized this chain method for estimating mortality rates with second degree terms, showing that this approach introduced a systematic bias and, in particular, overestimated expectation of life by approximately two years on average. With linear regression, they then calculated the probabilities ${}_4q_1$, ${}_5q_5$, . . . , ${}_5q_{80}$ from infant mortality ${}_1q_0$:

$${}_nq_x = A + B\ {}_1q_0$$

nonetheless drawing attention to the fact that a quadratic relation would be preferable for estimating ${}_4q_1$, at least for extreme values of ${}_1q_0$. Their aim was to estimate missing data in countries with incomplete—even quasi-nonexistent—or defective statistics.

2. The Princeton Tables

It quickly became evident, as shown notably by Sully Ledermann, Jean Bréas and Jean Bourgeois-Pichat (Ledermann, 1955; Ledermann and Bréas, 1956; United Nations, 1962; Bourgeois-Pichat, 1963), and Paolo De Sandre (1973, 1974), that a mortality schedule could not be adequately characterized by a single parameter. In 1964, Ramakrishna Kurup (cited by Valaoras, 1973) produced five groups or families of model tables, each corresponding to a level of socioeconomic development. In 1966, Ansley Coale and Paul Demeny published four families of model tables constructed from 193 male and female life tables, the great majority from European populations or those of European origin:

- the *East* family, based on 31 tables (5 from Austria, 13 from Germany, 4 from Czechoslovakia, 6 from Central or Northern Italy, and 3 from Poland), characterized by relatively high mortality during childhood and at ages above 50 years compared with other adult ages;
- the *North* family, summarizing 9 tables (4 from Norway, 4 from Sweden and 1 from Iceland), and characterized by relatively low mortality levels below the age of 1 year and above 45 or 50 years.
- the *South* family, based on 22 tables (5 for Spain, 8 for Portugal, 5 for all Italy, 1 for Sicily and 3 for Southern Italy), characterized by relatively high mortality below the age of 5 years and over 65 years, but relatively low between 40 and 60 years.
- a residual group, called the *West* family, was constructed from 130 other national tables for countries with relatively good statistics (7 from Australia, 4 from Belgium, 7 from Canada, 11 from Denmark, 11 from England and Wales, 1 from Estonia, 4 from Finland, 16 from France, 5 from Ireland, 3 from Israel, 6 from Japan, 1 from Latvia, 1 from Luxembourg, 10 from the Netherlands, 12 from New Zealand, 2 from Northern Ireland, 7 from Scotland, 5 from Sweden, 3 from Taiwan, 4 for the white population of South Africa and 10 from the United States).

A matrix of correlation coefficients was estimated for each family, and separately for men and women, between $\log({}_1q_0)$, $\log({}_4q_1)$, $\log({}_5q_5), \ldots, \log({}_5q_{75})$ and both e_0 and e_{10}. As the male mortality indicators were not as well correlated as female mortality indicators, the authors first created a set of female model tables, using least squares linear regression on life expectancy at 10 years (e_{10}) of ${}_nq_x$, for low values of e_{10}, and of $\log({}_nq_x)$ for high values of e_{10}, and an average of the values of ${}_nq_x$ obtained through the two regressions for the values of e_{10} in between. Each family of models included 24 mortality levels defined by female life expectancies at birth from 20 to 77.5 years, by steps of 2.5 years. Ansley Coale and Paul Demeny then derived the corresponding male model life tables, based on standardized differences in sex-specific mortality. The tables were closed using a life expectancy at 80 years estimated by a regression on the number of survivors at 80 years.

In 1983, Ansley Coale, Paul Demeny and Barbara Vaughan completed this set of model life tables by calculating a 25th level, corresponding to a life expectancy at birth of 80 years for women, and extending table estimates to the age of 100 years. Above 80 years, however, the Gompertz formula, based on the hypothesis that instantaneous death rates, $\mu(x)$, grow exponentially with age, was used to calculate the survival curve l_x.

In 1989, Ansley Coale and Guang Guo revised these model tables for very low mortality levels (e_0(F) over 75 years). They modified the tables at three levels:

1. for ages above 80 years, they replaced the exponential growth hypothesis of $\mu(x)$ by a hypothesis of a linear decrease of the ratio $\ln \frac{{}_5m_x}{{}_5m_{x-5}}$.
2. they constructed new model tables, from ages 0 to 100 years, for female life expectancy levels of 77.5 and 80 years for the West family, from 72.5 to 80 years for the East and from 65 to 80 years for the South family of models.
3. they estimated new model tables, common to the various family types, for female life expectancies of 82.5 and 85 years.

Their creators believed that these tables could prove useful for projections in 1989; in fact, from this point of view they very quickly became obsolete as, ten years later, women in some countries had already reached this level.

3. The Ledermann Tables

After demonstrating that entering a model table through a parameter other than the one used to construct it introduced a risk of bias, Sully Ledermann and Jean Bréas (1956) analyzed the principal components of 157 tables which enabled them to identify three vital components of age-specific mortality:

1. the first component close to e_0 depends especially on mortality between 10 and 45 years
2. the second component is defined by mortality over 40 years
3. the third component summarizes mortality over the age of 70 years.

Based on this analysis, Sully Ledermann (1969) then defined seven sets of one-parameter model tables and three two-parameter sets:

1. **One-parameter Sets**

For an entry X, the set is constructed on the relation:

$$\log(q_j) = a_{j0} + a_{j1}\log(X) + s_j\varepsilon$$

where a_{j0}, a_{j1} and s_j are three parameters, ε being a normal variable with a mean of zero and a standard variation of 1.

The seven parameters included are:

set 100: $100 - e_0(MF)$
set 101: ${}_5q_0(MF)$
set 102: ${}_1q_0(MF)$
set 103: ${}_{15}q_0(MF)$
set 104: ${}_{20}q_{30}(MF)$
set 105: ${}_{20}q_{45}(F)$
set 106: $T_{50+} = 44{,}93 + 0{,}5046t_{50+} - 0{,}5587f$

where t_{50+} is the observed death rate over 50 years and f is the proportion (%) of those aged over 65 years among the population aged over 50 years.

2. **Two Parameter Sets**

For two parameters X_1 and X_2, the set is constructed on the relation:

$$\log(q_j) = b_{j0} + b_{j1}\log(X_1) + b_{j2}\log(X_2) + s_j\varepsilon$$

where b_{j0}, b_{j1}, b_{j2} and s_j are four parameters and ε a normal variable with a mean of zero and a standard variation of 1.

The three pairs of parameters entered are:

set 1: ${}_5q_0(MF)$ and ${}_{20}q_{45}(F)$
set 2: ${}_{15}q_0(MF)$ and ${}_{20}q_{30}(MF)$
set 3: ${}_{15}q_0(MF)$ and T_{50+}

In addition to these ten sets of single and double-entry tables, Sully Ledermann published tables of regression coefficients as well as indicators of variation around the estimated central value. The probability (‰) at 85 to 89 years is calculated from the probability at 80 to 84 years, according to the relation:

$${}_5q_{85} = 337.8 + 0.698\,{}_5q_{80}$$

Henri Leridon and Laurent Toulemon (1997) demonstrated that "*the splitting of the single parameter $e_0(MF)$ into two tables* [. . .] *holds several surprises: life expectancies re-estimated for each sex can both be inferior (or superior) to the parameter's value for both sexes combined.*"[1] The same authors suggest a formula to correct the observed life expectancy (EV) and provide the life expectancy to be used (EVU):

$$EVU = 0.009EV^2 + 0.11EV + 17.0 \text{ for } 75 \le EV \le 90$$

The probability (‰) at 85–89 years should be corrected as follows:

$${}_5q_{85} = 200 + 0.9\,{}_5q_{80}$$

II. THE LOGIT SYSTEM

Brass's logit system does not provide a set of model tables but rather the relationships making it possible to create a life table for a given population from a known table, taken as the reference and dubbed "standard" (Brass and Coale, 1968). William Brass developed a method introduced by William Kermack, Anderson McKendrick and P. McKinlay in 1934 (cited by Brass, 1969) to establish longitudinal mortality perspectives, and based on the assumption of a constant relationship between the instantaneous mortality rates at age x of two succeeding generations:

$$\frac{\mu^*(x)}{\mu(x)} = \beta$$

or, since $\mu(x) = -\dfrac{d\ln l(x)}{dx}$.

$$\frac{\ln(l^*(x))}{\ln(l(x))} = \beta$$

William Brass (1971a) demonstrated that the association $\dfrac{\mu^*(x)}{\mu(x)}$ is not constant and that a preferable hypothesis is:

$$\frac{\dfrac{\mu^*(x)}{1-l^*(x)}}{\dfrac{\mu(x)}{1-l(x)}} = \beta$$

or

$$\frac{1}{2}\frac{d\ln l^*(x)}{(1-l^*(x))dx} = \beta\frac{1}{2}\frac{d\ln l(x)}{(1-l(x))dx}$$

[1] "l'éclatement de l'entrée unique $e_0(MF)$ en deux tables [. . .] réserve quelques surprises: les espérances de vie recalculées pour chaque sexe peuvent être toutes deux inférieures (ou supérieures) à la valeur entrée pour les deux sexes."

and, after integration,

$$\frac{1}{2}\ln\left(\frac{l^*(x)}{(1-l^*(x))}\right) = \alpha + \beta\frac{1}{2}\ln\left(\frac{l(x)}{(1-l(x))}\right)$$

or, by definition of logit$(1 - l(x))$,

$$\frac{1}{2}\text{logit}(1-l^*(x)) = \alpha + \beta\frac{1}{2}\text{logit}(1-l(x))$$

In practice, the standard series of survival probabilities from birth to age x, noted $l_s(x)$ by the function logit$(1 - l_s(x))$ is thus transformed, and the probability $l(x)$ for a given population is inferred from the linear relation:

$$\text{logit}(1 - l(x)) = \alpha + \beta\,\text{logit}(1 - l_s(x)),$$

which amounts to the assumption that:

$$\frac{1-l(x)}{l(x)} = e^{2\alpha}\left(\frac{1-l_s(x)}{l_s(x)}\right)^{\beta}$$

The parameter α sets the level of mortality in the sense that, if m is the median age at death in the standard table, then

$$l_s(m) = 0.5$$

$$\text{logit}(1 - l_s(m)) = 0$$

and thus

$$\text{logit}(1 - l(m)) = \alpha$$

Consequently,

- if the parameter α is positive, the probability $l(m)$ is superior to 0.5 and the median age will be higher than m;
- if the parameter α is negative, the probability $l(m)$ is inferior to 0.5 and the median age will be lower than m;

The parameter β translates differences in mortality's age structure in the sense that it controls the relationship between childhood and adult mortality since

$$\text{logit}(1 - l(x)) - \alpha = \beta\,\text{logit}(1 - l_s(x))$$

and thus

- if parameter β is superior to 1, logit$(1 - l(x)) - \alpha$ will be lower than logit$(1 - l_s(x))$ and x will be lower than the median age m whereas logit$(1 - l(x)) - \alpha$ will be superior to logit$(1 - l_s(x))$ if x is higher than m;
- if parameter β is inferior to 1, logit$(1 - l(x)) - \alpha$ will be higher than logit$(1 - l_s(x))$ and x will be lower than the median age m whereas logit$(1 - l(x)) - \alpha$ will be inferior to logit$(1 - l_s(x))$ if x is higher than m;

William Brass uses the logit system for the essentially pragmatic reason that it satisfactorily describes most mortality schedules. To give meaning to this system, William Brass (1975) assumes that the relation

$$y = \frac{1}{2}\left(\text{sech}\left(\frac{x-\alpha}{\beta}\right)\right)^2 = \frac{2}{\left(\exp\left(\frac{x-\alpha}{\beta}\right)+\exp\left(\frac{\alpha-x}{\beta}\right)\right)^2}$$

is used to define a symmetrical curve of mean α and standard deviation β, and that any other curve with the same form but a mean of zero and a standard deviation of 1 is defined by

$$y^* = \frac{1}{2}(\text{sech}(x))^2 = \frac{2}{(e^x + e^{-x})^2}$$

For each value of x, $1 - l(x)$ and $1 - 1^*(x)$ are defined as the proportion of the area under curves y and y^* between the origin and the abscissa x; the following relationship exists between $l(x)$ and $l^*(x)$:

$$\text{logit}(1 - l(x)) - \alpha = \beta\,\text{logit}(1 - l^*(x))$$

the quantity $1 - l(x)$ represents the proportion of deaths occurring before age x, and y is the mortality curve.

This model is good for populations with mortality close to the standard, that is for values of α not too far from zero and values of β close to 1. For a well-chosen standard, the parameter α varies between –1.5 and +1.0 whereas values of the β parameter fall between 0.5 and 1.5. Guillaume Wunsch (1978) demonstrated that β values close to 1 can, however, be as easily associated with very flawed adjustments as very good ones; the value of coefficient β is not therefore a good indicator of the quality of fit. William Brass (1971b), Norman Carrier and Thuang-Jig Goh (1972) and Guillaume Wunsch (1978) all emphasized the importance of the choice of standard. The general standard established by William Brass summarizes the patterns observed in Europe and, as a result, approaches the United Nations model tables or Coale and Demeny's West family of models. William Brass also constructed an African standard to correct data from countries with relatively high mortality in early childhood, and André Lambert (1973) summarized mortality patterns in Latin-American countries during the twentieth century into a standard for each sex. Alongside this diversification of standard tables, Basia Zaba (1979) developed William Brass's approach for generating a set of standards from a general standard in the following way:

$$l_n(x) = l_s(x) + \psi k(x) + \chi t(x)$$

where $k(x)$ and $t(x)$ should distort the mortality schedule at over 70 years and in infancy. The WHO (Murray et al., 2000; Lopez et al., 2000; Murray et al., 2003) elaborated new standards from data from developed and developing countries. Five strata were defined (from A to E) varying according to the ratio of mortality at 0–5 years (${}_5q_0$) to mortality between 15 and 60 years (${}_{45}q_{15}$). These tables were constructed with the aim of taking AIDS into account. Joseph Kamara (1988, 1989) created a three-parameter logit system which he applied to Peru in particular (Kamara and Lansana, 2001).

III. MODEL TABLES BASED ON REGRESSION METHODS AND DATA FROM DEVELOPING COUNTRIES

1. The OECD Tables

From 1977, the OECD Development Centre, with the support of the Department of Demography at the *Université catholique de Louvain*, the project's instigator, gathered raw data on population and mortality structures in developing countries; these were evaluated and adjusted to create mortality tables for these countries. Subsequently, model tables were put together (Clairin *et al.*, 1980) on the basis of data from developing countries whose mortality levels were still high, and including only the 125 cases where it was at least possible to estimate rates at 0, 1–4 years, 5–9 years, . . . , 60–64 years, for each sex. The tables were calculated from unsmoothed age and sex-specific rates and constructed from parameters adapted to the requirements of mortality analysis in developing countries.

Several measures were applied to the 125 tables to evaluate the death registration, and the 21 tables with an undercount of over 50% were rejected. The 104 remaining tables were compared with the Coale and Demeny West model on the basis of a median life expectancy at birth corresponding to different mortality probabilities. Four age groups were compared: 0–4 years (children), 5–19 years (adolescents), 20–44 years (young adults) and 45–59 years (adults). This made it possible to define 3 subgroups (A, B and C) with systematic deviations, and one residual group (D) with no specific characteristics:

- group A has high child, adolescent and young adult mortality, but low adult mortality,
- group B has low mortality among children and the elderly, but high adult mortality,
- group C shows high child mortality, low adolescent mortality, average mortality among young adults and high adult mortality.

From the 4 groups of tables, 4 linear and quadratic regressions were applied:

$$\hat{q}_x = a + b(100 - e_1)$$

$$\hat{q}_x = a + b(100 - e_1) + c(100 - e_1)^2$$

$$\ln(\hat{q}_x) = a + b(100 - e_1)$$

$$\ln(\hat{q}_x) = a + b(100 - e_1) + c(100 - e_1)^2$$

As information on infant mortality is often imprecise, e_1 was preferred to e_0 and the equation regressing $\ln(\hat{q}_x)$ on $(100 - e_1)$ was used to calculate $\ln(\hat{q}_x)$ for each group, and only tables with probabilities falling within the 95% confidence interval defined by $\ln(\hat{q}_x) \pm 2\sigma$ were included. Nine tables that could not be attached to any of the four groups were excluded, and some tables from the residual group (D) were incorporated into one of the first three groups (A, B or C). After these reclassifications, 95 tables remained, distributed between the four groups, known as regions, as indicated in Table 128–1. Region A is characterized by slightly above-average infant mortality, and a very high excess mortality between ages 1 to 9 years which declines until 25 years. Above this age, mortality is below average and becomes increasingly so with age. Region B's mortality pattern is almost the inverse of region A's. In region C, mortality deviates from the mean less markedly than in regions A and B. The mortality structure in region D (residual group containing 40% of the 95 tables) has no relative deviation of over 5%. Not only is there no obvious regional homogeneity but, for a same country, the tables can be classified into different regions according to the period and context. Substantial changes in health conditions affecting these countries have at times transformed radically age structures and mortality levels.

Two models were created: the first used regression and the second was based on median regional standards.

The model based on regression was founded on the relations:

$$\ln({}_n\hat{q}_x) = a_x \ln(q(1)) + b_x \text{ for one parameter}$$

$$\ln({}_n\hat{q}_x) = a_x \ln(q(1)) + b_x n(q(2)) + c_x \text{ for two parameters}$$

The publication contains all the regression coefficients that make it possible to calculate the models, for men and women separately, for the five regions (A, B, C, D and the four groups combined, termed E), and for the 7 one-parameter sets (${}_1q_0$, ${}_5q_0$, ${}_{15}q_{15}$, ${}_{20}q_{25}$, ${}_{15}q_{35}$, $100 - e_0$ and $100 - e_1$) and the 6 two-parameter sets (${}_1q_0$ and ${}_{15}q_{15}$ or ${}_{20}q_{25}$ or ${}_{15}q_{35}$, as well as ${}_5q_0$ and ${}_{15}q_{15}$ or ${}_{20}q_{25}$ or ${}_{15}q_{35}$) that combine information on both juvenile and adult mortality. The most precise single entry sets are those in which ${}_{20}q_{25}$, $100 - e_0$ or $100 - e_1$ are used as the entry parameter. For two-entry sets, ${}_5q_0$ is the best first entry associated with one of three parameters (${}_{15}q_{15}$, ${}_{20}q_{25}$ or ${}_{15}q_{35}$).

The OECD model tables stop at 65 years as most life tables end at 65 or 70 years; in cases where they are taken further, death rates tend to take on unrealistic values above this age. For probabilities above 65 years, the authors recommend linear extrapolation of their logarithms. Guillaume Wunsch (1984) considers it preferable to adjust a 3rd degree polynomial to the probabilities ${}_5q_{50}$, ${}_5q_{55}$, ${}_5q_{60}$ and ${}_5q_{95}$ (assumed equal to 1), and to use it to interpolate the probabilities between 65 and 95 years.

For each region, an $e_0(M)$ can be associated with an $e_0(F)$, and vice versa, using regression equations, although this may be imprecise if there is substantial variation around the central values. The document provides the regression coefficients, calculated for life expectancies at birth between 30 and 70 years. Region D has excess female mortality (women's life expectancy lower than men's) for life expectancies lower than 37.1 years.

The OECD publication includes separate standard tables for men and women, and for all families (A, B, C, D and E). For each family and each sex, these standard tables use median probabilities at every age. Using these standards is identical to Brass' logit approach.

The OECD model tables are the first to be created from mortality data from developing countries whose poor quality affects the precision of the estimates provided. The families do not always correspond to precise geographical areas. It is preferable to use regression coefficients as some tables in annex are abnormal and mortality at high ages is sometimes badly estimated. The current state of computing techniques means that the quantity of calculations needed is no longer an obstacle.

2. The United Nation's New Tables

The United Nations Population Division (1982) applied stricter selection criteria to data gathered by the OECD Development Centre. It included only 36 tables, some of which had been smoothed or corrected. Gaining with respect to data quality, however, entailed losses in terms of representation. Mortality was divided into four sets or "patterns": the Latin American, Chilean, South East Asian and Far Eastern patterns, the average of the four groups known as the "overall average pattern." The model tables were elaborated on the basis of principal components analysis.

The Latin-American pattern is characterized by excess childhood mortality, the Chilean pattern by excess infant mortality, the Southern Asian pattern by excess juvenile and elderly mortality and, finally, the Far Eastern pattern, by excess mortality at older ages. The overall pattern is close to Coale and Demeny's West Model.

IV. APPLYING MODEL TABLES TO DATA FROM DEVELOPING NATIONS

In order to apply model tables to data from the developing world, not already smoothed by some model (including one of the model tables), life tables were compiled from data gathered at the demographic surveillance sites at Agincourt (South Africa), Bandafassi (Senegal) and Matlab (Bangladesh), and published by the International Development Research Centre (IDRC, 2003, taken from http://web.idrc.ca, January 22, 2005). These INDEPTH sites (International Network of field sites with continuous Demographic Evaluation of Populations and their Health in developing countries) possess data on the number of deaths by age, as well as on the person-years at risk during the period 1995–1999. These are recent data. The estimated tables are similar to those presented by the IDRC http://web.idrc.ca/fr/ev-43000-201-1-DO_TOPIC.html, 22nd January 2005). For the Agincourt (South Africa) and Matlab (Bangaldesh) sites, the IDRC used values of ${}_na_x$ corresponding to high mortality countries (over 0.107), whereas we estimate ${}_na_x$ in line with the observed level of infant mortality (under 0.107). On the Agincourt site (South Africa), mortality under five years is low (15‰ for infant mortality and 18‰ for juvenile mortality) in relation to the national average estimate (infant mortality estimated at 45‰, http://www.measuredhs.com, January 22, 2005). On the Bandafassi site, infant and juvenile mortality is high (above 107‰). As for the Matlab (Bangaldesh) site, mortality among the under-5s lies between the high level (above 100‰) and low level (less than 30‰), with infant mortality higher than juvenile mortality. This mortality pattern falls between the Bandafassi (Senegal) pattern of high infant and juvenile mortality, and that of Agincourt (South Africa), characterized by low infant and juvenile mortality. The two graphs below present the death rates observed in each of the three populations (Fig. 128–1).

The three empirical tables were then estimated using the different systems of model life tables. The main results are summarized in the graphs in Figure 128–2.

At Agincourt (South Africa), most models overestimate mortality among children aged under one year, under five years and even under fifteen years, more for boys than girls. Male mortality between 20 and 25 years is precise enough whereas female mortality is estimated in diverse fashions. Mortality between 30 and 50 years is underestimated substantially. As for the two summary mortality measures—life expectancy at birth and at ten years—their estimates carries a maximal error of 10%.

The model life tables make a much more accurate estimation of Bandafassi (Senegal) mortality schedules, even if there is still a 30% gap between the observed and estimated mortality for some model tables.

Matlab's (Bangladesh) mortality is less well modelled than Bandafassi's. With respect to mortality among the under-15s, the Coale and Demeny model tables underestimate by close to 50% mortality probabilities under one, five or fifteen years. On the other hand, mortality between 20 and 25 years is clearly overestimated (up to five times for men by the Ledermann set).

In conclusion, these applications show that the model tables remain adequate for estimating global mortality levels, such as life expectancy at birth or at 10 years. Their ability to represent the age structure of mortality, on the other hand, varies enormously, and no system of model tables stand out as clearly better than the others. The new United Nations model tables or the OECD tables, based on data from the developing world, have no advantage over other, older tables constructed from developed countries' data.

CONCLUSION

Henri Leridon and Laurent Toulemon (1997) compared the different model life tables (United Nations, 1956; Princeton, 1983; United Nations, 1982; OECD, 1980; and Ledermann, 1969) for female mortality corresponding to a life expectancy at birth of forty years. There is clearly (see Table 13.6, page 233) enormous variation in the probabilities ${}_1q_0$ (between 126 and 216‰), ${}_4q_1$ (between 89‰ and 253‰), ${}_5q_{40}$ (between 43‰ and 94‰), and ${}_5q_{70}$ (between 200‰ and 395‰), which reflects the fact that many mortality patterns may exist for the same life expectancy at birth.

Although one might have expected model tables based on data from developing nations to have an advantage, this is in no way born out by the three applications presented. Only life expectancies at birth or at ten years are well reproduced by the model tables.

Almost twenty years after the publication of the OECD and United Nations model life tables, it would

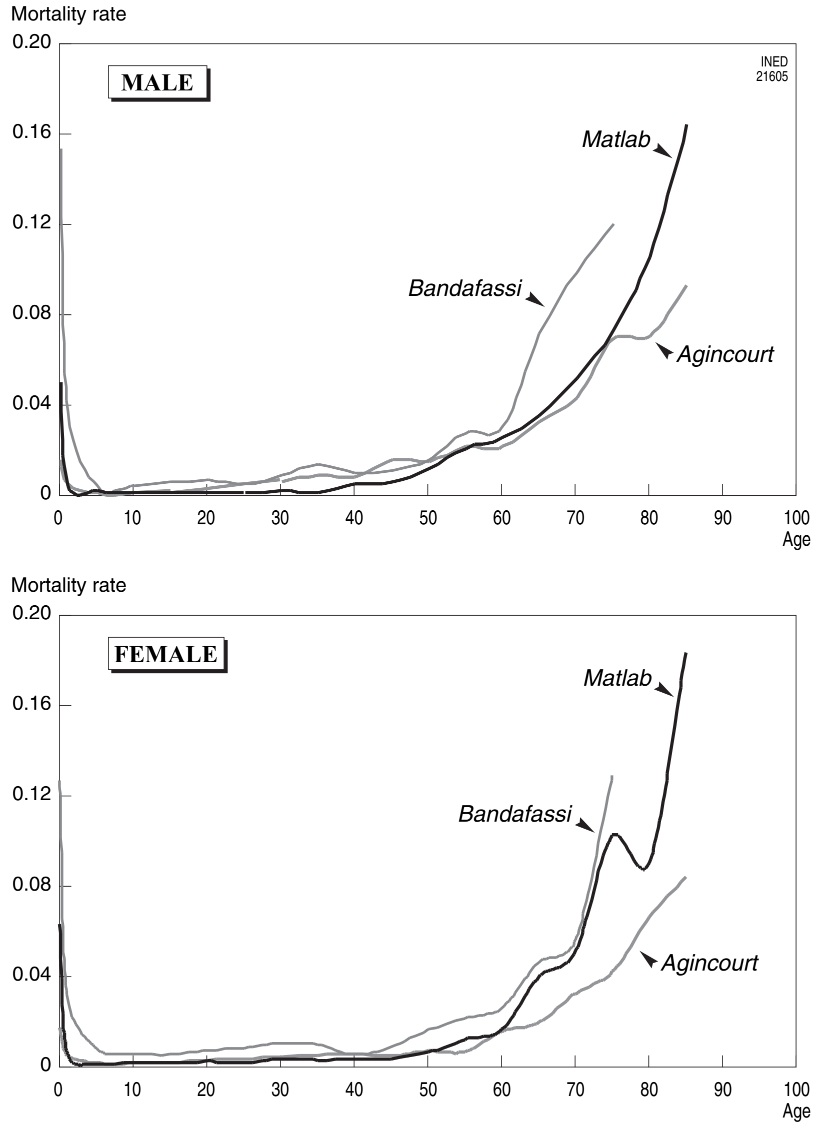

FIGURE 128–1 Age-specific death rates observed at Agincourt, Bandafassi and Matlab.

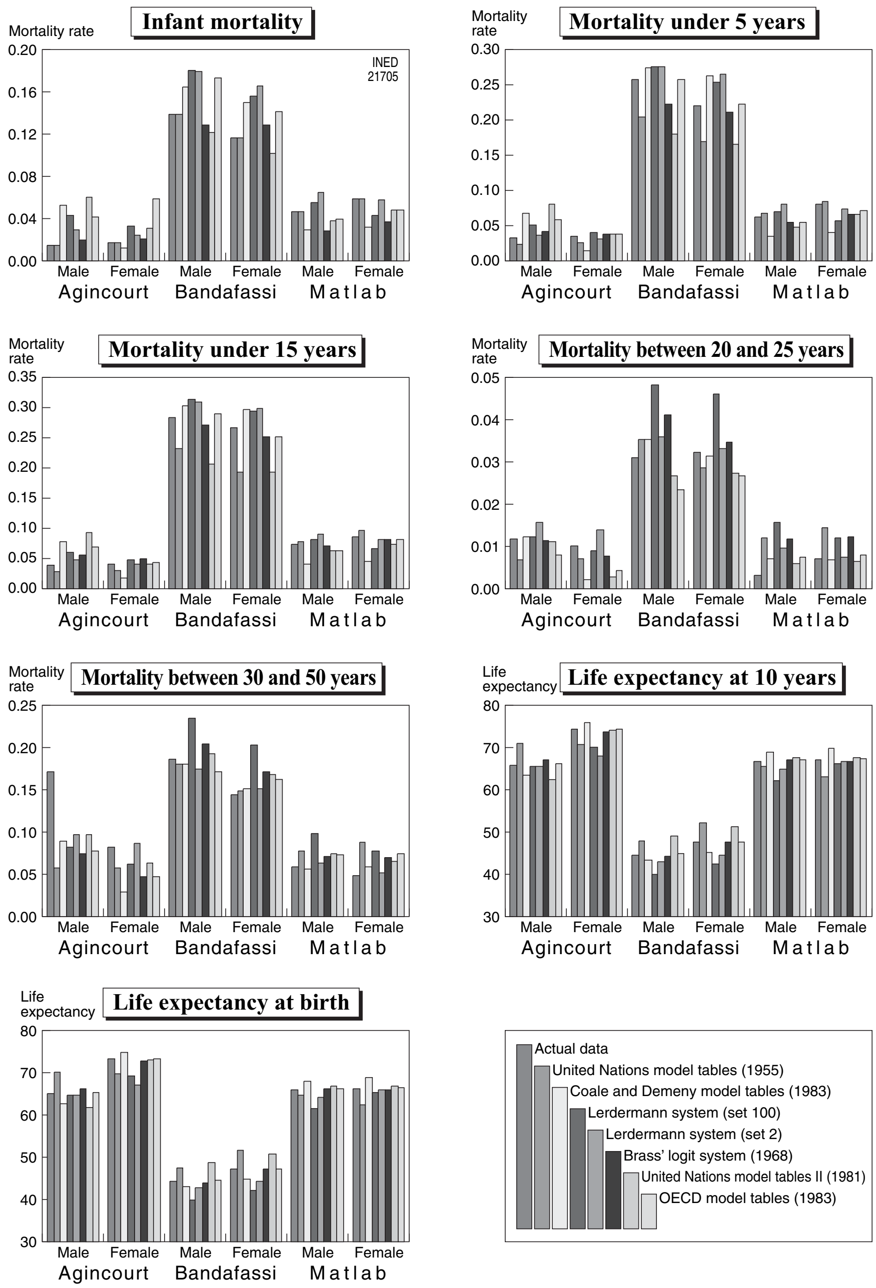

FIGURE 128–2 Results obtained with the different model life tables systems.

undoubtedly be useful to make an inventory of the new tables available for developing countries, and to repeat the exercise to establish new model tables or complete the existing ones, as the WHO did in the year 2000 when it wished to take AIDS into account.

Acknowledgment

The author would like to thank Jacques Emina Be-Ofuriyua for collecting and analyzing the data.

PART

II

STATISTICAL ANALYSES, SPECIFIC TOOLS AND QUALITATIVE APPROACHES

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

This second part brings together a number of methods that are auxiliary or supplementary to demography and are either simply borrowed from other disciplines, or the result of recent developments in particular methods which, while not entirely unconnected with demography, evolved out of (or are being developed from) exposure to approaches prompted by other disciplines. They cover a wide range of different standpoints from the philosophy of science to the most practical statistical methods. There are three main focal points to this section: the application of specific statistical methods to demography, how individual studies can inform demographic analysis, and the value of qualitative approaches in demography.

First, however, Hubert Gerard looks in Chapter 129 at the constraints on (in theory, at least) any attempt at theorization, especially verifying a theory in demography. As in any other social science, it is often impossible to satisfy all these constraints, and it would certainly have been extremely discouraging to commence this treatise on that basis, however logical that might be. But this vexed issue had to be addressed, even if only to agree on the overarching need to know one's limitations: the advancing of any particular theory should always be subject to a note of caution as to its universal applicability.

No less if not more demanding is the search for proof. Albeit one of the most quantitative social sciences, demography like all its fellow disciplines is all-but unable to furnish certain and incontrovertible proof of any causal link. In most cases, the best that can be established is some probability. And even that requires the basis of real causality to be established. A number of causal models can and must be defined so as not to stray from the objective. This is the topic addressed by Josianne Duchêne and Guillaume Wunsch in Chapter 130.

In the following two chapters, Laurent Toulemon reviews various general statistical methods that are particularly useful in demography: multidimensional exploratory analysis (Chapter 131) and regression analysis (Chapter 132). In both cases, the author highlights the value of these methods to demography, exemplified by particularly apposite cases in point from the literature.

Two Chapters then set out to look further into the issue already raised at several points in preceding volumes in relation to particular topics—that of the individual level. While the quantitative analysis of collective macro data is central to the demographic approach, the main aim of which is to understand the driving forces of population development, the question arises as to whether the micro individual behavior component of the mechanisms observed may undermine the undertaking at the final explanatory stage. The further the discipline advances, the more acutely its initial approach is felt to be approaching its limits. The issue then is about going back to the individual level. But how and using what methods? There are many possible answers to this. An outline of just three alternatives is given here.

In Chapter 133, firstly, Francesco Billari puts the question of whether there is really an unbridgeable gap between the micro and macro approaches, or whether an improved dialogue between the proponents of both might be mutually informative and advance matters somewhat more or somewhat better towards the ultimate explanation; although that may still be as unachievable a quest as finding the Holy Grail.

In Chapter 134, Dominique Tabutin addresses the less far-reaching but also more practical topic of developing individual demographic indicators that can in many cases, if not provide firm answers, then at least dispel some ambiguities, by verifying whether the ostensible findings from aggregate indicators are borne out at this more forensic level of study.

In Chapter 135, Alberto Palloni and Paolo De Sandre return to more traditional concepts of demographic analysis, but also come at explanatory research from a different, more advanced and detailed angle through further mathematical analysis of all-order and order-specific fertility.

The two concluding chapters move into an entirely different field, showing how areas which demographers would certainly be misguided in regarding as the preserve of sociology can inform demography. More specifically, Michel Bozon demonstrates in Chapter 136 the benefit that demographic research could derive from a more frequent and purposive use of qualitative methods, while Alexis Ferrand and Ainhoa de Federico de la Rúa offer insights into the potential that an emerging field of sociological study—network analysis—offers for many issues in demography.

129

Theory Building in Demography

HUBERT GÉRARD

Université catholique de Louvain, Louvain-la-Neuve, Belgium

In demography, as in social sciences generally, *theory* is a polysemous term whose different meanings have their own relevance and value. Proof of this can be found in scientific periodicals, in the chapters of this book, or in systematic studies, such as those of Peter Swanborn (1990) or Robert Merton (1945). The latter, published 60 years ago, has become a classic but remains completely current. A number of these meanings can be arranged along a continuum, progressing from a precisely defined and elegantly rigorous theory[1] to one that is flexible enough to encompass virtually anything.

This chapter does not pontificate on what is a "real" theory, reducing all other types to more or less close approximations; it seeks instead to present an approach—already shared by many demographers and social science researchers—that engages the problem of theory building and of defining theory in a less doctrinal fashion, one closer to research as practiced. Rather than defining theory at the outset and then presenting ways of constructing it, I prefer to start with the process of theory building, the process that leads to the construction of one or more theories, that compares theory with reality, and that incorporates these findings into a new theory, which itself is submitted to the process of testing and synthesis. Although I find it useful to present this process in a sequential manner, starting with formulation of the initial question and progressing through theory revision, in actual research, the process has no mandatory path. At any time, it may set off in a number of directions, according to the needs of theory building.[2]

I. THEORIZATION

Without becoming mired in discussions about the definition of science while nonetheless aligning myself with Jean Ladrière (1996), who characterizes the scientific process as both reflexive and prospective, I postulate that science can be viewed simultaneously as the controlled production and communication of knowledge.[3] I also attempt to demonstrate that theory building is the suitable procedure to ensure this control. For a demographer to maintain a critical distance from his or her research, to open it up to new avenues of thinking, and to better communicate the findings, it is essential to be aware of all the twists and turns of its layout, its rationale and foundations, its explicit premises, its strengths and weaknesses, its potential and limits.

[1] Such as Johan Galtung's definition of theory (1973, p. 451), "as a set of hypotheses structured by the relation of implication or deducibility," or that of Paul-Marie Boulanger (1980, p. 11), "a theory is a system of hypotheses relating to a determined factual object, such that each element in the system is either an initial proposition (axiom, postulate, datum), or a logical consequence of one or many of these initial propositions." As Hubert Blalock posited (1971b, p. 156), such theories are far from frequent in social sciences.

[2] This was also emphasized by Hox and Mellenbergh (1990, p. 133).

[3] This material is largely based on my contribution at the Chaire Quetelet, 1987 (Gérard, 1989).

1. Definition

I define *theory building* as "a process of critical systematization of acquired knowledge in a designated corpus of specified propositions generating hypotheses that can be tested against empirical evidence" (Gérard, 1989, p. 271).

First, the process is continuous throughout the research, ideally moving along four fundamental axes. The first axis refers to the scope of the burgeoning theory; this scope is limited to a single situation or specific cases or is more broadly applicable, even claiming universal validity. The second axis concerns the theory's formulation; it ranges from theories that are formulated in ordinary language and are relatively imprecise in the definition of concepts and of the relationships linking them to highly formalized theories. The third axis refers to the qualities of the theoretical framework organized in this way, moving from the simple juxtaposition of propositions to their integration into a hypothetical-deductive corpus.[4] The set of statements organized to create testable hypotheses are tested against empirical evidence, and the extent of testing forms the fourth axis, which ranges from sets that have never been empirically tested to sets that have already been confirmed or refuted by means of relatively substantial testing.

This process begins as soon as the initial question is formulated, and its progression along the four axes is far from linear because of opposing movements of expansion and contraction. Expansion broadens the developing theory's scope, for example, to include a greater number of concepts or to identify new dimensions of existing concepts and give greater complexity to their relationships. Contraction encourages a more rigorous definition of concepts and of their interrelationships, even to the point of reducing their scope, eliminating concepts that escape precise definition, or spelling out the theory's scope more rigorously. This dual movement condemns theory building to be forever incomplete and theory to be no more than an instrument of ephemeral knowledge, constantly to be questioned and improved.

Second, the process is one of critical systematization, aiming to build a set or a designated corpus of propositions in a critical way with clear awareness, explicit formulation, elucidation, justification, and evaluation of what is being constructed, of the manner in which it was achieved, and of its underlying rationale. This type of systematization should make it easier to move ahead on the four axes and should indicate the direction, the detours, and the furthest recesses of theorization. To do this, the concepts and their interrelationships, which together make up the various propositions integrated in this corpus, must have been defined beforehand in a critical manner.

Third, systematization is related to *acquired knowledge*, a generic expression designating the theories and findings of research carried out in identical or neighboring fields—whose relevance for the current research should be specified—and all the *a priori* beliefs, attitudes, value judgments, and stereotypes, which in subtle and hidden ways inevitably introduce all kinds of biases into the research. Rather than ignoring them, these biases need to be spelled out, criticized, and selected; those that seem relevant for the current theorization should be incorporated, and the others should be controlled for as far as possible.

Fourth, the acquired knowledge, thoroughly scrutinized and critically assessed in this way, is then transformed into propositions integrated into a designated corpus—a set of propositions whose characteristics and claims have been made explicit and evaluated. In demographic areas of study, this corpus rarely consists of a deductive set of propositions clearly defining its basic[5] and derived concepts and of its postulates[6] and the propositions inferred from them. Instead, it is a composite set, with contours in need of definition, and one integrating, in a relatively precarious manner, empirical generalizations or propositions founded on analogy, plausibility, or common sense, whose quality needs to be evaluated.

Fifth, identifying and understanding the characteristics and claims of this set, or designated corpus, depend on the manner in which its constituting statements and their relations are designated. Each proposition and every relation between propositions should be assessed in terms of their theoretical foundations and how they stand up in the face of empirical testing.

Sixth, from this set, which is defined, evaluated, and justified in the manner previously described, should follow *hypotheses that can be tested against reality*. Theory

[4] These are logically deduced from postulates that are not necessarily all true or sure (Lalande, 1988, p. 430).

[5] The basic concepts, also known as *primitive concepts*, are stated and often defined from the very beginning of theory building, during the course of which they continue to be added to. They are based on other theories, earlier research, premises stated from the outset, or empirical observation. Their meaning should be stated explicitly without requiring any justification from the elements of the theory being developed.

[6] Like primitive concepts, *postulates* are assertions posited as though they should be accepted as such, that do not need to be derived from the theory being constructed nor tested by it. This should not prevent us from supporting them up as much as possible and justifying their selection for the relevant theory.

built in this way operates as a tool for the production of knowledge, rather than being a mere statement summarizing the end results of research. "Taking note of new knowledge, theory acts above all to display, or ruthlessly expose, everything that contributes to formulate new questions and put forth new hypotheses to answer them, hypotheses elaborated in such a way as to be themselves testable" (Gérard, 1989, p. 172–273).

2. Basic Principles of Theory Building

If, like Mario Bunge (1975, p. 197), we admit that "no technique exists that makes it possible to construct a theory *ab initio*," it is nonetheless possible to suggest some principles that ease progress along the four axes and preserve the theory's status as an instrument of knowledge. I discuss four of the principles: transparency, clarity and precision, empirical testing, and relativity of the theory.

The whole process of theorization, from before the initial question through the results of empirical testing and their integration into a theory, should be as *transparent* as possible to the researcher and to those to whom the research will be communicated. Flaws, weaknesses, and badly constructed concepts or interrelations between concepts should not be disguised, nor should the *a priori* ideologic positions or preconceptions be concealed. Everything should be exposed to the critical evaluation of the author and his or her readers. The researcher needs to know himself and to make that knowledge known; he needs to openly state *a priori* his personal choices, even his feelings about his research object. He should be aware of his discipline's presuppositions and of the theories, methods, and techniques he is using. He should always know and explain what he is doing, how he is doing it, and why.

The principle of *clarity and precision* is fundamental for theory building to progress, even though it tends to lead to contraction rather than expansion. It should therefore be used with care to avoid hindering the type of creativity that thrives in blurred areas, a more fertile soil for developing new concepts or new dimensions of already established concepts, and for adding to the analytical tightness to the relations linking them. This principle leads to tracking down all implicit postulates, to understanding their relevance, and to defining concepts and the chosen interrelations with greater precision, while making explicit their necessary characteristics. It helps to explain the relations established between the different propositions integrated by the theory.

It may seem astonishing to consider *empirical testing* a principle of theory building. Testing often is relegated to the end of the process of theorization, and Hubert Blalock (1969, p. 5) even recommends a division of labor between those who build theories and those who test them. However, I consider theory and empirical evidence as obligate partners, whose relations are admittedly rather complicated. Theorizing can as easily take off from an abstract question, such as from one or more empirical observations. Theory and reality are in constant dialogue throughout the entire process to confirm or refute what one or the other suggests, to open up new avenues, and to refer to those that have already been traveled. As it progresses, theory will attempt to demand more from empirical evidence than mere illustrations or cursory analogies. For its part, empirical evidence will demand well-structured concepts and relations between these concepts to be able to elaborate relevant indicators for these very concepts and their associations, thereby answering theory's demands. To make this dialogue more relaxed and effective, it is also necessary to rely on such artificial constructs as the main and auxiliary theories proposed by Hubert Blalock (1990; 1971a; 1969, p. 5, 151–154).

The principle of the *theory's relativity* highlights the fact that theory is a tool for producing knowledge, not an end in itself. It claims no truth for its statements but presents itself as an ephemeral structure that can always be shaken by empirical testing and whose premises can be questioned at any time.

3. Markers for a Course with No Compulsory Route

Each research process is necessarily unique and is designed according to numerous elements arising simultaneously from the question studied, from the number and quality of studies already carried out on the topic, from the researcher's own characteristics, and from the objectives and conditions of research. Nevertheless, the course that research follows can usefully be marked by key points, or *moments*, when the decisions to be made involve the whole of the theorization process. I identify six moments: the initial question, the main theory, the auxiliary theory, the manner of testing them against empirical evidence, the techniques used for testing, and the results.[7] Even if, logically, they are set down in sequence, in practice, they are articulated in various ways that do not have to follow a linear direction; at any point, they often come back to earlier moments.

[7] These distinctions refer to Hubert Blalock's studies and to the work of Josianne Duchêne and Guillaume Wunsch (1985), who added the *statistical model.*

The *initial question* (i.e., object of the research) supposedly precedes all the other moments, but the latter may lead the researcher to specify, direct, and transform the question in various ways, depending on the case, or even to replace it with another one.

The process of theory building begins as soon as the initial question is formulated; so do elaboration of the main theory—the set of propositions constructed theoretically as well as empirically—and generating hypotheses to be tested empirically. In most cases, scholars present this main theory in ordinary language, even if they take particular care to construct clearly and explicitly the concepts to be used and their interrelations.

In general, the main theory cannot be directly tested against empirical evidence; it needs to be adapted to the concrete conditions of the testing procedure and to the real possibility of collecting and analyzing empirical data to test the hypotheses. The concrete conditions are determined by the objective of the research undertaken (e.g., responding to a request from a ministry or another organization, a term paper, longer-term academic research) and by the researcher's own ability, the time available, and the financial and technical resources at his or her disposal. Moreover, gathering and analyzing empirical data generally involves translating concepts and their connections in terms of the indicators required by the testing method and techniques selected. Adapting and translating the main theory in this way gives rise to one or more *auxiliary theories*, which should be used to assess if these necessary adjustments to the main theory, together with the new propositions that had to be postulated to do this, do not excessively reduce the possibility of empirical testing.

Equally important in the process is selecting a *testing procedure*. This choice also influences the formulation of the auxiliary theory or theories and indirectly influences the main theory that will actually be tested. Without assessing the different procedures available, I discuss quantitative and qualitative procedures and the procedures that use data that is or is not specific to a given research.

Despite the fact that some authors[8] have asserted the primacy or even the exclusivity of quantitative methods for conclusive hypothesis testing, others[9] have attempted to give rigor and quality to qualitative methods in this field. It appears completely legitimate to choose between the two types of procedures or to combine the two. Because these procedures have very different requirements in terms of operationalizing concepts and their associations and of the type of data needed, their auxiliary theory or theories are also different.

To test a theory against empirical evidence on the basis of data collected expressly for this purpose will undoubtedly meet fewer constraints than to do so using existing data gathered for other study purposes. The choice between these two types of data has a bearing on the auxiliary theory and, in some cases, on the main one.

The same applies to the *techniques of observation and analysis* used for testing. Far from neutral for the research, they are hedged in by various postulates and constraints that must be taken into consideration in the auxiliary theory and often in the main one.

After the *results* are in, they need to be assessed with respect to the main theory to ensure that all the hypotheses that the main theory required to be tested have been. If they have not, it is imperative to specify those parts of the main theory that have effectively been tested and, if need be, to decide on how the other results can be used. When the research is over, its findings should make it possible to appreciate the extent to which the main theory answered the initial question and to outline new directions for future research.

In practice, the researcher simultaneously works on the main theory, auxiliary theories, empirical testing procedure and techniques, and to some extent, the results themselves. This is generally the case in qualitative approaches and frequently so in quantitative ones, even in research based on extensive and specific observations that require the first draft of main and auxiliary theories to have been formulated and the testing procedure to have been chosen before starting to collect the data.

The research's key points or moments presented earlier are useful points of reference, but they are in no way a recipe. Each investigator must make the best possible use of them for the research in progress.

II. MAIN THEORY

Developed from an initial question about a given set of facts about the research, the main theory is a structured set of statements, from which are inferred hypotheses to be tested. This main theory and its derived hypotheses claim to reconstruct, partially but meaningfully, the initial set of facts. Usually, the latter

[8] Even Pau1 Lazarsfeld (1970), who was open to qualitative approaches, believed that the existence of a relation between two variables can be truly tested only by statistical analysis or experimentation and that qualitative studies lead only to confirmation or corroboration.

[9] Examples include Michael Huberman (1981), Michael Huberman, and Matthew Miles (1991), as well as the work of Barney Glaser and Anselm Strauss (1970).

is already partially constructed from other theories or from other types of knowledge, such as common sense.

To speak of a partial reconstruction is to recognize that theorizing is not about explaining the data's tiniest details or all the earlier constructions but is concerned with reconstructing the data set in a partial and simplified manner and according to a certain number of reasoned choices explained and assessed by the theory.

Although partial, this reconstruction is nonetheless meaningful; it makes sense in relation to the set of facts (or gives them meaning) and highlights from that set the elements that are essential and sufficient for that theory's project. The essential and crucial elements are those deemed necessary for the reality itself of the facts being reconstructed; they are sufficient from the moment they allow its complete reconstruction, at least relative to the theorization project. A theory aiming to account for high fertility in Africa reconstructs this fact differently when read from the perspective of demographic theory, economic theory, or sociologic theory.

When elaborating the main theory, three elements are particularly important: conceptualizing or constructing concepts, establishing relations between them to build premises and hypotheses, and organizing these assertions into a structured and coherent whole, which was previously called the *designated corpus*.

1. Conceptualization

a. An Absolute Necessity

Although often neglected in general research methodology textbooks in demography and other social sciences, the question of conceptualization is all the more important that social scientists generally use ordinary language rather than neologisms or formal terms or terms sufficiently formal not to be open to interpretations other than the intended one.[10] One exception is demographic analysis *stricto sensu*; its key concepts are rigorously defined, leave little room for various interpretations, and are usually directly measurable.

Everyday language enables us to communicate well in daily life. Up to a point, it makes it possible to label objects, express our moods, think, and communicate. Given the semantic and emotional load it has accumulated over time, it also works as a lens that distorts our perception. Words have an interpretative role that creeps into speech and affects our views. For instance, in the animated and sometimes violent debates at scientific meetings, speakers can use the same words, such as demographic policy, but give them different meanings without ever being aware of it. In the demographic literature, anyone can see the ambiguous nature of much-used concepts such as development, elementary needs, family, family head, household, education, and the desired, expected, or ideal number of children. It is therefore essential to break with the polysemy that words carry and to use words from everyday language in such a way as to make them rigorously and clearly express the only meaning we wish to give them.

An important postulate of our process is that concepts do not exist in themselves; they exist only through creation, use, and convention. In a given discipline or even more in its schools of thought, some concepts are created in a similar way and even codified in specialized dictionaries.[11] It is useful to standardize concepts in such a way as to make possible the communication of knowledge or its accumulation through time. Nonetheless, variations whose scope fluctuates according to the concepts, the discipline, the schools of thought, and other elements, including the context or evolution of the facts themselves, are also acceptable.

For several decades, civil marriage or its equivalent seemed to be the incontrovertible original event for legitimate childbearing, the main source of fertility in most Western countries. Evolution of the types of union since the 1970s has altered the demographic and social meaning of marriage radically enough to make it necessary to modify the standard concepts associated with it.

All investigators claiming to do scientific research must have a firm grasp on the conceptualization of all the terms they use, and these should be similarly understood by those to whom the research is presented. This level of understanding is produced through a new, well-explicated definition of concepts, or by adopting a particular conceptualization recognized by the researchers and those interested in reading the research's results, or by accepting, most often implicitly, the conceptualization generally held by the research's actual and potential readers and shared by the author. As the audience widens, their understanding of concepts risks becoming that of common sense, with all the imprecision and semantic variability that goes with it.

[10] This section of the chapter is mainly based on the work of Giovanni Sartori (1984).

[11] For instance, in demography, Louis Henry (1981) or Roland Pressat (1979).

b. A Complex and Finely Shaded Process

Concept building or conceptualization means giving a word a precise meaning in a manner that is relevant and grounded in sound reasoning and crafting it such that it designates the very objects related to that meaning. It also means breaking with the other meanings and emotional values attached to the word; this is often the most difficult task, so much so that some words need to be treated with extreme caution or even completely avoided. To different degrees, this is the case for ethnic groups, ethnic cleansing, race, and assimilation of foreigners.

The conceptualization should be relevant and built on solid foundations. Relevance is assessed against the aims of the given theorization and research. An exploratory study on the link between infant mortality and mothers' educational levels, based on national aggregate data, may rely on concepts defined in a relatively crude manner; this would be unacceptable, however, for a study of the influence mothers' education has on infant mortality in a particular country.

The foundations of conceptualization can arise from three main registers:

1. From theory, when concepts are constructed from an earlier theory or from an original use of diverse theoretical considerations
2. From empirical observation, when priority is given to individuals' life experiences and conceptualizations or to name and conceptually abstract new empirical observations
3. From usage, if we seek to explain how the concept is generally constructed within a particular discipline (as is generally the case with dictionaries), within one of its schools, or even by a particular author and, in some cases, by common sense

The process of conceptualizing can be grounded in the interaction between these three registers and be so intimately interconnected that it is often difficult to find out which one is at work in a particular instance.

Examples are provided by two definitions of population policy, one rooted mainly in use and the other in more theoretical considerations (Gérard, 1983). Definitions, as we shall see, are important but not sufficient parts of conceptualizing.

Deborah Oakley (1977) carried out a content analysis of 34 definitions published between 1940 and 1975 by well-known demographers or political scientists such as David Glass, Joseph Spengler, Alfred Sauvy, Kingsley Davis, and Hope Eldridge. Oakley observed widespread agreement on the fact that population policy is a governmental action (mentioned in 30 of 34 definitions) that influences or acts on (33 definitions) demographic variables (25 definitions), directly or indirectly (27 definitions). Opinions are more divided on whether nongovernmental organizations should be included (11 in favor, 17 against) and whether the action should be intentional (13 in favor). From this analysis, the Oakley discerns a definition of population policy based on those used by the scientists studied: "Governmental population policies are those actions of government that affect or attempt to affect the balance between births, deaths, and migration of human beings" (Oakley, 1977, p.18).

I wish to define population policy with respect to a question: To what extent can a society voluntarily control its demographic processes? On the basis of mainly theoretical considerations, I suggest the following definition: "A population policy is a system of integrated programs created and implemented with the explicit aim of guiding or changing population dynamics in a particular direction" (Gérard, 1983, p. 25). Such a definition makes sense only with respect to the question asked and in no way represents the definition of a population policy in itself.

Conceptualization should give words precise meanings to remove all uncertainty or avoid possible mistakes. If a definition that states and gives meaning (i.e., a *declarative definition*[12]) can largely reduce or even eliminate all ambiguity, it often remains inadequate for giving the desired meaning with precision and for identifying all the objects that it should designate. As a consequence, it is essential to identify the concept's every characteristic by distinguishing the characteristics that are necessary, without which the intended meaning cannot be given and no object can therefore correspond to this concept, i.e., from those that are contingent, whose presence or absence in no way affects the concept's meaning. A concept's whole set of characteristics and their division into necessary or conditional subsets constitute the concept's *comprehension.*[13] The process of constructing a concept to which a word is attached requires that its comprehension be delineated with care. After this designation established, the selected word no longer refers to anything else, except in a purely contingent manner, and no other word should be used to give this meaning.

In the text (Gérard, 1983, p. 13–26) from which the declarative definition of population policy has been taken, the concept's comprehension consists of the fol-

[12] This is Giovanni Sartori's term (1984, p. 29).

[13] Some authors also talk of the concept's *intention* or *connotation*. According to André Lalande (1988), these do not exactly mean the same thing; in the context of this chapter, however, they are used synonymously.

lowing: (1) to fall under the authority of an organization with powers of decision and implementation in the population sphere; (2) to be action oriented, made up of a set of integrated programs; (3) to have been deliberately created and implemented; (4) to guide or change population dynamics as such, not only one of its components; (5) to have a scientific and ideologic basis for setting the desired population targets, the means to reach these, and the ultimate objectives that these population goals should make it possible to achieve, such as development or well-being, for example. Of these characteristics and given the purpose of the suggested conceptualization—to know the extent to which a society can voluntarily control its population dynamics—the first four are necessary, and the fifth is contingent.

Conceptualization should make it possible to *specify flawlessly all the objects encompassed* by the established meaning and to exclude all others with equal rigor. In this manner, the concept's *extension* (some authors also speak of *denotation*) *is established*, which consists in setting up the criteria according to which every object can be evaluated without risk of error. These criteria are necessarily intimately linked to all the concept's necessary characteristics, because the latter, taken together, are the only ones to establish the concept's meaning. To make things easier, Giovanni Sartori (1984) suggests constructing an *operational definition*, a definition in extension, restricted to observable or even measurable characteristics and providing criteria better adapted to locating and, if necessary, to measuring the objects, even at the expense of reducing the concept's comprehension,[14] albeit only up to a level considered acceptable.

Using the population policy example, a concrete policy could be viewed as falling under the compass of the suggested definition if (1) it comes within the province of national government or of a political body answerable to it, insofar as it has the power to decide and implement the policy; (2) it constitutes a system of programs, not a series of measures taken independently; (3) its demographic objectives are explicitly stated; and (4) its relation to population dynamics as such is clearly explained.

Close to definitions in extension is the usual practice of associating a given word with a specific combination of observations—to indicate, for example, the factors in a factor analysis or some other constructions of empirical data reached through various statistical method, or through thinking and trial and error. The choice of words often seems left to chance or to the researcher's creativity. From the perspective taken here on conceptualizing and to break with the range of meanings and emotions attached to everyday language, it would be best to consider factors or other sets of empirical data as indicators of necessary characteristics of concepts to be constructed "in comprehension." The gap is often wide between what is proposed here and what is done in practice.

Concepts deserve particular attention and effort. Concepts are constructed to serve as tools of controlled knowledge, specifying single meanings for terms. The tools of controlled knowledge should make it possible to understand concepts in the same way when used in the context of the theory. Evidently, all other concepts—the secondary concepts used to construct the theory's concepts—need to be understood in the same unequivocal manner.

Should we therefore define all the secondary, tertiary, and higher-order concepts? Would there be no end to it? A healthy approach would be to construct all the concepts used, whatever their order, unless there are good reasons to believe that these concepts have a single, obvious meaning for everybody or that the possible range of semantic variation remains within the accepted limits to keep the same comprehension of key or primary concepts or because their precise meaning is of little relevance.

2. Establishing Relations between Concepts

The concepts constructed in this way are then related to one another to elaborate the theory's propositions and the hypotheses to be tested. As with the concepts themselves, these relations should be constructed in an appropriate and well-founded manner, to give them precise content. Their *appropriateness* is assessed with respect to the theory's objectives (i.e., to explain, predict, or act) and to the proposition's place within the theory being constructed.

The *foundations* or bases of the relation to be constructed can be (1) a system of postulates deemed satisfactory, when the proposition has been derived in a deductive manner; (2) findings from earlier studies that have held up to critical re-examination and that may not relate to the society under observation; (3) results of exploratory research; (4) a generalization from singular observations, if its grounds are explicitly stated and appraised; (5) the *a priori* argument, whose foundations the investigator attempts to spell out and critically examine; or (6) other elements as long as they are explained and stand up to critical evaluation.

[14] Giovanni Sartori (1984, p. 31) states, "The operationalization of a concept often entails a drastic and eventually distorting curtailment of its connotation."

These foundations are not equivalent and do not endow the constructed relations with the same validity; hence, the importance of identifying them and submitting them to fine critical analysis.

The *exact content* of these relations, except during an exploratory stage, cannot be elucidated merely by juxtaposing statements or through empirical observations. For example, since 1964, fertility has been falling in European countries, and divorce rates started to rise, slowly at first and then much more rapidly. In another example, Algeria's total fertility rate was 5.4 in 1991, with infant mortality at 74 per 1000; 10 years later, in 2001, the rates stood at 3.1 and 55 per 1000, respectively.[15]

As with concepts, relations should be defined "in comprehension," and their necessary characteristics should be identified so as to operationalize the relations, because such operationalization is essential to testing. How can these relations be given an exact content, or how can accurate relations be constructed between events (e.g., , the number of births and infant deaths) or between some variables (e.g., education) and some observed behaviors at the individual or aggregate leve (e.g., breast-feeding)?

For a first approximation, let us look at two main types of relations or models of relations: causal and systemic. In causal models, the constructed associations aim to clarify how effects are produced by earlier or at least concurrent causes (see Chapter 130). In the systemic model, the constructed relations form the framework of a system whose elements are in constant interaction. In the first case, we talk about causes, factors, favorable or unfavorable conditions, direct or mediated determinants, dependence, function, influence, or impact.[16] In the second, we find terms such as information flows, their transformation into action, regulation, balance, retroactions, positive or negative circle, and so on, although without completely rejecting any causal perspective.

Elucidating a relation implies *laying bare its mechanisms* and assessing the validity of our knowledge about them. The relationship between women's education and lower fertility levels in a high-fertility African country is a case in point. We may believe that education provides women with the necessary information for reducing their fertility. However, we need to ascertain that this is effectively the case, that classes are taught on this specific topic in the school program taken by the women and that the women have sufficiently assimilated this information to put it into practice when they need to. We may instead assume that education introduces women to social groups characterized by a cultural model[17] of lower fertility or by a greater openness to cultural models competing with the dominant one and more oriented toward reduced fertility. In the latter case, we would need serious analytic grounds to put forth such a thesis and, if possible, have substantial empirical evidence to sustain it.

Spelling out the mechanisms of this relation makes it possible to specify its content, which may prove much more complex than initially expected, and to identify the necessary characteristics. It also highlights possible intermediate terms between the related concepts and other elements that may be related to these intermediate terms. It therefore provides a clearer insight into the other characteristics of the relationship.

A standard set of questions[18] provides useful guidelines to help specify the relation's mechanisms. Originally devised for the causal approach, these questions seem to have wider application.

1. What model does the relation refer to: causal model, systemic model, or other types, such as relations of belonging, implication, or reference?
2. Does the relationship go in a particular direction and, if so, which? Does it start from one of the two concepts involved (i.e., irreversible relationship), or can it start from one or other of the two (i.e., reversible relationship)? In the latter case, we could also specify the possible conditions, such as time constraints on reversibility.
3. Is the direction positive or negative? Is it associated with an increase or a decrease of one of the given concept's characteristics?
4. With what level of certainty does the association occur? If it does so with complete certainty, the relation is deterministic; if not, it is stochastic.
5. Does it occur immediately (i.e., concurrent relationship), or does it involve a time lapse (i.e., sequential relationship)?
6. Are the two concepts involved sufficient to establish a relationship (i.e., sufficient relationship),

[15] According to data from *Population et sociétés*, 1991, no. 225, and 2001, no. 370.

[16] These terms are not all synonymous, and authors often prefer one or another without explaining the reasons for their choices or the exact meanings they give the terms. It is time to change this practice, which makes empirical testing impossible.

[17] "Cultural models crystallize and interpret the influence that different elements of the sociocultural system may have, even by chance and in an ephemeral way, on procreation, mortality or special mobility; in so doing, they form the type of mental orientations and behavior that society exudes, suggests and values with respect to each risk and to which the subjects adhere undoubtedly more unconsciously than consciously" (Gérard, 1995, p. 48).

[18] Inspired by Hans Zetterberg (1965, p. 69–74).

or is another concept essential (i.e., conditional relationship)?

7. Can the primary concept be replaced by another one, giving the same result for the other concept (i.e., contingent relationship), or is it indispensable (i.e., necessary relationship)?

To illustrate, let us take the example of the association between women's education and reduced fertility in an African country. Education would introduce women to a social world characterized by a cultural model of reduced fertility, one competing with the dominant model. As a consequence, it leads them to identify with this alternative model, to wish for fewer children, and to behave accordingly. This relation belongs primarily to a causal model; it can be broken down, however, into several relations of a different type.

One is a *relation of belonging* that educated women have with a particular social universe. This relation has a direction, starting from education, and it is not reversible.[19] It is neither positive nor negative, but it is possible to foresee a minimum education threshold necessary to belong to this world. Even without much information, a stochastic relationship can be assumed, although it would be necessary to estimate its probability. The relation is sequential, except perhaps for women with educated mothers; it is not necessary if education is not the only condition for belonging to this group and if it can be replaced by economic status. Neither is it sufficient if schooling does not prove to be the only characteristic on which this group is founded and perhaps not even the main one.

Another type is a *relation of reference* to a particular cultural model This relationship has a direction, moving from the group to which an individual belongs toward the cultural model; it is not oriented positively or negatively. It is stochastic if we assume that some of the group's women do not share this particular cultural model for various reasons, which would have to be studied in another research. It is concurrent even if we admit that the reference does not occur immediately on entering the group.[20] It is not sufficient, given the assumption that some women in the group may not adhere to this cultural model. It is necessary from first principles, because reference to a cultural model is posited as inescapable.

A *determinant relation* starts from the cultural model and ends in specific mental, behavioral, and physiologic elements that characterize the individual with respect to procreation.[21] This determining relation implies that the cultural model defines the limits of possible variations of the specific mental (e.g., representations, knowledge, opinions, attitudes, projects), behavioral (e.g., sexual relations, contraception, abortion), and physiologic (e.g., fecundability, infecund periods, intrauterine mortality, likelihood of twins) elements. This determinant relation is irreversible, and it is neither positive nor negative. It is also stochastic but highly probable. It involves a time lapse, one difficult to define, between the model's assimilation through socialization and its realization under social control; it is necessary and sufficient.

It is more problematic to try to describe *causal relations* between specific individual elements in this case, lacking any reference to a well-defined population. A first causal relationship starts from mental elements, proceeds through behavioral ones, and ends up with physiologic elements. Moreover, all kinds of causal relations exist between specific elements, including mental (e.g., effect of knowledge on attitudes, effect of attitudes on projects), behavioral (e.g., effect of frequency of sexual relations on contraceptive use, effect of contraceptive failure on abortion), and physiologic (e.g., effect of intrauterine mortality on temporary infecundability) ones. Relations can be observed that have their roots in physiologic elements and that influence mental and behavioral elements (e.g., lower fecundity brings about a greater lack of precision in the projected birth spacing and number of children or leads to lower contraceptive use). Despite the problems involved, it also seems useful to try to assess whether the cultural model is more closely related to aspirations, motivations, and projects than behavior or whether it affects behavior first.

This effort to spell out relations is rather onerous and involves many postulates that may hinder theory building. However, it makes for much more precise empirical testing.

3. Organizing a Set of Propositions

After they are made explicit on solid and rational grounds, the propositions are related in such a way as to form a coherent set or a set with at least some degree of coherence. This set defines the theory and gives rise to the hypotheses to be tested. Some of these propositions making up the theory's theoretical underpinnings or acting to link with other propositions are postulated without having to be tested within the

[19] It can be assumed that belonging to these groups through an educated mother implies that the young girl is more likely to be educated herself.

[20] We could also assume this reference to have developed before entering the group if a person strongly wishes to join the group.

[21] More detail on specific individual elements can be found in Gérard (1995, p. 46–47, 55–57).

current research because they already have been confirmed empirically or because they have been introduced through speculations deemed sound. Some propositions are undoubtedly better founded and more clearly explicated or relevant than others. When aware of this, it becomes possible to identify the theory's weak points, which may need to be strengthened at times.

In principle, the theory's propositions should be articulated into a hypothetical-deductive whole. Even though greater flexibility may be called for in demography and the social sciences in general, it seems essential to spell out how the different propositions fit together by identifying all the postulates—whatever their soundness and plausibility (assuming that we can evaluate them) and whatever their number (often quite high)—and to explicate as much as is possible and without forgetting to mention the manner in which the other propositions and hypotheses are linked to these postulates and themselves connected. This view on the organization of propositions and hypotheses follows the style of what Lee Freese (1980, 1981) calls *systematic theory*.[22]

III. AUXILIARY THEORY

To test the main theory empirically, it needs to be adapted to the concrete conditions of this testing, to the real possibility of observing the hypotheses to be tested, and to the testing models and techniques to be used. This adaptation requires a language other than that of the main theory: the operational language (Blalock, 1971a, p. 23–24). As Hubert Blalock points out, these two languages are interconnected neither naturally nor by definition, and it is essential to bind them to each other by stating the necessary postulates that, if not grounded in solid reasoning, can imperil the testing process.

Adapting the main theory and translating the hypotheses into operational language are the two tasks of the auxiliary theory. As a result, the auxiliary theory gains from being closely linked to the construction of the main theory.

1. Adapting the Main Theory

The *concrete conditions* to which the main theory needs to be adapted depend on the researcher and the research environment. First, it depends on the research's main purpose, such as work within the framework of a teaching program, a conference paper, an article or book, a study commissioned by a ministry or an international organization, or research within a long-term contract. Also important are the time available to carry out the research, the financial and technical resources at the researcher's disposal, and the idiosyncrasies of his or her training and preferred work methods (i.e., quantitative methods or specific statistical techniques, interdisciplinary comparative approaches, and qualitative approaches). The conditions also relate to the object of study, depending on the degree to which it has already been studied and on the wealth of data available.

The auxiliary theory must take account of the *real possibilities of observing* the hypotheses to be tested through observation of the concepts in all their wealth and many dimensions or through the relations established between them. In this regard, the connection between the main theory's language and the operational one to be developed by the auxiliary theory raises a considerable problem. This is discussed later with respect to the study of indicators. Usually, the auxiliary theory enforces greater precision in the definition of concepts and their relations and reduces the scope of their claims. In some cases, the main theory must be scaled down to remain the theory to be tested empirically.

The *testing models* and associated *techniques* also impose constraints, postulates, and predetermined *forms for receiving* the observed data on the concepts and their relations.

Several auxiliary theories are often needed, such as when combining testing models, when working with several populations for which the same indicators are not available, or when we wish to use parallel indicators within the same population. If, *a priori*, several auxiliary theories seem to better corroborate or refute the hypotheses to be tested, if at least the results converge, it remains to know how to integrate the findings, especially if they diverge, including what procedures to use, which techniques, at what conditions, and at what cost in terms of new premises to be posited.

The auxiliary theory makes it possible to specify the main theory's real scope, to construct the necessary

[22] According to Lee Freese, systematic theory is expressed in everyday language without needing to use mathematical formulations, although these are not precluded. It defines and gives foundation to concepts and to the relations between them, and it dissociates basic propositions from derived ones. Lee Freese also writes, "Systematic theories resemble hierarchies of propositions in which the more specific, ordinary propositions may be deduced from the more general theoretical propositions according to the deductions rules of ordinary language" (Freese, 1980, p. 196–197). This systematic theory, according to Freese, belongs to the type of theories that Hans Zetterberg (1965, p. 94–100) called axiomatic, and it has been used in the work of Wesley Burr and colleagues (1979) in family sociology.

indicators for some concepts and relationships, and to assess whether the adjustments made to the main theory reduces its compass too much. The *precision of the main theory's scope* is achieved (1) by appreciating how much is lost through the constraints imposed by the researcher's and the research environment's concrete conditions; (2) by specifying its precise subject matter, which may be more restricted than the one initially envisaged given these constraints; (3) if it has not already been done in the main theory, by indicating the population to be studied and the parts of it which will be observed.

If necessary, *indicators are constructed*[23] for concepts and their relations emerging from the hypotheses to be tested by identifying and appraising the postulates needed to accept that the selected indicators properly represent the concepts and their relations and to accept not to observe this or that concept, or part of a concept, or this or that relation, or part of a relation that, for reasons to be elucidated and understood, would not be observable.

The loss involved in all these adjustments should to be assessed. When the loss is too great, it may be preferable to discard the main theory and elaborate another one that is more open to empirical testing.

2. Indicators

The scientific use of the term *indicator* is flexible enough to be conceptualized in various ways. Here, an indicator denotes something observable and potentially measurable that encapsulates a given concept or relation.

Definitions "in comprehension" specify the characteristics of concepts and the links between them and classify them as necessary or contingent. For instance, the concept C is defined by C1, C2, and C3 as necessary characteristics and by C4, C5, and C6 as contingent characteristics. To observe C, the indicator should grasp each of the necessary characteristics, C1, C2, and C3, in as much as the following ideas are true:

1. There is no necessary connection between some of these characteristics. If such were the case, observing the relation's starting characteristic would be enough: if C1 leads necessarily to C2, observing C1 and C3 suffices; if the relation between C1 and C2 is both necessary and reversible, it is enough to observe one or the other, as well as C3.
2. No other concept, C′, necessarily characterized by C8 and C9 and necessarily or contingently characterized by C1, C2, and C3, exists. In this case, to observe C, an indicator is needed which ensures both that C1, C2 and C3 are present, and C8 and C9 are absent. For instance, let us suppose fertility planning to be characterized necessarily by (a) a project concerning the number of births, (b) the behavior to achieve this, (c) a project to space births, for each birth, and (d) the behavior to achieve this. If I wish to look at planning only from the point of view of the number of births among couples no longer procreating because the woman has reached menopause, I need to make sure that a and b are present and that c and d are absent.

[23] In demographic analysis, some concepts have already been operationalized, such as age, sex, total fertility rate, and infant mortality rate.

When some necessary characteristics of a concept or a relation cannot be observed, we can attempt to observe instead one or more instrumental variables, preferably necessary ones, or one or more consequences, preferably necessary ones. Alternatively, we can give up any attempt to observe them. In any case, it is important to be aware of the biases this introduces and to evaluate them as well as possible.

To study couples who plan only the number of births—who are necessarily characterized by the two elements a and b and by the absence of elements c and d, we could do the following:

1. We can keep as the indicator an almost necessary consequence in our societies: the number of two births. This means including couples who also plan birth spacing and those who do not plan births because their fecundity level is low and excluding couples who plan only family size but have fewer or more than two births.
2. Use an instrumental variable very common in the society studied, such as including sterilized couples only, if we already know that sterilization is commonly used by couples not wishing to have more children. This means including couples planning only the number of births this indicator adds, those who plan birth spacing, and those who, although not planning numbers of births, were sterilized for other reasons; it excludes couples who plan numbers of births but do not use sterilization.

Whatever the problems encountered and the solution chosen, the procedure must always control and critically scrutinize our research practices. We must be aware of what we are doing but keep a critical distance from it to appreciate the consequences for hypothesis testing.

Whatever the case, an indicator should do the following:

1. Be observable and, if necessary, measurable
2. Be highly predictive or have a good grasp of the particular concept or the relation studied

3. Be connected exactly to the concept or relation, with respect to the observed content (i.e., all, some, or only one of the necessary characteristics or one of the necessary consequences, the very likely consequences, the necessary instrumental variables, or the highly probable instrumental variables) and with respect to the observation's accuracy (i.e., the concept's or relation's reality or reality itself and, in the case of a gradient, the level of the concept or relation).

4. Be valid by representing the concept or relation studied properly, which can be recognized from the information collected in item 3.

5. Be faithful or reliable by always relating to the same content of the concept or relation

The indicators' validity and reliability determines their scope. In principle, to have universal application, the indicator must apprehend all the necessary characteristics. If not, its range is relative and must be reconfirmed every time.

The question of indicators changes when the research begins with data already collected in its raw form or after statistical analysis and when we reflect on the concepts or relations to which these data may correspond. This problem is far from simple, and its solution seems to involve much coming and going between the data and the construction of concepts and relations. For instance, (1) at the start, one or several pieces of information suggest a possible concept; (2) we then attempt to construct this concept and identify its characteristics, separating them into necessary or contingent types; (3) subsequently, we go back to the facts to find data for necessary characteristics for which we have none; and (4) we return to concept building to adjust it more closely to the available data. Evidently, these steps should be well founded and explicated.

CONCLUSIONS

The whole theorization process may appear highly persnickety, uselessly rigid, and at risk of producing meticulous, even obsessive, minds rather than particularly creative ones. What has happened to freedom of thought, the freedom to combine words into sentences that are striking, that arouse debate, and that make clear what the real stakes are, how rich society is, and so on? Nothing in the theorization procedure seems to bridle this freedom. In elaborating a main theory, the researcher can proceed freely and creatively at first. However, if he or she wishes to go beyond preaching to the converted to produce and communicate knowledge that everyone can understand and master, theorization must be transparent and precise, and empirical testing can strengthen these desiderata.

In practical research, theory building follows no mandatory course. To facilitate the presentation, however, I have followed a linear sequence to highlight the key moments of critical reflection, the elements to include, and the postulates to accept where and when they are essential for the process to continue. This does not seem to me more inflexible, persnickety, or obsessional than some statistical technique or content analysis. However, the latter methods are often assisted by computer programs that enable the researcher to avoid appreciating the degree of labor and meticulousness necessary to apply such techniques.

Undoubtedly, theorization as presented in this chapter will need to be refined and perhaps even simplified. It nonetheless seems to be adequate to ensure the controlled production and communication of knowledge needed for all scientific study.

Causality and Causal Models

JOSIANNE DUCHÊNE AND GUILLAUME WUNSCH

Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

One of the main objectives of science is to explain how things work. If some events are interdependent, explanation aims at disentangling the mechanisms that cause these events to occur as they do. Although the scientific approach is not necessarily causal, because science is also interested in functional dependences and in noncausal interdependencies (Robert Franck, 1994), the explanation objective is often achieved through causal analysis. We can therefore refer to causal explanation as the objective of basic research in social science. According to Edgard Morin (1985), "Explanation is a path which makes it possible to acquire objective knowledge by attempting to understand the causal relationships between objects as opposed to understanding based on inter-subjective knowledge, on self-identification with others."[1] Most philosophers and scientists acknowledge that explanation is basically investigation into causes, if we take into account a broad definition of *cause*.

In social science, causal modeling has become an important research tool in recent decades. The Simon-Blalock method for analyzing simple causal structures and the Sewall-Wright path analysis are at the root of many methods that have been developed to test causal hypotheses in social science. In his original article, Sewall Wright (1921, cited by Wright, 1968, p. 325) emphasized the fact that path analysis was developed "as a method of measuring the direct influence along each separate path in a system and thus of finding the degree to which variation of a given effect is determined by each particular cause."

Causal modeling is one of the main objectives of econometrics. The terminology of the *dependent* and *independent* variables used, for example, in linear regression models conveys the idea that a group of variables has an effect on the dependent variable. Consequently, the essential role of econometrics is to estimate and test the explanatory models derived from economic theories. In the preface of his book *Causality in Economics*, Sir John Hicks (1979) indicates two important tasks for economic theory; the first is descriptive, and the other is analytic in the sense that it is used as a means to explain: "We ask not merely what happened, but why it happened. That is causation."

Epidemiology is a field in which the analysis of causal relations has been significantly developed. In their publication on epidemiology, Milos Jenicek and Robert Cléroux (1982) affirm that research into the causes of a disease and its persistence within a human population is one of the main objectives of epidemiologic research. Causal modeling of the process of morbidity has become a basic aspect of epidemiology and a good example of the experimentation model that applies to human populations. However, Daniel Schwartz (1989) concluded his presentation to the Chaire Quetelet 1987 by pointing out "that it is always possible to act without understanding."[2]

These examples show that causal explanation seems to be one of the main objectives of the sciences that

[1] "L'explication est une voie qui permet d'atteindre la connaissance objective en tentant de saisir les relations causales entre objets en contra-distinction avec la compréhension qui est basée sur la connaissance intersubjective, sur l'auto-identification avec l'autre."

[2] "Qu'il reste toujours possible d'agir sans comprendre."

deal with human populations. However, this view is contested by some researchers in social sciences. According to Carol Gould (1983), for example, causality applies to the subject's relationship with the object but not to the subject's relationship with another subject, because causal explanations of human actions are incompatible with the freedom of the individual. Even if we accept Gould's ideas regarding the fact that human actions are guided by a goal, these views do not necessarily lead to the rejection of causality in social science. Carol Gould's argument, according to which objective conditions are necessary but not sufficient conditions of human actions, suggests only that strict determinism is not applicable in this field. If weaker definitions of causality are adopted, the question "what is the cause of human behavior?" remains a relevant one. Another criticism leveled against the Durkheim-like causal explanation in sociology was highlighted by Claude Javeau in his book, *Leçons de Sociologie* (1986). For this author, causes alone do not give meaning to social processes such as revolutions. We must also discover their reasons and motives. According to Javeau, the *cause* of a revolution is the ruling classes' abandonment of power, the *motive* is the will of the dominated classes to take power; the *reason* is their desire to relieve their misery. This view does not seem to be in contradiction with a causal explanation. Claude Javeau's example could be interpreted by a *causal chain* or a *causal process*,[3] which would coincide with current views on causality. Consequently, there is no reason to distinguish between causal explanation and the search for meaning, because the causal theory that we are testing can take into account (under *causes*) the reasons and motives of social actions.

In this context, we would like to develop two points: the concept of cause and effect in social science and the statistical modeling of causality.

I. CAUSE AND EFFECT IN SOCIAL SCIENCE

There is no unanimously accepted definition of causality. A large part of the debate on causality is rooted in the fact that scientists use the term *cause* with different meanings.[4] In epidemiology (Jenicek, 2003), a classic distinction relates to the difference between risk *factors* (i.e., modifiable causes such as smoking) and risk *markers* (e.g., age or sex), which cannot be modified. The same distinction is used by Paul Holland (1986) in statistics; he distinguishes causes that can be manipulated from attributes (e.g., age) that cannot. In social sciences, we speak of determinants or factors rather than causes, without generally making a distinction between risk markers and risk factors.

To what extent does an effect follow its cause? In addressing this point, we separate the deterministic theories of causality from the nondeterministic theories (Karhausen, 1996). Although causality in social science is primarily stochastic because the multiple causes of social phenomena cannot all be known, examining the deterministic theories of causality is a useful frame of reference. Even in social sciences, many researchers still refer implicitly to the deterministic nature of causality. Several concepts examined within this context, such as the disjunction or the conjunction of causes or the asymmetry between causes and effects, have their counterparts in the probabilistic approach.

A well-known supporter of the deterministic theory of causality was John Stuart Mill, and his ideas were outlined in *A System of Logic* (1843, republished in 1889). For John Stuart Mill, the cause of a phenomenon is a combination of all its conditions. When all the necessary conditions are present, they make up the sufficient condition. "The cause, then, philosophically speaking, is the sum total of the conditions positive and negative taken together; the whole of the contingencies of every description, which being realized, the consequent invariably follows" (Mill, 1889). More recently, the "necessary and sufficient" approach of causality has been supported primarily by Richard Taylor. For him, "X is the cause of Y" means that X and Y are two conditions (or combinations of conditions) that occur and that each one is (given all the other conditions that occur) necessary and sufficient for the other one to occur (Taylor, 1966).

A complex version of John Stuart Mill's "combination of all the conditions" was developed by John Mackie (1974). Let $AB\overline{C}$, for example, be the conjunction of sufficient factors for Y to occur. For illustration, Y is the start of a fire, A is the occurrence of a short-circuit, B is the presence of flammable materials, and $\overline{C}$ is the lack of a smoke detector and extinguisher (i.e., the combination of positive and negative conditions in Mill's terms). According to John Mackie, $AB\overline{C}$ is a minimal sufficient condition for Y. There are, however, other possible minimal sufficient conditions, such as $LB\overline{C}\overline{D}$, in which L represents lightning striking the house, D represents the absence of a lightning conductor, and so forth. The disjunctive plurality of the

[3] Other components of the process could exist and could also be taken into account.

[4] For an overall view, see Wunsch (1986); for a detailed discussion, see three papers presented to the Chaire Quetelet 1987 on explanation in social science: Callebaut (1989), Nowak (1989), and Swain (1989). On the historical evolution of the concept, Sosa and Tooley (1993) and Laudisa (1999).

finite number of conjunctions $AB\bar{C} \cup LB\overline{CD} \cup \ldots \cup KMG$ is a necessary and sufficient condition for the effect (i.e., the "complete cause" of Y). Each element (e.g., A) of one of the conjunctions (e.g., $AB\bar{C}$) is an *i*nsufficient but *n*ecessary part of a condition, which is *u*nnecessary but *s*ufficient for the effect (i.e., A is an *INUS* condition for Y).

1. Temporal Anteriority of the Cause over the Effect

An important aspect is the symmetry of the relationship between the cause X and the effect Y. If X is a necessary and sufficient condition for Y, then logically Y is a necessary and sufficient condition for X. To guarantee asymmetry between the cause and the effect, David Hume (1739, republished 1968) imposed the temporal precedence of the cause over the effect. For this author, simultaneous causality does not exist because "if one cause were co-temporary with its effect, and this effect with its effect, and so on, it is plain there would be no such thing as succession." All the objects would coexist, which would lead to the annihilation of time itself. David Kline supported the point of view of David Hume on the basis of the special theory of relativity (Kline, 1980). He starts with the counter-example given by Richard Taylor and taken up in a similar counter-example by Myles Brand (1976): If a force is exerted on a locomotive L at time t_1, it is simultaneously exerted over the wagon C. This implicitly presupposes that *causal information* is propagated from L toward C at a speed equivalent to or greater than the speed of light. This would produce an infinite relative mass that would require the deployment of an infinite force to move it, which is impossible. Kline concluded that for cases of simultaneous causality to have a chance of being verified, the events concerned should be distinct, linked causally, and not separated spatially.[5]

While acknowledging that no real cases of retrocausality have been observed, Michel Ghins (1989) argues in favor of the conceptual possibility of such a retrocausality in physics. He concludes, however, by stating that the possibility of retrocausality does not imply the possibility of influencing the future. Huw Price (1996) also examined the issue of the possible reversibility of the arrow of time and supported the idea of temporal symmetry in physics. James Griesmer (1991) insists that the asymmetry of the relationship is a necessary but not sufficient condition for establishing causality: All asymmetric relationships are obviously not causal.

[5] However, according to Salmon, the *intersection* of two processes can be simultaneous.

The condition of temporal precedence of cause over effect has been adopted by most causal theories because it enables differentiation of causal relations from false associations (Pearl, 2000). However, if several causes contribute to the effect, it is also frequently necessary to take into account the temporal sequence on which these causes occur. This is the reason why we have put forward a causal model where the effect (in this case, the death of an individual) would be the result of different *states* in which this individual had lived during his or her life, with the state defined as the conjunction of relevant variables for the effect, the *time* lived in each state, and the *order* of temporal succession of these states (Wunsch *et al*., 1996). The causal sequence can also be introduced into a path analysis. The main problem with these approaches is the lack of adequate data, except in cases of detailed individual longitudinal observation.

2. Probabilistic Theories of Causality

In many cases, purely deterministic causality is difficult to defend. If we opted for a combination of causes, and if on the basis of this combination, we predicted the occurrence of an event, this event should occur in all of the predicted cases. If the event occurs only in one-half of the cases, something must be incorrect in the deterministic theory. There are two possible explanations. According to the first explanation, the phenomena are by nature deterministic, but the theory is badly specified considering the limits of our knowledge, or our method of observation is prone to random errors. Within this hypothesis, there are "hidden variables" that, if they were discovered, would enable a deterministic description. This was the position adopted by Albert Einstein about the nondeterministic nature of quantum mechanics. In the second case, we are faced with the presence of intrinsically nondeterministic phenomena; in this situation, no additional information can lead to forecasts devoid of error. In the field of human actions, we are often faced with nondeterminism, even if choices are made with certainty (Wunsch, 1988). Consequently, there is a fundamental source of *fuzzy causality* in social sciences, because the events are the results of human actions, and these can be considered to a great extent as nondeterministic. This justifies a probabilistic approach to causality, including statistical modeling.

Several probabilistic theories[6] of causality have been developed. Among the most interesting approaches is

[6] Because of a lack of space, we do not develop the different concepts of probability or discuss their application in scientific explanation (see Jaynes, 2003).

that of Wesley Salmon, which was based on the concept of *statistical relevance* (i.e., *S-R* model) (Salmon, 1971). Later, Salmon (1980, 1984) developed a qualitative theory of probabilistic causality based on the concept of process, interaction, and conjunction of processes, meant to complete the *S-R* model based on conditional probabilities. According to Salmon, a *causal process* is that which transmits a marker, or a signal, of information, energy, or a causal influence from one region of space-time to another. The *S-R* model is therefore only the *basis* of a causal explanation, which needs to explain the ongoing causal process. According to the *S-R* model, let a property C divide a population A (a reference class) into two subgroups AC and $A\bar{C}$. The property C is said to be statistically relevant for an attribute B in A if $P(B/C) \geq P(B/\bar{C})$. For example, $P(B/C)$ is the probability of cure (B) for a reference class of patients suffering from lung cancer who are taking a medicine (C). For those who are not taking the medicine, the probability of a cure is equal to $P(B/\bar{C})$. We observe (Holland, 1986) that the determination of a possible causal impact necessitates at least two causes, C and $\bar{C}$ in the present case. If the medicine is an effective treatment, we should observe a significant increase in the probability of cure in the cases in which the medicine is taken compared with the probability in cases in which the medicine is not taken. For example, if $P(B/C) = 0.20$ and $P(B/\bar{C}) = 0.10$, the probability ratio (or *relative risk*) is equal to $P(B/C)/P(B/\bar{C}) = 2$ (i.e., there is twice a likelihood of cure for those who are administered the medicine compared with the control group subjects who have not been given the medicine). C can be considered in this case as a cause of B. The example shows that, if we follow Salmon, a correct probabilistic explanation does not require high probabilities. What counts is the statistical relevance of the factor (i.e. a significant difference between the *a priori* and *a posteriori* probabilities, or between the results of the target group and the results in the control group).

The reference class should be selected as the greatest *homogeneous* class to which the event belongs. Unfortunately, in most cases, we do not know how to partition the population into the largest group of homogeneous cells (i.e., we do not know all the relevant factors). In the example, if the treatment and the control groups do not differ other than in the fact that one takes and the other does not take the medicine, the difference between the two groups would be due (except for random errors) to the factor that separates the population—in this case, the fact of taking or not taking the medicine. In reality, the exposed and unexposed groups frequently differ in other factors. For example, the treatment can be administered to patients suffering from cancer in hospital M and the results compared with those obtained from hospital N, where this treatment is not used. In this case, the sampling is not perfect because the patients who attend hospital N may have characteristics (e.g., age, social status) different from those of the patients attending hospital M, and the difference between M and N can result from the treatment itself and from the other confounding variables that were not controlled for.

The preceding approach is a specific case of the *counterfactual* theory of causality, whose origin goes back to David Hume. A contemporary version, adapted to epidemiology, is presented by George Maldonado and Sander Greenland (2002). A target population, B, is receiving preventative treatment against an illness (e.g., influenza). During a specified period, let A_1 be the incidence of new cases of influenza observed within this exposed population. What would have been the incidence if this same population B had not had the treatment (i.e., counterfactual situation)? Let A_0 be this incidence. In this case, the *causal contrast* is written in terms of relative risks: $RR_{causal} = (A_1/B)/(A_0/B)$. The problem lies in the fact that we do not know A_0 as it is a counterfactual and therefore hypothetical situation. We must therefore find a substitute for the frequency (A_0/B); let this be, for example, (C_0/D), where C_0 is the incidence of new cases in another population D, which this time does not take the medication. In the case of an imperfect substitution, the causal contrast could be subject to bias as a result of the presence of confounding variables (LaLonde, 1986) (see Chapter 15). Consequently, the problem consists of choosing the correct substitute. *Double-blind randomization* would very probably be the best solution in this example. However, this approach is experimental and frequently impossible for ethical or practical reasons. In a nonexperimental approach that, for example, compares a target group receiving treatment with a control group that is not receiving treatment, for which *a priori* randomization cannot be carried out, we can use the approach proposed by Paul Rosenbaum and Donald Rubin (1983) using *propensity scores*. It is a matter of pairing the observations that have the same propensity score to see whether the treatment is effective or not. The propensity score is defined as the conditional probability of receiving the treatment, taking into account the co-variables observed. This method makes it possible to adequately control the explicit variables (Rubin and Neal, 1992), but it cannot guarantee the avoidance of potential errors introduced by the presence of implicit or hidden confounding variables.

II. CAUSALITY AND STATISTICAL MODELING

Although this chapter is devoted to methods of statistical analysis, epistemologically, there is no reason to limit the determination of causal impact in social science to multivariate statistical methods. In some cases, the theory of information, simulation, or acyclic directed graphs, for example, can also describe the causal mechanism; there are close analogies between the acyclic directed graphs and some statistical methods that are examined later. In other cases, qualitative approaches can be used to shed new light on causal relations that are difficult to understand through other methods. However, most of the work carried out in social science is based on statistical modeling, because many studies are carried out in nonexperimental contexts,[7] in which the researcher is not necessarily aware of all the relevant variables. In this case, the absence of checks in the experiment should be compensated by a series of conditions that should be set (and fulfilled) if statistical methods are used in a causal perspective. However, a statistical model, such as logistic regression, can be used for explanatory ends without explicitly referring to the causal structure of variables.

1. Causal Precedence and Longitudinal Analysis

Any cause needs a period of time, however short, in which to exercise its effects. The importance of the effect can vary over the period between the appearance of a cause and the measurement of its effect. This fact is illustrated by Harry Gollob and Charles Reichardt (1987) by means of a situation that is easy to understand for everyone. If two aspirins are taken to get rid of a migraine, the effect can be nil 2 minutes after ingestion, substantial after 30 minutes, close to maximum after 2 or 3 hours, very reduced after 5 hours, and once more nil after 24 hours.

If the only information available is cross-sectional, the causal effects are generally estimated on the basis of models that are also cross-sectional and that consider only the relationships between the contemporary values of the different variables. These models do not make it possible to specify the relationships between the value at a given time of one or more variables and the value at a previous period of some of these variables and other variables. Among the conditions that justify the use of a confirmatory analysis to evaluate the scientific usefulness of causal hypotheses, Lawrence James, Stanley Mulaik, and Jeanne Brett (1982) called on the condition of stability of the structural model (i.e., the invariance) over a certain period of the parameters of the equations. Harry Gollob and Charles Reichardt (1985) demonstrated that this hypothesis is neither a sufficient condition nor a necessary condition for the cross-sectional model to produce nonbiased estimates of causal effects. For example, if the variables X and Y are standardized in two simple models (Fig. 130–1) and if R is the correlation coefficient between X_{t-1} and Y_{t-1}, we can write $\beta^* = \beta + R\ \varphi_Y$, where φ_Y is the path coefficient between Y_{t-1} and Y_t. Consequently, β^* is a biased estimator of β as long as $R\ \varphi_Y$ is different from zero. Moreover, if the structural stability condition is not respected, the fact that X is the cause of Y is translated by a longitudinal causal system (Fig. 130–2). In this case, if the variances of X and Y and the correlation between X and Y are the same in $t-1$ and in t, $\beta^* = \beta[\varphi_X / (1 - \varphi_X \varphi_Y)]$ will be a nonbiased estimate of β if $\varphi_X = 1 / (1 + \varphi_Y)$, where φ_X is the path coefficient between X_{t-1} and X_t. This relationship is nevertheless as difficult to satisfy as when $R\ \varphi_Y = 0$.

The best method to estimate causal effects is to adjust longitudinal models to individual longitudinal data, while taking into account the presence of contextual effects if it is justified (Courgeau, 2003). If we only have cross-sectional data, Harry Gollob and Charles Reichardt (1985 and 1987) suggest applying longitudinal models with latent variables where unobserved variables are substituted for unavailable variables. To identify this model, additional hypotheses must be set; for example, if the variables are standardized, the equality of the correlations between the periods t and $t-1$ and $\varphi_Y = R(Y_{t-1}) - \beta R(Y_{t-1}, X_{t-1})$. Longitudinal models with latent variables are preferable to cross-sectional models because they oblige researchers

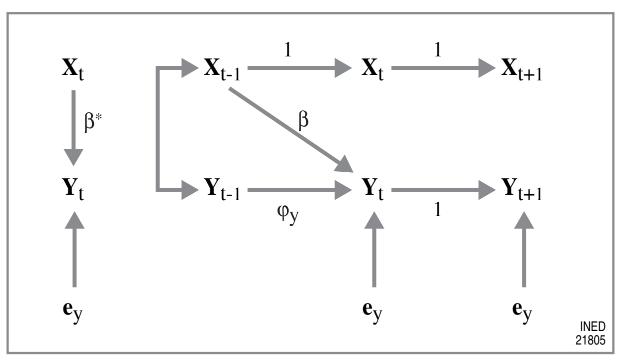

FIGURE 130–1. Causal System A.

[7] Double-blind experimentation is ethically unacceptable or impossible to implement in many cases.

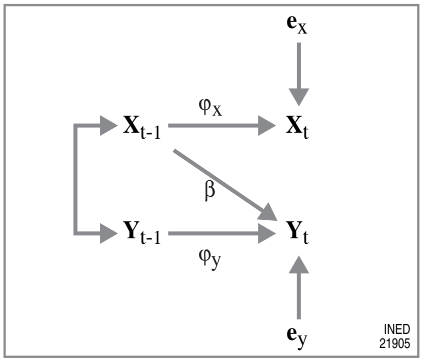

FIGURE 130–2. Causal System B.

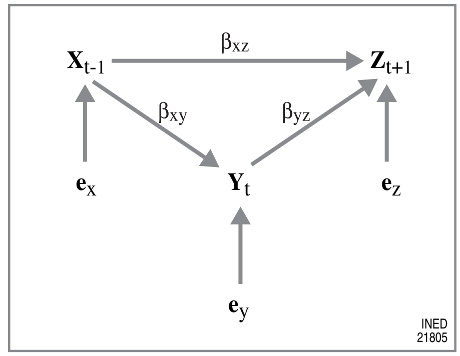

FIGURE 130–3. Longitudinal Causal Model.

to clarify their hypotheses. However, estimation problems can be avoided only by collecting longitudinal data and using longitudinal models, such as life-course analysis (see Chapter 23). However, every population is heterogeneous (see Chapters 10 and 21), and prospective longitudinal data can be affected by selection bias (e.g., the most vulnerable individuals die before others, the strongest individuals migrate and therefore leave the field of observation). Moreover, retrospective longitudinal data depend on memory recall and are therefore not always reliable due to recall lapses.

2. Correlations and Causal Relations

Paul Games (1990) draws attention to the fact that methods based on correlations, such as multiple regression, partial correlation, structural equation models, path analysis, and every method applied to data collected without experimental control, do not enable us to draw conclusions concerning any causal effect. They can only suggest hypotheses on causal relations that must be tested later; association does not necessarily mean causation. These methods are too often used incorrectly to discover causal relations, whereas they were developed to test hypotheses regarding these relations. Sewall Wright, the initiator of path analysis, very clearly defined the objectives of this method in 1934: "It has been emphasized that the method of path coefficients is not intended to accomplish the impossible task of deducing causal relations from the values of the correlation coefficients. It is intended to combine the quantitative information given by the correlations with such qualitative information as may be at hand on causal relations to give a quantitative interpretation" (Wright, 1934, p. 193).

When all the variables are observed on a longitudinal basis, they can be integrated into a linear and recursive causal model, which fulfills the following four conditions: (1) it includes neither causal loops nor reciprocal causal relations; (2) all the relations between variables can be expressed as linear equations; (3) the error terms are not correlated among themselves; and (4) the independent variables of each equation are not correlated with any error terms. Such a model, including three variables for example (Fig. 130–3), can be translated by the following set of equations:

$$X_{t-1} = e_X$$

$$Y_t = \beta_{XY}\, X_{t-1} + e_Y$$

$$Z_{t+1} = \beta_{XZ}\, X_{t-1} + \beta_{YZ}\, Y_t + e_Z$$

The path coefficients β_{XY}, β_{YZ}, and β_{XZ} are estimated by least squares regression methods such that

$$\beta_{XY} = (\sigma_Y/\sigma_X) \,/\, R_{XY}$$

$$\beta_{YZ} = (\sigma_Z/\sigma_Y)\, (R_{YZ} - R_{XY}\, R_{XZ})/(1 - R^2_{XY})$$

$$\beta_{XZ} = (\sigma_Z/\sigma_X)\, (R_{XZ} - R_{XY}\, R_{YZ})/(1 - R^2_{XY})$$

In a recursive longitudinal model, the direct and indirect effects can be estimated through path analysis, which applies to continuous data (Kendall and O'Muircheartaigh, 1977; Herbert Asher 1976). Christopher Winship and Robert Mare (1983) extended its use to discrete data, and Thomas Wilson and William Bielby (1983) applied it to polytomic data.

In the case of probabilistic causal relations between dichotomous variables, Frederick Ellett and David Ericson (1986a, 1986b) show that the β coefficients and three other measurements of association:

$$cov_{XY} = P(X \cap Y) - P(X)\, P(Y)$$

$$cov_{XY}/P(X) = P(Y/X) - P(Y)$$

$$cov_{XY}/\sigma_X\, \sigma_Y = R_{XY}$$

can give only a *qualitative* measurement of the different causal impacts. The signs of these indices indicate whether the causes are positive or negative. They cannot provide quantitative measurements of the causal impact of one dichotomous variable on another dichotomous variable. Ellett and Ericson (1984) also developed an approach based on conditional probabilities to analyze probabilistic causal systems with dichotomous variables. According to Gürol Irzik (1986), Wesley Salmon's approach (1984), which is also based on conditional probabilities, provides the same numeric results as those of causal modeling applied to dichotomous variables. The debate remains open with regard to the adequacy of methods based on correlation coefficients for measuring the causal impact of dichotomous variables.

3. Reciprocal Causal Relations and Temporal Precedence of Cause over Effect

The most frequently mentioned limitation of recursive models is the fact that they postulate the absence of a reciprocal causal relation. These reciprocal causal relations between, for example, X and Y are usually represented in graphs as $X \leftrightarrow Y$ without any reference (explicit or implicit) to the temporal precedence of the cause over the effect. To eliminate ambiguity on this point, it would be useful to employ any one of the following representations:

$$X_t \rightarrow Y_{t+1} \text{ and } Y_t \rightarrow X_{t+1}$$

$$X_t \rightarrow Y_{t+1} \rightarrow X_{t+2}$$

$$Y_{t-1} \rightarrow X_t \rightarrow Y_{t+1}$$

If the system is not in equilibrium (Strotz and Wold, 1960), it is not certain that different formulations will lead to the same results. With these notations, the non-recursive model can be substituted with a model that, of the four possible models, requires the fewest observations. For the model to be recursive, the error terms must not be correlated among themselves, and the independent variables of each equation must not be correlated with any error term. If the systematic measurement errors of variable Y in time $(t - 1)$ and $(t + 2)$ are avoided and if the possible common causes of the error terms are explicitly introduced into the model, most models can be made recursive, and as a result, we can avoid the maximum likelihood or the least squares method of estimation at two or three levels. David Sanders (1980) applied recursive (ordinary least squares) and non-recursive (two-stage least squares and maximum likelihood) models to the same data. Each of these methods provides results that partially contradict those obtained using the other methods.

4. Covariance Structure Analysis

The recursive linear model is sometimes presented as a specific case of covariance structure analysis,[8] combining the path analysis approach with regard to causal structure and the factor analysis approach for the relations between latent variables and their indicators. The use of this method became widespread due to the development of software such as LISREL (Jöreskog and Sörbom, 1996) and EQS (Bentler, 1989), among others. The ordinary least squares used by the correct recursive linear model exactly identified the result, and the maximum likelihood used by the software LISREL provide the same results as long as the matrix of correlations not include any random components, which amounts to presuming that large enough samples are being used. Bruce Biddle and Marjorie Marlin (1987) advised against using LISREL with small samples. Moreover, Peter Bentler and Paul Dudgeon (1996) examined the consequences of not respecting the hypotheses of the model in the case of nonexperimental studies, notably the hypothesis of distribution normality. Various solutions have, however, been suggested to take into account the non-normality of variables (Shipley, 2000). If we construct latent variables from several indicators using the LISREL or EQS software, we should be aware that this procedure is not equivalent to a regression by ordinary least squares, which would take into account the factor scores resulting beforehand from factor analysis applied to the indicators. Some studies have extended the approach to latent dichotomous variables (Eshima *et al*., 1996) and to multinomial variables (Moors, 2003, provides an example of the application). As is the case for path analysis, we must emphasize the fact that the sole analysis of covariance structures with latent variables cannot confirm a causal relation; causation needs modeling, background knowledge, and explanatory theory. A detailed discussion of this issue is provided by Judea Pearl (2000). However, it enables certain structures to be disconfirmed (or falsified) in favor of others that are better suited to the available data.

5. The Concept of Functional Relation

Stanley Mulaik (1986 and 1987) suggested using the functional relation concept with a view to synthesizing the deterministic and probabilistic formulations of causal relations between *continuous* variables. This concept makes it possible, according to Mulaik, to unify different models such as analysis of variance, the generalized linear model, structural linear equations, and log-linear models. It is a case of setting hypotheses whose *cause* variable values determine not the specific *effect* variable values but rather the conditional

[8] For an example, see Lopez Rios and colleagues (1992).

probabilities with which the different values of the effect variable are observed.

6. Correlation and Causal Link between Dichotomous Variables

Frederick Ellett and David Ericson (1986b) located, in social science research and in the philosophy of science, four conceptions of the correlation between two dichotomous variables X and Y.

First, the social science researchers Patricia Kendall and Paul Lazarsfeld (1950) and the science philosopher Ernest Nagel (1961) use the conception according to which two dichotomous variables X and Y are positively (or negatively) correlated if, and only if, the probability of X and Y minus the probability of X multiplied by the probability of Y is greater (or less) than zero. It can be shown that

$$P(X \cap Y) - P(X)\,P(Y) = P(X \cap Y)\,P(\bar{X} \cap \bar{Y}) - P(X \cap \bar{Y})\,P(\bar{X} \cap Y) = cov_{XY}$$

Second, for the science philosophers Hans Reichenbach (1956) and Patrick Suppes (1970), two dichotomous variables X and Y are positively (or negatively) correlated if, and only if, the (conditional) probability of Y if X minus the probability of Y is greater (or less) than zero. If $P(X) > 0$, it can be shown that

$$P(Y/X) - P(Y) = [P(X \cap Y)\,P(\bar{X} \cap \bar{Y}) - P(X \cap \bar{Y})\,P(\bar{X} \cap Y)]/P(X) = cov_{XY}/P(X)$$

Third, according to a third conception used by Wesley Salmon (1980), two dichotomous variables, X and Y, are positively (or negatively) correlated if, and only if, the (conditional) probability of Y if X minus the (conditional) probability of Y if $\bar{X}$ is greater (or less) than zero. If $1 > P(X) > 0$, one can show that

$$\begin{aligned} P(Y/X) - P(Y/\bar{X}) &= [P(X \cap Y)P(\bar{X} \cap \bar{Y}) - P(X \cap \bar{Y})P(\bar{X} \cap Y)]/[P(X)\,P(\bar{X})] \\ &= cov_{XY}/\sigma_X^2 \\ &= b_{XY} \end{aligned}$$

Fourth, social science researchers such as Herbert Asher (1976), Hubert Blalock (1964), and Herbert Simon (1957) use the fourth conception, according to which two dichotomous variables X and Y are positively (or negatively) correlated if, and only if, the coefficient ϕ is positive (or negative). If $1 > P(X) > 0$ and $1 > P(Y) > 0$, the coefficient ϕ is defined as

$$\begin{aligned} \phi_{XY} &= [P(X \cap Y)P(\bar{X} \cap \bar{Y}) - P(X \cap \bar{Y})P(\bar{X} \cap Y)]/[P(X)P(\bar{X})P(Y)\,P(\bar{Y})]^{1/2} \\ &= cov_{XY}/(\sigma_X\,\sigma_Y) \\ &= r_{XY} \\ &= b_{XY}\,\sigma_X/\sigma_Y \end{aligned}$$

These four measurements of association have the same sign (i.e., the cov_{XY} sign). Consequently, all the measurements lead to the same *qualitative* conclusion that X is not a cause of Y if they are equal to zero or that X is a positive (or negative) cause of Y if they are greater (or less) than zero.

A *quantitative* approach to causality attempts to establish whether X is a cause of Y and to measure the degree of causal influence that X has over Y. However, from a quantitative point of view, it is possible to show that if $1 > P(X) > 0$ and $1 > P(Y) > 0$,

$$cov_{XY} < cov_{XY} / P(X) < b_{XY} \qquad (1)$$

$$cov_{XY} < \phi_{XY} \qquad (2)$$

and if $\phi_{XY} > 0$, it satisfies one of the following three inequalities:

$$cov_{XY} < \phi_{XY} < cov_{XY}/P(X) \qquad (3.1)$$

$$cov_{XY}/P(X) < \phi_{XY} < b_{XY} \qquad (3.2)$$

$$b_{XY} < \phi_{XY} \qquad (3.3)$$

Frederick Ellett and David Ericson (1986b) stated the following:

> If some effect B has two causes, A and C, and if A is a sufficient cause of B, or if A is a probabilistic cause of B (with probability 1), in general, the correlation between A and B must be nonnegative but it need not equal 1. If A is a probabilistic cause of B (with probability p < 1), then the sign and the magnitude of the correlation will depend on background assumptions involving certain features of the other causes of B. . . . If A and the other causal factor are uncorrelated, the correlation between A and B will be non-negative, but in general, it will not equal p. If the expectation of A and the other causal factor is zero, or if A and the other factor are maximally negatively correlated, the correlation between A and B can be negative. We also claimed that the INUS conception of causation and the INUP[9] conception of causation produce results which parallel those obtained for the probabilistic conception.

III. TOWARD AN EVIDENCE-BASED DEMOGRAPHY

Causal relations cannot be highlighted by using statistical methods only. A statistical model can be suitably adapted to available data, and the results can be statistically significant. However, this does not mean that it alone can result in causal inference. Like medicine, in which evidence-based scientific conclusions (see Chapter 52) prove essential for patient survival, we can conclude this chapter by emphasizing some conditions that must be fulfilled if we wish to respond to causal-type questions.

[9] A probabilistic generalisation of the INUS cause.

According to Mark Elwood (1988), a causal influence necessitates the following questions. What hypothesis is being tested in this study? How has the observation been carried out (e.g., is it an experimental study or not; is it cross-sectional or longitudinal)? Which population has been observed? What was the main result? At the level of internal validity, have the results been influenced by observation errors, by confounding variables, or by randomness? The following questions could also be added. If a statistical model has been used in a nonexperimental approach, does the model fit well with the data?[10] If several models fit equally well with the data, have we used the simplest one, and if not, why not? With regard to causality, are the observed variables in the correct temporal order? Is the relation between presumed cause and effect a strong one? How does the effect differ according to the variation of the cause? Is the presumed causal relation observed within different subpopulations? At the level of external validity, can the results be extended to cover the whole population? For example, in the case of a longitudinal study, to what extent does loss from observation affect the extrapolation of the survey results to the general population? Can the results be extrapolated to other populations? Are the results consistent with those of other studies? Are they plausible with regard to what we already know about the subject and according to the underlying theory of the study? These questions are applied at various degrees according to whether the research is descriptive, explanatory, or intervention based. It is nevertheless useful to ask them, before coming (often too quickly) to any conclusions on the cause-effect relationship.

Acknowledgments

The authors are particularly grateful to Alberto Palloni and Federica Russo, as well as an anonymous referee, for their relevant suggestions about a previous version of this chapter. This chapter was translated from the French version by Accenta Ltd.

Multidimensional Exploratory Analysis

LAURENT TOULEMON

Institut national d'études démographiques (INED), Paris, France

Basic demographic data for a population are most often reported by age, sex, and year. Demographers may work with regional population counts by sex and age at different dates or events (e.g., births, deaths, marriages, entries or exits) categorized by sex, age, and year.

In addition to these fundamental components, demographic analysis can incorporate complementary information, such as rank among children of the same mother for births; causes of death; and reason, place of origin, or place of destination for migrations. The data can be extended to other areas for analysis dealing with more complex phenomena (e.g., transition to adulthood, which is marked by the occurrence of multiple events) or when the population is divided into groups with multiple characteristics (e.g., regions defined by a set of demographic and socioeconomic characteristics).

Regression models seek to *separate* the contribution of each *factor* to variation in the phenomenon being studied and can be seen as methods of standardization (see Chapter 132). Conversely, multidimensional exploratory methods serve to identify the *global structure* of the data and summarize it using indices constructed after the fact, with reference to optimality criteria based on the proportion of information explained. In this chapter, I present techniques for exploratory analysis of data and then describe several methods of multidimensional analysis and classification used in demography.

I. EXPLORATORY DATA ANALYSIS

Methods for *exploratory data analysis* are characterized by the refusal to impose an *a priori* model on the data. Their goal is to summarize as best as possible the structure of the information present in the data. Given a set of data, exploratory methods use different graphic procedures to summarize the variables, first individually and then in groups. They are also useful for identifying points that are outliers with respect to this structure.

Exploratory data analysis can focus on the distribution of a single variable, on conditional distributions, or on relationships between several variables. Once considered too simple for statisticians, this form of analysis has spread widely thanks to improved software, and it is now part of the basic statistical toolkit (Cleveland, 1993; 1994; Erickson and Nosanchuk, 1992; Hartwig and Dearing, 1979; Tukey, 1962). The practice of exploratory data analysis can also profit from the application of insights from statistical graphics (Tufte, 1990, 2000; Bertin, 1967). Eugen Horber (2004) has provided a well-annotated bibliography.

1. Distribution of a Single Variable

The box-and-whiskers graph, or *box plot*, is an efficient way to represent the distribution of a variable (Tukey, 1988; Chambers *et al*., 1983). Take, for example, a variable X defined by n elements and a set of values

$\{x_i\}_{i=1,n}$. This set of possible values can be described by a *five-number summary*. The median M divides the set into two equal parts; one-half of the elements has values lower than the median, and the other half has higher values. Around the median, the first and third quartiles Q1 and Q3 separate elements arranged by order of value into four quarters of equal size. Outside of the interquartile range [Q1; Q3], limiting values are defined to show the maximum dispersion of the variable. First, the limits within which the values should *normally* be found are calculated, with the interquartile range serving as a reference to determine the *normal* range of variation; $m = Q1 - 1.5\ (Q3 - Q1)$ and $m' = Q3 + 1.5\ (Q3 - Q1)$ are, respectively, the lower limit and the upper limit that can be assigned to this distribution. The observed extreme values m_1 and m_3 are, respectively, the smallest value larger than m and the largest value smaller than m'. Most often, m_1 and m_3 are the extreme values taken by X. If this is not the case, values outside the interval $[m_1; m_3]$ are considered to be outliers and are explicitly indicated as such. The distribution of *X* is represented by a *box* from Q1 to Q3, including the median M and *whiskers* linking the quartiles to the limiting values. Values outside the limits are shown as single points to complete the graphic (Fig. 131–1A). Sometimes, extreme values whose distance from the quartiles is more than three times the interquartile range are indicated using different points (NIST/SEMATECH, 2004). In the fictional example provided, the distribution of the variable *X* has a longer tail in the direction of the higher values; the median is toward the bottom of the box, the top whisker is longer than the bottom whisker, and there is an outlier in the upper half of the box.

Extreme values should first be verified, because the assumption is that they result from an error in measurement, coding, or data entry. They can then be the subject of a specific study justified by their exceptional position, or they may be suppressed when studying the distribution of X. The treatment and possible suppression of these outlying points is the first step in the examination of data. However, the general form of the distribution depends on the scale used to observe X, and scale may also influence the diagnosis of extreme values. If a transformation of X is observed instead of X itself, the form of the distribution is changed. For example, Figure 131–1B shows the logarithmic transformation ln (X) instead of X. An extreme value is now observed in the direction of the minimum values.

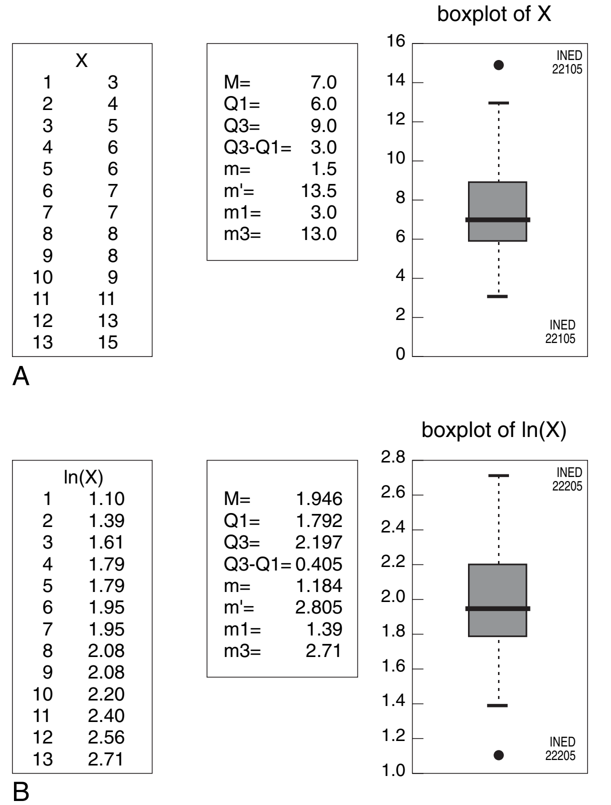

FIGURE 131–1 **A:** Example of a box-and-whiskers plot. **B:** Example of a box-and-whiskers plot after transformation of X to ln (X).

2. Conditional Distributions

Conditional distribution is particularly useful for comparing different distributions. Let us start with a very simple example using demographic data by age and by year, such as the probability of first birth for French women between the ages of 15 and 49 years, as observed from 1946 to 1989 (Ni Bhrolcháin and Toulemon, 1996; Rallu and Toulemon, 1993).

The series of age-specific birth probabilities, presented in two graphs for clarity (Fig. 131–2), can be summarized in a series of box plots graphed by age (Fig. 131–3) or by year (Fig. 131–4). Figure 131–3, which presents a series of box plots by age, shows that probabilities before age 25 are more variable than those at older ages during the period under study. The distributions are not symmetric at young ages or at older ages. The distribution of probabilities at young ages is more spread out in the direction of the low values, whereas at older ages, the reverse is true. In both cases, the extreme values are found at the end of the period, showing that birth probabilities in the 1980s are moving away from the distributions in earlier years, falling at young ages and rising at older ages.

The same data are presented from a different angle in Figure 131–4, which shows years along the x-axis and, for each year, the distribution of birth probabili-

FIGURE 131–2 **A:** First birth probabilities by age from 1946 to 1989 in France for women between the ages of 15 and 25 years. **B:** First birth probabilities by age from 1946 to 1989 in France for women between the ages of 25 and 45 years. (From Ni Bhrolcháin and Toulemon, 1996).

ties for ages 18 to 37 years. The compression of interquartile intervals Q1 to Q3 is clearly visible in this graph. The probabilities are less and less differentiated by age; the decrease in probabilities at young ages stretches the distribution toward the lower end, whereas at the other end of the distribution, the maximum value decreases. Starting in 1973, the extreme values decrease; on one end, the minimum probability (at age 18) falls, and on the other end, the ages where fertility is highest spread out around age 29 years.

The exploration could be made more precise by separating the data in Figures 131–3 and 131–4 into subsets. For example, Figure 131–3 could be separated into two figures showing the distribution of birth probabilities at each age for the periods 1946 to 1972 and 1973 to 1989, whereas Figure 131–4 can be divided by separating groups younger than 28 years, for whom fertility has been declining since 1973, from older groups, for whom fertility is stable or rising.

After having described the distribution of birth probabilities according to each of the variables age and

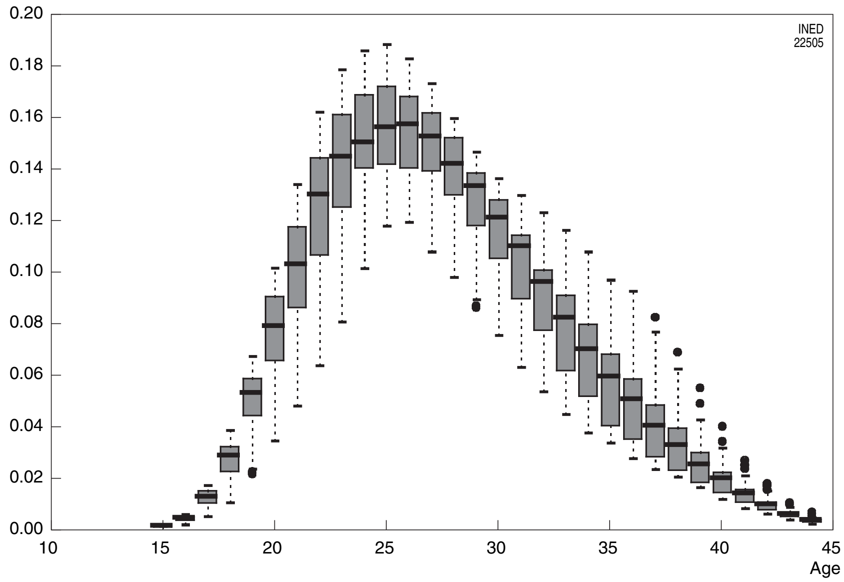

FIGURE 131–3 Box plots of first birth probabilities by age from 1946 to 1989 in France.

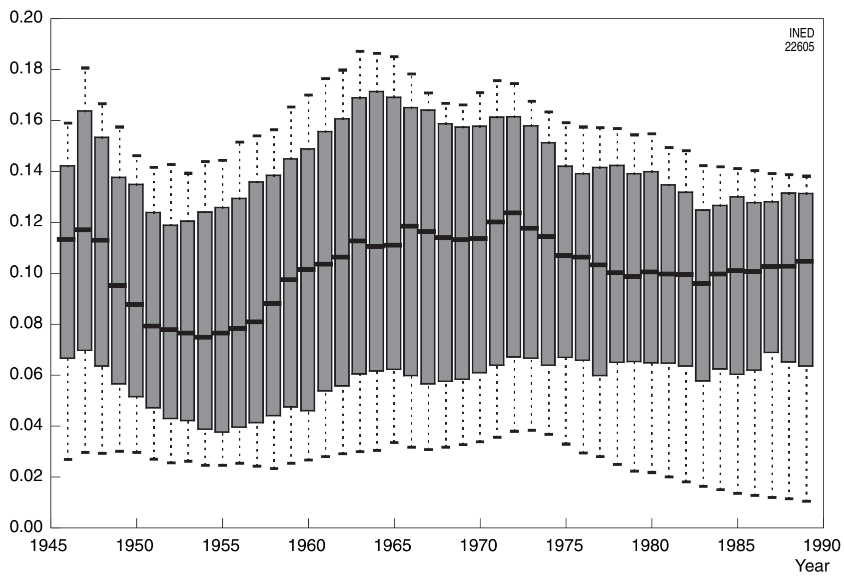

FIGURE 131–4 Box plot of first birth probabilities by year in France for women between the ages of 18 and 37 years.

year, it is possible to show variations in fertility by age and year simultaneously (see Chapter 7). Year and age can be used as geographic coordinates to map a landscape where altitude represents the variable of interest (here, the age-specific probabilities of first birth). Several possible representations are included in standard spreadsheet software, including the level curve (i.e., contour plots). In these figures, popularized among demographers by James Vaupel, Bradley Gambill, and Anatoli Yashin (1985), years are placed on the x-axis and ages on the y-axis, as in Lexis diagrams, and each age-year cell is shaded based on the value of the variable under study. This shading makes level curves visible, and the cartography makes it possible to observe all of the values taken by the variable of interest at a glance. Figure 131–5, for example, which presents the same data as in the previous figures, shows that the age when the probability of a childless women giving birth to a first child drops has grown steadily since the late 1950s. The increase in fertility in older ages preceded the decrease in fertility at young ages by 20 years.

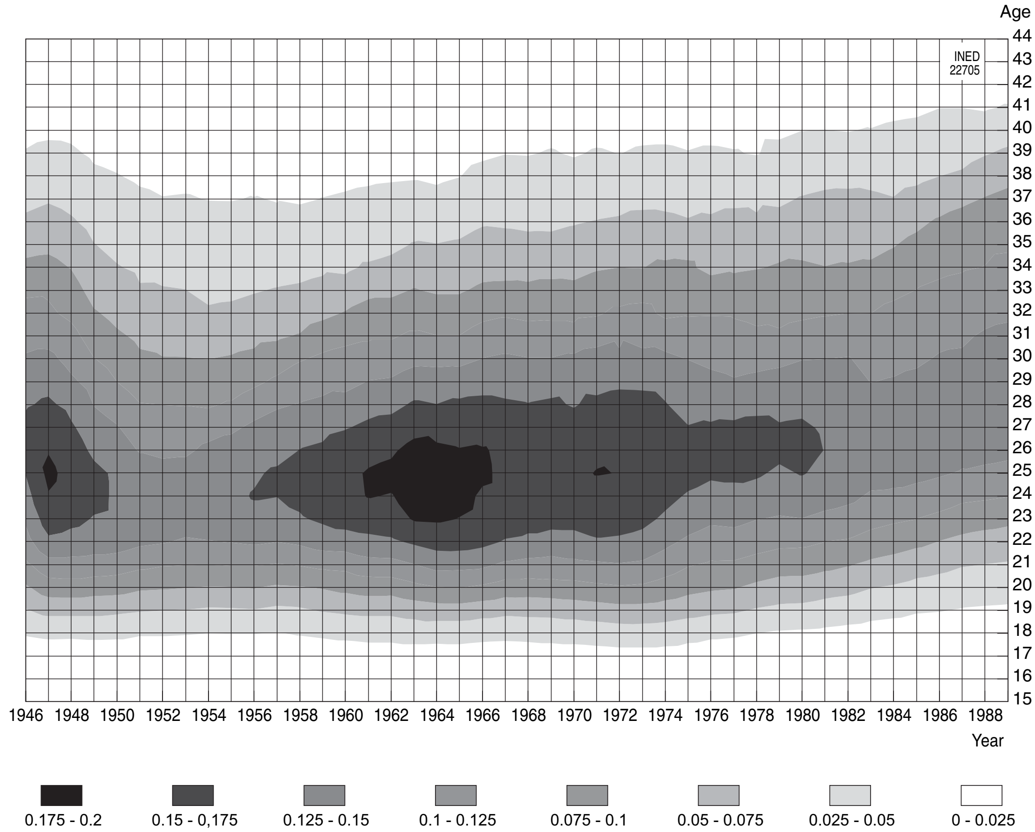

FIGURE 131–5 Contour plot of first birth probabilities among women between the ages of 15 and 45 years in France between 1946 and 1989.

3. Associations between Variables

The relationship between two variables can also be represented graphically by designating one variable on the x-axis and the other on the y-axis (Mosteller and Tukey, 1977). In graphs that cross two series of variables (i.e., scatterplots), each element is represented by a point; if the points are years, they can be connected. This is illustrated in Figure 131–6, which plots first birth probabilities in France for ages 25 to 30 against probabilities at age 24 for the years 1946 to 1989. The strong correlation between fertility at different ages reflects simultaneous variation at all ages from one year to another, a period effect. Figure 131–6 also shows a change in this relationship between 1947 and 1964, when the probabilities are strongly correlated among each other (see Fig. 131–6, black points), and the more recent period, where the significant decline in probabilities at age 24 is not accompanied by an equivalent decline at older ages (see Fig. 131–6, white points).

This type of figure can be generalized as a matrix of graphs (i.e., scatterplot matrix) presenting, for *n* variables described simultaneously, a table with *n* rows and *n* columns and with each cell (row *i*, column *j*) occupied by a graph comparing variables *i* and *j*.

4. Exploratory Analysis to Validate Models

The results of exploratory data analysis are rarely published as such. These analyses are useful as ways to become familiar with the data, but they do not provide easily quantifiable results. Nevertheless, exploratory data analysis is not solely limited to this first contact with the data. It can also be used as a tool to validate model-generated results. For example, in a study on the determinants of fertility decline in developing countries (Mauldin *et al.*, 1978), different regression models were developed as part of an attempt to separate or quantify the proportion of the decline due to economic development (i.e., social setting) and to family planning programs (i.e., program effort). The various regression models were compared and validated using exploratory techniques applied to the residuals of different models rather than to raw data. Figure 131–7 shows how exploratory analysis can be

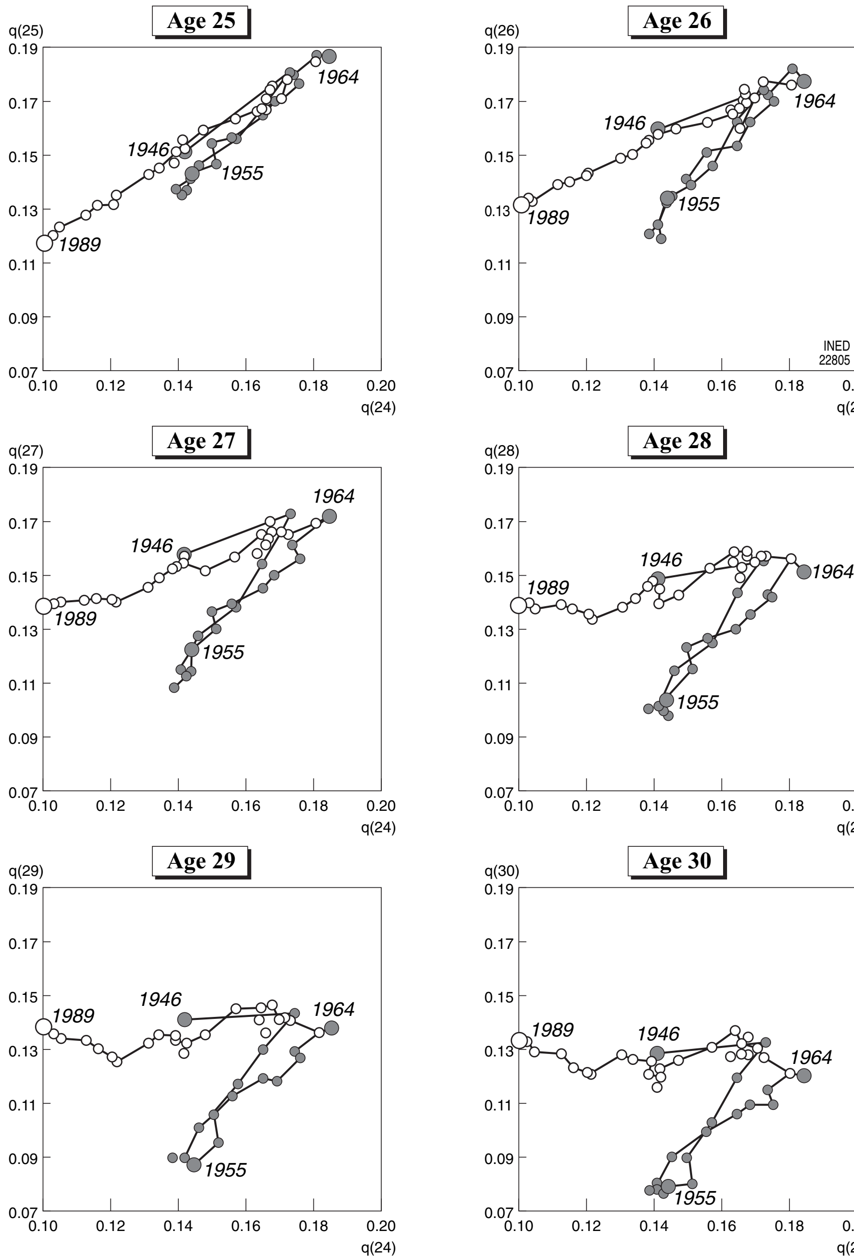

FIGURE 131–6 Scatterplots of first birth probabilities at ages 25 to 30 against probabilities at age 24, by year, France, 1946–1989. Interpretation: In each graph, first birth probabilities at a given age (age 25–30 years, respectively, in the six graphs) are plotted against the probability at age 24. Each point represents 1 year; points for the years 1946–1964 are blue, and points for more recent years (1965–1989) are white.

used to validate models. The magnitude of the residuals left by each model can be compared using box plots. The table referred to in the sixth box-and-whiskers plot in Figure 131–7 presents residuals from a model that includes an interaction between intensity of family planning program effort and socioeconomic context.

Exploratory analysis of the residuals confirms the regression results. Intensity of program effort is the primary factor differentiating country-specific fertility rates; residuals are smaller for model 3 than for model 2. There is also an interaction between family planning effort and socioeconomic context; differences in fertility due to the intensity of family planning programs are larger when the socioeconomic context is favorable. The two factors are correlated; family planning programs are more common and more active in countries where the socioeconomic situation is favorable. It is possible to estimate an indirect effect of socioeco-

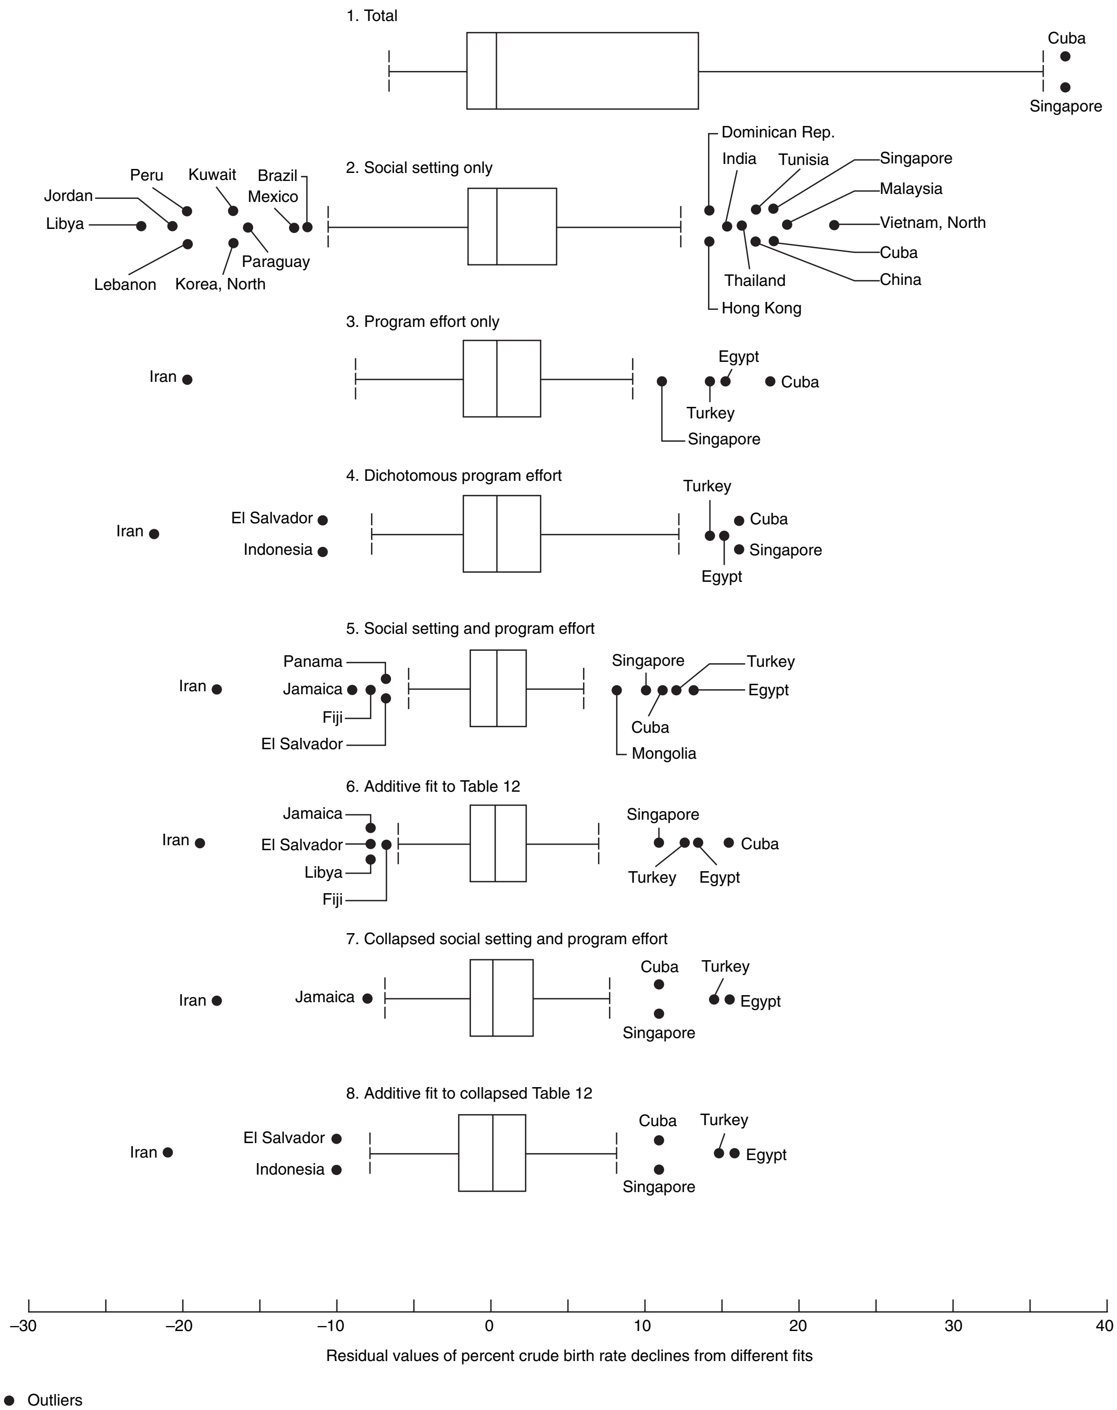

FIGURE 131–7 Residuals of different models explaining fertility decline between 1965 and 1975 in 94 countries as a function of socioeconomic conditions and family planning program effort. (From Mauldin *et al.*, 1978. Courtesy of Blackwell Publishing.)

nomic setting, because socioeconomic characteristics partially explain the presence of a family planning program.

The principal contribution of the exploratory analysis is to highlight the extreme values of the residuals for each model, showing which countries do not conform to the common model defined by each regression. There was almost no decline in fertility in Iran between 1965 and 1975, despite the presence of a family planning program introduced in 1967, whereas

Egypt, Turkey, Cuba, and Singapore experienced larger declines than would be predicted by the models.

II. METHODS FOR MULTIDIMENSIONAL ANALYSIS

Methods of *data analysis* deal with the common structure of different variables and aim to summarize the associations and oppositions among variables in the best way possible. For instance, the scatterplot could be generalized to more than two series by considering all the values taken by a set of variables (e.g., rates, probabilities) as points in a multidimensional space, a space with as many dimensions as there are variables. Given a set of observations of these variables, this type of plot produces a cloud of data that the analyst seeks to represent in the best way possible, losing as little information as possible and using the smallest possible number of indices. For example, in 1959, Sully Ledermann posed the question of the number of indices necessary to describe a mortality table and proposed "a solution independent of all *a priori* assumptions as to the structure of the phenomenon being studied" (Ledermann and Breas, 1959).

These methods of data analysis are all based on the effort to summarize the global structure of the data with a limited number of indices by reducing the number of dimensions of the information. We start by illustrating these principles using a concrete example and then present specific methods of analysis.

1. Principal Components Analysis

Following Sully Ledermann and Jean Breas, we consider the set of 157 mortality tables that served as the base for the construction of the model life tables published in 1955 by the United Nations (United Nations, 1955). These life tables can be described as a set of multidimensional data: two series of probabilities of death, one for men and one for women, defined for different countries (of which many are European) at different periods (groups of years from the early 20th century). For each sex, country, and group of years, we have a series of death probabilities for the age groups 0, 1 to 4, 5 to 9, . . . , 75 to 79, 80 to 84, or the series ${}_1q_0$, ${}_4q_1$, ${}_5q_5$, ${}_5q_{10}$, . . . , ${}_5q_{80}$.

The data are treated as 157 individuals (the life tables or country-years) characterized by their values on 38 variables (18 probabilities of death and life expectancy at birth for each sex) and represented by 157 points in a 38-dimensional space. The probabilities by sex and age are strongly correlated with each other. In countries (or periods) where mortality is high, it is high at all ages and for both sexes. This empirical observation is represented geometrically by the lengthened form of the cloud of data. Sully Ledermann and Jean Breas first presented 157 pairs of two probabilities (${}_5q_{30}$ and ${}_5q_{40}$, for men) as points on a two-dimensional graph (Fig. 131–8).

The cloud of points obtained by this method is two-dimensional. It can be represented on a new set of two axes, γ_1 and γ_2, chosen such that γ_1 corresponds to the major axis of the ellipse formed by the 157 points, with the axis representing the most inertia, and γ_2 is perpendicular to γ_1. The same principle—looking for the axes that contain the most inertia, that is, the axes along which the cloud of data points is most spread out—is then applied to the complete set of data series. Each data series (18 age-specific death probabilities and a life expectancy for each sex) is first transformed; the probabilities are replaced by their logarithm and the life expectancy by the logarithm of 100 years minus the life expectancy [$\ln(100 - e_0)$]. The variables are next centered and scaled[1] and each series is represented as a point in a 38-dimensional space. The 157 series form a *cloud* of 157 points in this space. If the mortality probabilities were all independent from each other, the points would be spread out in the shape of a sphere; because they are correlated with each other, the cloud is shaped like an extended ellipse.

Just as the pairs ${}_5q_{30}$ and ${}_5q_{40}$ were represented along the axes γ_1 and γ_2, the set of 38 transformed probabilities is analyzed along a certain number of axes. The first axis is chosen in the direction that maximizes inertia; the second axis is chosen according to the same rule, but with the constraint of being orthogonal to the first, and so on.

Principal components analysis is based on the correlation matrix for the 38 scaled and centered variables (Lebart *et al*., 2000).[2] The eigenvalues of this matrix are calculated along with the axes that correspond to them. The coordinate of each life table on each axis is a linear combination of the values taken by the variables in the table.

The coordinate on the first axis best summarizes the position of each table with respect to the others in the sense that, of all the combinations of variables,

[1] Variables are centered by subtracting their mean; the mean of the centered variable is 0. Variables are scaled by dividing by their standard error; the variance of the scaled variable is equal to 1.

[2] This work, the most recent in a long series of publications by the same authors, sometimes collaborating with Alain Morineau and Jean-Pierre Fénelon, offers an instructive overview of these methods and a complete bibliography covering French-language and English-language sources. Bry (1995, 1996) also offers brief graphical and mathematical presentations of these methods.

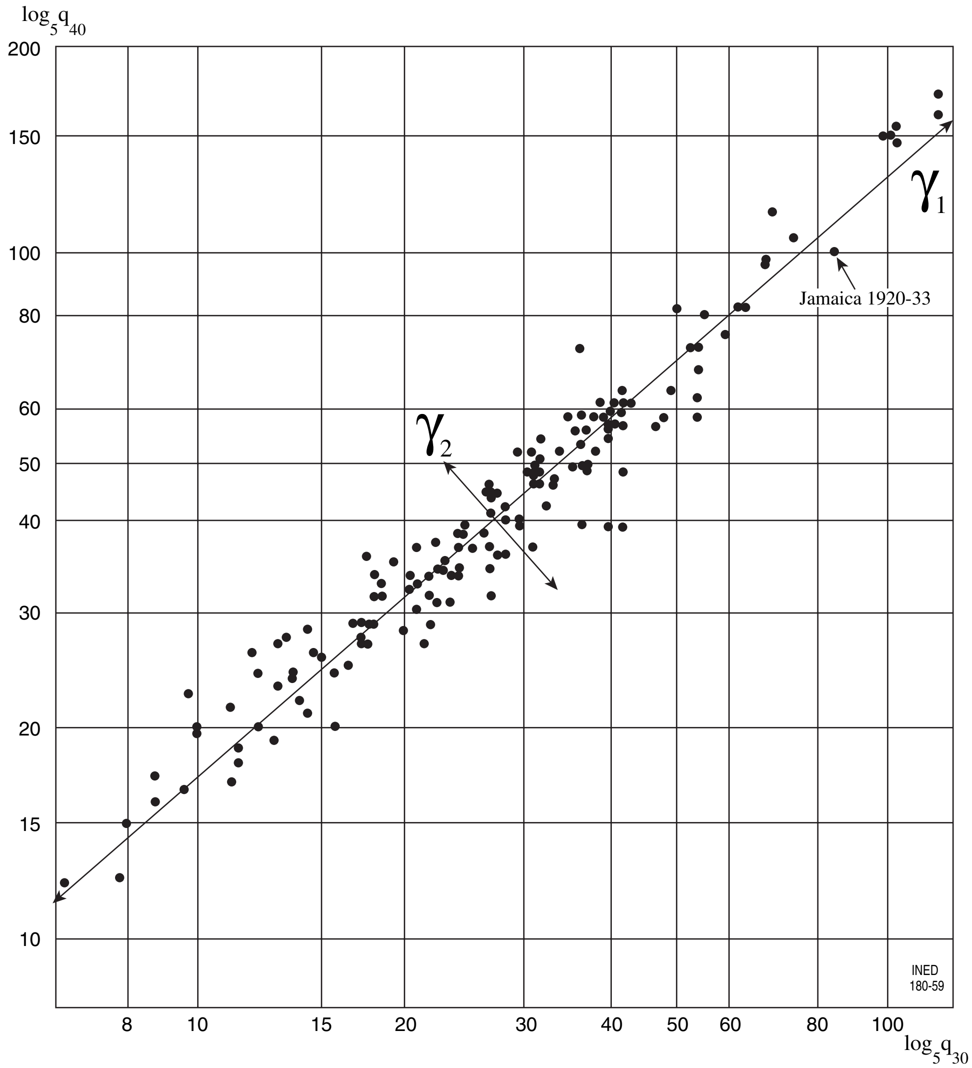

FIGURE 131–8 The probability of death for men between the ages of 40 and 45 years is plotted (logarithmic scale) against the probability of death between the ages of 30 and 35 years, using the United Nations life tables. (From Ledermann and Breas, 1959. Courtesy of *Editions de l'INED*, 1959.)

the coordinate on the first axis represents the largest proportion of the variance within the set of life tables. The first axis is therefore the best summary representation of the cloud. Similarly, the plane formed by the first two axes is the best two-dimensional representation, with each table represented by two coordinates on this plane.

To present summary indices that offer a concrete interpretation, the authors suggest restricting the analysis to the first three axes and then rotating these axes to give them a meaning more directly related to the mortality rates. The first three axes represent, respectively, 81.5%, 7.4%, and 3.7% of the total inertia of the cloud. The authors replace them with three new axes produced by two successive rotations. The first rotation, in the plane of the first two axes, transforms axes (1,2) into (1′,2′); the second rotation, in the plane (2′,3), transforms these axes into (2″,3″), as indicated in Figure 131–9. The first of these new axes corresponds to the general level of mortality and is very strongly correlated with the mortality of men between the ages of 10 and 34 years and women between ages of 5 and 44 years. It contributes 77% of the inertia. The second of the new axes (9.5%) represents adult mortality after age 30, and the third axis (6.5%) represents mortality at extreme ages, younger than 5 and older than 70 years (see Fig. 131–9). By construction, the cumulative inertia in the first three axes is conserved (92.6%), but the new axes correspond more closely to entries in the life tables. Sully Ledermann (1969) continued along this path in proposing single and double entry tables based on this principle.

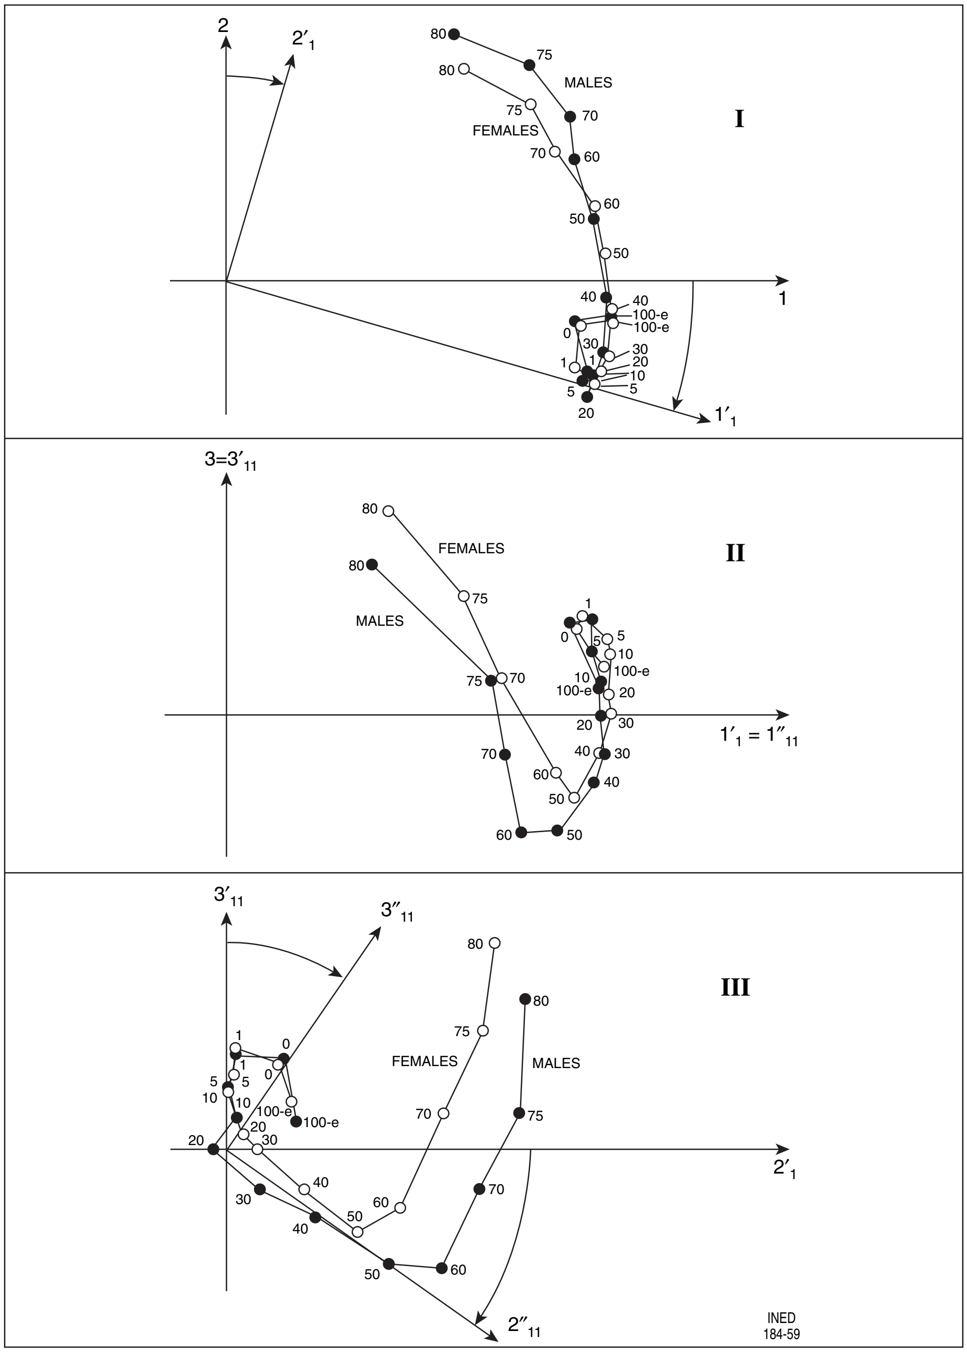

FIGURE 131–9 Rotation of the first three axes in principal component analysis. (From Ledermann and Breas, 1959. Courtesy of *Editions de l'INED*, 1959.)

2. Multiple Correspondence Analysis

Principal components analysis is based on the information contained in the correlations between different quantitative variables. When information is collected in the form of categorical variables, correspondence analysis is the method of choice (Lebart *et al.*, 2000). Given two variables X and Y, information is presented in a contingency table or cross tabulation, which divides the population according to the two variables simultaneously. Each row of the table *x*, corresponding to a value of the variable X, can be considered as an individual with a profile representing its distribution according to Y and a weight proportional to the number of individuals with the value *x*. We then compare each individual row *x* to the profile representing the average distribution of the variable Y. This comparison generates a distance between points x, which defines a cloud of individual rows in the space of values of the variable Y. The cloud of individual rows has defined axes of inertia, each of which is associated with an eigenvalue representing the proportion of inertia contained in the axis. Similarly, the individual columns y are distributed in a space defined by the possible values of X. The axes of inertia of these two clouds are associated with the same eigenvalues and can be linked by formulas known as transition formulas; both individual rows and individual columns can be represented in the same space.

Correspondence analysis can be generalized to include more than two variables. The method can be used to analyze vast sets of categorical variables, such as variables gathered in surveys. For a given variable, each value becomes an individual that takes its coordinates in the space defined by the set of other variables. As in principal components analysis, results are summarized using a limited number of dimensions, and the cloud of individual values is observed along the successive axes or in the multidimensional space defined by the first axes of inertia. Multiple correspondence analysis has been established and used in very diverse contexts, particularly in optimal scaling research based on categorical responses. Michel Tennehaus and Forrest Young (1985) describe some of the different labels for this method.

3. Active Variables and Illustrative Variables

The choice of variables used to summarize is arbitrary to some degree. For example, Sully Ledermann and Jean Breas (1959) reinforced the coherence of the set of mortality probabilities by adding life expectancy at birth—itself a summary of the life table—to the series of 18 probabilities for each sex. Alternatively, they could have not included life expectancy in the calculation of the axes of inertia, but instead used life expectancy at birth as an *illustration* of the axes by seeing where this indicator was located in the space defined by the three principal axes.

When analyzing data, it is always possible to supplement the active variables used to construct the axes of inertia with illustrative variables that do not contribute to the inertia of the cloud but illustrate the results by characterizing either diverse groups of individuals (for categorical variables) or specific directions in the variable space (for quantitative variables).

4. Canonical Analysis

Canonical analysis is a very general method, of which multiple correspondence analysis, linear regression, and discriminant analysis can be considered particular cases (Lebart *et al*., 2000).

Given a group of variables X and another group of variables Y defined for the same individuals, the goal of canonical analysis is to look for the linear combinations x and y that maximize the correlation between x and y. In an analysis of cause-specific male mortality in the age groups of 25 to 54 years and 55 to 79 years in different Italian provinces (Caselli and Egidi, 1981) (see Chapter 55), two sets of data are examined for each of 54 Italian provinces. The provinces are described by mortality from 16 groups of causes of death and by 38 variables related to socioeconomic conditions in the province (i.e., external variables). In the first step of the analysis, two principal components analyses are used to summarize the structure of each set of variables. A principal components analysis, including all of the variables, weights the external variables heavily. There are twice as many external variables as mortality variables, so this analysis provides very little additional information. Principal components analysis of the external variables makes it possible to suppress 11 redundant variables, reducing the number of external variables to 27. Canonical analysis shows four axes representing dimensions of correlation between provincial cause-specific mortality among men younger than age 55 and the socioeconomic characteristics of provinces. The first axis associates degenerative diseases, diseases of the digestive system, and accidents to variables measuring economic development, confirming the excess mortality of the north of Italy already revealed in the preceding analyses. The second axis associates diseases of the respiratory system and infectious diseases with indicators of poor economic conditions and indicators of isolation; a high proportion of bachelors and widowers and areas with mountains or inland hills. The correlation between cancers of the respiratory system and pollution and, at older ages, the consumption of tobacco appears more clearly using canonical analysis than by comparison of the two principal components analyses, although the dimensions demonstrated are not *a priori* optimal for describing the variation across provinces in cause-specific mortality or in socioeconomic conditions.

Canonical analysis is difficult to apply and to use, but it subsumes different methods of analysis as particular cases. If a group of variables Y is reduced to a single variable y, canonical analysis is equivalent to a linear regression of y on X. If X and Y are categorical variables, the analysis becomes correspondence analysis.

III. METHODS OF CLASSIFICATION

1. Ascendant Hierarchical Classification

Methods of data analysis can be used to summarize the structure of a set of data. Methods of classification are their complements. They are used to construct homogenous groups without specifying the criteria that define this homogeneity. The optimal classifications are those that minimize intragroup variance (i.e., variance among the members of a single group) and maximize intergroup variance (i.e., variance across members of different groups). The data set is represented as a multidimensional cloud, constructed from the full set or after having reduced the number of dimensions using a preliminary analysis. Groups are then constructed by minimizing the distance between members of the same group and maximizing the distance between members of a different group. The most frequently used methods are hierarchic classification methods. The principle of these methods is simple. First, the two closest individuals are grouped together, and the position of that group is calculated. The next two closest individuals or groups are then classed together. There are different types of classification methods, depending on how the position of a group, the distance between an individual and a group, and the distance between two groups are defined.

Each classification can be associated with the proportion of inertia that it absorbs, and the total inertia of the cloud can then be decomposed into the sum of the intergroup inertia and the intragroup inertia. Intragroup inertia is smaller when the members of the group are close, that is, when the grouping is appropriate. The association between group and inertia makes it possible to assign an index of inertia to each group. A hierarchic tree can then be drawn by placing each group along an x-axis according to the reduction of inertia associated with the grouping. Starting from the first grouping of two individuals and ending with the last grouping that gathers two groups into one single group, it is possible to see at what point the groupings become too costly in terms of the loss of information and to choose an optimal number of classes.

Figure 131–10, borrowed from France Meslé and Jacques Vallin (2002), summarizes classifications of four groups of 28 European life tables for men and for women in 1965 and 1995. For both sexes, heterogeneity across countries is best summarized by a dichotomy in 1995, whereas the trees for 1965 show more varied levels of groupings. For male mortality, a clear division between the western and eastern parts of the continent develops over the course of the period. By 1995, there are two very different groups of life tables; these groups almost exactly replicate the old political separation of the continent, with the exception of Portugal, which is grouped with the eastern countries because of its high adult mortality. For women, the countries of Central and Eastern Europe are grouped with Western Europe in 1995, with the exception of Bulgaria and Romania, which are grouped with the countries of the former USSR. These classifications do not provide explicit information on the details of the life tables that produce them, but they do show the uniqueness of the countries of the former USSR and the sex-specific divergence of the countries of the old Soviet bloc from other countries.

2. Discriminant Analysis and Segmentation

Multiple discriminant analysis can be a useful tool for data taking the form of a set of variables X and a variable y defining fixed classes of individuals. These methods are used to determine the linear combination of X variables that best separates the different classes. They are particularly useful if one wants to assign a class to individuals for whom the X variables are known but the y variable is unknown (Lebart *et al*., 2000). If y takes only two values, discriminant analysis is equivalent to a linear regression of y on X.

A competing approach to this problem is offered by segmentation methods based on decision trees, in which a series of choices is used to segment the population into subgroups assigned to one or the other class, rather than applying a linear combination of X variables. There are three primary advantages to these methods. First, the decision rules are easily readable and interpretable. Second, any kind of X variable can be used, without prior coding. Third, the method is robust to outliers and accepts missing data. These methods are especially efficient for prediction. They are not based on any model built a priori, and they follow specific strategies of inference. For instance, the replication of the same method on subsets of individuals leads to a “decision forest,” which leads to a very robust set of results; the predictive value of these methods is much better than for other strategies (Breiman, 2001). These methods are now used in demographic research. In a recent demographic application, Francesco Billari, Johannes Fürnkranz, and Alexia Prskawetz (2000) studied differences in the transition to adulthood in Austria and in Italy. These

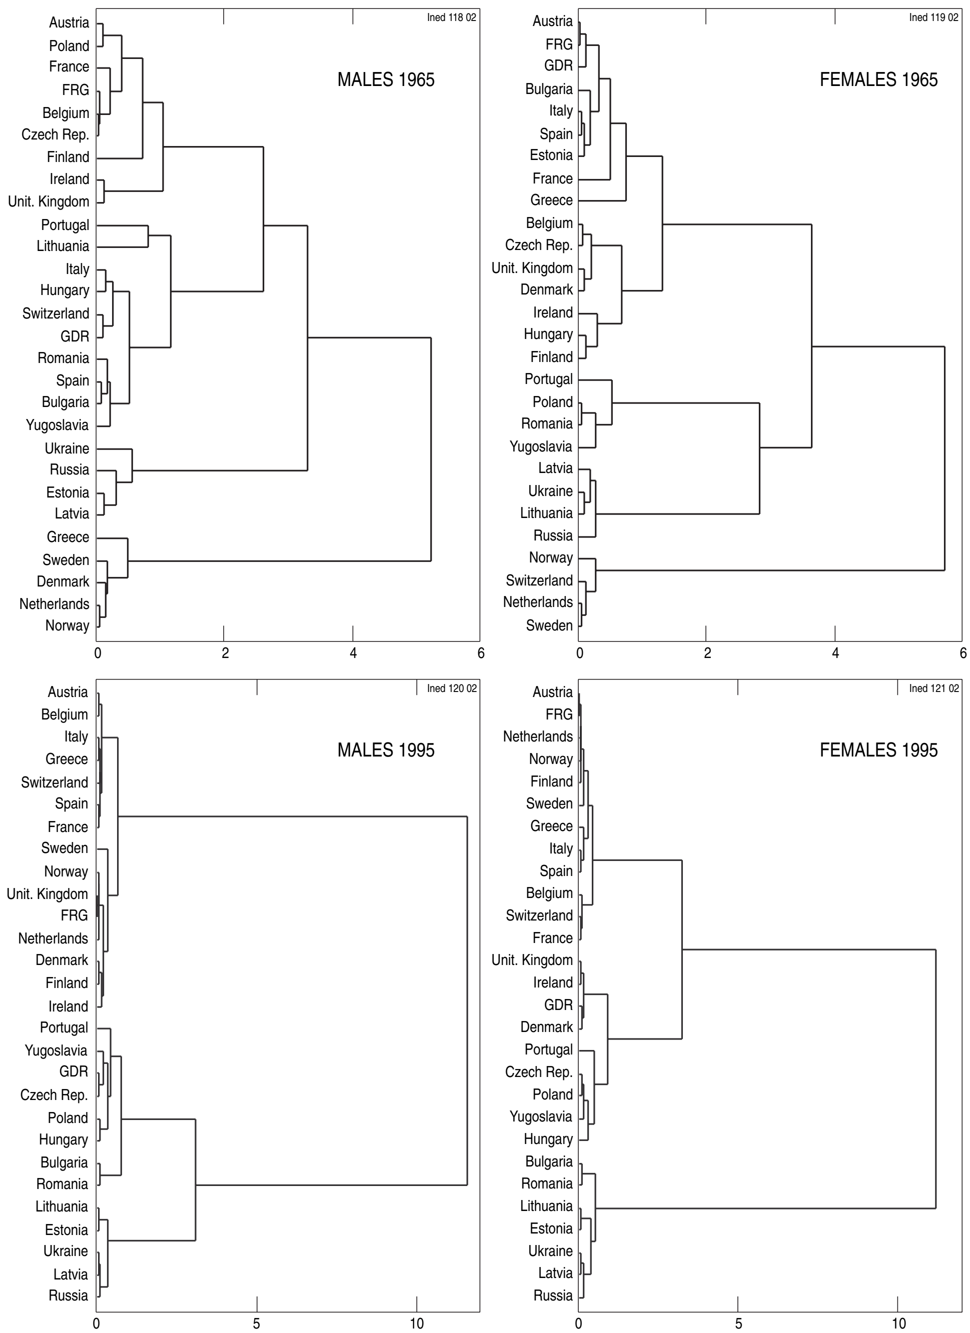

FIGURE 131–10 Tree diagrams resulting from the hierarchical analysis of age-specific mortality probabilities according to sex for 28 European countries in 1965 and 1995. (From Meslé and Vallin, 2002. Courtesy of *Editions de l'INED*, 2002.)

researchers constructed three sets of variables based on the dates of different transitions to adulthood collected by Family and Fertility Surveys: leaving school, first employment, leaving the parental home, first union, first marriage, and birth of the first child. For each of these transitions, they define dichotomous occurrence variables (i.e., quantum: whether the event took place), continuous calendar variables (i.e., timing: the age at which the event took place[3]), and placement with respect to the other transitions in four categories (i.e., sequencing, or placement relative to each of the other transitions: before, at the same time, after, neither took place). These variables are used along with sex, age

[3] For individuals who have not experienced the event, the age at the time of the survey is used.

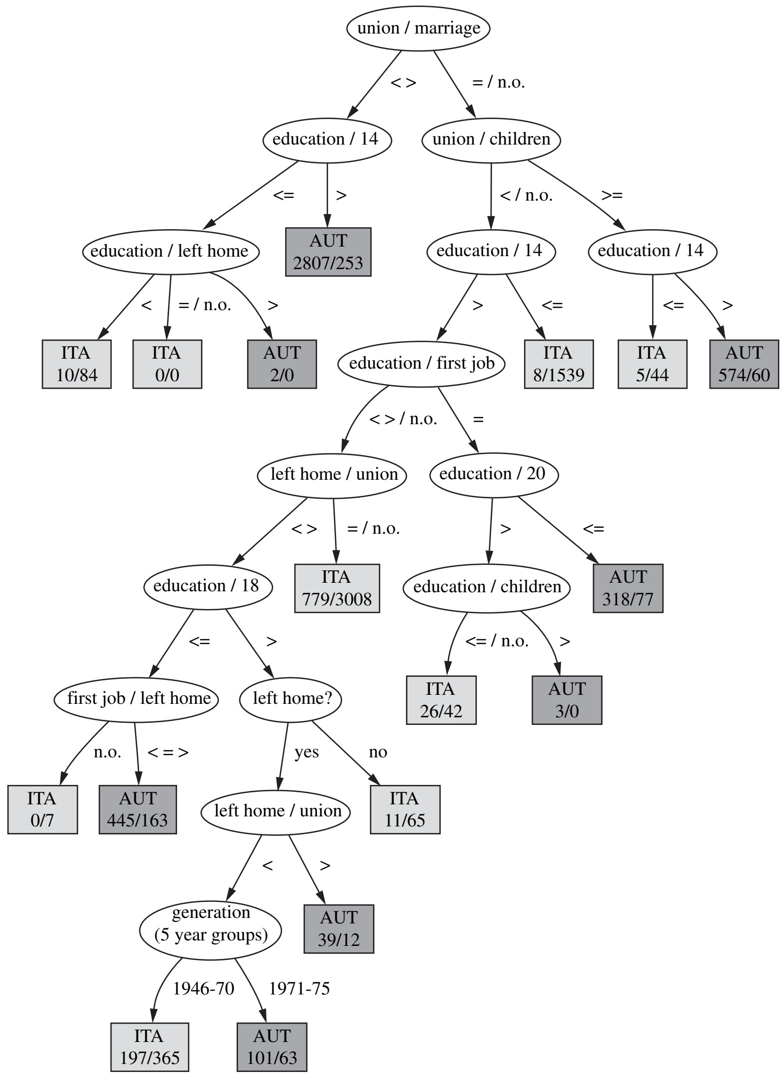

FIGURE 131–11 Decision tree applied to the transition to adulthood in Austria (AUT) and in Italy (ITA). Numbers at the end of each branch correspond to the number of Austrians and Italians, respectively, affected by the rule corresponding to the branch. (From Billari *et al.*, 2000. Courtesy of Max Planck Institute for Demographic Research, 2000.)

group, and cohort to best separate the respondents from Austria and Italy, using a sequence of tests to build a decision tree.

This decision tree is presented in Figure 131–11. Each ellipse presents a comparison between the dates of two events or of an event and an age. Depending on whether the first event takes place before (<), after (>), or at the same time (=) the second event or whether no event already took place (n.o.), the decision is made to put the individual on one branch or the other of the decision tree. The first test (which comes first because it is the most efficient and therefore the better predictor) is based on the comparison between marriage and first union; if the dates of these two events are different, the individual is assigned to the left part (most probably leading to Austria). If, the end of studies took place after the age of 14, the decision is made that the individual is supposed to be Austrian. Two tests are sufficient to isolate a group of 2807 Austrians and only 253 Italians. If marriage and first union were simultaneous or did not occur (i.e., right branch of the tree), the next test is based on a comparison between union and the birth of the first child. The principal result of this method in that example is the demonstration of the importance of sequencing of transitions to adulthood in distinguishing the two countries: Austrians are differentiated from Italians by having different dates of first union and first marriage, children born before the first union, and simultaneous first employment and completion of schooling.

Compared with classic demographic methods, which are attached to the timing of one or another event, this type of method can simultaneously capture the ensemble of transitions to adulthood. This analysis shows that it is the existence or absence of intermediate steps that best defines the differences between young adults in these two countries. Italians seem to be characterized by the simultaneity of familial passages; marriage is the first union, and there are no births before that union. Conversely, among the Austrians, steps toward economic independence appear to take precedence: first job (often simultaneous with the end of schooling) and departure from the parental home.

CONCLUSIONS

Methods of exploratory data analysis have three principal goals. First, by refusing to pose *a priori* hypotheses and by using criteria based on all available information, they make it possible to quickly identify the global structure of information. Second, they reveal outlying points (which could result from errors in measurement, coding, or data entry); because they are iterative in nature, they are a way to prepare for more detailed analyses.

Thanks to the progress of statistical software and spreadsheets, it is possible to become familiar with a complicated data set relatively quickly. Methods of exploratory data analysis provide varied tools for synthetic description that are complementary to methods of demographic analysis.

Regression Models

LAURENT TOULEMON

Institut national d'études démographiques (INED), Paris, France

Regression techniques have grown in popularity and sophistication, and they have earned a rightful place in every demographer's toolbox (Hoem, 1991). However, despite attractive flexibility and power, they, like all methods of demographic analysis, demand care in use and application.

The chapter begins with a description of features common to all analytic models, followed by an account of regression specifics. I conclude with an overview of different types of regression.

I. MODEL CONSTRUCTION

Even basic parameter estimation, such as the calculation of crude death rates, depends on an underlying model (Keilman, 1993). Although frequently overlooked in practice, a careful understanding of the underlying model is essential for proper interpretation of results.

1. The General Model

We begin with a simple example. Suppose we observe the ratio $m = D/P$, in which D is the number of deaths in a given year, and P is the average annual population. Then, m is a rate, expressed in events per person per year. The simplest (and most naïve) interpretation of m depends on two assumptions:

1. *Homogeneity*: the rate m applies to all individuals in the population and does not vary among individuals with sex, or age, or other characteristics.
2. *Independence*: the risk of death of any individual is proportional to the duration of exposure (e.g., once having moved into the area, incoming migrants face the same risk per unit time as original inhabitants).

Homogeneity is unsupported by the evidence so any interpretation of crude death rates, whether in comparing two populations against each other or making comparisons within one population across time, will be limited by the extent that the homogeneity assumption is violated.

Independence between mortality and external perturbations such as migration is often easier to accept because the perturbations are usually relatively small compared with the size of overall mortality.

In terms of statistical inference, exploratory or predictive methods can be used to describe the data as accurately as possible or to forecast with the least possible error future or unknown results (Breiman, 2001) (see Chapter 131). To link these data to the real world, it is necessary to come back to the modalities governing the construction of the data and the transition from the real world to the data (which are constructed and not given) and then from the data to the real world (Cox, 2001).

The lesson is that results can be interpreted only within the framework of a general model. We will build that model in three steps.

Step 1. Construct a general model of the real world with measures or indicators that capture the behavior of interest (e.g., mortality, fertility) and the relationships between the measures.

Step 2. Within the framework of the model, calculate results. The formalization of the model in step 1 makes it possible to estimate model parameters, to perform tests of statistical significance, and to assess goodness-of-fit.

Step 3. Link back to the real world, using the model parameters obtained in step 2 to describe real world behavior. The more complex the model, the more difficult it may be to make that link, but it is still critical for simpler models.

For the previous example, we construct the death rate m, intending to measure the general level of mortality (step 1). We calculate the rate (step 2) and then examine the results and build conclusions on mortality (step 3). If we see a secular decrease in the value of our model parameter, m, we conclude that the general mortality level in our population also decreased over time.

In practice, our model is only a rough representation of reality. For example, although populations are never homogeneous, we still calculate crude death rates but warn the reader about their limitations. The more we want our models to reflect reality, the more sophisticated our models become; for example, we may construct more homogeneous groupings (such as by calculating age- and sex-specific death rates) and formalize the relationships between groupings. For this, regression models are the tools of choice.

Before describing regression models, let us examine two assumptions formalized in regression but also common in the estimation of demographic rates, even if in an implicit manner, and contrast their interpretations.

For assumption, the rates we observe are the consequence of forces that each individual may experience in a probabilistic way. We begin by assuming the opposite, for example, by supposing that the population can be disaggregated into two distinct groups: those who are fated to die within the year (probability of death = 1) and those who will survive (probability of death = 0). In this case, the calculation of the death rate is exactly the proportion of persons who will die, and it suffices simply to enumerate these two groups. The measured rate represents the proportion fated to die, not the overall death rate of the population. The comparison between two populations will then focus on the proportion fated to die in both populations, not on the overall mortality. This assumption is often unrecognized in demography, so much so that a formalization of it has been described as a "new paradigm" (Courgeau and Lelièvre, 1996). We will return to this point later.

For assumption 2, the rates we observe are the result of an underlying stochastic process. The time path of mortality across years is interpreted as being decomposable into an underlying secular trend and random fluctuations around it. In the long run, we seek to identify the random component (e.g., year-to-year variations in influenza) from the secular trend.

We often consider survey results as if they were coming from one sample among the universe of all possible samples. These super-population models let us describe annual variations as a realization of individual variations (as in assumption 1) and macro variations, some of which are themselves stochastic. This is the basis for testing whether a particular annual variation in rates is exceptional or not (Suchindran *et al.*, 1979; Udry *et al.*, 1979).

2. Regression Models

Regression models are characterized by a *dependent* (sometimes called *endogenous* or *response*) variable, usually denoted y, and one or more *independent* (sometimes called *exogenous* or *factor*) variables, X, related by the equation $y = f(X)$. In general, we seek to estimate f based on the observed data. Most often, we postulate that the function f applies at the individual level (i.e., for an individual i), and we estimate the parameters of a relationship $y(i) = f[X(i)]$.

Once X, y, and the general form of f have been constructed (step 1), regression consists of choosing a particular and specific form for f that satisfies some optimality constraint, usually resulting from trade-offs between simplicity of form and fit to the data.

a. Linear and Least Squares Regression

The simplest form of regression is linear regression: X is composed of one or more variables $x_1 \ldots x_p$, and we write the following:

$$y(i) = \sum_{j=1}^{p} a_j\, x_j(i) + \varepsilon(i) \quad (1)$$

We are usually not concerned with the particular values taken by each X variable, but rather the manner in which y varies across individuals i, with each individual being characterized by the values of the variables X. Assumptions about ε allow us to make estimates of the parameters a and therefore of the value of the function f that minimizes the values of ε. In least squares regression, we calculate the values of the parameters a that minimize the sums of squares (thus the term *least squares*) of the residuals, $\varepsilon(i)$.

The Gauss-Markov theorem states that if certain conditions on ε apply, least squares regressions have several highly desirable properties. The conditions are that ε must have a zero mean, and that its variance, σ^2, is the same for all observations and independent of the values taken by X; in that case, the estimate of a based on least squares criterion is unbiased and of minimum variance among the unbiased estimates.

The Laplace-Gauss theorem further states that if ε follows a normal (or gaussian) distribution, the distribution of the parameters a can be estimated and statistical tests of significance can be performed.

b. Log-linear Models and Likelihood

In demography, we often use log-linear models, which are based on a different formulation of f (Hoem, 1987). When y is a rate, the log-linear model presumes a linear relationship between the logarithm of y and the variables X:

$$\ln(y(i)) = \sum_{j=1}^{p} a_j \, x_j(i) \tag{2}$$

For any individual, we cannot observe the true underlying event rate, $y(i)$, but we see the outcome of the event. In this case, the least squares method does not apply, and we use the maximum likelihood criterion to find the values of the parameters a that maximize the probability of seeing the $y(i)$ that we do (see Chapter 8). We create a likelihood function that conditions the observed data on the parameters a and then find the values of a that maximize the likelihood.

In practice, it is often easier to work with the logarithm of the likelihood function than the likelihood function itself. Because the logarithm is a monotonic function, the values of a that maximize the likelihood will also maximize the log likelihood. If L is the likelihood and A is the universe of individuals at risk for the event, the log likelihood over all individuals is given by the following equation.

$$\ln(L) = c + \sum_{i \in A} y(i) + \sum_{i \notin A} (1 - y(i)) \tag{3}$$

We estimate the most likely value of a (i.e., the one that maximizes L), and then we get an estimate of the function f.

c. Comparisons of Models

After the general framework has been defined (step 1), we can use it to analyze and compare models of increasing complexity. More sophisticated models can fit the data better—but any improvement in fit (e.g., by decreased mean squared error or by increased likelihood) must be checked against simpler models to determine whether the improvement occurred by chance.

II. WHY REGRESSION?

The regression approach has two compelling advantages. First, explicit specification of an equation such as $y = f(X)$ allows for the identification of the separable contributions of each independent variable x to the variability in y. Second, regressions make it easier to analyze alternative model specifications.

1. Correlation between Independent Variables

Regression treats each of the independent variables in an identical way. In practice, we often distinguish between one of the X variables as the variable of interest (e.g., x_1) for its effect on y, and one or more other X variables as confounders (e.g., x_2), whose effect we wish to control.

In that case, we could compare a model including only x_1 [$y = f(x_1)$] with one including both X variables (i.e., $y = f[x_1, x_2]$).

The first model lets us see how y varies with x_1 in a crude or uncontrolled way, whereas the second lets us see how y varies when x_1 changes and x_2 is held constant. This is a type of standardization. We examine the effect of x_1 on y, with this effect assumed to be constant whatever the level of x_2 may be. These adjusted variations differ from crude adjustments if two conditions hold: x_2 has an effect on y once adjusted for x_1, and x_1 and x_2 are not statistically independent (i.e., the distribution of x_1 differs over groups selected by their value of x_2). From this perspective, regression is a form of standardization midway between direct and indirect standardization (see Chapter 15). It offers two advantages. First, it is possible to standardize across many confounding variables. Second, the model lets us test the hypothesis of independence. This lets us think of regression as an enhanced form of indirect standardization (Hoem, 1991).

2. Interaction Effects

Sometimes, the way that y varies with x_1 can differ depending on the value of another variable x_2. In that situation, there is an interaction between x_1 and x_2 in their effect on y. The interaction between the x_i terms can be weak in the sense that the effect of x_1 on y can vary with x_2 but without changing the sign of the x_1 effect, or it can be strong if the sign of the x_1 effect changes (see Chapter 15). When the interaction is weak, sometimes it is possible to re-express the x_i terms in a way to minimize the interaction, but when the interaction is strong, in a strict sense, it may not be possible to speak of "the" effect of x_1 on y, because the effect is sometimes positive and sometimes negative, and it cannot be summarized by a single value.

Regression allows us to compare the fit of models with and without interactions. They provide one (but not the only) criterion for evaluating the importance of including interactions in a model.

3. Choosing a Model

Even without considering interactions, we can combine p potential independent variables into 2^p possible models. Systematic comparison and evaluation of all possible models is usually impossible. Some statistical software applications include procedures that can automatically select independent variables that meet certain statistical properties, such as stepwise selection. Forward stepwise selection first chooses the single independent variable whose inclusion improves model fit the most; subsequent independent variables are added to improve overall fit, building on the previously selected variables. Backward stepwise selection proceeds in the opposite direction by sequentially dropping the variable that adds the least to overall fit. Some procedures use a mixed strategy of both forward and backward steps, and they may allow the specific inclusion of certain key independent variables.

As in any standardization, the choice of the model can have a critical influence on any result. The choice of an *optimal* model depends on two disparate criteria: one related to step 2 and the other related to steps 1 and 3.

a. Statistical Criteria: Step 2

In a strict sense, it is only possible to compare two models that are nested: one model with a number of independent variables, X_1, and the second comprising all of the X_1 variables plus additional variables X_2. The null hypothesis is that the additional X_2 variables do not add any explanatory power. In practice, even when the null hypothesis is true, additional explanatory variables can improve model fit through randomness alone. For a test of the null hypothesis, we choose a critical value α, often 5%, which represents the chance we are willing to take that, through randomness alone, we could see an improvement in model fit even though the X_2 had no real contribution, leading us to conclude erroneously that X_2 had a real effect on y. After a critical value has been chosen, we can calculate the level of improvement in model fit needed to meet the threshold. If including the X_2 produces a larger improvement, we say that the effect of X_2 on y is significant. More precisely, this means that if the observed improvement in fit would have been observed with probability less than α under the null hypothesis, we reject the null hypothesis and accept the alternative that the X_2 do affect y.

Why is 5% the critical value? In general, the choice is a compromise. We want a high enough critical value so that we will know if the X_2 variables contribute to the model, but we also want a low enough value to avoid being fooled by random chance that they contribute when they do not. To ensure that we are not fooled, we would choose a low numerical critical value that is difficult to meet, such as 1 in 1000. In that case, if the X_2 variables did not truly contribute to the model we would run only a 1 in 1000 risk of being fooled into thinking that they did; the test of the hypothesis would reveal only highly significant relationships.

However, with such a low critical value, not being able to reject the null hypothesis does not mean that the null hypothesis is true (i.e., that the X_2 terms have no role in the model). In choosing a threshold that is so difficult to meet, we run the risk of overlooking important effects. The power of a test is its ability to ferret out true relationships and to reject the null hypothesis when it is false. In most cases, the power of the test cannot be estimated. However, it increases with the level α; with increasing the probability to reject erroneously the null hypothesis if it is true (i.e., no real effect of X_2 on y), we also increase the probability to correctly reveal that the null hypothesis is false (i.e., the variables X_2 have an effect on y).

Raising the level α increases, by definition, the risk of erroneously believing a relationship to be significant. This is called type I error, and in general, the scientific community is very concerned about this type of mistake. Peer reviewers of articles submitted to journals usually set by default a maximum critical value of 5% (i.e., when there is no effect, they are willing to tolerate a risk of 5% that you would erroneously conclude that there was, which means that one erroneous result will be given for each 19 cases without a conclusive result).

Type II error, the risk of erroneously overlooking a significant result when it truly exists, is considered a less damaging error. The inability to reject the null hypothesis is viewed as leaving the question inconclusive and in doubt, rather than proof of no relationship. It is the researcher's responsibility to reduce the risk of type II error as much as possible by ensuring that his or her research is properly performed, with sufficient sample sizes and correct methods.

b. Balancing Theory and Practice

The power of a test depends on effect size and sample size. Given a particular set of data, there are two ways to improve the power of a test to identify significant variables: one good; the other, bad. The proper way is to clarify as precisely as possible the alternative hypothesis. For example, if the analyst suspects that females experience lower death rates than males, but the test has insufficient power to spot this effect, he or she can construct the null hypothesis "female mortality is the same or higher than male mortality." Rejecting this null hypothesis leads to the conclusion that "female mortality is less than male mortality." We then perform the hypothesis test with a 10% critical value, and we reject the null hypothesis only if there is a difference in the supposed direction: females, rather than males, experience lower mortality. Under the null hypothesis, the critical value is one-half of 10%, or 5%. The trick consists of trading off the ability to spot higher female mortality for more power in detecting lower female mortality. If the *a priori* assumption about the relationship between female and male mortality is wrong, we are worse off; we are pointing more precisely but in the wrong place. We need as much knowledge as possible about the subject to produce the best testable hypotheses.

The wrong way to improve test power is to specify the null and alternative hypotheses *after* having examined the data. One variant of this approach is to perform many analyses and present only those with significant results. For example, with a 5% critical value and 20 different tests, even when the null hypothesis is true, we will erroneously find, on average, one positive result, and there is more than an even chance of finding at least one (falsely) positive result: 64% if the tests are independent and less if they are linked. If we present only significant results at a nominal 5% critical level, we will overstate the findings because the real critical value for the multiple comparison problem is much higher than 5%.

This is a very common type of error. In France, a physician reported that the number of births varied with the phases of the moon after having performed 30 separate tests (Toulemon, 1986). For another example, numerous researchers have reported a link between breast cancer and the contraceptive pill, including one meta-analysis (CGHFBC, 1996) that reviewed the studies available at the time. One-half of the studies concluded that no significant link was found, and the other half concluded just the opposite. However, among the studies that found a link, the groups at risk were never exactly the same; some studies found a higher risk for women who had never borne children, some found it for female smokers, and others found it for women who had started using the pill at an early age. Even if the null hypothesis of no statistical relationship were true, if each study had performed 20 tests to publish one positive result, it would be entirely consistent to see one-half of the studies (rather than 5%) finding an erroneous link between breast cancer and use of the pill. Moreover, the studies finding a link are published more often and faster than those that reported no link. Although there is still doubt about an overall link, one study appears to support the conclusion that the link reported by these studies are consistent with random chance and that there may not be a significant link between breast cancer and use of the pill (Lê, 2002; Marchbanks *et al*., 2002).

c. Nonstatistical Criteria: Steps 1 and 3

Model specification does not rely solely on statistical criteria, nor is the choice of the model specific to regression problems. Three examples are discussed in this section.

In example 1, interactions are ignored. In calculating the total fertility rate (TFR), each age gets an equal weight, and in essence, it is simply the sum of the age-specific rates. The TFR, reported in units of children per woman, is based on the artifice of an artificial (or synthetic) cohort (see Chapter 14). To analyze changes in fertility over time, calculation of the TFR represents a mean rate, or a regression in which fertility is a function of age and time. However, in most developed countries since the 1980s, age-specific fertility rates have decreased at the youngest ages and increased at older ages. There is a strong interaction between age and year (see Chapter 15), and it is therefore not possible to speak strictly about a rise or fall in fertility. It is only by the convention of an artificial cohort that we can examine the change in the TFR over time. We can see evidence of the interaction by examining how the mean age of childbearing changes over time.

In example 2, significant explanatory variables are omitted or overlooked. We know that the age of marriage strongly influences the risk of marital dissolution. To measure its change over time, we could describe a model in which the risk of divorce depends on the age at marriage and the year of marriage. One implicit model is that it is the age at marriage that specifically affects the risk of divorce. An increase in the mean age at marriage is accompanied by a decrease in the proportion of marriages at very young ages and a decrease in the overall divorce rate. An alternative model is that the age at marriage is an indicator of marriage at young ages, but the proportion of early marriages is fixed although the mean age at marriage rises. In the latter model, the significance of age at marriage changes with the year of marriage. A marriage at age

25 in the year 1980 occurs at the mean age at marriage, whereas a marriage at age 25 in the year 2000 is among the youngest quintile. Accordingly, a regression that examines changes in divorce over time may omit age of marriage because the same age of marriage at two different times has a different meaning; comparable ages are incomparable. Instead, we could introduce a variable that measures precocity of marriage, constructed to be statistically independent from the year of marriage and which splits each year's marriages into earlier or later groups (Hoem, 1996). When the meaning of a value of an explanatory variable changes according to the value of the variable of interest, it is often better to omit this explanatory variable or to construct a new indicator variable that is statistically independent of the variable of interest.

In example 3, several alternative strategies are possible. In studying marital dissolution, should we standardize for prenuptial cohabitation, the number of children, or premarital births (Toulemon, 1995)? The answer is not straightforward, and each model focuses on a specific question for which it was constructed (step 1). None of these models may be considered as the best one, giving the only answer. The usefulness and validity of the conclusions (step 3) depend more on the general model (step 1) than on the specific estimation (step 2).

4. Regressions and Demographic Analysis

a. Sex, Age, and Period

Demographers focus on three particular variables: sex, age, and period. Each of these must be carefully handled.

Male-female differences rarely can be reduced to a simple difference in levels, and in general, it is preferable to estimate one regression for each sex, which is equivalent to taking into account all possible interactions between sex and other independent variables.

In the previous section, we saw that age occasionally is better interpreted in a relative rather than absolute sense. In general, when studying nuptiality or migration, a good model systematically tries to eliminate age effects so that when all relevant variables are taken into account, the remaining effect of age on demographic behavior disappears. This happens, for example, in migration studies in which age effects and residence duration effects diminish when family status (e.g., marital status, number of children), housing status (e.g., owner, renter), and profession are taken into account. Age in and of itself is not a variable that directly affects mobility, but life cycle events (e.g., marriage, divorce, children leaving home, buying or selling a house) that are associated with age (Courgeau, 1985) are the variables affecting migration. When studying mortality, we could equally imagine that specific biologic indicators of aging or of health could substitute for age in determining risk of death. Nonetheless, we are not yet there, and age continues to be a key variable in describing demographic behavior. Calculating rates by age can be easy and informative, but we must keep in mind that systematic use of age as an explanatory variable can be abused.

After age and sex, period also holds a special place. When an individual's characteristics change, there is, by definition, a statistical dependence of that variable with time. To measure the effect on behavior of that variable, we can use event histories, in which time plays a peculiar role. The unit of analysis is no longer the individual but his or her complete biography, described as the succession of durations at which we observe the occurrence of events (see Chapter 23).

b. Regression Complements Demographic Analysis

A great advantage of regression is that it allows us to be more specific and precise in our analysis and then use the results in a conventional demographic context. For example, age- and parity-specific fertility rates calculated by regression methods show that, between 1975 and 1989 in France, the period fertility rate fell for women younger than 28 years of age having their first birth and rose above that age, whereas the rates for women having a second birth rose over all age groups. However, these changes in the period rates can be described in terms of quantum and tempo. The mean age at birth of first child rose, and parity progression ratios from zero to one child and from one to two children remained stable. Having their first child at a later age, women have less time to have a second child. The period fertility instant rate rose, but the length of duration at risk decreased, and the total fertility rate was constant (Rallu and Toulemon, 1993). This insight would not have been available if we were limited only to regression analysis.

III. TYPES OF REGRESSION

All forms of regression are based on the same general principles and seek a form that minimizes error (when we can directly measure the dependent variable) or maximizes the likelihood (when we can only observe the realization of an event). The choice between the two often depends on the characteristics of the dependent and independent variables.

1. Dependent Variables

Dependent variables can take several forms: quantitative variables, proportions, or rates. Characteristics of each of these types determine the type of regression used (Leridon and Toulemon, 1997).

Linear regression is designed for models characterized by quantitative dependent variables that can be measured along an additive scale, such as the number of children or the amount of income. We then examine how a change in one of the independent variables, Δx, translates into a change in the dependent variable, Δy, through some constant ratio a (i.e., $\Delta y = a\ \Delta x$). For several X variables, we often write an equation similar to the following:

$$y = \sum_j a_j\ x_j \tag{4}$$

Additive dependent variables can always be transformed if needed to make interpretation easier. A common and useful transformation is the logarithmic transform, which makes proportional comparisons easy because it transforms differences into ratios. Then, a change in one of the independent variables, Δx, is related to a change in the dependent variable, Δy, by $\exp(a\ \Delta x)$, and the change is proportional to the value of y: $\Delta y = y\ a\ \Delta x$. For several independent variables, we often write an equation of the form:

$$\ln(y) = \sum_j a_j\ x_j \tag{5}$$

or

$$y = \exp\left(\sum_j a_j\ x_j\right) \tag{5′}$$

and

$$\frac{\partial y}{\partial x_i} = a_i \exp\left(\sum_j a_j\ x_j\right) = a_i\ y \tag{5″}$$

These rates are most often interpreted on a multiplicative scale and are useful for studying relative risks or relative growth rates, such as in studies of income.

Probabilities are well modeled with a logit, or log-odds, transform. This transformation corresponds to the hypothesis that Δx is related to Δy in a way that is proportional both to y and to $(1 - y)$: $\Delta y = y(1 - y)\ a\ \Delta x$.

If y is the probability that an event will occur, then $y/(1 - y)$ is the odds of the event, and we can model the logit in the now familiar regression context:

$$\text{logit}(y) = \ln\left(\frac{y}{1-y}\right) = \sum_j a_j\ x_j \tag{6}$$

or

$$y = \frac{1}{1+\exp\left(-\sum_j a_j x_j\right)} \tag{6′}$$

and

$$\frac{\partial y}{\partial x_i} = \frac{a_i \exp\left(-\sum_j a_j\ x_j\right)}{\left(1+\exp\left(-\sum_j a_j x_j\right)\right)^2} = a_j\ y(1-y) \tag{6″}$$

2. Independent Variables

Explanatory variables can be quantitative or categorical; in the latter case, we often transform variables that take p categorical values into p dichotomous dummy variables; we create indicator variables x_p where $x_p = 1$ if $x = p$ and $x_p = 0$ if $x \neq p$.

3. More Complex Models

Regression methods have grown in number and sophistication as models have become more complex. Among the refinements most often used in econometrics are seemingly unrelated regression (SUR) systems of equations, which exploit correlations between different dependent variables measured over the same individuals; models with endogeneity, which allow for multiway dependencies among the independent variables; multilevel models, which allow for the unified handling of individual and group-level variables (see Chapters 24 and 133); and log-linear models, which build on structural effects and groups of variables without making the distinction between dependent and independent variables (see Chapter 92). The description of these models is beyond the scope of this chapter.

CONCLUSIONS

Regression methods have become indispensable in demography. They have allowed for the formalization of previously implicit hypotheses in the estimation of demographic rates (Courgeau and Lelièvre, 1996), and they allow us to generalize from the usual standardizations.

They also encourage the investigation and evaluation of many alternative model specifications by comparing their statistical significance. On a spectrum from crude rate models in which each independent variable's effect on the dependent variable is measured in isolation, "all other things kept unequal" (Héran, 1996), to full models in which the effect of each variable is measured, "all other things being equal," regressions allow us to measure and to test different intermediate formulations.

Regressions, like the other methods of analysis, can be understood only as being the middle step of a three-step process. Upstream from the regression, step 1 consists of defining the general model that links the data collected and the relationships between data to the real world. Downstream, conclusions are drawn from the results of the regression by linking back from the model to the real world.

Regression and classic demographic analysis complement each other. Some insights can be derived only by building on the structure of classic demographic behavioral relationships, but at the same time, regression analyses have quickly become essential in summarizing the diversity of behavior by using independent variables other than age and sex.

Bridging the Gap between Micro-demography and Macro-demography

FRANCESCO C. BILLARI

Istituto di Metodi Quantitativi, Università Bocconi, and Innocenzo Gasparini Institute for Economic Research, Milan, Italy

I. MACRO 1–MICRO 1: WHY DO DEMOGRAPHERS NEED TO BRIDGE THE GAP?

Demography can be defined as the study of human populations (Caselli *et al*., General Introduction). Populations are by definition aggregates of individuals, and they constitute entities at the aggregate or *macro* level of analysis. In the past, demography could be said to be a *macro-demography*, because individual lives entered in formal analysis when contributing to numbers of events, persons, years, and survivors—also the statistical analyses used to be located at the macro-level. During the last decades of the 20th century, a *micro-demography* emerged with a specific emphasis on the unfolding of individual-level demographic trajectories and on the consequences of individual heterogeneity for the study of population dynamics. The gap between macro-demography and micro-demography has since then undoubtedly widened, and this is rightly seen as a problem. This chapter documents the emergence of this gap and the answers to the challenges posed by macro-micro-micro links in other disciplines. It also focuses on recent proposals to bridge this gap and avoid a conflict between macro-demography and micro-demography.

Some hints about the reasons micro-demography has emerged can be found by having a look at disciplines that are strictly linked to demography and that have attempted micro-founding the study of specific types of behavior using some type of "methodologic individualism" approach. We look at three disciplines in particular: ecology, sociology, and economics. In *ecology*, what is defined as *individual-based modeling* (IBM) for the study of animal and plant populations has emerged starting in the mid-1970s as a research program that has lead to significant contributions. In a review, Grimm (1999) discussed 50 IBMs of animal populations published mostly during the 1990s. According to Grimm and Railsback (2005), individual-based models in ecology fulfill four criteria. First, they explicitly consider individual-level development. Second, they represent explicitly the dynamics of the resources an individual has access to. Third, individuals are treated as discrete entities, and models are built using the mathematics of discrete events rather than rates. Fourth, they consider variation between individuals of the same age. Individual-based models in ecology are aimed at producing "patterns" that can be compared with patterns observed in reality (Grimm and Railsback, 2005).

In *sociology*, the approach proposed by James Coleman (1990) proposes to found social theory ultimately on the micro-level decisions of individuals. Coleman suggests a three-part schema for explaining macro-level phenomena, consisting of three types of relations: (1) the macro-to-micro transition, which is how the macro-level situation affects individuals; (2) purposive action of individuals, which is how individual choices are affected by micro-level factors; and (3) the micro-to-macro transition, which is, how macro-level phenomena emerge from micro-level

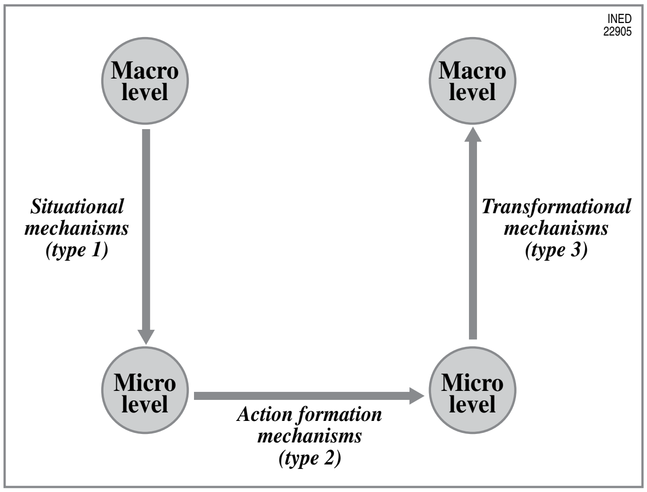

FIGURE 133–1 Coleman's conceptual framework in terms of social mechanisms. (Adapted from Hedström and Swedberg, 1999.)

action and interaction. Figure 133–1 represents Coleman's conceptual framework. It is embedded in the notion of "social mechanism" as the key concept to explain behavior in the social sciences, a concept proposed by Hedström and Swedberg (1999), who see the three types of relationships as *situational mechanisms*, representing the case in which "the individual actor is exposed to a specific social situation, and this situation will affect him or her in a particular way"; *action formation mechanisms*, representing "a specific combination of individual desires, beliefs, and action opportunities (that) generate a specific action"; and *transformational mechanisms*, specifying "how these individual actions are transformed into some kind of collective outcome, be it intended or unintended." The framework is very similar to the one presented recently by Daniel Courgeau (2003) in a review on the macro-micro link.

The micro level is now the natural point of departure in *economics* and when pointing to the macro level as the important outcome. As observed by van den Bergh and Gowdy (2003, p. 65) "During the last quarter century, the microfoundations approach to macroeconomic theory has become dominant." Mainstream economics, also known as "neoclassic" economics traditionally considers a "representative agent" that maximizes a potentially complex utility function subject to potentially complex budget constraints. This and other hypotheses lead to mathematically tractable models of macro-level outcomes. The new home economics approach that exactly applies the toolkit of neoclassic economics to demographic choices has been a key to the success of the work of Gary Becker (1980). This approach has reached a level of maturity that can be attested to by looking at recent textbooks on the subject (Ermisch, 2003) and at the importance of the literature on population economics (Zimmermann and Vogler, 2003). That we ought to start from the micro is also clearly stated by an economist who is particularly interested in population matters, Jere Behrman, who states, "For both good conditional predictions and good policy formation regarding most dimensions of population change and economic development, a perspective firmly grounded in understanding the micro determinants—at the level of individuals, households, farms, firms, and public sector providers of goods and services—of population changes and of the interactions between population and development is essential" (Behrman, 2001, p. 317–410). The attention on the policy relevance of research on population (including policy implications of results) is undoubtedly the main characteristic that comes to the surface when looking at research on population economics. Micro-based theories of behavior are used to cast "conditional prediction" of reactions to a given policy, with these reactions affecting macro-level outcomes. Within economics, several scholars have objected to the neoclassic paradigm from various perspectives (Behrman, 2001, offers objections to critiques concerning population-development relationships). Of particular interest for the reasoning of this paper are the critiques on mainstream economics that concern the assumption that agents are homogeneous and the lack of explicit interaction between agents (Kirman, 1992). Kirman's point is that even if individuals are all utility maximizers (an idea that has also been criticized by several scholars), the assumption that the behavior of a group of heterogeneous and interacting agents can be mimicked by that of a single representative individual whose choices coincide with the aggregate choices of the group is unjustified and leads to misleading and often wrong conclusions. To overcome this micro-macro "aggregation" problem, which is the transformational mechanism in Coleman's scheme, some economists have proposed to build models that resemble that of IBM in ecology. Models in agent-based computational economics explicitly allow the interaction between heterogeneous agents (Tesfatsion, 2001).

Let us now consider the approach of "micro-demography." The success of "micro-demography" is strictly linked to the emergence of the *life course approach* as an interdisciplinary program of study in the social and behavioral sciences (Dykstra and van Wissen, 1999) and to the development of appropriate statistical tools and data collection efforts (see Chapter 23). The life course approach has been under development since the mid-1970s (Mayer, 2000; Mayer and

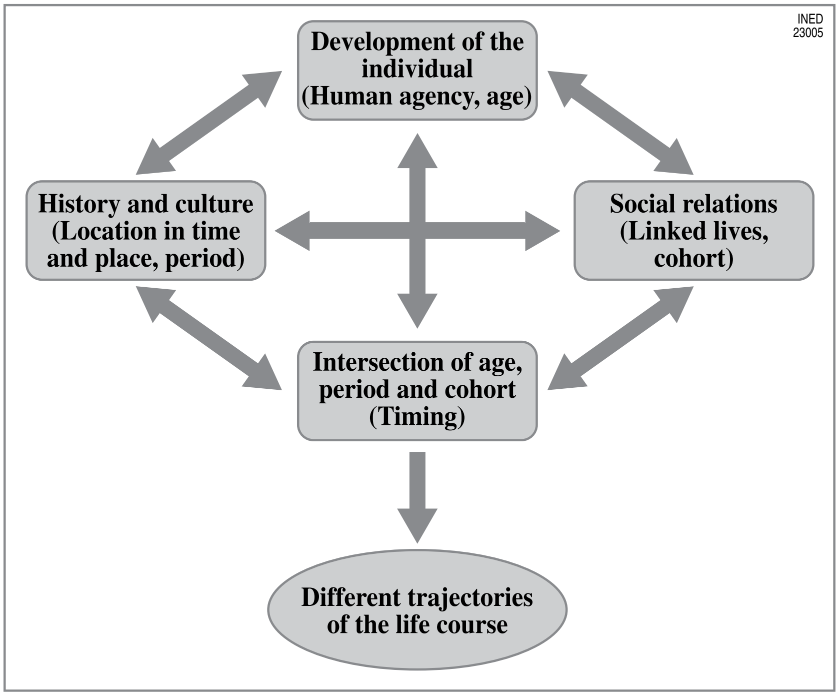

FIGURE 133–2 The conceptual framework of the life-course approach. (Adapted from Giele and Elder, 1998.)

Tuma, 1990). In their end-of-millennium review, Giele and Elder (1998) identify four chief elements as fundamentally shaping individual biographies; the first three are individual development (i.e., human agency), history and culture (i.e., location in time and place), and social relations (i.e., linked lives). In terms of the classification of social mechanisms by Hedström and Swedberg, location in time and place and linked lives are potential factors in situational mechanisms, whereas human agency is a potential factor in action formation mechanism. The intersection of such elements constitutes the fourth chief element: the timing of lives. Figure 133–2 shows the framework adopted by the life course approach. A set of interconnected *trajectories* lies at the heart of the life course analysis; trajectories are themselves shaped by *events*. The key elements outlined by Giele and Elder are naturally linked to notions used to define the coordinates of populations in demography. The human agency concept lies behind the use of *age* as a privileged time axis. Location in time and, to an extent, the idea of linked lives suggest *cohorts* or groups of cohorts as basic descriptive units for comparison. History and culture emphasize the importance of *period* and *location* in space. Because events lie at the very heart of the tradition of demography, it is not a surprise that the life course approach has been particularly influential in demographic research from a substantive point of view (Dykstra and van Wissen, 1999) and from a methodologic point of view, with a field of *life course analysis* emerging as an important part of research in population (Billari, 2003). Different from the conceptual frameworks developed in rational choice sociology or in economics, the life course approach does not explicitly provide a model for the micro-to-macro link (i.e., a scheme including a transformational mechanism). For this reason, the diffusion of the life course approach has so far probably contributed to widen the gap between scholars focusing on macro-level issues and those focusing on micro-level issues.

An important discussion of the tensions between what we may call macro-demography and micro-demography is made by Ronald Lee (2001). Lee says, "Demography is changing in profound ways, in its methods and topics of research, and in its training. There is less aggregate level (macro) analysis and more individual level (micro) analysis. There is less emphasis on process and dynamics, and more emphasis on individual decisions about demographic behavior. There is less formal demography, and more data analysis. There is much less funding of aggregate demography and formal demography, and much more funding of micro level empirical studies. Formal demography is not the same thing as aggregate or macro demography. There is also micro level formal demography, and much formal demography integrates micro and macro approaches. But for the most part, when I refer to formal demography, I will have in mind either macro level or integrative formal demography" (Lee, 2001, p. 1). Lee connects the rise of micro-demography to some factors, of which some are important for our argument. First is the increasing availability of survey data, contrary to the situation in the past, when data were mostly arising from aggregate-level population statistics. Second is the importance of the links with economics, particularly the development of the New Home Economics approach centered on the work of Gary Becker. Third, the links with other disciplines have pushed demographers to try to communicate as much as possible with colleagues from neighboring disciplines, and as we have seen before, micro-foundations have become important in neighboring disciplines. Lee concludes that demography is abandoning its core, mostly macro and mostly formal, and that this is a danger, because "key issues are macro demographic" (Lee, 2001, p. 3).

In the remainder of this chapter, I argue that there should be no "disciplinary soccer game"[1] between macro-demography and macro-demography. Micro-demography could and should be directed to the study and explanation of the key macro demographic issues mentioned by Ron Lee and should not limit itself to explaining how life courses unfold. I first review the way the macro-micro transition is dealt with (an issue that is discussed in depth in other chapters of this book). The next section discusses in particular the links between formal demography and statistical demography as related to the gap between micro-demography and macro-demography. I then present some challenges that are not solved if an explicit model of the macro-micro-macro link is unavailable. The next section of this chapter discusses the importance of looking at both levels when analyzing empirically demographic behavior. Choosing to adopt a Coleman-type of framework to bridge the gap and in parallel to approaches such as individual-based modeling in ecology, I propose simulation as a way to perform the micro-macro transition. A later section of this chapter discusses the potential role of computer simulation, particularly agent-based computational demography to bridge the gap between micro and macro, and the test ideas on transformational mechanisms. In the last section, I discuss research directions.

[1] Here I borrow and change a quotation on "interdisciplinary soccer games" from Lesthaeghe (1998), who starts from a paper by Hammel with "Economics 1: Culture 0" as the first words in the title.

II. FORMAL DEMOGRAPHY AND STATISTICAL DEMOGRAPHY: THE PARADIGM SHIFT

Formal demography has traditionally developed the advanced means of dealing with macro-level data that are presented in the first volume of this book, and these methods are proudly exhibited as flagship achievements of demography by Lee. Some specific examples are important. The approach developed for the analysis of demographic rates was specifically aimed at the analysis of homogeneous groups in a population (Henry, 1972), although Louis Henry took heterogeneity into account in his analysis of the components of fertility (see Chapter 34). Mathematical models of population dynamics that have been used in demography and in ecology have treated traditionally populations in an aggregate fashion and used differential calculus to derive results that are beautiful and useful at the same time (see Chapter 20). Age, period, and cohort models have been developed to analyze macro-level data with the aim of decomposing the effect of those three main factors (see Chapter 18).

In the first volume (fifth part) of this treatise we find a discussion of new pathways for formal demography. These pathways have been important in shaping the shift from macro-demography to micro-demography. First of all, the importance of recognizing that demographic "agents" are heterogeneous has brought important attention to the possible fallacies we incur in as we use mean rates as measures of the micro-level hazard of experiencing a demographic event. The importance of heterogeneity beyond traditional variables such as age, sex, cohort, and period was recognized by actuaries as early as the 1930s (Perks, 1932). The work of Vaupel and his colleagues (see Chapter 21) has shown that ignoring changes in the composition of a cohort leads to wrong inference about the dependence on age of the force of mortality. Since then, the importance of micro-level variation in frailty (also known as unobserved heterogeneity) has become primary in the interpretation of changes in demographic rates; this has been a key issue since the late 1970s for the statistical analysis of micro-demographic data. A similar movement toward including the possibility that individuals are heterogeneous has existed in ecology and economics.

The success of micro-demography is even more linked to what we could define as the new statistical approach to demographic data: "event history analysis." Although event history analysis clearly shares common origins with formal demography and with life tables (e.g., the title of the widely cited paper by

David Cox [1972] "Regression models and life-tables"), its development in the 1970s has been very much independent of progress in formal demography, with some exceptions. Early links between event history analysis and formal demography from the probabilistic and statistical point of view have been present in the work of Jan Hoem (Hoem, 1991; Borgan and Hoem, 1988; Hoem, 1976, 1987). The general idea of Hoem's approach was to show that macro-level quantities actually used in formal demography could be embedded in a probabilistic setting and be naturally linked to regression models. These regression models could be linked to indirect standardization techniques, focusing on counts, or to micro-level event history models. In their 1989 manual, *Event History Analysis in Demography*, Daniel Courgeau and Éva Lelièvre linked event history analysis to formal demography, explicitly saying that the move from longitudinal analysis in formal demography to event history analysis marked a paradigm shift in demographic research (Courgeau and Lelièvre, 1996). Since then, event history analysis had an important impact on demographic research, an impact that is likely to have triggered reactions such as the one documented earlier by Ron Lee, given a possibly excessive focus on the micro side (see Chapter 23).

The diffusion of event history analysis as the main technique for micro-demography has taken advantage of the theoretical basis of the life course approach, including the explicit reference to age, period, and cohort as key dimensions of that approach (see Fig. 133–2). The link was evident especially among scholars on the border between sociology and demography. Mayer and Huinink (1990), for instance, discussed the use of event history analysis to estimate age, period, and cohort effects—seeing event history analysis as a "farewell to Lexis," implying that in the era of micro-level data, age-period-cohort analysis would have overcome its classic problems deriving from the use of macro-level data (see Chapter 18). Event history analysis could be a way to fit micro-level age-period-cohort models when having access to detailed micro-level data, as shown in the application by Billari and Rosina (1998) to mortality in pre-transitional settings.

Fortunately, although the focus of studies using event history analysis has mainly been on the micro-level, on what in terms of Figure 133–1 we would call "action-formation mechanisms," some later studies have included macro-level determinants, seeing the timing of events as affected by "situational mechanisms" in a multilevel settings. Earlier papers have included macro-level covariates in micro-level event history models. Blossfeld and Huinink (1991) included a measure of the business cycle in an event history model of the timing of first marriage and of first birth. Later, event history models were generalized for the inclusion of unobserved heterogeneity at the aggregate level, creating fully multilevel event history models (see Chapter 24). These models have been systematized in their discrete-time version (Barber *et al.*, 2000) and in their continuous-time version, with a generalization to multilevel and multiprocess event history models (Lillard and Panis, 2004).

The development of multilevel event history analysis has influenced data collection. More advanced demographic data collection efforts that are based on micro-level data (e.g., getting information by individual- or household-level interviews) are more and more oriented toward the collection of macro-level data, including time-varying macro-level data. Axinn and colleagues (1997), with their Neighborhood History Calendar, design an instrument that is aimed at collecting neighborhood- or community-level histories to be used as inputs in multilevel event history models. This instrument could provide useful retrospective reports of a community history. An example of the outcome of such instrument is show in Table 133–1. The need to complement micro-level histories with macro-level time-varying data has been influencing recent efforts to collect internationally comparable demographic data. The Generations and Gender Program launched by the UN/ECE in 2000 (UNECE/UNFPA, 2000) includes the collection of retrospective and prospective individual-level survey data, complemented by the development of a longitudinal contextual-level database, allowing for a fully multilevel approach to the analysis of demographic event histories (Spielauer, 2004).

From the micro-level statistical modeling point of view, the study of situational mechanisms, including those due to unobserved factors, is allowed by statistical modeling techniques and increasingly by the col-

TABLE 133–1 Example of the Outcome of Aggregate-Level Data Collection using a Neighborhood History Calendar: Number of Neighborhoods with a School within a 15-Minute Walk

From Axinn *et al.*, 1997, p. 371.

lection of relevant paired micro- and macro-level data. Part of the micro-macro opposition within demography is overcome at least on this side. What event history models, including their multilevel generalization, could not and cannot do, by definition, is to bridge the final gap, specifying how "transformational mechanisms" lead from micro-level to macro-level outcomes. We shall return to this point later.

III. ON EMPIRICAL ANALYSES: MACRO-LEVEL CORRELATIONS AND TRUE MICRO-LEVEL EFFECTS

The risk of incurring in an *ecologic fallacy* (i.e., the inference that a macro-level relationship reflects a micro-level relationship) has been one of the motivations to introduce multilevel analysis in the social sciences and to move away from a pure macro-demographic approach (see Chapter 23). However, critics of micro-demography have rightly underlined the risk of incurring in an *atomistic fallacy* (i.e., the lack of attention to the context in which individual demographic action occurs) (Courgeau, 2003). At the beginning of this chapter, I argued that the life course approach provides a natural framework to study the impact on demographic choices of the *macro-level* context, the *meso-level* context constituted by relevant individual interactions among members of a group (Lelièvre *et al*., 1997), and *micro-level* determinants. The next section is devoted to bridging the gap from the micro to the macro level (and to the aggregation issue represented in the rightmost *arrow* in Fig. 133–1), and this section describes the issue from an empirical point of view, focusing on examples related to fertility.[2]

1. Are Micro-level Data Panaceas for Causal Analysis in Demography?

At the individual level, most studies report that cohabitation has the effect of lowering fertility. De Rose and Racioppi (2001), in analyzing data from Fertility and Family Surveys (FFS) with a multilevel statistical model, show that expected fertility in European countries is lower for cohabiting couples compared with married couples.[3] The causal relationships between partnership status and fertility are, however, not simple to isolate. The first issue that comes to mind is "macro": Some of the countries with the highest proportions of cohabiting couples and earlier ages at first union formation also have the highest levels of fertility in Europe. We know that macro-level relationships are subject to ecologic fallacy. Nevertheless, having access to micro-level event histories is no panacea for the study of causal relationships, because causal relationships may be estimated in a biased way in standard event history models. For instance, using United States data, Brien and colleagues (1999) show that the timing of partnership formation and of nonmarital conception depend on common unobserved factors; in other words, people may get married or start cohabiting *because* they plan to have a child. This type of unobserved heterogeneity, in part "shared" by two demographic processes—and often used in analyses of mortality to assess the role of common factors that affect the survival of two related individuals (see Chapter 21)—makes it difficult to evaluate the outcome of event history models using a causal interpretation. A solution is to use multiprocess event history models, explicitly allowing for the presence of correlated unobserved factors affecting more than one demographic choice at a time (Lillard and Panis, 2004). Using those models, the causal impact of being in a union has been confirmed by studies that take into account the presence of unobserved heterogeneity, and a comparative study between West Germany and Sweden has shown that for the hazard of first birth the distinction between marriage and cohabitation is not significant in Sweden (Baizán *et al*., 2004). Another point that seems clear at the micro level is the relationship between the number of unions and fertility; most scholars see separation or divorce as having an intuitive "clearly negative effect on fertility" (Pinnelli *et al*., 2002, p. 79). This intuitive idea may also be challenged, especially in reference to very low fertility settings, to hypothesize that in some specific situations the dissolution of a union may have a positive impact on fertility—union dissolution may trigger fertility. We can consider a simple, paradoxical example. In a case such as the one observed in lowest low-fertility countries, childlessness is relatively rare, and so is the situation of living as a single forever, but the progression to higher parities is also at particularly low levels. This implies that almost all couples have one child and that not very many progress to a second child. If the rule is one child per couple, the only way to reach replacement is to have individuals experience two-couple relationships! Children may be union-specific capital, symbols of the partners' commitment to their relationship (Griffith *et al*., 1985). Single-country analyses have shown that the first "shared" birth of a couple has a major commitment value (Vikat *et al*., 1999), although

[2] Part of the material presented in this section has been adapted from Billari (2005).

[3] Pinnelli and collegues (2002) provide a more detailed discussion on this issue.

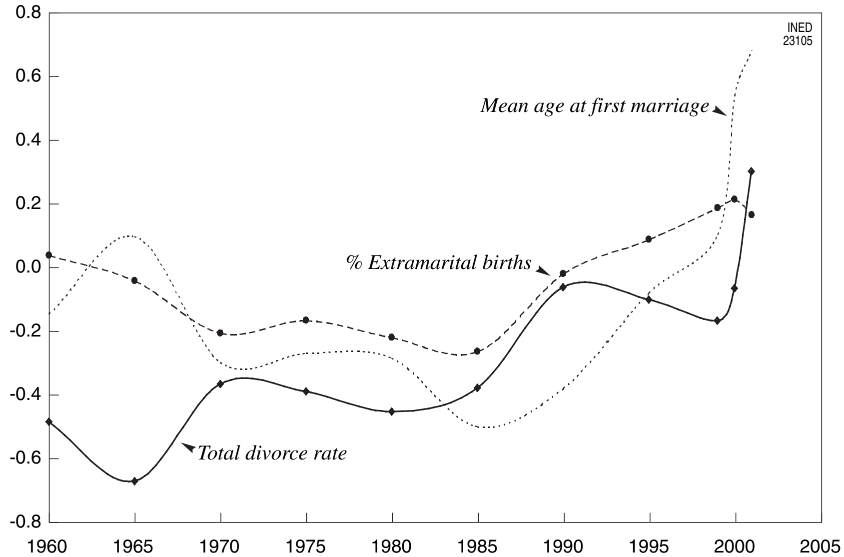

FIGURE 133–3 Changing correlations between indicators concerning union formation and fertility in the countries of the Council of Europe: cross-country correlation coefficients between the total fertility rate and total divorce rate (**A**), percentage of extramarital births (**B**), and mean age at first marriage (**C**). (From Billari, 2005.)

the effect tends to disappear with higher parities (Buber and Fürnkranz-Prskawetz, 2000). Evidence for the commitment value of a first shared birth has also been detected in the FFS analysis by Thomson and colleagues (2002).

Micro-level data alone are no panacea for assessing causality in studies concerning demographic choices. From the purely micro point of view, there is no warranty that the outcome of an event history model gives the causal account of the process. Event history modeling does not rule out the presence of unobserved heterogeneity, and this implies that the outcome of models based on analyses of micro-level data are not to be taken as true causal effects, although discussions in the econometric and epidemiology literature provide a series of tools to assess such effects (Billari, 2006).

2. Macro-level Correlations and Micro-level True Effects

Macro-level correlations between indicators are not necessarily linked to causal relationships at the micro level. The risk of incurring in the so-called ecological fallacy is one of the main justifications to move from macro-demography to micro-demography. We have, however, seen that using a micro-demographic approach does not necessarily lead to grasping causal relationships. What can macro-level relationships tell us? We argue that they help us to start considering the links between macro and micro, that is, the "situational mechanisms" of Figure 133–1. If "micro matters," as Behrman (2001) rightly claimed, we should be aware that macro also matters. Simple correlations can tell us about changes at a general level and give hints on situational mechanism and on the interaction between situational and action formation mechanisms (i.e., macro-micro interactions). The latter can be grasped in a better way using comparative research and/or multilevel modeling.

In the literature, a great deal of attention has been given to the fact that the cross-country correlation between total fertility rates and the share of women participating in the labor market has changed from negative to positive for Organization for Economic Cooperation and Development (OECD) countries. Billari and Kohler (2004) argue that this is one of the several cross-country correlations that have changed in correspondence with the emergence of lowest low fertility in Europe during the 1990s. The attention given to the study of the relationship between total fertility and labor force participation has been much more meticulous than any dedicated to the changing relationships between fertility and other related behaviors.[4] Figure 133–3 shows analyses for countries of the Council of Europe, including the correlation of total fertility rates and mean age at first marriage, the per-

[4] An exception is Dalla Zuanna (2001), who documents the change in the correlation between total fertility rates and the share of nonmarital births in 16 Western European countries from 1981 to 1996.

centage of nonmarital births, and total divorce rates. For all three indicators, the correlation with total fertility rates changes to become positive during the 1990s. Two lessons can be drawn. First, there is an additional fallacy with respect to the ecologic fallacy when looking at macro-level cross-country relationships; it is what we may call a situational fallacy. Cross-country correlations refer only to specific periods, and they may change and even shift in direction as the relevant institutional context of decisions change. Second, changing correlations may help us in discussing the potential role of situational mechanisms; even if at a micro level marriage is conducive to higher fertility, a macro-level focus on marriage may not necessarily be conducive to higher fertility.

Comparative research and multilevel statistical models are useful to understand that there is no such a thing as a "true" causal effect, independent on the context, even at the micro-level. This seems a relatively obvious assertion, but in our opinion another key problem of micro-demographic approaches is to ignore that conclusions based on micro-level analyses are to be declared conditional on the context they are embedded. Cohabitation and marriage have different impacts on fertility (e.g., in the United States, Spain, or Sweden), and the same is true for the impact of divorce on subsequent lives. Referring again to the framework of Figure 133–1, the action-formation mechanism may assume different configurations according to the situation they are inserted in. This can be summarized in the notion of macro-micro interaction effects; some micro-level effects can be different in different macro-level contexts. Some examples of such interactions in terms of multilevel statistical modeling are presented by Courgeau and Lelièvre (see Chapter 23). This is shown in an example about educational enrollment and the timing of first birth in young women's lives.

Most literature on the impact of pregnancy on students focuses on analyzing the United States (and rarely the United Kingdom) and stresses that becoming a mother has the effect of pushing women out of education. In terms of micro-level event history modeling, this translates to saying that when women become pregnant (ignoring cases of abortion), their hazard of dropping out of education increases substantially (Billari and Philipov, 2004). However, leaving education is seen as a major prerequisite to become a mother (Blossfeld and Huinink, 1991). Billari and Philipov (2004) conduct a comparative analysis using multi-process event history models to evaluate the (causal) impact of leaving education on the hazard of first birth and the (causal) impact of the conception leading to the first birth on the hazard of leaving education. Some results in terms of log-hazard related to the change in the relevant time-varying covariate are reported in Table 133–2. Table 133–2 offers two basic messages. First, it is true that finishing education triggers the transition to motherhood, because being involved in education has low compatibility with the role of mother. Nevertheless, the impact is different in different contexts, with the lowest levels in countries with a high welfare state support (Nordic countries) and a high support from parents and relatives (Italy and Spain). Looking at the impact of becoming a mother on educational career, the picture shows that the micro-level effect can be exactly opposite: Becoming a mother

TABLE 133–2 Estimate from a Series of Multiprocess Event History Models of the Impact of Concluding Education on the Hazard of First Birth and of the Impact of Conceiving the First Birth on Concluding Education[a]

	Finland	Norway	Sweden	Austria	Belgium	France	Germany	Switzerland	Greece	Italy	Spain
Impact of concluding education on first conception hazard	0.75	1.02	0.90	1.17	1.75	1.50	1.52	1.02	1.26	0.79	0.68
Impact of first conception on the hazard of concluding education	−0.60	−0.60	−0.83	0.22	0.80	0.43	0.27	−0.71	0.10[b]	−0.60	−0.56

[a] Age at conception leading to first birth is estimated as age at first birth minus 9 months and using the Fertility and Family Surveys data for 11 European Countries.

[b] The effect is not statistically significant.

From Billari and Philipov, 2004.

slows down the exit from education in Nordic countries (where welfare support may help mothers to continue their education at a slower pace) and in Italy and Spain (where the support is likely to come from parents and relatives). Becoming a mother *accelerates* the end of education in other Western European countries. The sign of the effects and the nature of action-formation mechanism may vary with the context and comparative research contributes to illuminate this weakness of pure micro-demographic analyses.

IV. FROM MICRO TO MACRO: THE ROLE OF AGENT-BASED COMPUTATIONAL DEMOGRAPHY

Using sophisticated multilevel models and comparative analyses, we can study macro-micro relationships, particularly the situational and action-formation mechanisms of Coleman's framework depicted in Figure 133–1. The missing part of the micro-macro gap concerns transformational mechanisms. How do we get from the findings and the ideas of micro-demography back to the macro level? This is perhaps the key issue raised by authors who think that demography should give answers about population processes at the macro level.

I previously mentioned the debates about aggregation problems that often pervade neighboring disciplines, particularly economics. Without the strong paradigm of the "representative agent" that underlies mainstream economics, demography has to solve aggregation problems taking into account that demographic choices are made by heterogeneous and interacting individuals and that demographic choices sometimes are made by more than one individual (e.g., couple, household). For these reasons and for the natural links to current micro-demography, computer simulation provides a way to transform the micro into macro without having to impose assumptions on the micro level one would not like to impose (e.g., homogeneity, lack of interaction). This is the way some scholars in neighboring disciplines have chosen when introducing individual-based modeling in ecology. The literature on agent-based modeling in social sciences has flourished. This has particularly been the case in economics (e.g., agent-based computational economics), political science (Johnson, 1999), and to a lesser extent, sociology (Macy and Willer, 2002; Halpin, 1999).

Agent-based computational demography (ABCD)[5] is a set of tools that models population processes, including their macro-level dynamics from the bottom up, starting from assumptions at the micro level (Billari and Prskawetz, 2003). ABCD includes microsimulation that has been used to derive macro-level outcomes from empirical models of micro-level demographic processes (i.e., event history models) and formal models of demographic behavior that describe micro-level decisions and for which we are also interested in macro-level outcomes.

Demography has for a long time been using simulation techniques, and microsimulation has become one of the principal techniques in this discipline; it is a widely discussed and applied instrument in the study of family and kinship networks and family life cycle (Tomassini and Wolf, 2000; Hammel and Wachter, 1996; Ruggles, 1993; Wachter, 1987; Hammel *et al*., 1979). Microsimulation has also been widely used in the study of human reproduction and fecundability (Nakazawa and Ohtsuka, 1997; Riley and Sheps, 1966), migratory movements (Courgeau, 1995), or whole populations (Land, 1986), and its role has been discussed in the general context of longitudinal data analysis (Wolf, 2001). Evert van Imhoff and Wendy Post (1998) provide a general overview of the topic. Microsimulation has been used to study and predict the evolution of population using a model for individuals.

What does ABCD add to demographic microsimulation in helping to bridge the gap between micro-demography and micro-demography? The emphasis of demographic microsimulation has been on the macro-level impact of a certain set of parameters estimated at the micro-level from actual empirical data. There has been no particular emphasis on the theoretical side. Agent-based models do not necessarily include only parameters estimated from actual empirical data, but it may include parameters that are relevant for a specific theoretical meaning. Microsimulation is to the event history analysis what macrosimulation (i.e., population projection based on aggregate-level quantities as in the cohort-component model) is to traditional, macro-level, formal demography. ABCD is the micro-based functional equivalent of mathematical demography. As outlined in Axelrod (1997, p. 4), agent-based computational modeling may be compared with the principles of induction and deduction. "Whereas the purpose of induction is to find patterns in data and that of deduction is to find consequences of assumptions, the purpose of agent-based modeling is to aid intuition." As with deduction, agent-based modeling starts with assumptions. However, unlike deduction, it does not prove theorems. The simulated data of agent-based models can be analyzed inductively, however the data are not from the real world as in the case of induction.

[5] This section drawn heavily from Billari and colleagues (2003).

There are reasons why ABCD may help bridging the macro-micro gap in demography (Billari *et al*., 2003, offers a full discussion). First, it is relatively easy to include feedback mechanisms and to integrate micro-based demographic behavioral theories (and results from individual-level statistical models of demographic behavior such as event history models) with aggregate-level demographic outcomes. This ability to include feedback is possibly the most important advantage of ABCD models. In such models, space and networks can be formalized as additional entities through which the agents will interact. Second, compared with mathematical modeling, it is relatively easy to introduce heterogeneous agents that are not fully rational—hence, the paradigm of the representative, fully rational agent that has and often still penetrates many economic and sociologic applications can easily be relaxed in agent-based modeling. Third, when building agent-based computational models, it is indispensable to adopt simple formulations of theoretical statements. Although agent-based modeling employs simulation, it does not aim to provide an accurate representation of a particular empirical application. Instead, the goal of agent-based modeling should be to enrich our understanding of fundamental processes that may appear in a variety of applications. This requires adhering to the KISS principle, which stands for the slogan "keep it simple, stupid" (Axelrod, 1997). Fourth, using agent-based approaches, it is possible to construct models for which explicit analytic solutions do not exist, such as social interaction and generally nonlinear models. Agent-based models are used to understand the functioning of the model and the precision of theories need not be limited to mathematical tractability. Simplifying assumptions can then be relaxed in the framework of an agent-based computational model. As Axtell (2000) observed, even when models can be solved analytically or numerically, agent-based modeling techniques may be applied because their output is mostly visual and therefore easier to communicate to people outside academia. In general, we can see formal modeling of population dynamics using differential equations and agent-based computational models as two ends of a continuum along the macro-micro dimension (Rahmandad and Sterman, 2004). It is possible to conceive "artificial societies" that need not necessarily resemble present societies; such artificial societies can be seen as computational laboratories that may allow us to reproduce past macro-events from the bottom up.

An example of macro-demographic issue that can be addressed using ABCD is the dynamics of marriage. Billari (2000) has proposed to derive what has been long known within demography as the shape of the hazard rate of marriage (i.e., a macro-level empirical regularity that has been sometimes modeled using "demographic laws") by simulating a marriage market at the micro level. Todd and colleagues (2005) present a series of such models. Figure 133–4 shows the shape of the hazard rate of marriage derived from a model in which individuals marry after a period of "learning" during adolescence (which has a normal distri-

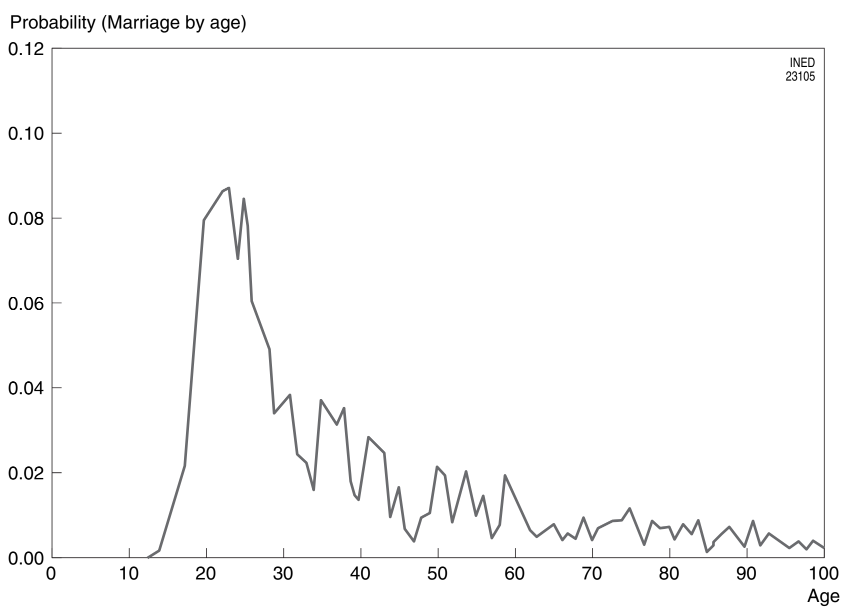

FIGURE 133–4 Hazard rate for marriage from an agent-based simulation of marriage. (From Todd *et al*., 2005.)

bution) as long as they find an acceptable partner who accepts to marry them. The shape of the curve is qualitatively similar to the ones observed in reality.

DISCUSSION

In this chapter, Coleman's framework for the analysis of social dynamics was presented as a potentially unifying scheme to bridge the gap between micro-demography and macro-demography. First, the study of the influence of macro-level factors on micro-level demographic decisions, as well as the interaction between macro- and micro-level factors, has been pushed by recent developments. The life course approach has provided a theoretical framework for demographic decision-making; multilevel statistical models possibly applied to event histories have been developed as key analytic tools; and data collection efforts with true multilevel dynamics have started and are currently planned. With these developments, micro-level analyses that do not take into account macro-level factors can be less justified by the difficulty of connecting the two levels. Second, I have argued that much less progress has been made in demography on the problem of transformational mechanism (i.e., the aggregation of micro-level results to obtain macro-level outcomes). If we are not willing to accept the idea of representative agents that has helped economists to micro-found macro-economics in a formal way, ABCDs (including microsimulation) provide an important toolkit to build a bridge from micro-level findings to macro-level dynamics. Future models may also be developed in a more statistical fashion by estimating the simulation parameters more directly from actual data.

Most of the ideas outlined for bridging the macro-micro gap, including multilevel statistical models, event history analysis, and the role of heterogeneity in the population, have become embedded in the mainstream of demographic thought. To build the final bridge, we need to accept that computer programming, specifically programming aimed at building simulation models, must become part of the mainstream technical tools in demography. As in the case of other approaches, learning and interacting with disciplines that are close to demography constitute an important advantage. Demographers ought not create a gap between micro and macro, and the existing gap needs to be bridged.

Acknowledgments

I would like to thank Paolo De Sandre for useful suggestions, Ron Lee for the permission to borrow ideas and quote from his 2001 paper, and Volker Grimm for sending me a prepublication version of his book with Steven Railsback. Many people have contributed to shaping my ideas on issues dealt with in this chapter. I am especially grateful to Tom Burch, Giuseppe Micheli, Alexia Prskawetz, and Fausta Ongaro.

Fertility, Child Mortality, and Nuptiality Indicators at the Individual Level

DOMINIQUE TABUTIN

Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

Over the past 30 years, notably due to the increase in surveys, demographic research has moved increasingly toward the analysis of individual data, with the hope of improving the explanation of observed phenomena. We have therefore moved from the long-preferred macro, aggregated level to the micro level[1] by attempting to extract the best from the various statistical tools available in the social sciences, including classification and regression (see Chapters 131 and 132). In a survey or a census, individuals are characterized by age, sex, marital status, level of education, occupation, and sometimes by their ethnic group or religion, which make up the variables known as explanatory or independent. How can dependent variables (i.e., those requiring explanation), such as a woman's or a man's fertility, a woman's or a couple's history regarding child mortality, or the intensity of marital mobility, be simply defined?

Can composite indicators be created at an individual level? Can indicators be created that summarize a life or an experience and avoid the perverse effects of confounding variables, which in demography are frequently the individual's age, duration of marriage, or the number of children already born? These indicators would enable the direct comparison of individual fertility of women (or men) and their integration into individual statistical analyses or (if needed) the creation of groups, according to the levels of excess fertility or subfertility (in comparison to the average level) or of excess child mortality or child undermortality.

There are sophisticated methods for analyzing individual data based on the occurrence of events during a given period. For example, has there been a birth (or not) over the last 5 years? Has a child died (or not)? Has contraception been used (or not)? Others are based on the number of events observed during a recent given period (the last 5 years, for example). However, this is not the main subject here, and I will not expand on the vast and complex issue of the statistical tools required for these analyses of individual determinants.

The aim of this chapter is to specify to what extent it is possible at a given time to summarize the fertility history of a woman (or a man), the mortality history of her children, or the history of her marital life through simple individual indicators that are representative of her fertility, her children's mortality, or of her nuptiality. Such indicators can be valuable tools for explanatory analysis in processing abundant data,

[1] With a tendency today to try and associate the various levels (i.e., multilevel approaches).

such as those provided by surveys such as the World Fertility Survey (WFS)[2] and the Demographic and Health Surveys (DHS).[3]

I. DATA AND GENERAL PROBLEMS

The WFS surveys[4] of the 1970s, the DHS surveys from 1985, and in the Arab countries, the Pan Arab Project for Children (PAPCHILD) surveys of the 1990s, and the Pan Arab Project for Family Health (PAPFAM) surveys from 2001, as well as most censuses carried out in developing countries over the past 20 years, have included simple questions on each woman's total number of live births and on the total number of these children who died. In most cases, the fertility surveys also provide the complete maternal history and the survival status of each child,[5] sometimes even including the marital history (i.e., marriages and successive remarriages with the dates of these events and the causes of separation).

Although the total number of events experienced since a given age (e.g., 15 years) or an original event (e.g., marriage) up to the time of the census or survey are individual measurements that are directly identifiable at the level of each woman, they are not measurements of fertility, nuptiality, or child mortality because they depend considerably on the different characteristics of each woman, such as her current age, age at marriage, or the duration of her marriage, to mention only the three factors that most affect the level of attained fertility.

Let us consider a few examples. Within the same context, one woman declares seven live births (of which three died); another, five (with two deaths); another, three (with one death). Without knowing the woman's age or the duration of her marriage, we cannot comment on her fertility level, and we cannot come to any precise conclusions on the mortality level of her children. The ratio of deceased children to the total number of children born provides a fair idea of their survival rate, but we do not know the time scale. Of these three women, we cannot judge which is the most fertile or which has had the most negative experience with regard to her children's mortality.

The idea is to create indicators of a woman's parity or of the mortality of one woman's children independently of variables other than fertility and mortality, which modify the level throughout each woman's life.

Two approaches are possible for creating these indicators:

1. *Adjusting the number of declared events to the duration of exposure to risk*, such as adjusting the parity by dividing a woman's number of declared children by the duration of her exposure to the risk of fertility (of which several definitions are possible)
2. *Calculating an indicator of relative level for each individual*, defined as the ratio of the number of declared events to a theoretical (or expected) number, taking into account notably her age and the duration of her marriage. This process of indirect standardization makes it possible to place each individual (or group of individuals) in excess fertility or subfertility, in excess child mortality or child submortality, in excess mobility or submobility, and so on, compared with a standard or average reference level.

These indicators allow much analytic freedom, because they can be used in aggregated approaches (e.g., comparison between subpopulations, social groups), as well as in analyses of individual level determinants (e.g., regressions). In the latter case, they make it possible to go beyond traditional demographic analysis (aggregated) and sometimes to synthesize various elements of information, to better specify risk factors or explanatory factors relevant to the individual. Having said this, they are not without their limitations or intrinsic problems, which we will be able to discuss after having defined the proposed indicators.

II. INDIVIDUAL FERTILITY INDICATORS

The most traditional cumulated fertility indicator and the most immediate at the individual level, which resumes a woman's (or a man's) fertility history, is *parity* (i.e., the number of live-born children declared by a woman at a given time). However, a woman's parity at a given time does not only depend on her fertility. To control for effects relating to the woman's age, her age at marriage, or the duration of her marital life, the *corrected parity*, taking into account the

[2] For the World Fertility Survey, the first large international program of fertility surveys, carried out in the 1970s and 1980s.

[3] For the Demographic and Health Surveys, the second large international program of surveys, which succeeded WFS during the mid-1980s. It is currently in its fourth phase.

[4] Chapter 121 is devoted to information systems in demography. Almost 300 national surveys have been conducted since 1970 in 120 developing countries.

[5] By calculating the number of successive births and deaths, we obtain the completed fertility and the number of deceased children per woman at the time of the survey.

duration of the risk of fertility can be calculated, or a *standardized indicator* (e.g., *duration ratio* [DRAT]) can be created that compares a woman's fertility to a standard level, independent of age or the duration of marriage.

1. From Observed Parity to Adjusted Parity

It is possible to directly analyze the individual parities observed, and this is even common practice, but it requires taking precautions that deprive us of a considerable part of the information available. The idea of calculating adjusted parities resulted from this problem.

a. Observed Parities

To study the relationship between fertility and socioeconomic variables, many authors use *parity* (i.e., the cumulated number of live births that a woman has had from the beginning of her reproductive life up to the time of the survey). Most frequently, the analysis only refers to married women. It is often available and simple (i.e., there is no need to date the events, there is no reference period, and therefore there are no problems in localizing the event in time).[6] In statistical analyses on observed parity, it is necessary to circumvent the effects of age or marriage duration. There are several possibilities:

1. *Using the parity of each woman as a dependent variable*, by introducing age and marriage duration among the explanatory variables; in this case, however, a considerable part of the explanation focuses on these two variables and, in particular, we must make the hypothesis that the relationship between fertility and the explanatory variables do not vary according to women's age or cohort.
2. *Limiting the analysis to a certain age group* (i.e., cohort) of women; in this case, several choices are available:
   a. *Working on only the oldest women*, those who have more or less completed their reproductive life (those between the ages of 40 and 49 or 45 and 49 years), but controlling for the marriage duration; the behavior of these women is primarily anchored in the past and the explanatory analysis will provide little information on the reasons behind current practices if fertility has changed recently. Furthermore, the characteristics of the women observed at the time of the survey can differ from what it was at the time in which they made their important decisions with regard to fertility, and this temporal shift between variables to be explained and explanatory variables can result in significant bias and errors in interpretation.
   b. *Centering the analysis on an intermediary age group*, in the prime of fertility and with sufficiently high numbers.[7]
   c. *Stratifying the sample of mothers into age groups* and undertaking separate analyses on those in the age groups of 25 to 34, 35 to 44, and 45 and older by introducing marriage duration as a control variable. This makes it possible to expose the explanatory factors specific to these three cohort groups, to different histories and experiences, but it also leads to working on smaller numbers and to the loss of statistical precision.

Each of these approaches has the advantage of simplicity, but they also have disadvantages, particularly that of limiting the analysis to small groups that require, in the best cases, at least much larger samples.

b. Adjusted Parities

To retain simplicity and to avoid this limitation at the same time, we attempted to control for age and marriage duration by dividing each woman's parity by the duration of her exposure to the risk of fertility. We create a *standardized indicator*, the equivalent of a rate at an individual level.

If P_i is the parity of a woman i and n_i the number of years of exposure to risk:

$$p_i = \frac{P_i}{n_i}$$

For a woman with four children in 8 years, $p_i = 0.50$; for another with four children in 12 years, $p_i = 0.33$. This indicator can be used in individual and aggregated statistical analyses (e.g., social groups, cohort

[6] This type of information is not without risks of omission (e.g., children dying at a young age) or confusion (e.g., between stillbirths and live births). These risks are generally greater among older women and those with greater completed fertility and within a higher mortality context. The women's age must also be correctly reported. It is common, especially in Africa, for young women to be declared as older and for older women to be declared as younger, which results in underestimates and overestimates of fertility.

[7] This is what Bruno Schoumaker (2001) did in a study of individual and contextual fertility determinants (i.e., multilevel analysis) in rural Morocco by taking the number of live-born children of women between the ages of 25 and 39 as a dependant variable and by introducing the age groups of 30 to 34 years and 35 to 39 years, as well as marriage duration, among the 20 explanatory variables. Access to the media, the contextual mortality level, age, and particularly marriage duration showed a significant effect on fertility.

groups), because it makes it possible to place women or groups into categories of excess fertility or subfertility according to an average level.

By considering only married women, *n* can be the period since the first marriage, or better still, if we also want to check periods of divorce or widowhood, the total number of years spent in union.[8] In societies in which a considerable proportion of births occur before marriage, the beginning of a woman's period of exposure could be fixed as being the year of her first birth minus 1 year.[9]

This indicator of individual performances can be calculated for women who are still married at the time of the survey or for all ever married women. It is advisable to exclude young women (15 to 19 years) and to limit the calculation to women who have been married for 4 or 5 years (or who had been married for at least 4 or 5 years). Although the construction of this indicator is simple in principle, it requires correct information concerning age at first marriage (or the time interval since the marriage) or the duration of each union, which is far from always being the case.

These adjusted parities (by duration of exposure to risk) have not often been used in statistical analyses of fertility determinants.[10] Nevertheless, we can mention some studies carried out using data from the WFS of the 1970s and 1980s (Pullum, 1987; Little, 1977).

In the same way, we can also work with *births occurring over a given period or within a given age range*. An already old example is provided by a study of the socioeconomic determinants of legitimate fertility carried out in Sri Lanka by Roderick Little and Soma Perera (1981), from the WFS of 1975. These authors analyzed the fertility of three large female cohorts defined by their marriage duration[11]: less than 10 years of marriage, 10 to 19 years, and 20 years and more. In each of these groups, the women had different durations of exposure. Let us take, for example, those with between 10 and 19 years of marriage; the duration of exposure is complete for the first 10 years of marriage but not for the following years (some women are at 11 years, and others are at 19 years of marriage). To control for these durations of exposure and be able to compare individual fertility, the authors created, for each woman, an indicator of the estimated number of births over 10 years; in other words, the fertility constituted between 10 and 20 years of marriage. For the cohorts with 10 to 20 years of marriage, if $N(10–19)$ is the parity of a woman who has had 10 to 20 years of marriage and $M(10–19)$ is the number of months lived by this woman since her 10th wedding anniversary, the estimated number of births over 10 years would be equal to

$$120\frac{N(10-19)}{M(10-19)}$$

and so on for the other cohorts. This fertility indicator can be used in individual analyses (e.g., regression) and in aggregate analyses (by marriage cohort or socioeconomic group).

c. A Variant on Male Fertility

Unions of various types, high marital mobility, high polygamy, and sometimes fertility outside of marriage are characteristics of numerous societies in sub-Saharan Africa. However, there are very few surveys of male fertility that trace the reproductive and marital lives of men, union by union, woman by woman, child by child. Nevertheless, this was the case of a survey carried out in South Benin in 1989 on 1650 married men aged 20 years or more (Donadjé and Tabutin, 1994). The completed fertility of married men was 11.4 children, with polygamy affecting about one-half of them. However, in such a context, how can the individual fertility of men be measured?

We could have created a DRAT indicator that controlled for age and marriage duration (but did not because we had not thought of it). To take into account the significant variability in the ages of the respondents and their experiences, we should verify the duration of each union. For each man, we calculated *the number of children per man-year* by dividing the total number of live-born children of each man (i.e., his parity) by the total number of years spent in marriage with each of his wives.[12] To eliminate very young husbands, cases of sterility, and quick divorces, this indicator was calculated using men who had spent at least 5 years in union and had at least one child.

This indicator made it possible to confirm high male fertility (the overall average was 0.30, or one child every 3 years) and to study the social or spatial dis-

[8] If we have the required data and it is of good enough quality to calculate it (i.e., duration of different unions or starting and ending dates of each union).

[9] Taking into account the nine months of pregnancy.

[10] Without really knowing why, the number of births occurring over the 5 years preceding the survey are often preferred, which is a better period indicator.

[11] The authors rightly preferred the duration of marriage to age because of the rapid increase in age at marriage in Sri Lanka and the decline in fertility that began in the 1970s.

[12] More precisely, from marriage up to the age of 49 for women, who at the time of the survey were older than 50 years or who left their union after the age of 50 years.

parities and the individual determinants, independent of union duration.

2. Duration Ratio

Let us consider the second approach, based on comparing each woman's parity with a reference model. We will then extend the procedure to men. With the dual aim of avoiding the segmentation of the samples due to the necessity of verifying both the age and marriage duration and to improve the explanation, Bryan Boulier and Marc Rosenzweig, in 1978, proposed an individual standardized measurement of cumulated fertility. It is an indicator of the *relative fertility level*, defined as the ratio of an observed fertility to a theoretical fertility. For each married woman, the number of children that she has had is compared with the theoretical number of children that she could have had in a natural fertility context considering her age and union duration. The DRAT of a woman aged *a* is therefore equal to:

$$\mathrm{DRAT(a)} = \frac{C(a)}{\int_m^a f(a)da}$$

where $C(a)$ is the number of children of the woman aged a, $f(a)$ the natural fertility rate by age and m the woman's age at marriage.

This is an indirect standardization, a kind of replica at the individual level of the marital fertility indicator that Ansley Coale (1973) created at the aggregate level.[13] DRATs are fertility indicators that make it possible to compare women (or groups of women) who have been exposed to the risk of reproduction at different durations. It is advisable to calculate them for women who have been married for at least 4 or 5 years.

DRAT controls the effect of age on fertility only to a certain extent as we make the hypothesis that theoretical fertility only depends on age, thereby excluding the role of age at marriage on fertility, frequently demonstrated in contemporary or historical realities. This model also assumes that observed and theoretical fertilities have the same tempo. This can lead to distortions. The choice of fertility reference is therefore important. The series of natural fertility rates calculated by Ansley Coale and colleagues (1975)[14] generally are used. However, as Bryan Boulier and Marc Rosenzweig have already stressed, other reference models more appropriate to the population studied can be chosen. Rather than a theoretical model or one based on old European data, there is no reason not to create one's own fertility reference based on the realities of the country or region studied. This is what Aloys Ilinigumugabo (1989) did in his multivariate study of fertility determinants in Rwanda, for example. The two standards (his and that of Ansley Coale and colleagues) lead to the same relationships, but the Rwandan standard doubles the explained variance. Another solution is to take the average fertility by age of the country studied as a reference; the subfertile women (or groups) would have a DRAT below 1, the overfertile would be above 1.

The DRAT reduces heteroscedasticity. This problem, which is quite common in regressions of the number of children according to age, is due to the fact that the variance of the dependent variable is related to an explanatory variable and that it is not constant. This is the case with the number of children whose variance increases significantly with the age of the women.

Without going as far as to supplant the observed parities, DRAT has been used in a considerable number of analyses of fertility determinants in developing countries. For example, Ron Lesthaeghe and colleagues (1985) took it as a dependent variable in their study of individual and contextual effects of education on the intermediate fertility variables in Kenya. Bruno Schoumaker and Dominique Tabutin (1999) used it in the same way in multilevel analyses of fertility in rural Morocco.

a. Is it Possible to Calculate a Male Duration Ratio?

In the same way, in a polygamic context or one of high marital mobility, it is possible to compare the total number of children that a man has had with his different wives (successive or simultaneous) to the theoretical number that he would have had if each of his wives had followed a natural (or theoretical) fertility reference plan during the period spent with this man.

If $C_1, C_2, C_3 \ldots, C_n$ are the number of live-born children that a man has had with his wives $1, 2, 3, \ldots, n$, if $m_1, m_2, m_3, \ldots m_n$ are the ages of entry into union of these women and $a_1, a_2, a_3 \ldots a_n$ their ages (at the

[13] Defined as the ratio of the real number of births observed in a population to the number of births that would have been observed if the women of this population had had the same fertility as the Hutterites, who had one of the highest marital natural fertility rates in history (i.e., total fertility rate of 12.4 children per married woman).

[14] A standard series calculated from 13 populations, mainly European, with natural fertility leading to a total legitimate fertility rate of 11.8 extrapolated for annual age groups to calculate the DRAT.

time of the survey if they are still married or at the end of their union if they are no longer married), the male DRAT is equal to

$$\frac{C_1 + C_2 + C_3 + \ldots + C_n}{\int_{m_1}^{a_1} f(a)da + \int_{m_2}^{a_2} f(a)da + \int_{m_3}^{a_3} f(a)da + \ldots} = \frac{\sum_1^n C_n}{\sum_1^n \int_{m_n}^{a_n} f(a)da}$$

This model adopts the same hypotheses as the female model. We should also assume, which is a considerable assumption, that a man's behavior (e.g., his sexuality) is independent of his age (i.e., he is young at the first union, significantly older at the *n*th) and the age of the different wives in the case of polygamy (i.e., no extreme discriminatory behavior). The calculation should no doubt be limited to men age 30 to 55 years. When both spouses are still together in their first union, the man's DRAT is equivalent to that of the woman's.

3. Individual Measurement of Recent Fertility

If we truly wish to understand and explain the current situation, it is not sufficient to work with cumulated fertility indicators (e.g., those that we have just discussed) that are based on a stock of children constituted over many years (Farooq, 1985). In the study of changes in fertility, we should attempt to measure recent behavior. In most cases, the available explanatory variables (e.g., education, place of residence, occupation, standard of living) relate to the survey date.

It is therefore necessary to use *the number of births reported by the (married or ever married) women over a recent period*. We could take the births of the last 12 months, information that is often available in censuses but that is sometimes of poor quality (e.g., misperception of the reference period, nondeclaration of the birth of recently deceased children); in detailed retrospective surveys, the information is better, but the number of events is quite low and therefore subject to significant sampling errors. It is better to increase the reference period.

It is most common to use *the number of births that occurred in the 3 or 5 years preceding the survey* (or sometimes the interval since the first marriage when that is less than 5 years), a kind of compromise between the wish to study current changes and the need to minimize reporting or sampling errors. Over a period of 5 years, it is even possible to study the intervals between births for women who have had more than one child in the period.

The duration of exposure to marriage during this period should be controlled for: from 5 years for a large number of women, less for others if they were married during the interval or have divorced. The ratio of the number of births in interval N to the marriage duration d leads to the following indicator:

$$f = \frac{N}{d}$$

At the individual level, it is equivalent to the marital fertility rate. This type of indicator is used as a dependent variable in many studies of individual fertility determinants in developing countries.

III. INDICATORS OF CHILD MORTALITY PER WOMAN

A few words on the principles and data are required before a presentation of the possible indicators.

1. Principles and Data

The study of mortality in demography remained for a long time very descriptive and was based on traditional tools (e.g., rates) (see Chapters 8, 11, and 14) or indirect approaches (e.g., Brass' methods) (see Chapter 127). We were satisfied with some differential approaches aggregated in terms of education level, social group, and zone of residence of the mother or the parents. It was and still is useful but completely insufficient to explain mortality, notably in terms of individual risk or populations at risk. Consequently, such as was the case for fertility but with a slight delay, during the 1980s, individual approaches were developed for child mortality that consisted of measuring for each woman an indicator of excess or submortality of her children compared with an average or a standard. Like any new methodology, this approach has its advantages and its limitations. Explanatory studies using various methods of multivariate analyses of the survival of children born in a recent period also multiplied, but we will not examine them here.

The creation of indicators per woman was started and developed by James Trussell and Samuel Preston at the beginning of the 1980s, then taken up again during the 1990s, notably by Amadou Noumbissi. Aimed at going beyond traditional analyses of the determinants of child mortality, it fulfills the dual aim of:

1. Improving differential analysis and research of the determinants of mortality at young ages by integrating individual heterogeneity into the study

of differences between groups, because at a given age, the children of the same group are not all exposed to identical risks of death[15]

2. Using in an optimal manner the mass of individual information on mothers and their children provided by the large samples of surveys such as WFS, DHS, and others.[16]

The principle in the construction of these child mortality indicators[17] (CMI) at the level of each mother is simple: we attempt to measure the relative experience of a mother (i) with regard to infant and child mortality by dividing the number of deaths that she experienced (Di) by the estimated number that she would have had (E_i) if mortality was at a standard level (theoretical or empirical):

$$CMI(i) = \frac{D_i}{E_i}$$

We postulate that the proportion of a woman's (or a group of women's) children who die give a measurement of child mortality if it is adjusted to take into account marriage duration or a woman's age.[18] This idea is already old[19] and is the basis for all indirect estimation methods (at the aggregated level) of child mortality from proportions of deceased children. The different variants of the approach come from the method adopted for estimating theoretical deaths.

2. Trussell and Preston's Indicators

James Trussell and Samuel Preston (1982, 1984) developed three versions of their models that differ in the way that they estimate theoretical deaths and in the data required (Amadou Noumbissi, 1996, p. 91–114). These go from the simple numbers of each woman's live-born and deceased children (resulting from the Brass questions) to the complete description of the fertility tempo by the birth dates of each child. Let us now consider the simplest and most common method based on the total number of live-born children and deceased children, simple information that is available in all surveys and in numerous censuses in developing countries, and the age and marriage duration of each woman.

The indicator for a woman i aged j (or with marriage duration j) is equal to the number of her children who have died D_i divided by an expected number of deceased children E_i:

$$CMI_{ij} = \frac{D_i}{E_i}$$

For a given woman, the number of deaths observed is the product of her births N_i by the real proportion of deceased children PD_j while the number of expected deaths is the product of her births by the theoretical proportion adopted PD'_j:

$$CMI_{ij} = \frac{D_i}{E_i} = \frac{N_i \cdot PD_j}{N_i \cdot PD'_j} = \frac{PD_j}{PD'_j}$$

The estimate of the expected proportion is based on the Brass method, which makes it possible to estimate the probability of death among children (from birth to age a) as being the product of the proportion $d(j)$ of the deaths of children of mothers of a given age j by a multiplying coefficient $k(j)$, reflecting the varying precocity of fertility (Brass, 1975):

$$q(a) = d(j) \cdot k_{(j)} \quad \text{or} \quad d(j) = \frac{q(a)}{k(j)}$$

These coefficients $k(j)$, which are a function of the fertility pattern, should be calculated from declared parities according to age (e.g., 15 to 19, 20 to 24, 25 to 29 years) or according to marriage duration (e.g., 0 to 4, 5 to 9, 10 to 14 years). Rather than using the original method of William Brass (which only uses age), we will use the variant by James Trussell (United Nations, 1984, p. 76–86; Trussell and Hill, 1980) based on the model life tables of Coale and Demeny.[20]

To estimate the expected proportion of deceased children PD', we select the probabilities of dying of a standard model life table, $q_s(a)$, and convert them into proportions of deceased children:

$$PD'_j = \frac{q_s(a)}{k(j)}$$

[15] It challenges the hypothesis of homogeneity within the group, which is typical of aggregated analysis based on averages meant to represent each person's risk. All children are born with a personal health capital that changes with varying rapidity over the course of their lives according to the external threats that they face, their health and nutrition, and other factors.

[16] These samples are frequently about 5000 women and make it possible to observe 15,000 to 20,000 live births.

[17] An excellent presentation, critique, and illustration is made in the book of Amadou Noumbissi (1996) on the methods of analyzing child mortality.

[18] A necessary adjustment insofar as the older the woman or the longer her marriage duration, the older her children and the longer they are exposed to the risk of mortality and the higher her proportion of deceased children.

[19] Developed by William Brass in 1964, they were then largely improved by him and by many other analysts during the 1970s and 1980s (see Chapter 127).

[20] In our opinion, nothing prevents the use of another version of the method, such as that of Alberto Palloni and Larry Heligman (1985), based on the United Nations' model life tables for developing countries.

The chosen standard model life table is the one that best represents the actual situation. James Trussell and Kenneth Hill (1980) give a choice between the North, South, East, and West families of Coale and Demeny's tables. Alberto Palloni and Larry Heligman (1985) propose a choice between five models of the United Nations' tables.[21] Attempts should be made to ensure that the number of real deaths is more or less equal to the number of expected deaths for the whole population.

The child mortality indicator of a woman *i* aged *j* is calculated as follows:

$$CMI_{ij} = \frac{D_i}{N_i \cdot q_s(a)/k(j)}$$

This is a standardized mortality indicator as it takes into account the age or marriage duration of the mothers. Like DRAT, it can be used in individual or aggregated analyses (in which it represents the average of a group). It is relatively simple to implement.

However, this indicator makes it possible to measure the relative experiences of mothers with regard to mortality, but not mortality levels themselves. It does not refer to any period or to a precise age group of children; the older the women, the older the average period and the more the age groups of mortality concerned are extended (e.g., infants, children, adolescents, sometimes adults). The choice of a standard level poses a problem that is inherent to all processes of indirect standardization, which is discussed in the section on the indicator proposed by Amadou Noumbissi.

The Trussell-Preston indicator was used in a large United Nations study (1985) on the socioeconomic differences of infant and child mortality in 15 developing countries (i.e., seven from Africa, five from Asia, and three from Latin America) based on WFS data or census data that included Brass' questions. This study uses the CMI as a variable to be explained, and according to country, from 10 to 17 explanatory variables (of which some were contextual). The dozen privileged variables[22] of mother or father's education, the zone and region of residence, ethnic group, religion, income, family structure were systematically made the subject of univariate, bivariate, and multivariate analyses, combining aggregated and individual analyses. This methodologically pioneering study demonstrated the benefits of using an indicator such as the Trussell-Preston CMI to identify the factors of child mortality.

3. Noumbissi's Indicator

At the beginning of the 1990s, Amadou Noumbissi took up the generalized problem of measuring child mortality per woman and taking individual heterogeneity into account and attempted to improve the Trussell-Preston method. Preserving the approach and the general hypotheses of the method, he proposed simplifying the calculation of the indicator by dividing the number of deaths derived from a standard model life table by the number of deaths observed in the whole of the population. For a woman *i* aged *j* (or with a marriage duration of *j*):

$$CMI_{ij} = \frac{D_{ij}}{E_{ij}} = \frac{D_{ij}}{N_{ij} \cdot PD_{tj}} = \frac{PD_{ij}}{PD_{tj}}$$

where N_{ij} represents the births of woman *i* aged *j*, PD_{ij} the proportion of her deceased children and PD_{tj} the proportion of children deceased for all women of age *j*.

The formula remains the same, but the reference to observed average mortality among women of the same age group (or marriage duration) avoids the problems resulting from using a standard model life table. Amadou Noumbissi (1996, p. 98–102) has demonstrated that the three types of indicators proposed by James Trussell and Samuel Preston (of which the simplest was presented above) were not sensitive to the choice of model life table, with the various possible standards leading more or less to the same results as the reference to actual average mortality. Logically, it is recommended to use Noumbissi's method, which is the simplest, and to apply it to women between the ages of 20 and 45 or 25 and 40 years, where it is most effective.[23]

Amadou Noumbissi (1996) applied these various methods to the data from two fertility surveys carried out in Cameroon in 1978 and 1991, combining univariate and multivariate analyses and multiplying the comparisons between different approaches. He concludes that socioeconomic and cultural factors have more weight than the bio-demographic factors of each child, stressing the importance of the individual heterogeneity of the mothers' characteristics, regardless of social group.

[21] "Latin America," "Chile," "South Asia," "Far East," and "General" (i.e., the average of four others).

[22] Each was the subject of a chapter in the United Nations' publication.

[23] It is better to exclude the youngest and oldest women because of the excess mortality of children specific to these extreme ages. There will be a slight loss in precision due to the decrease in the sample size, but there will be an improvement in quality.

IV. POSSIBILITIES REGARDING NUPTIALITY

In surveys in developing countries, nuptiality is generally treated more succinctly than fertility and child mortality. However, the WFS of the 1970s and 1980s focused some attention on it, revealing various elements of the nuptiality of each woman through eight questions in the questionnaire on the history of her current marriage and four questions on each previous marriage (if any). This information makes it possible to recreate the precise marital history of each woman (e.g., duration of the unions, causes of breakdowns). However, in the DHS, there is little information (e.g., date of first marriage, number of co-spouses) on the history of nuptiality.[24]

The stability of marriages, the number of marriages, and the total duration of marital life are crucial determinants of a woman's parity at a given age. All else being equal, the more stable a woman's marital life, the higher her fertility. The degree of marital mobility can also be considered as a psychosocial identity characteristic of personal life. Let us consider some examples of nuptiality indicators that can be created when past data on each union is available.

1. Marital Stability Indicators for Women

A marital stability indicator can be computed by comparing the total duration that a woman has spent in union to the total duration she would have spent in union if she had not experienced any disruption (e.g., divorce, widowhood). The numerator is obtained by summing the durations of all the unions the woman has experienced since her first marriage, and the denominator is equal to the difference between her current age and her age at first marriage:

$$MSI = \frac{D_1 + D_2 + D_3 + \dots}{x_a - x_m} = \frac{\sum_{m=1}^{n} D_m}{x_a - x_m}$$

where D_m is the duration of each union, from the first to the *n*th, x_a is the woman's current age, and x_m is her age at first marriage.

For a woman whose first union has not yet ended, the indicator is equal to 1; as soon as there is a union breakdown, it falls below 1, and the difference is greater when the duration of the union is shorter. It is advisable to limit the calculation to women whose first marriage goes back at least 5 years.

Inversely, a *marital instability indicator* can be defined by adding all of the periods spent outside marriage to the number of years since the first marriage:

$$MII = \frac{\sum_{m=1}^{n} H_m}{x_a - x_m}$$

where H_m is the series of periods of widowhood or divorce, from the first to the *n*th, and x_a and x_m are the current ages and the ages at first marriage. This indicator is the difference of the previous one at 1.

We can calculate a *relative individual marital stability indicator* by relating the indicator of a woman j of a given age *a* to the average indicator of women of the same age *a* (i.e., average of various individual indicators):

$$RIMSI_{aj} = \frac{MSI_{aj}}{MSI_{aT}}$$

where MSI_{aT} is the average indicator for all women aged *a*.

A woman has a lower marital mobility if her indicator is above 1 and a higher mobility if her indicator is below 1. The values of the indicators can also be separated into a few large groups (e.g., <0.70, 0.70 to 0.85, 0.85 to 0.95, 0.95 to 1.05, 1.05 to 1.15, >1.15), and a corresponding category can be attributed to each woman. Each one is therefore grouped into a type of relative mobility (e.g., very high, high, medium, low).

2. Male Indicators for Polygamous Societies

In monogamous societies, the same indicators that we presented for women can be used for men. However, the problem is different in polygamous societies. In these matrimonial systems that frequently combine cohabitation (more or less stable), monogamous marriage, and polygamous marriage, the marital life cycle of a man can be extremely diversified, from monogyny to bigyny, trigyny, or higher orders, with reversals after a marriage breakdown, all with periods between unions and extremely variable causes of separation and conditions according to his social status and age.

The study on male fertility in Benin (Donadjé, 1992; Donadjé and Tabutin, 1994) aimed at measuring the influence of different male marital models on the fertility of Beninese men. From the precise fertility and marital histories of each man (e.g., dates, durations, causes of breakdowns, fertility in each union) *four*

[24] In our opinion, this is an error on the part of the designers of these surveys, which has been condemned many times but not corrected in the recent phases of this program of surveys.

marital profiles combining stability and type of marriage were defined[25]:

Stable monogamy: a man having only experienced one union in his life, at least up to the time of the survey
Unstable monogamy: a man having had several spouses, but always successively
Stable polygamy: a man having taken, after his first marriage, a second and then possibly a third or a fourth wife, but without ever reverting to monogamy
Unstable polygamy: a man having gone from monogamy to polygamy, then reverting to monogamy before possibly taking another wife.

Simple individual indicators (which require appropriate data of good quality) of the same type as those established for women were created for each of these four categories of marital profiles. They made it possible to analyze the linkages between the nuptiality of Beninese men and their completed fertility after the age of 55 or their number of children per woman-year, controlling for the total duration of marriages. The monogamous men appear to be slightly more fertile (up to the age of 50) than polygamous men (0.35 children per woman-year versus 0.29),[26] whereas union stability does not have a significant effect on the fertility of the monogamous or the polygamous. The role of the intensity and rapidity of the remarriage of widowers or divorced men is very important.

V. LIMITATIONS

It is unnecessary to further emphasize the advantages of the individual indicators that make it possible, at low cost, to go beyond traditional aggregated analysis by controlling for the main confounding variables from the start, which are age or marriage duration. They make it possible to better specify the risk factors and other individual explanatory factors by taking into account the heterogeneity of the categories generally used in aggregated analyses. However, it is advisable to remember the principal limitations, which mainly come from the nature of the information used:

[25] After various other attempts at more detailed typologies that came face to face with a problem of small numbers while distinguishing groups of cohorts (or age groups) to avoid the effects of age.

[26] This is no longer the case after the age of 50, at ages when the wives of monogamous men are no longer fertile, whereas polygamous men—notably in unstable polygamy—continue to have children with their younger wives.

Selection risk. By definition, most of these indicators, like all the other demographic indicators created using data from retrospective surveys, are based on declarations made by the surviving women or men at the time of the survey. All retrospective observations (see Chapter 121) include a selection risk that is greater with higher mortality or mobility.

Gaps between explained variables and explanatory variables. All information on fertility and child mortality is by definition based in the past, but a past of varying remoteness according to the type of questions and the ages of the individuals. There is most frequently a chronologic gap between the variable to be explained, which is measured by these indicators, and the explanatory variables, which in most cases are prevalent characteristics at the time of the survey. This problem cannot be solved without complete social and economic biographies (see Chapter 24).

Quality of the information. The quality of the results depends on the quality of the data. However, we know that all retrospective questionnaires are faced with particular problems. For fertility, child mortality, and nuptiality we must rely on the memory of individuals to gather a mass of crucial information on ages, dates, and durations. Major errors come from omissions (e.g., of births and especially deaths of children), confusion (e.g., between still births and live births), or false declarations (e.g., of dates or ages). Individual indicators are highly likely to be more sensitive to these problems than aggregated measurements, which can benefit from compensation effects. This type of approach is only possible if, after rigorous verification, the data quality proves sufficiently high.

Random fluctuations. The low number of births or deaths of children observed for each woman is the cause of the considerable random variability of individual indicators. The effects can be reduced, but not avoided, by eliminating women with exceptional characteristics with regard to the phenomenon studied (e.g., very young, short duration of a stable marriage, not very fertile). In particular, this type of indicator is certainly not recommended in contexts of low fertility or low mortality.

Cohort and Period Measures of Fertility Based on Microdata

ALBERTO PALLONI AND PAOLO DE SANDRE

Center for Demography and Ecology, University of Wisconsin, United States

Dipartimento di Scienze Statistiche, Università degli Studi di Padova, Padova, Italy

Conventional demographic analysis of fertility is based on measures that require information on the final outcomes of the reproductive process—births or pregnancy termination—that are usually classified by age and less frequently classified by parity (see Chapters 12 and 14). In the case of total births, these measures are classic occurrence-exposure rates for repeatable events (i.e., fertility rates and age-specific fertility rates), whereas in the case of birth by parity, we normally employ occurrence-exposure for non-repeatable events (see Chapter 8). With the information data normally available to demographers, fertility analysis is almost always carried out using age patterns of fertility and summary measures of fertility, such as the total fertility rate (TFR) (see Chapter 14). Information of births by parity is used less frequently, and seldom are we in a position to evaluate patterns of fertility by age and parity, as well as synthetic measures derived from them, such as parity progression ratios (PPRs).

There are three problems associated with the use of these measures. The first is that we rarely interpret synthetic period measures such as TFR with the caution we should employ given that these measures are sensitive to the parity composition of women at any given period and, therefore, to the reproductive histories of women belonging to different cohorts. The second is that when we do focus on parity-specific measures, we seldom employ proper tools to establish a relation between them and the more commonly used age-specific rates. These relations are complex because they incorporate information on the reproductive history of women belonging to different age groups and or cohorts. We rarely are able to identify patterns of fertility by social groups within a population, and consequently, we are unable to offer even approximate causal interpretations.

All three problems can be addressed with microdata retrieved from fertility or more general-purpose household surveys that include birth histories as well as a number of characteristics for the population being studied. There are a number of ways to take advantages of the richness of information available in these studies to better understand fertility dynamic (De Sandre, 2000), to properly interpret conventional synthetic measures of fertility and, more generally, to produce an integrated set of indicators with well defined specification regarding their advantages and shortcomings.

In fact, it has been the advent of new, more detailed information on fertility processes, that prompted demographers to question the validity of conventional measures of fertility (Keilman, 1994a, 1994b, 1999; Rallu and Toulemon, 1993, 1994; Calot, 1994; Desplanques, 1994; Festy, 1994; Ni Bhrolchain, 1994; Sardon, 1994) (see Chapter 17). They argue forcefully in support of the use of modified procedures reflecting better the details and nuances of birth interval dynamics, which are only weakly if at all captured by conventional measures, such TFR (Rallu and Toulemon, 1993, 1994; Ni Bhrolchain, 1992; Feeney and Yu, 1987; Palloni, 1984; Feeney, 1983). Rethinking of fertility measures occurs on the heels, though independently, of critiques to the theoretical framework that assigns primacy of cohort over period approaches to the analysis of fertility (Ni Bhrolchain 1987, 1992; Ryder, 1964, 1965; Hajnal, 1959). The revisionist approach questions the importance of cohort effects on fertility, plays down the relevance of cohort-based approaches, and emphasizes instead the need to fine-tune and adjust period measures rather than de-emphasizing their importance on the grounds that they do not convey properly potential cohort effects. Newly proposed measuring tools can be categorized in two classes. The first are synthetic life table-based procedures that adjust for compositional effects by using full information on birth interval dynamics and are appropriate as a foundation for making broader inferences regarding the course of the fertility process. The second are extensions of life table-based procedures designed to adjust period-based measures of fertility levels (quantum) for possible changes attributable to the timing of births, not to changes in the underlying intensity of fertility.

In this chapter, we formulate initial outlines of a generalized framework for a new class of fertility indicators that include those referred to previously as a subclass and establish the relations between several subclasses. The chapter stops short of evaluating the performance of the various classes of indicators. In the second section of the chapter, we show that conventional measures of fertility are contaminated by compositional characteristics and derive synthetic measures to attenuate some of the distortions they may cause. The next section shows a general application of synthetic procedures to identify fertility profiles by subpopulations, and in the last section of this chapter, we review the effects of changes in the tempo of fertility on its quantum.

I. GENERAL FRAMEWORK

Paradoxically, the controversy about proper measurement of fertility in general and the TFR in particular (Bongaarts and Feeney, 1998; Keilman, 1994a, 1994b; 1999; Rallu and Toulemon, 1993; 1994) is not replicated with measures of mortality. Empirical research suggests that cohort effects are more likely to be present in and relevant for mortality trends than they are for fertility. It should be in this area where researchers could find plenty of room for controversy and where the selection of measures should be accompanied by a plethora of careful justification. This is far from being the case. In mortality analysis we rely exclusively on the use of life expectancy (e_o), a pure synthetic indicator. This practice is generalized despite the fact that time trends in life expectancy, for example, conceal and confound changes that affect all cohorts simultaneously (i.e., period effects) and those associated with particular birth cohorts (i.e., cohort effects) as much or more than measures of total fertility do in the case of fertility analysis. However, there is where similarities between mortality and fertility indicators end for there is an important difference that leaps into the open. Whereas we can assert that a synthetic measure of mortality, such as e_o, is not contaminated by compositional factors, it is not possible to make the same claim about TFR. This does not refer to the fact that both e_o and TFR are functions of the population composition according to factors that directly affect fertility or mortality levels (e.g., education, occupation), but to a less obvious feature. The e_o term characterizes the experience of a fictitious cohort that experiences an age pattern of mortality risks observed at time t, $[\mu(x,t)]$. TFR characterizes the experience of a fictitious cohort that experiences a sequence of observed fertility rates $[F(x,t)]$. Although the sequence $[\mu(x,t)]$ constitute the primary object of interest in mortality analysis, the sequence $[F(x,t)]$ is a result not just on fertility risks associated with women of different parities but also of the composition of women by age and parity. The latter introduces the same kind of compositional distortions that age distributions do when comparing crude mortality rates. The value of e_o is given by the following equation:

$$e_0(t) = \int_0^{\omega} \exp\left(-\int_0^{x} \mu(y,t)dy\right) dx \qquad (1)$$

where $\mu(y,t)$ is the age-specific mortality risk at exact age y in year t (experienced at time t by those born $t - y$ years before). Although one may quarrel about the plausibility of the assumption that the entire sequence of observed values $\mu(y,t)$ can ever be experienced by any of the cohorts contributing to it (e.g., due to possibly strong cohort effects), there is no question that $e_o(t)$ depends on these rates and nothing else. This is not the case of TFR.

1. Total Fertility Rate as a Function of Age-Parity–Specific Fertility Rates

We begin with the simplest of formulations according to which TFR is a weighted average of age-specific fertility rates.

$$TFR(t) = \sum_j f_j(x,t) w_{j-1}(x,t) \qquad (2)$$

where $f_j(x,t)$ is the conditional risk of a jth birth for women aged x and of parity $j - 1$ at time t, and $w_{j-1}(x,t)$ is the fraction of all women aged x at time t who are of parity j – 1. Thus, $w_{j-1}(x,t)$ is the parity distribution of women age x at time t. The quantity $f_j(x,t)$ is an occurrence-exposure rate so that $f_j(x,t)$dt, where dt is a small interval of time, is approximately equal to the conditional probability of having a jth birth among women aged x and of parity $j - 1$. The distribution $w_j(x,t)$ is not always the outcome of the set of observed values of $f_j(x,t)$ because it may depend on rates other than those we are interested in. To see this, notice that the expression for $w_j(x,t)$ is

$$w_j(x,t) = \int_0^x f_{j-1}(x-y,t-y)\exp\left(-\int_{x-y}^{x} f_j(v,t-v)dv\right)dy \quad (3)$$

where $f_{j-1}(x - y, t - y)$ is potentially different from $f_{j-1}(x - y, t)$ for all j, x and y.

Comparisons of TFR across groups or over time reflect disparities in the values of $f_j(x,t)$, the quantities of main interest to the analyst, and the differences in the distributions of women by achieved parity, a distribution that may not reflect current fertility risks at all.[1] When parity-specific fertility rates are constant, TFR will reflect correctly the prevailing fertility levels by parity. However, when fertility experiences short run shocks or even longer term fluctuations, the parity distributions at various point in time will differ as they will reflect parity-specific fertility rates experienced during the past. As a result TFR will not always be an accurate measure of the period levels of age-parity-specific fertility rates. Arguably, it is $f_j(t,x)$ that should be the main object of fertility studies, just as $\mu(x,t)$ is the main object of interest in mortality analysis. If so, TFR is no less contaminated than other demographic indicators that happen to be joint functions of rates of interest and of nuisance distributions.

The expression for TFR suggested previously also makes salient the fact that the analogy between it and crude mortality rates is of limited utility only. In fact, whereas the distribution that distorts crude mortality rates (the age distribution) is a result of past fertility and mortality rates $\mu(x)$, the distribution distorting TFR is a function solely of the past values of the age-parity–specific rates themselves.[2]

The solutions available to neutralize the aforementioned shortcoming of TFR are the same as those we resort to in the case of mortality. The first is to recalculate TFR using direct or indirect standardization (see Chapter 15). Indirect standardization could be applied when only the $w_j(x,t)$ terms but not when the $f_j(x,t)$ are known. Indirect standardization requires that we search for a standard set of age-parity–specific fertility rates and apply them to the observed and a standard parity distribution by age. Direct standardization requires knowledge of both $w_j(x,t)$ and $f_j(x,t)$, as well as a standard set of $w_j(x,t)$.

The second solution (Rallu and Toulemon, 1993, 1994; Palloni, 1984) is to create a fictitious cohort and apply to it the observed rates $f_j(x,t)$, much as we do in the construction of life tables for mortality or nuptiality. Systematic application of $f_j(x,t)$ to an arbitrary cohort of women results in the parity distribution intrinsic to the $f_j(x,t)$. As a consequence, all derived measures, including TFR, will be a function solely of these rates, not of the joint influence of $f_j(x,t)$ and of some potentially confounding observed parity distribution. As in the case of mortality, the second solution is preferable to the first and deserves closer scrutiny.

2. Description of the Life Table Procedure

The formulation proposed follows closely solutions developed by Rallu and Toulemon in a recent paper (1994) and much earlier on by Palloni (1984). Let us assume that we condition on age of entrance into union and we overlook altogether births that take place outside a union. These assumptions are not limiting because the procedure can be adapted easily to include out-of-union pregnancies. The fraction of a union-cohort who entered union at age y and who are of parity j at age x is given by the following equation:

$$W_j(x/y) = \int_0^{x-y} f_{j-1}(x-z)\exp\left(-\int_{x-z}^{v} f_j(v)dv\right)dz \quad (4)$$

We use W instead of w to emphasize the fact that this is the distribution by parity that results from the application of the observed age-parity–specific rates. From [4] one obtains the conditional (on age of entrance into union) intrinsic set of age-specific fertility rates and TFR (Palloni, 1984). To calculate the unconditional rates we integrate out the density of ages of entrance into unions. If TFR(y) is the expected TFR among those who enter a union at age y, then TFR $= \int_y$ [TFR(y) $dH(y)$], where $H(y)$ is the distribution function of age of entrance into unions. The intrinsic values of the age-specific fertility rates and of all other derived quantities (e.g., TFR, PPRs, means ages at birth for parity) are all life table quantities and therefore possess all the virtues and shortcomings of measures derived from a life table in the case of mortality (e.g.,

[1] The fact that $f_j(x,t)$ is also a function of parity-specific rates by duration and the duration distribution by parity is evaluated later in the chapter.

[2] This statement is accurate only when fertility and mortality are unrelated.

life expectancy, mean ages at death). In particular, they are synthetic measures and apply to a fictitious cohort. As in the case of mortality, the life table–based quantities for fertility reflect changes in quantity and changes in tempo of fertility. This topic is discussed later in the chapter.

3. Total Fertility Rate as a Function of Age-Duration-Parity-Specific Fertility Rates

The quantities $f_j(x,t)$ are themselves a function of the age-duration-parity–specific rates, $f_j(x,d,t)$, and the composition of the age group by parity and duration.

$$f_j(x,t) = \int_0^x f_j(x,d,t) v_{j-1}(x,d,t) dd \tag{5}$$

where $v_{j-1}(x,d,t)$ is the fraction of women aged x and achieved parity $j-1$ who have been d years in that parity. Equivalently, these are the women who experienced parity $j-1$ at age $x-d$ and have not progressed to the next parity since. As a consequence, an age-specific fertility rate and the corresponding TFR are affected by composition by duration and by parity; the fertility rate at age x is given by the following equation:

$$f(x,t) = \sum_j \int_0^x f_j(x,d,t) v_{j-1}(x,d,t)\, dd$$

and

$$TFR(t) = \int_0 \left\{ \sum_j \int_0^x f_j(x,d,t) v_{j-1}(x,d,t)\, dd \right\} \tag{6}$$

To remove the compositional effects of duration composition from the fertility measures we can resort to the standardization procedures (direct and indirect) or to the life table.

4. A Generalization of the Life Table Procedure

The procedure described earlier (Sect. 2) can be generalized in a straightforward manner to deal with composition by duration (Rallu and Toulemon, 1994; Palloni, 1984). Assume we start with an arbitrary cohort of women at some age y (exact age of union). We then recursively apply the rates $f_j(x,d)$ to generate the fraction of women at age x and duration d of parity j:

$$W_j(x,d) = \int_z \int_y f_{j-1}(x-z, r) \exp\left(-\int_{x-z} f_j(v, v-(x-z)) dv \right) \tag{7}$$

This expression looks intractable but its application amounts to nothing more complicated than building several life tables by duration for each age. If durations with nonzero risks are, say, not longer than 5 years, then for each age we will have 5 life tables. It is easy to calculate $f_j(x)$ from these life tables and, from these, all other pertinent quantities, including $W_j(x)$, $F(x)$, TFR, and PPRs.

Rallu and Toulemon (1994) apply the life table procedures described previously to the case of France and compare their performance to that of conventional fertility measures. They conclude that they are superior in terms of the accuracy with which they capture changes in fertility. In particular, they verify that the life table-based measures lead to lower values of TFR when the parity distributions are "too favorable" and the values $w_j(x,t)$ are positively correlated with the values $f_j(x,t)$ and lead to higher values of TFR when the quantities $w_j(x,t)$ and $f_j(x,t)$ are negatively correlated.

In an earlier application, Palloni (1984) used the same life table procedure to quantify the effects of intermediate variables on fertility in developing countries. As this represents an extension of the life table procedure, we will treat it separately.

II. EXTENSIONS AND APPLICATION OF THE LIFE TABLE PROCEDURE

Although the quantities $f_j(x,t)$ or, better yet, $f_j(x,d,t)$, are in some sense the elementary particles of fertility measurement, an analyst may be interested in evaluating the effects that certain conditions have on TFR or on associated measures. Equivalently, the researcher may be interested in creating scenarios by calculating what TFR, or other fertility measures, would be if the population distribution of conditions that directly impact fertility were changed in a predefined manner. A clear example of this is the evaluation of the role played by the so-called intermediate variables (Bongaarts, 1978). As shown elsewhere (Palloni, 1984) this can be achieved with an extension of the life table procedure suggested earlier.

1. Summary of the Procedure

Consider a simple case where the researcher is interested only in quantifying the effects of oral contraception, C. The observed population is consequently divided into those who practice contraception ($C = 1$) and those who do not ($C = 0$). Similarly the basic fertility rates, $f_j(x,d,t)$ attain two possible values, $f_j(x,d,t; C = 1)$ and $f_j(x,d,t; C = 0)$. Assume further that through the use of hazard models on appropriate birth interval data we establish that the ratio of the age-duration-parity–specific rates for individuals practicing contraception to the age-duration-parity–specific rates for those not practicing contraception is $\exp(\beta_j) = \zeta_j$ for parity j, with $\beta_j < 0$. Deployment of the life table procedure described before on two hypothetical cohorts, one practicing and the other not practicing contraception, will result in two sets of fertility rates $F(x; C = 1)$ and $F(x; C = 0)$ with corresponding TFR($C = 1$) and TFR($C = 0$). Similarly, the procedure can produce parity-specific measures, such as mean age and PPR for parity j. The overall effects of C on TFR can be gauged using the relative difference

$$\Delta_T = \frac{[TFR(C=1) - TFR(C=0)]}{TFR(C=0)}$$

The observed TFR is a weighted average of TFR($C = 1$) and TFR($C = 0$), and the weights are given by the observed distribution of the population according to the trait C. The total effect, Δ_T, can be decomposed further into contributing parts. In particular, it is possible to estimate the magnitude of the effects of C that operate by reducing the fertility rate at lower parities, say at parities $j < 2$. This can be achieved by first calculating the TFR that results after imposing contraception, ($C = 1$), for the first- and second-order births, say, TFR′:

$$TFR' = [P'_o + P'_o * P'_1] + \Sigma_{k=2,w}(P'_o * P'_1)\Pi_{[j=2,k]}P_j$$

where P_j is the observed PPR of order j and P_j' is the PPR of order j estimated after taking into account the effects of contraception. Finally, an estimate of the effect we seek can be calculated as the ratio $\Delta_p = [TFR' - TFR]/TFR$, and the contribution of contraception through the first two birth orders is the fraction Δ_p/Δ_T.[3]

The decomposition technique can be extended further. For example, we could investigate the effects of contraception on the age pattern of fertility. This is easily done computing age-specific fertility rates from life tables for synthetic cohorts that practice and do not practice contraception and then contrasting the two.

2. Estimation of Effects

The key quantity in the foregoing procedure is ζ_j. To estimate this parameter we need information on the birth interval dynamics of a population where some members practice contraception and others do not. A typical source are birth histories and recollections of associated behavior, including abortion, contraception, breastfeeding, and participation in unions. To retrieve an estimate of β we can choose between alternative models. In what follows, we describe the use of multistate hazard models, although other models could yield similar estimates. The idea is to represent parities 1, 2, 3 . . . as states that women attain at various points in their childbearing history. Transitions can only occur among successive states and only in one direction. Whether women experience a transition from j to $j + 1$ and, if they do, the timing (duration) of such transition depend on a number of factors, including the age at which she attained state j, behaviors adopted during the period of time during which she waits in state j, external conditions that take place during her sojourn in j, and some of her more or less permanent characteristics, such as family upbringing, education, age at first union, and even perhaps some community characteristics. The most general model for the conditional risk of passing from parity j to parity $j + 1$ at duration d for the ith woman has the following form:

$$f_{i(j)}(d; x, \mathbf{Z(t)}) = \mu_o(d) * \exp(\alpha * X + \zeta\,\mathbf{Z(t)}) * \exp(\varepsilon_i)$$

with probability $\Gamma_{i(j)}(\mathbf{W})$ and

$$f_{i(j)}(d; x, \mathbf{Z(t)}) = 0 \qquad (8)$$

with probability ($1 - \Gamma_{i(j)}(\mathbf{W})$, where d is duration in state (parity) j for woman i, x is her current age, $\mathbf{Z(t)}$ is a vector of covariates some of which are fixed (time invariant) and others are time dependent, such as contraception and breastfeeding behavior, ζ is a vector of effects, α is the effect of age, and ε_i is the effect of a fixed (time invariant) individual unmeasured condition characteristic of woman i. Although some women may experience a transition from state j to state $j + 1$, others may never do so. An estimate of this probability in the population is an estimate of the PPR of order j and we have denoted it as Γ_j ($\mathbf{W}$). This quantity can be function of individual or contextual covariates included in the vector $\mathbf{W}$. The population based PPR is the average of the individual probabilities of experiencing the transition or the average of Γ_j ($\mathbf{W}$). The parameters of this model can be estimated by maximum likelihood using software such as CTM (Yi *et al.*, 1987).

3. Application of Estimates

After the parameters of the model are estimated, we can deploy the life table procedure described previously and calculate the "predicted" parity distributions and occurrence exposure rates for any desired population profile. A population profile is simply a

[3] Expressions for the standard errors of each of these estimates can be obtained by straightforward application of the delta method. An analyst can test whether measured changes or contributions are of any statistical significance.

subset of the population with given values of the vectors of characteristics Z and W. For example, if Z and W each include only one fixed dichotomous covariate, we will have four possible population profiles, a two by two table. Application of the life table procedures described earlier using predicted occurrence-exposure rates for each of the four profiles will result in four different values for the quantities of interest, one for each cell of the two by two table, including TFR, mean ages at parity j and PPRs. The overall population values associated with these quantities are simply their weighted averages, where the weights are given by the proportional distribution of the population in the two by two table.[4]

In theory, at least, we can generate fertility estimates for any desired population profile we wish to study. It is certainly possible to assess the relevance of counterfactual scenarios involving, for example, no practice of contraception, significant delays in the age of entry into first union, absence of breastfeeding at higher parities, elimination of abortion and so forth.

4. Shortcomings

At first glance the suggested procedure may appear exceedingly complicated due to the large number of calculations involved. However, with the speed and capacity of modern desktops, estimation of life tables for various subgroups of the population cannot take more than a few minutes of actual computer time. The real difficulty is rooted in the decision making process in the hands of the investigator to determine the relevant subpopulations and scenarios for which calculation must be undertaken. These should be chosen so that they correspond to theoretically relevant constructs and are consistent with substantive questions and conjectures.

A second shortcoming is that we cannot ever be certain that a particular scenario is internally consistent. Imagine for example that the investigator poses a scenario where contraception is practiced for timing purposes in the first two parities but not thereafter. There is nothing intrinsically difficult in the life table calculations for such a scenario. The main difficulty is that calculations rely on two unverifiable assumptions. First, that the dynamic of birth intervals other than the first two, will be the same as those we observe in the current population even in the counterfactual scenario. Second, that characteristics with some influence on the birthing process will remain unchanged even after changing the behavior in the first two birth intervals. The first assumption pertains to interrelations between birth intervals. It is tantamount to believing that the estimates from the data capture thoroughly all relevant interrelations. The second assumption has to do with direction of causality, an issue neglected in the model formulated previously. It is tantamount to assuming that relevant individual characteristics are exogenous to the birthing process of higher order.

These assumptions may not be entirely realistic, but a similar level of unreality pervades the application of the life table procedure itself. The implicit assumption we make in constructing the life table is that the observed $f_j(d,x,t)$ can prevail in an hypothetical population even though we have no way of verifying this. It should be remembered that these rates are cohort-specific rates and could potentially be a function of the past history of some cohorts. Except for the trivial case when fertility is constant, cohorts will have different histories and we will have no way to state unequivocally that the observed values $f_j(d,x,t)$ and $f_j(d',x + r,t)$, for example, can actually be experienced by members of a single cohort.

III. ESTIMATING THE TEMPO AND QUANTUM DIMENSIONS OF PARITY-SPECIFIC FERTILITY

1. An Informal Introduction to the Problem

Previous sections of the chapter reviewed problems with conventional measures of fertility caused by the fact that these measures, as other crude demographic indicators, are the joint outcome of both rates and distributional characteristics. As in the case of mortality, the life table approach is an attractive solution for it attenuates the impact of distributional differences and permits to infer the contribution of well-identified determinants that are unequally distributed in the population.

There is, however, another issue that requires some attention. This is that in many situations it will be important to parse the effects of changes in the timing of events and of their intensity. This is a classic issue in fertility analysis identified as the problem of disentangling changes in *tempo and quantum* of fertility (1999; Keilman, 1994a, 1994b; Bongaarts and Feeney, 1998; Ryder, 1964). Although less popular or less commonly studied, a completely analogous problem exists in mortality analysis as well. In the case of fertility, the

[4] Throughout, we assumed that fertility risks are conditional on age of entrance into union. To calculate overall measures of fertility, such as TFR, we must integrate the density of waiting time to first entry into union. For example, TFR = $\int$TFR(y) dH(y), where H(y) is the distribution function of first age at union.

issue can be described as follows: Even when the overall fertility level experienced by women in various groups in a population may be identical, the timing of their births could be different. For example, although the total number of children born to women belonging to different cohorts may be the same–the intensity of fertility is constant–the youngest cohorts may be having children earlier (anticipating childbearing) relative to the older cohorts. If this phenomenon takes place over a period of time, conventional measures of levels of fertility or those associated with the life table approach, will reveal changes even though all women, regardless of cohorts, will eventually have the same number of children. The condition for this to happen is that there be a relation between fertility rates to ensure that if women of a particular cohort anticipate childbearing at some point during their reproductive lives, there will be an offsetting reduction later on.

Characteristics of a particular period, for example, may impel anticipation (postponement) of births without, however, altering the lifetime value of fertility. The change, however, will increase (reduce) measures of fertility for that particular period and could incorrectly lead to the impression that lifetime fertility levels are changing, when what is taking place is simply a change in the timing of births. Confusion between changes in tempo and quantum has been normally associated with conventional measures of fertility such as TFR, but they also apply to measures derived from life table procedures.

A similar phenomenon can occur in mortality. Suppose for example, that some cohorts experience unusually high mortality at young ages and that, as a consequence, these cohorts will benefit from unusually mild mortality rates when they reach older ages. Under some regular conditions constraining the relation between the force of mortality at various ages, it could happen that, even though the overall life expectancy by cohorts remains unchanged, the life expectancy for several periods of time will experience changes. However, because death is inevitable, the mortality quantum is always equal to 1, whereas the fertility quantum by birth order is usually less than 1 and can vary over time. Only tempo effects influence mortality; in the case of fertility, both the tempo and the quantum may change.

2. Formalization of Tempo and Quantum Changes in Overall Fertility Rates

Assume that age patterns of fertility differ only in their first moment so that we can speak unambiguously of a younger or older fertility pattern. A regime of fertility anticipation will occur when the population of interest shifts from an older to a younger fertility pattern without changes in the level of overall fertility. To formalize this idea we first write a age-specific fertility rate for time t as the product of a factor controlling the tempo (age pattern) and another controlling the quantum (TFR) or

$$f(y,t-d) = Q\,(t-d)\lambda(y,\,t-d)$$

where $f(y,\,t-d)$ is the age-specific fertility rate at age x (y) for women born in year $(t-d)$, $\lambda(y,\,t-d)$ is an age pattern of fertility for the same cohort, $Q(t-d)$ is the cohort TFR, and $\int \lambda(y,t-d)dy = 1$. Changes in the tempo of fertility imply only that while all cohorts experience $Q(t-d) = Q$ (for all d), the age pattern changes so that the cohort aged z at time t experiences $f(y,\,t-z) = Q\lambda'(y,\,t-z)$, subject to the restriction $\int \lambda'(y,t-d)dy = 1$. We now approximate the age pattern of fertility appropriate for a cohort born d years ago as

$$\lambda(x,t-d) \approx \lambda(x) + d\left.\frac{\partial\lambda(y,t-d)}{\partial d}\right|_{y=x} \tag{9}$$

This is a representation closely related to one suggested by Keilman (1994a,b; 1999). Two restrictions must be noted. First, the function $\lambda(x)$ can be thought of as a standard fertility schedule and must be a suitable representation of fertility in the population being studied. Second, because we require that $\int \lambda(y,t-d)dx = 1$ for any all d, it must be the case that $\int (\partial\lambda(y,t-d)/\partial d)dx = 0$ for all d. It can now be shown that the TFR at time t, $Q_{per}(t)$ is given by

$$\begin{aligned} Q_{per}(t) &= \int_x f(x,t-x) \\ &= Q\left(\int_x \lambda(x)dx + \int_x x\frac{\partial\lambda(x,t-x)}{\partial x}dx\right) \end{aligned} \tag{10}$$

or equivalently by

$$Q_{per}(t) = Q(1+\mu') \tag{11}$$

where μ′ is the annual change in the mean of the cohorts' fertility schedule, such as $\mu' = \partial M_{coh}(t-d)/\partial d$, and $M_{coh}(t-d)$ is the mean age of the childbearing schedule for the cohort born d years before t. The latter quantity can be approximated from the observed annual change in the mean age of the fertility schedules over a short period before t, such as between t and $t-h$:

$$\mu' \approx (1/h)(M_{per}(t) - M_{per}(t-h))$$

where $M_{per}(t)$ and $M_{per}(t-h)$ are the period mean ages of the fertility schedules at times t and $t-h$.

For all purposes, the function defined as the partial derivative of the cohort fertility schedule is nothing but an age pattern of fertility changes, such as $\phi(x)$. These are well known in demographic analysis dealing with the nature of fertility behavior and can be inferred by assuming regular and known patterns of fertility. However, not all of them satisfy the restriction. For example, if we assume that fertility behavior can be represented well by a Coale-Trussell function in which the only change is in the level of birth control, the function $\phi(x)$ has a very simple form that is proportional to the time derivative of the birth control parameter. In this case, however, the sum of all age-specific changes does not add up to 0. This is because when only the birth control parameter changes, there will be also changes in the cohorts' completed fertility unless offsetting changes in other parameters of the fertility pattern take place.

3. Formalization of Tempo and Quantum Changes in Parity-Specific Fertility Rates

Let $f_j(y, t-x)$ be the occurrence-exposure rate of order jth at age y for a cohort born $t-x$ years ago so that the corresponding cohort-specific PPR is $R_{j(coh)}(t-x) = 1 - \exp\left(-\int f_j(y, t-x)dy\right)$. Cohort-specific occurrence-exposure rates can also be represented as the product of a standard pattern of occurrence exposure rates and a level parameter, $f_j(y, t-x) = \lambda_i(y, t-x)C_j(t-x)\mathrm{f_j}$. To adhere to the framework developed before, assume also that $C_j(t-x) = C_j$; that is, cohorts only experience changes in the age pattern of occurrence-exposure rates, not in their overall levels. The cohort of age z at time t experiences the rates $f_j(y, t-z) = C_j\lambda_i'(y, t-x)$.

Because the mean age of the jth-order rates is only a function of the age pattern, not of the level parameter, a reasonable way to represent changes in the tempo of the jth birth is through changes in the mean age of occurrence-exposure rates. In particular, we assume that

$$\lambda_j(x, t-d) \approx \lambda_j(x) + d\left.\frac{\partial\lambda_j(y, t-d)}{\partial d}\right|_{y=x} \tag{12}$$

subject to the constraint $\int(\partial\lambda_j(y, t-d)/\partial d)dy = 0$. In what follows we let $\phi_j(y) = \partial\lambda_j(y, t-d)/\partial d$, an age pattern of changes in the parity-specific occurrence-exposure rates. Under these conditions, we can again derive an expression for the period PPR as a function of the cohort PPR and a measure of the rate of changes in the age patterns of the occurrence-exposure rates. In particular, the PPR of order j at time t, $\mathrm{R}_{j(\mathrm{per})}(t)$, will be equal to

$$R_{j(\mathrm{per})}(t) = 1 - (1 - R_j)^{(1+\eta j)}$$

where $\mathrm{R_j}$ is the parity progression rate for the standard occurrence exposure rates of order j, and η_j is the annual change in the mean age of the jth-order cohort-specific occurrence exposure rates [defined as the product $(\int\lambda_j(x)dx)^{-1}$ $(\int x\phi_j(x)dx)$]. This expression shows how changes in cohort measures (changes in the timing of births) translate into period measures of the quantum of fertility. It closely resembles the one inferred before to link period measures of fertility and changes in the timing of overall fertility.

From this expression we can derive a relation between cohort-specific changes in the timing of births of any order and period TFRs. Using the life table approach proposed before we calculate the period TFR, $Q_{per}(t)$, as

$$Q_{per}(t) = \Sigma_{\{k=o,w\}}[\Pi_{\{j=o,k\}}p_j]$$

where $\mathrm{p_j}$ is the synthetic (life table) parity progression rate of order j. We now use the expression relating the synthetic PPRs of order, say R, to their cohort equivalent and show how the timing in births of order R influences period TFR.

As an illustration, assume that the timing of first birth for all cohorts experiences a change following the pattern assumed before. It must then be the case that $Q_{per}(t)$, the period TFR at time t, is equal to the cohort TFR times the ratio of the cohort PPR of order 0 to the period 1:

$$Q_{per}(t) = Q(1 - (1 - R_0)^{(1-\eta_0)})/R_0 \tag{13}$$

where η_o is the annual rate of change in the mean age of the first birth occurrence-exposure rates and R_o is the parity progression rate associated with the standard first-order occurrence-exposure rates. The most important implication from this expression is that to adjust the period TFR for changes in the timing of first birth it is not sufficient to know what η_o is. We must also account for the (scaling) effects of the standard first-order cohort PPR R_o.

4. Three Generalizations

The foregoing relations are just a small sample of a much larger set of relations linking changes in quantum and tempo of fertility of various orders. First, it is possible to investigate the effects of changes in the intensity (quantum) of fertility on measures of fertility tempo (mean and variance of fertility schedule) using overall and parity-specific fertility rates. This is the inverse problem treated before, albeit a less interesting one; when intensity changes take place without affecting the timing of births. Second, the assumptions made at the outset about gradual changes across cohorts though convenient and tractable are not very realistic because they rely on the idea that gradual fertility across cohorts are tenable. As indicated at the outset there is no compelling reason to believe that any consequential fertility change is purely cohort based and that, on the contrary, there is evidence suggesting that period effects are of equal or even more import. Third, empirical illustrations based on historical cases and on simulation help us understand the accuracy of the relations suggested and to appreciate the set of conditions, some of which are more relevant than others.

These three generalizations are taken up elsewhere (Palloni, 1984). There we develop a more extensive set of linkages under more realistic assumptions about the nature of fertility changes, including cases with period changes, such as anticipation and postponement of childbearing, that affect all cohorts simultaneously. Empirical evaluation of relations through simulated data reveals that there are simple ways of inferring the nature of these changes from a very small set of observables.

CONCLUSIONS

This chapter identifies a seldom mentioned problem associated with conventional fertility measures and proposes a general framework for attenuating its confounding effects. The gist of the problem is that conventional measures of fertility may be contaminated by the parity composition of the female population. To circumvent the problem we propose, as have done before us Rallu and Toulemon (1993; 1994) and Palloni (1984), measures based on a life table approach. This solution can be made as complex and fine-tuned as available data allow. The life table procedure can shed light on the nature of fertility changes and leads to precise decomposition of changes by parity and by determinants promoting those changes.

Life table-based and conventional measures of fertility can lead to misleading interpretations that confound changes in the timing of fertility across cohorts and changes in the intensity of fertility rates. Following Keilman (1994a, 1994b, 1999), we adopt a simple model of fertility changes and show that there are simple relations between period-based life table measures of fertility and their cohort counterparts.

The methods described in this chapter require very good information on the evolution of birth intervals. These data can be obtained from a longitudinal prospective survey following women over time or from retrospective data on fertility histories. The latter are readily available but are affected by recall lapses concerning the dating of events. Longitudinal prospective surveys lead to better information on the number and dating of events, but they are very costly to carry out and are therefore rare. From a practical viewpoint, the methods developed here do not always yield reliable results. In some cases, for example, due to inadequate data, the biases may be higher than in the case of traditional period measures. One could then choose the simplest method, as the procedures proposed in this chapter require intensive computation and the use of software that is not widespread. The choice depends on the case in point.

Our review is limited in that we only focus on effects of changes in tempo on measures of quantum and not the reverse, rely on very simplistic representation of a regime of cohort-based fertility change and, finally, we provide no numerical illustration of the robustness of relations and estimates proposed.

The Contribution of Qualitative Methods to Demography

MICHEL BOZON

Institut national d'études démographiques (INED), Paris, France

The association of qualitative and quantitative methods in the study of population has not always been considered a delicate match. In British social and cultural anthropology and French ethnology up to the mid-20th century, it was customary to start every population case study by its outlining structure and, consequently, by a demographic description (Kertzer and Fricke, 1997, p. 3–4). Marcel Mauss, in his famous *Manual of Ethnography*, written in the 1930s, described the framework of an ethnographic case study: "A social morphology study should be completed by a proper statistical survey in demography. We should obtain trend statistics on each house, family, clan, tribe (when the society has many tribes). We can measure fertility, births by sex, morbidity, and mortality for which we should carefully distinguish between mortality by accident or violent causes and natural mortality" (Mauss, 1947, p. 20). Thereafter, anthropologists' interest in demography declined as the demographers developed and fine-tuned its statistical techniques.

Demography developed its autonomy then as it does in the current period, through the availability and the production of large quantities of numerical data from civil registration, censuses or registers, and single or multiround demographic surveys. Demographers invented increasingly sophisticated statistical methods that were at first meant to make sense of the figures.[1] At the same time, a group of demographers have always expressed an interest in methods belonging to anthropology or qualitative sociology, or shown a tendency to engage in dialogue with representatives of these disciplines (Courgeau, 1999; Basu and Aaby, 1998; Caldwell *et al*., 1988; Gérard and Loriaux, 1988; Roussel and Bourguignon, 1976, 1979).

However, not all demographers have an open mind about nonquantitative approaches, and interest in cooperation with demographers is not viewed with benevolence by all social science researchers, especially by the most qualitatively oriented among them (Kertzer and Fricke, 1997). According to some authors, there is a radical paradigmatic heterogeneity between research based on quantification (to which demography belongs) and that based on qualitative methods. Maryse Marpsat (1999, p. 13) sums up this opposition: "Quantitative methods are supposed to be attached to a strictly positivist or empirical vision inspired by natural sciences, which aim at testing hypotheses by showing the correlation between variables, while qualitative methods, by the very importance accorded to the meaning that actors themselves give to their own actions, are supposed to belong to other intellectual traditions (often cited is Weber's comprehensive sociology, phenomenology to which we can attach ethnomethodology and symbolic interactionism)." With this perspective, the opposition between the science of facts and that of interpretations becomes indomitable.

Other researchers believe that there are two different methods, but that they can be combined and articulated within complex research projects and

[1] Allan Hill (1997, p. 224) refers to such a phenomenon in demography as "the corrosive effect of too many numbers."

multidisciplinary teams according to the issues for analysis. I place myself unambiguously in the second stream, in the belief that to approach demographic issues and advance the discipline, it is possible and desirable to associate the two types of methods and to develop a comprehensive approach. Consequently, I would think that demography should be less defined by its sources or methods of analysis than by its object, which is the analysis of the reproduction of populations, seen from a broad perspective (Townsend, 1997; Greenhalgh, 1995).

The contribution of qualitative methods will first be illustrated here by examples of the diversity of the types of demographic research in which it can be found. The most frequently used qualitative techniques will then be discussed. The objectives assigned to these methods and the various roles that they play will be enumerated in detail. The effect of comprehensive approaches on demography itself will be envisaged. In certain cases, they only modify the presentation of results. In other cases, they have theoretical effects, invoking new quantitative methods, new interpretations, and even new issues.

It is hardly surprising that a large part of the examples are borrowed from research conducted in developing countries, where statistics are often poor and where it is often necessary to look for complementary data (Quesnel, 1988; Pison, 1980). On the other hand, we shall deliberately put aside historical demography, even though research associated with oral history (Leboutte, 1991) or historical anthropology (Segalen, 1985; Flandrin, 1976) can be considered as qualitative research in historical demography.

I. SAMPLES OF COMPREHENSIVE DEMOGRAPHY

In demographic research recourse to nonquantitative methods is often presented as an effort to widen the explanatory base of a phenomenon. This approach can be qualified as "comprehensive demography" (Bozon, 1992a). Research in this category does not ignore quantitative methods, it can be said that it attempts to introduce a continuous to-and-fro critique, a productive scientific tension between the determination of the area of validity of a phenomenon and the comprehension of its meaning.

1. Age Difference between Spouses and Social Age

In a study of the male-female age difference among (heterosexual) couples (Bozon, 1991), I used data collected from a survey on couple formation in France (Bozon and Héran, 1989). In this study, the questionnaire administered to 3000 respondents, who were aged below 45 and living as a couple, was part of a larger project, including 30 preliminary semi-structured interviews whose systematic analysis helped to design the questionnaire. After the main survey, a second series of 75 interviews were conducted among selected respondents of the questionnaire. The questionnaire itself included 40 open questions out of a total of 250. The phenomenon of spousal age difference is not considered a universal determinant that would be relatively invariant in marriage and that consequently would not require any explanation. The questionnaire survey showed that young women, more than men of the same age adhere to the model of couples in which the man is older. The analysis of the semi-structured interviews highlighted that women's idealization of men considered to be *mature* is accompanied by a clear rejection of young people of their own age group, considered to be immature and too young in a pejorative sense. "Available men are perceived, classified, and judged on the basis of their social age, which depends less on physical appearance than on social status and autonomy" (Bozon, 1991, p. 138). A man's social maturity at the time of the first meeting is linked by women to his experience, his professional status, knowledge, and residential autonomy. A return to quantitative data shows that this idealization of qualities and social assets associated with a man's maturity is higher among women who themselves have few educational or professional assets and are more dependent on the social status of a man.

2. Irregularities and Anomalies Are Theoretically Interesting

Demography may deliberately focus on irregularities. For example, in a study of an African population with very high fertility (i.e., rural Gambia), Caroline Bledsoe, Fatoumatta Banja, and Allan Hill (1998) started off with an ironical finding: women who had experienced reproductive mishaps (abortions, stillbirths, death of a child at an early age) tended to adopt modern Western contraception more frequently than others. This unexpected behavior according to Western thinking about high fertility patterns is interpreted by the authors as an effect of a local representation of the reproductive life of women. The study consisted of an initial survey to identify women of childbearing age in 40 rural villages (a total of 2,980 women), followed by a series of open interviews and field observation as well as a monthly survey over 15 months on a subsample of 270 women who had had a pregnancy in the last 3 years. This survey had both quantitative and open-ended questions. The anthropologic survey highlighted the fact that a woman's childbearing life is perceived as a *body resource expenditure*. The reproductive potential of a women is limited by her total endowment in fetuses (a number fixed by God, intangible for a woman, but variable from one woman to another) and this diminishes progressively, not according to age but according to the ordeals suffered by the body: irreversible loss of "muscles" associated with pregnancies and childbirth (including stillbirths), as well as loss of strength, greater during obstetrical trauma, but which can be partially restored by rest between pregnancies. Fertility is considered as a "potential to be expended" rather than a "time-bound capacity" (Bledsoe *et al*., 1998).

There is no idea of an individual biologic time, which would flow in a continuous manner, or of menopause as an upper age boundary of reproduction. Individuals refer to a reproductive age that is a discontinuous reality illustrated by different names borne by the woman at different phases of the expending of her potential.[2] In this system, it is not surprising that the most significant contraceptive initiatives take place after considerable aggression against the body, which, despite its harshness, does not entitle the woman to the sexual rest of postpartum abstinence. In certain cases, contraception is also a strategy that enables women to save their reproductive endowment while waiting for a possible remarriage. The study of one of the theory's anomalies reveals a whole hidden world of representations of the body and of fertility, showing that recourse to a practice considered as modern (Western contraception) may be perfectly adapted to a traditional rationality.

3. Demography without Numbers

Nancy Sheper-Hughes' research on infant mortality in a *favela* of the State of Pernambuco in the Nordeste region of Brazil may seem further from the traditional perspectives of demography (Scheper-Hughes, 1997). She qualifies it herself as "demography without numbers." It starts traditionally. The author studies the death records of children younger than 5 years at the civil registry office of a medium size town. One-third of the effective deaths are not reported (in most cases, the birth was unrecorded too). Among the deaths recorded, three-fourths do not indicate cause of death; the declared causes are characteristic: "heart stopped, respiration stopped," "hunger," "dehydration," "weakness," "fall," and so on. The low official presence of these demographic events encouraged the author to attempt to reconstitute the social and cultural reality of the death of babies and children through participant observation in the *favela* and an oral survey among all those who are involved with these deaths (e.g., mothers, neighbors, fathers, brothers, sisters, healers, priests, gravediggers). In this extremely precarious environment of sugar-cane cutters, mothers showed a certain fatalistic attitude toward their babies. This is displayed by a *laissez-faire* attitude and calm resignation in the face of destiny. It is current belief that certain children from the very beginning have no wish to live nor to fight, and consequently, it is not necessary to make great efforts to keep alive those who are destined to become "angels." An implicit selection takes place in the care given to children. Mothers' love takes root only very progressively when there is certainty that the child is no longer a temporary visitor to earth. This remarkable field observation helps to highlight the subjective internalization process of living conditions and social constructions of maternal attitudes on which history and historical demography, with notably research by Philippe Ariès on the emergence of feelings on childhood in the classic period (Ariès, 1962), had already cleared a path.

Research on the homeless carried out at the Institut National d'Études Démographiques (INED) by Maryse Marpsat and Jean-Marie Firdion (2000) is a good example of the systematic and reasoned injection of qualitative methods in a mainly statistical data collection. The principal survey is based on a questionnaire administered on a representative sample of users of shelters and food distribution centers during a winter month in Paris. The questionnaires were preceded by street surveys at night and preliminary interviews among homeless persons, followed by an interview survey among managers of the shelters, homeless persons as well as more ethnographic observations among persons who obtain their livelihood from begging. Exploratory interviews made it possible to identify "the recurrence of the trajectories of single men who had worked in itinerant professions (e.g., long distance drivers, sailors, the military)" (Marpsat, 1999), which led to the inclusion in the questionnaire of a specific question on this issue. In open-ended questions on housing, the respondents gave different meanings to this term according to their experiences and social situations.[3] It became evident that ques-

[2] A young woman without a child or a with a single child (*janka* in Wolof) is different from a young spouse or a woman at the beginning of her reproductive life (*jongoma*), a young married woman, or a woman in the middle of her reproductive career (*jegg*). (Hill, 1997, p. 238).

[3] For single men living in a shelter, a hotel room is already considered to be a home, whereas a woman with a child or children will consider home only as rented accommodation without time limitation (Marpsat, 1999).

tioning without further detail on respondents' last home tended to confirm the implicit definition of each individual. The interviews were conducted after the questionnaire so as to specify and qualify certain results: Although many men reported in the questionnaire that they had lost their homes after a family break-up, the biographical interviews showed that this was a respondent's interpretation within a more complex process. In the end, many difficulties encountered while administering the questionnaires in the shelters encouraged the researchers to embark on qualitative research on the shelters. This research in the field brought to light the existence of a hierarchic system of shelters in homology with a hierarchy of users (Soulié, 2000), which was confirmed by the results of the questionnaire.

4. Micro-demography, Community Studies, and Local Continuous Demographic Observation

In the use of qualitative methods in demography, a particular mention must be made of micro-demography as illustrated by the Australian demographer Jack Caldwell, in his own work in Africa and India and through those of the Committee on Anthropological Demography,[4] set up by the International Union for the Scientific Study of Population (IUSSP) (Caldwell *et al.*, 1988). These micro-demographic studies are community studies that, in a geographic area or a relatively limited group, associate the methods of demographic or epidemiologic surveys with various anthropologic techniques, often within the context of small, pluridisciplinary teams. *Pluridisciplinarity* refers to the collaboration of demographers and representatives of other disciplines rather than the conversion of demographers' to qualitative research. Micro-demographic studies require a generally prolonged stay by demographers in the field, providing the opportunity to set up real local demographic surveillance systems and conduct a number of in-depth investigations. Micro-demography is different from anthropology in its strong interest in change and innovation, observed at the community level that is also that of many population programs or projects.

The initial aim of this collaboration with other disciplines was to enrich demographic data collection and the interpretation of results. Gradually, these community studies have freed themselves of their initial objectives, taking on themes that were traditionally only considered in analyses as simple determinants of demographic behavior (particularly of fertility). In a study published in 1996 in *Population Studies* (Niraula and Morgan, 1996) comparing two Nepalese villages, the authors chose to look at women's personal autonomy through examination of its ties with marriage formation and with postmatrimonial contacts between women and their families of origin. The two villages (one in the hills of Katmandu and the other near the Indian border) are very different in terms of their social organization and general degree of female autonomy. The comparative double case study showed that individual differences between the biographic characteristics of the women in each environment were secondary in explaining the overall variation between localities in terms of specific contextual differences between the two villages. Even though a woman's personal autonomy is measurable at an individual level, it is above all the result of social organization and collective control and these must be observed in a holistic approach rather than through individual surveys.

The use of qualitative methods in demography occurs generally within complex and composite research strategies. A thorough examination of the major techniques used shows that each of them is adapted to particular issues, corresponds to a type of fieldwork, and enables specific types of analyses to be carried out.

[4] Created and initially chaired by Jack Caldwell.

II. QUALITATIVE OBSERVATION TECHNIQUES

It is possible to rank the various qualitative observation techniques used in demographic studies according to their degree of dependence on the statistical surveys with which they are associated.

1. Open-ended Questions and Nonstandardized Items in Demographic Questionnaires

An apparently simple practice to import into a demographic questionnaire is the use of the *open question* for which, contrary to closed pre-coded questions or questions that record quantities (number of children, date of entry into union), the content, form, or length of response is not fixed in advance. Recourse to open-ended questions is particularly relevant to investigate the representations associated with a term (e.g., the concept of environment, the word sexuality, the concept of bad health or that of a real home), or the justifications spontaneously given for a behavior or an attitude (for example, why one would refuse to marry a younger spouse). Semi-open questions in which a non pre-defined "other" category, is added to a series of items can also be included. In the procedures of questionnaire enrichment, we can also mention the systematic recording of observations on the interview itself: respondent's reaction to the questions (e.g., discomfort, hesitation, surprise), additional comments, possible presence, or reaction of a third party that may affect the answer. It is easy to introduce nonstandardized elements into the survey questionnaire, even if this requires further training of interviewers. It is more difficult to analyze them adequately. The remarks and comments on the interview could be simply used to remove ambiguities or resolve problems of consistency during data capture (by correcting the interviewer's pre-codification). In the same way, the statistical analysis of open-ended questions can take a simplified form, which through coding transforms them into closed questions with only a few modalities. On the other hand, it could be more thorough, with the objective of capturing the full extent of native expressions and formulations by designing a detailed nomenclature organized according to theoretically relevant principles[5] or through an exhaustive capture of all responses for onward computer-aided textual analysis.[6] This second option is more applicable to enumerative types of responses, whereas the first one is better for a complex narrative or argumentative structure. The exact wording of certain responses to open questions may be retained as examples in the research report.

2. A Flexible Procedure: The Interview Series

A research procedure often indirectly associated with quantitative demographic surveys is the *semi-structured interview series*, conducted before, during or at the end of a questionnaire survey. These interviews target a population and an issue expressed in an interview guide. The target population may be divided into subpopulations that are expected to provide specific information. The choice of the subpopulations depends on the hypotheses and available knowledge of the structural dimensions of the phenomenon. In an interview survey on family recomposition in France, it is necessary on the one hand, to interview persons from the lower classes and from other social classes and, on the other hand, to try to include all the actors concerned: children, parents with child custody, step-parents, parents without custody. Rather than representative samples, interview samples are like laboratory experiments of experience. The interview guide, designed according to initial hypotheses, is similar to a closed questionnaire but "in practice, it structures the interrogation but does not direct the speech" (Blanchet and Gotman, 1992, p. 64). It sets the initial instructions (e.g., "Tell me about your marital life since your marriage"), as well as intermediate ones that indicate the theme or themes. It includes a detailed thematic guide, which the interviewer is expected to know without having to specify and which corresponds to all the points that should be discussed freely by the respondent or after prompting by the interviewer. This procedure does not imply standardizing the way the interview takes place.

What most clearly differentiates an interview from a questionnaire is the great flexibility in its use. When an exploratory interview series is used to design a future questionnaire, the interview guide may be modified between the beginning and the end of the series. When a series of interviews is conducted after administering the questionnaire, possibly on a subgroup of the survey sample, the interview guide may also be adapted for each individual respondent by taking account of information already provided in the quantitative questionnaire. The advantage of an interview series over a questionnaire survey is to allow the introduction of a real to-and-fro reflection within empirical data collection. Even the number of interviews necessary is not decided beforehand, because it obeys the principle of saturation (Blanchet and Gotman, 1992); in principle, the qualitative survey ends at the moment, unknown beforehand, when further interviews no longer provide new information or processes.[7] To be analyzed, semi-structured interviews must be recorded and then transcribed. In its simplest form, this could be a thematic analysis, which gathers observations according to items or themes of the guide and highlights the range of situations and terms used by the actors. This type of analysis is generally well suited for the design of a questionnaire. More elaborate analyses can highlight the structure of a system of representations, for instance through "the analysis of relations of opposition" (Blanchet and Gotman, 1992), typical chains of events, correspondence between events experienced and perceptions, for example, the suffering of women who are unable to have a male child in Korea (Das Gupta, 1998).

[5] On the coding instructions of the circumstances of the "first encounter" (Bozon and Héran, 1987, p. 970–984).

[6] On the analysis of the question on representations of the environment, see Guérin-Pace (1997) and Collomb and Guérin-Pace (1998).

[7] On the contrary, in a quantitative survey, the number of respondents is calculated *a priori* to enable good statistical inference on the entire population or on a subpopulation.

3. Observing Interactions among Agents

Participant observation, which is very frequently used in anthropology, is less so in demography. Yet it is through this method, rather than by explicit reports in questionnaire surveys or semi-structured interviews, that we can highlight real and concrete inequalities in the treatment of children (quantity of food, health care) as observed in Africa between children of the current marriage and those of a previous marriage (Bledsoe, 1995), or in a certain number of Asian countries between boys and girls (Das Gupta, 1998), or in the Brazilian example cited above between the children who are considered to possess the energy to survive and the others (Scheper-Hughes, 1997). Direct observation is the best way to evaluate family planning programs or other health programs (e.g., diarrhea control programs, immunization programs, AIDS prevention or treatment programs) or institutions like dispensaries, health centers, or shelters for homeless persons. In these situations, direct observation makes it possible to define the object of inquiry as the interaction between the characters, especially interaction between those who are culturally or socially very far apart and whose representations of the body and of illness are very different (e.g., a nongovernmental organization doctor from a developed country and an Indian woman in Bolivia). The observer must objectively view all the elements of the situation and consequently take into account when analyzing what was observed or heard, the effects of the location, and the effects of his or her presence and his or her status with regard to the observed persons. Observation can in particular contribute to a better perception of the strategies and interests of those who are often considered to be none other than mere users or targets of programs or actions. The qualitative survey on shelters for homeless persons (Soulié, 2000) showed that centers select certain profiles of persons and that homeless persons themselves, depending on their situation, experience and aspirations, navigate through the system by choosing or avoiding certain shelters.

4. Focus Group: A Questionable Technique

Some demographers use focus group discussions especially in the exploratory phase of research. The use of this type of interview, organized by the researcher, may not be considered a rigorous research technique. It is difficult to systematically record the words spoken and the very complex nature of the interaction between participants, as the researcher is at the same time the group host, participant and observer. Moreover, the elements of these meetings are always cited in a vague manner. One can consider it as a technique for making initial contact or mobilization, an action or training technique, rather than a proper research tool. Demographers are fascinated by this method, which provides rapid results for a low investment (Knodel, 1998), but the data produced are rarely considered scientific, as they cannot really be transposed and used beyond the context that produced them. The method is misleading because it produces results, but these are simply reactions to a created situation: local representations are always shown as relatively homogenous because the effects of spokesmen, silences, and nonresponse are not considered and the expressed representations are not matched with individual practices. The artefact is close to the one produced in political science, when we assume the existence of a "public opinion" on all issues, whereas in most cases, it is simply a reaction to a situation, mainly induced by the practice of the opinion poll itself (Meynaud and Duclos, 1996; Bourdieu, 1980). Because elements of individual biographies are not collected, it is impossible for example, to identify the tactical or strategic usage of certain traditional or innovative representations in the justification discourse directed at the observer, and even less so, the existence of circumstantial contradictions between the official discourse and practice, which are very important for analysis. An argument often used to recommend the use of focus groups is the difficulty or impossibility of undertaking individual interviews. It is true that in many cases, creating the circumstances and the appropriate location for a face-to-face interview involves a relatively long process. However, a focus group discussion may not necessarily replace that which interviews and a good participant observation can offer.

5. Case Studies in Demography

A considerable amount of research in *comprehensive demography* takes the form of case studies. In itself, a case study is neither a technique nor a method. It is a type of approach and a scientific product, in which the objective is to highlight the social processes existing in an area or a human group. It is the opposite of a national demographic survey, aimed at putting in variables the behaviors and attitudes of a vast sample of the population to establish correlation between these variables. Unlike the case studies of anthropologists, those of demographers generally include quantitative surveys that provide background data or a local census for the rest of the investigation. They may be completed by multiple-round surveys. The choice of which group to study is generally not left to chance. The fact that a health program covers an area or that a nongovernmental organization settles there can weigh on the choice of that community. The fact that anthropologic research has previously been carried out in a given area may encourage demographers to revisit the area. The major methodologic asset of a case study, which requires a prolonged stay in the study area, is that it offers the possibility of varying points of view on the subject, by a combination of different sources and different approaches: "It is not the accumulation of data that is determinant, but rather the critical interplay that can be established between the various sources" (Bozon, 1984, p. 15). Maryse Marpsat cites the metaphor of triangulation used by American authors (Jick, 1983, quoted by Marpsat, 1999) to describe the combination of methods that clarify an object, like the adjustments that come from multiple viewpoints. A combination of methods can be used in strictly quantitative demography, such as the comparison between data from a population register and data from a retrospective biographical survey (Poulain *et al*., 1991). However, in a case study, the articulation of methods is the fundamental principle of a long procedure that functions in a to-and-fro manner and by a continuous adaptation of hypotheses. A quantitative survey on users of a health program or on a population may be associated with an anthropologic observation *in situ*, which helps to discover new elements. The use of a multiplicity of perspectives enables the description of processes and complex interactions, which do not reduce behavior to variable mechanics.

Recourse to qualitative methods is often considered by demographers as a simple preliminary step or a subsidiary guarantee of quality in data collection, but which does not modify the essence of things. Sometimes, but this is rare, a focus on the renewal of methods and on dialogue with anthropology and qualitative sociology contribute to the development of the demographic discipline toward other research issues, other concepts, and methods.

III. QUALITATIVE METHODS AND THE QUALITY OF DEMOGRAPHIC DATA COLLECTION

Demographers are permanently concerned with improving the quality and reliability of their data, and tracking errors and their effects on observations makes them sensitive to reflexivity and interactivity in the data collection exercise. The use of qualitative approaches in the initial phases of planning a survey has become a common way of enriching the initial stock of hypotheses and suggesting, then testing, different acceptable modes of questioning respondents. The idea of qualitative checks after data collection is equally becoming accepted.

The very first hypotheses of a study are necessarily derived from the literature already published or from more general theoretical premises. They must be made to undergo a first empirical test to give them substance. The improvement of research hypotheses on couple formation mentioned earlier (Bozon and Héran, 1989) is largely the result of a series of preliminary interviews: the choice of a spouse was redefined as the outcome of a *judgment* based on very structured systems of classification and evaluation of potential partners. These hidden classification systems become apparent in the terms employed by respondents to qualify their partners (e.g., serious, intelligent, simple, nonconformist, mature), which become significant indicators. More commonly, the vocabulary that appears spontaneously during semi-structured interviews contains native terms and formulations that can be used again in the wording of questions and response items.

A preliminary qualitative survey does not only contribute to the improvement of hypotheses, it helps in the design of practical procedures for the quantitative survey. Traditionally, only women were questioned on many demographic themes (e.g., fertility behavior, nuptiality, family), but qualitative surveys showed that questioning men, especially the spouses of female respondents, made it possible to reach a more realistic view of spousal negotiation and interaction.[8] Consequently, a strategy that involved the two spouses, at least on a part of the sample, was adopted in large scale surveys, like the Demographic and Health Surveys from the 1990s.

A demographic questionnaire is essentially a process where human behavior is defined in variables (and indicators), which seem natural when the behavior in question is already partially or highly objectified and formatted within a reality recognized by social statistics (Héran, 1984). Consequently, it is not difficult to formulate questions on the number of living children, on legal marital status, on housing that gives the status of home-owner or tenant, nor on contract employment. The design of variables is much more difficult and must be based on an initial qualitative approach when research is on poorly formalized, stigmatized, or hidden realities, or when the theme appears rarely in the literature: in the questionnaire on the homeless, designed by Maryse Marpsat and Jean-Marie Firdion (2000) after the traditional questions on current occu-

[8] Hertrich (1997) provides an example of a case study based on dual data collection from women and their husbands.

pation and last occupation, different types of probes were added concerning "work carried out without a pay-slip," "periodic, irregular work carried out for someone," "selling street newspapers," "selling salvaged or self-produced goods." On themes like informal work, the various types of informal housing, sexual violence (treated in depth in the Colombia Demographic and Health Survey, 1995), it is not possible to propose adequate response categories *ex nihilo*; an initial extensive exploration is always necessary.

Generally, an initial exploratory study, even indirect (*armchair anthropology*) of local social processes, including their ritual and symbolic aspects, makes it possible to avoid ethnocentrism or excessive legalism in the questionnaire design. Étienne van de Walle and Dominique Meekers, in their article *Marriage Drinks and Kola Nuts* (1994), showed that it is not possible for demographers in many developing countries to measure the date of marriage (even defined very loosely) in a simple way without taking into account the diversity of the traditional components of entry into union. After a review of the anthropologic literature on the subject, they analyzed the function of the very polysemous ritual of presentation of drinks and kola nuts, which was asked about in the Côte d'Ivoire Fertility Survey (1980–1981). In developed countries, the growing informality of transition to adulthood is greatly challenging the imagination of those who still wish to date the entry into union or the residential independence of young persons (Villeneuve-Gokalp, 1998).

The decision to include open-ended questions in a questionnaire, far from representing an incapacity to close questions (i.e., to limit response items beforehand), must be regarded as a deliberate wish to collect a certain number of spontaneous formulations, which are expressed through the social categories used by respondents themselves and not only through those of the analyst. In an INED biographic survey on transition to adulthood carried out among 25 to 34 year olds (Bozon and Villeneuve-Gokalp, 1995), the retrospective questions on family, marital, occupational and residential trajectories of respondents were followed by the open-ended question: "Tell me if an event in your youth has had a major impact on you (no matter whether you have already mentioned it or not). What event was this and at what age?" The answers showed that a number of events subjectively considered by respondents as striking are not even mentioned in the biographical reading grid of researchers: for example, the death of close relatives or friends, health problems or even historical events. This open-ended question could be linked with other closed questions in the questionnaire, such as, for example, the experience of depressive phases in a person's life (Archambault, 1998).

Apart from the now common use of qualitative approaches in exploratory research, complementary qualitative surveys are now being conducted after the administration of questionnaires. These complementary operations have various aims. Certain operations are essentially to verify and explore the contradictions in responses or even refusals. Unlike a traditional control survey, which essentially tries to measure the consistency between the initial questionnaire and the control questionnaire, a qualitative control operation does not consider problematic responses as errors but as an indicator of the respondent's perception of the survey or the fieldwork style. In the United States, a qualitative post-enumeration survey showed a high level of incorrect responses associated with respondent indifference to the task of filling the questionnaire and a feeling of social disaffiliation and distance from the State (Rehner-Iversen *et al.*, 1999).

It is also possible to organize complementary interviews to clarify the meanings of certain responses (contribution to questionnaire data capture) and evoke explanatory hypotheses on results (contribution to the construction of interpretative hypotheses). In INED's survey on couple formation, the post questionnaire interviews had this dual function. Many respondents had reported that in the process of building their relationship with their future spouse, they had gone through a phase of part time cohabitation (defined in the questionnaire as "a period when you were not yet permanently living together under one roof, but were already spending some days and some nights together in one another's home during the week"). The interviews showed that this response mixed up realities that were so different that it could not be interpreted as a distinct and real phase (Bozon, 1992b).

At the end of a quantitative operation, anthropologists and sociologists sometimes undertake a relatively independent qualitative survey focusing on a subpopulation or a group of individuals sharing a characteristic or relative to a problem that the questionnaire unveiled. In the 1970s, for example, Louis Roussel, in his work on the family, introduced independent qualitative surveys after traditional questionnaire surveys (Roussel and Bourguignon, 1976, 1979). The study on reproductive mishaps and Western contraception in Gambia cited earlier (Bledsoe *et al*., 1998) derives from a result of a questionnaire that would not adjust to standard data interpretation, thereby leading to a parallel anthropologic research that ended with another very different research framework.

The role of hypotheses in quantitative research is often presented unrealistically as a set of questions or rather of temporary responses that the *ad hoc* apparatus of a numerical survey would confirm or invalidate. Anthropologists and qualitative researchers see themselves rather as constantly redesigning and refining their hypotheses, exposed to the challenge of new observations. In reality, even in statistical procedure, the development of hypotheses that, at a given moment become interpretative hypotheses (or interpretations), is a very gradual process: "The progressive construction of hypotheses found in most qualitative surveys, corresponds to that which occurs in successive phases of a survey and statistical analysis, with the difference that it is impossible to return to the field at the analytical phase, unless by a new investigation, a qualitative approach or reiteration of statistical surveys" (Marpsat, 1999, p. 14). Integrating a qualitative approach in an essentially statistical strategy contributes empirically to the continuous reflection on the survey while it is taking place, then to self-analysis. The continuous production of hypotheses can be supported by more field trips, rather than by the demographer's imagination or presuppositions.

Greater flexibility and interactivity in demographic data collection contributes to making the demographic discipline "thicker" (Fricke, 1997). The interrogations brought about by nonstatistical approaches can renew certain fundamental concepts of the discipline and guide it toward new issues. Sometimes, demography invents new methods by systematizing initially qualitative approaches.

IV. QUALITATIVE APPROACHES AND THE RENEWAL OF DEMOGRAPHY

When demographers give an account of the changes in their discipline, for example at the anniversary-issues of their great journals (*Demography* in 1993, *Population* in 1995, *Population Studies* in 1996), they indicate the evolution in methods as well as in the issues (questions or debates), but rarely mention theoretical innovations, even if authors like Ron Lesthaeghe insist heavily on this dimension (Lesthaeghe, 1992, 1998; Lesthaeghe *et al*., 1994). It is particularly rare for recourse to qualitative methods and dialogue with disciplines that use them to be mentioned as factors in the evolution of the discipline. Yet, even though their contribution is not willingly recognized,[9] there are reasons to believe that the persistent existence of other methods for describing social phenomena explains a part of the development of the demographic discipline.

1. Using Variables or Describing Processes

Traditionally, demography and quantitative sociology focused on phenomena that could be defined in terms of quantifiable variables. After transforming the subject into variables by schematization[10] and data collection, analysts try through various statistical procedures to link the variables to be explained with the explanatory variables. The objective is to parsimoniously use a minimum of explanatory variables (also called determinants) to describe the phenomenon to be explained. Inversely, qualitative approaches focus on the *processes*, that is, the relations established between the attitudes, social behavior and objective structures. The process and its given descriptions may be relatively complex as no initial transformation of the behavior into simple variables has been made. The analyst nevertheless makes a parsimonious hypothesis as he assumes that the processes to be described, although complex, are few. In this type of approach, the opposition between dependent and independent variables or between phenomena to be explained and determinants fades, enabling us to move our focus more easily toward issues that theory did not initially consider as central or that appear difficult to transform into variables.

Take the example of nuptiality in African countries (Bledsoe and Pison, 1994). For a long time, it had been considered by demographers as a simple determinant of fertility that did not deserve any particular interest and second, as a difficult phenomenon to describe. When asking about date of marriage in the National Fertility Surveys of the 1980s, one was not too sure what was being measured. Through anthropology and its methods, a certain number of demographers learned how to observe and describe marriage as a process of union formation with a duration and with significant stages that were not all identical. The observation of these processes then took on the function of analyzer of social organization, especially of inter-generational relations (e.g., what is the influence of elders in the lineage?) and gender relations (Locoh, 1995).

2. Cultural Context of Individual Behaviors

Another characteristic of the approaches inspired by anthropology or comprehensive sociology is the

[9] This difficulty among demographers to recognize the contribution of qualitative approaches to their discipline is perhaps related to the obsessive desire by a large number of them to belong to the "hard sciences."

[10] Schematization is necessary and legitimate according to the research hypothesis; according to Gaston Bachelard, quoted by Hubert Gérard, there is a "right to overlook what is negligible" (Bachelard, 1938).

importance given to the analysis of social and cultural structures in which people function. They are different from certain analytical models traditionally employed in demography, for example in the analysis of fertility determinants, which place social actors in a strictly individual framework, with a possible sprinkling of general cultural traits that are meant to characterize them because of their membership of aggregate ethnic, national, or geographic groups. The impact of culture or social organization on demographic behavior remained for a long time *terra incognita* to population studies. To consider the effect of social and cultural organization other than as mere residuals unexplained by individual variables, some demographers, again influenced by anthropology, tried to integrate the analysis of individual behavior and social organization (Kertzer, 1995).

Take the example of the prolonged *post-partum* abstinence observed in African countries. The prevalence of this behavior was for a long time considered to be a determinant of fertility, something specific to each cultural group and not arousing any particular interest. The change in perspective that led to considering abstinence as an issue requiring explanation led to two developments both influenced by anthropologic approaches. The macro-level analyses of Lesthaeghe and colleagues (1994) looked at the relationship between the characteristics of the social and economic organization of various ethnic groups, systematized from earlier anthropologic studies, and the prevalence rate of *post-partum* abstinence of each group. Two social organization characteristics seem particularly related to low abstinence levels: matrilineal (versus patrilineal) lineages, and low productive value of women in the economy (which is the case of pastoral societies). Research on Gambia by Caroline Bledsoe and Alan Hill (Bledsoe *et al.*, 1998; Hill, 1997) made it possible to observe internal variations within a society. The authors first linked the practice of abstinence to a local representation of reproductive life, which constitutes the mental framework in which choices are made. Because the rule of abstinence is traditional does not mean that it cannot be strongly manipulated. First, abstinence is better expressed as a negotiated reduction of frequency rather than a total suppression of sexual relations (Hill, 1997, p. 233). Second, average birth intervals have been observed to regularly increase with parity: young women rather tend to reduce abstinence periods while women who already have many children increase them. On the whole, independently of factors of change associated by demography with progress in education, there are social and economic organizations that favor or discourage the tradition of postpartum abstinence, which appears to be a more strategical and negotiated practice for women than is generally assumed.

3. Comprehensive Demography and Emergence of Gender Analysis

Another example of the evolution of demography toward issues and perspectives that were initially foreign is the increased interest among demographers in gender analysis (Riley, 1997a, 1997b; Greenhalgh, 1995; Federici *et al.*, 1993). This new development is largely due to research and methods of less quantitative disciplines. Demography has evidently never ignored the sex of individual members of populations and has learnt very early to calculate life expectancy or infant mortality rates by sex as well as to establish the existence of inequalities in the status of men and women in levels of education, age at marriage and levels of occupational activity (Véron, 1997). The central role played traditionally in demography by the analysis of fertility has even promoted converged interest in a certain number of specifically feminine indicators: it has become the tradition to link female education to age at marriage, number of children, frequency of contraceptive use, and even level of infant mortality (see Chapter 93). In the classic versions of the demographic transition theory, which is basically an application to population studies of a sociologic theory of modernization, increase in women's education is considered as one of the factors that directly influences the decline of fertility and infant mortality. This focus on female education may distract from the fact that neither the rise in levels of education nor the drop in fertility necessarily lead to an increase in equality between the sexes. All societies have their own social and cultural construction of the relationship between men and women, called the gender system, which determines male and female roles, their respective resources and the power attributed to them. Although the result is not achieved in the same way in each society, men always have more power than women in the public as well as the private spheres.

Gender-sensitive demography is interested in the persistent factors that produce discrimination against girls and women, those that promote decisional autonomy in women, as well as modes of negotiation and constraint between men and women. Qualitative methods are invaluable for highlighting and linking these elements. They were first examined at macrosocial levels where anthropologic data, gender systems, and demographic processes could be analyzed. Fertility decline in several major Asian countries (India, China, Korea) occurred at the same time as an increase in the proportion of missing daughters, mainly by selective induced abortion. In these patrilineal societies, sons, as opposed to daughters, live with their parents after marriage and contribute to their upkeep. Technologic modernization in this case is reinforcing the expression of the traditional son preference. If demography is particularly suited to providing a quantitative diagnostic of the phenomenon, it needs to associate with more anthropologic approaches to describe the set of processes and dramatic consequences on the condition of women by contextualizing behavior beyond the individual level. Another possible application of a gender approach in demography relates to the description of the consequences of the AIDS epidemic on women in Africa. Essentially qualitative studies have shown on the one hand that women were rarely in a position to refuse unprotected sex from HIV-positive husbands and on the other, that their fertility was increasing rather than declining when they were HIV positive (Desgrées du Loû, 1998). Demographic or epidemiologic studies integrating an anthropologic approach would be needed to inscribe the overall logic of these behaviors in their cultural setting, without omitting the gender dimension and constraint and even the violence.

If demography is the analysis of the reproduction of populations, one can hardly be surprised *a priori* that one of the major issues of interest is the quantitative analysis of fertility. Contact with disciplines such as anthropology and sociology and more qualitative approaches have led to a critique of the demographic concept of reproduction as being too biologic and individualistic, as a reproduction of persons in which children are always assigned to a precise woman (Townsend, 1997). In the wider focus of other disciplines, reproduction must be understood as "the social reproduction of structures of relationship and social positions" (Kertzer and Fricke, 1997, p. 21). In this perspective, demography needs to also look at the processes surrounding social parenthood, like adoption, family recomposition, child fostering, and even guardianship, as well as the mechanisms behind the reproduction of gender relations. Contact with other approaches will immediately widen its scope and possibilities for interpretation.

4. Quantitative Systematization of Qualitative Approaches

A part of the qualitative methods used by demographers can finally be considered as a systematization of preexisting qualitative approaches. Family reconstitution in historical demography is based on the technique of genealogy. Biographic analysis prolongs the life history approaches of sociologists and anthropologists. The development of multilevel analysis results from concern with integrating the micro, meso and macro levels within the same analysis, and this is traditional in anthropology. The sampling methods used in statistical surveys on the homeless imitate the field procedures used by anthropologists (night surveys, surveys of shelters). The use of textual analysis in demography is a systematization of content analysis. The invention of new methods by the standardization of empirical field methods is particularly common in countries with poor statistics. Although quantitative methods produce schematization and homogenization of data corresponding to variable transformation, they often depend on a logic of interrogation and analysis of reality that is initially much more complex. In this sense, there is no barrier between qualitative and quantitative methods and dialogue with the disciplines that do not use quantitative methods remains essential to the development of demography.

Such dialogue does not imply conversion to another discipline, but the continuous recognition by demographers of results, issues, and tools suggested by qualitative methods. However, it does not seem desirable to imagine purely qualitative demography, which would exist as a subdiscipline next to mainstream demography. For example, even if a qualitative approach reveals in various cultures that age is generally perceived in discontinuous categories (what may be called *social age*), it is still necessary to link these native categories to a continuous measurable age. Comprehension is brought about by the tension between meaning and measurement, rather than a simple focus on meaning.

CONCLUSIONS

Even if demography possesses an incomparable statistical toolbox, refusing to use different approaches would be a short-term perspective that might block its development as a discipline. A wide and unrestricted analysis of the reproduction dynamics of populations requires *comprehensive demography*, both reflexive and interpretative. A tradition of critique of sources and rigor in data collection helps the demographer to accept the contribution of qualitative methods in the preliminary phases of the construction of research; the requirement of reflexivity should lead to more frequent invitations for qualitative confirmations of obtained numerical results.

Believing itself to be a discipline of facts, demography is often reluctant to the idea of interpretation. However, the demand for interpretation is merely a requirement for contextualization of behavior, to which qualitative approaches can be of assistance. This expansion of focus can take place in three directions: the association between the observed behavior and the meaning conferred on it by the actors, the analysis of interpersonal interactions that produce the behavior, the situation of the observed phenomena in a social and cultural setting that should be described beyond what is perceived by the respondents. This triple contextualization is necessary to reveal, for example, the constraints that weigh on the demographic behavior of women and their possibilities for taking initiatives within a given gender system. Interpretative demography is likely to appropriate new issues and invent other methods to treat them.

Methods of Social Network Analysis

ALEXIS FERRAND AND AINHOA DE FEDERICO DE LA RÚA

Institut de Sociologies et d'anthropologie, Universite des Sciences et Technologies de Lille, Villeneuve d'Ascq, France

Institut Federatif de Recherche sur les Economies et les Societes Industrielles (IRESI), Universite des Sciences et Technologies de Lille 1, Lille, France

The concept of networks is found "in almost all fields"[1] of science, including the social sciences. It has also become part of our everyday language, with a variety of meanings. In the social sciences, the word began to acquire a specific definition and to be used in a particular way more than 50 years ago. The examples of two pioneers will show how the concept has helped to advance knowledge in psychosociology and social anthropology.

In the early 1930s, Jacob Moreno in the United States suggested speaking of the "social atom," referring not to the individual as such, but to the individual plus the interpersonal relations of attraction and rejection centered on him. This introduced an intermediate object in psychosociology, between the individual, locus of emotion and personality, and the small group that is the basic form of social order. Moreno was studying a re-education institution and wondered why a series of girls ran away, following each other. He discovered they were linked in *a network*, and he identified this concept as applying to relations that cross boundaries of groups. He also gave it a specific theoretical status. Moreno defined it as a *structured* phenomenon; however, informal such relational networks may be, they are regulated, organized and structured by principles that need to be brought to light. He also attributed a function to such networks. They provide channels for communicating information, playing a part in the circulation of rumors and thereby helping to form public opinion, which has a social regulation function. By 1934, networks had gained an acknowledged place in psychosociology as functional, supra-individual entities, detached from and transcending social organizations, informal but not formless.

Twenty years later, English social anthropology—which, like psychosociology, practices direct observation of small social interaction systems—also discovered the importance of interpersonal relationship systems. John Barnes was studying a Norwegian parish, aiming to investigate its class system and how power operated. He distinguished three fields: an economic activity (e.g., fishing), a territorial field (e.g., neighborhoods, agricultural cooperation), and a third field that united the other two. "The third social field has no units or boundaries; it has no coordinating organization. It is made up of the ties of friendship and acquaintance which everyone growing up in Bremnes society partly inherits and largely builds up for himself. . . . Most of the ties are, however, between persons who accord approximately equal status to one another, and it is these ties which, I think, may be said to constitute the class system of Bremnes" (Barnes, 1954, p. 237). This enabled Barnes to answer his questions. In the first place, actors assess their social position within the network, where they are mainly in contact with fairly similar people; even if they know there are wealth differences, they can think of themselves as equal. Second, if each resident is linked to many others in the network, and in a variety of ways, these links would be endangered if sharp disagreements or conflicts were allowed to develop. Here, the

[1] "Jeux de réseaux," *Cahiers S. T. S*, no. 9–10, Paris, Center National de la Recherche Scientifique.

network's functional effect is to impose conflict avoidance on the community's power structure.

These two examples reflect the range of approaches that have adopted and refined the network concept. The first starts from relations between individuals in small groups and arrives at the notion of social regulation by networks through which public opinion is formed. The other starts from institutionalized groups to reconstitute the matrix of a society's institutions. Both recognize networks as a structured and structuring reality that fulfills specific functions. Although the two approaches are profoundly different and regardless of the major developments that have since taken place in the discipline,[2] both remain characteristic of the vast intellectual field now known as network analysis.

I. OBSERVED NETWORKS AND RELATIONAL SYSTEMS

1. Two Methods

Like these pioneers, we will start from empirical considerations to define the subject of this chapter; we will say that a social network can be identified if one can define *a set of actors*[3] and a *particular type of relation*, and *can observe relations of this type* (their presence or absence) between the actors. If we can examine the relations each person has with all the others, we can speak of a *total network* or *complete network*. In this way surveys can be used to observe relations between members of an association, elected officials in a local community, or co-workers in the same department, where the networks involved are not too large. One can also work on very large networks using relations that are systematically recorded (e.g., in administrative data, directories, registers).

If the number of actors is not defined, the network is an *open* one. Examples are friendship networks, kinship networks, neighbor networks, and sexual networks. By definition, open networks cannot be observed in their entirety. *Atomistic* surveys are used, with each respondent being asked to describe the partners with whom he or she has the type of relationship observed. The set formed by the direct relations between the respondent (called *ego*) and other people (called *alters*) is a *relational star*. If *ego* describes the links between his or her *alters*, *we speak of personal network*, *personal community* or *ego network*.

[2] For the historical development of social network analysis, see Scott (1991) or Freeman (2004).

[3] The term *actor* is used here in a very broad sense and may refer to an individual, a group, or an organization.

These definitions can be related to more conventional objects of study. *Kinship systems*, for example, are networks made up of three basic types of links: filiation, consanguinity, and marriage. The psychosociology of small groups also looks at relational structures within groups and some of their effects (e.g., communication, influence). It is often based on laboratory observation, which can be used to create small complete networks but does not take into account the fact that actors may belong to more than one relational system at a time. Network analysis is more precise than many sociability studies because it records the distinctive properties of the relationship with each partner and their overall sociometric organization. That is, rather than mentioning e.g. what kind of things he usually does with neighbors in general, the respondent will precisely describe what he does with each specific neighbor.

Complete networks and personal networks are different kinds of objects, constructed using different observation methods. However, they take similar theoretical approaches to their models of actor rationality and relational constraints, they use some similar methods for prompting respondents to elicit their alters, and, taking personal networks as small complete networks, they use some of the same sociometric indicators (e.g., network density, connectedness). The two types of networks are located at different levels: all personal networks are subsidiary parts of broader social networks, whether bounded or open, just as a nuclear family is a subsidiary part of a kinship network.

When observing a complete network, the analysis (a) concerns a *case*, (b) highlights a pattern of relations that actors may not be aware of, (c) can be used to systematically observe subgroups, the links between them and the rare positions occupied by central actors or intermediaries. When observing a personal networks, the analysis (a) identifies regularities, (b) concerns the network perceived by the actor, and (c) often provides for a more systematic analysis of an actor's diverse group memberships and the variety of roles he plays in different relationships.

2. Approaches Rather Than a Unified Theory

John Barnes argued that there is no such thing as a theory of social networks and that perhaps there never would be. Ten years later, Ronald Burt wrote, "Network analysis is not a single corpus of knowledge cumulating with each passing year. . . . A loose federation of approaches, progressing on many fronts as a result of the efforts of many persons, is currently referenced as network analysis" (1980, p. 79). A few years later, Michel Forsé and Simon Langlois identified at least some epistemologic attitudes common to practitioners of network analysis, which "bring together researchers around the world who, although they do not have exactly the same theoretical perspectives, do have a common conception of sociology as a positive and cumulative science" (1997, p. 28).[4]

The diversity does not belie a considerable underlying body of shared ideas. First of all, there is the idea that a network may display *regularities*, a certain *pattern* of relations. The term *structure* (in the weak sense of that term) refers to the main empirical features, measured by indices drawn from matrices of the links between actors. These indices include density, connectedness, segmentation into cliques or classes of structural equivalence, distances and centrality. How are such regularities to be explained? At the theoretical level it may be assumed that the creation of a relation or the impossibility of creating one depends on the way in which existing relations are structured. In that case the network is regarded as a *relational system*. This is a more theoretical notion than a network, because to define a system, hypotheses have to be formulated about the interdependence of the relations. Here the term *structure* refers to the principles and rules that *produce* this particular system (Ferrand, 1997). *Structure* is taken in the strong sense, referring to a generative model (e.g., the incest taboo is one of the structural rules of kinship, but other rules are needed to define a particular kinship system).

Depending on the analysis, the network as a collective form is treated as an independent variable explaining actors' strategies or collective effects or as a dependent variable explained by the motives and principles that lead actors to form a relation or to end it.

There are four main orientations in network analysis:

1. Explaining actors' behavior on the basis of the relations in which they are involved and the positions they occupy in a network. Their network positions are regarded as explanatory principles at least as powerful as the personal attributes that define them regardless of context, such as age, income and level of education (Wellman and Berkowitz 1988, p. 30). This approach considers three effects. One is a cognitive and normative effect: the network can affect the actor's *orientations*, opinions, standards and beliefs (Ferrand and Mounier, 1993, 1996). One is an instrumental effect: relations offer possibilities for mobilizing resources of all kinds, hence *means of action* (Lin, 1995, 2001). The third is a controlling effect: relationships impose *constraints* and limit the range of possible actions.

2. Explaining collective effects from the characteristics of the network concerned. The type of structure conditions the dissemination of information, social control and cohesion, differentiation of powers, and conflict (Lazega, 1992, 2001; Stokman and van den Boos, 1992; Galaskiewicz, 1985).

3. Explaining the network itself: why it exists, the preconditions for its existence, its particular properties and the conditions that determine whether it changes and how. Considerable progress is now being made in defining statistical models to assess changes in a complete network at different moments in time, and in building models to simulate such changes (Snijders, 2002; de Federico de la Rúa, 2004a).

4. Explaining the characteristics of personal networks (and therefore partly enlightening the formation of the complete network) by the influence of cultural models (Héran, 1988; Fischer, 1982a, 1982b), actors' strategies or the influence of structural constraints. Taking this approach, a dyadic relation between two actors may be understood in terms of its *embeddedness* within the actors' other relations. This reveals a feedback loop between actions and existing relations: actions may mean forming relationships and so changing the network, which affects actions and so on (Burt 1982). The *actors*, who are the network *nodes*, are distinguished by their reciprocal relations, but they are not determined by them. They have a margin of freedom that varies depending on the organization of the network and the position they occupy in it (Degenne and Forsé, 1994). The actor's position in the structure is never definitively settled, and it is a central issue for actions.

Almost any phenomenon or entity can reasonably be defined as a network of relations. There are few social realities that do not involve at least minimally organized relations between actors, and pointing out the existence of a network is stating the obvious.[5] If an observer thinks he is making an original contribution by showing that some phenomenon involves a network it is because he assumes (usually implicitly) that only a relational system with particular charac-

[4] "Regroupe à travers le monde les chercheurs du domaine qui, sans partager exactement les mêmes perspectives théoriques, ont en commun une conception de la sociologie comme science positive et cumulative."

[5] The reverse exercise is more challenging. Only in very special situations can it be shown that there are no interrelations or feedback between actors.

teristics could form a network. What he is actually doing is to show what *the particular structural features* of that network are—which is quite a different thing. One can only make scientifically interesting propositions by *comparing* the structural properties and effects of different types of networks.

II. PROPERTIES OF RELATIONSHIPS AND NETWORKS

Before defining the particular features of a network, one must define the type of relations that form the network's links. In the following sections, we consider the properties most often examined in personal and complete networks.

1. Characterizing Relations

How can the *type of relation*, the basic unit for identifying a network, be defined? Some have formal definitions, such as marriage, shareholdings between firms, hierarchy of command, and membership of an association. Others are less precise. For example, what is friendship? There is a paradox; relationships between people vary widely, but our everyday vocabulary for describing them is limited. We have words to define *categories* of kin, close or distant, and a few other general categories like acquaintance, colleague, confidant, old friend, true friend, neighbor, tennis partner or team member. These words define typical roles that more or less depend on the contexts in which people meet. They do not define the content of the relationship.

a. Role, Context, and Content of a Relation

These limitations arise in the procedures for observing the simplest social networks, in which the respondent is prompted with everyday words to define their relationship with each of their contacts: "neighbor," "colleague," "family member," "member of the same club," "friend," and so on. The interpersonal tie is characterized by the name of a *typical role* or the situation where it takes place. It may also be characterized by *content*, i.e. whatever exchange of resources it makes possible. Content is often complex and a long, meticulous ethnographic observation is required to reveal all its dimensions. However, network analysis is as much concerned with the way relations are organized as it is with their content, gaining in scope what it loses in detail. As a rule only a few *typical contents* are considered, such as informational links (e.g., exchanging information about job opportunities), emotional support (e.g., talking about a personal problem), practical help (e.g., stepping in to settle a problem with a public service, help with odd jobs about the home) and social links (e.g., going out together, or being regularly in conflict).

The naming of relationships raises two classic sociologic questions. One concerns *regulating relationships*: to what extent do role norms (or context[6]) impose a standard content on a relation, and how free are the actors to negotiate their own agreements (interactionist perspective)? The other concerns the *social variability of role content*. For example, Claude Fischer (1982b) has shown that there is no consensus among Americans as to what "friend" means; different groups use different rules, and a person may use the term imprecisely or in a very individual sense. François Héran (1987, p. 45) has shown that in France the definition of "neighbor" varies according to housing environment. Linton Freeman and Danching Ruan (1997) have shown that the link between relationship role and content is fairly similar among European countries, but differs sharply between Europe and China.

b. Formal Characteristics of Relations

Multiplexity

Most studies cover more than one type of link. In that case, a relation between two actors may involve one type of link only (a "simple" relation) or several (usually called a "multiplex" relation [Knoke and Kuklinski, 1982, p. 15.]). A multiplex relationship between two people has more than one role, or more than one type of content. This factor tells us whether different spheres of social life overlap, or are strictly separate. Stereotypically, communities where each person is constantly meeting the same others but in different roles (e.g., as kin, neighbor, colleague) contrast with life in the metropolis, where work, home life and leisure activities involve separate relational systems (e.g., a colleague is unlikely to be a neighbor, friends are unlikely to live near each other).

Frequency of Interaction

It is easy to observe whether contacts are frequent or rare. What does frequency tell us, sociologically? Does repeated contact indicate an intense relationship? "High interaction rates do not necessarily imply . . . high 'intensity' of links . . . , for which it is difficult to devise measures" (Price, 1981, p. 291). In a few cases, interaction frequency is not significant. In all other

[6] The notions of "context" and "role name" are often used interchangeably in the literature.

cases, it should be regarded as a measure specific to the type of link examined. For example, "frequency exaggerates the strength of ties to coworkers and neighbors" (Marsden, 1990).

Duration

Not all relationships are lasting, and sometimes the researcher can find out how long a relationship has existed. What can be said about duration? There are relationships that do not change over a 10-year interval, others that change fast. According to some approaches, duration is the condition for exchanges to increase and trust to develop (Blau, 1964). Others stress the "irretrievable investments"[7] that accumulate in a relationship (Rusbult, 1980; Sprecher, 1988); others allude to a natural history of relations (Bozon, 1998; Ferrand, 1989).

Symmetry and Reciprocity

Many social ties are directionally biased, implying that the two partners are differently positioned in expressing an attitude (choosing someone as a friend, or being chosen) or in circulating resources (giving advice or receiving it). *Symmetry* refers to a two-way link (A chooses B as a friend and B chooses A) and *reciprocity* means that resources circulate both ways (A gives to B and B gives to A). Symmetry and reciprocity are crucial questions for psychosociology (i.e., sociometry), anthropology, and sociology (i.e., social exchange theory).

Particular exchanges apart, the partners' subjective perception of the relation may not be the same. Edward Laumann (1973) asked 985 Detroit men to name "three men who are your closest friends and whom you see most often." When he cross-checked with the partners named, he found that fewer than half named the first respondent as one of their three closest friends. At this basic level of identifying best friends, one-half of all relations were asymmetric.

Homophily

When two actors are linked by a relationship, is it obligatory, encouraged, tolerated, or forbidden that they belong to the same category? All relations listed can be placed on a "choice matrix" showing the actors' attributes in rows and columns. The classic example of this type of analysis is the *choice of spouse*; in this case, homophily becomes homogamy. An *individualistic* interpretation suggests that subjective freedom in choosing a spouse involves interiorized, reciprocal selection, whereas a *structural* interpretation suggests that subjective freedom in choosing a spouse applies only within the margin of freedom allowed by the actor's sociability network.

The homophilic choice hypothesis receives much attention from analysts. It is an attractive model, because it can appeal to macro sociologic postulates: Social stratification imposes strict limits on chances of contact between different categories. However, some social interactions are possible precisely by virtue of a difference, or a gap, between the partners. Examples are helping relations that require a particular resource one partner has, or depend on a genealogic gap.[8]

Strength

Some observers have tried to rank social links and distinguish those that bind more strongly than others. To do this the researcher must construct an indicator from the available information. A variety of attempts have been made, often with doubtful results. Mark Granovetter's now famous distinction between strong and weak ties (Granovetter, 1973) enabled him to identify ties with a specifically sociometric function, acting as *bridges* between cliques that are not otherwise linked. However, *strength* has little intrinsic consistency.

Sense of Affective Closeness

The interviewer can ask the respondent for his or her subjective appreciation in terms of closeness, intimacy, or trust. From this information, the examiner can identify the "core network."

One can regard each relation as a *specific observation* and make statistical descriptions of the relative frequencies of their characteristics. This has shown that reciprocal relations are more common in some networks than in others. One can also use the psychosociology of relationships or certain role theories to *explain*, for example, the possibility of particular resource exchanges by the characteristics of the partners' roles in the relation (Petite, 2002; Freeman and Ruan 1997; Bonvalet *et al.*, 1993; Fischer, 1982a). These analyses are innovative in two ways. First, they concern interactions between two coordinated actors and produce somewhat unusual statements because the relationship itself is the subject of propositions, such as "a relationship is more easily established

[7] All the resources (e.g., time, energy, emotional cost, intimate confidences, money) that an actor devotes to maintaining a relationship and that cannot be taken back if the relationship is broken off.

[8] Ferrand and colleagues (1999) published a study of homophilic choices in different kinds of relations in France according to social class.

between two similar actors." Second, each actor may be a term in several relations observed, which raises the problem of co-dependency between observations; this suggests that multilevel statistical procedures should be used (Snijders and Bosker 1999; van Duijn *et al.*, 1999; Snijders *et al.*, 1995). However, we shall not further pursue the question of dyad analyses.

2. Composition of Personal Networks

In a structural approach, it is considered that relations may depend on each other. This is easier to analyze if the composition of the personal network is examined (i.e., the ways in which one individual's relationships are compatible, complementary, cumulative).

a. Network Size

The simplest property of a personal network is its size—the number of relations of a particular kind that an actor can accumulate. This property is socially determined: Numbers of links of different kinds cited routinely vary according to the age, sex, and status of the respondent. Moreover numbers of relations are not a mere matter of quantity, because they imply qualitative thresholds that, above two partners, involve interdependence. Zero relations implies a psychological inhibition, practical impossibility or a social prohibition; one means a mirror relationship and, for *ego*, dependency; two provide *ego* with an alternative, create competition, make a *tertium gaudens* possible and, with *ego*, form a triad—the smallest pertinent structure for sociology (Fischer, 1982a; Simmel, 1917 [1981]; Blau, 1964; Caplow, 1968 [1984];). With more than two relationships *ego* has resource allocation problems. When the number of relations named is small, that number in itself can be interpreted as a basic structural indicator rather than a quantitative measure. Wherever at least two people are named, this is a structural property that raises the question of competition and gives *ego* some choice: what happens in one relationship depends on what happens in the other.

Taken on its own, size is a very crude indicator. It basically indicates the respondent's social isolation or expansiveness, his or her *ability* to maintain active links with others and hence (if the relations examined involve exchange) his or her overall potential for mobilizing relational resources.

b. Composition in Terms of Individuals' Attributes

If the respondent counts the partners possessing this or that sociodemographic attribute (e.g., sex, age, qualification), one can see how many *alters* have this or that status or nationality, how many live far away, and so forth (de Federico de la Rúa, 2004b; Ferrand, 2002).

c. Composition in Terms of Relational Characteristics

Composition in terms of relational characteristics refers to the distribution of relations according to the characteristics mentioned in the last section. In examining roles, the interviewer asks how many kin or neighbors are in the network. This reveals, for example, that manual workers' personal networks include a higher proportion of family members than do those of senior executives. Examining content, how many people in the network provide emotional support, and how many are leisure companions or advisers? This may show that the respondent invests most in kinship network, friendship network, or exchanges among workmates. The proportion of multiplex relations—those fulfilling more than one role—indicates the strength of connection between different networks (e.g., kinship and exchanges between workmates).

3. Structural Characteristics of Networks

We now leave simple counting of relations to look at the sociometric organization of relations. A first step in structural sociology is to describe the links between relations and the way they form networks with identifiable characteristics. With more than ten actors, any graphical representation is unintelligible, misleading or defies any proper theoretical interpretation. The best solution is therefore to build numerical indicators from the matrix of relations between actors. Jacob Moreno (1934 [1970]) had begun to create such indicators. They were perfected and became far more numerous when graph theory was used as a formal language to suggest new measurements (Degenne, 1978; White *et al.*, 1976; Harary, 1969; Flament, 1963, 1965; Harary *et al.*, 1965). They were operationalized once data processing capacity made it possible to make iterative calculations on matrices. Highly sophisticated indicators were created, sometimes at the initiative of computer scientists and formalists rather than in response to substantive questions. In this chapter, we mention only a few to illustrate typical approaches used in introductory course books (Freeman, 2004; Mercklé, 2004; Molina, 2001; Lazega, 1998; Pizarro, 1998; Requena Santos, 1996; Rodriquez, 1995; Scott, 1992; Knocke and Kuklinski, 1982; Chiesi, 1980, 1981), and we suggest some reference works on methodology for readers wishing to specialize (Carrington *et al.*, 2005; Doreian *et al.*, 2005; de Nooy *et al.*, 2004; Wasserman and Faust, 1996; Degenne and Forsé, 1994; Freeman *et al.*, 1991; Marsden, 1990; Marsden and Lin, 1982).

a. Density: A Global but Poorly Informative Indicator

Network density is the ratio between the number of links between actors and the maximum possible number of links.[9] When many actors are interlinked, density is high, and it gives the image of a cohesive group, with all the associated theoretical connotations, such as strong social control and a sense of belonging. However, density is only a very rough measure of network structure.

b. Distance between Actors: Network Openness versus Disconnectedness

Density only counts *direct* links between two actors. However, common sense readily identifies a crucial feature of networks, which is that links are themselves interconnected, forming *paths* that can *indirectly* link two actors. Instead of a matrix showing the presence or absence of a direct link between two actors, one can calculate a matrix showing the *minimal distance* between two actors. This feature has attracted the curiosity of researchers who, like explorers trying to reach the edge of the world, wondered whether networks have boundaries or are open.

If two actors cannot contact each other (even by a large number of intermediaries), then the network is said to be *disconnected*. This is a normal property when all relations are exclusive (e.g., some kinds of commercial relations, monogamous love relations). If the network is open, one may ask how far any actor is from any other. Stanley Milgram's "small world" research (Milgram, 1967) suggests that two randomly chosen individuals can contact each other by a relatively limited number of intermediaries (in their 1969 survey, Travers and Milgram found an average of five intermediaries[10]). These findings have proven useful in connection with contagious disease transmission, but less useful for social science research. The substantive question is to *decide* whether, with the particular type of relationship examined, one can consider that two actors at distance n are still effectively connected or whether the link is a purely formal one.

c. Cliques: Subsets of Strongly Interconnected Actors

A *clique* is a subset of actors in a network, such that each clique member is linked to all others (density within the clique is 1). This mechanical criterion is rarely applicable, and has been replaced by less rigid requirements, e.g. that each be connected with others at least by indirect paths of a given maximum length ($n \le 2$ or $n \le 3$). The term used is *n-cliques*. This reticular clique notion is reminiscent of the sociologic concept of *group*. In practice, however, cliques may overlap or include smaller cliques, requiring a more complex concept of "group" that takes subgroups into account.

For any study of circulation processes (e.g., of information, goods, help), connectedness shows whether there are breaks in the overall structure,[11] and *n-cliques* identify subsets within which exchanges can take place, taking paths that are limited by the particular circulation constraints of the resource. These characteristics are far more differentiating than density.

d. Rare and Crucial Connections: Bridges and Break Points

A network may consist of two cohesive cliques, with only one or just a few links between them. Such links are called bridges. The existence of a bridge is a major structural characteristic, because without it the network becomes disconnected; it is unique (or rare) but crucial. Bridges counteract the paradoxical risk run by networks that are highly connected locally (in dense cliques) of being disconnected on a broader scale (if the cliques are not interconnected). For many purposes, networks made up of cliques with no bridges are not very operational. Mark Granovetter has suggested that an urban district made up of dense but poorly interconnected micro-neighborhoods would not have much capability to resist the threat of urban renewal (Granovetter, 1982).

[9] If P is the number of actors (network size) and L the number of actual links (here assumed to be symmetric links), density D is obtained as follows:

$$D = \frac{L}{(P \cdot (P-1))/2}$$

The denominator gives the number of squares in the total matrix, minus the diagonal of ego-centerd links: it indicates the number of possible choices. However, because reciprocal choices have been counted, only a half-matrix can be filled in, so the denominator is divided by 2. The numerator indicates the number of actual existing links.

[10] There has been new research into the "small world" idea (Newman, 2003; Barbási, 2002; Watts, 1999).

[11] Attention must be paid to *boundary effects* introduced by observation. If the respondent is asked to list no more than five friends, the resulting network may appear disconnected, but if 10 friends were listed, it might prove not to be.

e. Describing Positions in the Structure: Centrality Indicators

Centrality defines a position in the overall organization of relations in the network's structure. Three very different indicators are used to measure it. Let us call an actor *ego* and consider several propositions:

(a) *Ego* is central if directly linked to a large number of other actors: *degree centrality* counts the number of actors with whom *ego* has a direct link.

(b) *Ego* is central if linked to central actors. In practical relational terms, this formula is far more economical than the first one, but it ultimately records the same characteristic: the direct or indirect ability to contact numerous other actors.

(c) *Ego* is central, if able to prevent interactions between a large number of other actors because the paths that link them go through *Ego*; this is *betweenness centrality*.

f. Subsets of Actors Occupying Similar Positions: Classes of Structural Equivalence

Classes of structural equivalence are subsets of actors who maintain relationships with approximately the same other actors throughout the network. They need not be in contact with each other. Because the members of such a class have the same relational profile, that class is said to form a position in the structure. We can suggest a synthetic model of this structure by describing the typical relations between the few positions so identified; the very extensive matrix of relations among actors is replaced by a synthetic matrix of relations between a small number of typical positions. Emmanuel Lazega describes the informal structure of a law firm of 71 lawyers by grouping them into 11 different classes of actors who were, in a similar way, givers or receivers of professional advice (Lazega, 1998 p. 66; 2001 p. 103). For example, young trainees who were not linked to each other but who asked the same senior members for advice would be put in the same class of equivalence.

g. Modeling a Network: Counting Types of Triads

We are looking at the *structural* properties of networks that may be of any size. However, with increasing network size an exhaustive description of the components of a network soon becomes unintelligible and comparisons between networks impossible, as the number of different combinations of elements to be considered becomes astronomically large. Various ways are sought to synthesize the information. One way is to divide the network into triads: three actors and any relations between them, reciprocal or not.[12] This is the smallest subunit of a network that can be examined structurally (i.e., from the standpoint of how *one relation may be linked to other relations*. They present only a limited number of significant combinations (Fig. 137–1).[13] Any triad can be seen *from outside*, as in Figure 137–1 and *from inside* if one puts oneself in the place of one of the actors involved. A triad as seen from the standpoint of any one of its three members is called a *triplet*. The sociometric organization of a network is described by counting the frequency of each type of microstructure encountered (triad or triplet). This method gives a fairly accurate picture of structural properties of a network.

If the subject of the research is an open network (e.g., friendship or kinship networks, sexual networks) observed by a sample of independent personal networks, these microstructures will be counted using standard statistical procedures.[14] Conversely, if the research subject is a complete network in which one is observing all relations between the members of a defined social group, one must use procedures specifically developed to take account of the interdependence between the relationships observed.[15]

By observing these very elementary structures one can analyze basic propositions about the constitution of a social structure. For example, it is possible to examine the strength of the principle of *transitivity*, which is the extent to which the existence of relation *Rx* between P1 and P2, and between P2 and P3, implies the existence of the same type of relation between P1 and P3. Similarly, we can examine how relations *exclude* each other because they compete or because

[12] Any network, whatever its size, can be broken down into *x* triads, each formed by a different trio of actors.

[13] For a detailed presentation of structural analyses based on triads, see Burt (1980) or Holland and Leinhardt (1978, 1979).

[14] Preferably, multilevel analyses to take account of the fact that every relation observed depends on the ego it belongs to.

[15] Since the first U|MAN model (Uniform distribution, conditional on the dyad count: number of Mutual dyads, number of Asymmetric dyads, and number of Null dyads) suggested by Holland and Leinhardt (1976) and the *p1* model developed by Holland and Leinhardt (1981), proposals have gradually become more sophisticated. The model chosen must depend on the question asked; the *p2* model (van Duijn *et al*., 2004; Lazega and van Duijn, 1997; van Duijn, 1995) can explain the existence of a link between two actors based on the actors' relational characteristics (e.g., an analogous centrality) or on their attributes (e.g., sex, status, age). The *p** model (Snijders, 2002; Wasserman and Pattison, 1996; Frank and Strauss, 1986) makes it possible to count the types of triplets (properly speaking) in a network. The Siena model (Snijders, 2002) can be used to study the evolution of a network by observing typical changes in triads (e.g., closure of a network by transitivity, as when "my friends' friends become my friends") in combination with the effects of actors' attributes and relational preferences.

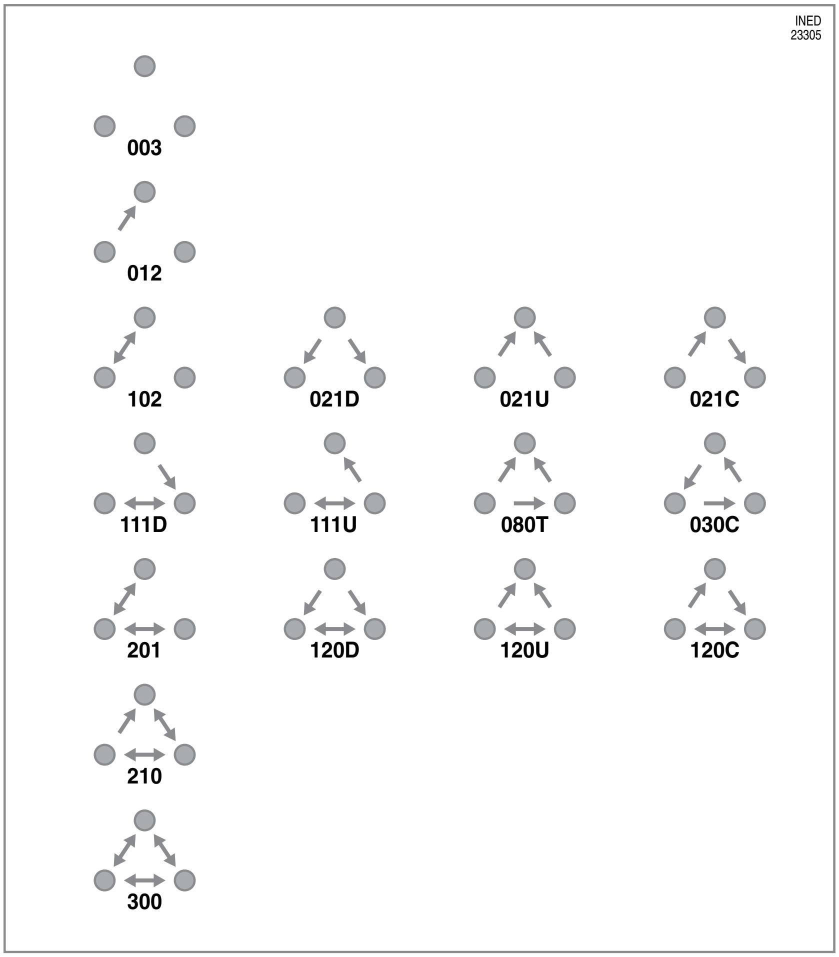

FIGURE 137–1 Isomorphic classes of triads according to Paul Holland and Samuel Leinhard (1976).

there is a rule forbidding them. With resource circulation and exchange, we can observe simple *reciprocity* (i.e., within a dyad) or the elementary form of generalized exchange in which A gives to B, who gives to C, who gives to A. These are major indicators of forms of solidarity and social control.

h. Complete Networks and Personal Networks

Although most of the characteristics we have just mentioned were defined in the context of complete network analysis, many can also be used to characterize personal networks. High density will mean that the actors are involved in networks where knowing each other can facilitate social control and make it easier to obtain help. However, density is a weak indicator. It is more discriminating to ask whether, apart from *ego*, the *alters* are all in direct or indirect contact with each other, or if the network is a disconnected one consisting of subsets isolated from each other. This may be the micro-social expression of a collective organization in which the domains of kinship, residence, and work are separate. Alternatively, it may be seen as resulting from *ego's* relational strategy: *alters* not connected with each other are more likely to be simple relations (*weak* links) giving access to *varied* sources of information (Granovetter, 1974). The investigator could stress the fact that, if the alters can only communicate through *ego*, *ego* occupies a privileged position as central intermediary. Ronald Burt (1992, 1995) has shown that a person can benefit from occupying this kind of *structural hole* position in a network.

This preliminary glimpse has identified the main network properties and relational characteristics that researchers have examined. The formal complexity of networks offers a vast domain to the methodologic imagination, and the specialized literature has produced an abundance of specific measurements. However, these basic indications are enough to give an idea of the many formally and qualitatively different types of possible measurements. Even these basics can be used to empirically validate many propositions suggested by the sociologic imagination Wright Mills extolled (Mills, 1959 [1970])—this being the sole source of actual knowledge.

III. SURVEY PROTOCOLS

Survey methods have been developed in which respondents are prompted to name and describe their relationships, enabling analysts to study networks. The problems posed by descriptions of relationships are the same whether the network to be analyzed is a complete one or a personal one, but naming relations is a more delicate matter when the network being explored is a personal one. Below, we mainly examine techniques that can be used in sample surveys for describing personal networks. These seem to be the most useful for addressing the questions about large populations that are the core of demographic analysis.

Every individual has some relationship with a large number of partners. In urban situations with a high degree of division of labor, social division, spatial specialization, and sharply segregated activities, relations take place in many different, often separate social contexts. An individual's complete relational universe is extensive and complex. Experiments have shown that the network a person accumulates over his or her lifetime may vary in size between 2000 and 5000 people (Pool and Kochen, 1978; Gurevich, 1961). The active relationships in an individual's personal network at a given time have been estimated at 290 on average, with a standard deviation of 250, people in the higher social strata having more contacts (McCarty *et al.*, 1997; Freeman and Thompson, 1989; Killworth and Bernard, 1978). Looking at an individual's close circle and most intimate contacts, figures of about 19 are given for close associates, using a wide range of criteria (Fischer, 1982a), with 3 to 5 taking specific criteria such as people with whom the respondent discusses important problems (this is roughly the number found in the General Social Survey's "confidant" module), and fewer than 3 confidants with whom emotional and sexual matters are discussed (Ferrand *et al.*, 1993). Only a *clinical* analysis could hope to explore an individual's complete personal network, the total sum of his or her relations.[16]

1. Selecting Relations: Name Generators

Most studies do not explore an individual's whole network but *parts* of it, *selected extracts* so to speak. The object of the analysis is an effect of the method—a *construction resulting from observation*. This is more radically true, and has more important consequences, than in other research fields. Because of the constructed nature of the findings, special care is needed when comparing different surveys, and conclusions and generalizations always need to be controlled by a careful examination of the observation procedures.

If the research concerns a fairly small social group (e.g., a company, a school class), the first methodologic preoccupation will be how to define the relations to be observed. If the research concerns open networks (e.g., friends, kin, neighbors) in large populations (i.e., societies), which is the approach on which we focus in the following sections, then observations must be selected in two successive steps. The first step is the procedure for choosing the survey respondents—the classic problem of designing a sample. The second step, which is specific to social network analysis, is the procedure by which each respondent is asked to select relations of a particular kind from their system of mutual acquaintances. In this way an ad hoc experimental sample of relations is extracted.

The problem here is how to get respondents to select what is wanted. It is a crucial question, because any distortion will not just result in variations in responses to a question, but will introduce what can be thought of as a *sampling bias*: it will change the lists of objects observed (an individual's relations). Respondents will select different types of relations depending on the instructions given. The questions asked to obtain a list of names determine the types of people regarded as network members, and so determine the operational definition of the network that is analyzed afterward (Bass and Stein, 1997; Campbell and Lee, 1991; McCallister and Fischer, 1978). The first methodologic preoccupation is *how to elicit the subset of relations that is relevant for the purposes of the study*. This is always the most important step for constructing, defining, and delimiting the networks studied.

Various types of questions can be asked to prompt a respondent to list their relations. They are called *name generators*, as the respondent replies by naming people according to a selection criterion (i.e., a particular type of relationship they have with them). The name generators are the most important questions in a social network survey, because the amount and quality of information obtained largely depends on them.

The process must select from among all the respondent's relations the ones that form the particular network the survey is intended to examine. The criteria applied vary; procedures may be based on *content* of the relation or a typical interaction (e.g., Who do you

[16] Jeremy Boissevain (1973) describes the "networks of two people" with 1300 and 840 relations, respectively.

discuss work problems with?, Who do you borrow money from?, Who do you ask to baby-sit?'); on a *role* (e.g., Who are your family members? Your friends? Neighbors?); or on *subjective assessments* about relations (e.g., Who are your closest or most intimate friends?). As well as the criterion for type of relation, an analyst can use *temporal* criteria (e.g., limiting the choice to people the respondent has frequented in the past 6 months) or *numerical* criteria (e.g., limiting the number of people mentioned to three, five, or more). The type of name generator and the limits imposed will depend on the purpose of the survey. Some surveys combine several name generators, as in the practical example set out below to illustrate in detail the types of questions used. After this example, we review a few classic or otherwise noteworthy surveys to show the particular data gathering techniques they have used.

2. Survey Example: The Social Survey on the Networks of the Dutch between 1999 and 2000

The Social Survey on the Networks of the Dutch (SSND) examined social network content and particularly its role in neighborhood life and in the workplace. The research sought to answer theoretical and methodologic questions about social capital, defined as the resources present in personal social networks. The aim was to measure the general distribution of social capital in a population and the efficacy and specificity of that social capital according to aims and contexts (Van der Gaag and Snijders, 2004; Flap, 1999, 2002; Lin, 2001). The survey was jointly conducted by the universities of Utrecht, Groningen, and Amsterdam. It used a representative sample of 1004 people from the Dutch population.

The emphasis was on access to the resources found in a social network rather than their use.[17] The fact that a resource exists in the network is not enough for it to be considered usable social capital. Hypotheses have to be formulated as to its availability, i.e. how *alters* may allow *ego to* use their resources. The authors' hypothesis was that resources are potentially available through a relation depending on the investment *ego* has made in that relationship in the past. Because the survey used a general population sample, the authors had to take care in choosing the resources referred to in their questions; respondents from different social milieus had to see them as relevant, useful resources.

The SSND survey uses three tools for measuring social capital, which the authors call the *name generator/interpreter* (McCallister and Fischer, 1978), the *position generator* (Lin and Dumin, 1986), and the *resource generator* (Snijders, 1999). The first two are adapted from the classic literature on social networks and social capital, and the third was used for the first time in this survey.

a. Name Generator or Interpreter

This is the oldest type of tool and is used in many surveys (Fischer, 1982a). Each *ego* is asked to list the people with whom he or she has exchanged (given or received) a particular resource. Each question about the exchange of a given type of resource *generates names*, identified by first name or initials, which are set down in a list. This list is then used to ask *ego* to characterize their relationship with each person using *name interpreter* questions. The list is then set out as a table to facilitate systematic coding.

Collecting name-generated data is a heavy burden for both interviewer and interviewee, because the number of data that are to be collected can become enormous, especially when many name-interpreting questions are included and larger social networks are encountered. However, it is especially recommended when detailed analyses of social network contents in specific populations are pursued.

Boxes 137–1 and 137–2 below present the questions used as name generators and name interpreters respectively. Tables 137–1 and 137–2 illustrate the grids produced for interpreting results.

b. Position Generator

This method, which follows Nan Lin's theory of social capital (Lin, 1982, 2001), measures relational access to what are regarded as high-prestige occupations and therefore, in a stratified and hierarchical view of society, regarded as social capital (Lin, 1982, 2001). The availability of each contact is measured by the strength of the link (e.g., family, friend, acquaintance) connecting *ego* to a person in each occupation. Box 137–3 presents the question asked and the data collecting grid.

This questionnaire is quick and easy to administer. However, it gives only an indirect measure of social capital and does not provide a basis for characterizing the relations because no reference is made to specific people, only to occupations and types of roles. For different populations in different countries, the choice of occupations needs to be adjusted.

[17] The actual use of social capital can be studied, but it would require a large number of additional questions. For the reasons why this particular choice was made, see Van der Gaag and Snijders (2002).

BOX 137–1 Name Generators: Questions to Elicit Names from the Respondent

1. *Contact-person for current/last job*

Now we get to a question that is important to discover your personal relations. I would like to know who helped you getting this job. May I have the first name and the first letter of the family name of the person who helped you get your current/last job? We will come back to this person later.

2a. *Asking advice*

If you have a problem at work, whom do you go to for advice?

2b. *Giving advice*

How is it the other way around? Are there also people who come to you for advice regarding problems that they have at their work?

3. *Sour social capital*

At work people not only cooperate, but also bother each other. How is that in your situation? Has any of your colleagues lately disturbed you in doing your job?

4. *Direct colleagues/cooperation*

Who are the two colleagues with whom you work most often?

5. *Boss*

May I have the first name and the first letter of the family name of your boss?

6. *Help to get house*

I would like to know the first name and the first letter of the family name of the person that helped you get this house, or from which you directly bought the house.

7. *Help with small jobs in and around the house*

If you are busy with a small job at home, and you need someone that gives you a hand—for instance, if you need furniture moved or a ladder held, whom do you ask for help?

8. *Keys*

Is there someone from outside your household that keeps a spare key to your house?

9. *Direct neighbors*

Who are your direct neighbors? We mean the people that live closest to you; for instance people live directly right, left, above or under your home? I would like to have two names of the people living directly next to you. For clarity, can you also give me the numbers of their address?

Neighbors are from house number ______ and ______

10. *Visiting others*

Many people sometimes visit others in their leisure time. Who do you go to for a visit?

11. *Core network*

Life is usually not only about going out and enjoying company. Everybody needs someone to talk about important matters from time to time. With whom did you discuss important personal matters during the last 6 months?

12. *Open network question*

Let's go through the list of names we have made together. Is there anybody else who is important to you and whose name is not yet on the list? If yes, I would like to add this person to the list. What are the activities you usually share with this person?

TABLE 137–1 Example of Register Used to Record Responses Describing Partners and Relations

BOX 137–2 Name Interpreters: Questions for Describing Relationships

The following questions all refer to network members identified with name generator questions 1 through 12 in Box 137–1. I would like to go through the list of people we have made once again.

1. Which of these persons is a woman?
2. How old are these persons?
3. How are you connected to these persons? (max. 3 role relations)
(1) partner, (2) parent, (3) child, (4) parent in law, (5) brother/sister, (6) another family member, (7) friend, (8) boss, (9) direct colleague, (10) another colleague, (11) someone who is working for you, (12) someone from the neighborhood, (13) direct neighbor, (14) a fellow club/association member, (15) acquaintance
4. Do you know the religion of these persons?
(1) Roman Catholic, (2) Netherlands protestant, (3) reformed, (4) other, (5) none, (6) I don't know
5. Which of these persons is married, or lives together with a partner?
6. Which of these persons has children that still live at home?
7. How often do you usually have contact with these persons? (six items for frequency)
8. How long have you known these persons?
9. Where, and at which opportunity did you first meet these persons?
10. Where and at which opportunity do you usually meet each other nowadays? (The list that follows is used for question 9 and 10.)
(1) during my education, (2) at a club or association, (3) at work, (4) at kin's homes, (5) at friends' homes, (6) at my place, (7) at their place, (8) in the neighborhood, (9) at a place to go out, (10) in church, (11) during holidays, (12) at a party, (13) elsewhere
11. Which of these persons lives within a radius of 5 kilometers from your house?
12. On a scale from 1 to 5, can you indicate how much you like these persons? Mark persons you like very much with a 5 and persons you don't like with a 1.
Interviewer: record corresponding marks in column Liking on list A.
(1) don't like, (2) don't especially like, (3) quite like, (4) like, (5) like very much
13. Can you also indicate how much you trust these persons? Mark persons you trust very much with a 5 and persons you don't trust with a 1.
14. Do you think that 5 years from now you will still have a relationship with these persons? With whom do you think you will not have a relationship 5 years from now?
15. How intensive is the relationship with these persons? Mark persons with whom the relationships is very intensive with a 5, and persons with whom the relationship is weak with 1
16. What kind of education did these persons complete?
(1) basic lower education, (2) high school, (3) higher vocational, (4) college or university
17. Which of these persons has a paid job at the moment?
18. What is the occupation of these persons? If they do not have work at the moment, I would like to know their last occupation.
19. Finally, I would like to now whether some people you know also know each other. How well do the following persons know each other? Do they know each other, and if yes, do they get along well or do they avoid each other?
1 = persons avoid each other, 2 = persons don't know each other, 3 = persons hardly know each other, 4 = persons know each other well, 5 = persons know each other well and get along well

c. Resource Generator

A third tool was invented for this survey (Snijders, 1999) (Box 137–4). It combines the positive aspects of the position generator (i.e., economy and internal validity) and the name generator (i.e., detailed information about resources). The questionnaire used for asking the respondent about their access to resources is structured like the position generator: a set list of resources, each one supposedly representing a subset of social capital covering several spheres of life. The potential availability of each of these resources is recorded by the strength of the tie between *ego* and *alter* (e.g., family, friend, acquaintance).

This questionnaire is quick to conduct and gives an easy representation of social capital. It can be directly processed statistically and quickly interpreted. Because social interaction and network formation are culturally determined, the content of the resource generator must be adapted to the population concerned.

TABLE 137–2 Sample Matrix Used to Record Responses Describing Relations between Partners

How well do persons no. 1 to no. 6			. . . know persons no. 2 to no. 6				
NG	Name[a]	No.	No.1 and no. 2	No. . . . and no. 3	No. . . . and no. 4	No. . . . and no. 5	No. . . . and no. 6

7		4					
8		5					
11		6					

NG, name generators.

[a] In the Name column, the respondent puts the first name mentioned in reply to each of the name generators listed in column NG. In the boxes of the grid, the person indicates whether partner 1 knows partner 2, and so on.

BOX 137–3 Questions for the Position Generator

Before asking you more questions about your work and your daily activities, I would like to know what are the occupations of the persons you meet and have contact with. I have here a list of different occupations that people can have. Does anyone in your family have one of those occupations? Anyone among your friends? Among your acquaintances? By acquaintance, I do not mean the salespersons you come across in the shop, but somebody that you have a small talk with or would have a small talk with if you meet him/her on the street and that you know by his/her name.

Job/function	Family	Friend	Acquaintance	No.
1 Physician	1	2	3	0
2 Cook	1	2	3	0
3 Engineer	1	2	3	0
4 High ranking public servant	1	2	3	0
5 Construction worker	1	2	3	0
6 Director of a company	1	2	3	0
7 Etc., up to 30 occupations				

3. Particular Features of Some Exemplary Surveys

There have been a number of sample surveys designed to describe personal networks from different angles. They concern a range of issues, such as how information is mobilized in the search for work (Requena, 1991; Granovetter, 1973), the influence of personal network structure on promotion in an organization (Burt, 1992), or political attitudes and sense of belonging with regard to the European Union (de Federico de la Rúa, 2003). They may also look at macrosocial factors that modify networks, such as. the effects of political regime change in East Germany (Völker, 1995) or the impact of urbanization (Fischer, 1982a). We present a few surveys to highlight their original methods or because their impact is well known.

a. East York

Barry Wellman's surveys of East York (Toronto, Canada) in 1968, 1978, and 1981 (Wellmann and Berkowitz, 1988) had three aims: to show that in an urban environment social integration does not simply mean integration in the home neighborhood; to explore the dynamics of interpersonal exchanges aimed at obtaining resources; and to back up a structural interpretation of actors' behavior and attitudes. The research is original for its successive use of in-depth interviews, face-to-face questionnaires and postal questionnaires and for the steps it took to observe the creation and dissolution of relations.

b. Detroit Area Study

Edward Laumann conducted a study in Detroit (Laumann 1973) to show the influence of the personal network on people's behavior and attitudes. It took a sample of 1013 white males between the ages of 21 and 64 years, born in the metropolitan Detroit area. The name generator is formulated as follows: "Now would you think of the three men who are your closest friends and whom you see most often. They can be relatives or nonrelatives, as you wish." Here the generator limits the selection to a single type of relation defined

BOX 137–4 Questions for the Resource Generator

Here I have a list of skills and resources. Does anyone in your family have this kind of skill or resource? Anyone among your friends? Among your acquaintances? By acquaintance, I do not mean the salespersons you come across in the shop, but somebody that you have a small talk with or would have a small talk with if you meet him/her on the street and that you know by his/her name.

	I. Do you know anyone who II. . . . and are you someone who . . .	No	Family	Friend	Acquaintance	Yourself
1	. . . can repair a car, bicycle, etc.	0	1	2	3	4
2	. . . owns a car	0	1	2	3	4
3	. . . can repair household appliances	0	1	2	3	4
4	. . . can speak and write in a foreign language	0	1	2	3	4
5	. . . can work with a computer	0	1	2	3	4
6	. . . can play music	0	1	2	3	4
	. . . etc., up to 20 skills or resources					

by a role label (close friends) and, within that, limits the answer to three names. For each friend named, the respondent is asked for sociodemographic information (age, occupation, educational level, how far away they live) and political preferences. *Ego* has to say how he perceives the mutual acquaintanceship links between his friends; this gives the basis for a simple analysis of the sociometric structure. These advantages counterbalance certain limits of the survey: close friendship is quite an ambiguous notion and is not representative of friendship in general, still less of the diverse types of relations that make up personal networks.

c. Northern California Community Study

Claude Fischer (1982a) set out to study the extent to which the size, composition, functional and cultural diversity of an urban area affected individuals' sociability and the emergence of subcultures. It was a contribution to the debate launched by the Chicago School pioneers. Its sample of territorial communities was stratified by degree of urbanization, and within that, random samples of housing units were taken, and 1050 English-speaking people were interviewed in 1977 and 1978. Claude Fischer wanted a relatively ample description of their personal networks, and used nine name generators based on precise exchanges: Who has helped you with a small job around the home? Who do you talk to about the way your job should be done? Who do you go out with socially or go to dinner with? Eight answers to each question were allowed. The questionnaire also allowed respondents to add "other people who are important to you." Claude Fischer then asked for information about each *alter*. The questionnaire then made a second selection, retaining only the first five people named in response to certain name generators. For this subnetwork, the respondent was asked for more ample information about the history of each relation and about linkages between the *alters*. With these data, quite refined sociometric indices could be used. This approach gives a fairly open description of the personal network, and a more thorough analysis of a small number of relations. It is a fruitful compromise between extensive enumeration and analysis of structural complexity.

d. Contacts between People

A 1982 survey on contacts between people conducted for the Institut National de la Statistique et des Études (INSEE), which is the French national statistics office, and the Institut National d'Études Démographiques (INED) by François Héran (1987, 1988), was designed to describe the sociability of the French from a representative population sample. A particular feature of the survey was that it described the practices of households taken as a whole (5900 households were used) and the sociability of one individual chosen at random within each household (4700 individuals). There were two levels of information. Another particularity was that, as in some *time budget* analyses, respondents were asked to note, for every quarter hour for 8 days, what they were doing and whether they had "talked with people not living in their household (strictly work-related discussions excluded). If several people were involved, note each one individually." The respondent is asked for the gender, first name, and age of each person they talked to. This "catch-all" name generator is the survey's strong point (describing exhaustively, on a representative basis, what people the respondent has relations with) but also its weakness, because it says nothing about the content of those relations.

e. General Social Survey

The General Social Survey (GSS),[18] conducted by the University of Chicago's National Opinion Research Center (NORC), is a periodic representative survey of the population of the United States (sample of about 1500 people) with core modules repeated every year and specific modules used only in particular years. The name generator used in the 1985 survey was straightforward: "From time to time, most people discuss important matters with other people. Looking back over the last 6 months—who are the people with whom you discussed matters important to you?" The specialists advising the NORC chose this question because it would be meaningful to any interviewee and would elicit a varied range of types of relations.

Respondents are then asked for information about the first five *alters* they mention: the characteristic roles of each relation (e.g., type of family relationship, friend, colleague, leisure companion) and which of them knows which others. Limiting names to five is not a problem because only 6% of respondents mention more than five people. Here the procedure examines the core network—a smaller and more specialized network than in the *contacts between the people* survey. However, the composition of this micro-network is still a good indicator of peoples' overall sociability. As Ronald Burt points out (Burt, 1990, p. 418), based on a precise analysis of the relations listed, "The GSS sociometric name generator is less a definition of relation content than it is a window through which one can view the respondent's interpersonal environment." One advantage of the procedure is that it is particularly quick and economical. Small relational modules on precise issues are also included. In 1987, for example, the GSS described three political discussion partners and the way in which *ego* perceived these partners' party support choices (Knoke, 1990). The module identified interpersonal consensus with regard to voting. In 1988, questions were asked about sexual behavior.

f. Lifestyles

Between 1988 and 1989, the INSEE and the Center National de la Recherche Scientifique (CNRS) conducted a joint survey on domestic production in French households (e.g., home cleaning and maintenance, feeding and caring for family members). The survey covered a representative sample of 6,807 households. One module took an original approach to examine exchanges of help in household tasks, because it examined a network of households rather than individuals, and recorded the reciprocity of the exchanges. The survey used 18 name generators for different types of help (e.g., baby-sitting, care functions, housework, loans of money) that had been exchanged, received, or given over the past year. For each household, respondents described the type of relation (e.g., kin, neighbor, friend) and a few sociodemographic attributes of the household head. This made it possible to study what types of relations allow people to exchange these types of help, and the way in which these particular resources circulate in our society (Degenne and Lebeaux, 1991).

g. Confidants for Emotional and Sexual Issues

The module on confidants for emotional and sexual issues was part of a larger survey funded by the French national AIDS research agency (Agence Nationale de Recherches sur le Sida [ANRS]), covering 20,000 individuals in France. Between 1991 and 1992, it was conducted among a subsample of 2343 people. The aim was to study the normative influence of a person's network of confidants on their sexual behavior. The central idea was that types of sexual activity are the result of transactions within the couple, involving normative references to, and models inspired or strengthened by, each partner's close relational environment (Ferrand and Mounier, 1993, 1998). The name generator used the question "apart from the person you live with, with how many people do you discuss your love affairs, sexual problems, sexually transmitted diseases or what goes on in your couple?" The number of people mentioned was noted, and the attributes of the first three: sex, age, occupation, duration of the relation, and frequency of interaction. The respondent was asked how they perceive the sexual behaviors of their confidants. The particularity of this survey is that it shows that people can be asked about relations involving very intimate subjects and taboos, and will give answers about quite private aspects of their confidants' lives.

h. The International Social Survey Programme's Social Networks and Social Support Surveys

The International Social Survey Programme (ISSP) coordinates major periodic surveys in several countries, making sure the data produced are comparable.

[18] For full, precise information about how the GSS works, see Marsden (1987) and Burt (1984).

The 1986 and 2001 surveys investigated social networks and social support systems. The 1986 survey used representative samples from seven countries.[19] It described frequency of encounter with close kin (parents, siblings, children), the size of the extended family network, and close friends. It identified the type of relation (spouse, parent, child, brother or sister, other kin, friend, neighbor, colleague, other relation) to whom the respondent turned first, and second, when in need of help in any of the six fields covered: help around the home and garden, illness, borrowing large sums of money, problems with spouse, feeling depressed, needing important advice. The 2001 survey was conducted in 34 countries[20] and concerned extended family, friends in different contexts (work, neighborhood, other), membership of organizations, information about job opportunities and questions about satisfaction, trust and political opinions. The comparative potential of the ISSP surveys is particularly interesting and has been exploited by Linton Freeman and Danching Ruan (1997) among others.

i. The Institut National d'Études Démographiques Survey on Close Associates and Kin

The 1990 Close Associates and Kin (*Proches et Parents*) survey conducted by Catherine Bonvalet on a representative sample of 1946 people from the adult French population (Bonvalet *et al.*, 1993) followed on from earlier research into family networks (Gokalp, 1978). It had three aims: (1) increase knowledge of the extended family (2) explore the affinity network (as a rule, the kinship group a person can describe is broader than the group with which they have close ties); (3) study the social habits of the family and friendship network. The method used was to record the resources respondents could mobilize through their network of family and friends: help and support, transmission of goods, exchanges of services and information. There were three parts to the questionnaire. The first concerned help received and given by *ego* over their lifetime in the fields of education, employment and housing. The second described the network of close associates using a name generator: "Now we are going to talk about the people you regard as being close to you. Can you list them, regardless of whether they are friends, members of you family or of your spouse's family?" The third part, which is highly original, consisted of drawing up a family record book over five generations (from grandparents to grandchildren and including uncles, aunts, cousins, nephews, nieces and their spouses). In this way the survey identified three types of network: extended family, those considered "close," and the self-help network. The three do not necessarily coincide.

CONCLUSIONS

To conclude, it must be said that not all fields have been covered. We have not discussed survey methods on complete networks or the use of archive data for reconstituting complete networks.[21] The questions raised by data analysis on complete or personal networks have not been examined in depth; nor have the particular statistical approaches used for relational matrices. We set out the general principles and then focused on survey methods for large populations that use common demographic research procedures among other methods.

Surveys on personal networks certainly have much in common methodologically with studies designed to give a detailed description of kinship groups. However, this does not mean that ultimately they are much like conventional surveys. In the first place, at the strictly empirical level, many social network studies have developed comprehensive analyses of different aspects of socialization. The same observation takes into account relations formed through work, in the neighborhood, or through membership of an organization, as well as kin. Such studies never claim to give an exhaustive description. They observe interdependencies between different types of relations. This leads us to a second, more theoretical distinction. Social network analysis methods can be used for research inspired by a wide range of theoretical paradigms, but it is fair to say that the structural approaches are based on the hypotheses that can best exploit the demonstrative potential of social network observation. They lead us to define an actor less in terms of their individual attributes than their position in a particular set of intersecting relational systems. There the actor will find resources, be subject to control and prioritize their preferences. Each actor is limited by the position they occupy in these systems' struc-

P A R T

III

HISTORY OF DEMOGRAPHIC SCIENCE, TEACHING, AND RESEARCH

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

Part III of Volume IV could equally have been entitled "Demography Viewed by Demographers" because the authors of its chapters, demographers themselves, were asked to consider demography in the making. It provides the expert views of the specialists whose careers have consisted of practicing demography from a perspective that is as critical as possible when required.

In Chapter 138, Eric Vilquin gives a more historical than demographic treatment of the history of demographic science, focusing more on its origins than on the most recent developments. These are considered at greater length in the later chapters on demographic research and teaching. Starting from the pioneers who invented the discipline without giving it a more specific name than *political arithmetic*, Vilquin also covers those who, from the 19th to the early decades of the 20th century, gave the discipline its name and structured it into a coherent corpus of issues and methods, while also developing the necessary sources of information and encouraging public awakening to the issues raised.

The next stages of the history are delivered in a very different form in the following chapters, because without addressing developments in the discipline in recent decades, there is no valid way of approaching demography teaching and the tools used (i.e., handbooks, treatises and other learning aids, software, and other educational programs) or demographic research and the centers that carry it out.

In Chapter 139, Annunziata Nobile and Alessandra De Rose focus on works published in the latter half of the 20th century by reference to developments in the topics addressed by authors whose choices largely reflect advances and shifts of direction in the discipline. The authors deliberately confined themselves to works in English, French, and Italian. Even though this sample is wide enough to cover the bulk of output in this field, it was useful to supplement this overview and its bibliography with short presentations of the teaching literature available in other languages that have had or still have some importance in the development of demography. Each is written by specialists with a background in the languages concerned: Russian, German, Spanish, Portuguese, Dutch, and Japanese. This argues that the same approach should have been taken for Arabic, Chinese, and other sources, but-, a limit had to be set, even if the one chosen may seem arbitrary.

In Chapter 140, Dionisia Maffioli mainly addresses developments in demographic research issues to trace what is the very recent history of demography teaching. The issues of science are not themselves wholly independent of the political, economic, and social issues that are the essence of demography, nor even the beliefs to which they give rise. However, in the educational sphere, the big issue of recent decades is still the introduction of demography into the university curriculum. It has been a sometimes eventful journey, and one that has taken very different pathways in different cultural areas, where there is a marked contrast between the way it has made inroads in a very practical way as a component of other disciplines in the English-speaking world and its much more assertive demands as a study in its own right in the French and Italian-speaking worlds.

Advances in the discipline and especially in technology are what prompted the emergence and development of demographic software, which is traced in Chapter 141 by Antonella Pinnelli and Anna Maria Birindelli. The case may be made that technologic development to some extent has supported the development of demography, because computers removed the restraints of computation times. Some approaches turned into real avenues of exploration only when computing power became sufficient to enable the development of software to implement appropriate methods.

In Chapter 142, Dionisia Mafioli examines centers of demographic research and teaching. Her assessment naturally reflects earlier propositions about the teaching, development, current state, and future prospects of demography.

Chapter 143, which is the end of Part III and of the entire book, gives a voice to demographers from the world over. Michel Loriaux and Tania Vishnevkaia summarize the results of a survey of the members of this small international scientific community on how they came to demography, how they approach and practice it, and how they see its future. It may not be a wholly representative sample, but it is sufficient to give a flavor of the main themes running through this microcosm and to indicate the scientific challenges of demography to be expected in the 21st century.

C H A P T E R

138

The Origins of Demographic Science

ÉRIC VILQUIN

Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

The birth certificate of demography (and of descriptive statistics and epidemiology) is generally considered to be a small book of roughly 100 pages published in London in 1662: *Natural and Political Observations Mentioned in a following Index, and made upon the Bills of Mortality. By John Graunt, Citizen of London. With reference to the Government, Religion, Trade, Growth, Ayre, Diseases, and the Several Changes of the said City.* The author, John Graunt, was a prosperous London merchant who happened in the Parish Clerks' Hall on the bills of mortality compiled over decades by the roughly 130 parishes of London. Graunt's intellectual curiosity led him to undertake a useful, intelligent compilation of the disparate accumulated information. The set of methodologic tools he fashioned for the purpose was called *Political Arithmetick* by his friend (and possible collaborator) William Petty (1686, 1687). The term *démographie* was coined only 2 centuries later, by Achille Guillard in his *Elements of Human Statistics or Comparative Demography* (1855), after which demography and statistics would be increasingly recognized as separate disciplines.

Following John Graunt, the pioneers of scientific demography made significant advances in methods for the observation, measure, and analysis of demographic phenomena. Focusing primarily on mortality for over 2 centuries, they really ventured into the area of fertility only on the eve of the 20th century and into migration even later. However, the measurement of population size and the description of its sociodemographic structures have historical antecedents that considerably predate the advent of demographic analysis.

I. DEMOGRAPHY BEFORE 1662

Since ancient times, data collection has been undertaken using procedures that are part of the history of demographic science: enumerations and registers. Although the purely demographic objective of such operations was often secondary or even nonexistent alongside military, taxation, and legal purposes, they are nonetheless ancestors of the modern census and vital registration system.

1. Ancient Enumerations

The earliest known enumerations were carried out in Egypt, China, India, Japan, and the Near East. These were generally initiatives by central authorities that aimed to establish a quantitative and qualitative inventory of the country's human resources. Interpretation of the statistical results is difficult because we must always suspect that the figures were arranged for political or religious reasons. However, precise information on the enumeration methodology is sometimes available. In regions with relatively strong, stable central authority, periodical census taking is part of the art of governing. This generally involves establishing in each district of the territory an inventory of hearths, houses, or individuals, divided into a small number of simple categories based on their relative importance to the state. For instance, if the purpose is to raise an army, the enumeration could identify adult males, without counting women, children, and elderly males, and an enumeration for tax collection purposes could count heads of taxpaying families (ignoring family size), without counting paupers or rich members of tax-exempt categories. Ancient enumerations often cover only a specific subset of the population.

The best-documented case is China. Numerous Chinese texts describe the administrative structures and procedures devised to enumerate the population; these began at least 3000 years ago and were frequently changed. Combined with a system of continuous registration of certain categories of the population (e.g., conscripts, persons subject to corvée labor, various categories of taxpayers, families granted imperial land), the process generally involved a massive counting operation based on the registers, with the total results forwarded in steps along strictly hierarchical channels from the base to the center. At the local level, the registers sometimes included highly detailed sociodemographic information on individuals. From the early 7th century to the early 10th century, the census was based on a family register (i.e., a list of household members specifying their sex and age, as well as the family's social, economic, and tax status); the register was supposed to be exhaustive, updated once each year by the village or district chief, and sent to the central government once every 3 years. It is difficult to determine to what extent this system functioned properly, but it subsequently underwent considerable changes. The highest degree of refinement occurred under the Ming Dynasty (1368–1644), with the use of Yellow Registers. These were permanent, standardized lists of persons and property that were kept in duplicate; compilations were periodically carried out at every level of the tax administration (i.e., *li-chia* or *lijia* system). Every 10 years, the registers were reconstituted family by family and the results tallied to form the census. The imperial government attached great importance to homogeneity and synchronization of the count throughout the territory, as well as to error correction and proper storage of the basic documents. This extremely sophisticated, bureaucratic system has left plentiful statistical data, but critical analysis is problematic. Later transformations and degradations of the system made the Chinese census an instrument for police control and tax administration, but virtually unusable for demographic purposes, from the 17th through the 19th centuries. In China, as elsewhere, the tax function of registration and enumeration almost inevitably caused a deviation, because the exhaustive list of individuals gave way to an increasingly fictive count based on notional tax units (e.g., *hearths*, *men*, *mouths*).

The Roman Empire's quinquennial *census* has left few traces, and little information is available. What was surely a partial and relatively crude count disappeared with the collapse of the empire. Europe would then remain without a census for 1000 years. Christianity inherited Judaism's distrust of the census (mysteriously associated with terrible curses in the Biblical tradition), and the West would hesitate for a long time before implementing one. The rare attempts to reinstate a nation-wide census (e.g., the English *Domesday Book* in 1086 or the French *État des Paroisses et des Feux* in 1328) proved to be short-lived. Locally, there are abundant lists and inventories of all sorts, often precise and detailed,[1] but their lack of homogeneity and continuity generally precludes any useful statistical analysis.

During the Renaissance, virtually all theorists of the art of governing (including Niccolo Machiavelli, Jean Bodin, and Antoine de Montchrestien) argued energetically for an exhaustive, periodical, nominative enumeration, detailing its benefits, and generally arguing that accurate measurement of needs, resources and changes would allow the economy and society to be administered in an informed manner, rather than blindly. Rulers sometimes took these arguments seriously: the 16th century has left traces of numerous censuses, particularly in smaller city-states, but this was not a reinstatement of the tradition of the Roman census.

2. Recording Demographic Events

Nominative registration of births and deaths, in connection with ancestor worship, has existed for at least 2000 years in China within the most powerful clans. This may be a private vital register for strictly genealogic purposes, but it is a gold mine for historical demographers. Vestiges of similar registration systems exist in other parts of the world.

In the 14th century, the Christian West slowly introduced into its administrative and legal practices a change that was to have incalculable consequences: the replacement of oral testimony by written evidence. The Church prescribed that certain important events in the life of individuals, hitherto regulated by custom or by faith, should be recorded in writing. Henceforth, *parish registers* would provide documentary evidence that a person had received the sacraments of baptism, confirmation, or marriage; that the person was alive or dead; and evidence of his or her marital status. It took 2 or 3 centuries for the rules and practices of church

[1] One of the finest examples is the *catasto* compiled in Tuscany between 1427 and 1430 in connection with a reform of Florentine taxation. The 60,000 families of Florence and its dominions were surveyed, with details of their composition, relationships, and individual characteristics of their members, activities, assets, rights, and debts (Herlihy and Klapisch, 1978).

registration to move toward homogenization and generalization. Roughly, the idea was definitively established that each church would register the christenings, marriages, and burials of its faithful in the 16th century in some dioceses and in the 17th century throughout Christendom (both Catholic and Protestant).

Church and civil authorities then relayed one another in imposing registers and specifying their content. Royal ordinances in England (1538) and France (Villers-Cotterêts, 1539) requiring that parish registers be kept predated the first general legislation of the Roman Catholic Church (the Council of Trent, 1563). The mass of regulations attests to difficulties in implementing registration and hesitations by authorities. Gradually, after successive reforms, a rigorous, homogeneous system was put in place. In France, this was accomplished with the royal declaration in 1736. These turbulent changes, combined with historical events (marked by the disappearance and destruction of documents), justify the precautions now taken by historical demographers in the statistical analysis of this prodigious mass of individual data on births, marriages, and deaths.

From 1670 onward, the parish registers in some large towns were systematically counted and compiled into more-or-less detailed, periodical tables. As early as 1736, Sweden experimented with what would become in 1746 the *Tabellverket*, the first national system of demographic statistics and analysis based essentially on the exhaustive extraction of data from parish registers.

After the Revolution in 1789, France "secularized" vital registration by creating the *état civil* (1792), a civil register modeled on church registration, but which removed the selection criterion of religious affiliation. Several European countries followed suit in the 19th century.

II. THE BIRTH OF DEMOGRAPHIC ANALYSIS IN 1662

Alongside the parish registers, in the 16th century, a number of large European towns began occasionally to produce *bills of mortality*. This was a rudimentary system for local monitoring of plagues (the generic and Biblical term for major fatal epidemics); in London, for instance, every Thursday, the parish clerk posted on the church door a bill reporting the number of deaths in the parish during the previous week and the number of deaths attributed to the plague. This was done to inform the population; if the number and proportion of deaths attributable to the plague increased week after week, it was time to take protective measures.[2]

In London, starting early in the 17th century, the practice had become routine and continuous. The parish clerks gradually extended their bills to include the number of christenings, the breakdown between males and females, and the cause of death. (The age at death was added in 1728.) The Company of the Parish Clerks of London (representing 109 parishes in and adjoining London around 1600 and 130 around 1660) received and stored all the bills, and it published an annual report with a summary account at the end of each year.

John Graunt (1620–1674), a wealthy London merchant who served on the Common Council, was an exponent of the experimental science movement that was then in full expansion. Happening on those records in 1660 or 1661, he subjected them (apparently with no preconceived intent) to an enormous amount of critical examination, analysis, and synthesis. The most elementary mathematical tools (what he called his *Shop-Arithmetique*) proved sufficient for him to forge the tools needed for a synthetic, cautious, and pertinent description of a large mass of analogous information; in so doing, he invented the statistical approach and the principal techniques of descriptive statistics.

Faced with a long series of data on systematic, continuous observations of a natural and social phenomenon (mortality), he sought to identify *laws*, in much the same way as his astronomer and physicist friends. With a subtle combination of method and intuition, he identified statistical regularities in an area where previously one had seen only the unfathomable secrets of Providence, including the sex ratio at birth, differential mortality by cause and location, comparative demographic dynamics between London and Paris, and the ratio of annual births and deaths to the population. The ratios, proportions, and disproportions that abound in Graunt's work are the ancestors of our modern proportions, means, rates, and ratios. Despite his many computational errors and some mistaken assumptions,[3] he indicated for the first time the actual magnitude of demographic parameters.

One of his concerns was to evaluate the population of a town or country in the absence of any enumeration. After observing the stability of the numerical ratios between the population and the number of births and deaths per annum, he used the relationship to calculate the population from parish statistics. This

[2] The only effective measure at the time was to flee the city.

[3] He thought, for instance, that the persons who died in a given year formed a representative sample of the living population.

multiplier technique remained the principal method of evaluating population size until censuses were restored and continued to compete with censuses through the early part of the 19th century.

Graunt did not have what was needed to construct a life table, but he is nonetheless the inventor. With no information on the age at death, he adopted an arbitrary (and unrealistic) distribution of deaths by age groups[4] to develop the theoretical model of the age-specific distribution of deaths that he suspected (Table 138–1). Thirty years later, Edmund Halley (1693) relied on John Graunt's model to construct the first life table based on an actual distribution of deaths according to age.

Graunt was also a pioneer in the critical analysis of data. Every concept and figure was subjected to inquisitorial scrutiny, after which he corrected or rejected the data. With scrupulous caution and modesty, he always tried to check calculations by several independent means and gave only limited credit to the numeric value of his results—but that does not prevent him from being affirmative and categorical when certain of having disproved generally accepted ideas. Graunt the precursor left an impressive set of tools, which his successors perfected while preserving their initial spirit.

[4] John Graunt grouped the causes of death specific to early childhood and logically attributed them to the ages younger than 6 years, but he was unable to do this for the other age groups.

III. DIRECT MEASUREMENT OF POPULATION

Tax registers naturally provided a census frame that, although incomplete, was frequently brought up to date. Tax registers were the basis for most population estimates in the 16th and 17th centuries. There were significant methodologic problems, however, and the resulting estimates remained highly inaccurate because some levels of society were not included on the registers and because the registers often provided only a list of *hearths* (households), with the aggravating circumstance that in several regions the *hearth* was a conventional tax unit unconnected to demographic reality.

In the absence of a simple, homogeneous method, many attempts to conduct local or regional enumerations in the 16th and 17th century (in Spain, Italy, and France) proved to be short-lived. Around 1680, Sébastien de Vauban, the French administrator and military engineer, developed a "general and easy" (*générale et facile*) counting method, which he personally tested in numerous towns and regions and then placed at the disposal of the French government, which first applied it in the colonies (Vilquin, 1975; Vauban, 1686). Vauban's innovation was to print blank tables that the census agents completed by following strict instructions. There is one table per parish and one line per house; each line recorded the composition of the household based on the main categories of sex, age, and social status.[5]

The 17th and 18th century European governments were eager for qualitative and quantitative information, but they deluged local officials with such wide-ranging demands that the answers were inevitably vague, if not mere conjecture. One such enterprise, which was better prepared than most, was a genuine success. This was the French *Enquête des intendants pour l'instruction du duc de Bourgogne*[6] between 1697 and 1700. With collaboration from Vauban, the Duke of Burgundy's tutors undertook a vast survey with multiple objectives in every province of France. After considerable prodding for information and adjustments,

[5] The column headings can be translated as "Men," "Women," "Grown boys," "Grown girls," "Little boys," "Little girls," "Female servants," "Male servants," and "Number in family." The first two categories include married adults (or priests and nuns) who are not servants; grown boys are unmarried males older than 14 years, and grown girls are unmarried females older than 12 years (below those ages, they are little boys and little girls); the number in family is the total number in the household.

[6] Louis, Duke of Burgundy, grandson of Louis XIV, later became *dauphin* (i.e., heir apparent), but he died before acceding to the throne.

they obtained a complete series of reports that, despite enormous failings, were used pretty much as official statistical yearbooks (often without being updated) by French ministries throughout the 18th century. Their interest and utility were such that the bookseller Saugrain published them in 1709 (*Dénombrement du royaume par généralités, élections, paroisses et feux*) and even brought out a second edition in 1720 (*Nouveau dénombrement du royaume*) (Saugrain, 1709, 1720). For the purposes of the survey, a genuine direct census of the population was taken in some provinces and towns, more or less in keeping with Vauban's approach; however, in most cases, earlier estimates of uncertain provenance were reproduced, or a rapid count using the tax registers was performed.

Genuine nominative, comprehensive censuses have been conducted since the 17th century in nearly every European country, in limited territories. The first modern nationwide censuses were those taken in Iceland in 1703 and Sweden in 1755. The case of Sweden is distinctive. All Swedish parishes had maintained detailed, up to date registers of their population since the late 17th century. In the 1750s, the government ordered a periodic compilation and analysis of the registers. Pehr Wargentin and Edouard Runeberg (1772), who were in charge of the initial work by the *Tabellkommissionen*, set very high standards at the outset, and for a long time Sweden maintained a half-century lead over the rest of Europe in the area of collection and analysis of national demographic statistics (for Wargentin and Runeberg, see Dupâquier, 1977).

In France, the welter of censuses and surveys ordered by an array of Revolutionary bodies were typically carried out by incompetent, overworked personnel, and almost never reached the processing stage. The creation of a Statistical Bureau in 1799 introduced some order, but the Empire soon made statistics a matter of state secrecy and eliminated the Statistical Bureau, which would definitively reemerge only in 1834. Meanwhile, Austria, Prussia, Russia, the Netherlands and Belgium set up their own statistical bureaus, followed in the third quarter of the century by the other nations of Europe.

One hundred fifty years after Vauban, the ideal of a uniform, thorough, and simple census method was taken up again in the 19th century by the Belgian mathematician and astronomer Adolphe Quetelet. The censuses in the Netherlands (1829 to 1830) and Belgium (1846) allowed him to test his ideas regarding standardization of procedures for collection and analysis (Quetelet, 1847). From defining concepts to training census agents, his systematic approach worked wonders, so the organization of the Belgian census was seen as a model by neighboring countries. However, his dream of every country in the world simultaneously taking identical censuses would never be realized.

IV. POLITICAL ARITHMETIC

John Graunt's invention found its first enthusiast in his friend William Petty, who used the term *political arithmetic* to describe his resolutely quantitative approach to social phenomena (Petty, 1686, 1687). Petty used Graunt's formulas to build arguments in support of his political theories, but was largely unconcerned with methodologic improvements. Their successors, often astronomers or clergymen, would advance theory and techniques in two main areas: indirect population estimation and the life table.

1. Demographers

The first demographers were English and Dutch: Edmund Halley, Matthew Hale, Gregory King, Charles Davenant, Louis and Christian Huygens, and Jan De Witt. Their shared concerns included evaluating population worldwide and in selected countries and towns; the long-term population trend in Europe and worldwide; and the actuarial computation of annuities. Some demographers also addressed the distribution of population by sex or age group, and even ventured population projections. In 1696, Gregory King computed ratios for births, deaths, and nuptiality by dividing the population by the annual numbers of births, deaths, and marriages (King, 1696/1973); it was not until 80 years later that the corresponding rates were computed, when Jean-Louis Muret (1766) reversed the numerator and denominator. The Dutch actuaries Willem Kersseboom and Nicolas Struyck, starting in 1738, quarreled over the determination of multipliers; in doing so, they unwittingly laid the bases of stationary population theory,[7] and more importantly, they systematically compiled statistical surveys of demographic data from various sources (Kersseboom, 1970; Struyck, 1912, cited by Dupâquier and Dupâquier, 1985, p.162–166). Gregory King and Nicolas Struyck are doubtless the most important figures in the first half of the 18th century because they improved on the methods of their predecessors, and they methodically weighed the relevance and validity

[7] Kersseboom applied the life table to the average annual number of births to determine the population pyramid for the (stationary) population. The size of the (stationary) population is then equal to the annual number of births multiplied by the average lifetime.

of the data and techniques. Nicolas Struyck was the first to investigate the disturbing role of migrations in demographic estimates, to be wary of computations based on small numbers of subjects, and the first who did not set out to prove at all costs that all is for the best in Creation.

The German pastor and mathematician Johann Peter Süssmilch (1707–1767) was the first demographer to achieve fame and the first to popularize the new science. His principal work, *The Divine Order*, published in 1741 and revised in 1761–1762, enjoyed genuine success. The book provides a synthesis of the state of political arithmetic on the two publication dates, and its application to an impressive amount of data. Süssmilch was a judicious critic but not really an innovator. His purpose was to accumulate scientific evidence to support his religious convictions.

In France, Antoine Deparcieux (*Essay on the probabilities of the length of human life*, 1746, and *Addition to the essay . . .* , 1760) made a notable improvement to the measurement of the death rate. Louis Messance (1766) conducted a methodical demographic analysis of three French provinces. The Abbé Expilly (1762–1770) collected astronomic quantities of demographic data. Jean-Baptiste Moheau published a veritable treatise on demography (*Researches and Considerations on the population of France*, 1778), which can be compared with *The Divine Order*. His arithmetic, though brilliant, remained classic, but he stands out from most of his peers by devoting several chapters to interpreting his results, evidencing a systemic vision of the sociodemographic dynamics of a nation.

Each European country had its political arithmeticians. Among dozens of others, two who stand out were the Swede Pehr Wargentin (1717–1783) and Switzerland's Jean-Louis Muret (1715–1796). Wargentin carried out in the 1750s an exemplary analysis of the data produced by the admirable Swedish statistical system (see Dupâquier, 1977), and Muret (Muret, 1766), who performed many differential analyses (by sex, by region, and by period), can be called the true inventor of the crude rates of births, deaths, and marriages.

In the 18th century, the political arithmeticians knew and corresponded with one another, and submitted their discussions to a learned audience by publishing in the first scientific journals (i.e., the published proceedings of the academies). Their methodologic problems came to the attention of mathematicians, including the Bernouillis, d'Alembert, Euler, Lagrange, and Laplace. The mathematicians cautiously advanced the initial mathematical expressions for the political arithmeticians' empirical parameters, and used their observations (e.g., the stability of the sex ratio at birth or the probability of survival from one age to another) to formulate the standard problems in the calculus of probabilities. For instance, at the request of Johann Peter Süssmilch, Leonhard Euler developed around 1760 the empirical recipe for computing the doubling time of a population, which had hardly progressed since John Graunt), and established the algebraic relationships between population size, structure and movement. Pierre-Simon de Laplace in 1778 called on probability theory to demonstrate that the sex ratio at birth differs significantly from 1 and to measure the ranges of variation of certain parameters (Laplace, 1781).

2. The Life Table

Even before the construction of the first true life table by Edmund Halley (1693), the brothers Christian and Louis Huygens, in 1669 (Huygens, 1669/1920), were attracted by the model developed by John Graunt. They developed the concepts of life expectancy and the probable length of life at any given age, as well as the graphical representation of the parameters of a survival table. However, this was not reported to contemporaries. Around 1680, Gottfried Wilhelm Leibniz outlined a theoretical life table (Leibniz, 1680?/1866), but failed to follow through with his work. It therefore fell to Edmund Halley (1656–1742), the British astronomer, who used the first statistics of deaths according to age, from Breslau in 1687 and 1688, to construct the first table based on actual data. Taking some liberty with the crude data, he computed a table of survivors by age, starting with 1000 infants younger than 1 year. The ages are expressed in complete years at the start of the table, and subsequently by age at birthday. However, lacking information on the age structure of the population of Breslau, he had to assume that the distribution of deaths by age was the same as the age structure of the living population (the cumulative deaths method), which (as he was aware) is the case only for a closed, stationary population. He did not calculate death probabilities or life expectancies.

Life table methodology made slow, modest progress in the 18th century. Kersseboom, Struyck, Smart, and Simpson eliminated the need to assume a closed population and stationarity. Before introducing the technique into France, Antoine Deparcieux (1746) analyzed his predecessors' work in detail and definitively distinguished between the mean length of life and the median length of life (i.e., probable lifetime). Deparcieux gave the life table its current form, breaking with the cumulative deaths method. Disposing of good life history data on small populations of rentiers or religious communities, he could establish the ratio of deaths at any age to the total population exposed to the risk of dying at that age. Because he had no data on children, he surveyed mothers from various social backgrounds at the end of their reproductive lives regarding the survival of their children. Pehr Wargentin was the first to dispose of the age-specific distributions of the population and of deaths for the same period (see Dupâquier, 1977).

Early in the 19th century, Emmanuel Duvillard de Durand (1806) used an essay by Daniel Bernoulli (1760) as the basis for calculating the gain in life expectancy that would result from the elimination of a cause of death (i.e., smallpox).

As rulers and *savants* showed growing interest in statistics, the number of national life tables increased. There were the first timid steps in also establishing tables for subpopulations (e.g., males and females, town and country). Around 1850, on the strength of the exemplary work of Adolphe Quetelet (1854, 1872) in Belgium and William Farr (1885) in England, the life table was definitively anchored to the corresponding population pyramid derived from the census.

3. Indirect Methods of Population Estimation

The old procedure for population estimation based on an enumeration of hearths did not disappear quickly, and the *multiplier technique* discovered by John Graunt seems to have been used little before 1750. Gregory King tried both methods in 1696 but did not publish his results.[8] Spurred on by the first French demographers (e.g., Messance, Moheau), enthusiasm for Graunt's method spread in the second half of the 18th century. The political arithmeticians, focusing on small portions of the territory, conducted exhaustive enumerations of the population and counts of christenings in the parish registers: the ratio of these two numbers was the *birth multiplier*, which could be used in any town or region to compute the total size of the population on the basis of the average annual number of births registered. Similar multipliers based on the annual number of deaths or marriages were tested. Fascinated by the stability—a relative stability, but astonishing nonetheless—of the numerical ratios they found, demographers cherished the secret ambition of determining the *universal multiplier*, but the quest was gradually abandoned as they recognized the need to calculate specific multipliers for different contexts (e.g., town/country, plains/mountains, north/south). The most extravagant enterprise in this area was conducted by the Abbé Expilly, who spent years working on the whole of France. He had baptisms, marriages and burials in the registers of every parish in France counted for the periods 1690–1701 and 1752–1763 (to identify the direction of population change). Funds ran out as he neared the goal, but he still managed to publish statistics for more than 15,000 parishes, in six volumes; the seventh was never released (Expilly, 1762–1770).

French ministers (Turgot and then Necker) ordered that the computations be redone on regional samples, while scientists (Moheau, Laplace) were refining the theory. However, the French Revolution chose to return to a Roman census.

The rare rudimentary attempts at demographic projections, as early as the 17th century (e.g., Petty, King, Vauban), use exponential extrapolation and are based on fixed, crude assumptions: Vauban (no date/1845), for instance, assumed that marriage is universal, that each couple produces four children on average, and that generations succeed one another every 30 years.

[8] First published in 1802 (as an annex in George Chalmers, *An Estimate of the Comparative Strength of Great Britain*)

V. DEVELOPMENT OF MODERN DEMOGRAPHIC ANALYSIS IN THE 19TH CENTURY

1. Death Rate

To construct his hypothetical life table, John Graunt implicitly used a mathematical function expressing the age-specific risk of dying,[9] but because this was not indicated in his book, the idea was not taken up immediately. After several attempts—more complicated but not more convincing—to mathematically model mortality by age in the 18th century (De Moivre, Euler, Duvillard, Laplace), the Englishman Benjamin Gompertz, in 1825, made the assumption that the number of survivors decreases exponentially as age increases; this was corrected in 1860 by the German William Makeham, who incorporated in the equation a term to represent deaths that were not dependent on age. This initial mathematical law provides a close fit to the death rate for adults, but not for infants and children. In the meantime, William Farr (1843/1885) provided the definitive formulation of the concepts of age-specific rates (including the infant mortality rate), death probabilities, the probability of survival, and standardized rate. Louis-Adolphe Bertillon (1866) discovered how the crude death rate is dependent on the age structure of the population. In

[9] In modern scientific notation: ${}_{10}q_x = 3/8$.

1868, Georg Friedrich Knapp, in analyzing the classification of deaths by years of age and year of birth, distinguished between longitudinal analysis and cross-sectional analysis.

The age-old dream of a mathematical law expressing mortality as a function of age was shattered in 1897 by Karl Pearson, who showed that the statistical curves of mortality by age must be decomposed into several mathematical laws that are juxtaposed or superposed.

2. Fertility

If the political arithmeticians focused more on the factors of fertility than on measuring fertility, it was because the necessary data were totally unavailable. Births were first classified by mother's age in Sweden in 1775, and the example was not imitated elsewhere until after 1850. Before then, considerations on differential fertility (between town and country, between monogamy and polygamy, and between seasons) were based on economic or moral arguments; the rare calculations were based on rough assumptions regarding "prolificacy" (e.g., that an average marriage produces four children). The nearly universal "populationism" among 18th century Europeans, including demographers, provided less incentive to measure fertility than to seek ways to maximize fertility. This explains the considerable persistence of extremely crude assumptions.

Even before it became possible to study age-specific fertility, a number of significant steps forward were made. The first fertility estimator was the birth multiplier (number of inhabitants per birth). The political arithmeticians all devoted numerous pages to this, as they sought to determine whether it was stable or variable, and the best way of evaluating it. After Gregory King, but independently, Jean-Louis Muret transformed the multiplier into a crude birth rate by reversing the ratio (number of births per 100 inhabitants). This use would not become widespread before the 19th century.

Some considered it more logical to take the ratio of births to marriages, and this parameter enjoyed considerable favor. The general legitimate and illegitimate fertility rates were developed in 1815 by Joshua Milne (1815). Even toward the middle of the 19th century, Quetelet believed the best measure of a population's fertility was the ratio of births to marriages and that the analysis could be further refined by classifying couples based on the age difference between spouses and age at marriage (Quetelet, 1835).

The breakthrough came from Scotland. Dr. James Matthews Duncan (*Fecundity, Fertility, Sterility, and Allied Topics*, 1866) took advantage of an exceptional statistical source, which decomposed births in Edinburgh and Glasgow by the mother's age and the duration of marriage; he used this to measure, among other things, the intervals between successive births, parities by age and by duration of marriage, and completed fertility. However, these methodologic innovations would be disseminated 30 years later, when the national statistical offices grasped the need to collect highly detailed data on fertility. Similarly, the clear distinction he introduced between fertility and fecundity was not entirely understood at the time, and was generally accepted only 50 years later. Because he conducted a cohort analysis of married women who had neither died nor become widows before the age of 45, mortality did not interfere with his estimates of completed fertility.

3. General Models

Adolphe Quetelet had met Thomas Malthus in 1833, and the two had briefly corresponded. Quetelet admired the English clergyman's theory but considered that it remained to be cast in the bronze of mathematics. He assigned a young colleague, the brilliant mathematician Pierre-François Verhulst, the task of finding the best mathematical model for Malthus' theory of population growth over time. The main difficulty was finding an exponential function (Malthus' *population increases in a geometric ratio*) that progressively generates a slowdown in the rate of growth (i.e., that incorporates Malthus' *checks*). After an initial attempt left Quetelet unsatisfied, in 1847 Verhulst discovered that the *logistic curve* was an excellent way to model Malthus' theory and that it provided the theory with a complement, if not the crowning touch, in that the curve tended toward a horizontal asymptote: the maximum population. Verhulst's work was published but passed unnoticed, and the logistic model was rediscovered only in 1920 by the Americans Raymond Pearl and Lowell Reed.

Advances from the concept of marital fertility to that of population reproduction required the modeling of nuptiality. This was done by Louis Adolphe Bertillon (1872). The Germans Richard Böckh (1886) and Robert Kuczynski (1931) could then define the crude and net reproduction rates. However, the concept of population replacement was to become operative through another channel. In 1907 and 1911, Alfred Lotka adopted a purely theoretical, abstract approach to study the renewal of a population that evolves as a function of inputs and outputs (Sharpe and Lotka, 1911; Lotka, 1907). Laying the bases for mathematical demography, he developed the theory of stable populations (Lotka, 1934, 1939) that would revitalize demographic analysis after World War I.

4. Graphical Tools

The first graphs in the history of demography were drawn by Christian Huygens (1669), who used curves to depict the numbers of survivors at various ages in Graunt's table, and the corresponding life expectancies. However, he showed them only to his brother, and they remained unknown. Setting aside three or four curious but largely impractical attempts at geometric illustration, which failed to gain acceptance, the first to make systematic, frequent use of graphical representations in statistics were Jean-Baptiste Fourier (1821) and Adolphe Quetelet (starting in 1827). Quetelet was virtually obsessed by means and variations, and privileged the representation of deviations between observations and their mean. Through his educational abilities and the international statistics conferences he was the first to organize and to which he contributed indefatigably, he led all European statisticians to use a broken line or curve to represent variations in the phenomena they observed.

The second half of the 19th century saw several ingenious but virtually indecipherable attempts at three-dimensional graphical representation (i.e., stereograms), which was soon abandoned. Another invention that proved more successful was the population pyramid. The initial idea came from General Francis Walker (1874), the Superintendent of the 1870 Census in the United States, who used it liberally to illustrate his analysis of the U.S. censuses of 1850, 1860, and 1870. In 1878, Heinrich Schwabe brought the shape into line with the principles of the histogram, and it has remained unchanged ever since.

In 1874, following up on the intuition of several precursors, three German mathematicians, Georg Friedrich Knapp, Karl Becker, and Wilhelm Lexis, looking for the most efficient way of plotting biographic events in a system with three coordinates (i.e., time, age, and date of birth), devised two alternative versions of what is now called the Lexis diagram. The modern version was developed by Roland Pressat around 1953 (Personal communication. See Vandeschrick, 1992, p. 1249.).

CONCLUSIONS

The origins of demographic science are recent. Only 350 years ago, it could seriously be claimed without incurring scientific refutation that men outnumber women six to one worldwide or that gout is a hundred times more lethal than influenza. John Graunt, in his simple but inspired constructions, planted the seed that has grown into a full array of instruments for measurement and analysis of demographic phenomena. Some developed faster than others. Progress in life table techniques was significantly stimulated by the quest for accurate calculation of annuities. At the same time, the political arithmeticians, eager to use their *multipliers* to prove that the population was growing (or declining), thought they could eliminate the need for complicated census taking. They also evaluated *the constants* of what Adolphe Quetelet would call *social physics*. Mathematicians then joined the fray, testing the concepts and theorems of probability theory on the only continuous statistical series available, vital registration statistics. Fertility had long been the poor relation to demographic research—not for lack of interest, but for lack of the data required to analyze fertility. The development of concepts and tools for demographic analysis has always been closely associated with changes in the production of population statistics, but quite often, the conceptual developments preceded the data. From its primitive, artisan, and utilitarian origins, the progress and results achieved by demography between the late 17th century and the early part of the 20th were remarkable. The considerable work by Alfred Lotka, before and after World War I, would unify demographic analysis and impart a new impetus, supported and amplified by fears of population explosion.

Demographic Textbooks and Treatises: Some Considerations

ANNUNZIATA NOBILE AND ALESSANDRA DE ROSE

Dipartimento di Istituzioni politiche e Scienze sociali, Università degli Studi Roma Tre, Italy

Dipartimento di Studi geoeconomici, linguistici, statistici e storici per l'analisi regionale, Università degli Studi di Roma "La Sapienza," Italy

Interest in the didactics of demography has been growing intensely. This topic is covered in Chapter 140. Here, we wish only to emphasize that interest is demonstrated by the numerous occasions this topic appears in the programs of major international conferences and the growing proliferation of articles in demographic journals that tackle various aspects of the content, methods, and the semantics of demography. This interest is accompanied by an increasing awareness of the epistemologic implications, particularly of the much-felt need to delve deeper into the causal analysis of demographic behavior (Boulanger, 1980; Véron, 1997).

The *vexata quæstio* of interdisciplinary discussion and research, or rather problems relating to the interplay with other disciplines interested in demographic phenomenology, demands our consideration. Such an approach, which is in keeping with an awareness of the limits of any endeavors toward self-sufficiency in demography, must focus on content and on the ways in which this information is transmitted. The fear of loss of identify and autonomy felt throughout the scientific community, not to mention the subsequent demotion of demography to a subsidiary role, provides further impetus to redefine how and what to teach students who attend a course on demography. To what extent does the educational substance that remains the basis of training in this subject as contained in the popular textbooks continue to be suitable? Would it be preferable to pursue an interdisciplinary approach to teaching that would promote an understanding of the causal mechanisms underlying demographic phenomenology? How should we respond to the demands made by a society that is increasingly aware of demographic topics and that compels research in the direction of analysis of topical issues? Some analysts believe this trend should be resisted (Livi Bacci, 1994), but others are convinced that it should be fully embraced (Caselli, 1997; Pressat, 1996), and the ultimate decision will no doubt influence future research and teaching content.

Beyond the traditional problems of how and what to teach, education in demography must address where and whom to teach. The academic environments in which demographic courses are offered and the students' didactic itineraries have an impact on teaching content and methods and how textbooks are written and targeted.

Although there is increasing awareness among demographers that the future of demography depends on the training of its practitioners, the same cannot be said for current textbooks. In terms of quantity, the situation is quite satisfactory. A glance at *Population Index* for the past 20 years, under the heading of "Textbooks and Teaching Programs," produces, counting handbooks, textbooks on demographic methodology, and exercises, a total of 162 titles (in different languages, but mainly English and French), many of them republished in the meantime (some on their seventh edition, and updates concern more than the documentary section). Most of these titles are solely destined for teaching and their substance is built to measure around a specific course. Other textbooks, aimed at a larger public or as a teaching aid, tackle demographic issues on a much more general level, without going into the methodology. Too few are textbooks that offer a wide overview, that probe the links between analyses and syntheses, and that to a fairly large extent reflect demographic concerns, trends, and progress in the field.

An analysis of these textbooks (listed in Appendix 139–1, which does not pretend to be exhaustive) lies far beyond our abilities with regard to read the many languages used and to assess the widely differing pedagogic approaches and aims covered. We instead consider only textbooks published in Europe, North America, and Australia that are printed in English, French, and Italian[1] and that are mainly from the more renowned schools.[2] In an attempt to compensate for this, brief comments are provided on texts published in Russian (Appendix 139–2), German (Appendix 139–3), Spanish (Appendix 139–4), Portuguese (Appendix 139–5), Dutch (Appendix 139–6), and Japanese (Appendix 139–7). Focus is on textbooks printed after World War II, when the production of pedagogic texts really took off.

A quantitative comparison of the content of educational textbooks published in this time span is not our goal. We instead focus as much as possible on the various approaches practiced and the differences among cultures and over time in some of the major and more popular textbooks available.[3]

I. EUROPEAN TEXTBOOKS DURING "WILD DEMOGRAPHY'S" YEARS

Before dealing in detail with the content of teaching textbooks in the fifty years considered it is worth taking a glance at the situation in the interim war years. In Europe, these mark the break from statistics and the point when demography begins to acquire a certain autonomy in the teaching sphere. This hastened the desire to fix the boundaries of the field of research, still the subject of discussion today. Despite expressing different positions, academics unanimously agree that demography as meant by Achille Guillard (1855, p. XXVI) to be "the mathematical knowledge of populations, of their general movements and their physical, civil, intellectual, and moral status,"[4] is too wide a definition as research could apply different approaches other than the descriptive approaches practiced by pioneers in the field.

Different positions engender different itineraries that are also determined by various cultural contexts where demography has begun to play a role. Their only point of contact, perhaps, is the naturalist concept underlying the subject, where the biologic aspects of demographic behavior prevail, at times disclosing eugenic concerns. It is during this phase that demography, to quote Alfred Sauvy (Sauvy, 1946), is a "science sauvage, sans maîtres, ni élèves, cultivée seulement par des 'amateurs,'" a savage science without masters or pupils, cultivated only by amateurs. The air of "savagery" that marked these years was by no means an obstacle but generated a series of treatises, not particularly numerous but certainly wide ranging, a lack of which is keenly felt today.

This is the golden age of the Italian school. Between 1935 and 1937, edited by Corrado Gini and crowning his career as organizer and coordinator of research in demography, his *Trattato elementare di statistica* is published, with the two tomes of the second volume entirely devoted to demography (Gini, 1935–1937). The topics covered, involving the collaboration of leading Italian academics of the day, range from historical demography to population policy, testify to the wealth of research underway in those years. Shortly after, Livio Livi published the two volumes of his *Trattato di demografia* (Livi, 1941–1942). This treatise offers an image of demography that is refined and open to addressing other social disciplines, which is clearly in the tradition of Rodolfo Benini, and the book is a compilation of his research. Livio Livi accords this subject a scientific systematization that totally differs from that of his contemporaries, assigning demography the task of finding the "biologic basis of the social structure," anticipating by many decades the sociobiologic thread of thought. A particularly fascinating hypothe-

[1] Our analysis risks underestimating the role played by textbooks published in emerging countries or for this market. However, this would require a separate section that is beyond our capacity. Teaching and training itineraries are closely linked to employment opportunities or to the training needs specific to each country and tend to lie beyond the scope of this study.

[2] This does not undermine the importance of other schools. Publications in German in the 19th century were particularly important, not to mention more recent publications in Spain. Russian demography also has a long tradition and has produced important scientific studies, particularly throughout the first half of the 20th century. Ideologic censorship after World War II led to isolation from the rest of the scientific community, but since the collapse of the USSR, demographic studies have enjoyed a new launch in Russia, with the publication of a substantial number of teaching textbooks. Regarding publications in these and other languages, see the notes included in the appendices.

[3] Only the title and authors are cited. A complete bibliography is provided at the end of the chapter.

[4] "La connaissance mathématique des populations, de leurs mouvements généraux, de leur état physique, civil, intellectuel et moral."

sis proposed in volume one of the *Trattato* (*I fattori biodemografici dell'ordinamento sociale*) considered the biodemographic matrices from which the social order may be derived.

The *Traité de démographie*, by Adolphe Landry (Landry, 1945), is a major theoretical work. Alongside a classic analysis of natural and migratory trends, which offers a description of methods and focuses on causal factors, Adolphe Landry gives ample coverage to what he calls "pure demography," the essence of which is the stable population theory. What interests the author is not the mere description of population processes, but rather the need for general truths, of a "population law." Although he never specifically tackled the question, Adolphe Landry drew attention to the question of a qualitative demography to be achieved by the introduction of qualitative methods.

A more classic text that devotes major space to methodology is Michel Huber's, *Cours de démographie et de statistique sanitaire*, widely distributed and well known in the French-speaking world (Huber, 1938). Michel Huber emphasizes the importance of a knowledge of both sources and statistical methods in demography, and in his introduction, he stresses the fundamental role of choosing the correct methodology to ensure the success of the research.

II. THE 1950s AND 1960s: DEMOGRAPHY AS A GLOBAL SCIENCE

Demography's pioneering years came to a close at the end of the Second World War. This discipline, albeit differing in timing and modality depending on the country's idiosyncrasies, became more institutionalized, with the creation of various research centers, both public and private, and offered as part of the university syllabus. This gradual process of institutionalization was hastened by the need to be acquainted with and understand the demographic trends that became prominent in the after war years, such as the drop in fertility in the Western countries and the rapidly burgeoning world population, a source of interest for academics and of concern for governments.

The academic acknowledgment of demography as a discipline unto itself proceeded quite slowly and differed in pace from country to country. North America was one of the first countries to award full academic status to the new discipline right from the beginning of World War II. However, demography was often included in the department of sociology or sometimes the economics department, which tended to limit its autonomy (Lee, 1997; Wargon, 1997). There was also a tendency for teaching staff to come from the ranks of sociologists or similar disciplines. The demographer as a professional figure was not the objective. Focus instead was given to providing the means to understand demographic themes, given further impetus by the international interest it attracted as well as by the work of the expanding Population Division of the United Nations. In France, the importance of training was clear from the outset, as witnessed by the founding in 1957 of the Institut de Démographie of the University of Paris (IDUP) to cater to the needs that arose from the intense research carried out by INED. An emblematic figure in this synergy between demographic research and university teaching was Louis Henry, a leading founder of the French School of Demography, which tended to favor a quantitative approach.

In Italy and in Germany demography was slow to be accorded academic recognition. Interest in demographic issues, both at a political level and among public opinion, was marginal and looked at with suspicion given the political use to which it had been put in both countries in the between-war years. The first 'chair' in demography in Italy was appointed as late as 1961 and the teaching of demography in the following years tended to be fairly restricted both quantitatively (small number of courses) and qualitatively (the training goals were unclear).

Hence pedagogic projects and training itineraries are quite different as they very much depend on the cultural context of the country in question. The conceptual foundations of demography follow two main threads that are quite different from each other. The most popular deals with demographic questions in a broad sense and researches into the causes and consequences of demographic processes. The other approach is more focused on quantifying population dynamics and on how different phenomena interacted. In English, a distinction is made between *population study* and *formal demography* (Bogue, 1969, p. 4), whereas in France, the distinction is between *démographie large* and *démographie pure*, which Alfred Sauvy (1976, p. 16) defines as a "comptabilité d'hommes" and a quantitative events' analysis, which gives rise to demographic analysis that has become another part of the university syllabus. Italy continued to pursue a more global approach to demography, and it was only in the 1960s that the mathematical measurement of demographic events and their interplay were recognized and that demographic analysis was first introduced as an autonomous area of study (Federici, 1968, p. 7).

Textbooks tended to apply a unique framework to demography, while taking into account the different approaches used. The largest and most widely available textbooks may be considered as true and proper treatises that provide a state-of-the-art of formal and conceptual study of population and offer a synthesis of current knowledge in the field and urge new research.

One of the most popular textbooks of the day in the English-speaking world was *The Study of Population*, published in 1959 and edited by Philip Hauser and Otis Duncan. At 800 pages written by various collaborators, this is a monumental work, of which only a section may be considered a textbook of demography. The rest is dedicated to illustrating the state of the art of research and is more suitable for specialists than for students.

Principles of Demography by Donald Bogue was published 10 years later. It proved to be very popular and became a classic in its field. This also may be classified as a treatise, and like *The Study of Population*, it is particularly long (about 1000 pages), but the language used is more suitable for students. The approach taken is encyclopedic; the introductory chapter offers a description of the foundations of demography and its links across other sciences. The approach used is not very technical with a strong emphasis on the principles involved. *Principles of Demography* was largely inspired by Warren Thompson's *Population Problems*, which was one of the more outstanding demographic textbooks in the 1930s and 1940s and which enjoyed numerous revised editions.[5]

Among the textbooks that give a secondary role to more technical and methodologic aspects is *Population Dynamics: Causes and Consequences of World Demographic Change*, by Ralph Thomlinson, which even in the title emphasizes the more problematic aspects of demographic processes and shows an early interest in the question of urbanization. In *Population*, by William Petersen, methodology is reduced to a minimum, understandable as this work is mainly geared toward sociology students. The author, however, devotes ample space to the social context in which demographic processes occur.

Compared with English-language textbooks, continental European textbooks tend to be more well defined regarding theory, albeit still of a comprehensive nature. A key role is played by the French and Italian schools. In France, Alfred Sauvy's *Théorie générale de la population* was a real milestone. This treatise is composed of two volumes. Volume I covers economic aspects of demographic trends, and volume II addresses sociologic aspects. Sauvy also deals with technique, which is dedicated only limited space because the overall aim is not methodologic, and he encourages research into the underlying causes and consequences of demographic processes, providing theoretical deliberations and a cross-discipline approach. Although firmly placed in the tradition of Adolphe Landry, a number of innovative viewpoints are explored, with Sauvy being among the first to draw attention to issues such as aging, which was taken up by most demographers many years later.

In Italy, the leading contribution made in this period was the work by Nora Federici, *Lezioni di demografia*. This volume, modestly defined by the author as a textbook, is a treatise on the state of the art of demography in Italy. Nora Federici firmly places demography at the center of the social sciences. She describes how demographic behavior, particularly in modern times, is the result of the interplay between natural and socioultural factors, the latter having a crucial role to play. Migration, with a special focus on internal migration, is another key topic covered, and seen to be a keystone in demographic and social change. This work is valuable in pedagogic terms as can be evinced from the importance given to technical aspects of this discipline, in the search for patterns and trends, and in the study of the interrelationships found when analyzing demographic processes. This work embraces a global line of research that Corrado Gini called *integral demography*. The volume is permeated throughout by references to the biologic aspects of population and related phenomena that is reflected in the idea of demography as a bridge-discipline between the natural and social sciences. This focus on biologic factors is typical of the Italian school of demography at that time and is again found in the work by Marcello Boldrini, *Demografia*, which tackles demographic issues from both micro and macro viewpoints.

A more formal and quantitative approach to demography is found in a limited number of works that tend to be almost purely pedagogic in their intent. In the English-speaking world Mortimer Spiegelman's *Introduction to Demography* proved to be quite popular. This is a more technical work, published in 1955, and targeted at teaching actuaries. It provides an accurate systematization of basic concepts, definitions and methods, as well as their application to North American and Canadian data, whose sources are discussed in depth in a critical introduction. In 1957, Peter Cox published another textbook, *Demography*, which has enjoyed a number of revised editions over the years. The author tackles methodologic issues using an analytic approach, but the language used is accessible even for beginners, and the book covers some aspects of demographic history. The year 1958 saw the publi-

[5] The fifth edition, in 1965, was updated in collaboration with David T. Lewis.

cation of *Techniques of Population Analysis*, by George Barclay; this was part of a project by the Population Council, which lamented that no technical manual existed based on the logic of demography rather than methods and that a text was needed that was more accessible to a broader public with fewer mathematical skills than actuaries. This volume is a classic pedagogic introduction to demography, covering topics such as population definition, rates and ratios, life tables, fertility measures, population growth, and migration.

Formal demography, defined as the mathematical description of human populations is first spoken of in the United States after the publication in 1968 of the path-breaking work by Nathan Keyfitz, *Introduction to the Mathematics of Population*. This constitutes a methodologic reference framework and provides the foundations for successive publications, including *Applied Mathematical Demography*, published in 1977, and *Mathematics through Problems*, which appeared in 1982. These volumes complete Keyfitz's first work, which contains a systemic and rigorous overview of the basic theories of demographic processes, although the language would be unfamiliar to nonmathematicians, and it offers a series of examples of applications and contextual references to historical and geographic realities.

In Europe, the quantitative approach to the analysis of demographic processes is dominated by the *démographie pure* of the French school as in *L'analyse démographique. Concepts, méthodes, résultats*, by Roland Pressat. The approach taken is quite different from that in the Anglo-Saxon culture, where the endeavor is to identify the mathematical models underlying demographic processes. In Europe, the focus on perfecting ways to measure the phenomena; identifying interrelationships; and distinguishing the effects of each demographic variable from that of others so that a pure measure can be taken of both longitudinal and cross-sectional analyses. It is not by chance that demographic analysis was born in a country with a long tradition of statistics and an efficient system of data collection and surveys. In this context a series of refined measures was possible, totally inconceivable in other contexts where the statistics system was more backward. This work enjoyed an enormous success with a number of translations into different languages.[6]

[6] Translations into other languages include Spanish, El Analisis Demografico, Metodos, Resultados, Applicaciones (Mexico, 1967); Russian, Narodonaselenie i Ego Izoutcheni, (Moscow, 1966); Polish, Analiza Demograficzna (Varsaw, 1966); English, Demographic Analysis: Methods, Results, Applications (Chicago, 1972), and Italian, Analisi demografica. Concetti, metodi, risultati (Milano, 1976).

III. THE 1970s: DEMOGRAPHY IN THE LIMELIGHT

Although time limits are fairly arbitrary and difficult to fix, especially, as in our case, when dealing with a cultural trend, no one can deny that the 1970s was a period of major change that merits particular attention.

The rate of growth of the world population increased, and the north-south socioeconomic divide became even more pronounced. During this time of social upheaval, when public opinion was increasingly vigilant and well informed, demography came to occupy a pivotal position on the international scene. The first World Population Conference was held in Bucharest in 1974.

University courses on demography increased by the score, along with the production of textbooks, both new and revised editions, many of which tackled recent advances in the discipline in methods and content.

One offshoot of the cultural climate of the time was the different approach applied to demographic trends, now interpreted in terms of social processes, moving away from the previous tendency in favor of biologic factors. Another crucial element, closely linked to this and vital for the future of the discipline, was the cross-pollination between demography and the other social sciences. This exchange among disciplines facilitated grasping the existing causal links and was fundamental in interpreting demographic processes. Although it had to be admitted that demography alone could not provide all the answers, demographers failed to defend their field's specific merits regarding measuring and analyzing demographic processes. Other disciplines did not hesitate to step in to teach questions of a demographic nature (Federici 1977, p. 394). A veritable explosion occurred in the publication of texts regarding population geography. In France, in the wake of the classic work by Pierre George,[7] Daniel Noin's *Géographie de la population* appeared. In the English-speaking world, particularly popular were *Human Geography: Theories and theIr Applications*, by Michael Bradford and Ashley Kent; *Population Geography: Problems, Concepts and Prospects*, by Gary Peters and Robert Larkin; *Population Analysis in Geography*, by Robert Woods; and Geoff Dinkele's deft handbook, *Population Geography*. Occasional incursions, accompanied by the publication of a minimum number of textbooks, were made by sociologists and economists. We should mention here Judah Matras' *Introduction to Pop-*

[7] Population geography first developed in France in the 1950s, mainly thanks to his publications, including the well-known Questions de géographie de la population, (George, 1959).

ulation: A Sociological Approach, in which basic demographic techniques are described in the second part of the volume. It is not until the 1980s that demography begins to recuperate some of the ground it had lost to other disciplines. A process of integration does not see it play a subordinate role, but rather furthers the proliferation of specialized courses.

As the number of university courses multiplied, so did the publication of textbooks, along with teaching aids and other volumes aimed at a more general public. These provided simple analytic tools in accessible language to cover the burning political, economic, and ethical issues triggered by the upheaval of world events. This resulted, particularly in the United States, in a shift from analysis to "policy." This change is reflected in the work by Ian Thomas, *Population Growth*, and in *Comprendre la démographie*. *Méthodes d'analyse et problèmes de population*, by Hubert Gérard and Guillaume Wunsch. Within the same category, we find *Démographie sociale*, by Roland Pressat, which met the growing need of a society that was becoming increasingly attuned to issues of a demographic nature and in which the author showed quite clearly that the scope of demography goes far beyond the "laborious accounts of men and events."[8]

A more generalized, comprehensive book is that by Lynn Smith and Paul Zoff, *Demography: Principles and Methods*, which describes classic population analytic techniques, conducts international comparisons of the main demographic indicators, and focuses on U.S. population trends.

Mention should also be made of *Population: An Introduction to Concepts and Issues*, by John Weeks. Although the layout is quite traditional in scope, coverage of basic methods in demography is accompanied by other, more unusual themes, such as the demographic basis of economic development, the environmental impact of demographic trends, and virtually untouched in other textbooks, women's emancipation.

In France, *Démographie: analyse et modèles*, by Louis Henry, was a major work born of many years' experience with teaching at the University of Paris. In the first section of the book, the author describes demographic analytic techniques and the underlying logic, whereas the second section focuses on trends in models development, particularly those regarding fecundability, a field in which Louis Henry made great strides. The latter approaches are the result of his vast experience in dealing with historical data. Louis Henry played a pioneering role ensuring that historical demography became an independent field of research in the 1950s, with pedagogic publications following somewhat later. Worth citing during the next decade is Jacques Dupaquier's synthetic and thorough *Introduction à la démographie historique*, which appeared in 1967 and which follows in the footsteps of Henry's *Manuel de démographie historique*.

More directly aimed at training the demographer we find the two volumes by Henry Shryock and Jacob Siegel, *The Methods and Materials of Demography*, considered the "red bible" (from the color of the cover) of demographic methods. Using a somewhat technical approach, in 25 chapters this volume covers the range of demographic issues, using updated data and a language accessible to all, making this textbook suitable for specialist training and for institution based teaching. Sharing a rather similar training goal, Alfred Pollard, Farhat Yusuf, and G. Pollard edited the volume *Demographic Techniques*, that offers a more synthetic description of the basic techniques as well as a series of pertinent exercises on the themes covered.

During the 1970s the number of textbooks that appeared in the branch known as *formal demography* also grew quite considerably. Nathan Keyfitz and Wilhelm Flieger published *Population Facts and Methods of Demography* (1971), describing the most commonly used models, with a particular emphasis on theory, without which it is impossible to interpret data. A novel aspect of this volume is the inclusion of computer programs needed to apply the models. A few years later the already cited *Applied Mathematical Demography* appears, the second volume in the trilogy by Nathan Keyfitz on formal demography.

In the field of demographic models, we should cite *Introduzione ai modelli demografici*, by Paolo De Sandre, and *Mathematical Models for the Growth of Human Populations*, by John Pollard. Pollard concentrates particularly on stochastic models and presents a series of models that had only appeared in scientific journals. Although the author makes every attempt to temper the mathematical language used, expertise in this field is necessary to be able to appreciate this work.

A new branch in demography, multiregional demography, begins to appear in these years and continues to expand successively. Early crucial contributions in this field were made by Andrei Rogers, publishing in 1975 *Introduction to Multiregional Mathematical Demography*. This offers a mathematical description of a certain aspect of trends in the human population in time and in space. More specifically, to quote the author, multiregional demography ". . . analyses simultaneously the spatial dynamics of a system of several interdependent populations linked by directional migration flows" (Rogers, 1995, p. ix).

[8] "Laborieuse comptabilité d'hommes et d'événements" (Pressat, 1971, p. 7).

In the Francophone world, but written in English, the painstaking and comprehensive text by Guillaume Wunsch and Marc Termote, *Introduction to Demographic Analysis: Principles and Methods* appeared in 1978. This is not merely a collection of techniques used in demographic analysis, presented quite analytically, but rather the authors focus on the demographic process itself. First of all the issues at stake are outlined and then the techniques to tackle them are described.

IV. DEMOGRAPHY AND DEMOGRAPHIES: TEXTBOOKS SINCE THE 1980s

Throughout the 1980s demography, making the most use of the many stimuli and opportunities that were created in the previous decade, enjoyed an unforeseen scientific expansion that however had to wait until the next decade before this materialized in the publication of textbooks.

Very briefly the multifaceted developments that occurred in demographic research fall under three main intrinsically linked headings: the emergence of new lines of research, hand in hand with new methodologies and interpretative approaches; greater experience in the use of statistical analytic techniques and models; the increased availability of a rich and "multivaried" documentary material and ever more rapid and accessible technology.

More focus on emerging countries and endeavors to understand demographic processes in an underdeveloped economic and social context demanded proactive demographic research. This produced more refined methods of demographic analysis, such as defining tools to deal with data from more backward statistical systems—for example the empirical application of population models and the construction of model life tables—as well as in the theoretical field and the elaboration of explanatory frameworks describing behavior, particularly reproductive behavior. Fundamental steps were taken at this stage in research, and new analysis strategies were forged, constituting a veritable store of experience for scientific research in the following years: the shift from observation to interpretation; from macro to micro, in other words from an analytic approach to aggregate data to the exploration of individual behavior; from focusing on the impact of behavior to seeking the underpinning motivations; from cross-sectional to longitudinal analysis applying a *life course* approach. All of this occurred in a context that generated a wealth of new data, the result of sample surveys on individuals and families that were internationally comparable (the *World Fertility Surveys* and the subsequent *Demographic and Health Surveys*, for example) and fostered greater technical skills in applying suitable statistical methods for processing enormous quantities of complex and multivariate data and for meeting the need to come up with satisfactory explanations dictated to by new research strategies. These ranged from the application of exploratory techniques to multidimensional data, to the development of generalized linear models to verify explanatory hypotheses, *event history analysis* models, and simultaneous equation models to identify the latent sides of behavior as well as the treatment of unobserved heterogeneity.

During what was a particularly stimulating moment for all the social sciences, demography encountered comparable sciences, particularly sociology and economics, with the intent of pinpointing conceptual frameworks of reference, and defining new analytic approaches alongside their peers in statistics. Although there is much interplay between the various sciences, different from the immediate past, an interdisciplinary approach is not pursued, but rather a process of specialization is favored in which demography profits from experiences in other fields while acquiring and elaborating specific competencies in determined sectors of research and scientific development. There is also a shift away in teaching from an interdisciplinary dominated approach toward the specific training of the demographer. Other sciences are borrowed from with regard to reading and interpreting population issues and emphasis is given, not to the need to merge with other disciplines but, rather, to the need to pursue a multidirectional approach to research and teaching in demography. In this period a series of specialist branches of demography were developed.

An offshoot of these developments during this 20-year span is the emergence of a number of "demographies" that generate in different cultural and geographic contexts autonomous university courses along with specialized textbooks in each sector.[9]

Great strides are made by *economic demography*, not only with regard to contents and the publication of textbooks but also due to the expansion it enjoyed in academic sectors as a "frontier discipline" (De Santis, 1997). Although sometimes labeled differently (e.g., *population economics*) economic demography focuses on the interplay between demographic and economic processes. A micro approach is favored in the United

[9] A vast number of textbooks were published during this period. There is not enough space to describe all of them, nor can the choice be limited to one of merit. Preference is given to texts that introduce an element of novelty in content or because they reflect progress in teaching methods or orientations.

States, one harking back to the theories of the economist Gary Becker, and it is based on the microeconomic analysis of individual, and especially family behavior. Authors of texts in the United States tend to be economists. In the book by Assaf Razin and Efraim Savka, *Population Economics*, ample space is given to analyzing the microeconomic implications of demographic behavior. European authors favor a more macroeconomic attitude, and textbooks, essentially those written by demographers, are classic demographic manuals that deal mainly with methods and data to study the population, with a limited number of sections near the end dedicated to selected aspects of links between demography and economics. Significant publications in the field are the French *Démographie. Analyse des populations et démographie économique*, by Gérard-François Dumont, and *Analyse dynamique des populations: Les approches démographiques et économiques*, by Marie Christine Challier and Michel Philippe. Another interesting work is that by Annie Fouquet and Annie Vinokur, *Démographie socio-économique*, which introduces the concept of "social populations," such as the school population or the employed population, for whom mobility (i.e., entry and exit flows) determines social renewal.

In Italy, the work by Gustavo De Santis, *Demografia ed economia*, offers a more global vision of links between demography and economic trends by applying micro and macro analytic approaches. Some of the issues tackled include family microeconomic theory, the cost of children, and the impact of demographic aging on welfare systems. Other books that are useful as teaching aids and that offer a collection of writings on aspects linking demography and economics are the work by Marcello Natale, *Economia e popolazione*, and that edited by Paul Schulz, *Economic Demography*.

With a special focus on the impact of demographic processes on the market, first of all in the United States and more recently in Europe, a new branch known as *business demography* has emerged that particularly favors scientific and professional collaboration with the world of business. The Population Association of America (PAA) founded the Business Demographic Interest Group (BDIG), which brings together business professionals and academic researchers. In 1987, Louis Pol published the first textbook in the field, *Business Demography*, followed 10 years later by *Demography for Business Decision Making*, co-authored with Richard Thomas. The explicit aims of the books are to describe demographic trends and their economic impact and to assess how demographic reasoning and analytic techniques can be effectively applied to business problem solving. Pivotal to this approach is the focus on dynamic-structural interplay and population forecasts.

Business demography falls under the broader heading *Applied demography* that entails the ". . . application of demographic methods, data, and theory to a host of real world problems" (Pol and Thomas, 1997, p. 3). Textbooks such as *Applied demography: an introduction to basic concepts, methods and data* by Steve Murdock and David Ellis or the more substantial and recent work by Jacob Siegel, *Applied demography: application to business, government, law and public policy* (686 pages, published in 2002), may be considered useful consultation books regarding basic methods, an overview of demographic and socioeconomic data sources, the possible implications of population trends, but also regarding the real application of certain demographic techniques, such as forecasts, in the business world, in government, the social reality as it is, often with clear reference to subnational geographic entities.

From this point of view, applied demography is not confined but can embrace very specific areas of study, producing very focused teaching textbooks, such as *Housing Demography: Linking Demographic Structure and Housing Markets*, by Dowell Myers, or *Principes de démographie politique: population, urbanization et développement*, by Eric Weiss-Altaner.

Many authors are of the opinion that applied demography may be considered an extension of *social demography*, defined as "the study of the determinants and consequences of population size, distribution and composition and of the demographic processes of fertility, mortality, and migration that determine them" (Murdock and Ellis, 1991, p. 4). *Population: An Introduction to Social Demography*, by Paul Zopf is a successful example of texts in this field. The first section covers the main issues in current demographic trends, including zero growth in developed countries, the population explosion in emerging countries, and the changed population age structure. The second section offers a moderately technical examination of the various components of the demographic process. The third section deals with the interplay between the population and social systems, such as urban-rural tension, ethnic conflict, family and marriage, and economic and educational systems. The fourth and final section assesses the impact of various possible measures and policies on demographic behavior.

Among the many topics tackled under the heading social demography, particular emphasis must be given to the family that generated a specific subdiscipline, *family demography*, namely the study of family composition and structure, as well as explicit aspects of family life. An important publication in this area is *Family Demography: Methods and Their Applications*, by John Bongaarts, Thomas Burch, and Kenneth Wachter.

The family and the identification of suitable research strategies to cast light on transformations underway was given a fresh impulse in Europe in the 1990s thanks to the new paradigm known as the Second Demographic Transition. The volume, *Household Demography and Household Modeling*, edited by Evert van Imhoff, Anton Kujsten, Pieter Hooimeijer, and Leo van Wissen is a witness to current trends, for the first time examining this field of study from a variety of perspectives: macro and micro, cross-sectional and longitudinal, static and dynamic.

Social demography, particularly in academic circles, has been traditionally seen to be in contrast with the *formal demography* of mathematical measurement of basic populations (Murdock and Ellis, 1991, p. 4), which is given a new momentum in this period in the Anglo-Saxon school of demography and in the French and Italian schools.

New introductory manuals to mathematical demography begin to appear or revised editions of texts published previously, such *Formal demography* by David Smith or the second edition of *Introduction to the mathematics of demography* by Robert Brown. These offer a thorough, moderately technical description of quantitative analysis methods, with a particular focus on mortality and population models. Although these books do not require specialist knowledge of mathematics or statistics, they do address students who must be "familiar with algebra and at least not intimidated by logarithms" (Smith, 1992, p. ix). There is no lack of other fairly elementary but broader ranging texts that are more inclined toward a description of analytic techniques, while also offering examples of applications. *Demographic Methods*, by Andrew Hinde, deserves particular mention. The author endeavors to show how fertility, mortality, and nuptiality analytic methods involve the application of a few basic but common principles, and he introduces more sophisticated topics, such as parity progression ratios, survival analysis, and birth interval analysis. Each chapter contains practical examples, and an appendix is included with sample exercises, using an electronic sheet and population data that can be downloaded from the Internet.

A more formal mathematical approach to demographic processes analysis, which provides a superior description of demographic interrelationships and of population dynamics, is not an easy task. This is not easy for students or authors who strive to maintain a similar approach to a material that is highly specialized according to the processes studied and that over the past decades has been enriched by methodologic progress in statistics and the increasing availability of data. This difficulty is witnessed by the work by Krishnan Namboodiri, *Demographic Analysis: A Stochastic Approach*, which, after an introduction to the basic concepts and to single- and multiple-decrement life tables, presents a markovian approach to multistate processes, compositional analysis, and spatial distribution, as well as a thorough introduction to the topic of heterogeneity and how to deal with it. This book is exemplary with regard to the meticulous treatment it offers, but it is rather tough going for nonexperts. A more recent publication (2001), simpler to use, is the book by Samuel Preston, Patrick Heuveline, and Michel Guillot, *Demography: Measuring and Modelling Population Processes*. The text illustrates much mathematical material in demography through clear and concrete explanations, even though the material is targeted at students who have mathematical skills. It deals with basic concepts, rates and probabilities, life tables, single- and multiple-decrement processes, fertility and reproduction, population models, indirect estimation models, and increment-decrement life tables (by Alberto Palloni). Other texts describe certain methodologies adopted from statistics and then apply them to demographic processes. A pertinent example is the book by Shiva Halli and Vaninadha Rao, *Advanced Techniques of Population Analysis*, which is aimed at students and researchers and which covers, among other topics, age-period-cohort (APC) modeling, covariance structure models (e.g., LISREL), logit and probit models, and proportional hazards models.

In manuals from the French school, the approach to formal demography remains strictly anchored to the "elegant mathematics"[10] of Roland Pressat, who with the publication of *Eléments de démographie mathématique* in 1995, draws to a conclusion a lengthy itinerary dating from the early 1960s, when he proposed methods to quantify demographic processes. This itinerary began with *L'analyse démographique* and was followed in the 1980s with *Manuel d'analyse de la mortalité* and *Les méthodes en démographie.* Of particular prominence is the more specialized book by Jean Bourgeois-Pichat, *La dynamique des populations: populations stables, semi-stables et quasi-stables*. This is the fruit of 11 years' teaching experience, and it remained for a long time unfinished; it was finally completed by his students. It offers comprehensive coverage of the theory of stable populations and related topics.

Among the introductory texts published mention must be given to Alain Hillion's, *Les théories*

[10] "Mathématique élégante," Keyfitz, 1995, p. 1691.

mathématiques des populations, published in the *Que sais-je?* series. Special mention goes to the book by Julien Amegandjin, *Démographie mathématique*, which is intended as an introduction to the work of Nathan Keyfitz and is particularly suited for students that never tackled the study of demography in a classic sense in that it proposes a simple reading of demographic processes directly in continuous time, making it easier to pass from a stepwise to a continuity approach, essential for an understanding of more complex demographic processes and models.

Mathematical demography texts were also published in other European countries, such as Janina Jozwiak's *Mathematical Models of Population*, published by the Netherlands Interdisciplinary Demographic Institute (NIDI), or that edited by Giuseppe Micheli and Piero Manfredi, *Matematica delle popolazioni*.

Italy successfully contributes during this period to the teaching of demographic methods with the appearance of Antonio Santini's *Analisi demografica. fondamenti e metodi*. The result of many years' teaching and research, the book, which is divided into two volumes, pursues mainly pedagogic aims, although it reaches beyond this as it is also directed at research and makes use of techniques and data. The approach is more theoretical than pragmatic and supports the idea that analysis and measurement must adapt to the reality at hand rather than to the strictures posed by the data available. Another volume in the field of demographic analysis, published in Belgium, is Christophe Vandeschrick's *Analyse démographique*, which places greater emphasis on interpreting demographic concepts and the results of analyses than on methods and techniques.

Population geography, a discipline that was born in the field of geography but with strong demographic connotations, so as to be defined as "the study of population by geographers" (Schnell and Monmonier, 1983, p. 7), pays increasing attention to aspects of application in this period. Alongside more classic texts such as *The Study of Population. Elements, Patterns, Processes*, by George Schnell and Mark Monmonier, and the numerous revised editions of older texts, such as *Population Geography: Problems, Concepts, and Prospects*, by Gary Peters and Robert Larkin, a number of innovative texts begin to appear. These include *The Geographic Analysis of Population, with Applications to Planning and Business*, by David Plane and Peter Rogerson. The text, divided into two sections, deals mainly with fundamental notions of geography and population analysis, with a particular emphasis on spatial aspects and mobility. The second section offers concrete examples from the United States regarding the implications of population trends on territorial planning (urban infrastructure, transport, building) and locating a business (e.g., market segmentation).

During the last 20 years of the 20th century, interest was still very much alive among population experts regarding historical demography, which is a restricted field of research but one that enjoys expertise from other fields such as history, geography, and genetics and that avails itself of specific analytic techniques suited to the particular nature of the sources of information used. Two texts that stand out are Louis Henry and Alain Blum's *Techniques d'analyse en démographie historique*, which offers a re-reading of classic analytic techniques using historical data and, in this case, French data, and the work by Lorenzo Del Panta and Rosella Rettaroli, *Introduzione alla Demografia Storica*, which in Italy fills a gap because there are no other comprehensive texts on this material in Italian and existing texts do not adequately describe the wealth and specific nature of the documentary material available. The text also contains references to more recent trends in methodology and techniques to tackle complex data, such as *record linkage*. Researchers and students with a good background in mathematics and statistics who are attracted to more advanced methods in the field of historical demography can consult the book edited by David Reher and Roger Schofield, *Old and New Methods in Historical Demography*, which brings together the most significant addresses made at the IUSSP Committee Seminar on Historical Demography in 1991 and that ranges from the application of methods of time series analysis, family reconstitution techniques, to event history analysis and simulation procedures applied to historical data series.

There was during these years a considerable increase in the number of introductory demographic texts; alongside revised editions of previously published texts, a series of first editions also appeared. This editorial dynamism was generated by the need to adapt contents to the different educational training of the student and to the different teaching goals of demography courses. In some instances, the task is to furnish the student with a knowledge of complex techniques, whereas in others, they need an introduction to specific issues covered by a particular course. Two types of introductory textbooks are available; one type is more focused on techniques, and the other is focused on issues related to demographic change.

Training needs and the approach used are also reflected in the very definitions the authors provide of demography. In these definitions, we can detect an attempt to define the boundaries of demography that had become somewhat blurred because of the multiplication of the different natures of the "demographies" that had been generated. Elsewhere, a certain reticence was expressed regarding establishing restrictions, opting more for affinities with other disciplines than defining the content, methods, and aims of demography as such. There were also the "minimalists," who do not perceive the need for definition and are happy with the definition provided by the multilingual demographic dictionary published by the IUSSP at the beginning of the 1980s.[11]

Another aspect that deserves attention is the attitude on the part of authors to interpretative paradigms that are only rarely covered in the texts mentioned. We could expect, particularly when a major effort is made to define demography, to find some trace of discussion, even critical, about possible "laws" underlying demographic change. Although this is the object of scientific discussion, any attempt to elaborate a general model or paradigm, a theoretical interpretation to contain partial explanations of single processes, is rare in teaching and usually only refers to the first demographic transition theory. Other major theories, such as that of John Hajnal on forms of nuptiality and economic trends or that of Richard Easterlin regarding cohort size alternation as the theory of fertility fluctuations, are never covered.

For the reasons previously given, we address only the more popular textbooks or those that offer certain novelties compared with previous publications. With regard to Italy, mention should be made of the book by Luciano Petrioli, *Demografia. Fatti e metodi di studio della popolazione*. This work tackles traditional aspects of demography along with in-depth analyses of the main mortality and fertility models that once again implies a good grounding in mathematics. A diskette is also supplied with the book that contains programs created by the author to analyze themes covered in the text, a novelty as far as Italy is concerned. The most popular textbook available in Italy is Massimo Livi Bacci's *Introduzione alla demografia*. This is a text on methodology that also describes to what extent demography is intertwined with other biosocial processes and that critically steers the interpretation of the results obtained by the application of various methods. The store of analytic techniques supplied is particularly rich, and the methods presented are sometimes quite sophisticated, but they are accessible to anyone who is approaching demography for the first time.

[11] The *Multilingual Demographic Dictionary* defines demography as "the scientific study of human populations primarily with respect to their size, their structure and their development; it takes into account the quantitative aspects of their general characteristics" (van de Walle and Henry, 1982, p. 15).

Textbooks in English destined for a wider public, even beginners because only a limited knowledge of mathematics is requested, include *Demographic Methods and Concepts*, by Donald Rowland, which contains a wealth of exercises; *A primer of Population Dynamics*, by Krishnan Namboodiri, which has an unusual layout, with each chapter containing a number of questions and answers on the topics covered; and *Beginning Population Studies*, edited by David Lucas and Paul Meyer, which is widely used by Australian universities.

Other textbooks ascribe a secondary role to methodology privileging themes regarding demographic processes. One such work is that by Helen Daugherty and Kenneth Kammayer, *An Introduction to Population*, which is targeted at students from different educational backgrounds. Demography is described as an interdisciplinary science, and ample room is awarded to how this relates to economic, political, and sociologic factors. Charles Nam and Susan Philliber's work, *Population. A Basic Orientation*, also focuses more on issues than on techniques, particularly emphasizing the causes and effects of population change and population policies. The same approach is applied in French publications, and most demography primers are quite comprehensive, not mere introductions to demographic methods. Examples include is *La Science de la population*, by Gabriel Poulalion, which also covers environmental policies; the work by Georges Tapinos, *Eléments de démographie. Analyse, déterminants socio-économiques et histoire des populations*, in which population change is explained within an economic context; and *Démographie*, by Michel Dupaquier, which largely concentrates on an analysis of the family and its current crises.

A more innovative text is *Démographie: approche statistique et dynamique des populations*, by Henri Leridon and Laurent Toulemon. The authors successfully combine a methodologic approach with the treatment of demographic issues. The work concentrates on methodology (covering recent developments and purely demographic techniques, little known among the other social sciences, such as life course transition or event history analysis), while ensuring that the reader is introduced to the socioeconomic causes and consequences of population trends. This guarantees that it is a valuable volume even for the expert.

Alongside primers and textbooks an increasing number of books and publications that also act as teaching aids are published. Furthering an encyclopedic style, on behalf of UNFPA, *Readings in Population Research Methodology*, edited by Donald Bogue, Eduardo Arriaga, Douglas Anderton, and George Rumsey, appeared in 1993. This consists of eight volumes that systematize the great bulk of methodologic research that was conducted in the period in question, offering a state-of-the-art work that is updated to January 1 of the year of publication. It contains a collection of selected reprints from journals, treatises, textbooks, and research reports that were mainly focused on the methodologic content of specific demographic topics. Each volume is dedicated to a single topic: *Basic Tools*; *Mortality Research*; *Fertility Research*; *Nuptiality, Migration, Household and Family Research*; *Population Models, Projections and Estimates*; *Advanced Basic Tools*; *Contraception and Family Planning*; *Environment and Economy*. Although the authors aim "to promote decentralization and widespread diffusion of population research and population planning" (vol. 1, p. iv), this reader is targeted at experts, even though it could be used in introductory courses as an aid "to cover methodologic facets not covered in their favorite textbook" (vol. 1, p. iv).

Another aid to teaching is the *Handbook of Population and Family Economics*, a two-volume work with a total of 1344 pages, edited by Mark Rosenzweig and Oded Stark. This is a collection of readings on classic themes (e.g., family, fertility, mortality, and migration), this time constituting a state-of-the-art work regarding theory and the most recent empirical evidence.

Besides these rather weighty volumes, a substantial number of smaller and more manageable textbooks were published. They cover demographic topics and provide elementary analytic techniques, and they are clearly designed as teaching aids or designed for the layman, in line with a tradition going back to the 1970s. Among the former, there is Shirley Hartley's *Comparing Populations*, which fosters collaborative learning in which each student chooses an emerging and developing country and then compares it with a developed country using a selection of sociodemographic indicators. Among the latter, is the particularly effective (already at its fourth edition) *The Population Reference Bureau's Population Handbook*, by Arthur Haupt and Thomas Kane. It is a quick guide to population dynamics for journalists, politicians, teachers, students, and the general public.

Pursuing a similar approach is the French series *Que sais-je?* that published *La démographie*, by Jean-Claude Chesnais, and the series *Repères* that published *La démographie*,[12] by Jacques Vallin, each of which have been republished several times. Other pocket books that enjoyed a certain success are *Déchiffrer la démographie*, by Michel Lévy; *La démographie. Population, économie et sociétés*, by Georges Tapinos; *Population et développement*, by Jacques Véron, which uncovers links between demography and economics; and *La Popolazione del pianeta*, by Antonio Golini, offering a competent synthesis of population issues in the modern world.

V. FUTURE HORIZONS: TEXTBOOKS AND MANUALS IN THE NEW MILLENNIUM

As we begin a new millennium, we understand that demography has grown steadily as a science and as a teaching discipline. In the United States alone, there were as many as 250 research and training centers at the end of the past century (Roussel and Chasteland, 1996, p. 436). In Europe, numerous university syllabi now offer demography as a subject—although this is often a complementary course included in other departments, such as statistics, economics, political science, sociology, not to mention architecture, urbanism, natural sciences—and various prestigious nonacademic research centers and postdoctoral training bodies closely tied to more traditional centers, such as the Institut National d'Études Démographiques (INED) in France, the Istituto di Ricerche sulla Popolazione e le Politiche Sociali (IRPPS) in Italy, or the Netherlands Interdisciplinary Demographic Institute (NIDI) and the International Institute for Applied Systems Analysis (IIASA) in Austria. Special mention must be given to the Max Planck Institute for Demographic Research in Rostock, set up in 1995, whose activity is emblematic of the recognition from the other sciences that demography now enjoys (the Max Planck Society has founded more than 80 research and training organizations in the natural and social sciences). Thanks to a substantial budget and the caliber of their highly qualified staff, the Max Planck Institute has added further impetus to the international nature of the training of professional demographers. Doctoral students come from all over the world to study within the framework of an international doctorate program, and postdoctoral fellows and junior researchers participate in ongoing research activities, achieving outstanding results and actively promoting international collaboration and the global dissemination of knowledge, aided in this by the online journal *Demographic Research.*

In the near future, the global diffusion of knowledge will make great strides, and opportunities of access offered by the Internet will become central to research and to professional training and teaching. Two aspects

[12] This series also contains two other publications by the same author: *La Population mondiale* and *La population Française*, each of which are complementary, and describe the concepts and analytic approaches pursued in the first volume.

are particularly important. First, there is the increasing availability of free, easily accessible databases that offer resources that cut across various branches but of assistance for teaching purposes in that they offer concrete examples of issues treated in the traditional classroom, as well as direct applications of statistical analytic techniques on real data and case studies, an alternative to the more simplified invented situations used to date by the teacher. It is not by chance that data provider institutes, often also doubling as research centers, offer support aids to facilitate the use of their databases, which are increasingly consulted for pedagogic purposes. An example of this is the U.S. Bureau of Census; it is possible to download from their site data to construct population pyramids for populations throughout the world and the pyramids themselves. A number of national statistic bureaus also provide resources for use by university students, while others, such as ISTAT (Italy), make material available for schools with a special online course on statistics—more or less in line with Power from Data, Statistics Canada, with frequent reference to population data. Another aspect of the Internet revolution is the availability of electronic journals, online catalogs, virtual libraries—in other words, immediate access to scientific information around the world, a valuable tool for research and for teaching purposes that is easy to access and cheap, cutting through barriers of time and space and offering a multitude of stimuli to further knowledge and establish unexpected links right across disciplines.

This brief comment on the opportunities provided on the web regarding access to data and information across the globe creates awareness of the new horizons looming in teaching in terms of content and method. Generally, demographic didactics lends itself to a multimedia approach, using interactively a variety of tools, both real and virtual and global, capable of tackling issues at a theoretical level and their application, grasping their implications regarding international comparisons and multifactorial explanations.

What are the texts to be for teaching demography in the new millennium? We do not pretend to provide an exhaustive list nor propose new "typologies" of teaching aids. Our real scope is to offer some suggestions regarding the book material available today within an information framework and teaching context that is continually evolving.

Classic texts, used primarily for basic institutional courses, will continue to cover basic demographic concepts and fundamental analytic techniques, but they will become less essential for providing examples of the issues covered and applications of the techniques studied, replaced in this by resources available on the web. Easy-to-use textbooks, which are on the increase but by no means exhaustive in their coverage of the complexity of the population system, are a useful teaching aid within a multimedia course, particularly where demography is a complementary examination.

Less and less use will be made of anthologies, such as "readers," containing reprints of scientific articles or parts of books on specific topics, still valid learning tools yet destined to be replaced by electronic resources and virtual libraries. With the web, a dream may come true: global sharing of all science and culture, thanks to the growing online access to research, proceedings, and scientific forums, a witness to the desire on the part of the scientific community to make their work available even through the use of nontraditional channels of communication.

Textbooks on methodology remain fundamental, offering a systematic and thorough description of the techniques of formal demography and statistical analysis and their potential application to demographic data and issues. The web offers sources and data for the description and interpretation of events, but the correct use and scientific accuracy of the application of the logical principles and analytic techniques depends on the culture and skills of the individual scientist.

Although method is still pivotal in forming a demographer, trends focusing on population issues applying a global approach tend toward the "construction" of a whole researcher, one not isolated in a methodologic ivory tower but one who is more attentive, using the techniques of the trade, and is ready to explain the processes underway and assess their many possible impacts.

There is a real need for a comprehensive work that covers the underlying principles of demographic analysis, including mathematical and statistical techniques, and that offers detailed illustration of the sources, a theoretical guide to understanding population processes and a conceptual framework to assist in researching causes and consequences. In an increasingly global society, a treatise such as this one, which was lacking during the last 20 years of the 20th century, becomes a necessity. The promoters of this enterprise, who have pursued the ambitious endeavor of gathering for the future the rich heritage of demographic knowledge and skills, have ensured that this gap is filled.

Acknowledgment

Teaching Demography in the Russian Language

ALEXANDRE AVDEEV AND MARIA AVDEEVA

Université de Moscou, Moscow, Russia, and Université Marc Bloch, Strasbourg, France

Departement de bibliographie et de l'information, Centre d'etudes demographiques, Faculte d'economie, Université de Moscou, Moscow, Russia

The Russian school of demography has its origins in the conjunction of a strong mathematical tradition with the first sociologic population studies. Very early on, Russian demography adopted a mathematical direction in the wake of the work of mathematicians and statisticians from Russia, or who had studied in Russia, such as Daniel Bernoulli (1700–1782), Leonhardt Euler (1707–1783), Viktor Bouniakovski[15] (1804–1889), Vladislav Bortkewicz[16] (1868–1930), Alexandre Tchouprov[17] (1874–1926), and Aaron Boiarski[18] (1906–1985). The sociologic direction appeared more recently, from the mid-20th century, influenced by the ideas of Adolphe Quetelet, Achille Guillard, and Jacques Bertillon. One of the promoters of these ideas, a professor at the University of Saint Petersburg, Iuliy Ianson[19] (1835–1893), published a book entitled *Compared Population Statistics* in 1895, which can be considered a demographic textbook.[20] According to Iuliy Ianson, the word "demography" was synonymous with "compared population statistics." Within this discipline, it included:

"Population statistics," or "anatomy of society," based on numbers, spatial distribution and population age and sex structure, as well as family composition

Population dynamics, or "physiology of the social organism," including nuptiality, fertility, and mortality

Several Russian demographers and statisticians were trained by Ianson, including the brilliant Vladislav Bortkewicz, who went on to teach at Berlin University.

At the end of the 19th century and at the beginning of the 20th, as in other countries, population statistics and health statistics were closely linked in Russia. Most demographic research at that time was the work of physicians and many statisticians had a medical training. As a result, the first post-Revolutionary Russian demographic textbook was a translation of George Whipple's manual,[21] *Vital Statistics: An Introduction to the Science of Demography*, published twice in the United States, in 1919 and 1923. However, this basic manual had been considerably improved and completely revised by the Russian demographer Serguey Novoselski[22] and his publication in Russian in 1929 was jointly signed by Serguey Novoselski and

[15] Виктор Яковлевич Буняковский.

[16] Владислав Иосифович Борткевич.

[17] Александр Александрович Чупров.

[18] Аарон Яковлевич Боярский.

[19] Юлий Эдуардович Янсон.

[20] Юлий Эдуардович Янсон. This author can be considered the founder of statistical teaching in Russia. In 1885, he published the first statistics manual, which was reprinted four times.

[21] George Chandler Whipple (1866–1924), American demographer, is known for his method of smoothing the population pyramid, which eliminates the attraction effects of round ages (see Chapter 4).

[22] Сергей Александрович Новосельский (1872–1953), Russian demographer, co-author (with V. Paevski) of the first national life tables calculated from census data. From 1930 to 1934, he directed the Institute of Demography of the USSR's Academy of Sciences. This institute was closed in 1934.

George Whipple under the title *Bases of Demography and Health Statistics*.[23] Despite its origins, this publication can be considered as the first Soviet textbook. It was aimed at medical students and, according to the administrative practices of the period (which lasted until the end of the Soviet era), it was recommended as essential for health-related teaching.

Two years later, a new textbook entitled Elements of Statistics, a Textbook for Agents of the Maternity Protection System, Infanthood, and Other Branches of Social Hygiene,[24] was published for those working in the health sector by the assistant director of the USSR's Academy of Science Institute of Demography, Vladimir Paevski.[25] Although the term *demography* does not appear in the title, this textbook included a description of all the basic methods of demographic analysis. These two textbooks were used as a basis for teaching demography in universities until the mid-1940s.

In 1945, a new demography textbook, *Lessons in statistical demography*,[26] by the brilliant demographer and statistician Aaron Boiarski[27] was published. This textbook was aimed at statisticians. It was mainly devoted to the methods of formal demographic analysis and the application of mathematics to population studies. Although it was an excellent textbook that included all the demographic contributions of the period, it did not remain on the agenda for a long time. A short time after its publication, ideologic persecutions began in the USSR that were aimed at suppressing the use of mathematical and statistical methods, not only in the social sciences, but also in the hard sciences, such as biology. The law of large numbers was a particular target for criticism; the Stalin administration considered it as a threat to its social development theory. According to Stalinist doctrine, statistics cannot and should not interfere with the law of social development as Adolphe Quetelet stated, as all the principles are already recognized and defined by the Marxist-Leninist and Stalinist theory of social development. Statistics should merely provide an illustration of the success of the Socialist system and the crisis in Capitalist society. Within this atmosphere of reinforced ideologic pressure, Aaron Boiarski was obliged to rewrite his textbook to a considerable extent and to the detriment of the mathematical aspect, and was also obliged to add ideologic banalities on the successes of Socialism. The new version was published in 1951 in the form of a textbook entitled *Demography Statistics*,[28] which was jointly signed by Aaron Boiarski and Pietr Shousherin.[29] In the preface, the authors apologized for their exaggeration of the role of mathematical analysis in demography. The book was republished in 1955. Despite its shortcomings, it was used as the basis for training Russian statisticians and demographers until the end of the 1960s.

The first half of the 1960s saw somewhat of a rebirth in Russian Soviet demography (Avdeev, 1997). A statistical research institute was created by the State Statistics Committee with Aaron Boiarski as its chief. A laboratory and a Chair of Demography Studies were created within the Faculty of Economics of Moscow State University and placed under the direction of Dimitri Valentei.[30] Today, they are known as the Center for the Study of Population Problems of the University of Moscow, where students acquire a specialization in demography over the course of five years of advanced education and three years of doctoral studies. These new needs required new textbooks. One of the first was the Russian translation of Roland Pressat's *Demographic Analysis, Methods, Results, and Applications*, published in Russian in 1966 under the title *Population and the Study of Population*.[31] The translation was carried out by V. E. Shprink under the supervision of Boris Ourlanis,[32] who himself was fluent in French. However, during the following year, in 1967, a 100% Russian textbook was published, which resulted from a considerable collective effort, carried out under the supervision of Aaron Boiarski: *Demography Lessons*,[33] republished in 1974 and 1985. This publication discussed all the aspects of demographic analysis (e.g., fertility, mortality, migration), the stable and stationary population model in matrix and continuous form, methods of building and applying demographic tables, and population forecasts. There were also ele-

[23] С.А.Новосельский и Дж.Уиппль: Основы демографической и медицинской статистики.

[24] Элементы статистики. Пособие для работников охраны материнства и младенчества и других отраслей социальной гигиены.

[25] Владимир Владиславович Паевский (1893–1934), Russian demographer, co-author (with Serguey Novoselski) of the first national life tables calculated from census data. From 1930 to 1934, he was assistant director of the Institute of Demography of the USSR's Academy of Sciences. He died of a heart attack on the same day as the Institute closed.

[26] Курс демографической статистики.

[27] НАарон Яковлевич Боярский (1906–1985), Russian and Soviet statistician and demographer, holder of the Chair of Statistics at Moscow State University, and founder and first director of the State Statistical Committee's Research Institute.

[28] Демографическая статистика.

[29] Петр Павлович Шушерин (1895–1958).

[30] Дмитрий Игнатьевич Валентей (1922–1994).

[33] Курс демографии.

ments of world population history, the history of demography, a description of the demographic situation in the USSR, the history of demographic doctrine and population policies, as well as the birth of the encyclopedic tendency that has since prevailed in the works used in Russia for teaching demography. At the time, this textbook was possibly one of the best in the world. However, its use required that students had a solid knowledge of mathematical analysis. A high level of mathematical teaching was provided in the Faculties of Economics and Geography of Moscow State University and the Institute of Statistics and Economics, but for students from social (e.g., history, philosophy) and administrative (e.g., medicine, protection of health) backgrounds, this textbook was difficult. The textbook by Aaron Boiarski, Dimitri Valentey, and Alexandre Kvasha,[34] *Bases of Demography*,[35] published in 1980, was a compromise; all the aspects of demographic analysis and population theory were also included, but the mathematical aspect was reduced and the Lexis diagram for the classification of demographic events was introduced in the version proposed by Roland Pressat. In 1971 and 1977, two textbooks by Ilya Venetzki[36] were published, in which the mathematical (*Mathematical Methods in Demography*,[37] 1971) and statistical aspects (*Statistical Methods in Demography*,[38] 1977) of demographic analysis were developed in detail.

The necessity of teaching students the qualitative aspects of demography, demographic doctrines, and population policies led to the publication in 1973 of a specific textbook, written under the supervision of Dmitri Valentey, *Foundations of the Theory of Population*,[39] which was republished in 1977 and 1986. In its structure and ideology, this textbook had many similarities with Alfred Sauvy's *General Theory of Population*, which was itself translated into Russian in 1977 and used as a textbook by both students and teachers.

At the end of the 1970s, a work of colossal proportions was undertaken, involving around one hundred authors, and completed in 1985 with the publication of the *Encyclopedic Demographic Dictionary*,[40] supervised by Dmitri Valentey and Dmitri Shelestov.[41] This work is made up of approximately 2000 articles. It describes demographic terms and methods of analysis in detail (including calculation formulas) and includes biographic articles, information on all national and international organizations dealing with population issues, and information on all the specialized journals in the world. This dictionary is without a doubt the best textbook in the Russian language. It was republished in 1994 under the title *Encyclopedic Dictionary of Demography*.[42]

Since the end of the 1990s, many demographic textbooks have been published, most have been written by professors for their own courses and are aimed at specific categories of students. In contrast to earlier textbooks, which were of a general nature and were used in general preparatory courses for demographers, the textbooks of this new wave, although they provide a general introduction to demography, demographic indicators, and some analysis methods, are far from being exhaustive, although this does not diminish their educational qualities. (Zvereva *et al*., 2004; Borisov, 2001, 2003; Medkov, 2003;).

However, *Introduction to Demography*,[43] under the supervision of Vladimir Iontsev and Alexandre Sagradov (1st edition, 2002; 2nd edition, 2003) is an example of a successful old-type encyclopedic general textbook; it was written by a group of authors teaching at the Faculty of Economics at Moscow State University (MGU). The presence in the title of the word *introduction* must not be misunderstood; it is a voluminous, essential textbook. It includes all the contemporary knowledge of demography (e.g., analyses, models, forecasts); it describes the current problems of fertility, mortality, and migration, as well as the role of demographic variables in development models and biometric fertility models. It also includes a small Russian-English-French dictionary of demographic terms and a bibliography at the end of each chapter.

Demographic Treatises and Textbooks in German

ALEXIA FÜRNKRANZ-PRSKAWETZ
Vienna Institute of Demography, Vienna, Austria

In the wake of the *Divine Order*, by the great Johann Peter Süssmilch (1775), demography and the production of treatises and textbooks relating to the field experienced a significant upturn in German-language countries during the 19th century, notably with the works of Christof Bernoulli (1841, 1843), Georg Knapp (1874), Wilhelm Lexis (1875, 1903), Arthur von Fircks, and Kuno Frankenstein and Max von Heckel (1898), and again at the beginning of the 20th century with the works of Paul Mombert (1929), and Alfred Lotka (1932). However, the tendencies of the Nazi period discredited the discipline and it is only very recently that it has regained scientific recognition in German-language universities.

It was not until the 1970s that new research centers began to emerge,[47] again stimulating the teaching of demography in universities and the production of textbooks in German. Neighboring disciplines such as statistics, economics, sociology, geography, anthropology, biology, and medicine had nurtured the flame by including a little demography in their *curricula* and demographers working within these various disciplines were able to establish a certain corpus of basic demographic concepts, methods, models, and techniques for the analysis of demographic processes and structures.

[47] Notably the creation of the Bundesinstitut für Bevölkerungsforschung (BIB) in 1973 in Wiesbaden, the Max Planck Institute for Demographic Research/Max-Planck-Institut für demografische Forschung in 1995 in Rostock, and the Vienna Institute of Demography/Institute für Demographie in Vienna in 1978.

However, because of the absence of specific demographic teaching, demographic textbooks in German remained few up to the 1970s. Among the most recent textbooks, many are very clearly similar to statistical textbooks, even though they are less mathematical (e.g., Feichtinger, 1973; Esenwein-Rothe, 1982; Rinne, 1996). Of these, three works of reference dealing formally with demography, its concepts, and developments should be singled out—those of Hans Reiner Dinkel (1989), Gustav Feichtinger (1979), and Flaskämper (1962). Among allied disciplines, in German-language countries as is true elsewhere, sociology has the closest links with demography. Other important contributions include the work of Gerhard Mackenroth (1953), published at the beginning of the 1950s, and the population sociology textbooks of Josef Schmid (1976), Jürg Hauser (1982), and François Höpflinger (1997). The range of demographic methods extends to many other fields. Some are covered by German literature such as, for example, population geography (Bähr, Jentsch and Kuls, 1992), historical demography (Ehmer, 2004), and the demography of health (Mueller, 1993). The recent demography textbook by Ulrich Mueller, Bernhard Nauck, and Andreas Diekman (2000) is far more comprehensive and provides an extensive and thorough overview of various applications of demography. The first part of the handbook is devoted to methods and models of demography, and the second part provides an extensive and comprehensive overview of the different applications of demography.

Low fertility rates and continued increases in life expectancy, as well as their implications for population aging, have brought demography back into the forefront of political, economic, and scientific debate in German-language countries. It is hoped that this increasing interest in demography will be accompanied by the development of the discipline. New generations of German-speaking demographers have already appeared within prestigious centers of demographic research and increase confidence for such a development. However, the teaching of demography in German-language countries relies increasingly on English-language textbooks. Within the context of this trend, the need for demographic textbooks in Germany must be discussed.

Acknowledgment

I am grateful to Richard Gisser, Wolfgang Lutz, and Jacques Vallin for their valuable contribution.

Demographic Treatises and Textbooks in Spanish

ROSA GÓMEZ REDONDO AND MARÍA EUGENIA COSÍO-ZAVALA

Universidad Nacional de Educación a Distancia (UNED), Facultad de Ciencias Políticas y Sociología, Madrid, Spain

Center of Research and Documentation on Latin America (CREDAL), Paris, and Université de Paris X-Nanterre, Paris, France

Demographic literature in Spanish is abundant, and even in the context of this short article on the production of treatises and textbooks (i.e., the works that make up the major part of the discipline), we can mention only the main publications, those that have had the most influence on teaching and research. It is also quite diverse, and although the same publications are frequently used on both sides of the Atlantic, the teaching and practice of demography has developed differently, and we thought it desirable to divide this article into two sections, one dealing with Spain and the other with the Latin American countries.

INTRODUCTION TO TREATISES IN SPAIN[53]

In Spain, the first treatises and handbooks appeared in the middle of the 20th century,[54] both original Spanish publications (Ros Jimeno *et al*., 1945) and translations from Italian (Gini, 1952). After the barren period that the years between 1950 and 1960[55] constituted for all scientific disciplines, the publication of demographic treatises and textbooks was somewhat delayed. Population studies really began to take shape at the beginning of the 1970s, mainly in two particular fields: historical demography, with the translation of works by Anthony Wrigley (1969), and Louis Henry (1971, 1976, 1983), and demography as a supplement to socioeconomic studies in relation to the modernization process. However, it was not until the 1970s that the publication of a comprehensive demography textbook written by a Spanish author occurred (Leguina, 1973); this textbook was used by successive generations of students and researchers as a result of several republications. Juan Lasterra's textbook was also published in 1976, and Spanish versions of Hubert Gérard and Guillaume Wunsch's small textbook (1975) and the more substantial demographic analysis by Roland Pressat, *La Pratique de la Démographie* (*The Practice of Demography*) (1977a), were translated and supplemented by an appendix on the Spanish population (Pressat, 1977b).

Toward the end of the 1970s and, particularly during the 1980s, demography developed rapidly in Spain. The period is characterized by consideration of data sources, analysis methods and techniques, and the basic mechanisms of population dynamics. Researchers became aware of American works published and translated into Spanish, such as those of Mortimer Spiegelman (1972) and Nathan Keyfitz (1975; 1979), as well as those published by international organizations, such as the United Nations (1975, 1980, 1986), the Population Reference Bureau (Haupt and Kane, 1980), and CELADE.

[53] The collaboration in this section of Yolanda Morcillo, librarian of the UNED, is acknowledged.

[54] With the exception of some minor works such as Elementos de Demografía by Felipe Paz, dated 1915.

[55] During that period, Spain was isolated from contact with international organizations.

In response to the needs of the period, population forecasts were of undeniable interest at the time. With the democratic transition and setting up of autonomous regional governments, the demand for demographic analyses became pressing from local authorities and autonomous communities and as from national governments. More works by Roland Pressat were translated (1983, 1985) that to this day have a major influence on the teaching of demographic analysis in Spain.[56] In the same decade, the Spanish version of the publication of John Weeks (1984) was published, which had a very educational sociologic approach making demography accessible to students of social science. During the same period, the work of Julio Vinuesa, Ana Olivera, Antonio Abellán, and Antonio Moreno was published (1982, republished 1988), which emphasized spatial dynamics and which is very useful for public administration. At the same time, surveys on fertility, migration, disability, and health were developed, but this was not reflected by an increase in the production of textbooks.

During the 1990s, textbooks written by Spanish authors were published in addition to new translations that were much appreciated for teaching, such as those of Georges Tapinos (1990); Massimo Livi Bacci (1993), an author who has great knowledge of Spanish demography; and the short book by Jacques Vallin (1995).[57] As for Spanish authors, they notably published two recent textbooks: the collective and multidisciplinary publication of Julio Vinuesa, Francisco Zamora, Ricardo Génova, Pedro Serrano, and Joaquín Recaño (1994), and the book by Graciela Sarrible (1996) on population theories.

At the beginning of the 21st century, demography is consolidated in Spain, both as a field of research and of education, and it is often included in social science courses in universities under various names. Within most public and private universities and research centers, the study and research of population are conducted within a multidisciplinary framework. However, demography is still not a specific university degree and there is no official qualification in demography, which explains why more specialized works are published rather than real demographic treatises or textbooks that provide an overall view of the discipline.

[56] A first little-known Spanish edition was published in 1967.

[57] Information on the Spanish population by Rosa Gómez-Redondo were added to this version.

INTRODUCTION TO LATIN AMERICAN TREATISES

In Latin America, the first publications or Spanish translations of textbooks appeared in the context of a training program set up by the UNFPA[58] in CEPAL,[59] for which during the 1950s in Santiago (Chile) the *Centro latinoamericano de Demografía* (CELADE) was created, with Carmen Miró as director. This program also had a considerable influence on national publications of demographic treatises and textbooks when, from the 1960s, the first graduates of CELADE returned to their respective countries (e.g., Argentina, Brazil, Colombia, Costa Rica, Cuba, Ecuador, Mexico, Peru) to set up Master's programs in demography in various Latin American universities.[60]

The first Spanish textbooks used within this context were translations of United Nations publications (Naciones Unidas, 1968, 1975, 1986), and then new textbooks were prepared by CELADE (1984) or translated into Spanish by the same organization (Bourgeois-Pichat, 1985; Brass, 1972; Carrier, 1975; Keyfitz, 1975, 1979; Granados, 1986; Ortega, 1987; Pinto, 1973; Somoza, 1975; Tabah, 1962; Vieira, 1973). At the same time, Spanish translations of North American treatises were used as textbooks in different Latin American demographic training (Bogue, 1973; Haupt, 1980; Hauser and Duncan, 1975; Keyfitz and Flieger, 1975; Potter, 1983; Spiegelman, 1972; Weeks, 1984). Spanish versions of the works of European authors, mainly French, Italian, Spanish, and English, were also widely diffused, some of them very recently (Courgeau and Lelièvre, 2001; Vallin, 1994; Livi-Bacci, 1993; Wunsch, 1992; Tapinos, 1990; Henry, 1971, 1976, 1983; Leguina, 1973; Pressat, 1963, 1977, 1981, 1983a, 1983b, 1985, Wrigley, 1969, 1985; Gini, 1952). Treatises and textbooks written by Latin Americans were published in countries where demographic research and teaching is very active: Argentina (Recchini de Lattes, 1978; Bottinelli, 1963), Cuba (Bueno, 1993, 1997; Catasus and Rodriguez, 1978), Chile (Castillo Muñoz *et al*., 1990; Mattelard, 1964), Colombia (Gonzalez, 1998; Carvajal, 1978), Mexico (Canales and Lerner, 2003; Rodriguez Cabrera, 1992; Welti, 1997; Corona *et al*., 1978; Navarrete and Vera, 1964), Nicaragua (Ocón, 1990), Venezuela (Ramírez, 1994).

The various treatises and textbooks published in Spanish and widely used in Latin America have

[58] United Nations Fund for Population Activities.

[59] United Nations Economic Commission for Latin America (Santiago, Chile).

[60] Notably the Maestría de Demografía of the Colegio de México (Mexico) was created in 1964.

several things in common. Initially, the objective was to provide tools and methods to become acquainted with and measure the main demographic phenomena explaining the very rapid population growth (e.g., mortality, fertility) and to make population forecasts. It was necessary to estimate these phenomena on the basis of data available in the 1950s, which were frequently partial or imperfect, mainly from censuses, because in Latin America, civil registration data were at the time practically unusable. The textbooks had to take this into account.

Then the objective moved toward a comparative and more detailed study of Latin American populations as a result of the development of international survey programs: PECFAL surveys,[61] World Fertility Survey (WFS), Demographic and Health Surveys (DHS), and numerous national and local sociodemographic surveys. The tools used were diversified to take the greatest advantage of the new data collected and the development of computing. During the 1970s and the 1980s, the emphasis was placed on fertility determinants and family planning.

Knowledge of demographic phenomena has been extended to nuptiality, internal and international migration, and aging. There is an increasing number of sociodemographic surveys and they have benefited from new methods of biographical surveys, such as is the case in Mexico (la Encuesta demográfica retrospectiva [EDER], 1998; Mexico City survey, 1970; Monterrey survey, 1968). The problems of urbanization and socioeconomic development (1960 to 1980) have been gradually replaced by the current issues of poverty and migration (1990 to 2000).

There is now an active Latin American school of demography, because Latin American demographers are very aware of their role with regard to the problems posed by the acceleration of population growth in the construction of modern states from the second half of the 20th century and were very much involved in the Third World movement of the period. However, the Latin American approach attached to the historical-structural mindset that predominated between 1960 and 1990, analyzing social relations of power at every level and seeking to define family strategies as units of analysis, has not produced any real demographic treatises, with authors preferring to express themselves in other types of publications, frequently in critical essays on particular issues.[62]

[61] A program of comparative surveys on fertility in Latin America, organized by CELADE during the 1960s and aimed at studying fertility in different countries in urban and rural areas.

[62] More attached to the sociology of populations than demography.

In 2005, this specific Latin-American movement of thought is barely represented in demographic literature, and Latin American demographers have been largely integrated into North American and European movements and increasingly work directly in English or French.

Demographic Treatises and Textbooks in Portuguese

ELZA BERQUÓ

Cento Brasileiro de Análise e Planejamento (CEBRAP), Sao Paulo, Brazil

TREATISES, TEXTBOOKS, AND EDUCATIONAL PUBLICATIONS

The number of demographic textbooks published in Brazil is quite small because the systematic teaching of this discipline has only recently developed. The study of demography at university level began 20 years ago. It began with postgraduate courses in 1985 in CEDEPLAR,[64] the Regional Center for Development and Planning at the Federal University of Minas Gerais (UFMG[65]). Thereafter, a doctoral course was introduced in 1993 at the Institute of Philosophy and Human Sciences[66] at Campinas State University[67] (UNICAMP), in partnership with the National Center for the Study of Demography (NEPO[68]), which was recently supplemented by a masters course. The National School of Statistics, created in 1953, in collaboration with the Brazilian Institute of Geography and Statistics (IBGE[69]) has provided a masters course in demography since 1998.

The abundant international demographic literature, notably American and French, plays a very important role in teaching in Brazilian universities, as a result, fluency in at least one of these languages is essential.

[64] Centro de Desenvolvimento e Planejamento Regional.
[65] Universidade Federal de Minas Gerais.
[66] Instituto de Filosofia e Ciências Humanas.
[67] Universidade Estadual de Campinas.
[68] Núcleo de Estudos de População.
[69] Instituto Brasileiro de Geografia e Estatística.

In addition, the Brazilian Association for the Study of Population (ABEP[70]) has channeled, over almost 30 years, the important Brazilian scientific production in the area of population in its journal *Revista Brasileira de Estudos de População* (*Brazilian Journal of Population Studies*), created in 1982. Through its 22 issues, it reflects the country's evolution with regard to scientific knowledge of demography. The following paragraphs provide the few Brazilian works published since 1980 that can be included in the category of demography textbooks.

Dinâmica da População: Teoria métodos e Técnicas de Análise, published in 1980 and edited by Jair Santos, Maria-Stella Levy, and Tamas Szmreczanyi, is a collection of articles on demography. It discusses the objectives and the field of demography; the sociohistorical process of the evolution of the population; the factors related to population dynamics, notably mortality and fertility; the nature of demographic data and their sources, the main methods of analysis and projection; nuptiality, fertility, mortality, and migration; the relation between population and economic development; the contribution of demography to the issues of development, education, public health, and population policies.

Pequeno Histórico do Desenvolvimento da Demografia no Brasil: A História, o Ensino, a Pesquisa, as Instituições e o Financiamento para Demografia (Berquo and Rocha, 1982) is a retrospective study (1970 to 1980) of the

[70] Associação Brasileira de Estudos Populacionais.

development of demography. The work is based on a compilation of 587 articles dealing with population studies and demographic analyses, listed according to several criteria, and the organization responsible for each article.

José Alberto Magno de Carvalho, Diana Oya Sawyer, and Rodriguez Nascimento published *Introdução a Alguns Conceitos Básicos e Medidas em Demografia* in 1992, which introduced the fundamental bases of demography and the calculation of the principal indicators of the components of population dynamics by presenting applications and illustrating their potential. Population growth, fertility, mortality, and reproduction are discussed in a simple, critical, and objective manner with examples of applications to real data. The publication aims at providing a practical and realistic overview of population trends in Brazil, in the light of the major changes that have affected the components of its dynamics over past decades.

Fontes de Dados Demográficos, by Ralph Hakkert (1986), provides an analysis and a discussion of demographic data sources, distinguishing stock data (population) and flow data (births, deaths, migrations).

Introdução a Métodos de Estimativas Interpolações Populacionais, written by Gustavo Naves Givisiez (2004), discusses the interpolation of demographic data by presenting different graphical and mathematical methods useful for adjusting the most frequently used demographic indicators, thereafter it discusses the most common methods for estimating the distribution of a population by age and sex from a total number or on the basis of different age groups to that which is required.

Demographic Treatises and Textbooks in Dutch

GIJS BEETS AND JOLANDE SIEBENGA

Nederlands Interdisciplinair Demografisch Insituut (NIDI), Den Haag, Pays-Bas

The Netherlands has a long-standing demographic tradition. After the famous study by John Graunt (1620–1674) of the London "bills of mortality," the Dutch mathematician Christiaan Huygens (1629–1695) reflected further on life table theory. During the 18th century, Nicolaas Struyck (1687–1769) and Willem Kersseboom (1690–1771) published some basic demographic studies. "Kersseboom had already pictured the methodologic outline of demographic forecasting in the 18th century" (De Gans, 1999, p. 93). As a tribute to him, the NIDI staff planted a cherry tree (*Kersseboom* in old Dutch) in the NIDI garden.

The 20th century was a particularly thriving period for Dutch demography. The Netherlands Demographic Society (Nederlandse Vereniging voor Demografie [NVD]) was created in 1928 at the same time as the creation of the IUSSP. Almost immediately, annual meetings were convened with presentations and discussions on a wide variety of topics, such as aspects of rapid population growth, fertility rates, and population projections. Some famous names from the first half of the 20th century are Angenot (1901–1979), Delfgaauw (1905–1984), Holwerda (1887–1944), Methorst (1868–1955), 't Hooft (1896–1941), Van Lohuizen (1890–1956), Van Zanten (1874–1944), Verrijn Stuart (1865–1948), and Wiebols (1895–1960). In Belgium, the statisticians Quetelet (1796–1874) and Verhulst (1804–1849) in the 19th century merit special attention.

This overview briefly summarizes the most important contributions to demography made by native Dutch speakers over the past 100 years. In the wake of the above-mentioned demographers, several others contributed to questions such as: What is demography? What are demographic tools? How does one become a demographer? What makes demography different from other scientific disciplines?

From the NIDI library's online documentation system, we have selected 25 demographic treatises and textbooks published before 1980 in the Dutch language and 12 that were published during or after 1980. At first glance, it may be surprising that the number of publications decreased while the field of population research increased significantly after 1980. Many of the most basic treatises are already available, some in Dutch but mostly in other languages, and understanding other languages is not a problem for native Dutch speakers, Moreover, Dutch researchers mainly publish in English rather than their native language. To judge whether Dutch-language demographers have also published treatises in other languages we made another search on the online documentation system, and as a consequence added 7 more publications to the list; all of which were published in 1982 or later. In total, our appendix includes 44 publications, more than half of which were published before 1980.

The 25 demographic treatises published before 1980 were mainly published in the Netherlands, apart from one title published in Belgium and two in South Africa. Most of these treatises are basic introductions to demography as a scientific field in its broadest sense, although a large minority can be classified as focusing mainly on specific demographic topics, such as mathematical and analytic demographic issues, demometrics, population forecasting, and some have a specific geographic or sociologic perspective. Also of interest is the fact that six of these treatises are translations into Dutch. All of them were originally written in French—

one by Beaujeu-Garnier, one by Pressat, and four by Sauvy—and published between 1960 and 1975 in a series of Dutch pocket books devoted to popularized science (i.e., very accessible to a wider audience, including students). It is remarkable that during this period no publications in English or any other language were translated into Dutch.

After 1980, two of the twelve demographic treatises were published in Belgium, the others in the Netherlands. Again, most of these treatises are basic introductions to demography. Three were produced at NIDI and are specifically aimed at students and the wider public (NIDI, 2003; Van Imhoff *et al.*, 1995; Bronsema, 1990). Some treatises look forward to the 21st century, another focuses on life course issues. Lesthaeghe and Van de Kaa launched their well-known theory of the "second demographic transition" originally in Dutch (Van de Kaa and Lesthaeghe, 1986). During the following year, a translation of a practical population handbook (from English to Dutch) was produced at NIDI (van de Kaa, 1987).

Increasingly, we see that demographic output from the Dutch-speaking world is published in English-language journals (not included in the appendix). Dutch native speakers have written books in English as well. Among these are nine demographic treatises, originally published in English but co-produced by Dutch-speaking scientists (i.e., Cruijsen, De Gans, Dykstra, Keilman, Lesthaeghe, Overbeek, Van de Kaa, Van Imhoff, and Van Wissen). Three of these focus specifically on forecasting and modeling issues. Because these Anglo-Dutch publications are missing in this chapter, we have listed them separately in the appendix.

Acknowledgment

The authors would like to thank Frans van Poppel, Nico van Nimwegen, and Frans Willekens (all from the Netherlands Interdisciplinary Demographic Institute) for their valuable contributions.

Demographic Textbooks in Japanese

SHIGEMI KONO
Faculty of International Economics, Reitaku University, Chiba-Ken, Japan

There are not too many demographic textbooks in Japanese. This is partly because demography is not often taught in Japanese universities. Moreover, although demography is usually taught within sociology departments in the United States, in Japan, it is usually taught in economics and uncommonly in geography departments.

The first comprehensive demographic work in Japanese was published in 1960 by Minoru Tachi: *Keishiki Jinkogaku: Jinko Gensho no Bunseki Hoho* or *Formal Demography: Methods of Analysing Population*. Tachi was regarded as a leader by Japanese demographers from the 1950s to the 1970s. With this 829-page publication, he succeeded in producing practically all the basic data and indicators regarding population, methods of analyzing components of population dynamics (e.g., fertility, mortality, and migration), and population models, from model life tables to stable populations. However, Tachi's main objective in writing this volume was not merely to present an illustration of demographic methods, but rather to establish empirical regularities and even some sort of population laws for the interaction between fertility, mortality, and migration, and population structure and its geographic distribution.

Jinko Tokeigaku, or *Demographic Statistics* (1980), by Yoichi Okazaki, is easy to read and introduces practical calculations. The book deals with basic population growth indicators, and population composition, methods for analyzing fertility, mortality, and migration, the calculation of life tables and their application, as well as population estimates and projections. This work, which to a certain extent resembles George Barclay's *Techniques of Population Analysis* (see Appendix 139–1), has been very widely used in Japan for introducing students to basic demographic methods.

Another book that is easy to read and use in specific situations is *Jinko Busnseki Nyumon*, or *An Introduction to Population Analysis*, edited by Kiichi Yamaguchi in 1989. To a certain extent, it is an update of Tachi's work, due to the incorporation of new methodologic developments. However, it is also simpler to understand and use for applications to real data, and it includes some very useful illustrations. Similar to Tachi's book, and in contrast to most American and European textbooks, it focuses more on analyzing migration and spatial distribution. However, there are several new features in this book. It introduces a wide range of tools for analyzing fertility, and then it demonstrates functional projections for the labor force, families, and households. It also paves the way for the analysis of multistate demography.

Suuri Jinkogaku, or *Mathematical Models for Demography and Epidemiology*, by Hisashi Inaba (2002), explains mathematical models that make it possible to describe population dynamics. According to Inaba, technical or formal demography is mainly inductive, as it attempts to find empirical regularities in demographic phenomena and to approximate them by mathematical functions, while mathematical demography is essentially deductive, focusing on the process of human reproduction and population replacement. The main chapters concentrate on the development of stable population models and the development of two-sex models.

Because life tables are an essential tool for demographic analysis, reference should be made to *Seimei-hyo Kenkyu*, or *Life Table Methods*, edited by Kiichi Yamaguchi, Zenji Nanjo, Takao Shigematsu, and Kazumasa Kobayashi (1995). The book begins with the general concept of life tables and then discusses simple-decrement tables and their specific applications, such as life tables by cause of death or by marital status. It then discusses multiple-decrement tables, such as working life tables and nuptiality tables, and it concludes with a discussion of multistate or multiregional life tables. The book includes interesting methods for creating tables for small populations, based on a Bayesian approach and other approaches.

Sekai no Jinko, or *World Population*, by Shigemi Kono (2000), provides an overview of demography based on the demographic situation in the world and its regions. It includes chapters on world population growth, methods for demographic estimates and projections, mortality and life expectancy, fertility trends and determinants, population composition and aging, migration and urbanization, the relations among population, resources, and the environment, and population policies.

Demography is most frequently taught within economics departments in Japan and it would therefore seem pertinent to mention a textbook on population economics recently published (2001) by Hisakazu Kato: *Jinko Keizaigaku Nyumon*, or *An Introduction to Population Economics*. This very useful publication discusses the development of population economics from Malthus to Keynes, macroeconomic and microeconomic theories of fertility behavior, the economics of nuptiality, the relation between female labor force participation and fertility, as well as population aging and social security problems.

Jinko Dai Jiten, or *Encyclopaedia of Population*, edited by the Editorial Committee of the Population Association of Japan (PAJ, 2002) is not precisely a demographic textbook, but it has been extensively used as an essential reference book in public and university libraries. It contains 999 B5 format pages and includes eight major sections and 192 articles. These eight sections are world population, its history and its geography; population issues of the world and Japan; population ideas and theories; population statistics and methods of analysis; family and population replacement; spatial mobility and population distribution; socioeconomic aspects of population, and population and family policies.

Demography Teaching and Research

DIONISIA MAFFIOLI

Università degli Studi di Bari, Bari, Italy

I. THE CHALLENGES TO BE MET

Teaching and research in demography must be closely linked. Knowledge transmission must be regularly updated as progress is achieved in the discipline. If training is meant to prepare the students for ever-renewed social demand, particularly through evolution of the labor market, scientific research must contribute to providing the instruments to meet that objective. It is essential to understand whether, in concrete terms, those principles are actually applied, and how. Several significant initiatives have been taken in the past few decades, aimed at appraising the teaching of demography across the world, the latest of which was conducted by a Union for the Scientific Study of Population (IUSSP)[1] working group. This made available a large mass of updated information, the need for which had been acutely felt. However, it remains difficult to pass judgment on such a complex, multifarious, or even contradictory situation, which varies from one country to another due to differences in the background and the organization of university training, as well as demands on the labor market. The following sections discuss certain points that, at the international level, seem crucial for the development of the discipline in terms of scientific acquisition and academic strength and positioning; the consequences for demographic and population training, in view of the various teaching objectives, are also examined.

Demographers have good reasons for feeling gratified with the way their discipline, although comparatively recent, has progressed. While its objectives and frontiers could—and should—be questioned, the identity of the discipline, as far as its central core is concerned, is well defined and characterized by strong elements, the pride of all demographers—a sound methodologic system, specifically designed for the needs of understanding demographic systems, and which has grown more sophisticated and consolidated in the past few decades; the empirical approach and the refusal to build or accept theories unless they are based on objective observations on whole populations or statistically representative samples; the numeric measurements that can be statistically processed and make it possible to formulate mathematical models that can explicitly and clearly represent how events are linked between themselves and to their causes, as opposed to qualitative descriptions (sometimes perceived as vague and potentially contradictory); the abundance of available data derived from official sources and large-scale surveys, which makes it easier to meet quantification needs. The very first aim of demography is to describe "demographic systems,"[2] along with their changes in time and space and to analyze the ways in which the various components of a system relate to one another and interact. In many cases, particularly in the past, description was the main core in the work of many demographers, but it

[1] The work of the Group, which was coordinated by Graziella Caselli, culminated in the Demographic training in the Third Millennium seminar, which was held in Rabat, Morocco, on May 15 to 18, 2001, under the aegis of the IUSSP. For information on earlier initiatives, see Chapter 142.

[2] "Il sistema demografico" (Livi Bacci, 1994, p. 11).

was never perceived to be a sufficient or exclusive objective. As shown by the definitions of the discipline, expressed at various periods in time by different authors with different scientific priorities, demography has always aimed to identify the "general principles that determine the evolution of populations,"[3] highlighting the cause and effect relations between demographic dynamics and social dynamics in a broad sense. In other words, the aim is to understand the *causes* of the behaviors and processes that belong to its field of study, and the *consequences* of population dynamics on all other aspects of social life. In its quest for causes and consequences, the approach of demographic research is typically inductive—based on measurable facts that have been verified as rigorously as possible, to build constructions and theories that, once formulated, must always be verified again, through the appropriate statistical procedures, so that their degree of generality can be established. All that is part of the *genetic code* of demography and a strong feature of identity, not only for the discipline, but also for demographers, inasmuch as they are really direct heirs to Comte's positivism, as stated by John Caldwell (1996, p 311). As a matter of fact, as the same author writes (1996, p. 310), demographers are usually intolerant about the practices of other social disciplines that, in their opinion, "seem to build one unsubstantiated assumption upon another, . . . which can be tied to the observable world indeed without foundation which can be in some way measured or shown to be real and have ascertainable magnitude" (Caldwell, 1996, p. 310).

However, criticism of demography may also stem from the very features that make its strength. The same tradition of quantitative construction of reality, which contributes so much to clarity of observation and constructions, has limits because, as Guillaume Wunsch (1987) remarked, "while facts can generally be expressed in numbers, ideas cannot"[4]; however, ideas are quite often an important factor in demographic changes. Actually expressing *facts* in numbers implies a reduction of meanings and the risks of *variabilization* (Micheli, 2000) (i.e., of restricting construction of realities only to those aspects that can be processed along demographic canons). An urge is widespread to ignore the confines between disciplines—appropriate in university organization, but not required by scientific research—and to bring together all the abilities necessary to analyze complex phenomena. There are causes for frustration and uneasiness, which are related to the (in)adequacy of the tools and approaches commonly used in demographic research, if the latter, rather than simply describing demographic systems, is to address the crucial nodes of the causes and consequences of the changes and evolution that occur in the systems. The matter becomes all the more serious if the results of research, beyond the interest in scientific progress, also is meant to have operational scope by providing social policies with the information needed. This seems inevitable in view of Guillaume Wunsch's statement (1987, p. 411) that "demographers, any more than other scientists, cannot remain aloof from the social usefulness of the results of their research."[5] The *causes* and *consequences* of demographic processes are not (only) demographic: the causes are rooted in societies, cultures, economies, histories; the consequences are widely spread across the various sectors of the social system. Studying them consequently implies extending the field of research to new issues, on the borders of other social sciences that are also focused on humans and their activities. This implies probing into the very roots of human behavior reconstructing decision-making processes and linking them to the context in which they were shaped. This means that demographers must adopt contributions in knowledge, awareness, or tools that were developed within other disciplines or invent new ones for themselves.

An aspiration to examine relations between societies and demographic systems has always been discernible in population studies. That is where the demographic transition theory, the main paradigm in the interpretation of modern demographic upheavals, originated. However, despite many significant exceptions, that aspiration had largely remained theoretical, and hardly materialized in the daily research work of population specialists. But it seems to have conquered now a status as a priority requirement, to avoid impoverishment and fruitlessness of the discipline. In the last ten or fifteen years, many authors gave evidence about that phase in the history of the development of demography. A few are mentioned, although no full list of the most significant contributions can be offered here. Massimo Livi Bacci (1994, p. 11), describing the progress of demography, has shown how in the past few decades most of the progress achieved was "on the construction of a formal structure of how the

[3] "Principi generali che reggono l'evoluzione delle popolazioni" (Savorgnan, 1936).

[4] "Se i fatti possono essere generalmente tradotti in numeri, altrettanto non si può fare per le idee" (Wunsch, 1987).

[5] "Il demografo, come ogni scienziato, non può disinteressarsi dell'utilità sociale dei risultati delle sue ricerche" (Wunsch, 1987, p. 411). The statement was made by Guillaume Wunsch in Rome in 1985 during a meeting held in honour of Nora Federici.

demographic system works"[6] and how, although further improvement remains desirable, the time has come for focusing on the research of the causes of phenomena variability, which is now possible because of the extraordinary increase in available data, particularly at a micro level. According to John Caldwell (1996), "It is appropriate to return to theory, because the ability to construct theory from empirical data, and then to test its potential for correctly predicting future or past but unexamined events, is the hallmark of both social and other sciences" (p. 332). Giuseppe Micheli (1997) suggests that views be widened and new roads explored, asserting that "no further progress could be achieved in understanding complex phenomena such as demographic processes unless we give up that oversimplifying method that consists in solely quantitative verification and sterile, if reassuring, reference to ourselves."[7] Bart de Bruijn (1999, p. 1) was referring to Frans Willekens and Guillaume Wunsch when he wrote, "Although the mathematical interest is a distinctive and indeed an indispensable feature of demography, it is not sufficient for a mature science capable of interpreting, understanding, forecasting demographic reality; even less for conceiving conditions for behavioral intervention strategies or policies related to population change. Such capabilities can only emerge from a body of explanatory theory: a set of interrelated concept and propositions that specify relevant entities and events, the relations between them, and the underlying causal mechanisms" (de Bruijn, 1999, p. 1). Paolo De Sandre (2000, p. 10) observed a trend toward "interpretative and explanatory objectives superseding descriptive ones,"[8] whereas Graziella Caselli (2000, p. 142) sees new developments of the discipline "in the specialization phase being outgrown and the integration phase emerging. The field for investigation has been significantly widened and multidisciplinary research is now offering new, exciting experiences."[9] Many more examples could be quoted, showing that such a view is widely shared.

[6] "La costruzione di un'architettura formale del funzionamento del sistema demografico" (Livi Bacci, 1994, p. 11).

[7] "Passi in avanti nella comprensione di fenomeni complessi come i processi demografici potranno esser fatti solo abbandonando la strada di troppo semplificate verifiche empiriche di tipo esclusivamente quantitativo e di rassicuranti ma sterili certezze autoreferenziali" (Micheli, 1997).

[8] "Recupero degli obiettivi di interpretazione e spiegazione su quelli descrittivi" (De Sandre, 2000, p. 10).

[9] "Nel superamento di una fase di specializzazione e nel delinearsi di una fase di integrazione. In effetti il campo di indagine si dilata notevolmente e la ricerca multidisciplinare propone nuove interessanti esperienze" (Caselli, 2000, p. 142).

The effort to reach the objective of comprehension, although mainly motivated by the aim of knowledge, also supports another fairly common aspiration among population specialists—to help policy-makers and public opinion reach better understanding of how useful demographic research can be for good governance, considering the multiple interrelations identified between the population dynamic and the evolution of society. Among other things, clearer perception of the social usefulness of demography must have positive repercussions on the demand for demography qualifications on the labor market and therefore on the ability of the university structures to attract students and on the academic position of the discipline, which would be reinforced. Making more room in academic training and in research for the creation and development of such competence as may be required in the productive sector may launch such a process, although it must be admitted that in many countries there is little hope of sensitizing the business world, as is the case in the North American context. Although the place of demography in the context of university curricula may seem a minor academic concern, it is crucial for the very survival of population studies. As Frans Willekens emphasized (referring to the European case, but his remarks are valid everywhere), the rather marginal position of demography in departments or structures that have more general training objectives becomes dangerous when, as is currently the case in many European countries, competition to attract more students and resources leads to refocusing every training program onto what is considered its central core, which usually is not demography: "Demography, being small in scale but great in scope, is often situated in university departments that do not consider demography their core business. . . . To boost productivity and the competitive edge, departments retract to what they consider is their core business. Demography is often the victim of that process because the field has been unable to demonstrate that either it is part of the core business of the department in which it is located or has a core business of its own" (Willekens, 2001). It seems desirable to pursue the strategy of interdisciplinary collaboration that, besides promoting scientific understanding of complex phenomena, remains the best way of rousing more interest in demography and its scientific perspectives.

The main challenges, which are partly interrelated, that demography needs to meet can be summarized in three points: develop the capabilities of understanding demographic phenomena; develop the capacity to participate in *social management*; and develop the expertise that can be used in the productive sector. Meeting those challenges requires in-depth re-thinking about teaching orientations (methods and contents) and about the potential target of demographic training supply.

II. UNDERSTANDING DEMOGRAPHIC BEHAVIORS

The first point refers to a widespread need that has been asserted by many authors in the past 15 or 20 years: the need to find the means of shifting from the *description* of demographic phenomena (which are traditionally placed at macro level) to *understanding* demographic behaviors and hence population dynamics. On the contemporary scene the need to understand has clearly influenced the evolution of concepts, observation methods, theoretical approaches and methodologic tools.

Understanding (or accounting for) demographic behaviors means that individuals, their motivations, and the decisions they take along their life course are taken into consideration. This requires a much greater wealth of information than can be provided by official statistics, on which traditional demographic analysis has been based. Individual decisions and behaviors, even though they imply various degrees of freedom and are based on psychological preferences, must be placed within the contexts in which they were generated. Contexts are extremely difficult to delineate and embrace in all their complexity, because they are made up of features such as institutions, standards, values, and economic constraints. Eventually, it becomes necessary to see inside the mechanisms through which ideas are transmitted, values are disseminated, and cultural and ideologic changes occur. Demographers soon find themselves stepping into the areas of other disciplines, adopting research strategies and analysis tools typical of other scientific fields. In some cases or to a certain extent, it also becomes useful to leave the familiar, safe field of quantitative analysis and take up the tools necessary to process qualitative information.

However, it must be admitted that significant progress has been achieved in the past few years toward *understanding* demographic phenomena. The possibilities to understand behaviors (at individual level) and processes (at aggregate level) have fast improved, because of the extraordinary accumulation of new data (particularly those derived from retrospective surveys at individual level, which made it possible to study aspects beyond the scope of official statistics, such as attitudes, motivations, personal behaviors), and of the huge improvement of computer processing capacities. Both factors, but especially the first one, were highly stimulated by the researchers' determination to systematically explore new research paths. Thanks to the availability of individual data, demographic analysis is no more confined to the macro level, where observation is largely supplied by data from official statistics.[10] In particular, reliable individual data are available on reproductive behavior and the family; such information is largely comparable among many countries, including developing ones, and makes it possible to go far beyond the macro level of usual demographic analysis and get access into the field of individual behaviors, sometimes even in a longitudinal perspective. The longitudinal observation of demographic events and processes, through which analysis can be framed round the notion of life course, represents the emergence of a high quality tool, which is sometimes hailed as a revolutionary one, because it affords an opportunity to comprehend the succession of facts in their chronologic order, which is essential information for approaching causal processes.

Other, equally significant progresses have been possible thanks to the advancement in statistical sciences and the development of a large array of new statistical methods. These were suitable for processing large masses of data and individual variables, both with merely descriptive purposes and with the aim to interpret relations and detect causalities, in a statistical sense, through the particular way in which information is organized or modeled (Coppi and Pinnelli, 1990): multivariate analysis (see Chapters 132 and 133), event history analysis (see Chapter 23), path analysis and causal modeling (see Chapter 130), contextual analysis, multilevel analysis, and latent structure analysis (see Chapter 24).

In short, the discipline has experienced an evolution along a general axis, moving from the macro-period to the micro-longitudinal (according to Antonio Santini's diagram, 1999) through two phases, a macro-longitudinal and a micro-period one, which chronologically more or less coincided. This substantially improved the capacity to explain demographic changes, by taking into consideration the behaviors and motivations of individuals. However, a real causal explanation is still out of reach,[11] because as it is appearing ever more clearly, it would also be necessary to understand the mechanisms through which the environment (in a broad sense and at all levels) influences individual decisions, and how individual behavior and decisions

[10] It is precisely the wealth of information that may have caused "overdevelopment of observation . . . at the expense of theoretical thinking and analysis" at a certain phase of the development of that discipline (Santini, 1999, p. 5).

[11] The suggestion (Billari and Rosina, 1999) that the event history analysis should be used in that way also deserves mention.

then combine into a collective result, in a circular, ever renewed process; in other words, it is necessary to understand how "interaction between the individual sphere and social transformation processes works" (Salvini and Santini, 1999, p. 54).

As they grew aware of the need for causal research, demographers were confronted with the limits of their tools of analysis. This difficulty, which is inherent to the cultural training of most population specialists,[12] urged them to seek for the methodologic and conceptual instrumentation necessary to explore causality and build interpretative theories of demographic processes which, in the past few decades, have been formulated, if not within other disciplines, at least with the contribution of knowledge drawn from other disciplines—to mention only Richard Easterlin's and Gary Becker's well-known demographic-economic theories or John Caldwell's theory on inter-generation flows, which is rooted in anthropologic conceptions (see Chapter 37).

The need for interdisciplinary cooperation stems from the very nature of the issues to be analyzed, the complexity of which cuts across disciplinary divisions that only reflect institutional needs. Surveys of actual problems require extremely varied abilities. Studies on the evolution of fertility imply a variety of knowledge—economic and econometric (when the economic factors related to individual behavior are to be brought out), sociologic (to understand the dissemination of the ideas and values that influence choice), and anthropologic (to explain the way the type of social organization determines specific normative responses in reproductive behaviors). That extensive base of knowledge must converge toward an explanatory framework:

> Marital fertility decline emphasizes the multiplicity of potential alternatives. At one time or another, every feature that is thought to distinguish societies with high from those with low fertility has been advocated as a cause. Most of the central ideas have at least superficial plausibility and some intuitive appeal. Moreover, they may be inextricably intertwined. Structural modernization and transmission of new ideas go hand with hand, and their impact on the economic role of children, on material aspirations, and acceptance of the principle of the birth control are likely to change in concert. As always in the social sciences, the separation of cause, from concomitant or consequence is difficult. Plausible post factum explanations for particular trends abound, but an understanding of causal mechanisms, such as would allow confident prediction is out of reach. Nevertheless, it is possible to confront these central ideas with the empirical mass of historical and contemporary research findings in an illuminating way" (Cleland and Wilson, 1987, p. 9).

Many more examples could be given by reviewing all the other areas of demographic studies. The study of mortality, and its corollary, morbidity, requires knowledge in health statistics, epidemiologic science, medicine, and biology. The study of various aspects of migration, excluding the measurement of flows and migrant characteristics, largely draws on economics and political science—even more so for subjects such as marriage, the family, the consequences of demographic aging, and the relations between population and development or between population and environment.

It appears that the results, as far as causal research and the production of interpretative theories on population dynamics are concerned, are still far from satisfactory. The thinking necessary to improve the situation must probably be done in several directions, seizing all the opportunities derived from the methodologic progress in the area of demography and statistics and "using the methods and survey protocols that the results of related disciplines may suggest, to break through the complexity and reach the multiform roots of demographic change."[13]

Most crucial is the exploration of possibilities of acquiring new abilities inspired from other disciplines, which could make it possible to build more powerful and relevant frameworks for interpretation of population dynamics. The capacity to manage nonquantitative information must also be improved, among other things, to reach better understanding of the part played by ideas in behavior changes, which can hardly be measured and expressed in terms of numbers. That extension of conceptual tools and survey methods, precisely because it would correspond to demographic issues, would not entail any distortion of demography, but it would provide the discipline with elements to reinforce its identity.

However, the issue of multidisciplinary competence is not easy to address. There are too many disciplines likely to provide contributions to demographic research (e.g., economics, sociology, anthropology, political science, epidemiologic science, medicine) for demographers to take up all the knowledge that may be useful to them. If researchers must allow the specific needs of their research to guide them in widening their abilities, the problem is in the design for training demographers and future researchers, particularly

[12] Those who, as John Caldwell wrote (1996, p. 319), seem "in their element when there are massive but limited data which must be used skillfully to throw light on a matter which really needs much more information to explain it fully."

[13] "Affiancando loro metodologie e protocolli di indagine che i risultati di discipline contigue possono suggerire, per 'ingabbiare' la complessità e le multiformi radici del mutamento demografico" (Micheli, 1997).

about the choice to be made concerning complementary training in other disciplines—which fields, with what divisions, and with what contents?

Providing such training, open onto the contributions of other disciplines while keeping its completeness in the specific methods of demographic analysis and the statistical knowledge, may help eliminate or at least reduce what has sometimes been denounced as the *intellectual isolation* of demography compared with other social sciences. This would have positive effects on population research and may contribute, through better communication with other researchers, to improving the prospects of demography in universities and the perception of its usefulness in developing social policies.

III. PARTICIPATING IN SOCIAL MANAGEMENT

Demographic changes are likely to have significant repercussions or even cause major upsets in social organization at local, country, or global levels. The dynamics of birth and mortality and the migration flows that partly result from them have triggered off mechanisms that are likely to produce deep changes in the structures of current societies and cultures. The unequal growth of the population in the various parts of the world and the large migration movements are affecting the cultural, political, and economic balance on a global scale. In developed countries, the decline of birth and death rates, as well as the resulting unprecedented aging of the population, are the preconditions of deep changes in the perception of the relations between generations and even in the concept of life and death. The first short-term repercussion is that the retirement system and the whole structure of social welfare are being questioned. In developing countries, although fertility rates are fast declining, the rapid population growth phase has not come to an end due to populations that are still comparatively young. The sustainable development issues resulting from that dynamic still remain to be addressed. The consequences of world population growth on the environment are still largely ignored, whether it is because of short-sightedness, the selfishness of the current generations, or faith in the future, although thoroughly unjustified. The problem cannot be removed by simply stating that environmental degradation results far more from the consumption level in rich countries than from the growth of the populations in the poor ones.

Beyond the major demographic changes and their large range of repercussions on social reality, the importance of knowing demographic trends at the local level is also evident, particularly in terms of numbers and age structures, knowledge of which are essential for sound administration (e.g., schools, hospitals, housing, labor). For all those reasons, it would be highly desirable for political decision-makers to better appreciate the competences of population experts and fully consider the findings of demographic research. However, the relationships between demography and policy-making have proved to be very difficult.

It is generally admitted among demographers (although much less so among policy-makers and the general public) that the sound management of a country's affairs requires political attention to the demographic situation, because it is necessary to find the means through which unwanted consequences of the population dynamic can be prevented or curtailed by making the necessary adjustments on the social level. Many also believe it is possible and useful to try (using permissible democratic means) to contain or redirect demographic dynamics to check undesirable trends—in practice, this would mostly consist of policies aimed at controlling or encouraging fertility and at controlling migration flows.

Social and demographic policies are admittedly never quite neutral, because they inevitably include a normative view of social relations. The extreme complexity of demographic causality often allows more or less ideologic interpretation of reality, and political interventions often are grounded on controversial theories. That is what happened when fertility control policies in developing countries enlisted international support, which was inspired by neo-malthusian conceptions on population and development relations that had never been fully proved, although it could have been justified on non-economic grounds. The delicate relationship with policy-making—which demography has in common with other disciplines such as economics—is made still more complicated by the bad reputation of demography in some countries, where in the past it became more or less involved with racist and nationalistic policies of fertility support. This induced many demographers to reject interventionism and instead engage in pure research, casting wary looks at population policies. Even in the best of cases and with the most honest purposes, decision-makers and population experts have to work in a minefield, striving to reconcile democratically made choices and efficient interventions, collective and individual interests, social justice and individual rights—squaring the circle.

Many examples could be cited to illustrate how difficult collaboration can be between population researchers and decision-makers (Colombo, 2000; Keyfitz, 1985). This problem reflects policy-makers' well-known reluctance to deal with unpopular issues on which consensus can hardly be secured and a set of reasons intrinsically related to differences about the ideas and objectives of decision-makers and demographers.

Political action is often demographically shortsighted because it considers only times far shorter than those needed for demographic processes. It is very difficult for a politician who wants to be re-elected in the short term to implement unpopular measures that would bring no perceptible benefit at individual or family level until decades had passed, whereas the sacrifices to be made would be immediate. The painful process of reforming pension systems is a good illustration of this problem.

The problem partly originates in a certain policymakers' cultural imperviousness to population issues, which can probably be accounted for by lack of training and information. Demographers must never neglect the popularization and dissemination of basic demographic culture through school curricula. At the university level, specific attention should be focused on the integration of population issues into the various channels of future administrators' training.

There are causes other than blindness, opportunism, and lack of cultural sensibility to politicians' difficult relations with demographers. The perspectives and objectives of politicians and scientists are very different. Scientists seek knowledge and may focus their research on issues of no immediate practical interest. Freedom in research is vital and is probably the best guarantee of the social usefulness of research in the long term. This does not preclude that some research topics may be of operational interest. However, serious research takes time, and the findings are often uncertain and provisional, whereas action requires certainties, or at least convictions, and short times. Researchers and political decision-makers have their own reasons. A demographer who has decided to study an issue that is important for social life must gather the necessary statistical documentation, design an appropriate methodology, develop indicators, analyze the results, and draw conclusions. This may take a long time, and the conclusions may be assumptions that require further verification. This is thoroughly normal because the truth about demographic behaviors and population processes, barely detected in the jumble of interactive relations that surround and condition it, is never simple, unambiguous, or conclusive. However, action requires safe knowledge to be made available at the dates imposed by political circumstances, which are usually much earlier than it is possible for scientific investigation. Otherwise, decisions would be taken (inaction itself is a form of decision) regardless of the demographic knowledge or by using it very badly, based on opportunity considerations that are sometimes quite foreign to the elements of scientific knowledge. Such considerations inevitably also have ideologic and ethic bases. This is no reason for demographers to shut themselves away in their ivory tower and refrain from expressing their opinions. In such cases, the issue of clarity and intellectual honesty must be addressed, as emphasized by Paolo De Sandre (2000) who, remarking that "as the means used for research and action are not akin or logically linked enough for them to be automatically integrated,"[14] recommended that "sharp attention be paid so that no ideologic or political principles seep into the scientific field, or "acquire scientific value"[15] (De Sandre, 1994, p. 453), to avoid a disturbing confusion of the different points of view and criteria of judgment.

However, it should also be remarked that opinions are not always optimistic about the possibilities of efficiently contributing to the solution to social problems. Among the most skeptic authors is Nathan Keyfitz, who mentioned several convincing cases of failed or even counterproductive policies to illustrate his point: "As a result, our discipline, demography, does not have enough means to account for the past, anticipate the future or imagine the choice and lines of action likely to ward off unpredictable, pernicious effects"[16] (Keyfitz, 1987, p. 399). A few years later, in a long article published in *Population Studies* (1996), Keyfitz explained his opinion as follows: "When social scientists make policy recommendations they often forget that life in society is more complex than any of the disciplines that profess to interpret it and that offer policy recommendation based on their interpretation. Legislation recommended by economists and other social scientists and passed by governments with the best intentions can lead to results that are the very opposite of those aimed at" (Keyfitz, 1996). He concluded: "I cannot provide a constructive answer in such cases. What I do know is that our knowledge as well as our

[14] "Le strade della ricerca e dell'azione non sono così contigue e consequenziali da essere automaticamente integrabili" (De Sandre, 2000).

[15] "La vigilanza affinché non si abbia un'intrusione surrettizia di principi di preferenza ideologico-politica nell'ambito scientifico o, viceversa, non si dia valenza scientifica indebita ai principi di preferenza" (De Sandre, 1994, p. 453).

[16] "Risulta così che la nostra disciplina, la demografia, non ha mezzi sufficienti per spiegare il passato, per anticipare il futuro e per escogitare scelte e linee d'azione in grado di evitare effetti imprevisti e pervers i" (Nathan Keyfitz, 1987, p. 399).

powers to do good are bounded and that moral dilemmas exist we cannot buy our ways off" (Keyfitz, 1996).

Such remarks, however pessimistic, seem truthful and convincing. Still, they simply suggest that there is a limit to human knowledge in every field, particularly in social sciences. They call on us to be careful by emphasizing how uncertain and provisional our knowledge is, but I do not believe that they provide enough arguments for us to neglect our duty to contribute to social policy as best as we know. Above all, they remind us that we should never forget that doing that duty necessarily implies a trade-off between the disadvantages of inaction and those of action based on imperfect knowledge. If necessary, the unfortunate experiences described by Nathan Keyfitz also remind us that it is necessary to invest more in designing procedures to assess the results of policies, so that their implementation can be monitored and gradually reshaped in a continuous process of adjusting them to the real necessities.

The aim to participate in social management has important fallbacks on the orientation of research, because in such a perspective, it is essential to take causal processes into consideration. This further stresses the necessity of progressing in identifying the causes and consequences of demographic phenomena. This also provides further motivation for paying attention to the dissemination of demographic research findings. Concerning teaching aspects, the objective of social participation requires a sound orientation and particular contents for the training courses for future demographers, who must get ready to contribute to that endeavor with scientific and professional abilities at various levels. In particular, for the needs of social policies, not only the *causes* of population dynamics should be taken into consideration, but also their *consequences*. This is still an issue of causal research, although presented in opposite terms. In a broader sense, all kinds of interactions between the individual sphere and social changes are of concern, and hence the teaching of the methods of integrating micro data into their context deserve a place of primary importance in the training programs. For issues that are of interest for social policies, although research on very specific subjects may sometimes prove useful, what is mainly at stake is research with interdisciplinary borders on complex issues, such as gender and population, the relations between population, development, poverty, resources and environment, population aging and the welfare state, mortality by cause and morbidity, migration issues, and forecasting techniques.

Eventually, although communication with policymakers and managers usually requires reorientation of research toward the current issues and sometimes demands results within shorter periods than are suitable for research, the problem is not insurmountable. Research must be carried out between the two opposite ends of a continuum, skirting the perils of either—that of the ivory tower, where it is perfectly free but in danger of being sterile, and that of applied research, which may become an obstacle to real progress of the discipline if too closely linked to current issues.

IV. DEVELOPING ABILITIES OF INTEREST FOR BUSINESS

The market evolution, the enlarging sizes of business firms, and increasing complexity of their environment make the need for statistical and demographic information, beyond the traditional economic and financial data, more pressing, in order to design more efficient production strategies and policies of business. The idea is to get to know the characteristics and dynamics of the potential pools of customers for their products and the possible means to prepare to seize opportunities or ward off possible setbacks. It is also important to keep informed on the evolution of the labor force in quantitative and qualitative terms for better management of staff, the human capital of businesses. Demographic methods (e.g., analyses by cohort, life tables) have been offered and disseminated for a sound management of the personnel of various categories or levels. Similar methods, derived from demographic research, can be useful to address other problems in business, such as those concerning assessment of the quality and longevity of products. This type of approach is of primary interest to big business, especially to firms with large numbers of workers and operating in large markets. However, they seldom show enough interest in such approaches to recruit experts in demography for permanent positions, and they instead usually call on external consultants.

The set of abilities useful for business is usually gathered under the concept of "business demography" and is part of a particular branch of demography called *applied demography*. The latter, according to the pragmatic definition by one of its most eminent supporters (Siegel, 2002),

> explores the practical issues with which demographers working for government agencies, private non profit organizations, and businesses deal. . . . Applied demographers may be called on to advise in planning the operations of local governments and businesses to the degree that demographic skills, knowledge, and perspectives are viewed as useful for such planning (p. xvii–xviii). . . . Accordingly we can characterize applied demography as a decision-oriented science concerned with aiding managers, administrators, and government officials in making practical decisions congruent with the policy, or goals of the organization, or of the institution for which they work (Siegel, 2002, p. 2).

In the area of applied demography, as well as that of business demography, the American experience remains most advanced; it is even unique in the world. In the United States, the demand for applied demographers is such that (Casacchia and Racioppi, 1992, p. 3) this branch of the discipline has become a kind of private industry, the activity of which consists of providing other lines of business with its abilities and products. The activity of the sector is also intense in scientific research and academic training and includes the setting up of scientific committees within the prestigious *Population Association of America*, organizing the biennial *North American Conference on Applied Demography*, producing *ad hoc* academic texts, establishing targeted programs in the major universities, publishing various specialized journals, including *American Demographics*, to which thousands of firms have subscribed.

In many other national contexts, the current conditions of the markets do not seem to encourage the emergence of a demand in business demographic abilities comparable with the American case, but knowledge and competences in business demography must undoubtedly be expanded, as part of a demographer's training, so that all opportunities for employment can be seized. Moreover, it is important to develop information programs in order to sensitize the productive sector on the abilities that will then be available. Concerning the field of public administration-oriented applied demography, I previously mentioned the themes that should be developed and showed the necessity to cover that field in academic training and in research.

V. TEACHING DEMOGRAPHY

To highlight the teaching consequences of the challenges that demography as a discipline must meet, an overview of the main characteristics of the current organization of population studies, as far as research and teaching are concerned, is given. The form and contents of the teaching at different levels depend on the present situation, which therefore must be taken into consideration, if only to question it.

1. A Brief Survey of the Current Situation

From the information available in the literature,[17] it appears that universities are the main institutions for demographic research and teaching. Although there are also external institutions and bodies of all kinds that cover a wide range of scientific and teaching needs, the training courses offered by extra-university institutions are usually short ones, and they deal with specific subjects—mostly as part of summer schools or retraining courses.

The organization and objectives of demographic training are closely related to the position of demographic research and teaching centers within universities. There are very few courses of study that are wholly on demography, unlike sociology or economics. It is widely agreed that the demand for demographers' specific professional abilities is too low for them to constitute the core business of any undergraduate university degree. As a result, the teaching of demography, particularly in universities[18] of the developed countries, aims at providing highly specialized professional training (i.e., graduate or postgraduate' level) or supplementing broader training curricula. In other words, the training is intended first to produce future researchers and teachers and second to impress awareness of population issues on the general culture of other professionals who are likely to work in one of the many fields in which the influence of demographic processes is to be felt. However, it seems that professional training for demography specialists, which was rare until recently, is being consolidated, as exemplified by the United States, where demand from the market exists, and by developing countries, although with different characteristics and objectives, where intermediate-level skills are in demand for data collection and management; techniques in the use of imperfect statistics; and for the implementation, monitoring, and evaluation of population policies.

This situation affects the place and status of academic centers dealing with demography, and it conditions their organization and, to a large extent, the orientation of their research. The departments and other autonomous university institutions that deal exclusively with the study of population issues are comparatively few. It is much more common to have the discipline nurtured and taught by researchers who belong to other departments—sociology, statistics, economics, geography, history, epidemiology, genetics, and others, depending on the alliances between disciplines that were formed and consolidated in the history of the different countries or universities.

However, the current world population trends, their influence on public opinions and political decision-makers, particularly through the action of interna-

[17] The contents of this paragraph are based on a general review of the literature conducted a few years ago (Maffioli, 1997) and updated for the Rabat Seminar on Demographic Training in the Third Millennium (May 15–18, 2001).

[18] Jane Menken (2001) emphasizes the existence of a few demographic courses leading to undergraduate degrees in the United States.

tional agencies, and the resulting wealth of studies and writings have given prestige to many demographic research and teaching institutions. The latter consequently acquired significant independence, particularly in universities whose organization is most flexible. The number of demography departments kept increasing, and many population centers, although they were only subdivisions within larger autonomous structures, then became able to issue university degrees at graduate or postgraduate level.

Besides the traditional forms of demographic teaching, a more flexible type of training is fast emerging, with a variety of courses to offer for different university degrees, and it is intended to meet very diversified needs. Undergraduate university training is being offered in some developing countries, although with rather variable curricula and contents, often depending on the teachers' interests and abilities. Short courses are also being developed; they do not necessarily lead to formal university degrees but aim at providing persons who are already involved in government activities or planning with abilities in various areas of population policy management.

2. Diversifying the Courses Offered

Teaching must keep in line with the developments and acquisitions of the discipline, but if it is also to meet the demands emerging from society, particularly from the labor market, it must also examine the profiles of the students that it is meant for, so that the methods and contents can be targeted more accurately, in function of their occupational objectives. I think that the main training needs, involving currently existing or emerging demographic knowledge, with more or less wide prospects and comparatively good chances of consolidation, could be summarized in four groups:

Training staff for scientific research and teaching
Training population policy specialists
Training professional demographers
Training policy-makers or administrators to make them aware of population issues (with demography as a training supplement)

Each of these points deserves considerations in terms of their characteristics, methods, and the main contents of demography teaching and how research can contribute to improving curricula. However, it is impossible to be specific about their concrete implementation, because the organization of courses and teaching programs is too closely related to the multiform structures of school and university systems in the different countries and to the demands on the labor market, which are exceedingly different from one country to another.

3. Training Future Researchers and Teachers

Future researchers or teachers, who are bound to guarantee the development of the discipline and continuity in the faculties, should be given comprehensive training at doctorate level. Although they may initially come from various backgrounds, doctorate students should be required to become perfectly conversant with the conceptual perspectives, methodologic instruments, and concrete issues specific to basic demography, but they should have in-depth study only in the sector in which they plan to conduct their future research activities. The gradual segmentation of demography, the mass of knowledge accumulated on a very wide range of heterogeneous issues, and the enrichment of the array of methodologic tools that are increasingly specific to the themes to be addressed make it impossible to cover all demographic knowledge in a single doctorate course.

Such specialization is all the more necessary as a multidisciplinary approach correspond to the very nature of many population issues overlapping *(at the cutting edge)* with other disciplines, that are bound to emerge and account for the most significant future progess of demographic knowledge. So that it is highly desirable for doctorate students to get the conceptual and methodologic knowledge from one or several related disciplines, which would be identified in view of their research interests. Besides the doctorates related to some single sector of demography (e.g., economic demography, historical demography, social demography, anthropologic demography), which will still be necessary, there must also be doctorates on in-depth study of complex thematic cores (e.g., population and development; aging and society; population, health, and health systems), and doctorates organized on different overlapping disciplinary sectors (such is the case of the sociology and demography doctorate created at the University of Berkeley).

Despite the huge diversity of possible doctorate training proposals, a few common characteristics can be identified. One of them consists of sharing a knowledge package that would include the methodologic core of demographic phenomena analysis, as well as in-depth knowledge of the demographic processes that historically have had a strong influence on humankind and their relations to social reality in the broadest sense. Another common characteristic should be the requirement of sound statistical abilities, particularly those commonly used in a wide range of research situations, such as individual data analysis (i.e., multivariate analyses), implementation of the longitudinal approach (i.e. life course studies), or the study of causal nodes (i.e., latent structure analysis); others are useful mostly for particular curricula (i.e., techniques for evaluation of social policy effects, population policy interventions, and development policy adequateness). One of the main keys to identifying the statistical abilities that should be common knowledge to all demographic doctorates lies in the strategic objective of the exploration of causal nodes hindering the comprehension of the relations between population and social dynamics.

The specialized training needed for areas of overlap with various other disciplines (e.g., economics, sociology, anthropology, epidemiology) must be tailored to the specific research interests of the students. On no account must the teaching of elements of related sciences give mere generalities, with no practical impact on demographic research; it must be focused on issues that are of interest for investigation in the area of population studies.

Because of the training of future researchers, most decisive progress has been achieved in the past few years. According to the comprehensive review by Jane Menken (2001), in the major universities a set of highly desirable circumstances exist—a high degree of specialization on themes that require vast multidisciplinary abilities; training courses that meet an extremely diversified range of needs; and a high degree of integration with related disciplines on themes of common interest (including the creation of joint doctorates, such as in demography and sociology at Berkeley). This set of circumstances is likely to guarantee subsequent disciplinary developments and is the precondition for further improvement in the academic status of demography. The conditions and constraints imposed on research and teaching programs by donors' political and cultural orientations, although not necessarily an element of restraint to disciplinary development, establish a link with the needs of society. In her analysis, however, Jane Menken wonders if sufficient attention has been devoted to fields of study that attract students from developing countries to American universities, and she deplores the focus of teaching and research on subjects that reflect only the teachers' cultural interests, possibly rendering American demography "quite individualistic and even, perhaps, idiosyncratic" (Menken, 2001).

European universities (Willekens, 2001) are going through a special phase of uncertainty because of the ongoing general reorganization of courses and reduction of public funding. Many new doctorate programs have just been created, and it is too early to assess their chances of success. Moreover, the number of students has decreased, as a result of population trends, and there is fierce competition between the different courses of study. From the rather special viewpoint of Italian universities, however, it is possible to measure to what extent the academic training of younger researchers has been more specific and comprehensive on the level of disciplinary acquisition than the self-taught type of training of previous generations. Various factors about the organization of training courses have contributed to that evolution, including intensified—if still insufficient—relations with foreign universities, which helps make the different types of training more homogeneous, at least at European level. However, much still remains to be done—and no wonder, considering that the contents of the teaching change along with research acquisitions and the abilities available on the side of the teaching staff.

In developing countries, where material and human resources for the training of population specialists, although still largely insufficient, have substantially increased in the course of time, there are many excellent centers that have the capacity to train researchers, particularly in the field of development. The main causes for concern is related to continuity of the resources necessary to keep up the close international relations that promote teachers' and students' mobility and to ensure constant adequateness between training programs and needs, by gradually incorporating new scientific acquisitions, new tools of analysis, and updating interpretation frameworks in the wake of disciplinary evolution.

4. Training Population Policy Specialists

Training in population policy is a type of professional specialization consisting of abilities that are in high demand in the international environment or in the developing countries that are implementing population policies but that are neglected in traditional demographic university training. The themes of population policies, particularly in their relations to the themes of development, involve practical needs such as pedagogic ones that are not the sole concern of academics. On the contrary, the major international organizations (e.g., FAO, ILO, UNESCO, UNFPA, and other specialized United Nations agencies, as well as other institutions) have experience and abilities that are far superior to those of universities (even taking in account the frequent cases of collaboration between academics). The training that such organizations provide on those themes to their staff or to agents in developing countries is probably more specific and specialized, more soundly rooted in the experience of concrete situations, and more effectively transferable into operational contexts than that likely to be provided through university training.

It is highly desirable for universities to take greater interest in the training of such types of professionals at various levels, as well as in scientific research on the difficult themes of policy evaluation, which in certain aspects are akin to causal research. In that area, it would be profitable to strengthen collaboration with the world of international organizations, in that it would make scientific research more sensitive to the various aspects of social demand, while greatly reducing the risk of improvisation, which occurs when, for market-related reasons, agencies, nongovernmental organizations, or consultants work without well-established knowledge or skills.

Ideally, this type of professionals should be able to do the following:

- Design development and social policies incorporating the population variables (numbers, structures, geographic distribution) and reckoning the interrelations between demographic processes and social dynamics
- Formulate, implement, monitor, and evaluate population policies that may have a wide variety of contents
- Prepare sensitization campaigns and dissemination programs on issues concerning population dynamics

To meet these objectives, specialists in population issues and demographic policies must have varied and extensive abilities in different areas. Their basic preparation concerning demographic knowledge and statistics must be complete and combined with the knowledge of facts and methods from other disciplinary sectors. In particular, they must have skills in socioeconomic and anthropologic areas, although skills in epidemiology may also be useful, considering the importance of health policies. The methods of causal analysis and all the techniques useful in estimating the effects of policies must be given primary attention.

Training in that area may be conducted at very diversified levels, depending on the specific objectives of professional location, ranging from the doctorate level, which is necessary for anyone who intends to deal with policy formulation and evaluation systems development, to the Master's level or annual specialization courses for those who intend only to work in implementation, control, and monitoring, and on to the levels of short courses with specific, limited aims, courses meant for those already active in a particular sector and who wish to acquire, update or improve special abilities.

To complete this overview of the type of training useful in what I have referred to as participation of demographers in social management, I must mention that professional demographers who work in collaboration with public bodies and local administrations for better management of public affairs must be given the abilities specific to the sector of applied demography, which is discussed in the next section.

5. Training Professional Demographers

Training professional demographers is better justified in the countries where the nonacademic labor market offers more opportunities for this type of professional qualification. However, with the globalization of markets, the growing complexity of the business environment, and the increasing average size of firms, the demand for professional demographers is likely to expand. A similar evolution can be expected concerning public administrators. It is therefore advisable that universities become prepared to meet this emerging demand in research, by reinforcing the study areas relevant to applied or business demography, and in available training courses. An appropriate campaign to popularize the professional values in demography, conducted by defining purposes and reinforcing linkages with the world of work, could also help in meeting the demographers' claim to better consideration for population variables in many fields of action, ranging from political and administrative ones to productive activities.

In the current training systems, the professional aspects of demography learning do not always seem to be clearly identified or addressed in any coherent way. As a result of a lack of specificity about the professional profiles of nonacademic demographers, demography is virtually never the backbone of any training course leading to an autonomous undergraduate university degree. This occurs even in the United States, although Americans have long made a habit of making professional use of demographic skills. More than 15 years ago, Nathan Keyfitz stated in one of his analyses that in his country "using demographic planning and data is a constant practice in all planning activities, to build structures, sell products, provide public and private services"[19] and that "for demographers from American universities . . . most job opportunities come from that sector."[20] The situation is very

[19] "L'uso di proiezioni e dati demografici è prassi costante in tutte le attività di progettazione per costruire strutture, vendere prodotti, fornire servizi pubblici e privati" (Keyfitz, 1987, p. 384).

[20] "Per i demografi sfornati dalle università americane . . . l'occupazione in questo settore costituisce uno degli sbocchi principali" (Keyfitz, 1987, p. 384).

much the same in other countries, particularly developing ones, where the lack of undergraduate or graduate training courses in the sector is all the more acutely felt because they could provide precious abilities that are very much in demand in ministries and public administrations.

Training of professional demographers could include all three university levels, depending on the objectives of their professional insertion, but the second one (e.g., Master's, specialty degrees) is most crucial. The contents of the learning should be the same as those of applied demography, the scope of which is very large (see Siegel, 2001), ranging from production of demographic estimates and forecasts for small areas to migration forecasts, to applications of demography to marketing, and to family demography. Comprehensive manuals have been published at the international level that could be useful in defining study programs.

The training for professional demographers, only recently introduced in the university system and still not well established, deserves special attention. Even in the United States, where demographers' professional abilities are more in demand in the labor market and their training more widely provided for than in any other countries, there is heated debate about how adequate the training provided by the university systems is in that sector of studies.

> It is not clear to what extent many of the programs are emphasizing new skills that are demanded, especially for students who will enter the nonacademic world. One such skill is carrying out high quality surveys—from design to implementation to analysis (quantitative methods at the cutting edge for the social sciences, qualitative methods, and the complementarities between quantitative and qualitative approaches). Another is the evaluation of intervention programs. A third is demographic forecasting. For the social science programs, there is almost no mention of biology or disease or morbidity, or reproduction, and surprisingly little on migration or urbanization, forces that surely will shape much of population change in the coming decades" (Menken, 2001, p. 13).

6. Training Policy-Makers and Administrators for Awareness of Population Issues

University training in demography is sometimes very short and summarized in a single course or a limited number of credits, when it constitutes a mere supplement to studies that are meant to train specialists in other disciplines. This occurs quite frequently because demography often has marginal standing in departments of economics, sociology, or political science. We may wonder if any appropriate thinking has ever been done to define the contents of demography teaching in such courses, which sometimes are wrongly considered of minor importance.

The complementary demographic training for specialists in other sectors deserves peculiar attention, because it plays a crucial part in emphasizing the importance of demographic factors, which is often neglected, in the various aspects of human activity. It is essential in such cases to avoid giving an image of demography as autonomous and unconnected with the teaching and scientific context in which it dwells. If demography were to keep aloof from the students' cultural interests, it would become marginalized from the academic mainstream.

The transmission of demographic knowledge in other teaching contexts, although limited to a few classes, requires special efforts in embracing and adjusting to the issues peculiar to the studies in which it is inserted. While selecting the contents, priority should be given to those that highlight interdisciplinary linkages, emphasize the interest in a demographic key to the understanding of events, and provide methodologic tools that are useful to the students' vocational training. That approach alone can guarantee that demography is harmoniously incorporated into various teaching contexts and that its teaching potentialities are emphasized on a professional and cultural level.

To sensitize professionals, policy-makers, and administrators to population issues, short training courses could be organized in which the linkages with the specific aspects of the beneficiaries' activities would be emphasized. The range of topics may be very wide, but a typical case of short training courses in developing countries is on the relations between development and population policies. Such training courses, which are still few but quickly expanding, have been promoted and organized by non-university institutions, ranging from the major international organizations to nongovernmental organizations, which have been carrying on significant work (in quantitative and qualitative terms) and have acquired greater abilities in the area than exist in universities.

VI. PRE-UNIVERSITY TRAINING AND POPULARIZATION

Before closing these remarks on the teaching of demography, it seems appropriate to include a brief survey on whether a demographic component is included in primary and secondary school curricula.

In general, demography is not a subject matter in pre-university training,[21] any more than the other social sciences, which are virtually never included in programs that are traditionally established in conformity with an essentially humanistic conception of human sciences. However, considering the pedagogic value of knowledge of population issues, it would be advisable to make some space for them in school curricula.

It seems that the high ethical value of training in population issues is more easily recognized in countries where in the past few decades the need for population policies intended to affect individual behaviors has been felt to reconcile society's general objectives with those of families and individuals. As stated by African researcher Daniel Mpembele Sala Diakanda (1997, p. 11), the main objective of studying population issues in schools

> is not only to raise awareness . . . of the problems and challenges with which one's community and the world at large are faced (particularly those relating to social production and reproduction), but also to give rise to firm commitment to contributing, individually and collectively, as far as possible and within the limits of everyone's sphere of responsibility, to solving those problems. The interest for population and development issues in higher education (whether as a subject for specialization or a complement to other areas) and in all the spheres of society, including the higher level of decision taking, as well as the expected impact on society at large, will be all the greater as sound population education has been provided at the lower levels of the school systems.

While recognizing that issues that do have ideologic aspects are extremely sensitive, I believe that the students of primary and secondary schools should discover (with proper objectiveness) the major themes of global population explosion, responsible procreation, sustainable development, respect for the environment, gender issues, fall in birth rates, and aging of the population.

Although not wishing to give the discipline a dominant place in pre-university studies,[22] in which it would have to compete with the equally important contents of other disciplines, the introduction of population issues may take place through allied disciplines such as history, geography, or biology, whose position in school curricula is established by a centuries-old tradition. The modern disciplinary orientations of history and geography, the programs of natural sciences that often highlight the importance of populations, and their structures and dynamics in relation to the environment, available resources, and sustainable development, are a good prerequisite for insertion of demographic issues into school curricula. Moreover, classroom work ignoring the disciplinary borders may also allow a better use of the pedagogic potential of demography, because its object (population and its evolution) is suitable for studies requiring contributions from many disciplines, including human studies and natural sciences.

Little information is available on the teaching of demography at pre-university level. Although there are great differences from one country to another, it appears that the possibilities, however limited, offered by school curricula are not always fully exploited, because population issues are hardly included in the teachers' training, awareness, or cultural interests.[23] If the possibilities of partial transmission of demographic knowledge through other disciplines are to be properly tapped, demographers and population specialists must actively undertake to update the training of pre-university teachers and produce the relevant teaching documents.

The need to recognize the formative value of demography in school curricula is only one aspect of the larger question of sensitizing public opinion in general as the basis for accurate appraisal of the social consequences of individual demographic behaviors and the necessary presupposition for socially agreed and democratically based population policies (Sonnino, 1987). Scientific popularization, which is not much practiced by demographers, should receive greater attention through more frequent and polished use of mass media and through publication of books in which scientific accuracy would be combined with accessibility and gratifying reading for nonspecialist readership.

Acknowledgment

This chapter was translated from the French version by Mireille Rabenoro.

[21] There are exceptions, particularly in certain African countries.

[22] Concerning Italy, the area that is more familiar to me (Lombardo and Maffioli, 1985), the debate on the question of teaching demography in schools was particularly heated in the 1970s and 1980s, leading to substantial convergence of opinions on the appropriateness and methods of transmitting demographic knowledge through adequate inclusion of demography in history and social sciences teaching. The approach was selected as preferable and more realistic than independently introducing the discipline, which was thought difficult to implement.

[23] An analysis conducted more than 20 years ago on curricula and manuals (Lombardo and Maffioli, 1985) showed that on that point, the situation in France and Belgium was outstandingly good in many respects, probably as a consequence of the more firmly asserted historiographic orientation of the *Annales* and a tradition of advanced human geography, into which demographic contexts and themes can be inserted more easily.

Advantages and Limitations of Demographic Software and Simulation Programs

ANTONELLA PINNELLI AND ANNA-MARIA BIRINDELLI

Department of Demographic Science, Università degli Studi di Roma "La Sapienza," Rome, Italy

Dipartimento di Statstica, Università degli Studi Milano-Bicocca, Milan, Italy

I. COMPUTING AND DEMOGRAPHY

The advent of micro-computers revolutionized working conditions in demography, as well as in other fields. However, the extraordinary spread of this device and the assiduity with which it is employed could undoubtedly not have happened without the development of software to facilitate its use and increase the performance of users, not only at the level of general computing tools but also at that of more specialized professional tools. Over the past 2 decades, a certain number of software packages that facilitate the handling of demographic data and phenomena have been developed.

In the beginning, it was a question of developing procedures to increase the speed of calculations or to make operations more user-friendly, such as facilitating the application of demographic analysis methods. Quite early, it became accepted that the computer could facilitate the teaching of demography due to the development of teaching software. Software producers immediately took this route, and software packages for teaching demography quickly came on the market. For example, the first version of Pyramids, one of the best-known programs, was produced in 1988. It is necessary to distinguish two types of demographic software: that which is mainly aimed at research or the practice of demography and that which facilitates the work of teachers.

The demographic software developed for the application of methods used well-known statistical and mathematical packages as reference models. There is more experience in these fields, and the packages integrated already have a solid position in the market of essential tools for researchers and practitioners. On the basis of this success, demographers are attempting to develop a new field of education and research, *computational demography*, which combines computational expertise with demographic skills, breaking with a past of considerable amateurism and little professionalism.

However, developing software for teaching and training in demography poses more problems than writing programs that improve the speed of calculations or that help in the application of demographic analysis. In addition to skills in computing and demography, it requires a solid knowledge of education. Because teaching and the production of manuals are an integral part of the work of many demographers, it could be said that teaching is a natural element of the culture of demographers. Although this statement is partly acknowledged, producing teaching software poses very specific educational problems. It opens onto a field of specific research that aims at establishing the reference framework for teaching software, whether in demography or in other disciplines. It is because of this specificity that we begin by devoting the first section of this chapter to software for teaching demography, before making as comprehensive an assessment as possible of the demographic software packages that are available.

II. USING SOFTWARE FOR TEACHING DEMOGRAPHY

Is computing useful for teaching demography? The transmission of knowledge requires a method of communication. There are different types of media for this, and each medium opens the way to a specific type of training (Olson, 1979). Each one makes a specific contribution to the development of human knowledge and intelligence. It is essential for a teacher to be capable of using the different media available and to evaluate what each new medium can provide in specific or additional functions compared with the traditional media already in use.

Each communication tool, if it is used correctly, can be a learning opportunity. A *multimedia* tool, capable of using several media that each make a different contribution to the development of multiple aspects of the intellect can enable students to approach the same issue from different perspectives. The computer largely provides these advantages, and it should therefore be possible to use it to the advantage of teaching, especially because it is dynamic, programmable, and interactive (Greenfield, 1984). As a result of these assets, it is possible to design software packages that

Are adapted to the various levels of knowledge and ability of students
Enable students to consider and test different possible solutions to a given question
Enable users to play an active role in the learning process
Allow a greater personalization of the teaching or learning process than traditional media (Pontecorvo *et al.*, 1989)

To take full advantage of the specific resources of a medium, it must be used correctly. The computer itself does not present any disadvantages, but its potential can be considerably diminished and even destroyed if its use is not adapted to its objective. Much therefore depends on the software. Great efforts have been made to produce quality teaching packages capable of promoting and guiding self-teaching and to create and facilitate the accumulation of personal knowledge in users. It is therefore necessary for teams of multidisciplinary experts to be involved at different stages in the creation of a teaching software package: experts in demography, experts in software development, and what is most frequently lacking, experts in educational communication. The best software benefits from comprehensive knowledge of educational issues and uses resources provided by computing in the most creative manner.

We have reviewed the opinion of demographers on the usefulness and the reasons for using educational software. Six different, but recurring, points of view have been identified.

1. No Need for Software Specific to Demography

A first point of view is that specific software is unnecessary for teaching demography, apart from some very explicit exceptions. However, students must learn to use statistical or traditional mathematical packages, because these normally make it possible to apply nearly all the methods of demographic analysis (Burch, 1992).

The use of computers and data processing software should be included in the training of demographers. Essentially, this is sufficient for rapid calculations, to transform results into graphs, to rapidly change entries (data or parameters), and to observe the influence of these changes on results.

The preference for a particular package depends on the type of demography taught. More mathematical tools are necessary for teaching formal demography, but statistical software and spreadsheets are essential for practical applications. Spreadsheets are a category of software that is particularly appreciated by demographers because it can fulfill different needs for a low investment in terms of training. According to this approach, using software is advantageous when theoretical teaching is extended with practical applications and when the appropriate tools available on the market are sufficient for this. Students can learn to use software themselves or during *ad hoc* lessons, and the demography teachers need only recommend the applications.

2. Using Nondemographic Software to Teach Demography

Demography teachers themselves can also learn how to use software and create examples of demographic applications for the students to carry out. This is what Antonella Pinnelli and Mario Porri (1989) proposed in a small handbook that enables students with little or no computing knowledge to start using a computer and Lotus-123 for carrying out the operations necessary for applying basic methods generally taught during the first demography lessons.

From a slightly different point of view, nondemographic software can also be used for teaching demography by using these packages to "change the demography to be taught" (Burch, 1992). The use of mathematical software, for example, can be made extremely easy and pleasant, with very few problems, by transforming the methods taught, by changing the approaches, and by making this first contact with demographic analysis a point of entry into more formal and mathematical demography, which has existed for a long time but which is not widely taught (Burch, 1992; Hakkert, 1985).

3. The Usefulness of Software Specific to Demography

Many analysts focus more attention on the use of software that is specifically demographic, thinking, for example, that it is preferable to illustrate the teaching of methods by using the software designed for their application. The pioneers of this idea were Nathan Keyfitz and Wilhelm Flieger (1971). It was developed further by Eduardo Arriaga (1992), who proposed a text accompanied by 45 worksheets, with which the application algorithms are developed. The theory is learned, and the means for its application are immediately available, avoiding the phase of algorithm development, which can cause problems and errors, while clearly specifying the stages included in the procedure and the formulas used in the worksheet.

Other demographic packages can be used to the same end, as long as their use is explicitly associated with the theoretical course (Srinivasan, 1992). However, we must avoid those that are based on a kind of black box, which allow students only to enter the data and to recover the results without any knowledge of the formulas or the algorithms used (Burch, 1992). Such packages should be excluded from teaching; they are useful only for tasks of execution. As stated by Peter Holmes (1988), the difference between teaching software and application software lies in the fact that in the former, the procedure remains obvious, whereas the latter aims for speed of execution and precision of results.

Whereas the first point of view was to invite students to take themselves from the theory to its application by experiencing the development of the necessary algorithms, this third point of view consists of immediately placing the students in a situation where they are able to carry out applications without risking error. The emphasis is placed on the teaching of the practical aspects and the main underlying concepts of the methods, the required data, the advantages and limitations of each method, the possible errors when the data do not match the hypotheses made during method design, and the analysis of results (Arriaga, 1992), instead of simply presenting the theoretical aspects and asking students themselves to transform the theory into operational algorithms.

These two points of view are based on different educational objectives. One of them is typical of the university approach and the training of researchers, and the other is oriented more toward professional applications. There is no doubt that this second type of teaching uses demographic software to enable decision-makers to undertake demographic analyses, including very sophisticated ones, and to obtain useful and correct results (Burch, 1992). In reality, this type of approach should not be relegated to second place in university courses because it introduces educational perspectives whose benefits are not limited to training practitioners and that can be just as useful for training researchers and teachers, without being exclusive of the first strategy.

4. The Usefulness of Complex Demographic Analysis Software

Regardless of opinion on this debate, most demographers are in agreement with regard to the specific usefulness of demographic software that enables the application of certain very complex methods of demographic analysis, which would otherwise necessitate the development of algorithms whose construction is well beyond the ordinary abilities of mere students. Students would never have the opportunity of applying these methods if *ad hoc* packages did not exist. The same applies to multistate models, micro-simulation, and complex models of the interrelations between population and development (Burch, 1992).

Moreover, such software is useful to a large number of researchers and scientists as well as to teachers and students. Regardless of the user, the undeniable advantage of these packages is that they discharge the user from dealing with vast series of calculations and from programming the implementation of the necessary algorithms. The user can then concentrate more on the input and output, on the necessary data, and on the results. If users gain all the qualifications required to work with the same rigor as professionals and to interpret the results, they could probably learn to apply more methods in less time than if they followed a traditional teaching method, which is a considerable advantage for their general training.

5. Simulation Software, a Pioneer of Teaching Software

By using a population projection algorithm, it is possible to understand demography better than through studying the issue in a purely theoretical manner. For example, it is possible to test the effects of the implementation of different hypotheses of fertility, mortality, and migration trends on population size and structure using real or imaginary populations (Burch, 1992). By using different simulation models that link population projections to different variables of economic and social development (e.g., concerning education, the labor market, savings, investment, health), it is possible to test the consequences of demographic trends on the problems that economic and social policies would have to resolve. With micro-simulation family models, it is possible to take into account the effects of different demographic changes on family structure and size. Simulation is a very useful tool for answering the "what if?" question, and the software packages that today facilitate its use contribute to the teaching of theory.

This was possibly the idea that most excited demographers as soon as they first had access to the computing tool, although at the time, it was still crude, difficult to access, and hard to use (as described in the pioneering studies of Étienne van de Walle and John Knodel in 1970), and this is possibly the area in which demographic software has developed the most.

6. Software Instead of Books

Some demographers have suggested that educational software packages are useful in teaching demography and could partially or totally replace books and teachers' handbooks. It is perhaps necessary to date this idea back to historical packages such as Popshow or Pyramids, which aimed at explaining one or more demographic issues by using only computer science. Going to the extreme of this reasoning, some authors have since suggested replacing the entire text of a traditional handbook with a package that explains and demonstrates all the demographic theories and methods and that provides all the useful aspects of online help. For example, the concept of *demographic hypermedia* (Leete, 1996) is associated with this idea. With this approach, we enter feet first into the world of so-called educational software.

However, the desire to replace traditional didactics with teaching software has caused skepticism and perplexity: "The best software is not a substitute for a good course in demography . . . it only facilitates the application of methods, techniques, and models" (Willekens and Hakkert, 1996), and "No software or hardware will replace well-trained demographers" (Gerland, 1992).

It is not completely unreasonable to consider that some subjects could benefit more than others from the possibilities provided by computers and that some of them could be dealt with completely or largely with the help of specially designed software, provided that it has clear advantages over traditional courses.

It seems necessary to repeat that traditional mathematical or statistical software such as spreadsheets and worksheets, as useful and sometimes even essential as they are for teaching demography, do not form part of what is generally known as demographic software. Demographic software must be specially designed for the application of demographic methods or for the illustration of theoretical courses in demography. Moreover, to be considered as educational, it must have, in addition to the characteristics that make up an appropriate demographic software for research or professional use, the characteristics that make it an educational tool fulfilling educational requirements, or it must be a substitute for a handbook or even for a teacher.

III. DEMOGRAPHIC SOFTWARE: INVENTORY AND CHARACTERISTICS

Despite the fragmentary and sporadic nature of the information available, it can safely be said that the development of demographic software has increased significantly since the late 1980s. At the end of the 1980s, the International Union for the Scientific Study of Population (IUSSP) considered that the time had come to make a first evaluation, and in 1990, it set up the Working Group on Demographic Software and Micro-Computing (WGDSMC). One of the tasks of this Working Group was to make an inventory of demographic software (Willekens and Hakkert, 1996). To make a list of the existing packages, the WGDSMC used the small number of inventories and reviews already available in gray literature or in published literature. This enabled it to collect information on more than 200 demographic software packages. Between August and October 1991, the Working Group sent a questionnaire by mail (followed, if necessary, by a reminder) to all producers and distributors of the demographic software packages identified. Of these, 90 replied by providing more detail and information on their software or packages that the group did not have (Willekens and Hakkert, 1996). In reproducing the inventory here, we excluded programs concerned with data collection, storage, and publication and with cartography or presentation of data that, although useful for analyzing demographic data and in some specific cases created to that end (e.g., Integrated System for Survey Analysis [ISSA] undertook to memorize and analyze the data from the Demographic and Health Surveys [DHS]) are not really demographic packages. Seventy-two packages remained that could be listed in the category of interest. With the impetus of the Working Group, updates of the initial inventory by the WGDSMC were then published in *Population Index* up to the year 2000, describing the new versions (updates or additions) of these packages or of new programs. Since the second half of the 1990s, the production of demographic software seems to have left its first phase of amateurism. The tendency to place demographic packages in circulation outside of the circle of initiated scientists was consolidated at this time. Two important factors contributed significantly to acknowledgment of a wider circle of potential users: first, the near generalization of a work station, Windows, now largely considered a standard, and second, the increasing readiness to disseminate advertisements or the products themselves (i.e., freeware) at the global level on the Internet. As is the case in other fields of study, the tendency to provide information online on the production of new programs or on updated versions of existing programs has spread. The Internet makes it possible to visit sites that include sections dedicated to demographic software (e.g., www.nidi.nl, www.un.org) and to use all kinds of hypertext links that generally appear in the numerous sites of national and international organizations and universities working in the field of population studies. Twenty-eight additional programs have been added to the inventory made by the WGDSMC, which is used as a base here.

Table 141–1 provides the list of these programs and some information on the main characteristics of the demographic software. The information included is the acronym of the software or package, names of the authors, version, year of publication, type of distribution, type of user interface (i.e., guidance by menu, use of commands, or a sequential command procedure called *batch*), the availability of online assistance, main type of use (i.e., education, research, and application), the main fields of application (e.g., projection, macro- and micro-simulation, indirect estimates, life tables). Table 141–2 summarizes all of this information.

1. Production Rhythm

The chronology of the appearance of these different packages on the market has been subject to considerable discontinuity. The number of packages increased rapidly between 1986 and 1991, when the WGDSMC was established, only to fall again quite significantly. Because of the survey, it was possible to verify the existence of a far greater number of software packages than were detected by the later updates published in *Population Index*. This highlights a certain lack of dynamism on the part of producers to promote the distribution of their products among potential users, perhaps due to the amateurism of many of the packages. Nevertheless, almost one-half of the packages have been updated once or several times, a fact that bears witness to a certain commitment to maintaining and improving these tools, probably linked to the fact that the number of users was not all that low.

2. The Producers

The largely proven amateurism that reigns in this sector can be seen in the copyright status and the distribution method. Most of the packages listed are in the public domain (43%), a low percentage (7%) of them are shareware, and only 25% are commercialized. Moreover, no information at all is provided on this subject in 23% of cases. However, the fact that a package is commercialized does not provide any information on its real cost because numerous international organizations are committed to providing technical assistance and professional training to staff in many developing countries, and they provide the software free of charge or at a low cost. The fact that some software is available for sale confirms the professional nature of the product.

3. Technical Characteristics

The technical characteristics provide indirect information on the level of update and sophistication of the software. With regard to communication between the program and its user, weighty procedures such as the sequential command system (i.e., batch) linked to programming within the computer are rare (7%) and generally only relate to old versions. Most programs (84%) are installed in interface with a menu, which makes it possible to select commands on the screen.

Online help is missing for 47% of the programs listed here. Among those that have it, the context-sensitive system is the prevailing one, usually as online help, or default responses are displayed with the help of a prompt from a menu of help subjects (usually by pressing the F1 button). Some packages provide help windows that can be opened at will. This is currently considered as the most modern form of help. It enables great flexibility in navigation and is generally organ-

ized in a hierarchical and structured manner according to level (e.g., global, context, methodology).

4. Targeted Users

Programs are distinguished according to whether they are intended for teaching, research, or the application of demographic methods. About 15% of the programs have been designed to respond simultaneously to all these needs, and 44% have been designed to respond to various combinations of these three targets, with the combination of application and research (26%) being the predominant one.

TABLE 141–2 Demographic Software According to Year of Publication, Distribution Type, User Interface, Online Help System, Major Use, and Main Objective

Year of publication	%	Distribution type	%
1986	3.5	Shareware	4.6
1987	5.7	Public domain	44.8
1988	10.3	Commercial	20.7
1989	12.7	Public domain and commercial	2.3
1990	11.5	Information unavailable	27.6
1991	33.3		
1992	8.1		
1993	1.1		
1994	4.6		
1995	3.5		
Information unavailable	5.7		

User interface	%	Online help system	%
Batch	8.1	Context sensitive	26.4
Command language	5.8	Access to online help	15.0
Menu-driven	83.9	Both	2.3
Batch and command language	1.1	All help online	56.3
Command language and menu	1.1		

Major use	%	Main objective	%
Teaching	16.1	Population projection	19.5
Application	9.2	Retro projection	2.3
Research	12.6	Integrated projection	9.2
Teaching and application	10.4	Integrated projection and planning	8.1
Teaching and research	6.9	Macro-simulation and development	5.8
Application and research	26.4	Indirect estimates and other analysis techniques	10.3
Teaching, application and research	18.4	Biographical analysis, transitions, and multistate tables	11.5
		Model life tables	10.3
		Micro-simulation	8.1
		Fertility and family planning	5.7
		Education	6.9
		Integrated packages	2.3
Total number of programs	87		

5. Software for What Purpose?

Projections are dominant (34%) in the issues and problems dealt with in demography. The available programs are mainly aimed at long-term projections. Most of them are designed to make analytic population projections (i.e., cohort component method) for a given country or territory or for a group of countries, territories, or regions, whose results are aggregated *ex post* to provide more general results. Generally, the input (i.e., mortality, fertility, and migration) and output options are very detailed, and the methodology is traditional.[1] With other software (11%), it is possible to make projections on specific categories of the population, such as the labor force, students, or health workers.[2]

With regard to the wider subject of relationships between population, policy, and development,[3] it is possible to distinguish the programs that associate traditional projections to a development model (3%) and macro-simulation programs (3%), which by allowing multiple scenarios, show how different hypotheses can affect socioeconomic results.[4]

[1] Richard Leete's People program includes numerous traditional procedures, among which is the possibility of using the Brass models for mortality and fertility. For an evaluation of numerous projection programs, see McGirr and Rutstein (1987), Hermalin (1988), and McMurray (1996).

[2] Projections for these subpopulations can be carried out within general projection programs (e.g., Meds) or by specific programs that are based on the input and output of general programs (e.g., Hrp and Lf-Emp, linked to Nproj, and Workers, linked to People).

[3] Bogue (1996) has evaluated these programs. Arminger and Galler (1991) have compared Lipro and three other programs.

[4] These programs (e.g., Pdpm and Game, developed by the United Nations; Tm1, developed by BIT) frequently have the objective of training specialized staff in developing countries.

Other software (37%) is distributed more or less equally between the following four subjects:

1. Indirect estimates of mortality[5] and fertility, associated (or not) with other methods of analysis such as procedures for age adjustment of demographic curves
2. Analysis of transitions and multistate tables
3. Procedures for creating and analyzing model life tables (all causes or by cause)
4. Micro-simulation (particularly with regard to family)

Other software packages cover subjects linked to the specific analysis of fertility and family planning (2%).

Some software packages (20%) have been specifically designed for teaching. Some of them cover specific subjects,[6] but others have multiple functions and cover the different areas included in a basic course,[7] and there also are macro-simulations.[8]

From the prospective point of view, significant progress could be made if a general effort was made to integrate the functionalities of the software produced regarding different research objectives to enable users to develop their own analyses in sequences or in parallel. The Futures Group provides an interesting example of the combining of programs placed separately on the market between the 1980s and the beginning of the 1990s due to the creation of new procedures. The Spectrum program is a succession of models of population policies used for projecting requirements for reproductive health and the consequences when these needs are not fulfilled.[9]

[5] This category includes packages that can produce indirect estimates and different types of projections at the same time (e.g., Mortpak, developed by the United Nations; Cairo, designed by M. Sivamurthi; MCPDA, developed by the Westinghouse Institute of Resource Development).

[6] For example, Fert by the Applied Population Laboratory (University of Wisconsin), Piramides Animées by Henri Leridon (INED), and Pyramids by HPN Technologies.

[7] For example, Popshow by George Immewahr, Pas/Rup by Eduardo Arriaga, Prodemog by Luciano Petrioli, and Ifs by Barry Hughes.

[8] JAVA Demography, which simulates exponential demographic growth, enables the user to modify the characteristics and the dynamics of the population and to see the long-term effects. The objective of the World Health Chart program is to visualize the development of world health; it makes it possible to use international data for training, lobbying, and generating hypotheses. The PopTrain software (version adapted to Windows by NIDI in 2001) is a program for teaching demography in secondary schools.

[9] The models included in the Spectrum system are DemProj, FamPlan, AIM (AIDS impact model), Rapid (resources for the awareness of population impacts on development), PMTCT (prevention of maternal-to-child transmission, NewGen (reproductive health for adolescents), and BenCost (financial benefits and costs of family planning programs).

IV. CRITERIA FOR EVALUATING DEMOGRAPHIC SOFTWARE

Evaluation is an essential and very delicate phase in the production of any software. It aims at ensuring that the objectives have been fulfilled. The criteria proposed at the beginning of the 1990s by the IUSSP Working Group, which was greatly inspired by the evaluation studies of the late 1980s, are still relevant today:

Range: What can the software do? Does it incorporate significant variants of the method provided? Can it deal with different data structure?

Portability: Can it function on different machines? Does it include interfaces with other software?

Documentation

Exactitude and precision: Is the software likely to lead to incorrect results with bad data? Does it include warning systems?

User-friendliness

Effectiveness: Is the calculation time reasonable?

Help: Does the distributor provide appropriate assistance if there is a problem?

Beyond the general evaluation criteria of demographic software, specific requirements for teaching software must be emphasized. We focus more on this topic in the following section.

1. Evaluation of Teaching Software

For software to be considered as useful for teaching, it should fulfill a certain number of basic conditions. It should be very easy to use, it should not pose more problems than the subject covered would normally pose, navigation within the software should be easy, and the user should always be informed of the possible options available. Effective reactivity must be guaranteed, and the software should be capable of neutralizing any potential user errors (e.g., typing errors during data entry). Good communication should be established with the user, the screen should not be overburdened, and the text should be in large characters, legible, and accompanied when possible with good-quality graphics. The possibilities provided by micro-computing should be employed to their full potential by using animation to clarify many of the concepts presented as graphics, for example. The exactitude and relevance of the content should be verified. Moreover, the educational objectives of the subject proposed by the software should ensure, through the quality of the interaction between the student and the software, the possibility for the student to play an active role and to have control over the learning process.

To make a comprehensive evaluation, it is also necessary to test the results of the use of the software on the targeted population. When we wish to evaluate software that has been designed for teaching, it is essential to consider what can be achieved before and after the computer by other methods of communication. Why use a computer? Does it provide additional help to students in acquiring skills or a certain qualification? For example, there is no benefit from using a computer to present long sequences of linear texts; it is much better to read a book. The crucial point for investing in the design of teaching software is whether it will provide a real advantage over traditional courses and manuals. Such an advantage can be educational or economic and organizational. For example, it can enable students, aided by a good teaching program, to learn a series of basic concepts necessary for a university course, reducing the requirement of teachers to a minimum of intervention on some aspects. Another, more specific evaluation criterion is based on the exact subject of the software in question.

2. Computerized Tutoring

Software aimed solely at teaching objectives can be separated into two categories: tutoring and simulation. In the first case, they are self-sufficient teaching tools, although sometimes this condition may not be entirely fulfilled. There is a lack of effective teaching software that gives a sufficiently active role to students and that personalizes the learning process through knowledge testing or, better still, "problem solving" or "world in reduction" experiments. This means that the progress of scientific research in the field of teaching software has not been used to its full potential by the demographers and developers who design demographic teaching software.

It is not known whether these programs have been greatly used in teaching or whether it is possible to evaluate the impact on students' preparation and the manner in which teaching is organized. Such an evaluation is desirable because it would make it possible to establish whether new resources should be invested in developing programs of this kind. Multimedia teaching is expected and desired. However, the necessary resources must be invested to take full advantage of the possibilities available, because computers are not themselves a guarantee of a better or a cheaper education.

3. Simulation Software for Teaching

Among the macro- and micro-simulation software, some programs have explicit teaching objectives, and others are halfway between this objective and others. Their importance for teaching demography is undeniable because it is possible to experiment with the relations between demographic changes and, for example, the size, structure, and dynamics of families; the size, structure, and dynamics of the population; educational needs; and demand for employment and health structures. The educational aim of these packages is, however, not clearly visible in their formulation. Greater interaction with experts in education and computing involved in the development of simulations in teaching would help to make these programs more relevant to the targeted objectives.

Demographic projection software packages are the easiest ones to use with complete self-sufficiency. This is an extremely useful characteristic in the professional world and in the context of teaching.

Application programs offer considerable advantages, as much for researchers as for professionals. To promote greater use of them, more attention should be paid to encouraging autonomy and to making them easier to use.

The authors responsible for developing teaching software should include characteristics that facilitate learning and use, including the following:

Ease of navigation (e.g., possibility of going back, accessing the main menu, using a glossary, going to a given page)

High-quality graphics and animation possibilities

Pages that are not overburdened and enough of them for a presentation (i.e., to understand a concept, it is not necessary to go to a new page; a new screen should correspond to new content, even if it is linked to the previous page)

Help at different levels, as much with regard to procedures (what do I do next?) as to methodology (explanation of formulas) and to content (what is this?)

Providing the possibility of evaluating the results (by giving a few examples of results that have already been interpreted)

Allowing experimentation with futuristic or improbable hypotheses

CONCLUSIONS

The production of demographic software appears to have entered into a professional phase, in which it has become possible to consider it as a new specialization in demography, *computing demography*, which is deserving of more human and financial resources. Whoever is interested in producing software now has access to the necessary information for identifying the international network of potential users, as well as what already exists on the market, and is aware of the essential conditions required and the experience already acquired on the subject in other fields.

Statistical and mathematical software are a natural point of reference for demographic software. Educational software should also be included when it constitutes demographic software for teaching. Each of these disciplines (i.e., statistics, mathematics, and education) have great experience in software design and have accumulated ability and expertise that needs to be added to that which we already possess to be able to produce tools that take full advantage of the latest developments in this area. A new field of research is now open in software production, testing, evaluating performance, and monitoring their evolution. All this requires time, will, and patience, essential virtues if we wish to produce software that is easy to use, that functions perfectly, and that potential users are aware of and can easily acquire (Pinnelli, 1994).

Centers of Demographic Research and Teaching: Origin, Development, and Characteristics

DIONISIA MAFFIOLI
Università degli Studi di Bari, Bari, Italy

A study of the centers of demographic research and teaching can illustrate the place this discipline occupies at the heart of the social sciences and enlighten us on the value, both pedagogic and political, accorded to studies on population as a key to understanding social relations and dynamics or as a means of influencing their evolution. The characteristics of these centers; their scientific, pedagogic, and operational activities; their place within or outside the university; and their integration in all kinds of public or private structures reflect the contribution of demography to scientific and social development and the expectations of the scientific community and of society. Naturally, contributions and requests are strongly interactive and variable in time and in space. They are closely linked to demographic events and to currents of opinion that they provoke, and, in the matter of teaching, and they also depend on opinions about the aims and content of school and university education. An examination of the origins and the current situation of the centers of teaching and research in demography is an exercise that is more stimulating and instructive than could be imagined *a priori*. The inventory of existing institutional and human resources in the matter of demographic research and teaching constitutes a strong base for thinking about the future of the discipline in a moment of its history that can appear as a critical turning point.

To study demographic centers of research and teaching and their activity at an international level, it is necessary to have access to a set of basic information whose collection demands patient and costly labor, exceeding the capacities of an individual initiative and demanding the mobilization of institutions and specialized agencies. Among the latter, special mention must be made of the Commission for International Cooperation in National Research in Demography (CICRED), an institution that, to promote scientific cooperation between countries, has adopted the goal of identifying the existing potential at the international level in the matter of research and teaching of demography and therefore of establishing and updating a repertory of centers. Between 1994 and 1997, CICRED realized an almost complete census of demographic centers, along with a special inquiry on the research programs of many of them (Gendreau and Huix-Adamets, 2003; Collomb, 2001). This allowed CICRED to establish a directory of centers of demographic studies and researches (Annuaire des Centers d'Etudes et de Recherches en Démographie [ACERD]), of which CICRED has already published two editions (1995, 2000). Since then, the directory has become available on the net and is continuously updated. It recent years, more and more centers have created their own web sites, greatly facilitating access to detailed information about their features, functions, activities, and scientific resources. The tools for the construction of an almost comprehensive picture of the situation are therefore available.[1]

Less than 20 years ago, the situation was quite different. The information available was scanty and incomplete, and specific literature was rare. This was partly because questions about scientific and pedagogic organization are not very attractive for researchers, but also because of the difficulties to be overcome to gather a sufficient documentation. Only recently have different international institutions and some researchers within them fully interested themselves in the subject and consequently arranged for the collection of information. A series of initiatives were organized (e.g., seminars, meetings, publications, directories) aiming to analyze and confront the existing situation in different parts of the world (Baldwin and Roy, 1997; Baldwin, 1996, CICRED-UPAS-ECA, 1995; CICRED, 1990, 1989; ECE, 1992; Tabutin, 1988; Jain, 1986; Cagiano de Azevedo, 1985; Martine, 1985; Farooq, 1985; De Graft Johnson, 1985; Federici, 1974, 1973, 1969, 1968, 1966).

The analyses presented here are based on these historical materials and on information provided by CICRED's ACERD. The whole of the documentation examined permits us to assess the existing structures in the field of population studies and suggests an initial general conclusion. The positioning of demography in the university structure appears quite varied and multiform as far as thematic and disciplinary links, teaching programs, and the ties with other disciplines are concerned. In a similar way, outside the university, studies of population or some of their aspects are developed in extremely varying contexts. Thanks to their vast thematic range, as much of a social nature (sociologic, anthropologic, cultural, economic, geographic) as biologic (epidemiologic, genetic, sanitary), population studies are combined with a number of other disciplines in centers devoted to research, teaching, scientific promotion and dissemination, collection of data, or the direction of programs of intervention in different sectors (e.g., birth control, health, family). From the juridical administrative point of view, these centers can be equally private companies or public enterprises or administrations; have a local, national, or international vocation; and be autonomous or depend on larger organizations. The research that they practice can extend from pure research to more or less applied studies to so-called operational research. The classic example of this latter category, more common in developing countries, is that of centers of family planning or of reproductive health, where scientific interest (when it exists) is quite marginal in relation to operational objectives. The extreme heterogeneity of demographic centers is accompanied by a marked geographic differentiation in numbers and characteristics.

This variety of forms and positioning, as much of the discipline as of the centers dealing with it, is an outcome of the history of the academic and scientific development of demography and of demographic events, which at different periods have aroused the interest of researchers and the preoccupations of politicians at the international or national level. To better understand the current situation, it is useful to retrace the origins and history of the principal institutions all over the world that have devoted themselves to the study of population. Only the main features of the narrative are addressed, with attention drawn to events that marked fundamental changes, because it is very difficult to summarize a multiform and geographically diversified history in a few pages.

[1] Without wanting to *a priori* define the notion of "demographic center," which would engage discussions as complex as lacking of general interest, criteria must be established for the collection of objective information and their quantitative analysis. The definitions adopted for the establishment of any repertory will therefore be specified when they are referred to.

I. THE ORIGIN OF INSTITUTIONS DEVOTED TO DEMOGRAPHY

1. From the Origins to the Foundation of IUSIPP in 1928: A Long History

Born with statistics, in which population was the first and the principal object, demography was for a long time considered as one of its branches. From the point of view of theoretical reflection, the birth certificate of demography can be seen in the work of Johann Peter Süssmilch (1707–1767), which constituted the first global and organized approach to the subject (Livi, 1940, p. 5). However, recognition of the new discipline's autonomy at an academic and pedagogic level appeared much later, in the second half of the 19th century. The first general assertion of the unity and independence of population studies dates from the first International Congress of Demography, organized in Paris in 1878 by Jacques Bertillon, Arthur Chervin, and Pierre-Emile Levasseur.

This Congress, which assembled researchers free of all official representation of their respective governments and which marked the adoption of the term *demography*, forged in 1855 by Achille Guillard for the designation of the new discipline, aimed at providing an exclusive space for the discussion of all subjects related to the "mathematics of population." Until then, these subjects could not be treated systematically except in the context of International Congresses of Statistics.[2] In this framework, population questions had been able to play a primary role, but only through the intermediary of official government representatives of participating countries (IUSSP, 1985; Dupâquier and Dupâquier, 1985). However, contrary to expectations, the Congress of Paris did not lead to the creation of a permanent organization of researchers on the subject. For a long time, the meetings of the new international association of statisticians, the International Statistical Institute (ISI), founded in 1885 with exclusively scientific aims, remained the only important forum where themes of population could be discussed, an increasingly unsatisfactory solution, because the field of statistical interests and methods was rapidly growing and the space left to demographic debate proportionately decreasing. During these same years (straddling the 19th and 20th centuries), demography had also found its space within international congresses of hygiene (which took the name of "Congress of Hygiene and of Demography"). This new alliance opened up broad horizons of research and gave a new impetus to the study of the biologic foundations of the demographic evolution, according to the openly naturalist vision of social phenomena that prevailed at the time. However, this sort of "strategic withdrawal" (Dupâquier and Dupâquier, 1985) translated the difficulty of the evolution of population studies into a disciplinary individuality.

The initial strong link with statistics and the proximity of interests with certain biostatistical sciences were not exclusive. The intrinsic multidisciplinary character of the object of study (i.e., population and its issues) favored the plurality of convergences and gains. If contiguity with the biostatistical sciences was linked beyond certain affinities of content and interests to a naturalist conception of the origins and future of human populations, seriously underevaluating the historicity of their evolutions, it can be affirmed that there also existed, since the beginnings, an even more intimate relation with the social sciences (Sgritta, 1994; Scardovi, 1994; Sylos-Labini, 1987). Demography had taken form within a melting pot of ideas common to all the social sciences, drawing inspiration from the same positivist conceptions, by observing populations and societies in the same theoretical perspectives, exploiting the same basic statistical materials with the same methods, so well that "the origins of demography and sociology, besides those of economy and statistics, appear, from several points of view, as essentially coincidental"[3] (Sgritta, 1994, p. 215), and for a long time, the disciplinary perspectives were hardly distinguishable.

Placed at a crossroads where the scientific contributions from different spheres of knowledge converged and drawn from the fields of human sciences and natural sciences, population studies attracted personalities from very heterogeneous cultural and disciplinary backgrounds and interests. The range of scientific interests of researchers who, until the first decades of the 20th century, can be placed in the category of demographers or who made important contributions to the development of demography is eloquent. Among them can be counted mathematicians, statisticians, actuaries, economists, and a number of sociologists, anthropologists, geographers, biologists, hygienists, geneticists, physicians, and epidemiologists. Since the beginning, the field of demographic research extended to current canonical themes (e.g., reproduction, mortality, mobility)—to all aspects that attach demographic facts to the biologic substrata on which they are based and to the social tissue of which they are an expression.

Until the end of the 1920s, there did not exist scientific organizations devoted to demography, nor was this discipline the object of independent university teaching. Most of the promoters of demography, whatever their cultural training, held administrative responsibilities consisting of coordination and management in the field of official statistics. It was to them, more than to university academics, and to the efforts they made to resolve concrete problems of analysis and interpretation of data, that the first theoretical and methodologic advances were due. Teaching of demography during the entire 19th century and the first 2 decades of the 20th century, when it did find a place

[2] The first of these Congresses was organized in 1853 in Brussels by Adolphe Quetelet under the patronage of the Belgian government. It had the specific object of harmonizing national statistics between themselves. This requirement of international cooperation, which followed the birth of the first national offices of statistics (since 1827) and the first national scientific organizations in the field (i.e., the Manchester Statistical Society was the first one founded in 1833, while the Statistical Society of London was founded the following year in 1834) gave way to numerous international conferences of a semi-official nature. The rejection in 1878 of this initial form of international organization of statisticians arose from difficulties born from the ambiguity of governmental positions with respect to the resolutions adopted in the frame of the conferences. In 1885, a society of an exclusively scientific character was founded in London. This was the International Institute of Statistics (ISI), which renewed different forms of international collaboration on new bases. The ISI published international statistics of population until 1939, from which date this function was filled by specialized agencies of the League of Nations, which itself was soon replaced by the United Nations Organization.

[3] "Le origini della demografia e della sociologia, come peraltro quelle dell'economia e della statistica, appaiono, sotto molteplici riguardi, sostanzialmente coincidenti" (Sgritta, 1994, p. 215).

in university studies, was done in the context of other disciplines to which demography was closely linked, because of the history of its disciplinary evolution. In particular, the teaching of demography existed within the faculty programs or schools teaching statistics. According to the conceptions of the period, statistics was also retained as a fundamental element in the economic and sociopolitical or geographic training. Instruction of demography could thus be found in certain programs organized within these disciplines. This strong integration between statistics and demography at the level of teaching has left traces in the university texts and manuals of the period. The chapters dealing with statistical methods and their applications are generally accompanied by a substantial discussion of demographic themes.[4]

It was in 1927 that the emancipation of demography and its separation from statistics really took shape at the international level during the organization of the first World Population Conference in Geneva. This initiative was taken in the context of malthusian preoccupations. The idea of organizing the Congress came from Margaret Sanger, an avant garde activist of the birth control movement, wishing to prove that the growth of the human population would be "creating social, economic, and political situations that threaten to profoundly alter our present civilization" (IUSSP/UIESP, 1985, p. 4). Despite this link, the Congress did not have a militant nature but was based on criteria of rigorous scientific neutrality. On the basis of agreements made on the occasion of the Geneva Congress, a permanent organization independent of governmental institutions was founded in 1928: the International Union for the Scientific Investigation of Population Problems (IUSIPP, now IUSSP), which set itself the mission of promoting and coordinating population studies in all their forms. This organization became the intellectual center of demographers and population specialists throughout the world.

This genesis of an institution with strictly scientific aims evokes the risks always underlying the intersection of scientific studies and preoccupations of a social and political order—legitimate and even appreciable preoccupations in principle, but carrying a serious danger of non-objectivity. The study of population can with difficulty be ideologically neutral, as is nature. The orientations of research are often suggested by the existence of contingent problems, for which solutions can be sought in harmony with considerations of an ethical or political nature, and it is for the rest quite licit and useful that the results of research offer elements for a governmental action founded on scientific knowledge. The entire history of the disciplinary assertion of demography is marked by the search for equilibrium between scientific independence with its risks of isolation, and an investment of its competence in the service of the *polis*, or society, with the dangers of subordination to practical necessities or to a political ideology. The contrast between these two contradictory aspirations characterized in many respects all the principal phases of the development of demography: from the initial search for scientific autonomy from state organizations that troubled its beginnings as a part of statistics to the creation of big institutions affiliated with the United Nations for education and research in developing countries, initially in the setting of a neo-malthusian ideology of population growth and its relations to economic and social development, until the current debate on the contribution that scientific approach must make in the search for political solutions to problems engendered by the levels of fertility.

2. From the Foundation of IUSIPP to the Second World War: The Assertion of Autonomy

Creation of the International Union for the Scientific Investigation of Population Problems in 1928 was a fundamental step in the world organization of population studies, with numerous fallbacks and consequences at the national level. It was on its trail that the first institutions were constituted that were devoted exclusively to the study of population. In the universities, the first courses specifically devoted to demography appeared and began to spread within the framework of training in statistics or the social sciences.

Sixteen countries (of which 12 are European: Belgium, Czechoslovakia, Denmark, France, Germany, United Kingdom, Italy, Netherlands, Spain, Sweden, Switzerland; 4 are American: Argentina, Brazil, Canada, United States) founded a National Committee of the Union in the years immediately after the creation of this institution. Some remained active very long, even after detaching themselves from the Union (e.g., the Italian Committee for the Study of Population Problems [CISP]), or still are active today (e.g., Dutch Society of Demography). Others were slowly

[4] For Italy, this affirmation is documented by a vast analysis led by Annunziata Nobile (1989) on Italian texts destined at the time to university teaching of demography. No similar study is known for other countries, but the bibliography established by the Dupâquiers in their *Histoire de la Démographie* (1985), although referring only very marginally to the production of university teaching in proper, supports the opinion according to which the situation described must be general.

transformed giving birth, in different ways, to the institutions forming the present configurations.

This period saw the appearance of certain journals that today are or have been among the principal means of expression of contemporary demography. *Population Index* was founded in 1933 by Frank Notestein (its final form[5] shaped by Ansley Coale) with the help of the American National Committee of the Union (created in 1928) and of the Population Association of America (PAA), which was born independently in 1931[6] (Hodgson, 1991). In 1964, *Demography*, the current journal of the PAA, was born. In 1933, the British journal *Population* appeared, supported by the British Population Society, but it, like the association itself, had a very short life and was replaced in 1947 by *Population Studies*, in the framework of the Population Investigation Committee, founded in 1936 by David Glass and Eugene Grebenik. The Italian journal *Genus* appeared in 1934, published by the CISP. The latter was created in 1928 by Corrado Gini, first as a section of the IUSIPP and then as an autonomous committee. The French journal *Population* appeared in 1945 as an official publication of INED, founded the same year by Alfred Sauvy on the ruins of the French foundation for the study of human problems created in 1941 by Alexis Carrel (Girard, 1995; Bogue, 1993; Crimmins, 1993; Keyfitz, 1993; Hodgson, 1991). Only recently, with the ramifications and the fragmentation of demography and with the arrival of new issues and the enrichment of the methodologic tools, more specialized reviews began to proliferate, devoted to particular aspects of the discipline. The most well known is *Population and Development Review*, founded in 1974 at the Population Council by Paul Demeny; it covers a vast horizon of themes and perspectives linked to population developments. Without citing all of them, mention must be made of *Theoretical Population Biology*, *Population Research and Policy Review*, *Population and Environment*, and *Social Network*. Today, the *Revue des Revues Démographiques*, edited by the CICRED, lists about 90 journals in the world (15 of which are in the United States) that are totally or partially devoted to population issues.[7]

Between the 1920s and 1930s, demography began to acquire the status of an autonomous university discipline, by positioning itself in different ways in the university systems, according to a set of local conditions. The current variety of positions of demography in the framework of university education resulted from the initial heterogeneity and cultural diversity of the scholars devoted to demographic themes. In each country, the independence of demography followed different paths that were marked by the scientific personality of those who strove to introduce the subject into university programs. The general cultural heritage that underlies the construction of the different pedagogic systems, and evolutionary rhythms of other disciplines, especially sociology, was also very important. The links between population studies and sociology were generally very close, even at the level of university organization, where sociology, born of currents of thought such as positivism in France, empiricism in England, and historicism in Germany, had had a precocious development or had enjoyed growth at the right moment. This happened in the United States in the interwar period, when in Russia, Italy, and Germany, dictatorial regimes attempted to suppress the teaching of sociology. In the first case, the accord between the two disciplines was favored by the natural intersection between the objects of study and the common recourse to empirical methods. In the latter, contacts remained feeble, even nonexistent. In Italy for example, the long cultural predominance of an idealist philosophy proved to be an obstacle to the development of sociology, and it made its discourse abstract and foreign to the empirical and statistical methodology characteristic of demographic analysis (Sgritta, 1994, p. 227). In such conditions, reinforced by the political context, no privileged relationship developed between demography and sociology, whereas the links between demography and statistics were permanently reinforced, as much at the level of research as of university education. These different relations between demography and allied disciplines have not failed to influence the frontiers and orientations of population research, as well as the type of education given to demographers of different countries, in a varied but enduring manner.

3. From the Second World War to the Present: A Short but Tumultuous History

On the brink of the Second World War and after the recreation of the Union in 1947 under the name of the International Union for the Scientific Study of the Population (IUSSP), the broad structures of research and teaching of demography were instituted and permanently installed in Europe and in North America. Even in this geographic area (the only one that had until then contributed to the disciplinary maturity of

[5] Alas, *Population Index* does not exist anymore.

[6] Sponsored by Margaret Sanger, it found itself at the beginning in competition with the National Committee of the Union.

[7] In reality, among the journals considered by the CICRED, at least 10 deal with different themes (e.g., statistics, economy, epidemiology, sociology) but frequently devote particular attention to related population issues.

demography), the situation was still quite uneven, and in certain countries where the studies on population had nonetheless borne fruit among scholars, there did not yet exist specialized centers of research on population nor independent university teaching of demography. Overall, however, the spaces for academic insertion, the necessary disciplinary alliances, and the relations with governmental institutions became clearly defined.

With the exceptions of some cases where, after the war, demography knew a more or less long period of stagnation or of crisis,[8] the 1950s and 1960s were most often years of definitive affirmation and of university expansion. The different demographic evolutions that played a prominent role in the socioeconomic transformations of many countries oriented the interest of researchers to themes likely to awaken the concerns of politicians and public opinion: the low fertility in Great Britain and in France, the international migrations into the United States, the internal migrations in Italy, and especially, the acceleration of world population growth, destined to have an immense influence on the development of demography on the scientific plane and in institutional settings. The latter experienced the full consolidation of its structures of research and teaching in the developed countries, and it began to implant itself in the developing countries and very rapidly spread there, although it was still almost completely absent in the immediate aftermath of the war. However, this did not signify that all the developed countries, especially European states, would henceforth be equipped with pedagogic structures in sufficient number and quality. It can be said that the opinion advanced at the beginning of the 1970s by Nora Federici (1974, p. 27), according to which, in many a case, an acceptable situation had not yet been reached at the level of the training of professional demographers remains valid, even if the demand for this kind of competence in the European labor market is quite limited.

In the second half of the 20th century, the emergence of Asian, Latin American, and African countries on the international scene and the epic of their development was accompanied by an acceleration of their population growth that was without historical precedent, long felt to be a danger as much for the global equilibrium of the planet's resources as for the perspectives of each countries development. The population dynamics of the Third World became the focus of an international scientific debate, and important means were mobilized for the diffusion of knowledge of the subject and research on paths that would permit the modification of the course of events. The most widespread opinion in the 1950s and 1960s was favorable to interventions for the promotion of birth control, particularly in countries such as the United States or Sweden, where there already existed a long tradition of activism on this issue. It was in this climate that a movement of institutional reinforcement and creation of new centers of population studies in developing countries took place. The principal actors were the big international institutions, but significant contributions also came from bilateral and multilateral cooperation. In the United States, enormous financial resources, as much private as public, were mobilized in the context of bilateral cooperation. This was also the case in countries such as the United Kingdom, France, Belgium, which had interests and special ties inherited from their colonial past with the Third World. A number of other countries had offered their support to the projects of multilateral cooperation, whether coordinated or not by international organizations.

In the United States, these international orientations had extremely important effects at the national level, as John and Pat Caldwell demonstrated (1986) in their well-known book on the contribution of the Ford foundation to the growth of centers of American population studies. The abundance of funds directed to population research in the Third World countries and to collaboration with researchers of these countries[9] gave the centers of research and demographic training an unprecedented force and independence, especially within the sociology departments of the universities, and it enabled their numbers and scientific prestige to increase. Even in the absence of other equally detailed case studies, it seems that an analogous, if more limited, process also took place in some universities of other developed countries (e.g., Great Britain, France, Belgium, Canada, Australia). In any case, this is what is suggested by the abundant literature available in these countries on the demography of the Third World, the importance of specific methodologic works in the collection and analysis of data of developing countries

[8] Essentially, it was Italy and Germany that were concerned where there was defiance toward a discipline that had somehow compromised with regimes backing populationist and racist policies. It had consequently attracted to itself a serious scientific discredit. This was also the case of Soviet Russia, where the ostracism against the discipline decreed by the regime in the 1930s would continue (Vichnevski, 1995).

[9] This availability was born essentially from the orientations of private foundations. such as the Ford Foundation and similar organizations, until the 1950s. It was extended in the following decades thanks to governmental institutions. The Kennedy Administration officially declared itself concerned about the control of population growth in developing countries, and it was open to finding financial means to achieve this end (Caldwell and Caldwell, 1986, p. 98).

(e.g., demographic surveys, analysis of defective data), and the institution of numerous courses aimed specifically at satisfying the particular needs of students coming from the developing world.[10]

The United Nations manifested impressive activity in the field of demography, directly and through its regional agencies (i.e., Economic Commission for Africa [ECA],[11] Economic and Social Commission for Asia and Pacific [ESCAP],[12] Economic and Social Commission for West Asia [ESCWA],[13] and Economic Commission for Latin America and the Caribbean [ECLAC][14]), all strongly implicated in the conception and application of population policies, or through their specialized agencies, many of whom (e.g., Food and Agriculture Organization [FAO], United Nations Educational Scientific and Cultural Organization [UNESCO], World Health Organization [WHO],[15], International Labor Organization [ILO][16]) handled issues closely linked to demographic questions. With regard to these various international organizations, two fundamental aspects should be emphasized. The United Nations, especially through its Population Division and its Statistics Division, fixed as its essential goal a task earlier entrusted to the ISI of producing internationally comparable statistical data and disseminating them. From 1945, the Statistics Division yearly published the *UN Demographic Yearbook*, and the Population Division has published an impressive quantity of works of demographic analysis, whether in its series of *Population Studies* or in other collections, along with the *World Population Prospects*, which are regularly updated. They also carried out another crucial mission, that of helping scientific authorities of developing countries in the institution of an educational system in demography through the creation of five important organizations with a regional vocation. They are: the International Institute for Population Studies (IIPS) in Bombay in 1956; the Latin America Demographic Center (LADC) in Santiago in Chile in 1958; the Cairo Demographic Center (CDC) in Cairo in 1963, with inter regional competences for the countries of the Middle East and of North Africa; the Regional Institute for Population Studies (RIPS) in Accra in 1971 for the Anglophone countries of sub Saharan Africa; and the Institut de Formation et Recherche Démographique (Institute of Training and Demographic Research [IFORD]) in Yaoundé in 1972 for the Francophone countries of sub-Saharan Africa. To these must be added the creation in 1988 of the Population and Human Resources Development in Africa of the Institute for Economic Development and Planning[17] (PHRDP/IDEP) in Dakar.

To financially support all these activities initially entrusted to the UN Population Division, a relatively independent fund of the United Nations was created on the basis of voluntary contributions of state members (see Chapter 120). In the 1970s, the United Nations Fund for Population Activities (UNFPA) was born, and it quickly took the leadership of most of the population activities of the United Nations, even if its original mission (i.e., the institution of services of family planning and more generally of reproductive health in developing countries) remained its first priority (UNFPA/FNUAP, 1977, 1987, 1995). The UNFPA invested extensively in the development of research and training in demography through a Global Program of Training in Population and Sustainable Development, intended for persons engaged in administrative or governmental responsibilities in developing countries.

The fear of the consequences of a population explosion, especially in the field of economic development, and the search for a solution by birth control policies first appeared among researchers of developed countries (e.g., especially the United States, Sweden), whose debates and research issues they nourished. These concerns, the same from which the principal theories about the relations between population dynamics and society were born and developed, from the malthusian and neo-malthusian propositions to the framework of demographic transition and the microeconomic theories of the family, were adopted very slowly by the scientific and political personnel of developing countries, usually under the pressure of the dominant ideology and as a result of long-term international debate. Three world governmental conferences organized by the United Nations on the theme of population and development (Bucharest in 1974, Mexico in 1984, Cairo in 1994) marked this debate and reflected the evolution of demographic-economic

[10] A look through the issues of the IUSSP Newsletter can provide a good idea of the topic.

[11] Headquarters of the Economic Commission for Africa are in Addis Ababa, Ethiopia.

[12] Headquarters for the Economic and Social Commission for Asia and Pacific are in Bangkok, Thailand.

[13] Headquarters for the Economic and Social Commission for West Asia are in Beirut, Lebanon.

[14] It then became Economic Commission for Latin America and the Caribbean (ESCALPC), with headquarters in Santiago, Chile.

[15] Headquarters for the World Health Organization are in Geneva, Switzerland.

[16] Headquarters for the International Labor Organization are in Geneva, Switzerland.

thought toward a world consensus that oriented the strategies and activity of international cooperation, one of whose ambitions was to reinforce the bodies of research and teaching of demography in the Third World countries.

In this process of increasing awareness of population problems at the world level, the United Nations played a fundamental role supporting the dissemination and institutionalization of demography in the less developed countries, and it remains today at the center of a network of specialized agencies and international institutions (including the World Bank), which, in a more or less coordinated way ensured a technical-scientific assistance and financing for the research activities and teaching of demography. In particular, the five demographic regional centers previously mentioned developed competences, organized trainings at different levels for nationals in their geographic areas, published didactic works and other pedagogic instruments conceived in relation to specific local needs, locally organized occasions for meeting and discussion among researchers, cooperated with national institutions in the field of collecting data and improving their quality, and in certain cases, even undertook research and published the results in books or articles. In short, these centers constituted focal points for the diffusion of demographic knowledge and had, thanks to their activities of support, an important effect of multiplying efforts made by the different countries to reinforce or create their own research institutions and courses of demography. Once they had accomplished their mission, or because the source of their international financing had been reduced,[18] these centers had to merge with local institutions that they had had the mission of creating or helping. In this way, their skills, especially in the matter of teaching, were progressively absorbed by the national institutions.

The birth of more or less independent institutions, more precocious in Asia and in Latin America and much later in Africa, was effectively intensified in the second half of the 1970s, after the Bucharest Conference. A complete and well-documented panorama of the structures and pedagogic initiatives of the period, drawn up on this occasion by Nora Federici for the United Nations, underlined the great deficiency that still reigned at the beginning of the 1970s, although geographically uneven. If the universities that offered classes of demography in the departments of economy, sociology, geography, and statistics were already numerous and if several attempts had been made to insert elementary notions of demography in secondary teaching or in adult literacy classes, the countries where there existed a complete post-university training program, expressly destined to form demographers, were rare. This was true even of Asia, where the interest in family planning had manifested earlier, drawing attention to the usefulness of research and teaching of demography. The lack was more understandable in Latin America, where opposing points of view clashed on the problem of population growth, and in Africa, whose population growth was not yet as lively and which had benefited from only a very thin development of its university structures (Frederici, 1974). But growth was soon accelerated everywhere.

In the decade of 1975 to 1985, many countries of Latin America, Asia, and Africa equipped themselves with structures of research and training in demography and were able to offer courses leading to Masters' degrees and doctorates.[19] In general, it is estimated that the possibilities offered at the national or regional level were henceforth adequate for the training of traditional demographers, especially for the needs of official statistics and collection of data (Cagiano de Azevedo, 1985; Miro and Potter, 1980). Nonetheless, an important effort remained to be made to reinforce education on the theme of "population and development" with more interdisciplinary contours and more diverse and complex applications, essentially answering the needs of socioeconomic planning and population policies (Farooq, 1985, p. 300). These questions of frontiers are well in the line of disciplinary maturity of demography. After a period of concentration on the creation and improvement of data collection systems of the corpus of methods necessary for the "construction of a formal architecture of functioning of the demographic system"[20] (Livi Bacci, 1994), priority was given to the study of relations between the demographic processes and transformations of society.

The history of the next 20 years until today is that of a progressive reinforcement of university structures in developing countries, accompanied by improvement of the quality of studies and, in some cases, of

[18] According to a close observer of the evolution of the situation at CELADE, the crisis that hit these big centers from the middle of the 1980s was "possibly as a result of the fertility decline, which led to decreasing interest on the part of donors" (Martine, 1985, p. 102).

[19] In 1985, in his examination of the situation in Latin America, George Martine affirms that "Overall, however, the doctoral programmers that are beginning in Brazil and Mexico are as strong as many offered in developed countries, with the advantage of being tailored to problems specific to the developing countries' problems (1985, p. 110).

[20] "Costruzione di un'architettura formale del funzionamento del sistema demografico" (Livi Bacci, 1994).

catching up on levels of excellence. Without wishing to generalize the exceptional cases of China or of India, where demography had extraordinary success, it can be observed that in nearly all the countries of the world (and in all the big countries), there are now several centers of population studies within or outside universities.

The case of developed countries was different, especially in Europe, where an unprecedented proliferation of centers of population studies took place, perhaps partly created by the phase of expansion experienced by universities. Nonetheless, because of the particular fluidity of the context attributable to restructuring in university systems, the future of research and teaching of demography is not without problems. In this case, the place occupied by demography in the officially recognized university programs demands attention.[21]

II. THE CURRENT SITUATION

CICRED's ACERD, available on the Internet, listed 708 centers of research or demographic training as of September 2003, 147 of which are in Africa, 84 in Latin America, 18 in Australia and Oceania, 76 in North America, and 217 in Europe.[22]

The importance of these figures (among which CICRED judged it right to include, in some cases, the headquarters of international institutions present in different countries[23]) depends on the definitions adopted and on the care that persons contacted took to provide information. Cases of omission cannot be excluded nor can doubtful insertion of centers in the repertory. Even without wishing to give the figures presented later more meaning than they have,[24] we can base our ideas on the general picture provided by this enumeration, which CICRED considers as "quasi-exhaustive" (Gendreau and Huix-Adamets, 2003, p. 2). In particular, Table 142–1 leaves no doubt about the reality of the reinforcement and the dissemination of the demographic discipline during the past 25 years. Comparison with two of the earlier repertories of CICRED (1973 and 1995) shows a quadrupling of the number of centers in 30 years, with much more rapid growth in places where they were earlier more uncommon (i.e., a multiplication by 11 in Africa). Even if a part of this growth can be attributed to an improvement of the comprehensiveness of the repertories, the founding dates of the centers are there to prove the actual expansion; in Africa, about 75% of the centers whose foundation date is given were created after 1970, as is the case for 57% in Latin America, 73 % in Asia and Oceania, 69% in Europe, and 54% in North America. If the history of demography is already old by some centuries, its scientific and institutional autonomy date back only to the 1930s, and its general dissemination at the world level began only in the 1960s.

ACERD reports of the names and addresses of different centers allow us to distinguish university institutions from others. University institutions can be distinguished from others. For the former, the university status (i.e., department, institute, or other) and the type of institutional disciplinary alliance can be identified.[25] For the latter, a typology distinguishing public or private institutions, governmental offices, departments of national institutes of statistics, international organizations, and others can be established.[26]

The university is the principal institutional place of research and teaching of demography (Table 142–2). Without wanting to give an exaggerated weight to numeric aspects, most of the centers devoted to this discipline reside within academic structures.

Outside the university, institutions and organizations of quite varied kinds covering a large range of scientific and operational needs are found. In some

[21] The International Symposium 1945–1995 that celebrated INED's 50th anniversary in Paris in October 1995 (Chasteland and Roussel, 1997) reviewed the disciplinary evolution of demography in a number of industrialized countries. In most of the cases, the stages of institutional organization of the discipline were recalled (see the papers of Alain Desrosières on France; Gérard Frinking on the Netherlands; Andras Klinger on Hungary; Christopher Langford on Great Britain; Roland Lee on the United States; and Anatoli Vichnevski on Russia), as well as future perspectives (see the papers of Maire Ni Bhrolchain on Great Britain; Samuel Preston on the United States; Frans Willekens on the Netherlands; Graziella Caselli on Italy; Alexandre Avdeev on Russia; Jean-Claude Chasteland and Louis Roussel on industrialised countries in general). For the history of demography in Italy, we also refer to Massimo Livi Bacci's paper (1994).

[22] CICRED considers a demographic *center* a "unit of research or national studies on population, whose existence is proved by the title of center and by a specially nominated head and consisting of at least two full-time people (or its equivalent of part time)" (Gendreau and Huix-Adamets, 2003, p. 5).

[23] In most cases, the international institutions interested in questions of population are not considered to be "centers of demography," but they are ranked apart in the category of "other useful addresses."

[24] A report of the United Nations Population Division on the programs of population studies in various developing countries identified 181 centers of teaching in Asia, 111 in Latin America, and 75 in Africa, very high estimates that the authors of the report themselves considered as over-estimated figures (Baldwin, 1996).

[25] According to CICRED's definition, a department of sociology could constitute a "center of demography," just like a department of demography.

[26] The classification of centers presented in Tables 142–2 and 142–3, which is uniquely based on the denomination of centers, can contain arbitrary elements that cannot be controlled. It can, however, be considered as significant in its broad lines.

cases, we found entities entirely devoted to research of a broad range in all the sectors of demography. They enjoy public financing and are strongly linked to the university with which they cooperate on scientific and pedagogic levels. The most well known examples are the National Institute for Demographic Studies (INED) in France, the Netherlands Interdisciplinary Demographic Institute (NIDI) in the Netherlands, the Institute for Research on Population (IRP, recently rebaptized the Institute for Research on Population and Social Policies [IRPPS]) in Italy, and the Max Planck Institute for Demographic Research (MPIDR) in Germany. Similar centers constituted in the framework of academies (e.g., Academy of Sciences, Academy of Economy, Academy of Medicine) are common in Eastern Europe. Most often, it is a matter of independent centers with public or private financing (e.g., foundations) that are inclined toward some particular aspects of the study of population, such as the family, migrations, health, and family planning.

In many countries, units of population research can be found at the heart of national institutes of statistics and are responsible for the census and vital statistics. This respects an old tradition and at the same time answers the basic need of ensuring the link between the collection of data and the orientations of research. Another type of population centers, very widespread in Africa and to a lesser extent in Asia, are those that function within ministries with economic competences (especially economics, planning, development, cooperation) or with social competences (health, work, family, social policy) or other governmental structures. Their principal interest is applied research, aimed at making available to the government knowledge useful for the integration of demographic variables in development plans or even for the formulation, application, and evaluation of policies in the matters of health, reproduction, family, and distribution of population on territory. Their presence in many African countries (where they constitute 12% of the centers identified by ACERD) are proof of the growing interest in population dynamics as a development factor shown by political decision-makers.

Another category of centers is constituted by international organizations, for the most part established within the United Nations. They represent about 4% of centers of ACERD (8% in Africa), but their importance goes well beyond this numeric aspect. They have played an essential role for a long time in the dissemination of demographic knowledge, and they are equally important in the field of harmonization and production of data. It is enough to mention here the backing given, also in recent years, to important data collection operations such as the World Fertility Survey (WFS), the Demography and Health Surveys (DHS), and the censuses.

Mention must finally be made of a small number of scientific associations that do not fir into any of the preceding categories. They do not directly exercise teaching or research functions but can develop activities of great importance for the promotion, coordination, and orientation of scientific discourse, especially through the organization of occasions of exchanges and debates among researchers. The history of the development of the demographic described has shown the role of catalyst played by the IUSSP. Along with the IUSSP, there exist a number of national scientific associations (the most prestigious is the Population Association of America, which supports the journal *Demography*) or regional groups, such as the European Association for Population Studies (EAPS, supporting the *European Journal of Population*) and the Union for African Population Studies (UAPS) that take important initiatives relating to their geographic zones.

III. UNIVERSITY CENTERS OF TRAINING AND DEMOGRAPHIC RESEARCH

1. Status and Organizational Structures

The configuration of centers of research and teaching of demography within universities is closely linked to the acknowledged ideas about the aims of demographic training. The specific professional competences of the demographer correspond to a restrained demand in the labor market, which limits university programs for obtaining a Bachelor's degree in demography, as is the case for economics or for sociology. This is why almost no university program is entirely devoted to demography. Instead, the teaching of demography aims at providing highly specialized professional preparation (i.e., postgraduate study) or, on the contrary, complementary education in the framework of more general learning itineraries, especially in the universities of developed countries. In other words, it is most often intended for producing future teachers or researchers, but it also aims at creating a general awareness of population issues among those operating in various fields in which demographic processes have an influence. The training of professional demographers with competences ranging from the assessment of demographic parameters useful for the planning of public and private services to the formulation, application, and evaluation of population policies is less widespread, except in the

United States, but these programs are expanding in developing countries (Palloni, 2002; Maffioli, 1994).

These conceptions of the profession of demographer have repercussions in the academic positioning and scientific organization of centers interested in demography. Departments or other autonomous university institutions exclusively devoted to demography are rare. Centers or individual researchers devoted to this discipline often are integrated in departments of sociology, statistics, economics, geography, history, epidemiology, or genetics. The situation varies from one country to another or even from one university to another within the same country, according to the disciplinary alliances that were forged during the course of history. All the same, the recent developments in world populations and the effects they have had on the public opinion and on policy makers, including through the activity of international agencies and the flourishing of specific studies, have reinforced the means and prestige of many research and demographic training institutions, so that in universities where organization is more flexible, they have succeeded in acquiring some independence.

To analyze these aspects of university positioning of demography, the centers listed by ACERD have been classified according to the disciplines figuring in their denomination. In the analysis that follows, the centers whose name explicitly mentions demography or one of its branches, alone or in association with other areas of studies, are opposed to those whose name makes an exclusive reference to other disciplines (see notes to Table 142–3). The former are considered as having the unique objective or priority of demographic research, contrary to the latter, where the studies of population represent only a more or less important part of scientific activity. The degree of independence of the first kind of centers has also been taken into account; centers that are directly affiliated to their parent University and do not constitute a section of an intermediary body were defined as autonomous.

Tables 142–3, 142–4, and 142–5 provide a view of the spread of demography in the most varied contexts. Among ACERD's centers of demography, a considerable proportion (41% at the world level, 52% in Europe) are structures whose principal object of studies is not demography; these are departments dealing with sociology (10%), geography (9%), statistics (8%) economics (4%), or other disciplines, only a part of whose scientific activity concerns population. Moreover, it can be observed that the centers devoted principally or uniquely to demography or its branches (59%) are often also closely linked to other disciplines, in the sense that they do not constitute autonomous university entities but form part of structures with larger scientific interests, among whom sociology predominates, Only about 27% of the centers (36% in North America) constitute autonomous units specifically devoted to demography or to demography associated with another subject, and they are often authorized to bestow degrees.

Particular mention must be made of centers (15.8%) in whose denomination demography figures in association with other disciplines (e.g., demography and social sciences, population and development, population and resources). The number of these centers is expanding. According to an earlier analysis based on the CICRED data of 1995 (Maffioli, 1997), less than 10 years ago, only 27 centers of this kind could be counted, compared with 52 listed in ACERD in April 2004. This tendency toward the creation of units of research and teaching where demography is in the foreground but in a larger framework of scientific interests, results from a new university strategy that refuses marginalization within large organizations and autonomy that carries the risk of isolation; it also seems to correspond to an evolution of research toward issues that are less strategy on the core relations internal to demographic processes and more focused on the study of relations between these processes and other aspects of social dynamics. In principle, the closest alliances forged in these mixed centers should have multiple positive effects. The interdisciplinary collaboration should be beneficial to research and to teaching, by encouraging scientific exchanges and maybe permitting to escape from the intellectual isolation from which may affect demography because of its role of a minor discipline in relation to the principal field with which it is allied. The teaching of demography, placed in the foreground but not closed in on itself and open to contents chosen with respect to programs of studies in which it is enrolled, should permit validation of the discipline's educational potentialities, as much on the professional level as on the cultural level. In the same way, research oriented toward exogenous and larger issues favoring interdisciplinary aspects should contribute to the advancement of knowledge and also consolidate the relations between demography and allied disciplines. However, it is necessary to ensure that this circular process is effectively realized in the daily practice of teaching and research of mixed centers and does not remain at the level of aspirations.

2. Teaching in University Centers

If research on questions of population has developed in a great variety of institutions, the teaching of demography is handed over in an almost exclusive way to university centers with diverse aims. It aims at

[a] The centers of *demography* (in the CICRED meaning) constituted within universities or equivalent higher institutes are classified according to the disciplines displayed in their denomination. Those that are directly affiliated to the university and do not form part of an intermediary body are considered autonomous. For example, under the rubric of "sociology," departments or faculties of sociology are included, which constitute centers of demography because they shelter demographers. The rubric "only demography" features departments of demography and other institutes of population studies, autonomous or organized in the frame of larger university entities (e.g., faculty, departments) devoted to other disciplines. The rubric "demography and others" includes institutes of demography and social sciences, statistics and demography, population and development, and population and resources in general (often in Africa) inserted within departments or faculties whose scientific field is larger.

[b] Including mixed situations (essentially economics and sociology or sociology and statistics).

offering access to the levels of the highest specialization (a research doctorate in particular) and providing specialized knowledge in the framework of programs of exogenous studies.[27] Complete training in demography is given in general only by departments exclusively devoted to this subject. Demography as a complementary program is common and assumes varied forms and contents, sometimes weakly connected to the branch of affiliation.

A university education entirely focused on demography is not generally foreseen, but the idea is beginning to take root, especially in developing countries, although in a nonsystematic manner and with variable contents, often linked to available didactic competences rather than a precise program of teaching.

A more flexible kind of education, with the promise very differentiated programs leading to a broad range of degrees, is in the process of being instituted in an attempt to satisfy very different needs. A number of classes, not necessarily leading to formal degrees but offering the minimum of necessary demographic knowledge for the accomplishment of their missions to persons implicated in administrative activities or governmental programs related to questions of population, are now available in universities and other institutions and international organizations.

Classes on demography given at university centers generally offer a large range of subjects, particularly in developed countries. The contents have tended to diversify over the years in the course of the discipline's evolution, with enrichment of its methodologic corpus and the acquisition of an increasingly broad body of knowledge in different fields related to demography. Besides basic teaching on the foundations of population dynamics (e.g., demographic analysis, population theories, mathematical demography, other technical aspects), subjects such as historical demography, population economics, social demography, demography of the family, regional demography, and many more testify to the consolidation of the discipline's more recent advances and also to the exploration of new approaches that have not yet found their definitive systematization. Some fields of teaching are still more fluid, mixing education and research in progress, because they correspond to the growing interest of researchers for the study of relations between behaviors and demographic processes and the social and cultural contexts in which they manifest themselves, such as gender and population, population and development, or population and environment. These newer kinds of courses, which are in the trail of recommendations adopted at the World Conference on Population and Development in Cairo in 1994, have spread rapidly, especially in places where the organization of classes is the most flexible and the necessary teaching skills are available.

The teaching of *applied demography* (i.e., business demography) has developed over the past 20 years, particularly in the United States (Keyfitz, 1987a). This new branch of the discipline aims at giving professional competency by teaching students to apply

[27] The information on the principal programs of European demographic training is taken up in the *Réseau européen de formation en démographie* of the Catholic University of Louvain's Institute of demography (Louvain-la-Neuve, Belgium). The European Economic Commission (EEC) of the United Nations in Geneva publishes study programs of European and North American institutions. Besides, for different years, the *IUSSP Newsletter* published demographic teaching programs of institutions of different countries that submitted the information. For developing countries, a work of the Division of population of the United Nations on the program of demographic studies (Baldwin, 1996) as well as an extensive research conducted earlier by Stephen Baldwin (1986) provide information on the type and activity of centers identified as offering demographic training and on the content of the teaching.

demographic techniques (especially the techniques of forecasting) to very diverse fields of economic activity: marketing, management of personnel and human resources of an enterprise, follow-up of the production of goods and services, cohort analysis for all kinds of lucrative or charitable ends, and for private or public organizations.

The international debate on the modalities of transmission of knowledge on the matter of population has been very lively in the past decade. It highlighted the widespread dissatisfaction, linked to a sometimes too rigid architecture of teachings that did not leave enough room for new ideas or methods, did not adapt itself sufficiently to the educational needs of different categories of students, or did not always satisfactorily answer the questions raised by increasingly complex phenomena. The multiplication and diversification of teachings observed are beginning to answer to these needs.[28]

The geographic imbalances of distribution of pedagogic resources are in the process of diminishing. Although the most prestigious universities of developed countries remain the most attractive for numerous students coming from developing countries, the situations of research and of teaching in these countries have improved. In many cases, the reduction of international financing has temporarily produced difficult situations. However, very often, local institutions, especially universities, have succeeded in appropriating competences previously ensured by the centers created by the international organizations (e.g., CELADE, CDC, IIPS). In Latin America and in Asia, alongside still quite archaic situations that prevail in certain countries, a number of excellent centers have emerged in the field of demography, capable of ensuring education that accords importance to formal demography and to demographic statistics. China, going from zero in 1979, equipped itself with a dense network of centers of demography through the country's universities (in April 2004, ACERD listed 32 centers of demography). India is not very different, with at least 35 centers. India and China are at the head of the world honor's list of countries having the most population centers, respectively occupying second and third place, just after the United States (60 centers) and before France (31 centers) and Great Britain (29 centers). Africa is less well furnished with population centers, but initiatives abound, as much at the national as at the regional level, partially supported by the centers of the United Nations. The African Interuniversity Network for the Development and Study of Population (RIADEP) is a network of institutions linked to European and American universities, and the Center of Study and Research on Population and Development[29] (CERPOD) was established in Bamako, Mali.

CONCLUSIONS

From this study of the centers of teaching and research in demography, based on the very rich data provided by CICRED and on a systematic exploration of information available on the Internet, a panorama of half-tones finally emerges.

The reasons for satisfaction are numerous because of the growth spurt that demography has had since the 1950s that led to the recent multiplication of centers of research and teaching for the benefit of a discipline whose field has not ceased to grow in response to increasingly complex and diversified social demands.

However, there has been insufficient acknowledgment of the kind of training capable of ensuring the transmission of useful knowledge. In particular, it appears that demographic expertise does not fully succeed in incorporating itself in professional sectors that could benefit from it for practical purposes. It would be appropriate to undertake a more precise analysis of problems posed by the recruitment into the labor market of persons trained in demography. On the pedagogic level, it would also be good strategy to further develop the professional aspects of demographic training in view of adapting the teaching content to the needs of society.

University centers of teaching and research in demography and the modalities of their incorporation in academic structures reflect the eclectic positioning of the discipline, in the sense of its aptitude for developing different functions and contributing to a variety of subjects according to the programs of education with which it is allied. However, these effects also reflect the marginal nature of the discipline, which rarely constitutes the heart of autonomous university education and often has only a complementary position. The promises of the development of the discipline

[28] The International Symposium, which celebrated INED's 50th anniversary, devoted an important place to questions about training and research (Chasteland and Roussel, 1997). Special sessions devoted to teaching of demography were also organized during the annual meeting of the PAA (New Orleans, 1996) and the General Population Conference of the IUSSP (Beijing, 1997). Numerous other initiatives were taken at the same period in different parts of the world (Bogue, 1997). In recent years, the IUSSP's study group has coordinated its acitivity with that of by Graziella Caselli. It culminated in a seminar, Demographic Training in the Third Millennium, organized at Rabat in Morocco, on May 15–18, 2001, and the results were published in *Genus* in 2002 (Burch 2002; Caselli, 2002; Palloni, 2002).

[29] Centre d'étude et de recherche sur la population et le développment.

in the university framework are great, but so are the limitations. In this contrasted picture, the future lies in demographic research that is open to social issues and capable of explaining social phenomena. Scientific advances in this direction would permit it to consolidate the place of demography among social sciences, stressing at the same time its eclectic nature and its centrality for specific professional trainings.

Demography Viewed by Demographers: Considerations Based on the Results of an International Electronic Survey Carried Out in 2000

MICHEL LORIAUX AND TANIA VICHNEVSKAIA

Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, France

Institut national d'études démographiques (INED), Paris, France

I. DEMOGRAPHY IN SEARCH OF ITSELF

Demography is frequently catalogued as a social science, even though its links with the life sciences are just as strong. Moreover, it can be considered relatively old and surprisingly young. It is old because its date of birth is known exactly, if we accept the publication in 1662 of John Graunt's *Natural and political observations* as a date of reference. It is young, insofar as its introduction as a university discipline occurred much later, and its first entry into academic circles dates back barely a century (and much less in many countries), confirming Alfred Sauvy's (1946, p. 7) reference to demography as "une science sauvage" (i.e., a wild science"), because it was not developed initially within university circles but rather began within statistical institutes to fulfill the need for administrative data on population trends. Demography was initially an analytic method aimed at understanding the mechanisms of population changes, and would probably have remained confined to a panoply of statistical and mathematical tools (e.g., life tables, projection methods) if it had not taken the risk of venturing out of its protective cocoon to deal with the delicate issues of the causes and consequences of the observed population movements and changes in structure or, in other words, issues of explaining and understanding phenomena.

The risk of being entirely colonized by its invasive neighbors (e.g., psychology, sociology, anthropology, economics) was even greater because this discipline was originally relatively poor in content (i.e., limited to the three traditional phenomena of fertility, mortality, and migration) and in conceptual frameworks and theories, such as that of the quite unique demographic transition.

Fortunately, the need to understand the why and the how of population trends, as well as the linkages that they have with other societal changes (e.g., technologic, social, cultural, economic, political), has resulted in extending the field of demography and increasingly making it a discipline that acts as a bridge between formal demography and the other sciences and that participates as a relay between the various disciplines that study major events connected to human life, such as birth and death, and that can communicate in an interdisciplinary manner through demography (e.g., social science in its relationship with biology and medicine). It is in this sense that David Coleman (2000) can define demography as "the statistical study of the processes of reproduction, migration and death in the human species, their interrelations with the distribution and dynamics of population, and their biologic, environmental, and socioeconomic causes and consequences” (Coleman, 2000, p. 27).

However, demography definitively remains in the hands of demographers or those who so identify themselves. Beyond intellectual debate about whether it is a science or a method, whether it is closer to natural sciences or cultural sciences, and whether it is one or several, it is useful to ask how demographers see their own discipline and its development and which population issues are of real interest to them in their professional lives.

The community of demographers is not only a relatively vague unit, but it is also a group on which very little information is available, with the exception of some celebrities whose biographies and scientific paths are quite well known.

The idea of carrying out a survey within this community was nearly self-imposed, when two well-known Institut National d’Études Démographiques (INED) demographers, Louis Roussel and Jean-Claude Chasteland, both approaching retirement age, decided to focus on their discipline by studying its development from the period when they were its honorable representatives (one as a famous family sociologist, and the other for having directed the United Nations Population Division) and when demography had a valued status and considerable recognition, both academically and politically, up to the beginning of the 21st century, when rumors of loss of specificity and even a crisis within the discipline were spreading from one end of the planet to the other, leading to real concern among some people about its survival.

II. A RATHER PECULIAR SURVEY

The survey, some of the results of which are presented here, was originally designed as a qualitative survey with the aim of examining the so-called demographic crisis (Chasteland *et al*., 2004).

Very quickly, the small group of key people formed by Jean-Claude Chasteland and Louis Roussel[1] redirected the project toward a quantitative opinion survey whose originality lies notably in the method of observation, insofar as it was one of the first attempts (in this sector) to carry out a survey using the internet. A web questionnaire was developed and placed on the network by several servers (the gateways used were those of INED, the United Nations Population Division, NIDI, and Moscow State University).

For the respondents who could not use the HTML form, two alternative methods were provided, an MS Word version sent by electronic mail and a questionnaire completed by hand and sent through the post. The questionnaire was available in four languages (i.e., French, English, Spanish, and Russian), which was quite uncommon (Fig. 143–1). A total of 636 responses were collected in the period between October 1999 and July 2000, and a server breakdown probably caused

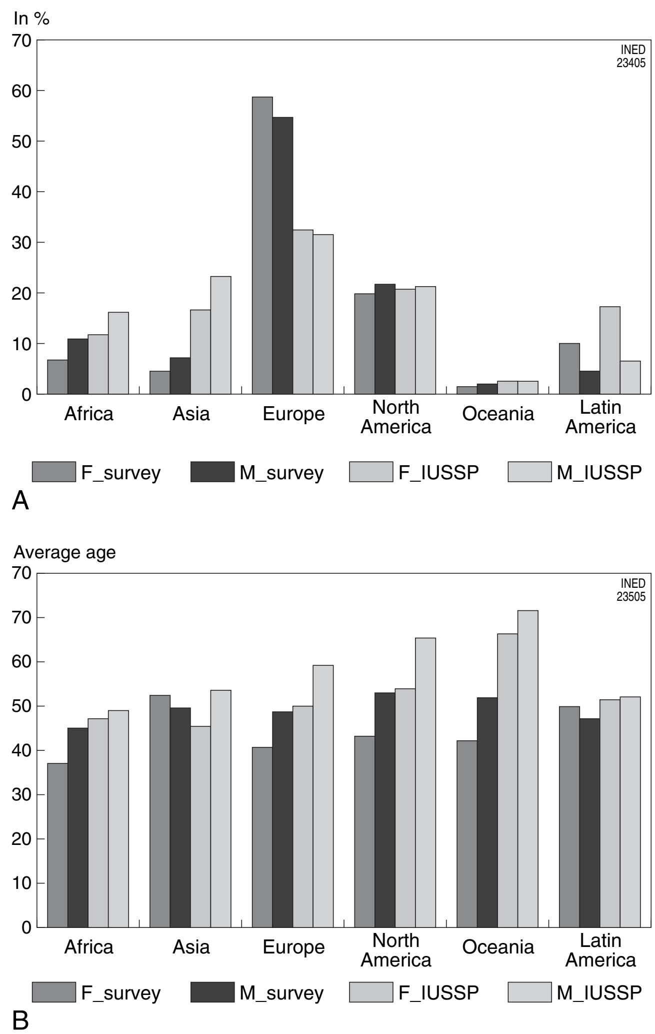

FIGURE 143–1 Languages and delivery method of questionnaires, as well as regional localization and respondents’ membership in large international associations.

[1] The group was made up of Alexander Avdeev (Moscow State University), Máire Ní Bhrolcháin (University of Southampton), Jean-Claude Chasteland (INED), Thérèse Hibert (Paris), Michel Loriaux (Université catholique de Louvain), Giuseppe Micheli (Catholic University of Milan), Anatole Romaniuc (University of Alberta, Canada), Louis Roussel (INED), and Tatiana Vichnevskaia (INED). Moreover, the group gained from the contribution of several other individuals at different phases of the research, notably Hubert Gérard (Université catholique de Louvain), François Héran (INED), and Alain Desrosières (INSEE).

the decrease in the anticipated size of the sample because some potential respondents were unable to send their replies through the web.

This technical hitch undoubtedly caused some errors, but beyond this unfortunate (and unforeseeable) occurrence, the issue of representativity would have been raised regardless due to the method of observation used. The reference population is vague and not precisely defined, and using the web to distribute and collect the questionnaires is similar to an old type of postal survey with a higher risk of representativity errors than is usually encountered in surveys using direct interview of a nominative list of respondents. Admittedly, it was partly the randomness of encounters on the web that led researchers all over the world to read the questionnaire before deciding to respond to it, but in this coincidence can hardly be compared with a random selection from a table of random numbers, as postulated by probabilistic theory.

Various selection errors could have occurred, without it really being possible to correct them *a posteriori* as there was no exhaustive sampling frame available and the only ones that could have been used (e.g., membership lists of the large demographic associations, such as the International Union for the Scientific Study of Population [IUSSP], the European Association for Population Studies [EAPS], the Population Association of America [PAA], and the Union for African Population Studies [UAPS]) were themselves only partial and were far from completely covering the whole of the field in question. These potential distortions led the originators of the study to abandon any global statistical inference and even, by precaution, to avoid any mention of a representative sample or even any kind of sample, preferring to speak of a reference group. As they wrote "The sample is, to some extent, representative of itself" (Chasteland *et al*., 2004), which does not necessarily limit the scope of the study, insofar as it is more concerned with revealing the diversity of situations and the relations between the variables than with precisely describing the levels of the phenomena.

Nevertheless, to better inform our readers, for whom the traditional probabilistic survey based on a random selection of statistical units from an exhaustive list of the observed population remains the preferred method of collecting representative information, we have carried out a comparison between our database and the membership list of the IUSSP, which is the only worldwide association of demographers. This comparison relates to three traditional identification variables that were used to a considerable extent in the Démographie 2000 survey as segmentation criteria for our reference group (Fig. 143–2).

Numerically speaking, the Démographie 2000 survey did not suffer from an excessively low number of respondents (636) compared with the total number of IUSSP members (1672), because it represents 38% of the total, while being aware that not all of the respondents were members of the association (only 331, or about 20% of members).

In terms of geographic origin, although North America is proportionally correctly represented (a little more than 20%), Europe is, as we would expect, over-represented (56% compared with 32% in the IUSSP membership database), and the other regions of the world are under-represented, particularly Asia (6% versus 21%). For Africa, whose limited accessibility to the Internet could have caused a massive under-representation, the deficit is moderate (9% versus 14%).

The distribution by sex in both databases is very similar; in both cases, about 40% are women, although the numbers are slightly greater in the survey than in the IUSSP list, and the male-female differences are *grosso modo* correctly respected, regardless of the continent of birth. However, the average age of the respondents is systematically lower than that of European Union members, with gaps of sometimes as much as 10 years (notably among European men and American women).

Despite the observed differences, no attempts were made to rectify the sample insofar as the reference populations themselves were not exempt from selection errors and could present significant distortions from one source to the other (the various existing professional associations of demographers). For example, we know that, mostly because of the IUSSP's procedure for becoming a member, the average age of this association's members is far higher than that of demographers. This is one reason that explains why almost 50% of the respondents were not IUSSP members (and 30% declared that they were not members of any international association).

Démographie 2000 is undeniably original because of the communication method used, although it poses the same problems (no more, no less) as any more traditional survey in which the target population is not precisely delimited and constitutes to some extent a vague group with imprecise borders.[2] There is therefore no real reason for calling into question the validity of the information collected here any more than for

[2] This population was defined as "the group of researchers and specialists who feel involved one way or another with demography or population studies or, although not demographers, who are members of an association of demographers, or who work within a demographic organization or project" (Chasteland *et al*., 2004, p. 13).

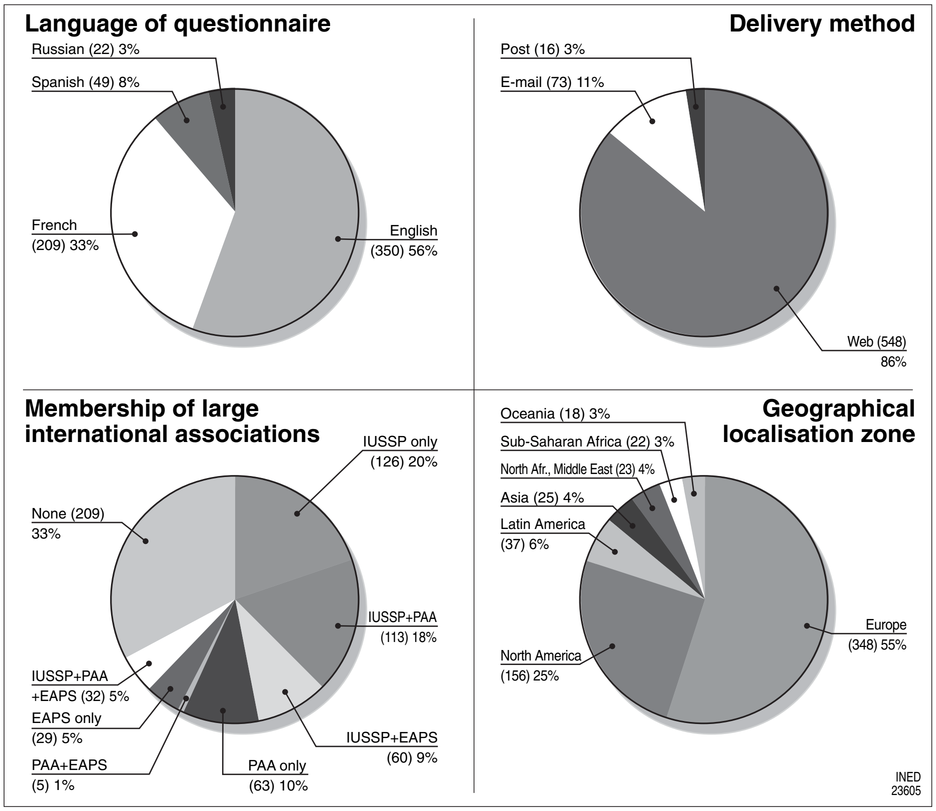

FIGURE 143–2 Compared distribution of the Démographie 2000 sample and of the Union for the Scientific Study of Population (IUSSP) database of members (enrolled before 2002), according to sex, average age, and continent of birth. **A:** Comparison of structures by sex and continent of birth (in percentages). **B:** Comparison of average age according to sex and continent of birth (in years).

other surveys that often have very high rates of non-responses and that as a result also have high risks of selection errors.

This survey on demography and demographers at the crossroads of the second and third millennia was all the more imperative because no similar exercise had ever been undertaken, with the exception of the much smaller survey carried out in 1995 by Francesco Billari and Giuseppe Micheli on the participants of the European conference organized by EAPS in Milan (Billari and Micheli, 1995).

As Jean-Claude Chasteland (2004) points out, unlike their colleagues from other scientific disciplines, demographers seem to be less interested in periodically carrying out general and critical assessments of their discipline. We can mention only a few special issues of journals such as *Demography*, *Population Studies*, and *Population* published at anniversaries celebrating their 30th, 40th, and 50th year of publication, respectively, as well as the *Chaire Quetelet*, which is devoted to themes such as causality and explanation in demography (Tabutin *et al*., 1999; Duchêne *et al*., 1989), the role of qualitative approaches (Gérard and Loriaux, 1988), or the role of projections and forecasts (Wattelar and Duchêne, 1999), in addition to *Les Contours de la démographie au Seuil du XXI ème siècle*, published by INED at the time of its 50th anniversary celebrations (Chasteland and Roussel, 1997).

> That journals devoted to population issues wait 30 or even 50 years before carrying out these assessments is either an indication of the difficulty of the exercise or of demographers' more or less conscious resistance to launch into introspective exercises. This reticence could be explained by the discipline's unresolved identity problems within itself and in relation to other social sciences (Chasteland, 2004, p. 12).

Such were the considerations that led the promoters of Démographie 2000 to fill a gap that seemed worrying to them by asking demographers the world over to describe their professional practices and gathering their perceptions of current and future problems for the discipline, rather than undertaking an analysis of demographic literature as had previously been done by the few authors concerned with establishing an inventory of the discipline of demography.

With two such radically different processes, we did not wish to attempt to systematically compare their results, but a table has been produced by one of the contributors of Démographie 2000, Giuseppe Micheli, who through a 4-year examination of *Population Index* at 10-year intervals (1963, 1973, 1983 and 1993) describes the demographic publications listed by this bibliographic journal according to several categories of scientific orientation (Table 143–1). We discover that

> the central themes of the discipline (fertility, mortality, nuptiality, family, migration) have constantly gained importance . . . and that as a result they have overtaken more demographic areas, more conceptual approaches (logical and methodological), and especially interdisciplinary and cross-sectional themes that can nevertheless contribute to understanding the processes studied, and naturally themes that we consider, *stricto sensu*, as being demographic (Micheli, 2004, p. 206).

III. A DISCIPLINE TORN BETWEEN ITS HISTORICAL DIVISIONS

Today, most people working on population issues define themselves as demographers (67%), and they have also had specific demographic training. However, double (or triple) training disciplines are common, with sociology largely in the lead, followed far behind by mathematics or statistics and economics (Fig. 143–3). It can therefore be said that self-taught people, who were previously in the majority, have been largely replaced by professionals who have benefited from specific training in population science.

Because of this eclecticism of original disciplines, most respondents do not demand a strict definition of demography based on the concept of demographic analysis (formal demography: only 8% of responses) and prefer to rally around the broad concept of population studies (84%), whether it is carried out in collaboration with other disciplines or not (Fig. 143–4)?

Only a small proportion of respondents continue to believe that the discipline's role should consist of "explaining demography using demography" (self-explanation: 5%), with one-fifth believing the opposite ("explaining demography using other factors"), whereas the others (75%) are more undecided but also

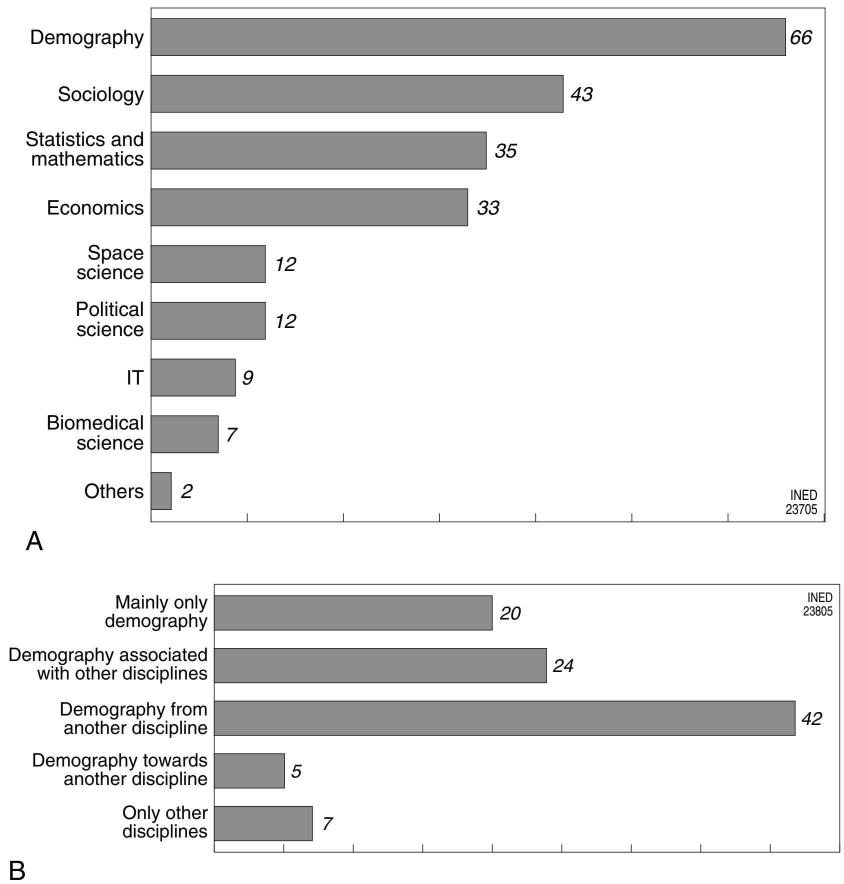

FIGURE 143–3 Respondents' training disciplines and professional history. **A:** Main discipline of training (in percentages). Most respondents (74%) have trained in two disciplines, and some (34%) have trained in three or more. **B:** Professional histories since the beginning of careers.

doubtless more realistic and opt for a dual reciprocal determination ("both"), thereby confirming that demography is no longer confined to a narrow conceptual framework, without a window to the outside world, but plays its role fully as an interdisciplinary science, accepting external influences on the phenomena that it observes, convinced that population issues can significantly affect society's other phenomena.

The distribution of the respondents is appreciably similar regarding whether the discipline is of a descriptive or explanatory nature; only 6% consider it as being essentially descriptive and 16% as explanatory, compared with 77% who consider it as being both (1% with no opinion).

This clear unanimity is strengthened by the question about whether demography belongs to social sciences or to natural sciences; however, this time, almost no respondent opts for natural sciences alone and only 22% for a combination of both, but most (76%) opt for an exclusive social sciences orientation.

Figures 143–4 and 143–5 demonstrate these choices. They are two-dimensional graphs that illustrate the ties between the elements of the survey introduced into the analysis by software called *Réseau-Lu*,[3] which is not unlike the more traditional multivariate analysis programs but which nevertheless introduces additional factors for flexibility and facility of interpretation.

For example, graph D in Figure 143–4 establishes the dominant attachment of demography to social sciences, with a minority opting for a combination of social sciences and natural sciences (and the near-elimination of natural sciences alone due to the lack of numbers). We see that the respondents who chose the social sciences option have themselves been trained in social sciences (e.g., sociology, geography, history) (see Fig. 143–5), which is relatively logical, whereas those who chose the dual option are physicians, epidemiologists, mathematicians, statisticians, actuaries, biologists, anthropologists, specialists in environmental science, or political economists.

[3] Designed and developed by Andreï Mogoutov, AGUIDEL (www.aguidel.com). For a description of the statistical method, see Mogoutov and Vichnevskaia (2004).

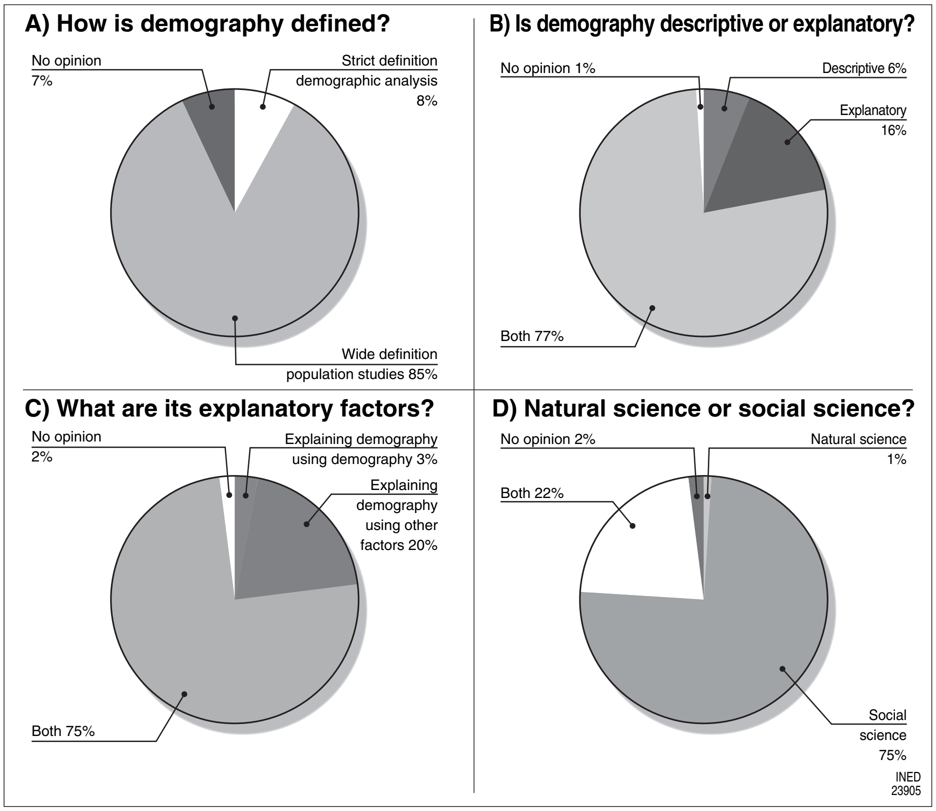

FIGURE 143–4 Overview of the discipline.

Curiously, no discipline acts as a bridge between these two poles, which are clearly disassociated, and demographers, who are nevertheless in the majority in terms of training, do not themselves have any relations with these to the benefit of a simple connection with the least-mentioned pole ("natural sciences"), which is a similar situation to that of economists and lawyers who generally decline to give an opinion (see Fig. 143–5).

The situation is significantly different if we put the training disciplines in correspondence with the conception of demography as a descriptive or explanatory science (see Fig. 143–5). Several subnetworks disassociated from each of the three possible options (i.e., descriptive, explanatory, or both) surround the nearest disciplines, but this time, there are quite numerous transition points that appear and that link the subnetworks. While actuarial scientists unilaterally opt for the descriptive aspect of the discipline and biologists for the explanatory aspect, other disciplines (e.g., medicine, geography, genetics) are simultaneously attached to both poles.

The choice of the dominant option ("both at the same time") is that of demographers, sociologists, environmentalists, town planners, and to a great extent, mathematicians and statisticians, whereas members of other disciplines reported a preference for a combination ("descriptive/both"); this is notably the case for historians, psychologists, and anthropologists.

If we look at the choice of the explanatory principle (see Fig. 143–5), we find a situation that is quite comparable to the previous one insofar as the division of opinions is not as clear as that regarding the scientific membership of disciplines. Although demographers almost unilaterally opt quite for the dual determination of phenomena, sociologists are split between this and explaining demography through demography, and economists express a dual choice, but this time in favor of explaining demography through other factors (in addition to dual determination).

Many specialists from other disciplines remain clearly monofactorial; this is the case of historians, geographers, geneticists, and political economists who prefer the option of explanation by external factors. Only psychologists and mathematicians or statisticians opt in favor of endogenous explanation (explaining demography through demography), as well as some choices of no opinion.

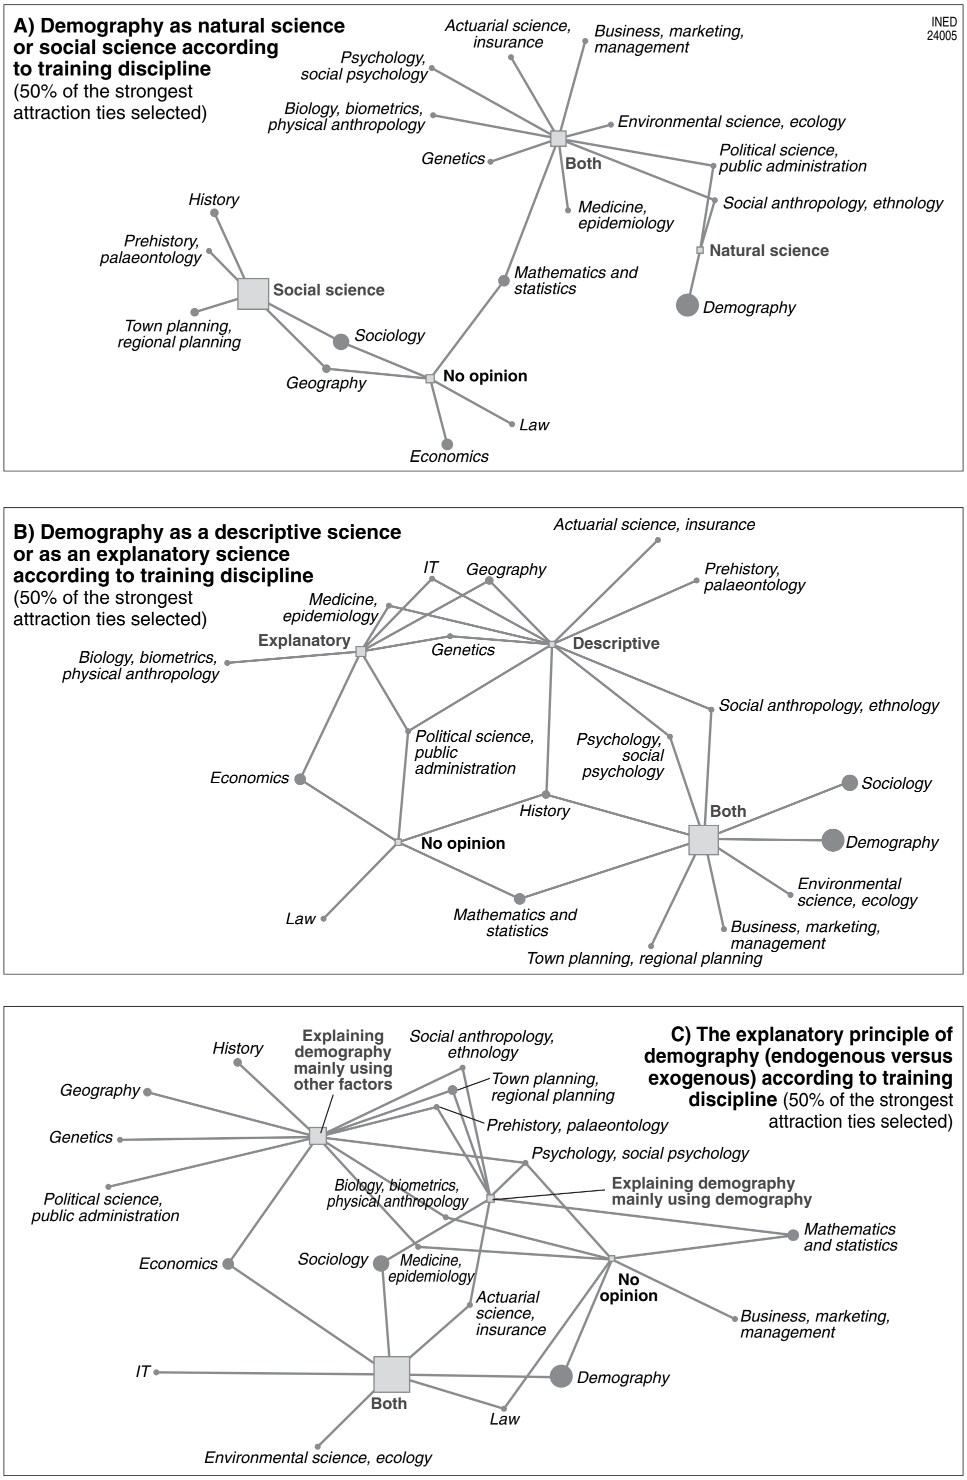

FIGURE 143–5 View of demography according to respondents' training discipline. **A:** Demography as a natural science or as a social science according to training discipline (50% of the strongest attraction ties were selected). **B:** Demography as a descriptive science or as an explanatory science according to training discipline (50% of the strongest attraction ties were selected). **C:** The explanatory principle of demography (endogenous versus exogenous) according to training discipline (50% of the strongest attraction ties were selected).

IV. A STROLL THROUGH DEMOGRAPHERS' GEOGRAPHIC, LINGUISTIC, AND INSTITUTIONAL SPACE

Like everyone, demographers (or experts in population science) are born somewhere, sometimes migrate from their countries of origin to other countries, work within different types of institutions, and write their reports or their work in certain languages (which are not always their mother language).

Among the respondents to the Demography on the Threshold of the Year 2000 survey, 24% write only in English and 8% in French, whereas taking into account bilinguals and trilinguals (or beyond), English is used by 60% of them, which makes it incontestably the dominant language among demographers.

The distribution between types of work organization is more balanced. Universities are in first place (25% of responses) but are closely followed by research centers (20%) and, trailing significantly behind are international organizations (14%), national statistical institutes (13%), national or federal administration (11%), nongovernmental organizations (NGOs) (9%), local administrations (8%), and private foundations (5%).

The graphs of Figure 143–6 illustrate this basic information. Figure 143–6 shows the type of organization matched against a question mentioning the regions of the world on which the respondents' work is based. A first glance at this graph shows considerable segregation between the regions, such as Europe, which undertakes self-investment through the population studies carried out in its universities and research centers, and regions, and such as Africa, which receives aid in this field only through international organizations and NGOs. Moreover, the management structure of population studies is very different in Europe and North America, because research funding in the latter region comes from universities and from private foundations and NGOs.

Graph B in Figure 143–6 is more complex because it results from a simultaneous projection of several variables: the country of birth, the usual country of work, the temporary country of work, the country of training, and the languages used for scientific production. The geographic and linguistic components are highlighted in this graph. We can distinguish a French political-linguistic pole that represents the Francophone world, including France and its former colonies or protectorates, with the slightly eccentric position of Belgium and Canada.

Another pole structured around Spanish, and to some extent Portuguese, unites most Latin American countries, even though Spain has only a marginal position. The Scandinavian countries, including Estonia, and the Austro-Hungarian world are placed closely to the countries of Eastern Europe, which are structured around Germany (but not necessarily around the German language). The same Eastern European countries are also attracted by the former Soviet space, partly due to the Russian language.

The central part is made up of European countries, among which are multilingual countries such as Belgium and Switzerland that are attracted by several poles in a structurally similar way. The most developed pole remains that of the English language dominated by the United States and the United Kingdom, even though it is at the same time the least specific one. Surrounding the United Kingdom is a group of countries that have traditional historical links with it (e.g., India, Egypt, Kenya).

Graph 6C provides a complimentary view of the respondents' migration space by summarizing migration for initial training, i.e. any movement from the country of birth and the country of first university training. All the countries of birth mentioned are represented, and the lack of a link of most of them to another country confirms that a large number of respondents received their training in their country of birth. However, France and the United States distinguish themselves as two considerably attractive poles, and at the same time they gather students from countries or regions with which they have traditional links.

Nationals of some countries such as Egypt, Lebanon, Argentina, and Germany are shared between the two dominant poles that, in addition, have little exchange with each other. Other centers, such as Belgium, Germany, and the United Kingdom also appear as centers for training and exchange at a European level, whereas Canada, the Netherlands, Austria, and Hungary form an exchange subnetwork for initial training. Russia has a relatively isolated position and attracts only some countries that were part of the former Soviet empire; it has not created any significant links with other European centers.

V. MULTIPLICITY OF STUDY THEMES

To think that demographers exercise all their talents in virtually identical fields would be completely wrong. Démographie 2000 asked respondents to choose between 23 study themes and to answer this question for three different dates of reference: "currently," "10 years ago," and "20 years ago." Because of age, not everyone could provide answers to all three dates, and the number of respondents inevitably decreases over

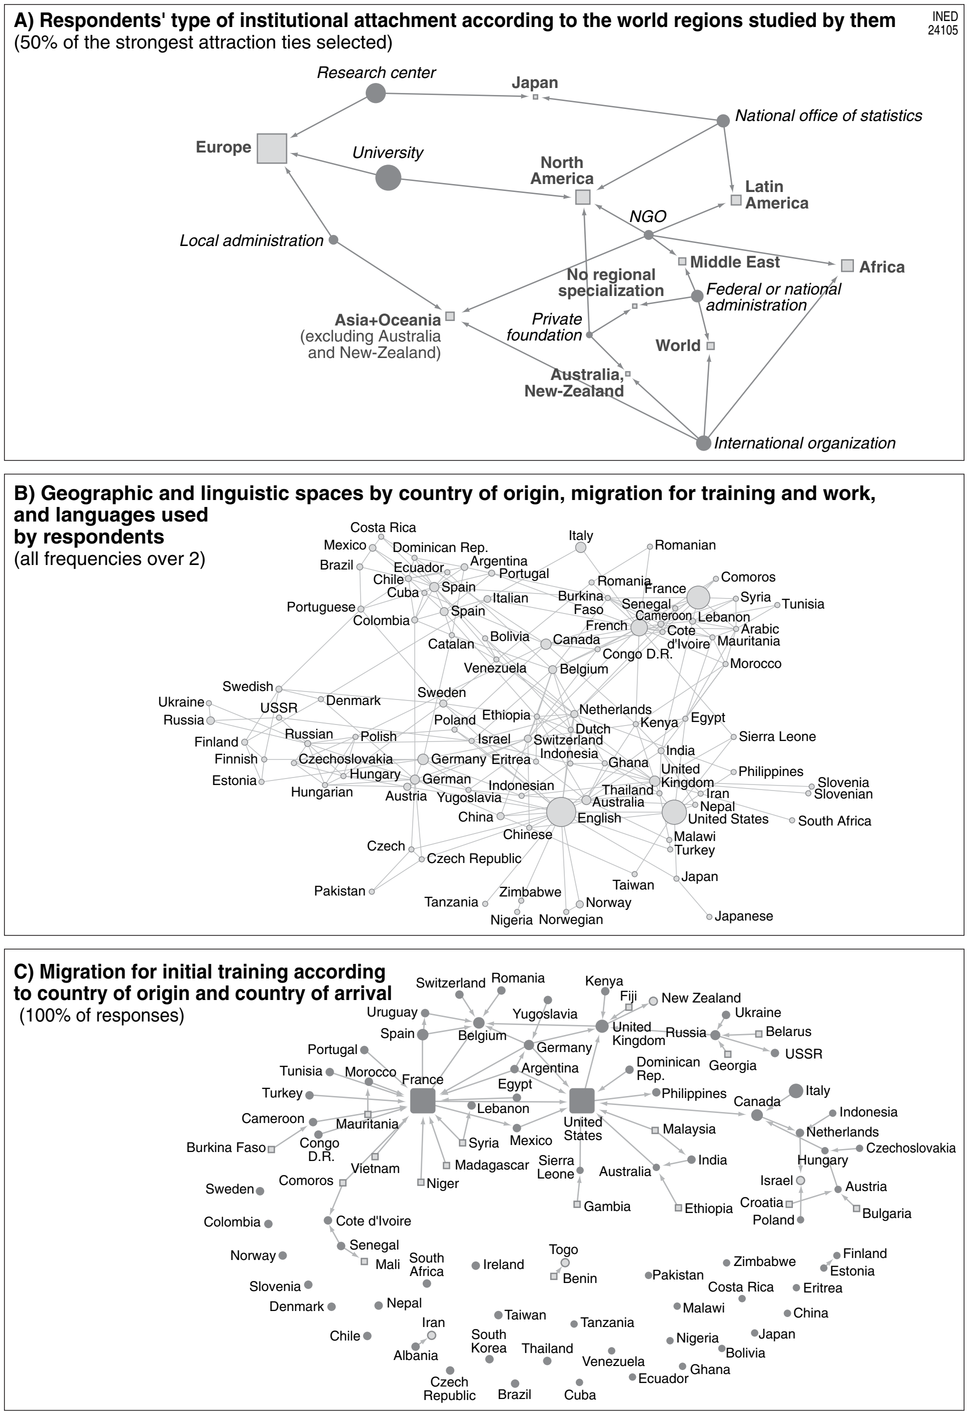

FIGURE 143–6 Country, place, and languages of work: a multivariate summary. **A:** Respondents' type of institutional attachment according to the world regions studied by them (50% of the strongest attraction ties were selected). **B:** Geographic and linguistic spaces by country of origin, migration for training and work, and languages used by respondents (all frequencies more than two). **C:** Migration for initial training according to country of origin and country of arrival (100% of responses).

time: 621 valid answers for the current period, 468 for "10 years ago," and only 320 for "20 years ago."

Nevertheless, the order of study themes has not been upset with the progress of time, and within the hit parade of themes, the same ones have remained more or less in the top ten for the three dates. As can be expected, studies on fertility and fecundity have remained the uncontested leaders over the last 2 decades (Fig. 143–7). However, the study of mortality, morbidity, or epidemiology have progressed over time, going from fifth position (20 years ago), to third (10 years ago), and finally reaching second place (currently). This is not the case for the third fetish phenomenon of demography, migration, which is currently only in 10th place with regard to internal migration and the spatial distribution of populations and is in 12th place with regard to international migration, which may be surprising. However, studies on nuptiality and family structures have progressed well and moved up from ninth position 20 years ago to fifth place currently, whereas for the study of population in developing countries, the reverse has happened because it seemed to be of greater interest 20 years ago (fourth place) than it is now (ninth place).

At the bottom of the scale we find, without any significant variations from one period to another, economic demography (currently in 18th place), the study of populations in relation with natural resources (19th), anthropologic studies and case studies (20th), cultural demography (21st), the history of demography (22nd), and epistemology (23rd).

The examination of the co-occurrences of study themes from graph A in Figure 143–8 confirms that the traditional fields of demography are strongly connected among themselves and form a clearly defined pole: fertility, mortality, nuptiality, population of developing countries, and population policies. At the opposite end, a more technical-methodologic pole emerges, with methods and modeling, prospects and projections, and migration and economic demography. Between the two, a third horizontal pole groups the less popular poles, but it is nevertheless connected to the other two, such as historical and cultural demography, anthropologic studies, or epistemology.

Two other graphs (see Fig. 143–8) make it possible to verify whether there is a clear differentiation in the choice of study themes according to the two major

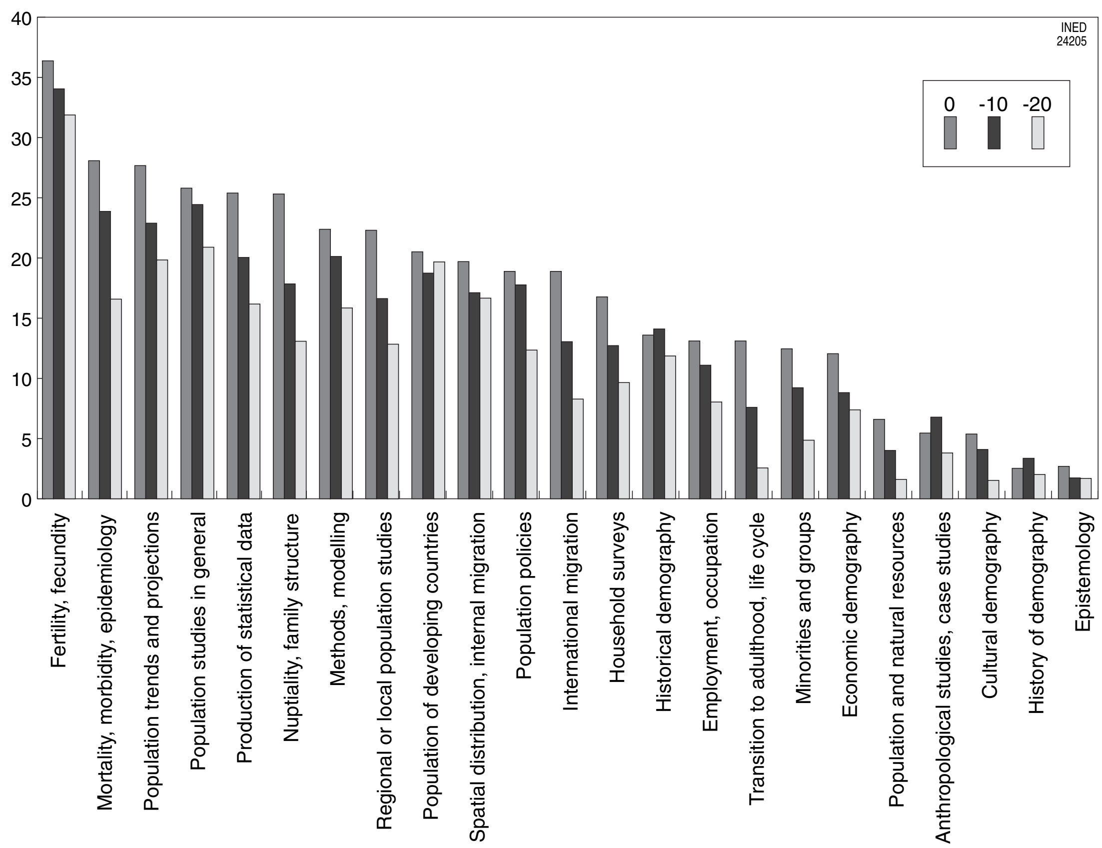

FIGURE 143–7 Classification of study themes identified in three reference periods (descending order from current responses).

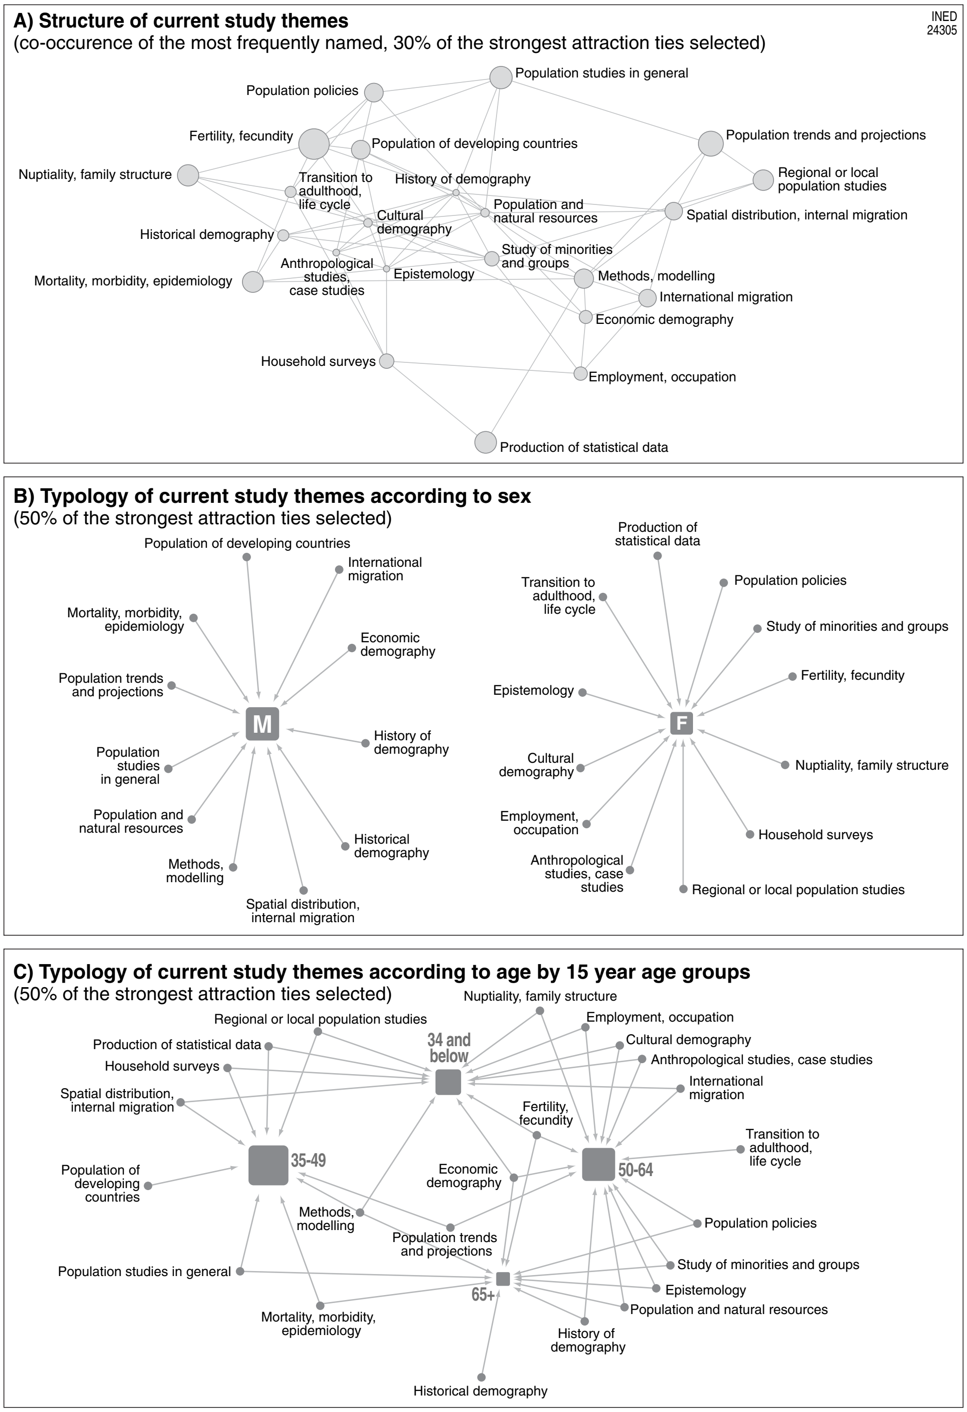

FIGURE 143–8 Interdependent structures of study themes according to sex and age. **A:** Structure of current study themes (co-occurrence of the most frequently named, 30% of the strongest attraction ties were selected). **B:** Typology of current study themes according to sex (50% of the strongest attraction ties were selected). **C:** Typology of current study themes according to age by 15 year age groups (50% of the strongest attraction ties were selected).

variables of social identification: sex and age. The structure by sex (see Fig. 143–8) is particularly interesting, insofar as it places men and women in complete dualization. Women are more concerned by fields connected to fertility, nuptiality, life cycles, household studies, the production of statistical data, the study of minorities and groups, and cultural demography. Men clearly state their preference for more technical themes such as demographic trends, methods and models, economic demography, natural resources, and the spatial distribution of population.

From the point of view of age distribution (see Fig. 143–8), the separations are not as clear as with the male-female divide, but the associations of preference are nevertheless unambiguous and reveal substructures that are easy to identify. For example, the oldest demographers (who are also the smallest group) state preferences for historical demography and the history of demography, the study of minorities and groups, but also population studies in general and population policies, even though they share these choices to a great extent with their nearest age group of 50 to 54 years.

At the bottom of the age scale, we observe that the youngest group (aged 34 or younger) and the demographers of average age (35 to 49 years) partly share the same choices; they are in favor of regional or local population studies, household surveys, the production of statistical data, and internal migration. The study of nuptiality and family structure, as well as international migration, are the prerogative of the more mature demographers (50 to 64 years) who nevertheless share these study themes with the youngest ones (aged 34 or younger). Each age group, apart from the first, has at least one study theme that it does not share with any other age group: population in developing countries for those between the ages of 35 and 49 years, the study of life cycles and transition to adulthood for those between 50 and 64 years, and historical demography for those 65 years old or older.

VI. DEMOGRAPHY'S MAJOR FACTORS OF CHANGE

Demography, like any other science, is subject to internal and external influences that contribute to its development and shape its current physiognomy. The choice of eight large factors of change was proposed to the respondents. The classification differs slightly according to whether first choices or multiple choices (four cumulated responses) are referred to, but it is clear that the introduction of individual or longitudinal data has been an important internal factor of development, as the development of information technology has been an equally decisive external factor (Fig. 143–9).

Other factors have played a more discreet role, such as the introduction of new demographic concepts, the increased availability and comparability of macro-demographic data, or the development of human and financial resources. Nevertheless, beyond a simple classification, these data indicate that the interaction of certain external developments such as computerization and the advent of micro-computing, with internal factors, such as some developments in demographic analysis and the availability of individual data, has resulted in a general dynamism of the discipline that otherwise could have sunk into a kind of inertia and regressive stability. In any case, it would be difficult to disassociate the two types of influence, external and internal, because of their considerable reciprocal overlaps, even though by grouping the different types of causes within the questionnaire we observe the slight advantage of external causes over internal causes.

Whatever the case, if demography is changing, it is undoubtedly because of the changes in influences at the level of its scientific approaches and work methods. The discipline is also changing simply because the world is changing and it is therefore constantly faced with new situations that did not exist previously or did not have the same significance or intensity.

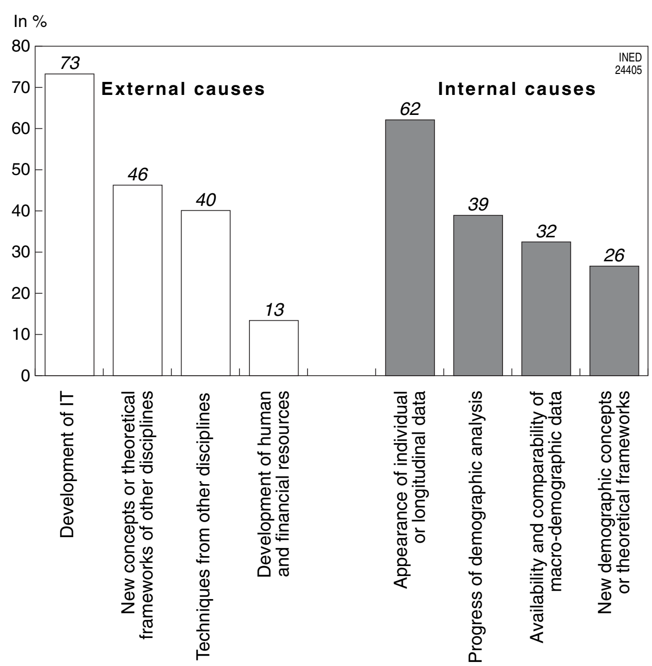

FIGURE 143–9 Factors responsible for the development of demography: internal or external causes?

A group of 26 large phenomena or societal changes that have affected the world over the past few decades were proposed to the respondents and they were asked to specify which one of them had had an impact on their personal practice of demography (five levels of impact were proposed: none, low, medium, high, very high), as well as generally on demography as a discipline.

Among these factors, which are inevitably all external, even if some of them have more demographic connotations than others (e.g., "the spread of contraceptive methods," versus "the decline of the state"), the three emerging phenomena are without contest "Rapid population growth in developing countries," "population aging," and "persistent low fertility in developed countries."

"The development of international migration" is in fifth position, preceded slightly by "the increased role of women." However, the change in women's roles, in fourth place, comes to the top of the list when it is in the context of demography in general and the impact on the respondents' practices. All the more economic or political factors are grouped together near the bottom of the list, even though "environmental threats" and "economic and financial globalization" are in the middle of the list, residing in 11th and 12th place.

An analytic graph of the co-occurrences of the various phenomena mentioned and described in Fig. 143–10, completes the vision that demographers could have of the impact of societal developments on their work (Fig. 143–11). Despite the relative complexity of the relations map, several poles are quite clearly detached. This is the case on the left of the subnetwork, which integrates nearly all the political-economic phenomena (e.g., unemployment, Third World debt, the welfare state crisis, globalization, new forms of poverty); only "the collapse of the Soviet bloc" and "European unity" appear decentralized on the right of the nodal point of unemployment.

In the bottom right corner is a second subnetwork organized around developed countries and their issues: low fertility, aging, and the increase in life expectancy. In the middle and toward the top, a third subnetwork expresses the demographic-epidemiologic problems that face developing countries, notably African countries, with the correspondence of themes such as rapid population growth, fertility decline, the spread of modern contraceptive methods, the AIDS epidemic, and the development of health systems.

On the right, a group of phenomena related to the female condition with changes in the roles of women, the increase of co-habitation outside marriage, and adolescent pregnancies bears witness to a significant problem in both the North and the South and to the existence of a bridge between the problems perceived as being dominant in developing countries and those that have a greater effect on countries that are in the second demographic transition.

VII. BETWEEN PARADIGMS AND METHODS: PUTTING DEMOGRAPHERS' TOOLS TO THE TEST

Demography is generally considered to be a quantitative discipline, dominated by statistical models and methods, so much so that some demographers would sometimes wish for it to be assimilated into a general

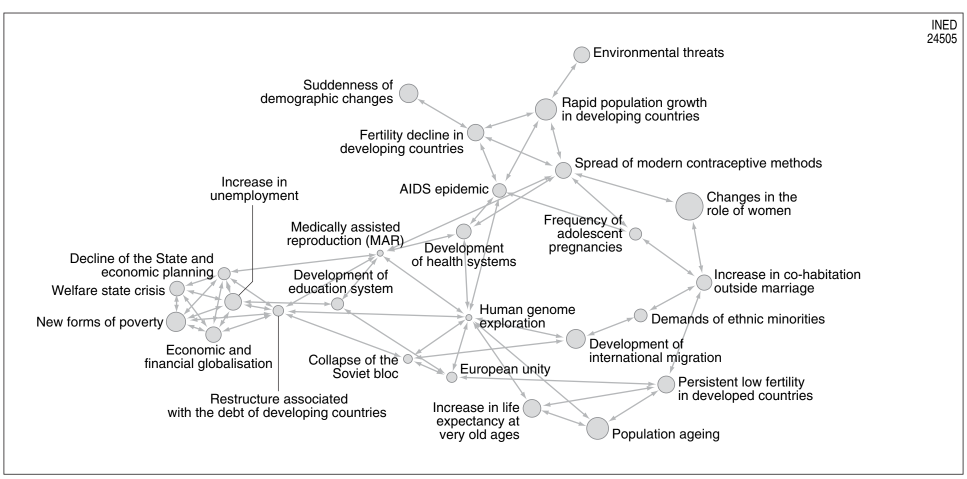

FIGURE 143–10 Cartography of societal phenomena with a high impact on respondents' professional work (20% of the strongest attraction ties were selected).

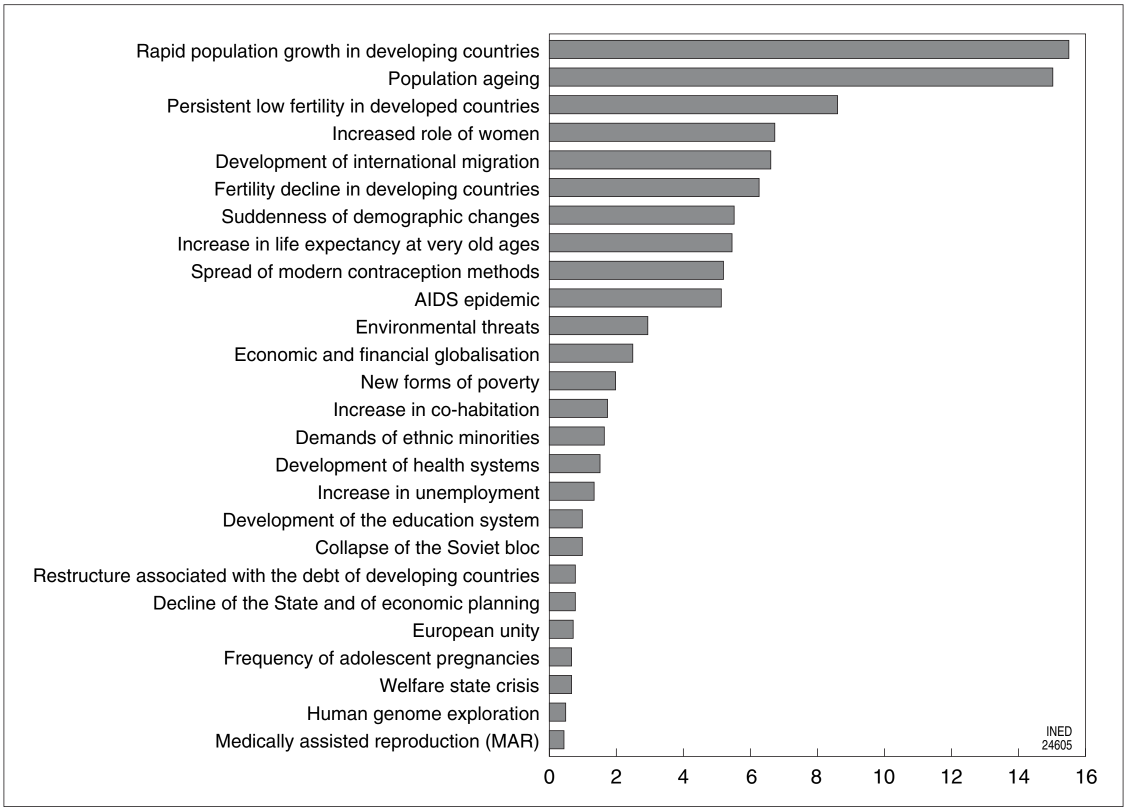

FIGURE 143–11 The impact of recent societal changes on demography as a discipline (classification in percentages by descending order of themes mentioned).

group of methods. However, it would undoubtedly be a dishonor to demography to reduce it to a science without a heart or a soul, providing a perspective of humans and the world through a heap of numbers and curves.

It is true that its isolation from other disciplines and the fact that it is locked away into its narrow field of analysis create a feeling of insularity that has occasionally protected demography from external influences harmful to its development, but that has also delayed the rise of awareness of the necessary interdependence of all social phenomena, of which population issues are only one integral part. Is this still true today?

Apparently not, at least if we judge from the wide diversity of paradigms, methods, and techniques of which modern demographers claim ownership and which are to a great extent borrowed from other disciplines or from the statistical-methodologic sources common to all sciences (see Fig. 143–11). This is the case with regard to regression methods, logistic models, life course analysis, or multilevel analysis, which were created and developed within other disciplines; however, this is much less true or not at all true with regard to life tables, stable populations, or indirect estimation methods that are of fundamentally demographic origin.

But what do the respondents think of them? With regard to paradigms, it is not surprising that the first one mentioned is the "demographic transition" theory (78% for the discipline in general and 53% for the respondents' personal research). However, we may find it strange that "changes in the roles of the sexes" is in second place (52% and 44%), and practically *ex æquo* with "family life cycle" (50% and 44%), and ahead of "health transition" (46% and 29%), or even "evolution in mortality at very old ages" (31% and 17%) placed last but one ahead of "sustainable growth" (29% and 14%).

It was not possible to decide between four or five of the proposed paradigms: spatial analysis, micro-macro relations, inter-generational transfers, health transition, or even "social networks," and the two categories "for demography in general" and "for personal work" are practically the same.

Perhaps the beginning of an explanation is found in the fact that some of the proposed items are concepts rather than analytic frameworks and that they do not

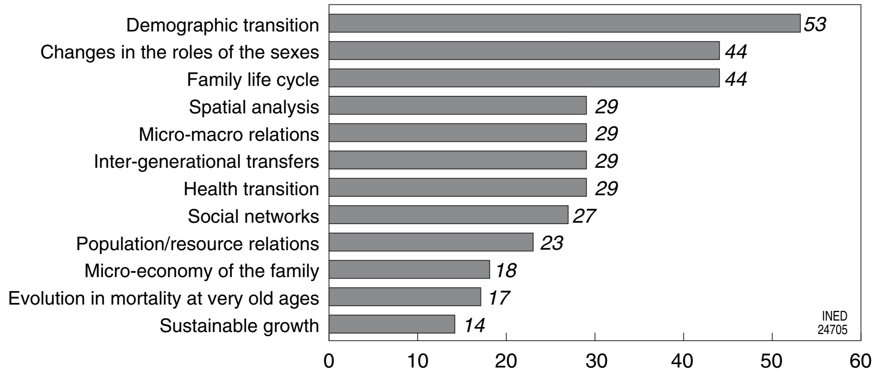

FIGURE 143–12 Classification of the main paradigms used by demographers in their personal work.

necessarily reach their outcomes in the formulation of a processed theory, as is the case for the demographic transition.

It must be emphasized that not all the respondents accord the same importance to the different paradigms proposed, according to their personal characteristics, especially sex; men refer more frequently to what could be called a heavy artillery made up of the demographic and health transitions, the evolution of mortality, sustainable growth, and population-resource relationships, and women are more attracted by "softer paradigms," such as family micro-economics, family life cycle, changes in the roles of the sexes, the analysis of social networks, or inter-generational transfers (trends not illustrated here).

If we leave paradigms and concentrate more on methods and techniques, we observe that the dominant values remain at the level of demography in general, "life tables" (74%), and "data collection methods" (60%). Other relatively traditional methods and techniques fall to the bottom of the list, such as "standardization through standard population" (39%), "modeling variables related to fertility" (39%), "logistic models" (26%), and "markovian models" (16%). Around the middle of the list are "stable populations" in seventh place at 43%. It is interesting to observe the breakthrough of the methods and techniques that have only recently been introduced into demography, such as "APC[4] models" (53%), "life course analyses" (40%), "survival analyses" (36%), and "multilevel analyses" (35%) (Fig. 143–12).

It is also true that the classifications can differ significantly according to point of view: that of researchers for their personal work, or that of the discipline in general (Fig. 143–13). This is why "life tables" receive 74% of the general vote but only 47% of the personal vote.

[4] For "age, period, cohort" (see Chapter 18).

The two graphs of Figure 143–14 provide an additional view of the relations between paradigms and various techniques and methods. The first graph (see Fig. 143–14) is structured in a diamond shape and reveals the close links between these two great dimensions. On the left of the map are the two classics of demographic analysis: "the demographic and health transitions" and "the evolution of mortality at very old ages"; on the side of the paradigms are life tables, stable populations, methods of standardization through standard population, and modeling of variables related to fertility. On the right are the methods and techniques, concentrated quite compactly around the paradigms "changes in the roles of the sexes," "micro-macro relations," "the analysis of social networks" and "spatial analysis," "multilevel and life cycle analyses," as well as "data collection methods."

At the top, another paradigmatic trio, "family life cycle," "intergenerational transfers," and "family micro-economics" attract the APC models, duration models, and survival analyses while keeping strong links with "life course analyses" that becomes a bridge between this subnetwork and that centers on "changes in the roles of the sexes."

The second graph (see Fig. 143–14) illustrates the relations between the researchers' choice of methods and techniques for their own work according to sex and age combined (binary variables: below the age of 50/age 50 and over). Among men, regardless of age, there is a strong attraction for life tables, APC models, stable populations, indirect estimates, and simulation methods. The markovian models are the prerogative of those aged 50 and over. On the female side, while age is relatively undiscriminating, women differ from their male counterparts by a sustained interest in data collection methods, life course analyses, and multilevel analyses, as well as in duration models and standardization by regression methods.

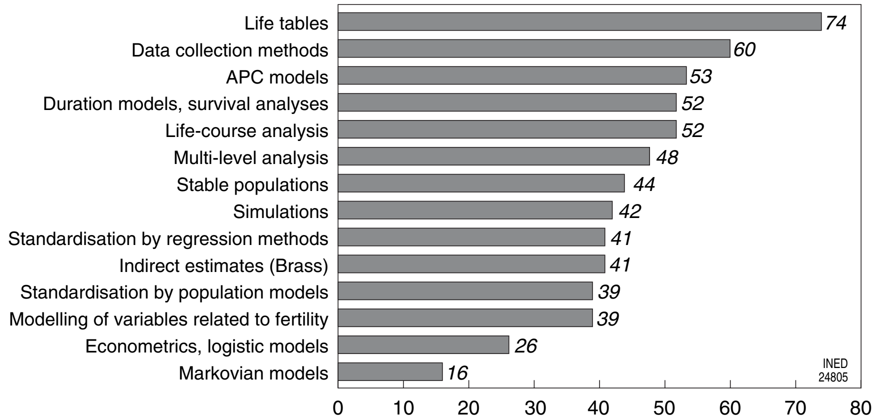

FIGURE 143–13 Classification of methods and techniques according to their importance to demography in general.

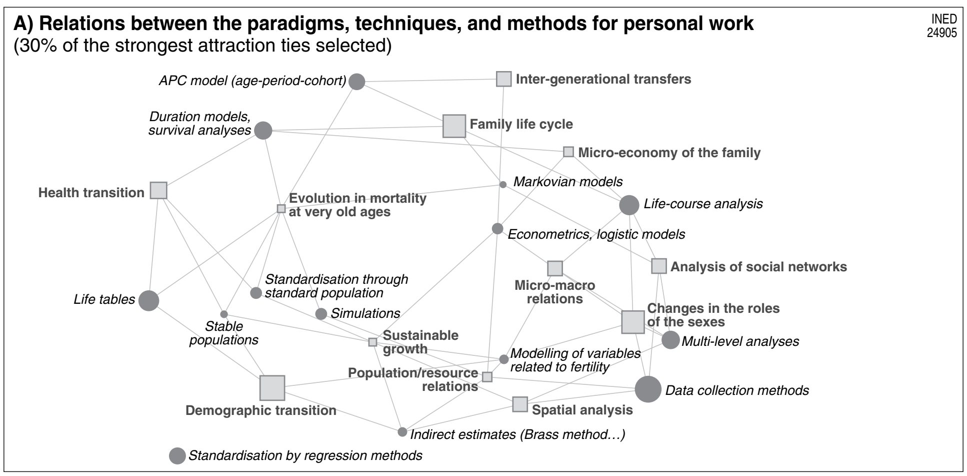

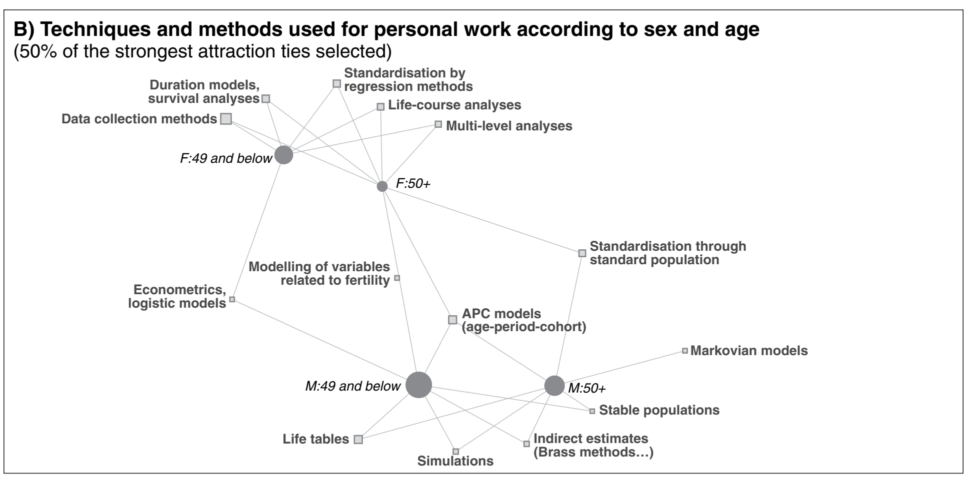

FIGURE 143–14 Paradigms, methods, techniques: what are the relationships and the preferences? **A:** Relations between the paradigms, techniques, and methods for personal work (30% of the strongest attraction ties were selected). **B:** Techniques and methods used for personal work according to sex and age (50% of the strongest attraction ties were selected).

However, the two groups distinguished by sex are not entirely isolated in their methodological preferences insofar as three nodal points ensure the connection between the men and the women, namely standardization by population models, modeling variables related to fertility, econometrics, and logistic models, although these methods and techniques appear nearer the bottom of the list by order of importance.

VIII. A DISCIPLINE IN CRISIS OR A DEVELOPING SCIENCE: DOES DEMOGRAPHY STILL HAVE A FUTURE?

We could not end this review of the professional characteristics and practices of demographers without also mentioning their perceptions about the future of their discipline, the question that initially motivated the Démographie 2000 survey: What are the fears and hopes of demographers concerning their discipline? Do they believe that there is a crisis specific to demography that could eventually call into question its existence as an autonomous discipline and reduce it to a mere store for methods for the use of other disciplines?

Let us immediately reassure ourselves: This hypothesis does not correspond at all to the dominant opinion of the demographers questioned. In the questionnaire, five levels of appreciation were proposed to the respondents: "is demography currently experiencing (in the fields in which you work personally) usual problems, serious problems, or a real crisis at the conceptual, technical, explanatory, ethical, political, or financial level?." The "crisis" response did not exceed 8% for any of these levels and was sometimes as low as 4% (at the conceptual and technical levels). However, 20% to 25% of the respondents believe that their discipline, although it is not experiencing a crisis, is having serious problems, with "usual problems" fluctuating between 50% and 70% (Fig. 143–15).

The question remains whether these usual or serious difficulties are specific to demography or whether they are generally shared with the other social sciences (Fig. 143–16). Although two-thirds of the respondents (68%) believe that the problems are common to all the social sciences, one-fifth (26%) consider that they are specific to demography, and the others (6%) prefer not to give an opinion (Fig. 143–16).

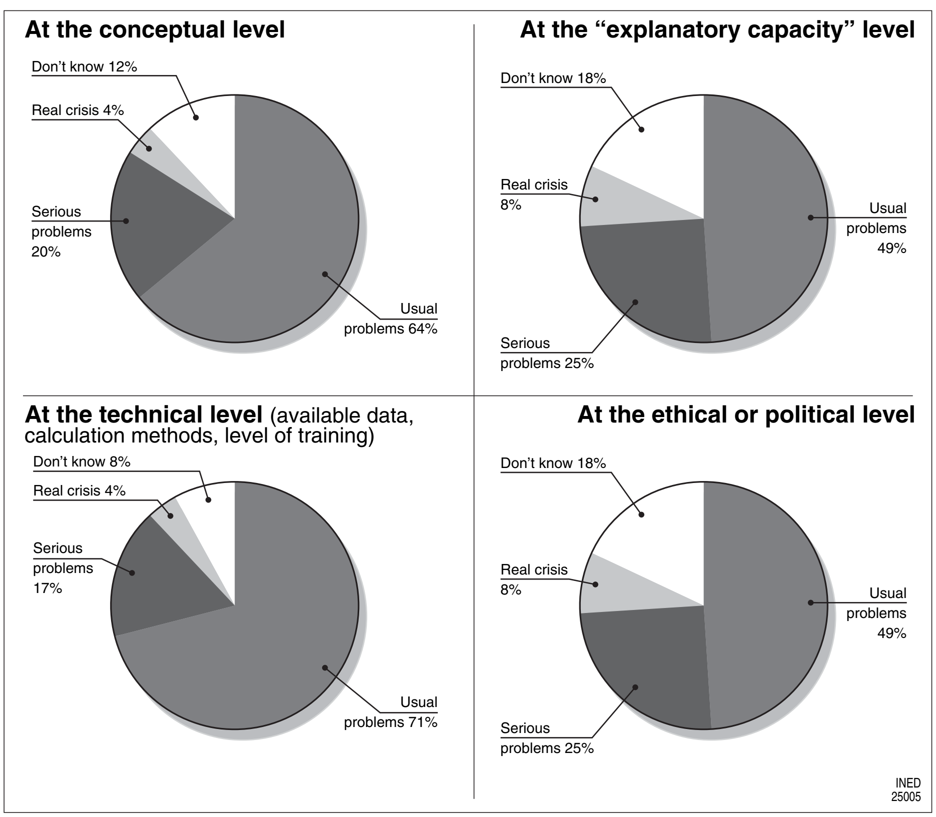

FIGURE 143–15 Crisis in demography or mere problems?

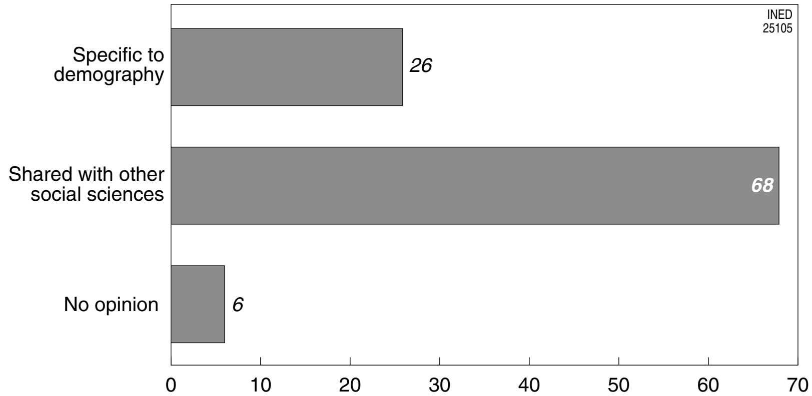

FIGURE 143–16 Problems specific to demography or problems shared with other disciplines?

Another danger facing demography is the possibility of exploding into a large number of relatively autonomous specializations (e.g., economic demography, family demography, demography of migration, mortality studies) to the point of losing its unity and finding itself split among other disciplines (e.g., statistics, economics, sociology, biology).

Do the respondents share this pessimistic vision? Only partly, insofar as they mainly think that in the future there will be an increase in autonomous specializations (52% agree compared with 30% who disagree; 18% did not respond), and they consider that the threat of demography looking inward is a serious risk that should be taken into consideration (50% versus 38% who consider that the risk is low or nil). The most pessimistic (26%) even fear that the discipline will collapse and that the fragments would be recovered by other powerful neighboring disciplines such as sociology, economics, and statistics.

The authors of the questionnaire thought that it would be interesting to find out what motivates the commitment of demographers. Fourteen reasons (and two free responses) were proposed to the respondents. The first choice is not surprising because it corresponds to a very common stereotype: "contribute to scientific progress through research and/or education" (19% of cumulated preferences). Three motivations then follow in nearly *ex æquo* order, with 9% to 10% of responses: "satisfy intellectual curiosity," (common) but more committed "to promote social integration and equality of conditions" and "to fight against North/South disparities." Immediately following are the objectives of "reducing inequalities in health and gender" (7% and 8% of responses).

"To control migratory flows," "to warn governments and opinions about excessive population growth or, on the contrary, about the threatened reproduction of generations," or "to safeguard the demographic bases of national identity" no longer appear to be very important objectives for most demographers.

Examining the graphs of Figure 143–17 reveals the existence of two clearly defined ideologic poles. The one on the left (see Fig. 143–17) groups the modalities corresponding to the most common motivations at the center of the pole, such as "to contribute to the progress of science" and "to satisfy intellectual curiosity" jointly with less common motivations that reflect concern for the preservation of national identity, the wish to regulate migratory flows, or the denunciation of threatened reproduction (in the North) and excessive population growth (in the South).

On the opposite side, a second pole reveals more innovative or more social values such as the reduction of social inequalities and those related to gender, the fight against racism and xenophobia, the search for equity between the generations, and the fight for integration and reducing North-South disparities.

The second chart (see Fig. 143–17), which compares the respondents' motivations with the type of organizations for which they work, highlights the different purposes of demographic research according to the place in which it is carried out. The universities, on the left of the graph, are mainly concerned with reducing inequalities between men and women and in health, as well as reducing racism and xenophobia and fighting against the pernicious use of demography. On the opposite side, the research centers want to contribute to scientific progress and satisfy intellectual curiosity, while warning of the risks of excessive population growth and the non-reproduction of generations. The local administrations and the national offices of statistics, which are structurally close on the graph, share the latter concern while wishing to ensure equity between the generations and regulating migratory flows. The international organizations and NGOs are

more concerned with excessive population growth and reducing North-South disparities, as well as wanting to promote social integration.

In any case, demographers have many challenges ahead of them that they will be able to rise to, alone or in collaboration with representatives from other disciplines, if they are not too timid, or as Alfred Sauvy said about aging, overcautious.

In the South, the previous priority themes of population growth and excess fertility are being supplanted by concerns regarding health. In the North, family and household life "remain at the center of social demography concerns, but the emphasis is moving away from traditional marital behavior toward new behavior" (Romaniuc, 2004). The massive intrusion of biogenetics into reproductive and health fields will no doubt contribute to the natural science aspect of demography, without weakening its attachment to the social sciences, as these problems of poverty and inequality between populations and within populations are increasingly intolerable, just as the increasingly pressing ecological constraint is imposing more activity in favor of sustainable development.

From the point of view of Western countries, all the attention of political leaders will for a long time remain focused on issues of immigration and low fertility insofar as they "call into question social cohesion, national identity, and the power struggle in the world" (Romaniuc, 2004).

All things considered, the vision sometimes evoked of demography as a discipline that is running out of steam and having difficulty finding its second wind could lessen, and even disappear, at the dawn of the 21st century, if demographers realize that beyond pure knowledge and scientific neutrality (which remain fundamental concerns), they also need to give more preference to knowledge applied to the service of humanity, without hesitating to intervene in public debates surrounding major regional, national, and world issues.

By abstaining for too long from making any normative judgments and taking any ideologic stands, demography has perhaps lost view of the fact that the essence of society is fundamentally political, and it will regain a full place within the social sciences (as demology?) only if it endorses the lucid sentence of Pareto when he stated in 1916 "that there is no scientific solution to the problem of human actions, nor for that of social organization."
