Female participation in the labor force is often confused with the *status of women*, although they are not at all the same thing. Employment does not automatically entail autonomy, although it may help. Women's wages may be a better approximation, as they show upon what terms women had paid jobs and, unless someone has control over their income, the purchasing power that it permits them.

Blank (1993) points out that individuals are differently empowered to take decisions and make choices affecting their lives, for social, psychological, and economic reasons. Relatively low empowerment of women relative to men is a characteristic of gender relations in many societies, but there are differential levels of autonomy across different groups. As the distribution of empowerment changes, one should expect shifts in decisions about the formation of families.

5. Collective Interests

The distribution of costs and benefits depends not only on the division of labor between the sexes, but also on the family organization and availability of other *care givers* and the societal provision for bearing some of the costs of reproduction (Lloyd, 1994). The costs of fertility may be partly shared by the wider community, for example, in the form of free or subsidized health and education services or tax allowances and cash benefits for children in a modern welfare state. Similarly the collectivity may have an interest beyond the individual in the size of coming generations as contributors to the pension scheme or as home-grown members of the labor force or military recruits. As such, they bring benefits to other citizens besides their parents, particularly those with no children of their own, and particularly where immigrants would not be satisfactory substitutes. In countries where fertility is considered too high, this could be because the public sector is bearing more of the costs than the private decision-makers (e.g., in the Caribbean departments of France) and/or because people beyond the family have to bear adverse consequences of congestion, competition for scarce jobs or resources. Such spillover consequences for others than the decision-maker are technically known as *externalities* and constitute a reason why one might want public authorities to intervene in private decision making.

The effectiveness of public policy to change population trends is discussed in subsequent sections of this chapter.

III. A SOCIOLOGICAL VIEW

A sociologic perspective considers the context of social organization, cultural norms and the sanctions by which societies have attempted to regulate reproductive behavior. Culture, religion, and ideational change mediate the economic influences on fertility, and offer normative constraints on behavior.

Cultural sanctions on reproductive behavior are the meanings organized and shared by groups that emphasize criteria of right and wrong (Kreager, quoted in Kertzer, 1995). Ideology, custom and culture also reinforce the authority structure within the family—between parents and children and between men and women. The importance given in most societies to the regulation of sexuality and marriage and to family and kinship systems, which determine and are the result of reproductive behavior, is evidence that fertility processes are a central concern of cultural systems and social organization (Kertzer, 1995).

Fertility behavior is influenced by both sacred and secular values. The first statement of *demographic transition theory* by Notestein (1945) suggests that religious values and the moral codes predominant among pretransition societies are important in keeping fertility high. With the movement toward a secular society, brought about as by *modernization*, the taboos surrounding deliberate control of fertility break down, bringing on the transition to low fertility.

In this view, all aspects of life are integrated in traditional societies; family life, economics, and politics are all governed by religious norms. With the coming of modern industrial forms of economic organization, these aspects of social organization become differentiated, and individuals are freed from the all-encompassing constraints of the dominant value system. They gain more freedom to choose different values and beliefs, particularly those related to family life. The process of modernization and the development of capitalism in Europe were believed to be accompanied by a move toward secular individualism. Traditional religious ideas gave way to self-expression, in turn affecting the individual expression of sexuality and family values. Parenthood was no longer a dominant moral obligation dictated by religious or social values (Simons, 1986). Lesthaeghe (1983) has suggested that this emergence of individual autonomy in European cultures led to behavioral patterns oriented toward the welfare of nuclear households rather than toward larger kinship groups. As individuals perceived themselves to be more self-reliant, changes in family formation, dissolution, and reproduction took place. These changes, he suggests, involved an increased orientation toward child welfare, and this pattern contributed to reinforcing greater independence from the family itself, as economic production shifted from familial to nonfamilial modes.

The sociological view of fertility focuses attention on how particular forms of cultural and social organization lead to norms and values that influence when and how childbearing takes place. One well-known example of such social norms is those found in parts of West Africa, which regulate when sexual relations may begin following a birth. Such culturally prescribed practices may have arisen to protect the new infant from the competition of a sibling whose birth follows too closely and interrupts breast-feeding, which can lead to malnutrition and ill health or death. Although traditional values dictate abstinence until the child is weaned or walking, these norms may break down with the influx of new ideas or values, such as those accompanying the spread of Islam or the increasing influence of the West. Islam proscribed sexual relations for a 40-day period, much shorter than the traditional norms. With the advent of modern technologies, however, women are able to maintain the prescribed spacing of their births, while resuming sexual relations with their husbands, who may use the new norms to justify their own pressure to resume relations (Bledsoe *et al.*, 1993).

Religious values may be upheld only among small groups, who are able to maintain fertility norms quite distinctive from the society in which they function. One such group is the Hutterites, an Anabaptist religious sect living on the American Great Plains, whose religious principles prohibit contraception and lead to a completed family size of almost 10, a much higher level of fertility than of the surrounding society. Secular society will tolerate nonconformist fertility behavior as long as it remains the choice of a minority and does not threaten to destroy the legitimacy of the prevailing norms and values (Simons, 1982).

Chamie (1981) studied religious differentials in fertility among Lebanese women, and found that non-Catholic Christians had higher fertility than Catholics and both groups had lower fertility than Muslims. However, he also found substantial differences among the different Muslim groups, fertility highest among Shia women, slightly lower among Sunni Muslim women, and among the Druze somewhere between that of Catholics and non-Catholics. It seems it is not religious norms and values, *per se*, that lead to these differences, but other norms shared by different religious groups. Such would fit with Folbre's view that group membership helps to determine reproductive behavior. In some cases these pro-natal norms are strengthened by the minority status of the group, feeling the need to keep up their numbers in a somewhat hostile environment. Such an explanation has been offered for the relatively high fertility of Muslims in India and Walloons in Belgium.

There is also heterogeneity in the fertility of Israeli Jews, dependent not on ethnicity, but on the *religiosity* of certain groups (Friedlander and Feldmann, 1993). In Israel, a modern developed society by most standards, the fertility rate of around 2.8 births per woman is still well above most European countries. This national average disguises large differences in fertility between religious groups. The total fertility rate (TFR) is 4.5 among all religious Jews in Israel, while ultra-Orthodox Jews have very high fertility, a TFR of 7.5. This group of highly religious Jews shuns the values of the outside world, while sharing group norms that lead to early marriage and very high fertility. However, their high fertility does not entail extra cost to parents because family arrangements are such that younger children are looked after while women work and men spend their time in religious study.

Although rejecting the values of the outside world, this pattern of childbearing and rearing is supported by the wider society. The success of these pronatalist religious values is due in part to arrangements in the wider society, which provides economic supplements such as child allowances and housing assistance, and contributions from external religious groups, their own institutions and the government. In this case, it appears that the pressure on individuals to conform to religious sanctions and fertility norms is powerful, and as the size of this community increases, their family-building pattern could result in increased political power.

The historic evidence from the European Fertility Project (Coale and Watkins, 1986) exposed the shortcomings of Notestein's classic theory of demographic transition. This relied heavily on *modernization* and changes in the mode of production to explain fertility change. This project suggested that fertility was most strongly related to cultural boundaries, defined by language, ethnicity, or geography. Cleland and Wilson (1987) synthesized this historic evidence and contemporary findings of the World Fertility Survey program, conducted in less-developed countries around 1975. Their findings counter the economic view of fertility behavior as the product of rational decision-making. They present evidence that fertility decline was related less to socioeconomic factors than to *social variables* and that the diffusion of new ideas about the acceptability of modern birth control was its main determinant. The formation of the nation state in the process of modernization creates another mechanism for direct and indirect influence on reproduction, at macro- and microlevels (see Casterline, 1989 and subsequent sections).

Many attempts to explain demographic processes, including fertility behavior, have been post-hoc explanations for observed changes, mostly driven by the types of data conventionally collected in surveys (McNicoll, 1980). Lacking a theoretical perspective, these explanations have yielded a puzzling array of possible factors and configurations that may lead to reproductive change. McNicoll elaborates what has been called an *institutional theory* of fertility change. Unlike *ideational* theories, this allows some role for the vastly differing contexts, both historic and current, in which communication about fertility takes place. He argues that institutions rooted in the history of each society give rise to local patterns of social organization: the family and local community; law, and the local dimension of public administration; stratification and opportunities for mobility; the labour market; and state-individual relations. These institutional *endowments*, as well as the transactions individuals make in adapting their *hopes and expectations about the future* to the institutional constraints, together trace the path a particular society takes to fertility decline (McNicoll, 1994). Individuals are not merely passive receptors of social norms, but actively try to re-negotiate the institutional constraints in their own interest. Such a theory attempts, as Greenhalgh (1995) puts it, to *situate fertility* in its cultural, political, and economic context. Such an approach provides the possibility of testing hypotheses about how particular aspects of social organization translate into microlevel reproductive behavior, providing a role for individual action in shaping reproductive outcomes. Folbre (1994) would add collective action by interest groups to the script. Writers concerned with the influence of social values on fertility include Lesthaeghe and Surkyn (1988), who cite the demonstration by Simons (1982) that the baby boom and bust of 1945 to 1985 in England and Wales was foreshadowed by an indicator of religious adherence (Easter Day Communicants). Preston (1986) also believes that value changes play an important role in fertility trends, although he feels they can ultimately be traced back to an economic rationality.

Even in societies that have not yet undergone a fertility decline, people are not merely passive acceptors of normative constraints. Recent evidence from West

Africa suggests that individuals *tinker* with social norms regarding the spacing of births (Bledsoe *et al*., 1993). However, in West Africa cultural norms do not include the idea of *stopping* after a preferred family size has been reached. This suggests that although the means of fertility regulation are well known, it is changes in ideas regarding the acceptability or desirability of family limitation within marriage that leads to the *stopping behavior* characteristic of significant fertility declines.

The *social construction of the family* differs across cultures and may explain why fertility has not declined in some regions, even those where development is far advanced. Cleland and Wilson found that sub-Saharan African and Middle Eastern societies differ from other regions in fertility preferences. Socioeconomic differences in fertility preferences in these regions are more pronounced than divergences in fertility itself.

The social organization of the household—itself an outcome of *cultural* forces that lead to different configurations of household structure—influences marriage timing and the ability of the household to support dependents. Because these seem bound up with fertility differences, a key question, then, becomes, "What determines family systems?" In much of sub-Saharan Africa, the boundary of the family extends to a large kin or lineage group, which makes it more likely that the larger group to which individuals owe allegiance will retain much control over fertility behavior. Practices such as child fosterage, arrangements where the extended family provides child care, and state provision for education, "break[s] down household economic boundaries and spread[s] the impact of additional children on family resources across a wider kin network" (Lloyd, 1994, p. 11–12). Such institutional supports to high fertility may prevent the spread of the *small family norm* in these regions.

The *family mode of organization* framework hypothesizes that the extent to which the family organizes individual members' activities plays a role in fertility change (Axinn *et al*., 1992). This can occur in two ways. Fertility change may be caused by a changing demand for children as a result of desiring to maximize the outcome of the new, nonfamily organization of activities (structural economic change) or may be due to ideational change, a result of the diffusion of new ideas and fertility goals through alteration of the group (nonfamily) with whom family members have contact. In this way, this approach attempts to connect macrolevel social change to individual-level fertility decisions and behavior. This seems a promising way to approach a test of the rival economic and sociologic theories of fertility change, but there is still scant evidence on which to judge these hypotheses.

IV. QUESTIONS ABOUT FERTILITY AND SOCIETY

This section looks at some of the answers, and controversies, that social scientists have offered to certain questions. Answers are summarized at the end of each section.

1. Why Does Fertility Decline with Development?

One of the greatest paradoxes facing the *demand approach* to fertility is to reconcile the historic (at least) association of fertility decline with economic development. In the economist's view, the latter increases the resources available to potential parents. If their decision making resembles that of a consumer demanding a *normal good* (i.e., one for which demand increases as income increases), one might expect economic growth to raise the demand for progeny.

One interpretation is that positive income effects are outweighed by increasing costs of parenthood as economies develop. There are higher standards of consumption to be provided, fewer opportunities for child labor, and increasing investment in education and training required by an increasingly sophisticated economy.

Just as economic growth involves the accumulation of physical capital, it also requires increasing standards of skill and sophistication among the workers. New home economics appeals to its distinction between child quality and child quantity in this context. Economic development offers improved opportunities for investing in child quality (better survival, better schools, better employment prospects). This encourages parents to invest more resources per child than they would have done at a lower level of income and, given the right assumptions about relative income elasticities, to substitute quality for quantity. They cut family size to raise the quality of life for each child in the smaller family. This resembles propositions reached independently by evolutionary biologists. Although the detailed apparatus of this theory is difficult to prove or disprove, it is consistent with much historic experience. Fertility decline is associated with improvement of child health and the spread of schooling (investment in human resources) and with accounts of the prospective cost of education as being a motive for controlling fertility (Crook, 1997).

Other ways in which economic development may reduce the *demand for children* could be pressure of space in urbanization; competing employment opportunities for women, as the home and the workplace become separate; and the reduced risks in the economic environment against which a large family may be viewed as insurance. Women's employment and insurance are discussed in subsequent paragraphs.

The classic demographic transition theory was based on the idea that differences in fertility are rooted in economic structures. Traditional peasant economies are organized along familial lines, whereas capitalist economies are not. With increasing industrialization comes disintegration in the familial mode of production and the pronatalist structures it engenders. As industrialization spreads, economic *modernization* is accompanied by the diffusion of the small nuclear family norm. As we have seen, the findings of the Princeton European Fertility Project did not support the classic view of fertility transition. Change spread to all social groups too quickly to reflect real changes in structural economic conditions. A threshold was apparent: when fertility declined by 10%, it tended to proceed quickly to low levels (Watkins, 1986). The timing of fertility change seemed to follow cultural boundaries and to be associated with indicators of social development, such as education or literacy, rather than with economic development (Cleland and Wilson, 1987; Brass and Kabir, 1982), and its pace was closely associated with a shift from fundamentalist to secular world views (Lesthaeghe and Wilson, 1986).

Cleland and Wilson (1987) argue that the fundamental force behind fertility decline is not the changing balance of costs and benefits of childbearing, but a change in ideas and norms, acting independently of the level of economic development. They suggest that "the fundamental forces of change operate at the societal level" (p. 24), not at the microlevel of individual decision making. Differences between high- and low-fertility groups in the World Fertility Survey are not to be found in their reported preferences for children, but in couples' willingness or ability to regulate their fertility in accord with these preferences.

Fertility transitions, both historic and modern, are predominantly driven by *stopping* behavior. After a specified number of children, couples adopt birth control or otherwise limit the size of their families. One suggestion is that *modernization* (by this we mean the shift in economies driven by technological advances that result in increased output) brings about a spread of new ideas, a change in mentality, from a belief that family size is a result of chance to a clear notion of what family size *ought to be*, in van de Walle's phrase *numeracy about family size*. Means of regulating fertility are known in most societies, but "any contraceptive technique is probably most effective after the couple has reached the number of children they do not want to exceed" (van de Walle, 1992, p. 501).

How these new ideas arise and why new norms develop are still unanswered questions. Cleland and Wilson (1987) argue that the growth in human *mastery over nature* and widespread mortality decline has facilitated the spread of fertility control by *undermining the reproductive imperative*. Once the latent desire for lower fertility appears, it is the spread of knowledge regarding effective means of birth control that eliminates excess or *unwanted* births.

Development is likely to facilitate the spread of knowledge. Development is also likely to induce the latent desire for lower fertility, particularly if it is of a broad-based, rather than *trickle-down* nature. But economic development cannot be claimed as a necessary and sufficient condition for fertility decline as implied in the *Best Contraceptive* slogan.

Finally, the explanations of the link from development to fertility decline are multiple and not mutually exclusive: reduced benefits; increased costs; demand for quality; improved contraceptive technology or delivery; changed perceptions of what behavior is advantageous, appropriate, or even thinkable. These could act singly or jointly. What operates in any particular situation does not necessarily apply in others. Just as economic development cannot be simply replicated from one country to another, the course of demographic development can follow diverse paths, reflecting local features of both social and economic structures, and drawing on the technology and experience of those who have gone before.

2. Can Fertility Decline in Poor Countries?

A closely related debate is whether fertility decline is possible without economic development. The view that it is not, or at least not likely, goes back at least as far as the Bucharest Population Conference of 1974, when the slogan was coined, "Development is the Best Contraceptive." This echoes classic demographic transition theory that social and economic development is its prime cause. Development reduces dependence on children or raises the cost of rearing them. Thomas (1991) restated this slogan. He argues that programs offering the means of fertility control will find more willing takers if accompanied by measures to reduce the risks or provide alternative sources of insurance to poor parents.

In poor societies, the need for child labor, either for wages or in family enterprise, is one source of the demand for children. Insurance against risk in old age or in times of crisis, which children can provide, is another (Cain, 1982). One source of security, available to some, is land holding, but any impact this may have on the need for a large family through greater security may be offset by a demand for child labour. (For further discussion of old age security see subsequent sections.)

In the joint-family systems of much of Asia, old-age support is a family concern (Cain and McNicoll, 1987). Sons bear the primary responsibility for care of elderly parents, leading to a demand for sons, and a good probability that at least one will survive to support his parents in old age. Considerations of security, therefore, can outweigh the cost-benefit accounting, which might precede the decision not to have another child (Cassen, 1978).

Furthermore, the high mortality levels usually prevalent in the poorest societies may lead to more births in order to *replace* children who die to ensure that at least some children, especially sons, survive to adulthood. In poor societies, where education levels are low, the costs of raising children may be exceeded by the benefits those children will bring when they reach the age at which they are net contributors to the family income. For a number of reasons, therefore, when parental income is low, the emphasis is on child *quantity* rather than *quality*.

Nevertheless, traditions of filial support may be compatible with low fertility (Cleland, 1993; Weinstein *et al*., 1990). Examining fertility decline in Bangladesh, a range of factors thought to reduce demand for children were reviewed (Cleland *et al*., 1994). No significant changes in school enrollment, the value of children's labour, social security benefits from the state, female participation in the labor force, or improvements in the educational or social status of women were found. Conversely, some argue that economic reversals can induce fertility decline. For example, increasing landlessness could drive families from agriculture to the service and sales sector, where fewer children are needed to supply labor and costs of raising them increase. The Bangladesh study detected no significant deterioration in the economy to an extent that might decrease demand for children. Despite the evidence that factors affecting demand for children had not changed, fertility began to fall in the late 1970s, accelerating in the mid 1980s, reaching the level of about 4.5 children per woman by 1990. The authors suggest that the long-term decline in child mortality in Bangladesh led to a greater willingness to adopt innovative behavior. All that was necessary was access to the means of fertility control, provided by a strong government family planning program, which effectively removed barriers to use of contraceptives by delivering advice and supplies at the doorstep. Despite the evidence that demand for family planning was low before the initiation of the national program, its comprehensiveness appears to have maximized the spread of new behavior and sustained it.

These conclusions may be compared with those of Dow *et al*. (1994) for Kenya. Here too, the resurgence of a family planning program accompanies fertility decline, but a deterioration of economic conditions is judged to have triggered the motivation to seek its services. However, identifiable transfers (that is, support) to the elder generation did not appear to have changed.

In yet another context, Martine (1996) examined the fertility decline over a period of intense social change and deep recession in Brazil. Total fertility fell dramatically and very quickly from an average of six births per woman in the early 1960s to 2.5 births per woman in the mid 1990s. This was achieved primarily through high rates of abortion and sterilization. Martine traces increased motivation for fertility regulation to institutional changes in health and social security. The expansion of health services served to legitimize the use of birth control, even in the face of strong church opposition, and increased the level of knowledge about, and access to, effective means of regulating fertility. Government-sponsored attempts to *modernize* also accelerated rural–urban migration, and increased interest in consumer goods, which in turn increased the costs of childrearing. Mass media are also given credit for promoting consumption and eroding traditional ideas about male authority. Coverage of the social security system was expanded and a guaranteed income in old age established. This shifted responsibility for the elderly from the family to the state, and despite deliberate pronatalist elements of the social security system, such as child allowances, the impact of the system was in fact antinatalist. Changes in government policies played an unintended role in Brazil's fertility decline.

Martine (1996) places less weight than others on the argument that Brazil's economic difficulties lessened demand for children (Carvalho *et al*., 1981). Rather, his evidence suggests that a constellation of factors—structural and ideational—are at the heart of the sustained transition. The aggregate analysis is persuasive, but does not directly connect these changes in the larger society to mechanisms at the individual level. Can diffusion of new ideas be linked directly to changes in individual behavior?

To put it briefly, fertility has declined in poor countries and poor communities. This is not necessarily as a result of poverty. Ideational and structural factors short circuit any iron link between development and fertility decline.

3. Women's Education: Materialist or Ideational Influence?

One oft-cited benefit of development is the increased access to educational opportunities that may accompany changes in the demands of the labour market. How increased access to education affects the status of women in general, and their fertility, is a major concern of policy makers today.

It is well known that, for a number of reasons, educated women are more successful than their uneducated *sisters* in bearing and rearing healthy children. They are thus less likely to bear more children than their family size goals (see Cochrane, 1979 and Cleland, 1986, for evidence on maternal education and fertility; Cleland and van Ginneken, 1988 for a review of the evidence regarding child survival). The strong and nearly universal link between female education and fertility decline has provided further evidence on how and why reproductive change occurs. It suggests that the effects of education are both material and ideational in nature.

Education can indirectly influence fertility through several pathways: by affecting supply factors, the demand for children, and the *costs* of control. The mechanisms through which it works are unclear, partly because in some circumstances very small amounts of school attendance—just a few years—are sufficient to observe an effect. Given the unequal and very uncertain quality of education widely available in many societies, this effect can hardly be due to actual knowledge imparted and makes it unlikely that strikingly different attitudes toward the world are imparted and absorbed by girls in so short a time. Some have proposed that besides exerting a powerful independent effect on fertility, education (or *schooling*) may act to change reproductive behavior by increasing a woman's autonomy (her ability or freedom to make decisions about her own fertility) (see Basu, 1996, for a detailed exposition of these issues). Moreover, the relationship may partly reflect *selectivity* especially where the general education level is low. That is, educated women are more likely to come from families of higher status or wealth, who want to educate their daughters and also may impart an orientation to lower fertility. This confounds the relationship between fertility and education (Sathar, 1996). We now look at the evidence for all of these relationships.

Jeejebhoy (1995) provides us with an extensive review of evidence on the matter from demographic surveys. Education can influence the *supply* factors by breaking down traditional norms about breast-feeding and postpartum abstinence. Even a little education shortens the duration of breast-feeding. Breast-feeding may be incompatible with the employment educated women seek. They are also more likely to be aware of and able to afford alternatives to breast milk. As education increases, postpartum abstinence decreases, and this is thought to be due to a greater intimacy between husbands and educated wives. These education effects raise fertility, unless countered by effective birth control.

On the other hand, education raises the age at which a woman marries (Appleton, 1996), reducing the length of her reproductive life. The reasons are many: Educated women have a greater role in decisions about whom and when they marry; they are likely to have greater control over resources due to employment before marriage; and, in some settings, they are less marriageable than uneducated women (Jeejebhoy, 1995). However, postponement of marriage may simply be followed by couples *catching up* to those marrying earlier by increasing the pace of subsequent childbearing (Sathar, 1996).

Women's education, at least beyond a few years of schooling, can also reduce the number of desired children. Economic explanations emphasize the increased costs of an educated mother's time and increased *rationality* of decisions about family size and desired sex composition. When the education of women becomes widespread, the value of their labor increases. They become more active in the labor force, and more economically independent. This in turn can reduce the felt need for male children, either as labor or as security in old age (Cochrane, 1979).

Women's education can also reduce the obstacles to contraception, lessening the psychosocial *costs*. There is a direct relationship between education and the practice of contraception, due in part, perhaps, to more frequent interactions with the outside world (Basu, 1992). Thus, educated women are also more likely to know about birth control and to have better access to effective methods because they have more experience in dealing with the world beyond the household. In this sense, education may work by facilitating the spread of knowledge about reproduction.

Another mechanism proposed is that education increases a woman's status and autonomy, giving her more control over her own fertility and affecting her motivation to bear children. There is a good deal of evidence that a higher threshold level of education must be reached in highly stratified societies than in egalitarian ones before fertility starts to decline (Jejeebhoy, 1995). This may be especially true where gender stratification is strong, because it limits the domains over which educated women can make decisions and determines the amount of education necessary before they are taken independently. The social context also conditions the relationship between education and a woman's motives to bear children. Where her opportunities are greater, she may gain status in other ways than by bearing sons, and may need to depend on them less for security in old age. In gender-stratified societies, more education is necessary before women are confident of their own economic and social status to revise their fertility goals (Jeejebhoy, 1995). It may be that the education–fertility link is strongest where education actually can be translated into employment.

Education may also help to increase a woman's autonomy over her own body, including her right to refuse sex (Orobuyloye, 1995). It may also lead to increased husband–wife communication regarding fertility decisions and use of contraception. Evidence from Africa suggests that educated women are more likely to be in agreement with their spouse's fertility preferences than uneducated women (Bankole and Olalaye, 1995), but this does not always result in lower fertility. In Kenya and Ghana, for example, men and women share a common goal of high fertility.

Educated women are more likely to marry men who are also educated, and although women's education is a consistently stronger predictor of fertility than their husband's education, his role in shaping fertility behavior is clearly pertinent. Husbands' roles in family-building strategies and decisions are important, but the meager evidence available does not reveal any consistent associations between husband and wife preferences and other factors (Mason and Taj, 1987). Basu points out that both men's and women's fertility preferences are likely to be affected by the position of women in society, so that for example, if women are denied a place in the labor market, both husband and wife should want more sons. This may extend to the other actors in the household who influence family-building strategies, such as mothers-in-law (Basu, 1992). Others have suggested that a husband's non-family experiences (such as changes in residence, and work and leisure activities outside the family) have a positive effect on contraceptive use (Axinn, 1992). Opportunities for work and residence outside the family may depend to some extent on the husband's educational attainment. If research designs exclude men, important mechanisms involved in behavior change may be missed.

Jeejebhoy's extensive review of education-fertility linkages concludes that in societies with strong gender stratification, the most powerful effects of education are to reduce traditional inhibitions on the *supply* factors—to raise fertility. Only in more egalitarian settings do the fertility-inhibiting effects of education—on marriage age, family-size preferences and use of contraception—counterbalance or exceed these. This may explain why the relationship between education and fertility is less clearcut than the relationship between education and contraceptive practice. In some settings contraception may be initiated only after unwanted births have already occurred. Jeejebhoy (1995) argues that this may be the case where women achieve the power to make reproductive decisions rather late in their married lives, when desired family size has already been exceeded, rather than earlier in their life course.

In highly gender-stratified societies, religion and patriarchal kinship structures shape marriage practices and female economic roles and sometimes make them seem impervious to education, or at least resistant to its effects. Cultural systems and social organization that strongly influence reproductive behavior often have their roots in the predominant economic structures and modes of production, at least historically. For example, higher levels of literacy and employment among South Indian women do not explain observed differences in female autonomy—and fertility—between North and South India, which have deeper historic roots (Basu, 1992).

This may be one reason why community context—community-level effects—seems to operate when we look at the relationship between fertility change and education. Generally speaking, high societal levels of education are strongly correlated with low fertility at the aggregate level (Cleland and Jeejebhoy, 1996). However, the overall level of education in a society can exert a powerful effect on its own to influence the fertility behavior of individuals regardless of their educational attainment. Cleland and Jeejebhoy show that, in the Indian states of Kerala and Tamil Nadu, where literacy rates are high, fertility at the individual level is inversely related to years of schooling. Both states have much lower total fertility than the low-literacy states of Uttar Pradesh and Bihar. In the latter, however, there is no consistent relationship between a wife's education and fertility at the individual level. The contextual effect of education exerts a strong influence on fertility behavior that is independent of its individual effect.

A striking example of how contextual factors may change is illustrated in a study examining education and fertility decline in two Chinese provinces (Freedman *et al*., 1988). Early in the shift from moderate to low levels of fertility in both provinces the educational level of the production brigade had an effect on fertility that was independent of the effect of an individual woman's educational attainment. In rural areas, fertility of women at each level of education increased steadily with the proportion of the local population that was illiterate, and where the proportion illiterate was as high as 40%, the effect of individual educational level was inconsistent (as seen in Uttar Pradesh and Bihar).

Following large-scale campaigns and intensive family planning program effort, these local (contextual) differences were leveled, and the overall level of literacy in the area was no longer consistently related to the level of fertility. Moreover, the effect of education at the individual level also disappeared very shortly after inception of the government program. Where the government family planning program was strong, knowledge and supplies quickly became available to everyone in the area, and social differentials in fertility disappeared (Riley and Gardner, 1997). Government policies seem to have the power to diminish educational differences in contraceptive use and fertility.

LeVine *et al*. (1991), tried to investigate what processes at the individual level that lead to lower fertility might be affected by increased education. Their study in two Mexican communities found that mothers with more education used child health and family planning services more frequently than less-educated mothers. Both factors increased child survival and lowered fertility, but some intervening processes were found that provide clues to how increased schooling may translate into changes in fertility.

Using in-depth interviews and observation, they found that in contrast to less-educated women, more schooling led women to aspire to higher status for themselves. They were more likely to report making major household decisions jointly with their husbands. Educated women also spent more time talking to their infants and were more responsive to them than uneducated women. Such behavior has long-term effects on an infant's cognitive development. They expressed higher occupational aspirations for their children, while reportedly expecting less help from their children in old age. These findings confirm that schooling influences the attitudes of individuals, and also points to the effect education appears to have in increasing parental investment in a child's *human capital* or *quality*, directly raising the costs of children by demanding more of a mother's time. Whether new fertility preferences and practices preceded and promoted these educational differences in attitudes and behavior or resulted from them cannot be deduced, but this study is evidence of schooling's wide-ranging effects.

Finally, there are multiple mechanisms by which increased female education affects fertility behavior, and good evidence that its influence is both materialist and ideational in nature.

4. Is Childbearing for Old Age Security?

Caldwell's theory of the fertility transition is an elegant synthesis of material and social forces (Caldwell, 1982). In the process of development, not only does fertility decline but there is also an associated reversal of intergenerational wealth flows. In the high-fertility society, the elders are in control and draw economic support from their adult offspring. This creates a motive for high fertility, or at least an obstacle to the adoption of family limitation. The more surviving children, the more secure will be those parents who survive into old age. Those with few or no surviving children will be endangered themselves. In the course of development, children become a less reliable source of support; the gerontocracy weakens, especially as the younger generation gains skills and becomes more mobile. Even without enforcement problems, alternative sources of security become more attractive: physical assets, purchased insurance, the capital market and related institutions like credit unions or friendly societies, and, eventually, social insurance pensions providing old age security through the state. Caldwell notes that the transition does not just involve the cessation of wealth flows from younger to older generations, but a reversal. Parents invest more resources in the human capital of their offspring, and bequeath to the next generation whatever has not already been used up.

There is conflicting evidence on whether the wealth flows are always in the directions Caldwell posits (e.g., Dow *et al*., 1994). In rich counties there are gross flows in both directions, and mutual dependence, in some cases of the elderly and the middle-aged (Thane, 1989). In some poor settings, fieldwork among primitive groups in South America suggests children do not contribute more than they consume and points to other motivations or drives to reproduce (Kaplan, 1994).

People may still want to call on family members to provide physical care, companionship, or emotional support in old age, and in some cultures it is important to know that a descendant will be on hand to lead one's funeral rites. In India, it has traditionally been important for a son to survive to perform this function, but isolated, although significant, incidents have recently been reported of daughters taking this responsibility (P. Visaria, personal communication).

In more developed societies, with increased life expectancy, the issue of old age dependency gains salience over that of who takes care of the funeral. The establishment of collective institutions for the material support of the elderly in developed countries removes one reason for having children. Cigno (1991) points out that there must be other reasons keeping childbearing going at all. He also points to the irony that the pay-as-you-go pension systems, mostly established when the elderly were relatively less numerous than they are becoming, are facing severe difficulties because of the declining size of the contributing generations. If their existence is deterring childbearing, pension schemes can be said to contain the seeds of their own destruction. One may not need to have children to provide a private source of income in old age, but someone has to rear the next generation of contributors to the pension scheme. This externality has led to the suggestion that pension entitlements should be relinked, positively to the number of offspring produced (Demeny, 1987; Vallin, 1992).

At present, a large class of prolific pensioners are actually penalized in the cash support they can expect. Most state (and all private) pensions are positively related to the earnings. Women who have raised children often forgo at least some of their earnings during their labor force years, which tend to be reflected in lower pension (Joshi and Davies, 1994). Thus the opportunity costs of childbearing are carried on into old age, reinforcing low fertility and further undermining the long-term viability of the pension scheme. In the short term, elder dependents and child dependents appear to be in competition for the resources available. In the longer term, investment in the young is still essential to ensure resources for the old (Qvortrup, 1994).

Developed economies have many institutions other than parenthood to secure income and services for the aged. Less-developed societies have hitherto had relatively few aged people to support and these have not necessarily been dependent on their own offspring. The empirical importance of the old age security motive for childbearing has been inconclusively debated. Old age security is still a reason for reproduction in aging societies, but one that is more likely to be acted on collectively than individually.

5. What Makes Fertility Fluctuate in Rich Countries?

Has the fertility transition finished? Have the developed countries with their high-quality population, their highly developed state and market institutions, and their high levels of birth control technology reached a new low-fertility equilibrium? Will decline continue to be sustained below replacement and beyond or is it the nature of reproductive behavior in advanced societies to fluctuate?

Richard Easterlin's famous hypothesis is that in mature and stable posttransitional society, fertility would have a tendency to fluctuate, sometimes below, sometimes above replacement. As spelled out in his popular book, *Birth and Fortune*, the central mechanism is relative generation size and its influence on aspirations relative to earnings (Easterlin, 1980). Members of small cohorts would reap advantages in education and the labour market; young adults would find life relatively easy, so that their aspirations for living standards would be attained sooner, and permit the forming of larger families than generations who were more numerous relative to their predecessors. A key link in the chain is the assumption that standards are set by those the cohort enjoyed during their upbringing. This *relative income hypothesis* is an example of how preferences are determined within the system (*endogenous*). Easterlin argues that relative generation size determines a number of other series, from wives' labour force participation, to divorce, suicide, and crime. The evidence that relative generation size affects earnings is mixed (Wright, 1991). The evidence that a small generation became the parents of a baby boom is strongest for just one cycle in the United States and perhaps Australia, Canada (Wright, 1989), and France (Leridon, 1978; Chenais, 1983). Ermisch (1988) did find a modest contribution of relative generation size, among other variables, to his analysis of parity-specific birth rates in England and Wales between 1952 and 1985.

The prediction of self-perpetuating swings has not been borne out. By the 1990s, the children of the 1960 to 1970s *baby bust* should have been generating a new boom, but fertility in the United States has only moved from around 1.8 in the 1980s to around replacement (2.1) in 1990 to 1992 (Monnier and Guibert-Lantoine, 1995). Perhaps the conditions of economic stability on which the hypothesis was founded have not held out or perhaps the model never really worked.

A rival model, which also predicts fluctuating fertility in advanced economies, was proposed by Butz and Ward (1979) building on the microeconomic Chicago school model of Willis (1973). Their prediction was, contrary to Easterlin's, that fluctuations in fertility would be *counter-cyclical*: more births in hard times than times of prosperity. Their reasoning was based on the growing proportion of wives in the labour force, for whom increased wages would mean *substitution* away from childbearing. As the proportion of two-earner couples increased, presumed positive *income effects* of men's wages would be outweighed by the negative effect of rises in women's wages. The upswing of the 1950s baby boom would fit with a regime where income effects dominated. The end of the boom would be triggered by sufficient two-earner couples confronting a continued wage growth. The model was fitted to data for 1948 to 1956 and successfully predicted 1957 to 1975, but its fit to the earlier part of the century or to subsequent years is questionable (Olsen, 1994). Given continued rise in women's labour force participation, we should expect continued decline in fertility into the 1990s, but as we have seen, such a trend has reached a plateau (in most other advanced countries except Southern and Eastern Europe and Japan).

One reason for the failure of these models to find confirmation in statistical data may be the annoying habit of history not to stand still long enough for a cyclic process to display any regularity. Another view, perhaps another way of saying the same thing, is that there are other factors to be taken into account. These include the policies adopted by governments (described in subsequent sections), the growing compatibility of motherhood and employment, particularly via the purchase of child care, the growing instability of marriage, the dissociation of fertility from marriage, and a climate of uncertainty and global insecurity (Ermisch, 1990, Olsen, 1994). Most of these factors point to continued low fertility, if not continuing *flight from parenthood*. Hobcraft and Kiernan (1995) see "little prospect of a resurgence of parenthood" without the help of "biological and social pressure to reproduce."

A word is necessary about the role of contraceptive innovation in accounting for fluctuations in fertility in industrial countries. In particular it is very widely believed the introduction of the contraceptive pill brought about the 1960s baby bust, and that periodic scares about the health hazard of the pill bring about blips in the birth rate as users rush away from that type of birth control without substituting another. Murphy (1993) argues that changing attitudes to the contraceptive pill are a major element in short-term fluctuations in British fertility. In the work by De Cooman *et al*. (1987), evidence of *pill scares* was not abundant, but one year did show a slight excess of births, otherwise unexplained. An alert about the health effects of some types of pill in October 1995 was followed by a modest rise in both abortions and maternities in England and Wales (Wood *et al*., 1997).

The fact that there is a range of modern and traditional means of contraception should mean that changes in the price, availability or quality of one product would result in people choosing another method. Some of the boom births were described as *unwanted* in demographic surveys (Westoff and Ryder, 1977). Using demographic surveys for France, Leridon (1985) estimates that 21% of births in 1965 were not desired, and an equal number were not planned to arrive at that particular time.

It is not only the absence of effective methods of birth control that made this situation possible, but also a general context in which the child that was one too many was not altogether so . . . Contraceptive practice may have slackened during the 1960s due to the fact that couples' intentions had become less certain during this period.[1]

Over the years 1965 to 1975, as contraception improved, unwanted fertility was halved, accounting for a drop of 0.32 on the period fertility rate. However, most of the births in both 1965 and 1975 were planned. The fall in planned births accounted for 0.28 and in mistimed births by 0.21. Even the unwanted births could not have been too seriously unwanted as the knowledge, in principle, existed of how to prevent them. Even if the methods were somewhat old-fashioned, inconvenient, and/or unreliable they served to keep fertility low in the 1930s. One therefore needs an explanation of the motivation, as well as the means, to end the baby boom. Certainly, the demand approach would admit that improved means of birth control would tip the balance in favor of its use at the margin, and could theoretically have a large impact if the conventional methods were insuperably distasteful. There is also the argument that the users of birth control became more effective, or careful, as well as the methods themselves.

Reliable birth control, accessible to all women has a number of other consequences, which could in turn help bring about fertility decline. It has permitted widespread sex outside marriage. This increased opportunities to form, and move between, partnerships. It has increased the freedom of both men and women, which has arguably led to the revision of norms about the formation of sexual unions. The easier sexual mores added to other factors weakening the institution of marriage (and ironically led to extramarital births). With partnerships less solid, people become more cautious about committing themselves to parenthood (Ermisch, 1990).

Posttransitional fertility is still relatively recent, even in industrial countries. It may still be too soon to generalize, but it does not seem to be characterized as either a regular cycle or an inexorable downward trend. No universally robust predictor has been found. Those that have been considered include the relative

[1] Ce n'est pas seulement l'absence de méthodes efficaces de regulation des naissances qui a rendu une telle situation possible, mais aussi un contexte général dans lequel l'enfant "en trop" ne l'était pas tout à fait. . . . Il a pu se produire dans les années 60 un relâchement de la practique contraceptive, parce que les intentions des couples étaient devenues plus incertaines à cette époque.

generation size of men, the relative wages of women, the reliability of marriage, the level of religiosity, and the effectiveness of contraception. The latter may be the outcome of choices rather than a determinant.

6. Are State Policies Effective in Accelerating Fertility Decline?

Few issues have raised such heated debate in international circles as the question of whether population growth is so rapid that its effects should be curbed through deliberate antinatalist government policies. The effectiveness of state policies in curbing the rate of growth through promotion of family planning is a major concern of demographers. There is still a good deal of skepticism that policies can be effective in accelerating fertility decline due to the widespread belief that only socioeconomic transformation can succeed in providing couples with the motivation to reduce the number of children they bear. Crook (1977) points out that there was no state encouragement of the fertility decline in England and Wales, in the 19th century, quite the contrary. Yet almost all third world fertility declines involve some degree of state involvement. Mauldin and Berelson (1978) and later Lapham and Mauldin (1984) were among the first to attempt a systematic analysis of the impact of family planning program. These studies pointed to the association between the level of socioeconomic development and a measure of *program effort*, but the major conclusion was that strong programs do reduce fertility, a finding that reassured governments and donor agencies (Lee *et al*., 1995).

The 1994 International Conference on Population and Development, held in Cairo, marked a growing consensus among developed and developing countries, and among women's and environmentalist nongovernmental agencies, that they share an interest in advancing women's access to family planning. National policies and plans of action were agreed in Cairo, which had the objective of "incorporating population concerns in all relevant national development strategies" (United Nations, 1995, p. 67). There remains a need, however, to examine the factors that promote the effectiveness of policy and related public family planning services (Lee *et al*., 1995). The debate still hinges on whether family planning programs can effectively reduce *unwanted* fertility, in the absence of other broader social change.

Pritchett (1994) argues that the challenge is to reduce people's fertility desires, not to address the *unmet need* for family planning. He argues that the question is still whether family size preferences are determined by economic influences or social and cultural forces, concluding that family planning program effort, which provides knowledge and access to the means of control, is not a dominant factor determining differences in fertility. Rather, a low level of demand for children is both necessary and sufficient to reduce actual fertility. While pronatalist policies that reduce access to contraceptives will weaken the effect on fertility of any changes in preferences, the reverse may not work. Improvements in access to contraceptives are neither sufficient nor necessary for fertility reductions to occur, he contends, contrary to the study in Bangladesh. Some *active* family planning programs have gone on the offensive to recruit users using coercion. The Emergency in India in 1975 and some stages of the One Child Policy in China would be cases in point. Economic incentives (and sanctions) are then focused on the *motivators* and officials of the program (Crook, 1997). Curiously the much resented manner of the Emergency Family Planning Drive resulted in the overthrow of the Government of India, but not a sustained family-planning backlash.

New work to assess the demographic consequences of divergent population policies in a series of comparisons between pairs of countries similar in terms of crude socioeconomic indicators has recently been completed (Lee *et al*., 1995). This study's main conclusions were that when *policy elites*, responsible for putting family planning on the policy agenda, did not sustain momentum by building broadly based political coalitions, the family planning agenda was less well formulated and implemented. The study supports the view that government policies and programs can make a major difference, at least to the timing of fertility decline. In three of the four pairs, in countries with stronger programs the fertility decline started earlier; in the remaining pair, the pace of decline was sharper in the country with the stronger program. Moreover, countries with weaker family planning programs displayed more pronounced social differences in contraceptive use. In those with stronger programs, the main function of the program was to accelerate the spread of fertility control from the urban and educated elite to the rural and less educated. National policy-making by elites, and strong institutional and financial support for family planning programs are unlikely to have had direct relevance to fertility desires of individuals in these countries. These conclusions are in direct contrast to Pritchett's.

Both analyses appear influenced by ideology. Neither presents direct individual level evidence that might indicate which changes first, fertility preferences or access to the means of control. Thus, we return to the lament of Coleman and Schofield (1986) that demography suffers from lack of a theory that would integrate the influence of societal factors, such as social policies or economic development, with the individual-level behaviors of which national fertility levels are made up, a theory to integrate macro and micro.

In short, there are findings that government policies can make a difference to fertility, but also suggestions that they may not always be successful.

7. Are State Polices Effective in Preventing Fertility Falling Below Replacement?

Over the past century, there has been a gradual increase in political interest in population and family matters in developed countries. Common developments and diversity within them across countries are fully described by Gauthier (1996a) and in greater detail for Canada, the United States, Australia, and Great Britain by Heitlinger (1993). They include public regulation of abortion and contraceptives, cash benefits to families, policies facilitating the employment of women in general, policies facilitating the combination of paid work and parenthood, provisions for childcare and (although not specifically treated in these books) housing policy and immigration control. Few governments, other than the French, have explicitly stated pronatalist goals, although Nordic countries, especially Sweden, have a tradition of facilitating family life through liberal policy on voluntary parenthood, relatively generous social security, and a deliberate policy of promoting sex equality through recognizing a woman worker's right to parenthood (rather than a mother's right to employment). Since the 1970s the parental insurance scheme for the workforce has established right for fathers as well as mothers to have paid leave from employment in connection with their children, in an attempt to make gender equality and family life more compatible. The package of family friendly policies in Scandinavia also includes widespread public involvement in childcare. Elsewhere, policies affecting the family have been more likely to subsidize a traditional breadwinner–housewife division of labor between parents. The history of the development of this complex of policies suggests that they are in part the outcome of demographic change (Gauthier, 1996a). Their effectiveness at changing demographic trends is more debatable.

Gauthier (1996b) reviews evidence of effects on fertility (and family structure) of the impact of fiscal incentives on fertility. The evidence is for nothing more than a very modest effect (which was not altered when she included maternity provisions and child care provision in a study of twenty-two industrialized countries). The study by Ekert (1986) of eight European Community countries suggested that cash benefits of the order offered in France raised total fertility by 0.2 children. A similar result was confirmed by Blanchet and Ekert-Jaffé (1994) using data on 11 European countries, and by Ermisch (1988) on the basis of births of different order in England and Wales. His estimate was that a doubling of child-benefit would, eventually, raise completed family size by 0.15 children. This implies that should the government wish to be so un-British as to manipulate the birth rate, the costs of achieving significant change through cash benefits would be prohibitive.

Ermisch's analysis (and that of the study that preceded it, De Cooman *et al*., 1987) suggests that most of the reaction of births in England and Wales to changes in economic *signals* was in timing, particularly of the first birth, rather than completed family size. Postwar swings in period fertility have generally had a larger component of *tempo* rather than *quantum*, timing and spacing rather than completed cohort fertility. (Olsen, 1994; Hopflinger, 1994; Walker, 1995) While swings in birth timing may not make any difference to the family's ultimate size, they make a difference to the overall age structure, and make it difficult to plan age-specific services like schools, jobs for school leavers, and, eventually, pensions. It therefore remains important to understand and anticipate movements in births, even if there is little prospect of controlling them. Cigno (1991) suggests that governments are unintentionally fueling the deferment of childbearing through tax policies conducive to female labour force participation. This argument could be countered with the suggestion that female labor force participation need not be incompatible with childbearing, if policies are in place to facilitate their combination.

Such policies have been developed in Sweden. In the early 1990s, Sweden had one of the highest levels of fertility in Europe, and many commentators have been tempted to suggest that the package of family-friendly policies were responsible for raising the birth rate up to replacement levels. Two recent studies cast some doubt on such an interpretation. Both stress the importance of re-timing of Swedish births around historic and projected cohort fertility close to two children for all cohorts born this century. Hoem (1990) explains how a specific change in the parental leave regulations in 1986 created an inducement to space births more closely. There is evidence people did this, a response, perhaps unintended, to a policy change, but mainly one of tempo rather than quantum. Walker (1995) also concludes that there has been little effect of economic variables on life-cycle fertility between the 1950s and the 1990s, and that the impact of state policy was less important than broad trends of economic change in the labor market. He reaches this conclusion by estimating how the cost of childbearing (the *shadow price*) has changed over the years. He constructs series for the value of parental benefits, public child care, and child allowances that are compared with direct costs and opportunity costs in the labor market including foregone opportunities to accumulate human capital. The compression of wage differentials, another aspect of Swedish policy, during the 1970s and 1980s, is said to have reduced incentives for early childbearing and could also account for the shift in birth timing over the period (see also Cigno, 1991, Chapter 8), but pronatalist policies would have had to be even more generous than the standards set in Sweden to have much importance in the short or long term. The last resort for those who wish to defend Swedish family policy as a pronatalist instrument (rather than something that has merit in its own right) is that without parental leave and childcare apparatus the size of the Swedish family would have been smaller. This is an unfortunately unverifiable proposition. Drops in fertility in Sweden (and Eastern Germany) in the 1990s, may still prove to be temporary adjustments.

It remains to be seen whether pronatalist policies are likely to be effective at changing anything other than timing, and it is unlikely that we will see this put to the test. Hobcraft and Kiernan (1995) offer another reason to be skeptical of the state as engine of a reversal of the fertility decline—that it is unlikely that the public budget would ever devote substantial enough resources to make much difference. As Folbre (1994) would put it, the vested interests against investing in children as public goods, leave social reproduction increasingly the responsibility not just of private families, but the women left *holding the baby* as male responsibilities are eroded. She calls for a new definition of family policy enshrining an egalitarian restructuring of the genders.

Although state policies can certainly help to speed up the decline of high fertility, there is little evidence that they can successfully apply the brakes, should they want to, when the process falls below replacement level. Fertility and family life might be facilitated by a wide range of economic and social changes, but there is unlikely to be a substantial sustained response to measures aimed only at women and to the proximate determinants of their fertility.

CONCLUSIONS

The mastery of nature displayed in the control of fertility is itself one aspect of economic development. It is possible for this aspect to run ahead, behind, or alongside the mastery of other theaters of endeavor. When they run together, ideational and materialist explanations are compatible perspectives on the same process, the economist's signal is the sociologist's sanction. However, development is not always even, nor can one driving force always claim primacy. In some situations it may be possible to test the predictions of economic and social explanations against one another, but not all. Explanations that are observationally equivalent may have different implications for policy or prediction according to what the underlying mechanism is. It is thus difficult to reach simple conclusions about the social and economic determinants of fertility, other than to point to their complexity. Different forces on beliefs and behavior operate at individual, family, community and societal levels with different strengths, on different time scales and in different points in time and space. Furthermore there is feedback between the economic and the demographic, reflecting human kind's capacity to adapt and negotiate. The data one would ideally need to test such a model quantitatively defy description, let alone practicality in poor countries (David, 1998).

The lack of suitable longitudinal, multilevel, data (on paid and unpaid work, family history and structure, attitudes in the home and outside, and so on) may be one reason why social scientific knowledge of the determinants of fertility is not a clear consensus. It is easier to draw some conclusions about the beliefs of social scientists than about the beliefs and reproductive behavior of *real people*. The economic approach sees rational agents deciding to invest in child quantity, child quality or birth control according to changing price signals in the economic environment. The sociological view is that changing norms regarding reproduction lie behind fertility decline, accompanying, preceding and perhaps even promoting economic development. The *ideational* theory of fertility change has been criticized because it appears to allow no role for the cultural context in which diffusion of ideas takes place. *Institutional* theories of fertility contend that particular historic and political configurations shape social institutions in any society, and give rise to particular patterns of social organization. The sociologist's emphasis on the diffusion of ideas complements the economist's model in which agents are assumed to be equipped at no cost with perfect information that is assumed to permeate society (for an exception see Pollak, 1985).

Economic and sociologic analysts of fertility are too often in competition, but there is common ground. Notable attempts to synthesize across disciplines are offered by Folbre (1994), Hobcraft and Kiernan (1995), Pollak and Watkins (1993), and Pritchett (1994). For Folbre, constraints are gendered (men and women do not always face the same choices about social reproduction), but the salience of gender differences has varied over time and space.

Cigno's exposition of economic decision making in and about the family takes a more narrowly focused view. He confidently concludes that the decline in size of the family, and in its role as *an organizer of transactions between generations* are brought about as a response to *changes in the structure of incentives and disincentives associated with economic development*, rather than caused by changes in preferences or culture.

Indeed, some of what goes under the name of *culture* may be interpreted as the debris of past states of the economic environment—a consequence of the fact that, when the structure of incentives and disincentives changes, it takes time to realize it, time to decide how best to respond to it, and time to modify the pattern of one's life (Cigno, 1991, p. 195).

Most other economists writing about the family have been less sanguine about the completeness of the explanations to be offered by models of constrained optimization. Montgomery and Trussell (1986, p. 266) point out that the family still has to be set aside from other subjects of economic research because of "the pervasive roles played by individual physiology, by uncertainty, by irreversibility and by social norms." Irreversibility refers to the fact that responsible parents at least cannot trade in their children even if they turn out unsatisfactorily, like Gary Becker's Rotten Kid.

Readers may be more comfortable with the line taken by Pollak and Watkins (1993). They suggest that different cultural settings mediate how preferences and opportunities operate within groups differentiated by "language, ethnicity, region, and dress" (p. 488). They also suggest that opportunities and preferences are inseparably bonded, as the warp and weft of a fabric, and warn against pulling it apart. In declaring the need for a multidisciplinary approach they remark:

> The rational actor model is silent about the boundary between choice behavior and nonchoice behavior and about the determinants of nonchoice behavior. Perhaps 'culture' can fill this analytic vacuum by describing or explaining the location of the boundary separating nonchoice and choice behavior (p. 499).

The strength and diversity of social norms helps explain variation in behavior between and within societies. Secular and sacred values help to set targets and to sanction deviant behavior. But just as individuals may not be purely rational actors, neither are they merely passive agents of culture. They can shape and re-shape their culture, and may re-negotiate the norms, rules or values to their own benefit. The political and economic forces shape the cultural context of behavior, and individuals continually renegotiate their behaviors, rationalizing them within the context of social norms (Bledsoe *et al*., 1993).

Neither the view of individuals as passively adhering to cultural values, nor as rational utility maximizers is satisfactory. The notion that human motivation extends beyond economic incentives is useful not only for the understanding of fertility, but also relevant to other fields of activity, including the management of a paid workforce. No one set of explanations is sufficiently developed to provide an integrated view of why and how reproductive change occurs. There is a need for testable theories for how sociocultural and economic forces can be linked to variations in individual behavior. Both macro- and microlevel analysis is required to provide an understanding of how the political economy evolved and how the individual creates his definition of *proper* behavior (Greenhalgh, 1995; Kertzer, 1995).

The theories and evidence we have assembled paint the picture of the process of social reproduction as vitally connected with the process of production. They are not always harmoniously adjusted to one another. The gender division of labor and power sets the terms of cooperation and conflict between men and women in the reproductive and productive spheres. As their work so often spans reproductive and productive fields, it is obvious that women's lives need more than economics to explain them, but so do men's. Just as men and women have seldom been successful at cooperating on equal terms to achieve reproductive and productive goals, social scientists have not always found cooperative solutions to the challenge of understanding these important processes. We hope this chapter points toward a constructive renegotiation of the division of social scientific labor.

The Geography of Fertility

Maps, Narratives, and Demographic Innovation

RON LESTHAEGHE AND KAREL NEELS

Interuniversity Program in Demography, Vrije Universiteit Brussel, Brussels, Belgium

Maps are not solely indispensable instruments for navigation on a plane or in space. Maps, and particularly historic ones, may also offer startling testimonies on how we have altered our environment, both urban and rural. Spatial representations of social science data furthermore offer clues about relationships between forms of collective behavior. Deductively, they can be used in hypothesis testing, or, inductively, for proposing broader theories. In other words, maps produce good narratives, and these in their turn are valuable for theory formation as well (van de Kaa, 1996).

In the sections that follow we will give two examples of such map-based narratives and their statistical elaboration. The first example deals with the history of the fertility transition in France, and subsequently with Coale's much broader formulation of preconditions for behavioral innovation (Coale, 1973; Lesthaeghe and Vanderhoeft, 1999). The second example illustrates with Belgian data how successive waves of demographic innovation, from adoption of contraception in the 1880s until the spread of premarital cohabitation in the 1980s, can follow stable diffusion patterns over a period of a century. The latter finding can be matched by counterexamples in which new behavior forms are spreading along different lines, but both types of spatial patterning beg the question of stable versus changing underlying causes and mechanisms. But before turning to the details of illustrations, a word needs to be said about the feature of *ecological fallacy*.

Maps representing social science data have a crucial drawback: They only tend to represent averages, not distributions, for spatial aggregates. Of course, outcomes of multivariate analyses, even if they use individual level data, showing means or relative odds for subclasses of covariates do exactly the same. In both instances, we are not producing Quetelet's single *homme moyen*, of which all real men would be imperfect copies, but a set of little average men, each representing a robot picture of the real ones that are brought together in the various categories of our covariates (Desrosières, 1993; Lesthaeghe, 2001). Hence, the covariate of *spatial proximity* is just as relevant as the others, such as age, gender, educational level, or social stratum. Nevertheless, statistical analyses performed on data for spatial aggregates have frequently been accused of falling into the trap of ecological fallacy. But there are two issues here, not just one. First, since individual variance within an area is dramatically reduced by just retaining the area's average, correlations between such averages are higher than correlations computed for individuals as data points. This is indeed a statistical artefact. But the *real* ecological fallacy only arises if relationships observed at the level of aggregates are being projected on individuals. An indicator reflecting an attribute of an aggregate (e.g., the proportions used in agriculture) cannot automatically lead to the pronouncement that individuals with this attribute (e.g., farmers) would exhibit the same statistical association (e.g., with fertility). In fact, coal-mining regions in Belgium in 1900 had lower fertility, but coal-miners themselves did not. In short, associations between characteristics of specific aggregates only have interpretations at this specific level of aggregation, and at no other, higher or lower. This holds *a fortiori* also for individual level data: If coal miners have higher fertility, then the same must not of necessity be true for coal-mining regions. Coal mining could trigger other forms of industrialization, which could raise aggregate incomes and so forth, and the whole industrialization package—of which the proportions in mining would be an excellent *indicator*—could produce lower, not higher, fertility. Attributes of regions and of individuals can have very different *meanings*.

Armed with this major caveat, we can now turn to our two examples and their relevance for theory.

I. A NARRATIVE OF THE HISTORIC FRENCH FERTILITY DECLINE

The control of fertility in France has attracted the attention of demographers and historians alike because it occurs very early (i.e., already in part during the second half of the 18th century) and precedes the great transformations of the 19th century associated with urbanization and industrialization. The history of the French fertility decline has been a major challenge to classic demographic transition theory because rising real incomes, investments in education, did not drive it nor did declines in child mortality.

1. The Geography of French Fertility at the Beginning of the 19th Century

Detailed descriptions of the geography of the fertility decline in France have already been presented by other authors (van de Walle, 1974; Wrigley, 1985; Bonneuil, 1997), but it is clear that by 1831 highly contrasting levels of marital fertility had come into existence. For instance, at that date, Coale's index (see Chapter 34) of marital fertility I_g indicates that the level had already dropped below 40% of the Hutterite standard of uncontrolled fertility in several Normand departments and in the Garonne valley, whereas it had remained in the vicinity of 80 percent of Hutterite fertility in Brittany, the southern part of the Massif Central and the Hautes-Alpes. The map of the index of marital fertility I_g as of 1831 and reconstructed by van de Walle is also shown in Figure 38–1 (map C) and clearly shows that there were essentially five zones of high fertility and late control:

The smallest area is the Département du Nord, which corresponds to parts of Flanders and Hainaut (former parts of the Austrian Low Countries);

To the east there is a larger zone made up of Lorraine, Vosges, Alsace and the Franche-Comté;

In the middle, there is an extended zone of high fertility linking departments north and south of the Massif Central (from Nièvre to Aveyron), and continuing across the Rhone valley into the departments of Ain, Isère and Hautes-Alpes. This also includes the Savoie area, which was then not yet a part of France.

The southern zone of high fertility is located along the Pyrenees and in the Landes, and also includes Corsica.

The western area, finally, covers the departments of Brittany and stretches as far south as the Vendée.

In an independent reconstruction of the index of overall fertility (i.e., without the partitioning in the shares of marital fertility, illegitimate fertility and marriage postponement), Bonneuil (1997) equally shows that there are essentially three zones of innovation of fertility control before 1830. These are:

The Normandy area, stretching further south to the Pays-de-Loire;

The departments of the Champagne area and northern Burgundy;

The southwestern area located in the Garonne valley and also comprising adjacent Charentes. It should be noted, however, that this southwestern corner had relatively low fertility to start with (i.e., before 1790), possibly as a result of a more marked pattern of birth spacing and more prolonged lactation (Lesthaeghe, 1992).

To sum up, van de Walle's map of the marital fertility index I_g as of 1831 still gives a good picture of the geographic demarcations of areas with an earlier rather than later pattern of fertility control.

In addition to innovation with respect to fertility control, France is also the country with a pronounced correlation between the levels of marital fertility and the degree of marriage postponement (van de Walle, 1974). More precisely, areas with lower marital fertility tend to have the earliest ages at first marriage, and areas with higher marital fertility are also the ones with the latest and least universal marriage pattern. This can easily be seen on Figure 38–1 (map D) by comparing Coale's index of early marriage (I_m) to his index of marital fertility (I_g). In the North, the Malthusian pattern of late and nonuniversal marriage (i.e., higher definitive celibacy at age 50 for women) still prevails

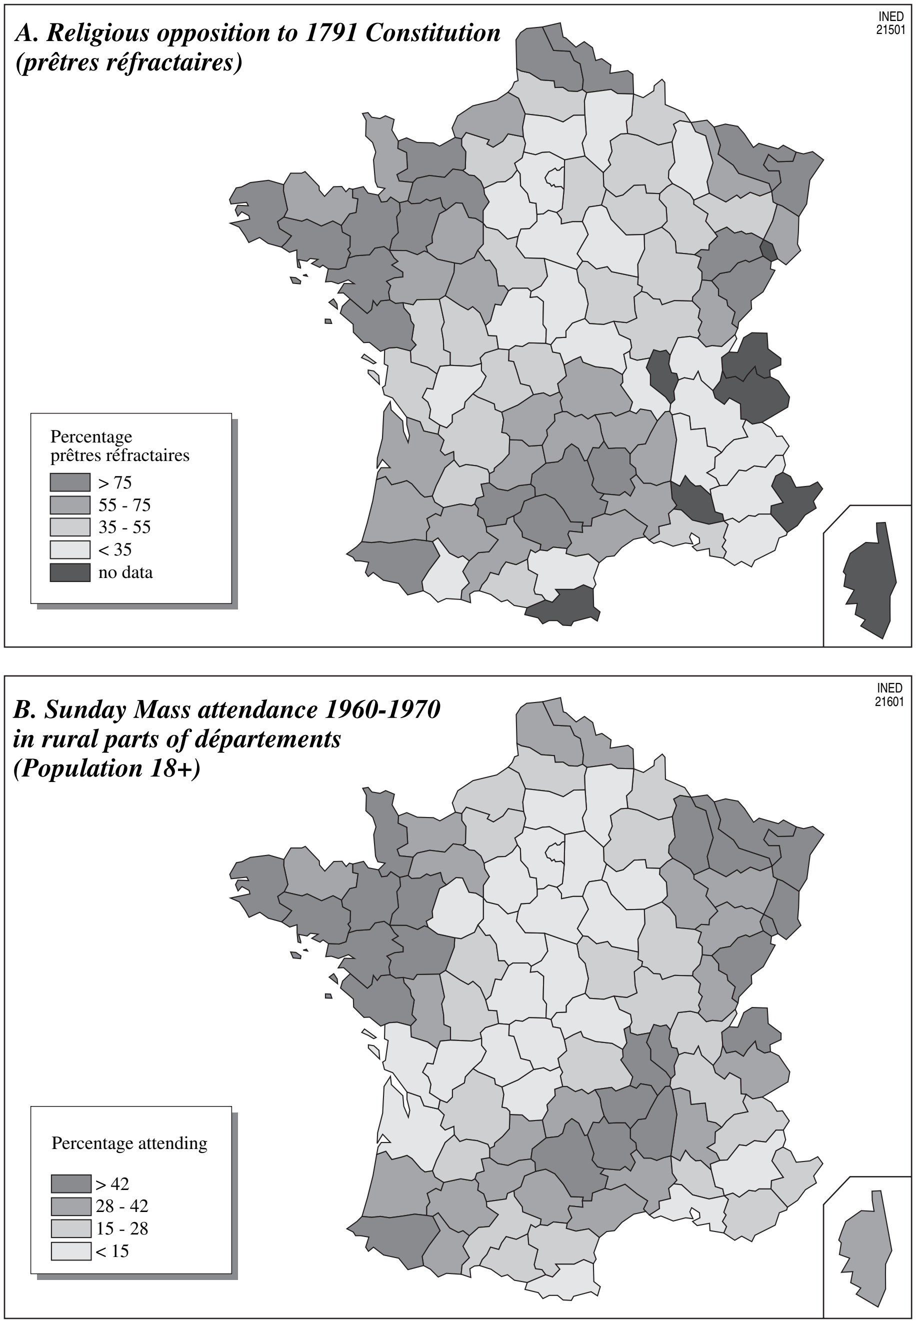

FIGURE 38–1 Geographic variations in secularization, compared with those in fertility level and in the marriage model. Source: **(A)** Tackett T., 1986. *La révolution, l'église, La France*. Paris, Editions du Cerf, 481 p. **(B)** R. Boulard, reprinted in Le Bras Hervé and Todd Emmanuel 1981. *L'invention de la France*. Paris, Librairie Générale de France, 511 p.

in 1831 in the departments of Nord and Pas-de-Calais. The eastern zones of high fertility from Lorraine to Franche-Comté are almost perfectly replicated on the map of late marriage. The southern half of the central area of high fertility and the Alpine area across the Rhone are also represented on the late marriage map, and the same holds for the western Pyrenees and Landes, and for the Brittany-Vendée western area. In short, with relatively few exceptions (parts of Normandy, northern half of the Massif Central), areas that had reduced marital fertility levels were equally the ones that had earlier marriage patterns and therefore deviated the most from the typical Malthusian system with postponed and nonuniversal marriage.

2. Explanatory Hypotheses

In this section we will treat four major hypotheses in accounting for the spatial patterns of marital fertility control and nuptiality. The first one deals with the production structure and with the economic motivations for reduced fertility centering on child utility. The second one links fertility to household structure, parental control, and patterns of inheritance. The third one is the secularization hypothesis and focuses on the moral legitimization of a new form of behavior. The last argument is of a political nature, and deals with the process of nation building and with patterns of regional and linguistic particularisms.

In earlier work dealing with the Western European fertility transitions (Lesthaeghe, 1983; Lesthaeghe and

Wilson, 1986) we have argued that familial forms of production such as small-holder or tenant-agriculture, whether or not in combination with cottage industries, are characterized by a high economic utility of children and by strong parental control over such family labor. Conversely, both the utility of children for household-based production and parental authority would weaken in systems with proletarization (i.e., with the growth of a wage earning class employed outside familial production sectors). Such wage earning populations can be used either in agriculture or in industry, but for the early French history of fertility control, only agricultural wage sectors are of importance.

Microeconomic theory has a similar point of departure. Weir (1982) argues that it is the relative value of children over the parents' life course that determines fertility. The value of family labor in its turn is a function of the economic situation of the family and of the prevailing labor market conditions in the community or wider area. Hence, Weir makes a distinction between the French areas with traditional peasant agriculture operating on a familial basis and redistributing any surplus labor via a domestic service outlet and areas with an early proletarization and a labor market recruiting wage earners for large agricultural states, typically owned by nobility, bourgeoisie, or the church.

According to these views, familial forms of production are conducive to the maintenance of high fertility, whereas the growth of agricultural wage labor fosters a fertility decline by virtue of reduced child utility over the parental lifetime.

The *mode of production* argument is of further significance for the nuptiality system as well. Peasant agriculture based on family labor is characterized by limited opportunities for an earlier establishment of new and economically independent households. Hence, according to the Malthusian principles of neolocal marriage (i.e., no coresidence of two or several married couples) and of economic independence, this means that those areas with small-holder and tenant farming ought to be characterized by late marriage. Furthermore, the circulation of surplus labor via domestic service (maids, manservants) also forcefully contributes to prolonged or even definitive celibacy (Hajnal, 1965, 1982). At this point, the interaction with the prevailing inheritance system has to be introduced. In regions with unequal division of property marriage postponement is typical for those who do not inherit or only get a smaller share, often in the form of a pension. Such persons tend to be pushed out of the system and enter other branches such as domestic service, army or navy, administration, or the clergy. They are also prime candidates for emigration.

One can also expect that families tied to small farms or to artisanal workshops are more heavily involved in arranging their children's marriage. A younger son from one family would be an ideal match for another family's heiress. The protection or enlargement of familial property is served by endogamy and even more by consanguineous marriage. By contrast, the predominance of wage labor in capitalist forms of extensive agriculture would not be associated with further marriage postponement or celibacy, since wage laborers have little to inherit and to wait for. Households can be set up independently more easily on the basis of wages earned outside the familial sector, and there is no pressure for arranged marriages and consanguinity.

The *mode of production* hypothesis has the advantage that it explains both the nuptiality and the fertility pattern: The duality between peasant agriculture and capitalist agriculture can be viewed as a common cause capable of explaining the observed correlation between nuptiality and marital fertility. In statistical terms, the strong negative correlation between Coale's indices I_g and I_m in France should largely vanish once a control is introduced for the prevailing form of agricultural production.

We now turn to the hypotheses focussing on patterns of parental and institutional authority. Todd (1983, 1988) introduces the parental control variable through a cross-tabulation of two other key variables—generational coresidence and form of inheritance system. He distinguishes between four types of family systems:

The nuclear residence pattern with equal division of property;
The nuclear residence pattern with unequal division;
The stem-family with a privileged son (primo- or ultimogeniture) who does not leave the family of origin upon marriage (whereas all others do);
The extended family in which coresidence of parents and married sons is maintained. Upon the death of the older generation, coresidence between married brothers remains possible, and inheritance tends to be egalitarian.

In Todd's patterning, the egalitarian nuclear family with equal division of property is characterized by weak parental control, and it would therefore also be a weak basis for authoritarian religious or political doctrines. By contrast, the stem family with its marked inequality among children and the extended control of the parental generation over the privileged son would be most supportive of strongly hierarchic religious structure. Todd's reasoning, although originating from variables other than those connected to the mode of production, bears some resemblance to our own line of argument. In our view, parental control is strongest in areas with familial forms of production by virtue of the restricted opportunities for adult children to set up their own independent household and because of the need to control marriages.

The argument of parental and religious authority is equally of relevance for the marital fertility decline since it provides a basis for the secularization hypothesis. If the act of consciously controlling fertility depends on the *moral legitimization* of the act as well as on the *calculus of advantage*, then areas with strong structural props in favor of institutional moral or religious patronage would lag behind in the fertility transition, whereas those without these props would be characterized by earlier secularization and by an earlier or faster fertility transition.

The last argument is of a political nature and deals with the process of nation building, and more particularly with regional or linguistic forms of particularism. It equally relates to patterns of spatial diffusion with particularisms of this nature acting as barriers to the spread of new forms of behavior. France obviously provides an example of early nation building with a central government gradually extending its unifying influence. As a result we should expect that characteristics of the core (here the larger Parisian Basin) would gradually be exported to the structurally and linguistically different periphery. Also Le Bras and Todd (1981) have stressed this feature and its corollary (i.e., the power of linguistic particularisms in France in defending the original structural characteristics of the periphery against the pressures stemming from the core). In addition, both authors point again at the importance of the various agricultural systems, but in contrast to Weir, much more attention is also being paid to other structural and cultural variables. Their position can be summarized as follows: Fertility control emerges in regions with early secularization, which in turn is fostered by the existence of a large rural proletariat and by nuclear family systems with equal division of property. Fertility control and secularization are both slowed down by the survival of peasant agriculture with inegalitarian inheritance and endogamy protecting the family capital from fragmentation, authoritarian family relationships, and linguistic particularism.

3. Empiric Evidence

The strong spatial resemblance between the fertility levels and marriage patterns of French departments and the pattern of secularization can be appreciated from the maps of Figure 38–1. Map A shows the religious divide as measured via the proportion of priests who refused to take the oath of allegiance to the secular government of the new Republic in 1791 (i.e., *prêtres réfractaires*). These priests remained loyal to the Pope, and their spatial distribution shows the extent of Catholic resistance to the Revolution. Tackett produced the original map in 1986. About 160 years later (i.e., in 1960–1970), Boulard's map of Sunday Mass attendance in the rural part of the departments (map B) exhibits a striking resemblance to Tackett's map of *prêtres réfractaires*: Five zones of greater fidelity to religion again appear. These five zones correspond once more with higher marital fertility in 1831 and later ages at first marriage as well.

A more elaborate statistical analysis is required to check our hypotheses. To this end, we have created a set of variables that characterize (a) the properties of the demographic regime (marital fertility, nuptiality, illegitimacy, endogamy); (b) the agrarian production system (peasant farmers versus wage labor, i.e., journaliers and métayers, domestic servants) and related inheritance systems; (c) the degree of secularization (prêtres *réfractaires*, ordinations, priests among army recruits, vacant vicarages, and Sunday Mass attendance); and (d) indicators of linguistic particularism and literacy. These indicators are defined in Table 38–1 for easy reference, and all but one pertain to the period between 1790 and 1900. Hence, they can be taken as typical for the 19th century.

In Table 38–2 we report the zero-order correlation coefficients between the level of marital fertility in 1831 (I_g) and the other indicators characterizing the agrarian modes of production, the cultural dimensions, and the nuptiality patterns. The structure is clear: high marital fertility and a late fertility transition are positively associated with two characteristics of peasant agriculture (servants in households, inegalitarian inheritance), with Catholic strength (refusal of revolutionary oath, priests among army recruits), linguistic particularism (no writing in French, survival of other languages) and with endogamy (cousin marriages). A low level of marital fertility and an early transition are associated with capitalist agriculture operating with wage labor, with high secularization (vacant vicarages), earlier marriage and higher illegitimate fertility.

The indicators used by Weir (1982) corroborate these findings in Table 38–3. The three indicators of the presence of familial peasant agriculture (fallow land, survival of the commons, and high percentage of owner-cultivators) are all three negatively correlated in a sample of 40 French villages with the amount of fertility decline witnessed among two sets of marriage cohorts (cohorts married between 1790 and 1819

TABLE 38–1 Definition and Sources of Indicators in Analyses of French Reproductive Regimes in 19th Century

A. Demographic indicators		
*I_g (1831, 1876)	Index of marital fertility relative to the Hutterite standard of uncontrolled fertility (Coale)	van de Walle, 1974: 226–467
*I_m (1831, 1876)	Index of proportions married (Coale)	ibidem
*I_h (1831)	Index of illegitimate fertility (Coale)	ibidem
*Age difference at marriage (1861–65)	Husband-wife difference in age at marriage	Le Bras & Todd, 1981: 440
*Endogamy (1911–13)	Rank order of départements according to the percentage cousin marriages (grouped from 0 = lowest to 11 = highest incidence)	Le Bras & Todd, 1981: 215
B. Agricultural system and inheritance pattern		
*Capitalist agriculture (1852)	Areas of large farms operating with *journaliers* and areas with *metayage* (=1) versus areas with smallholders and tenants (17% + fermage) (=0)	Todd, 1998: 84
*Inegalitarian inheritance (1900)	Inegalitarian system (=1) with primogeniture or other preferential treatment, versus egalitarian system (=0)	Todd, 1988: 32 (based on A. de Brandt, 1901)
C. Secularization		
*Refusal revolutionary oath (1791)	Refusal of revolutionary oath by clergy: 2 = more than 50% refused, 1 = 40%–50% refused, 0 = less than 40% refused	Todd, 1988: 64 (based on T. Tackett, 1986)
*Priests among army recruits (1825)	Priests per 10,000 recruits	Le Bras & Todd, 1981: 430
*Ordinations (1876)	Ordinations of priests per 100,000 population	ibidem
*Vacant vicarages	Proportion of vicarages that were vacant, i.e. without priests. Grouped values: 0 = less than 6%; 1 = 6%–15%; 2 = 15%–21%; 3 = more than 21%	ibidem: 379
*Sunday Mass attendance (1960–1970)	Percent of rural population attending Sunday Mass	ibidem: 430 (based on R. Boulard)
D. Literacy and language		
*No writing (1872)	Percentage of the population that can at most read French, but cannot write it	ibidem: 454
*Linguistic particularism (1863)	Persistence of patois or languages other than French. Grouped values: 0 = all speak French; 1 = traces of patois; 2 = large proportions or entire villages do not speak French; 4 = more than 50% non-francophone	ibidem: 279

compared to those married before 1770). Conversely, the indicators of the predominance of capitalist agriculture (artificial meadows, high percentage absentee landlords and high prices of arable land) are all three positively correlated with a faster decline of marital fertility.

The overall patterning can be brought out by means of a canonical correlation analysis. In this analysis we have brought together all demographic variables in one set (Y) and all the other indicators in a second set (X). From both sets, latent dimensions (canonical variables) are constructed in such a way that there is a maximal correlation between them. As the results in Table 38–4 indicate, the first canonical variate yields a correlation coefficient of 0.87 between the first Y-dimension and the first X-dimension (r_{x1y1}). For each of these dimensions, the best indicator can be listed by means of the correlations between dimension $Y1$ or $X1$, and their respective indicators. In this fashion, dimension $Y1$ is best identified by the indices of proportions married (I_m), the indices of marital fertility (I_g), the index of illegitimate fertility (I_h) and by endogamy. The signs reveal that $Y1$ captures a *slow* demographic transition: marital fertility and endogamy are high, proportions married and illegitimate fertility are low. These features are strongly correlated with the best indicators of the dimension $X1$: Strong adherence to Catholicism (five indicators), inegalitarian inheritance, and linguistic particularism. Conversely, negative correlates of dimension $X1$ are capitalist agriculture and vacant vicarages, which are associated with faster demographic innovation. Finally, the second canonical variate, which is uncorrelated with the previous one, tells us that there is a separate dimension indicated by a high difference in ages at marriage between spouses. This specific demographic feature is more exclusively correlated with areas of inegalitarian inheritance and with the survival of languages other than French.

An analysis of correlations brings out the general pattern of association, but it says little about synergistic or combinatory effects. A Boolean analysis highlights these interactive effects by exploring

TABLE 38–2 Correlation Coefficients Between Level of Marital Fertility (I_g) in 1831 and Selected Agricultural, Socioeconomic, and Cultural Variables; French Départements, 19th Century

Correlates (various dates)	Correlation coefficient with I_g
A. Modes of production	
Capitalist agriculture (versus smallholders and/or tenants), 1852	–0.46
Servants in households, 1856	+0.33
Inegalitarian inheritance, 1900	+0.40
B. Secularization	
Clergy refusing revolutionary oath, 1791	+0.46
Priests among army recruits, 1825	+0.31
Vacant vicarages, 1885	–0.52
C. Literacy and language	
No writing in French, 1872	+0.55
Persistence of patois or language other than French, 1863	+0.40
D. Nuptiality system	
Index of proportions married (I_m), 1831	–0.73
Index of illegitimacy (I_h), 1831	–0.30
Endogamy (cousin marriage), 1911–1913	+0.47

TABLE 38–4 Canonical Correlation Results for Indicators of the Demographic Regime and for Socioeconomic or Cultural Indicators, 19th Century France, 90 Départements

First canonical variate:		Canonical correlation r_{x1y1} = 0.87 Wilks lambda: 0.05 Eigenvalue: 0.76	
Best indicators reproductive regime (**Y1**) (r > 0.40)		Best indicators socioecon/cultural dimension (**X1**) (r > 0.40)	
*I_m, index of proportions married 1831:	–0.86	*Sunday Mass attendance, 1960:	+0.90
*I_m, index of proportions married 1876:	–0.82	*Proportion not writing French, 1872:	+0.73
*I_g, level marit. fertility 1871:	+0.77	*Refusal revolutionary oath, 1792:	+0.70
*I_g, level marit. fertility 1831:	+0.75	*Ordinations per 100,000 pop., 1876:	+0.66
*I_h, level illegitimate fertility, 1831:	–0.65	*Capitalist agriculture, 1851:	–0.68
*Endogamy (cousin marriage) 1911–1913:	+0.46	*Vacant vicarages, 1855:	–0.61
		*Priests per 1000 recruits, 1825–1835:	+0.59
		*Inegalitarian inheritance, 1900:	+0.53
		*Linguistic particularism, 1863:	+0.50
Second canonical variate:		Canonical correlation r_{x2y2} = 0.74 Wilks lambda: 0.21 Eigenvalue: 0.54	
Best indicators reproductive regime (**Y2**) (r > 0.40)		Best indicators socioecon/cultural dimension (**X2**) (r > 0.40)	
*Husband–wife age difference at marriage 1861–1865:	+0.64	*Inegalitarian inheritance, 1900	+0.59
		*Linguistic particularism, 1863	+0.49

combinations of factors that are propitious in producing specific outcomes (Ragin, 1987). In the present example we have first dichotomized the independent variables as follows:

C: Capitalist agriculture with a substantial rural proletariat of *journaliers* and *métayers*
c: Peasant agriculture with a dominance of smallholders and tenants (1852)
P: Mainly partible inheritance
p: Mainly impartible or inegalitarian inheritance (1900)
F: Mainly French-speaking area
f: Matois or major non-Francophone groups (1863)
S: More secularized, with 50% or more of the clergy taking the oath of allegiance to the Revolution (1791)
s: Less secularized, with less than 50% taking the oath.

The dependent variable is equally dichotomized and indicates whether a department had marital fertility levels higher or lower than the mean in 1831 (mean $I_g = 0.56$). With four dichotomous predictors, one can inspect 16 different combinations ranging from cpfs to CPFS. The use of lower-case letters in cpfs means that none of the characteristics that are propitious to producing lower than average fertility are present, whereas the use of capitals in CPFS identifies the areas where all four of the conditions for a faster marital fertility transition are present. Among the possible 16 combinations, two have empty cells: CFps and CFSp, or simply CFp. In other words, we encounter a case of *limited diversity*. This is common in social science applications: systems have a degree of functional consistency and may therefore lack a number of *inconsistent* combinations. In this instance there were no departments with capitalist agriculture (C), and French speaking (F) and with impartible or inegalitarian inheritance (p): The latter seems to be inconsistent with capitalist agriculture or vanished during the course of history in the core regions of France.

Boolean minimization allows us to combine two Boolean expressions that differ in *one and only* one condition, yet produce the same outcome, into a new expression without that single contrasting condition. For instance if both CPfS and cPfS produce a faster fertility transition, the contrasting condition (here c versus C) can be dropped and the condition can be simplified to PfS. We have considered two types of outcomes for the 14 cells. First we wanted to establish which combinations of conditions are associated with less than a quarter of departments in each cell having I_g-values below the mean. In other words, what combinations lead to a strong majority of departments with a late or slow fertility transition? The resulting Boolean expression for strongly lagging is:

$$\text{LAG} = \text{Fcps} + \text{Cpfs} + \text{Pfc}$$

This expression states that Francophone (F) departments failed to experience a fast fertility decline by 1831 if this characteristic was combined with three counteracting conditions (i.e., c *and* p *and* s). Similarly, departments with only capitalist agriculture (C) also largely failed if the other three obstructing conditions (p *and* f *and* s) were simultaneously present. Finally, departments with egalitarian inheritance (P) also failed if they had a dominance of peasant agriculture and were not Francophone (c *and* f). If the last term were Pcfs, the rule would have been very simple: The effects of F, C and P, which on their own are propitious for low fertility, are neutralized if they are combined with the *joint* operation of counteracting factors. Stated differently, *if three of the four factors pushing in the direction of a faster fertility decline are missing, then the vast majority of such departments would lag behind in the fertility transition*.

The Boolean expression for the combinations leading to at least three quarters of the departments having lower than average levels of marital fertility in the 14 cells is:

$$\text{LEAD} = \text{CP(F + s)} + \text{S(Cpf + Fcp)}$$

The first term, CP(F + s), describes the prevailing conditions in 21 of the 24 departments that have a very early fertility decline. It indicates that the joint presence of capitalist agriculture and partible inheritance was necessary but not sufficient. These two conditions need to occur in tandem with either being Francophone or having low secularization. The second term, S(Cpf + Fcp), spells out the prevailing conditions in the remaining three departments (Creuze, Dordogne, Lot et Garonne). For these secularization is necessary but not sufficient since it has to be combined with another factor (either C or F) that is conducive to a low fertility level. Equally striking is that these three departments are located in the southwest and may have had the more marked pattern of birth spacing, leading to low pretransitional marital fertility already referred to for the Garonne area.

The main conclusions to be drawn from the Boolean analysis are as follows:

The sole distinction with respect to the type of agriculture does not constitute a sufficient condition for lower marital fertility in 1831. Other propitious factors need to be added to the combination.

When partible inheritance is added, the results are much stronger.

Cultural factors strongly interfere as brakes on the transition. This holds in particular for religious fidelity and linguistic particularism, as can be seen in the Boolean expression for *LAG*.

The present analysis is only based on regional cross-sectional data, and not on a more elaborate time–space analysis. Bonneuil (1997) offers such a more complete picture for the period 1831 to 1906, using Coale's index of overall fertility (I_f). This added time dimension leads this author to consider extra variables such as urbanization, the decline in mortality, the rise in education and migration. All of these become much more important after 1830. Yet, by that date, the basic map of the French marital fertility transition was already largely drawn, and as we have shown, it was shaped by more general systemic characteristics of both a structural and a cultural nature. Most of these are absent in Bonneuil's analysis for the subsequent period. In essence, these systemic characteristics have their roots in the diversity of agrarian production systems that developed in France prior to the 19th Century. These agrarian systems are associated with different nuptiality systems, differential use of nonfamilial labor (servants versus wage earners), contrasting inheritance patterns, strong timing differences in secularization, and patterns of marital fertility control. The diffusion of the latter innovation probably originated in more than one *center*, and it followed the lines of *weakest resistance* as spelled out by the covariates used here. Of equal importance is that this diffusion was hitting the obstacles formed by both linguistic and religious barriers. These barriers were not crossed so easily after 1830 either: In 1901 the map of marital fertility (van de Walle, 1974) still reflects the five zones of high fertility shown by the map for 1831, and the same holds in 1906 for Bonneuil's index of overall fertility, despite its contamination by differential marriage patterns.

II. NARRATIVE OF BELGIAN DEMOGRAPHIC INNOVATION

The Belgian example is an even more striking case of consistency in the spatial patterning of new forms of demographic behavior. We will try to document the following:

The features of the *second demographic transition*, such as the rise of divorce and of cohabitation after 1970, are strongly spatially correlated with the geography of the *first demographic transition* (i.e., the control of marital fertility and the weakening of the Malthusian marriage pattern after 1850);

Both are reflect a basic socioeconomic and cultural map that started to differentiate Belgian regions since the middle of the 19th century.

1. Background

As in France, there was older contrast between Belgian regions characterized by more intensive and more extensive farming. The former type was operated by family labor supplemented by unmarried servants, and it was mainly located on the sandy soils of Flanders. Since the beginning of the 18th century, such small-scale intensive farming was often combined with cottage industrial activities (especially textiles). The more extensive form is more common in the southern part of the country (i.e., in Wallonia) and uses wage labor as well. Cottage industries are rare. The demarcation is, however, not always clear-cut and does not exactly follow the linguistic border between the Dutch-speaking North and the French-speaking South. There are also exceptions within each of the linguistic areas. For instance, in Flanders more extensive agriculture is practiced on the rich alluvial clay soils of the Polders along the North Sea coast and of the Scheldt river estuary, whereas many Walloon farm laborers also operated their own small plots.

Nevertheless, political and religious differences developed along these lines, and most noticeably from the French period (1794–1815) onward. In fact, there was a first groundswell of secularization inspired by the ideals of the French Revolution, and carried by intellectuals and bourgeoisie, and later on (i.e., after Belgian independence [1830]) by the Liberal party. At the same time, Catholic opposition had also hardened, first against the French occupation (peasant revolts) and then against the Dutch king during the period of reunification of the Low Countries (1815–1830).

At the time of independence in 1830, two political pillars had formed, Liberal and Catholic, and until the 1880s these two were increasingly vying for popular support. Crucial for our purposes is the fact that the Liberal party remained strong, not only among the urban bourgeoisie, but also in the Walloon countryside. By contrast, the Catholic party remained firmly anchored in rural Flanders and particularly in the high population density belt characterized by intensive farming and cottage industries. For the period 1841 to 1847, for instance, we already have a good measurement of secularization for the entire territory via the percentage of annual marriages taking place in March and December (i.e., violating the Catholic ban on marriages during the two *closed periods* of Lent and

Advent). During the French period, there were clear signs of a weakening of this ban in various Walloon areas, but the map for 1841 to 1847 leaves no doubt: The secularization movement started from rural southern Wallonia and from the Liège area, and stops at the language border with Flanders by the 1860s. Contrary to common belief, the initial roots were not to be found in differential industrialization, since many strictly rural Walloon arrondissements showed levels of secularization that were as high as those witnessed in the emerging Walloon industrial belt (Lesthaeghe, 1991). In Flanders, there were only a few pockets with somewhat higher levels of secularization: the two towns of Antwerp and Ghent and to some degree the Polders strip along the coast.

The second wave of secularization is more closely associated with industrialization and urbanization, and its effect emerges essentially during the second half of the 19th century. It is also linked to the growth of the third political pillar (i.e., the socialist movement). At the same time, it is also matched by the Catholic revival and popular mobilization, as in other parts of Europe. New shades are then added to the map of secularization. By 1880, this map looks as follows:

There is a Walloon zone with the highest levels in the industrial belt, but also in all adjacent rural arrondissements (e.g., Thuin, Philippeville, Huy). The northern edge of this zone corresponds perfectly to the linguistic border with Flanders.

A second Walloon zone with somewhat lower levels dates back to the first secularization wave, and it is entirely made up of rural arrondissements, mainly located in the Ardennes region.

High levels are found in Brussels, the bilingual capital.

Moderate levels are found in a number of Flemish urban areas (Antwerp, Ghent) and in a few industrialized towns (e.g., Aalst).

Low levels prevail in the central part of Flanders (provinces of East Flanders and Brabant) and along the coast.

Very low levels are encountered in the western and eastern corners of Flanders, i.e., in the interior of the province of West Flanders and in the Antwerp Campine area and adjacent Limburg. These areas remain strongholds of Catholicism until the 1960s at least.

Much of this story is reflected in the statistical correlations presented in Tables 38–5 and 38–6. In Table 38–5 we have brought together the correlations between our various measurements for secularization, starting with the index of marriages during Lent and Advent (MLA) in 1841 to 1847, continuing with the parliamentary election results for 1919 (male universal suffrage) and 1958 (last *school war* between the Catholic pillar and the other two), and ending with absenteeism in the Sunday Mass attendance survey of 1964. As was expected, the spatial pattern of secularization measured through MLA in 1841 to 1847 is an early indicator that remains valid till the 1880s (correlation with MLA 1860 to 1865 = 0.91 and with MLA 1881 to 1884 = 0.83), but the added effect of the second wave of secularization, associated with the rise of the Socialist pillar, leads to a reduction of the spatial correlation (r with vote for secular parties in 1919 = +0.55). If, on the other hand, we start with MLA in the 1880s, the spatial pattern remains more intact, and if we take the election results of 1919 as a starting point, the subsequent maps of secularization remain almost identical till the 1960s. Table 38–6, finally illustrates that the rural character of arrondissements was less discriminating with

TABLE 38–5 Correlation Coefficients Between Various Indicators of Secularization, Belgian Arrondissements ($N = 41$)

	Marriage index during Lent and Advent			Socialist + Liberal + Com. vote		Absenteeism Sunday Mass 1964
	1841–1847	1860–1865	1881–1884	1919	1958	
Marriage index Lent + Advent (MLA)						
*1841–1847	—	+0.91	+0.83	+0.55	+0.36	+0.26

MLA, marriages during Lent and Advent.

respect to secularization levels until the 1860s, and these were better predicted by adult literacy (higher in Wallonia than in Flanders, also in Walloon rural areas) and by the proportion French speakers. The rural–urban distinction emerges more strongly after 1880, but the linguistic divide survives. The effect of differential adult literacy disappears of course during the 20th century as a consequence of universal primary education.

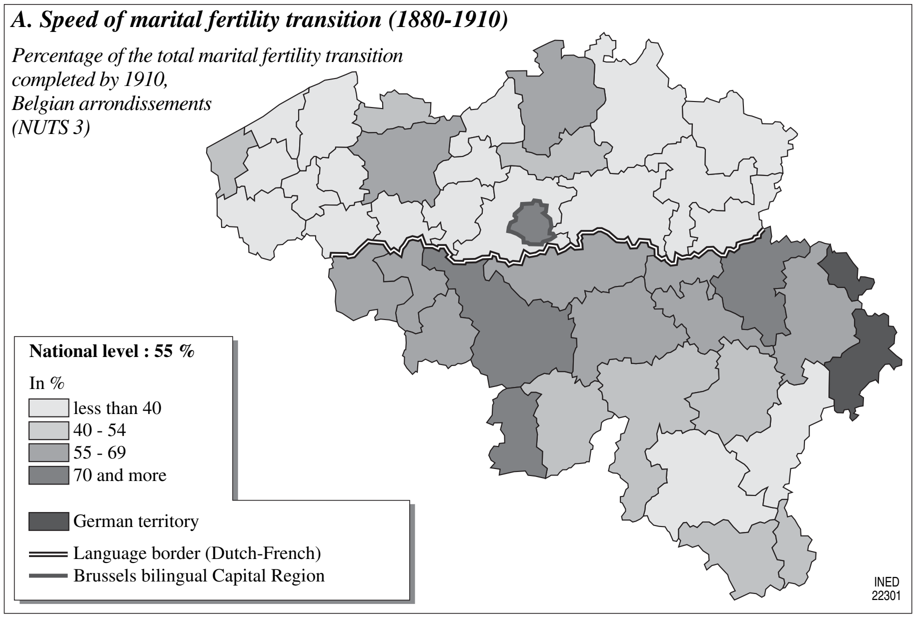
The overall outcome of the two-wave secularization process was a profound *pillarization* of Belgian society. Many aspects of public life (e.g., cooperative shops, labor unions, charities, pension funds, schools, leisure activities, media, and so forth) were organized by the three political families (Catholic, Liberal, and Socialist). In addition, the Flemish-Walloon contrast was further enhanced. Only after the 1960s would the political pillars weaken. The growth of other parties is related to this new process of *depillarization*, such as the Greens during the 1970s and right wing extremists (e.g., Vlaams Blok) during the 1990s. Both Liberal and Socialist parties had abandoned their anticlerical ideology, and at present, even the Christian democrats are debating whether the *C* should represent *Christian* or *Centrum*. But, as we will show, old and new forms of demographic behavior are still closely related to the older maps of secularization. It apparently takes longer for Belgian demography to *depillarize* than for the Belgian political scene.

2. Belgium's Spatial Aspects of the *First* and *Second* Demographic Transitions

A first impression of Belgian spatial pattern stability can be gleaned from the four maps presented in Figure 38–2. At the top we have juxtaposed the map of the speed of the marital fertility transition for the period 1880 to 1910 (map A) and the map of voting for the secularized parties in 1919 (map B). On both maps the central Walloon belt of industrial and adjacent rural arrondissements emerges very clearly. This was the area of early demographic *innovation* with respect to the adoption of birth control and the weakening of the Malthusian late-marriage pattern. This zone stops at the language border over its full east–west length. Fertility control has only spilled over this border in Brussels, which was already then a largely French-speaking city. It also started to develop in the urban arrondissements of Antwerp (to the north) and Ghent (to the west). The two zones of late adoption of fertility control and of Catholic loyalty also show up clearly at the eastern (Limburg + Campine) and western ends (Interior West-Flanders) of the Dutch-speaking region.

The last two maps in Figure 38–2 present two indicators of the second demographic transition (i.e., the rise of unmarried cohabitation during the 1970s and 80s [map D]) and the concomitant increase of the share of births out of wedlock in the 1980s (map C). The central Walloon zone shows up again in tandem with a broad ring of rural French-speaking arrondissements. Only in the southern corner of Wallonia is the rise of cohabitation more modest. The linguistic border is once more a major dividing line. In Flanders the growth poles are again the urban areas of Antwerp and Ghent, now followed by the urban area along the coast. The eastern and western corners of Flanders stand out by virtue of low levels of cohabitation and small shares of nonmarital births, in the same way as they were the last regions to practice fertility control a century earlier.

The story can also be told with a larger set of indicators measured over a period of about 150 years. These indicators are presented in Table 38–7, and include early and later measures of secularization, socioeconomic indicators in 1900 and 1970, and



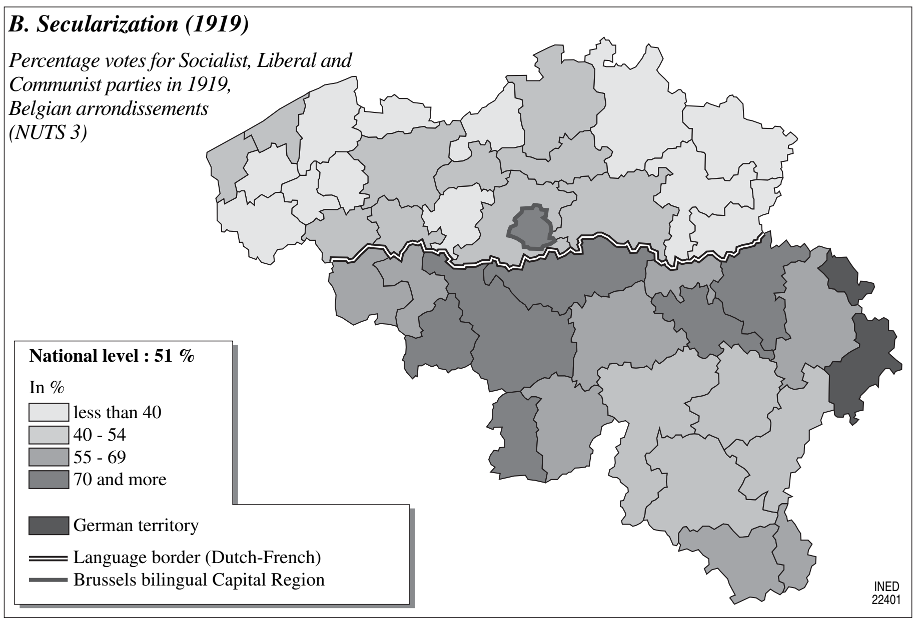


FIGURE 38–2 Pace of the marital fertility transition at the end of the 19th century **(A),** and level of secularization in Belgium **(B)**.

historic literacy differentials. They are paired to indicators of the *first* and *second* demographic transitions, including levels of marital fertility and nuptiality for the earlier period, and indicators of divorce, cohabitation, and nonmarital fertility for the later period. As in the example of France, a canonical correlation analysis has also been performed on these indicators, and the results are shown in Table 38–8.

As before, the demographic indicators are brought together in the *Y*-set and the socioeconomic and cultural factors in the *X*-set. The first canonical variate absorbs most of the information, and Y_1 and X_1 are very strongly correlated ($r = 0.98$). Virtually all demographic indicators load strongly on Y_1, starting with the speed of the marital fertility decline in 1880 to 1910 and with the recent level of nonmarital fertility of 1992 and the divorce incidence in 1967 to 1970. The current levels of cohabitation are next in line, together with the level of marital fertility more than 100 years earlier. The historic indicators of the weakening of the

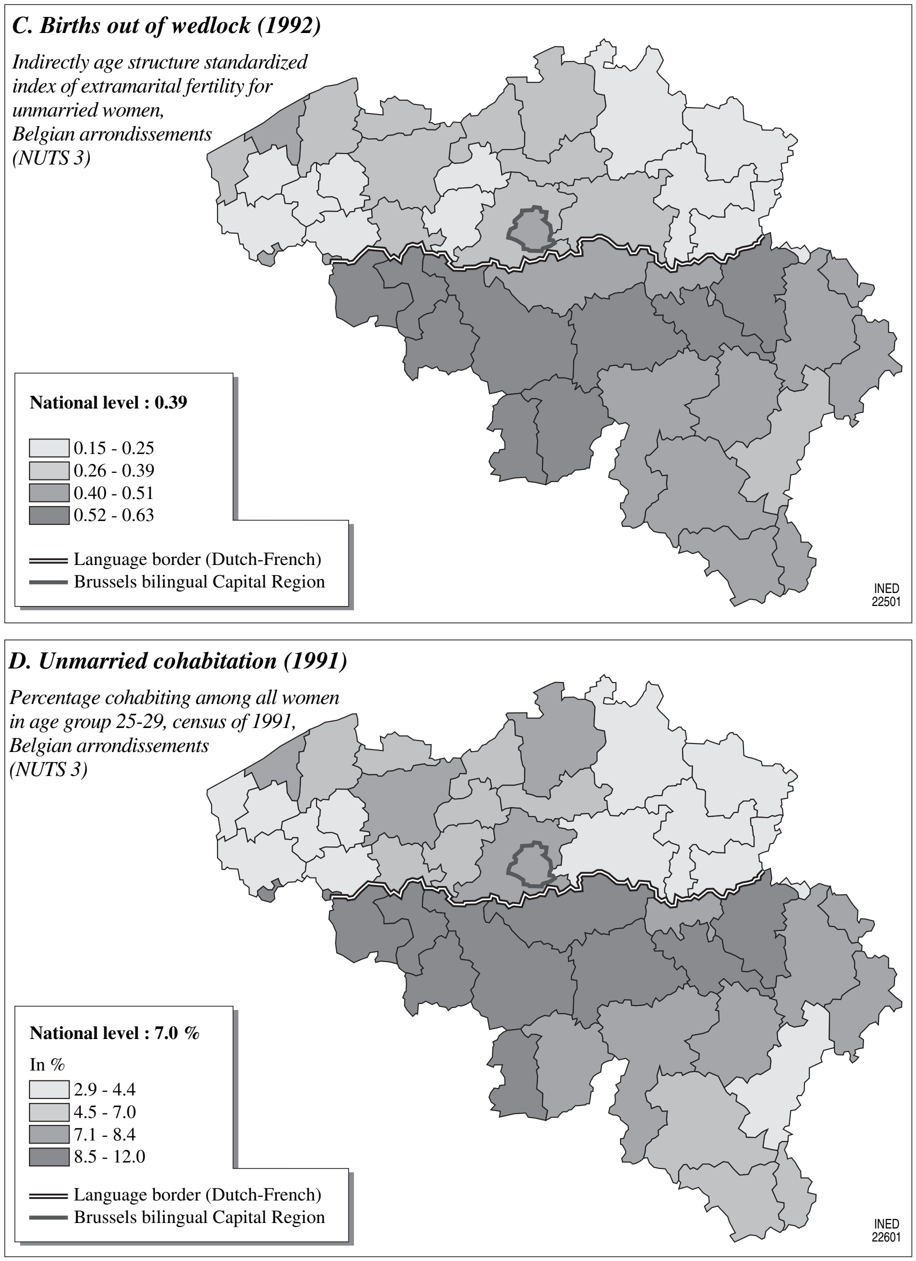

FIGURE 38–2 (*Continued*) Births out of wedlock in 1992 **(C)**, and unmarried cohabitation in 1991 **(D).**

Malthusian late marriage pattern are the weakest correlates of the dimension of demographic innovation, but still have loadings of +0.070. The corresponding X_1 dimension is almost perfectly identified by the voting for secularized parties in both 1919 and 1958 (loadings of 0.90 or more), closely followed by Sunday Mass absenteeism in 1964. This also reflects the socioeconomic structure as it existed in 1900 and indicated by the proportions then employed in agriculture and cottage industries. The 19th century measures of secularization are weaker indicators, but the index of marriages during Lent and Advent (MLA) of the 1860s still correlates with X_1 to a respectable degree (+0.69).

The only demographic indicator that identifies a second and uncorrelated canonical variate is the level of illegitimate fertility near the end of the 19th century. This map does not correspond as well to the secularization dimension, but is much more in line with the urban–rural divide and 19th century literacy levels. At that time, urban and especially industrial environ-

TABLE 38–7 Definitions of the Demographic, Socioeconomic, and Cultural Indicators Used in the Analysis for 41 Belgian Arrondissements

I_g	Coale's index (1963) of marital fertility, indirectly standardized for age and marital status composition and based on the Hutterite fertility standard; measured for 1880 and 1900.
Speed fertility transition	Percentage of the total marital fertility transition already completed before 1910; measured as $I_g(1910) - I_g(1880)/I_g(1880–0.200)$, where $I_g = 0.200$ is considered as the end point of the transition.
I_m	Coale's index of proportions married weighted by Hutterite fertility, 1880.
EM	Percentage ever-married women aged 20–24 years, 1880.
I_h	Coale's index of illegitimate fertility, 1880.
Divorce	Divorce rate per 10,000 married women, 1967–1970.
I_c	Index of nonmarital fertility comparable to Coale's I_h, except weighting by Belgian national age-specific fertility rates of 1989–1991 instead of Hutterite fertility, 1992.
Cohab	Percentage of all women aged 20–24 or 25–29 years currently in cohabitation, 1991.
MLA	Marriage index Lent and Advent (i.e., percent of total annual number of marriages in March and December divided by 2/12 [normal share for 2 months]); averaged over several years to neutralise effect of variable date for Easter. Measured for 1841–1847, 1860–1865, 1881–1884.
Sec vote	Percentage of votes for socialist, liberals and communists, parliamentary elections of 1919 and 1958.
Absent Mass	Percentage of adult population 15+ absent at Sunday Mass, 1964.
Agcot	Percentage of male active population employed in agriculture and cottage industries, 1900.
Agric	Percentage of male active population employed in agriculture, 1970.
Literacy	Percentage of population 15+ able to read + write, 1900.

Note: There are currently 43 arrondissements instead of 41. The old Brussels arrondissement has been reformed by bringing the Brussels Capital Region together with the Flemish arrondissement of Halle-Vilvoorde, whereas the newly formed French-speaking arrondissement of Mouscron (formerly a small section of the Flemish arrondissements of Ypres and Kortrijk) was dropped from the analysis. In other words, we have stayed as closely as possible to the historic division of the territory.

ments with a concentration of low literacy working class populations were the main settings of high illegitimacy. The present levels of nonmarital fertility are, as already indicated, spatially differentiated along the axis of the first canonical variate since they reflect much more the fertility levels of cohabiting couples, and are therefore typical indicators of the second wave of demographic innovation developing since the 1960s.

III. OTHER NARRATIVES: AN INVITATION FOR NEW RESEARCH

Obviously similar narratives can be produced for other European countries, and not all should exhibit similar degrees of spatial continuity over time as the examples of France and Belgium used here. For several countries a good start of the analysis is available, and many possess the necessary range of socioeconomic and cultural indicators. For instance, Livi-Bacci's work on Portugal (1971) and Italy (1977) clearly indicates that there are promising avenues to be followed for documenting the survival of older spatial patterns in the genesis of newer forms of demographic behavior. For Italy, the author is rather disappointed about the statistical explanatory power of classic socioeconomic variables in accounting for the historic marital fertility transition, but he finds that provincial fertility levels measured as early as 1911 are the best predictors of the regional voting results in favor of a liberalization of divorce laws in 1974 (Livi Bacci, 1977). Also the Swiss and Austrian narratives can be explored further because these countries too have long histories of spatial heterogeneity with respect to cultural, socioeconomic, and demographic variables. Both of them are therefore excellent testing grounds for the study of spatial continuity of first and second demographic transition variables.

There are of course counterexamples. The British history of the fertility decline is still an elusive case. Except for the initial Scottish–English divide, there are no clear geographic patterns of innovation and subsequent diffusion (Bocquet-Appel, 1997), nor are regional socioeconomic indicators providing convincing explanations (Teitelbaum, 1984). Social class distinctions rather than geographic ones may have been more important. Some Scandinavian countries may also produce a distinct class of narratives. For instance, unmarried cohabitation and concomitant extramarital fertility may have been features that were pushed to the northern frontiers of Norway and Sweden during a first phase, only to spread back south during the *second demographic transition*. Such a *revenge of the fringe*-hypothesis needs, however, more detailed doc-

umenting than is hitherto available. Furthermore, both Norway and Sweden have their more traditional Bible-belts, and to our knowledge, there has been no systematic investigation of this spatial cultural feature and its impact in shaping both first and second demographic transitions.

To sum up, many European countries provide settings of highly spatially differentiated cultural, socioeconomic and demographic developments that can be captured statistically since the 19th century. With a bit of imagination and luck, new indicators can be mined. The socioeconomic and demographic ones are easier to find, whereas the cultural ones may need more probing. However, a greater reward in the form of a more complete narrative may be down the line.

IV. NARRATIVES AND THEORIES OF DEMOGRAPHIC INNOVATION

The narratives produced in the Princeton Project of the 1970s on the history of fertility control and the modernization of the nuptiality systems in Europe inspired Coale (1973) to specify three preconditions for demographic innovation and adaptation. They are known as the *Ready, willing and able* specification. These terms refer to the following:

Ready: The new form of behavior must be economically advantageous and more so than the older form;

Willing: The new form must be culturally acceptable and not run counter to prevailing ethical or religious (or other ideational) convictions and values;

Able: There must be means, old or new, to implement the choice. This implies that these means must be known and are accessible.

In the narratives, readiness has been connected to socioeconomic structures and changes, to the evolution of real wages (Lesthaeghe, 1992, for France) and to economic aspirations (e.g., Dumont's *social capillarity*, 1880, or Denis' relative deprivation theory, 1899). At the micro-level, readiness also refers to the terms of economic calculus as for instance defined in Easterlin's (1978) demand function for children: utilities, disutilities, and relative means or income. Willingness, on the other hand, has been operationalized through the secularization indicators on the assumption that religious barriers would inhibit the adoption of new forms of demographic behavior, whereas secular outlooks foster the adaptation of behavior to new objective circumstance. The ability condition has not been operationalized here since we obviously do not have spatial information on the methods of contraception being used in historic times. In studies of much more recent fertility transitions, however, the ability condition could be operationalized via spatial patterns of knowledge and availability of modern methods of contraception.

At the micro-level, we can imagine that an individual or household i has a score on readiness (R_i), willingness (W_i), and ability (A_i), each ranging from low or unfavorable (0) to high or favorable (1), and with a zone of uncertainty in the middle (0.5). Coale's specification is a *bottleneck model* because the three conditions need to be met simultaneously. This means that the final decision score (S_i) is the *minimum* of the individuals' values for R_i, W_i and A_i. In other words:

$$S_i = \text{minimum}(R_i, W_i, A_i)$$

A particular person or household would only switch to the new behavior if his or her S_i is greater than 0.5 (i.e., when the minimum of the three component scores has crossed the boundary of indecision). Aggregating over all individuals or households implies that we are dealing with distributions for R, W, and A and for the minimum S (Lesthaeghe and Vanderhoeft, 1999). This, however, is a model for a single, homogeneous population. The spatial patterning requires a disaggregation according to distinct regional networks. A classic specification focussing on individual and network effects (Montgomery and Casterline, 1996) takes the following form:

$$Y_{i,t} = \beta_i X_{i,t} + \delta_i \sum \omega_{i,j} Z_{j,t-1} + e_{i,t}$$

The Greek letters indicate coefficients or weights, and the roman letters refer to variables. In this equation an outcome Y for individual or household i at time t is made up of the influence β_i of a set of *individual* characteristics $X_{i,t}$ and the influence δ_i attributed to the influence of a *network* composed of N persons or households. In this network, members j have characteristics Z_j, but the actor i gives differential *credibility* scores $\omega_{i,j}$ to each of them. These are then summed over all network members. The last term, $e_{i,t}$, is the error term.

Applied to Coale's conditions, we have to set up three such equations, one for R_i, W_i and A_i, respectively:

$$R_{i,t} = \beta_i X^R_{i,t} + \delta_i \sum \omega_{i,j} Z^R_{j,t-1} + e^R_{j,t}$$
$$W_{i,t} = \beta_i X^W_{i,t} + \delta_i \sum \omega_{i,j} Z^W_{j,t-1} + e^W_{j,t}$$
$$A_{i,t} = \beta_i X^A_{i,t} + \delta_i \sum \omega_{i,j} Z^A_{j,t-1} + e^A_{j,t}$$

The superscripts of the individual and network members' characteristics X and Z imply that these characteristics may vary or be of unequal relevance, depending on whether R, W, or A is considered. These characteristics can of course be objective attributes (e.g., wealth, income, and so forth), forms of behavior, or opinions and values. The individuals in the actor's network are likely to belong to the same kinship group, social class or have a shared location. The credibility weights are highly likely to vary according to social distance. The model above does not imply that R_i, W_i and A_i have to change at the same time: one of the three can be lagged and this would cause the minimum S_i to lag as well. Nor does the model imply a fixed sequence such as R→W→A (i.e., readiness increasing first, thereby causing a reevaluation of normative barriers, and then leading to a search for appropriate means). It may well be, as possibly in the case of the early French fertility decline, that normative barriers had weakened before (early secularization) and that means (e.g., coitus interruptus) were already well known before the economic motivations developed. In this instance, it would be the population distribution for R that would be the last to shift, and the bottleneck condition would not be defined by the distributions of W or A.

Let us now consider how the French and Belgian narratives fit with the model above. Familial forms of production (small-scale owner or tenant farming or cottage industry), inegalitarian inheritance (avoidance of fragmentation of land) and endogamous marriage strategies imply lower scores on readiness. Conversely, capitalist agriculture (C) and partible inheritance (P) imply higher scores on R. Early secularization (S)—whatever its initial cause—means higher scores on W. And linguistic particularism signals nonmembership of the core network. In this fashion, the Boolean expressions for LEAD and LAG describing the French marital fertility transition can be translated into the RWA model. Recall that the presence of one propitious factor (either P or C related to R, or S related to W, or F related to a core connection) but the absence of the other three are closely associated with a slow fertility transition. In other words, there was not one but a combination of bottlenecks (pc, ps, cs . . .) that produced the LAG-outcome. All such departments are low on secularization (s), and all of them have a missing element of the CP combination. Conversely, this CP-combination was the best predictor of a faster fertility transition and in the majority of LEAD departments, this was also combined with F (i.e., being part of the innovating core).

The Belgian fertility decline is characterized by two separate models as a result of the linguistic divide. In the South, the levels of secularization were already high before the start of the fertility decline so that W was no longer the bottleneck condition. The fertility transition can then be seen as advancing in tandem with the socioeconomic changes that influenced child utility and child costs. In the North, by contrast there were several urban centres of innovation with respect to fertility control, but this new form of behavior could only spread to the eastern and western corners of Flanders when moral and religious obstacles were weakening. In fact, the adoption of family limitation in these Catholic parts of Flanders may, at a later stage, have contributed to the gradual secularization of these areas as well (reversed causation).

The importance of region-linked networks in the Belgian example is further highlighted by the survival of subcultures that are either more permissive or more obstructive with respect to the typical features of the second demographic transition. Stable local networks then explain the replication of the diffusion model exhibited during the first demographic transition on both sides of the linguistic border: (a) diffusion from the Walloon core region towards the Ardennes in the southern corner of the country, and (b) diffusion from Brussels and urban areas in Flanders to the middle of Flanders first, and to the two Flemish corners later on. The connection with the secularization maps prior to 1970 furthermore indicates that the local subcultures kept their differentiation along the normative or the willingness dimension, even if the issues have changed (now: divorce, cohabitation, procreation within cohabitation). To sum up, countries characterized by strong and stable subcultures are also likely to produce narratives of long-term demographic continuity, similar to the Belgian experience.

CONCLUSION

The conclusion can be brief. In social science theories developed after the 1960s, it has become fashionable to attribute innovation of new behavior to the powers of individual agency. Individuals can cut all ties with tradition and adopt modes of action that are economically and functionally most suitable for a given objective situation. But, as our narratives have shown, demographic innovations over more than a century can originate in very much the same places, they can diffuse geographically in the same hierarchical fashion, and this can be steered along the same *lignes de force* governed by a *normative* dimension. Clearly, such a pattern can only emerge if (a) there is a continued and locally differentiated ethical and political socialization of successive generations, (b) if members of local and regional networks reinforce each others ways of thinking and of acting, and (c) if no outside forces (such as large migration streams) upset the stability of normative subcultures. In this sense, many Europeans may be more the product of their regional roots than that the primacy of individual agency has led them to believe.

Acknowledgments

The authors thank Didier Willaert for the production of the maps and Patrick Deboosere for the production of the recent Belgian cohabitation data by arrondissement.

Fertility: Theories, Frameworks, Models, Concepts

BART J. DE BRUIJN

Netherlands Interdisciplinary Demographic Institute (NIDI), Den Haag, Netherlands

Demography *is largely a social science and is becoming more so*. In the special issue of *Population Studies* to commemorate the journal's 50th anniversary, John Caldwell reached this conclusion after an assessment of demography's position in the scientific world (Caldwell, 1996). The unique character of demography may lie in the discipline's emphasis on quantification, analytical models, censuses, and large-scale sample surveys. It remains, nevertheless, a social science in that the central subject it deals with—population and population dynamics—is a social phenomenon: emerging from the aggregation of individual life events, to a great extent socially determined and with profound social consequences. The situation is aptly described by Schofield and Coleman (1986) in their introduction to *The State of Population Theory*. They characterized demography as a discipline with a hard mathematic core and a softer surrounding of an explanatory body of theory. Whereas this mathematic core has been called *a point of proper disciplinary pride* (McNicoll, 1989, p. 433), its development is not paralleled by an equally mature development of theory. The emerging picture of demography is that of an accurate, but relatively dull science; strong in accountancy, but relatively weak in conceptualization.

This unbalanced state of affairs is a matter of concern to many demographers. Schofield and Coleman, for instance, stated that

> Any subject which finds it necessary, or indeed possible, to consider its material divorced from an appropriate body of theory must be in trouble. This seems to be the case with demography at present (Schofield and Coleman 1986, p. 1).

During the development of the discipline of demography in the past decades, similar statements have repeatedly been made (e.g., Vance, 1959; Ford and De Jong, 1970; McNicoll, 1980, 1992; Greenhalgh, 1995b). Indeed, a one-sided sophistication of data collection and mathematic analysis can never substitute the role of theoretical fundament for the formulation of research questions and the interpretation of data. To reach a true understanding of demographic phenomena, we require theories, conceptual frameworks, and models that identify the causal mechanisms underlying the relations between relevant variables (Wunsch, 1995).

Demography traditionally focuses on three main subjects—fertility, mortality, and migration—and of these three, fertility has perhaps the most abundant and comprehensive theoretical foundation. However, even here complaints can be heard that although demography has yielded adequate descriptive instruments, the emerging vision is still insufficient; at least insufficient to be relevant for concrete situations (e.g., Freedman, 1987; Handwerker, 1986; McNicoll, 1992; Ryder, 1983; Willekens, 1990a). This may seriously impede development in areas in which demographic expertise is called on, such as the provision of sound population forecasts (Willekens, 1990b) or the underpinning for efficient and effective population policies (Andorka, 1989; Tsui *et al.*, 1992; World Bank, 1992). These complaints should not, however, disguise the fact that these inadequacies are not typical of demography alone, but represent the situation of social sciences in general. Furthermore, over the years a substantial number of theoretical orientations have entered the realm of fertility studies, leading to new and complementary insights.

I. THE STRUCTURE AND DEVELOPMENT OF FERTILITY THEORY

More than probably any other social science, demography is identified and demarcated by its subject matter—population and population change—rather than by conceptual premises of how to study it. The easily quantifiable nature of the major phenomena of interest bolsters up this empiricist bias. Other disciplines—economics, sociology, history, anthropology, biology, psychology and medical science—have invaded the relative vacuum of theoretical substance, justifying the label demography as an *interdiscipline* (Mayone Stycos, 1987). If this represents the status of demographic theory in general, it equally pertains to that of the theoretical body that deals with fertility, although several approaches are firmly grounded within the borders of demography itself. The resulting theoretical landscape of fertility is a colorful and mountainous patchwork of ideas, often without much coherence or substantial cross-fertilization. Leridon (1982) depicted the situation as a *cubist painting*, and in a recent overview of half a century of research into the determinants of fertility, van de Kaa (1996) recounts it as an evolving story consisting of a series of subnarratives from different disciplinary orientations. Each of these disciplinary approaches introduced a different perspective, a specific focus, methodology, level of analysis and assumptions about the mechanisms underlying reproductive behavior. In this respect, Hauser and Duncan's observation that demographic inquiry did not yield a principle coherent body of knowledge to explain the discipline's phenomena of interest is still valid today (Hauser and Duncan, 1959). A *grand unifying theory* remains far beyond the capacities of the discipline (Freedman, 1987; van de Kaa, 1996; Schofield and Coleman, 1986; Wunsch, 1995) and, for that matter, of any social science.

However, the inclination to adopt insights from neighboring sciences to study the determinants of fertility has not proven to be a guarantee to keep up with the developments at the frontiers of knowledge in these fields (Greenhalgh, 1996; McNicoll, 1992). The application of micro-economics theory has largely stuck to the new-home economics of 15 to 20 years ago and there seems to have been little development in psychological theorizing in demography since the emergence of the *value-of-children* concept in the 1970s and the early applications of the Fishbein-Ajzen type of attitude models. The notion of culture in demographic studies is notoriously reduced to austere proportions—if it is conceptualized at all—and stands a long way from the evolution of cultural understanding in the last decades (Greenhalgh, 1995b; Hammel, 1990; Handwerker 1986). New institutional approaches, social learning theory, and cognitive sciences in general have hardly touched the work of demographers or have only recently entered the field (Burch, 1980; McNicoll, 1992). Some theoretical traditions—like phenomenology, holistic anthropologic approaches—have never made it into the canonical streams of demography because they stand too far apart from the starting points of objectivity and quantification that are valued in demographic inquiry.

Nevertheless, theoretical developments in other social and behavioral sciences had their share in the shifts that occurred in the main orientations of fertility research. A prominent example is the application of economic decision models to fertility since the 1960s in the wake of the general expansion of the economic principles of consumer choice into other life domains. But other forces also operate on the direction of fertility research and its conceptualization. Thus, the availability of a huge amount of data after the series of the World Fertility Surveys (WFS) and the Demographic and Health Surveys (DHS) has been an important factor in the popularization of Bongaarts' model of proximate determinants of fertility. Partly also, demography followed the fashion of the day in scientific and policy circles: the prewar flirt with—and subsequent hasty abandonment of—eugenics, the attachment to the family planning movement, the nexus between population and environment and, especially since the run up to the 1994 International Conference on Population and Development in Cairo, the issue of reproductive health. Several authors have dealt in this respect on the influence of governments, pressure groups, scientific journals, funding agencies, and intellectual and institutional backgrounds (e.g., Caldwell, 1996; Caldwell and Caldwell, 1986; Demeny, 1988; Greenhalgh, 1996; McNicoll, 1992; Szreter, 1993).

In spite of the disciplinary variety in the approaches to fertility and the various orientation shifts over time, explaining the differences and changes in patterns and levels of fertility continues to be a central concern for demographers. In this respect, the theory of demographic transition offers a paradigmatic framework in which each of the theoretical contributions can be viewed as part of the total explanation of the generally observed trend from high to low fertility (Beaver, 1975; van de Kaa, 1996; Kirk, 1996). To organize a review of theories and models of fertility, one dimension that may therefore be used is the relevance of these theories for the explanation of fertility in the different stages identified in the perspective of demographic transition. Thus, the model of proximate determinants and its underlying concept of *natural fertility* bears particular relevance for the situation in (pretransition) historic populations and in many contemporary developing countries, whereas psychological choice models are fairly limited to the explanation of fertility in (post-transition) developed countries, and diffusion approaches seem to apply to the transition stage in between. Another, and perhaps even more important, criterion to classify theories and models of fertility is their emphasis on macro- or microlevel explanation. To provide a full understanding of fertility and fertility change, we must encompass both the structural determinants of the embedding context and the role of individual and intraindividual processes, and, consequently, the mechanisms that relate macro- and microlevels (de Bruijn, 1999; Greenhalgh, 1990; McNicoll, 1994; Wunsch, 1995).

The subsequent sections will address the major lines of thought in current demography as far as they are relevant to the study of fertility. We will leave aside strict mathematic demographic theories—stable population theory, the work of Lotka, model life tables, and so forth—and theoretical considerations in other disciplines that deal with the analysis of fertility—such as economics and anthropology—but remain outside mainstream thinking in demography.

1. Malthusian Thoughts and Population Theory

Ideas and observations with regard to fertility and population can be traced back to classic antiquity and ancient Chinese philosophers. Although these considerations foreshadowed the development of many principles of population, population growth, and development, and often addressed the implications for public policy, they remained largely speculative and at a low level of generalization (United Nations, 1973). The writings of Malthus at the end of the 18th and beginning of the 19th centuries are usually credited with being the first systematic account of the principles of population change. Malthus' body of thought was clearly rooted in the political, economic, and social issues of his time. The core of his first *Essay on the Principle of Population*, published in 1798, is the idea that the capacity of human populations to reproduce is (in principle) unlimited and proceeds with a geometric ratio, whereas the capacity to produce the means of subsistence is necessarily limited and increases at best in arithmetic fashion (Malthus, 1976). In subsequent versions of his *Essay*, Malthus further developed his theory and added various considerations.

The belief that population and means of subsistence increase with different ratios means that populations will grow where food production increases, but that eventually they will face a level where no more people can be sustained and any surplus population will die of starvation. Whereas Malthus maintained that populations always tended to a maximum increase, they were limited by the *positive checks* of mortality. These positive checks not only included famine and starvation, but also other *misery*, such as epidemics, wars, and plagues. In addition, he conceived of a number of *preventive checks*, which operated through people's voluntary acts to limit their number of children. The major principle Malthus saw in this respect—although it surprisingly only appeared in his later writings—was deferring marriage or refraining from marriage altogether. The other *moral restraint* he acknowledged—sexual abstinence within marriage—was considered ineffective because of the overpowering *passion between the sexes*. Malthus' world view (particularly as that of a clergyman) was violently opposed to other means of birth control, like abortion and contraception.

Since its inception, the Malthusian project has been often and severely criticized on empirical as well as ideologic grounds, and indeed it is still the subject of heated debate among scientists and policymakers (Rothchild, 1995). One of the main lines of attack concerns Malthus' assumption of the capacity to increase agricultural output. Preceded by many others, Boserup's orientation is a main contender of Malthusian theory. She advances that technologic progress might keep food production ahead of population increase (e.g., Boserup, 1981; see also J. L. Simon, 1977). In her view, population growth, and particularly increasing population density, is a main stimulus to innovative techniques in agriculture. Moreover, she reverses the Malthusian logic by suggesting that technologic progress only occurs under pressure of population growth. In other publications, Boserup elaborated on the intricate links between technology and fertility, asserting that modes of production have far-reaching effects on marriage patterns, gender relationships, and reproduction (Boserup, 1970, 1990).

Another shortcoming of Malthusian reasoning is its failure to distinguish the power of populations to increase from their tendency to do so. Many anthropologic studies (e.g., Bledsoe, 1990; Kreager, 1982, 1986; Howell, 1979, 1986) have shown that populations have a large variety of mechanisms at their disposal to keep population size in accordance with the carrying capacity of their environment, ranging from marriage patterns and migration to contraception and child fostering. However, this is an adaptation of the Malthusian scheme of balancing population and subsistence rather than a rejection, and in this respect Malthus' ideas remain an important background of fertility analysis.

This is also the case with regard to public policy and developmental issues. Despite the recognition that technologic innovations keep on pushing up the limits of population growth, the essence of the problem continues to permeate the debate, not only with regard to the food supply, but also in the broader perspective of sustainable development with regard to the exhaustion of non-renewable sources of energy (Meadows *et al*., 1972), global warming (Flavin, 1989), water scarcity (Falkenmark, 1990), soil erosion (Brown, 1989), global deforestation (Myers, 1990), and so forth.

2. The Theory of Demographic Transition

For most of this century, demographers and social scientists have been intrigued by the regularities of demographic change in many different settings all over the world. These regularities were considered so remarkable that their occurrence spurred the development of the major body of conceptualization available to demography. The apparent process of *demographic transition* proceeds in the course of modernization and economic development from a situation characterized by high mortality and high fertility to one where mortality and fertility are low, via a stage with declining death rates and declining birth rates lagging behind. This notion of demographic transition gained full momentum only after the seminal publications by Davis (1945) and Notestein (1945), although the full essence of the contingency between modernization and declining mortality and fertility, as well as the three-stage evolution had already been comprehensively formulated by Thompson in 1929. The major elements had also been addressed by Landry (1909, 1934) and in the ethnographic wealth of the work of Carr-Saunders (1922, 1964/1936).

The classic representation of the demographic transition, as for instance sketched by Notestein, claimed that mortality declined in the wake of the industrial revolution, which brought material changes in the sense of agricultural innovation, better communication, higher productivity, and improved health conditions. Fertility was much less responsive to such modernization and its decline depended to a large extent on the collapse—following mortality decline—of ideational and normative systems that supported high fertility.

In the past decades, what started out as a mere description or explanation of historic trends of mortality and fertility in Europe has become increasingly elaborated and has incorporated additional considerations, like different conceptualizations of modernization and the shift from socioeconomic to cultural–ideational and psychological determinants of fertility decline. The principles of historic demographic transitions were thought to be applicable to any contemporary situation in the sense that every nation, region, or population could be located on the evolutionary track of modernization and mortality and fertility decline. Other notions that transformed the concept from empirical observation to theoretical assumption posit that a substantial mortality decline invariably precedes a major decline in fertility, that the mortality decline is followed inevitably by reduced fertility, and that once a substantial fertility decline has been established, the process is irreversible and inescapable. In these respects, the notion of demographic transition has increasingly been considered as a theory with universal validity and predictive power. It is in this respect worthwhile mentioning that Dudley Kirk, another demographer who contributed to the initial formulation of the demographic transition concept, claims that neither Notestein nor Thompson initially thought of their ideas as a theory (Kirk, 1996).

In 1973, Ansley Coale stated that

> The power of the demographic transition concept . . . lies in the undeniable fact that with sufficient modernization fertility and mortality change in a predictable manner.

But the weakness of the concept, according to Coale, is

> The difficulty of defining a precise threshold of modernization that will reliably identify a population in which fertility is ready to fall (Coale, 1973, p. 64).

Thirteen years after Coale's remarks in what can be considered the last monument in the tradition of the demographic transition theory, Chesnais had to phrase the strengths and limitations of the theory in almost identical terms (Chesnais, 1986). Meanwhile, Coale and his associates from Princeton University had tried by means of a large-scale survey to identify the crucial variables that had determined the onset and pace of Europe's fertility transition. Their attempt failed in the sense that their study could not find any socioeconomic indicator of modernization that could unequivocally explain the occurrence of fertility decline in Europe (Watkins, 1986). Socioeconomic factors, which were emphasized by transition theory, appeared to be either spurious or inconsistent in the explanation of the timing of the decline or its tempo The simultaneous fertility decline in Hungary and England is a case in point, as in terms of socioeconomic indicators, Hungary lagged far behind England, at that time economically the most advanced nation in the world. With regard to contemporary societies, China, Kerala State, and Sri Lanka may also serve as illustrations, because there fertility is near or even below (Kerala) replacement level without meeting the assumed requirement of socioeconomic development. Bangladesh, one of the least-developed countries in the world, may be another good candidate, given the significant fertility reduction observed there. Evaluating the contemporary record on the onset and pace of the fertility transition, Bongaarts and Watkins (1996) found an enormous diversity in each of the socioeconomic indicators applied, confirming the conclusions of the Princeton study of historic Europe.

The presupposed sequence of mortality and fertility decline has also been called into question. In a historic perspective, France is the classic example of analysis contradicting the idea that mortality decline preceded fertility decline (E. van de Walle, 1978). Evidence from the Princeton study suggested that France was not an isolated case, and there is no statistical evidence for a general trend in the sequence of mortality and fertility decline (F. van de Walle, 1986). Sometimes fertility decline was found to follow a fall in infant mortality, sometimes it preceded it, and often they dropped simultaneously. Chesnais (1986), however, argues that some of these findings are based on methodologic inadequacies and in second instance results appear to be in accordance with the theory. Nevertheless, the exact causal relation between the decline in mortality and fertility remains difficult to establish (van de Kaa, 1996).

Although the theory of demographic transition suggests a historic perspective, the construct is largely devoid of time and change except for the intermediate stage of transition (Greenhalgh, 1995b). In the framework of transition theory, there is no history in either the pre- or the post-transition stage: In terms of development, time stands still. According to Greenhalgh (1994), many descriptions and analyses of fertility within the perspective of transition theory exist in historic vacuums and are not guided by the notion that the specific histories of the social environment can bear much relevance to their fertility patterns (McNicoll, 1994). The suggested homogeneity and immobility of *traditional* societies—historic or contemporary—is indisputably refuted by the empirical demographic record, which shows a large variety of fertility patterns and levels (Blake, 1985). Neither could transition theory adequately cope with the significant (although temporary) posttransition, postwar reversal of fertility trends in a number of Western countries, which resulted in the *baby boom* cohorts. To dispose of such phenomena as *temporary blips* (Kirk, 1996) is totally unsatisfactory and unacceptable given the huge impact they can—and do—have on society. Also, to find solace in an equilibrium or homeostatic framework, as Kirk suggests, to take account of the problem of where the fertility decline will eventually end, probably reflects more normative hope than a realistic forecast. The observation that in most European countries fertility dropped below the level of mortality—where transition theory assumed it to end—and a supposed historic inflection point in European society, inspired the conceptualization of a *second demographic transition* (Lesthaeghe and van de Kaa, 1986; Lesthaeghe and Verleye, 1992; van de Kaa, 1987).

Greenhalgh, among others, rightly claims that many of the assumptions of transition theory closely resemble those of evolutionary theories that formerly featured in anthropology and raise similar contempt with regard to overdue generalization, Eurocentrism, and supposed unilinearity of development (Greenhalgh, 1989, 1995b; Handwerker, 1986). Although the concept of demographic transition (or its fertility transition subset), if seen from sufficiently afar, stands better against the empirical record than comparable evolutionary thought in anthropology, closer scrutiny supports this criticism: There seem to be many roads to lower fertility, and onset and pace of the decline cannot be predicted anywhere near satisfactorily. This confirms the truth of Greenhalgh's statement "that the closer we get to understanding specific fertility declines, the further we move from a general theory of fertility transition" (Greenhalgh, 1990, p. 85). Therefore, the practical content of transition theory—either in terms of revealing the specific determinants of demographic change or in terms of providing tangible handles on population policies—is less than it initially promised. Szreter in this respect reflected that

> The principal [sic] virtue and function of the idea of demographic transition has always been in providing a graphic metaphor that summarily describes—and predicts—a long-term overall emergent pattern of change. As such it has enormous justification, motivational, and communicative value for agencies and institutions wishing to effect change. But, . . . a summary description of this metaphorical sort offers no necessary assistance or insight into the causal explanation of how such change occurred or occurs in any particular case (Szreter, 1993, p. 692).

What we need to explain and predict population development or design population policies is specific knowledge of particular settings and the mechanisms of social change and structure–agency interaction (Greenhalgh, 1988, 1990; McNicoll, 1992, 1994; Szreter, 1993; Teitelbaum, 1976; Willekens, 1990a, 1990b) and this cannot be adequately provided by the transition framework.

3. Biology and Proximate Determinants

A notion often associated with the transition from high to low fertility is the idea that in the posttransition stage, fertility is under complete control of couples and individuals, whereas in the pretransition stage it is to a large degree left to biologic principles, although constrained by socially constructed bounds. This notion was already conceived in the work of Landry, but the analysis of fertility in pretransition populations has immensely improved since Louis Henry's (1953) development of the concept of *natural fertility*. Henry defined this concept as fertility that existed in the absence of deliberated control through abortion or contraceptive practice, implying that reproductive behavior does not depend on the number of children already born to a couple. In these natural fertility situations, reproduction is determined by biologic principles, such as age at menarche, fecundability (the monthly probability of conception), time required for gestation, intrauterine mortality, and postpartum amenorrhea. In addition, fertility is determined by a number of social–behavioral factors, which are—at least from the point of view of the couples concerned—not intended to restrict childbearing. These factors might include marriage patterns (in particular as far as related to marital duration), spousal separation, (religious) rules for sexual abstinence in certain periods, and duration and intensity of breast-feeding, with its effects on the period of postpartum amenorrhea. The observed levels of natural fertility differ widely between societies especially because of the wide differentiation in these social mechanisms (Blake, 1985). It is, however, not always easy to establish whether behaviors are socially or individually determined and whether birth control considerations are involved. Thus, although people may want to abstain from sexual intercourse on the basis of normative rules, the efficacy of this may depend on motives of child health, birth spacing, and, for that matter, limitation of offspring (Caldwell *et al.*, 1982; Kakar, 1989; Knodel, 1983).

The concept of natural fertility has evolved over time (Henry, 1957, 1961; Leridon, 1977; Leridon and Menken, 1979) and has found its culmination point in the model of proximate determinants as developed by Bongaarts (Bongaarts, 1978; Bongaarts and Potter, 1983). Earlier, Kingsly Davis and Judith Blake provided a seminal contribution with the development of an analytical framework of intermediate determinants of fertility that affected either the exposure to intercourse or the exposure to conception or gestation and successful parturition. Divided over these three categories they identified eleven behavioral and biologic factors "through which, and only through which, any social, economic and environmental variable can influence fertility" (Davis and Blake, 1956, p. 214). Bongaarts further developed this framework by quantifying the effect of Davis and Blake's intermediate variables and collapsing them into eight, and later seven, proximate determinants of fertility. This resulted in a simple but powerful model for analyzing how fertility changes over time or differs from one group to another: Any level of fertility in a population can always be traced to variations in one or more of the following determinants:

1. The proportion of women of reproductive age that is married (as a measure of the proportion exposed to sexual intercourse)
2. The use and effectiveness of contraception
3. Induced abortion
4. Postpartum infecundability (as primarily determined by the duration and intensity of breast-feeding)
5. The frequency of intercourse (including the effect of temporary separation and abstinence practices)
6. The onset of permanent sterility (particularly as related to menopause)
7. Spontaneous intrauterine mortality

Each of these factors contributes to a reduction of the approximately 15 children a woman can have during her reproductive career. The empirical evidence showed that marriage, contraceptive practices, abortion, and postpartum infecundability have by far the strongest effect on levels and differentials of fertility (Bongaarts, 1993; Bongaarts and Potter, 1983). The model suggests therefore that the total fertility rate can be described as:

$$TFR = C(m) \times C(c) \times C(a) \times C(i) \times TF$$

where TFR is the total fertility rate, C(m) is the index of proportion married, C(c) is the index of noncontraception, C(a) is the index of induced abortion, C(i) is the index of lactational infecundity, and TF is the potential total fertility.

The framework's exceptional clarity and organizational power had an enormous impact on the research agenda of fertility studies—particularly for developing countries, but also for historic populations—and the WFS and DHS provided the necessary data to apply the model in a comparative perspective. The significance of the model is partly situated in the structuring of attention and efforts in the search for the ultimate determinants of fertility and fertility change.

Fertility itself is no longer the sole subject of research; in addition we need to look for the institutional and behavioral backgrounds of marriage, contraceptive use, breast-feeding, abstinence practices, and so forth or, to cite Freedman, we are faced with "the challenge of specifying the determinants of the proximate determinants" (Freedman, 1986, p. 30; Hull, 1983; Leridon, 1982). Whereas any such attempt was completely absent in the work of Bongaarts, Davis and Blake in fact used their framework of intermediate variables as a starting point to determine and analyze the institutional factors affecting fertility. Their explanation of fertility rested on the comparative analysis of social organization, which largely boiled down to an explanation in terms of family and kinship organization.

Whereas Bongaarts' model of proximate determinants, as well as the version of Davis and Blake, analyzes fertility at the level of populations and societies, several researchers tried to translate it to the individual level. Hobcraft and Little (1984), for instance, calculate fecundity and fertility as the outcome of the fecundity-reducing effects associated with the particular set of states that describe women's positions in their reproductive career (states related to pregnancy, absence from sexual relations, contraceptive use, post-pregnancy infecundity). Becker's model of adolescent fertility (S. Becker, 1993) specifies conditional probabilities of live birth, conception, and coitus on the basis of individual data. Hull (1983) and de Bruijn (1999) explicitly incorporate the proximate determinants in a decision-making approach. The value of this integration is that fertility is not seen as the product of one single decision, but as the possible combined effects of numerous decisions with regard to the—behavioral—proximate determinants such as marriage and divorce, contraceptive use, abortion, frequency and patterns of sexual intercourse, and breast-feeding practices. This reformulation represents a means to increase the relevance of the concept of individual choice for situations under conditions of natural fertility.

Although the popularization of the proximate determinants model is mainly due to its application to developing countries, it is perhaps a mistake to presume that its value may be discarded completely for developed countries (Easterlin and Crimmins, 1985). Although in Western countries fertility is considered to be under volitional control and childbirth to be a matter of demand rather than supply, it is worthwhile recognizing that here too fertility not only depends on behavioral factors, but also on biologic processes. Until recently the main fertility problem was the control of unwanted childbearing and the attainment of a *perfect contraceptive population* (Bumpass and Westoff 1970). In this respect Menken *et al.*, reflected that

> With great effort, fertility has been "turned off": People had come to believe that controlling fertility was the real problem and to expect that having children was easy (Menken *et al.*, 1986, p. 1393).

With respect to the ease of having children, they indicated the growing concern in both the popular and scientific literature with problems related to infecundity and infertility in Western countries, which have become increasingly evident with the generally observed rise in age at birth (see also te Velde, 1992).

4. Economic Theories of Fertility

The writings of Malthus left their mark in the field of classical and Marxist economics in the 19th and early 20th centuries, and later in the economic analysis of population and development in less-advanced countries, particularly in view of their unprecedented rates of population growth (United Nations, 1973). These macro-economic approaches never became standard material in demographic theorizing, unlike the micro-economic orientations that firmly entered the field in the 1960s.

Harvey Leibenstein (1957) may be called the progenitor of the view that the number of children is the result of individual decision making within an economic context of income and prices. Among others, Nerlove (1974), Willis (1973), Schultz (1981), and, most prominently Gary Becker (G. A. Becker, 1960, 1965, 1976, 1981, 1991; Becker and Lewis, 1973) developed the consumer choice theory into what became known as the new home economics of the Chicago school. This micro-economic approach not only involves the traditional variables of income and prices, but also the *quality of children* and budget constraints in terms of allocation of time and opportunity costs. Given these variables, households are assumed to produce a bundle of consumer commodities—including children—in accordance with the maximization of household utility. The model thereby links fertility decisions to other household decisions, including labor force participation and consumption. The notion of *child quality* became a key factor in Becker's work to account for the inverse relation between income and number of children as experienced in the fertility transition. The quality of children is assumed to be elastic with respect to income, whereas the quantity of children is not. This implies that the desired number of children may fall as income increases because the average cost per child may increase even faster.

The economic approach to fertility has been challenged on several grounds. Part of the criticism can be traced back to the concepts of choice and decision-maker that underlie micro-economic theories: strongly individualistic, decontextualized, static, relying on a narrow, substantive notion of rationality, and without a sufficient degree of (psychological) realism (de Bruijn, 1999). Obviously, representatives of rival disciplines embark upon such general criticism, but it is also voiced by a number of (behavioral and institutional) economists themselves (e.g., Simon, 1987; Lea *et al*., 1987; North, 1994). Among the economists working in the field of demography, Leibenstein and Arthur share some of these concerns. Arthur, in a critical review of Becker's *Treatise of the Family*, "call[s] for the use of rules, rights, agreements, hierarchies, organizational institutions—in short, structure" (Arthur, 1982, p. 395). These remarks touch upon the neglect by most economists of the social, cultural, and political environment of decision making. Leibenstein (1977, 1981, 1982) articulates that the concept of choice as used in economic choice theory is only selectively applicable in the study of reproductive behavior, and much of the fertility outcome must be seen as the result of routine and rule following procedures. With regard to the static nature of the new home economics, it can be observed that by and large economic analysis in demography does not allow for changes in preferences over lifetime as the result of learning and personal experience, and it assumes couples to have defined these preferences at the onset of marriage. Changes in behavior over time are in this perspective considered to be the result of variations in restrictions facing the decision-maker. However, a number of economists provide a more dynamic perspective by applying a life-cycle approach to fertility or accept the possibility of preference shifts (e.g., Moffit, 1984; Namboodiri, 1980, 1983; Rosenzweig and Wolpin, 1980; Siegers, 1987; Turchi 1991).

Although crucial to Becker's interpretation of fertility, the notion of child quality is not free from controversy, both in terms of conceptualization (e.g., Robinson, 1997) and with regard to the assumption that all children born in a family embody the same quality. The last assumption is refuted by the empirical findings that the value of children may differ by parity (Bulatao, 1981; Bulatao and Fawcett, 1981; Namboodiri, 1983) and by sex (e.g., Miller, 1981; Koenig and Foo, 1995; Nag, 1991; UNICEF, 1991). Criticism of the new home economics approach to fertility also refers to the assumption of a single joint household utility function. For one thing, it assumes altruism (with which Becker [1981] tries to deal) and harmony on behalf of both partners, which does not seem very plausible as both power and the distribution of costs and benefits of children may differ substantially between them (Caldwell and Caldwell, 1987; Lee and Bulatao, 1983; Fawcett, 1983; Simmons, 1985). Economic decision-making models are usually completely silent about the bargaining processes that settle possibly conflicting interests with regard to progeny. In several societies, even the absolute authority on fertility decision-making by the parents themselves may be seriously questioned (Khan and Singh, 1987; Koenig and Foo, 1992; Ryder, 1983). Furthermore, the definition of the household concept is notoriously difficult, not only with regard to relevant criteria, but also because of possible shifting and rotating membership of both parents and children. The widespread phenomenon of child fostering, especially in West Africa (e.g., Bledsoe, 1990, 1995; Page 1989), puts the standard economic view on direct and substitution costs of raising children in a different perspective. For these reasons, and because in many instances fertility is not a matter of demand but a matter of supply, the new home economics model is still relatively ill-suited for the analysis of fertility in developing countries (Simmons, 1985).

With regard to the neglect of supply mechanisms in the standard consumer choice theory and its new home economics version, a very important extension is provided by Richard Easterlin and collaborators (Easterlin, 1975, 1978a, 1978b; Easterlin and Crimmins, 1985; Easterlin *et al*., 1980). Easterlin's approach complemented the strictly demand-oriented model of new home economics with notions concerning the production side of fertility as derived from the intermediate variables framework of Davis and Blake and that of Bongaarts and the concept of natural fertility. In this synthesizing effort, he brings together the scientific paradigms of economics and sociology; but this effort clearly should also be considered as an attempt to bridge the gap between fertility analysis in contemporary Western situations and that under non-Western or historic conditions. This *Easterlin synthesis* has gained wide acceptance in demographic research and provided the basis of the agenda of the U.S. National Academy of Sciences (Bulatao and Lee, 1983). The model assumes that all determinants of fertility—public health, education, urbanization, family planning programs, and so forth—work through the categories of the demand for children (depending on household tastes for children and alternative goods, income, and costs and benefits of children), the supply of children (reflecting natural fertility determinants like exposure and frequency of intercourse, postpartum amenorrhea, spontaneous intrauterine mortality, and sterility) and the costs of fertility regulation (lumping together attitudes toward and access to fertility control methods and supplies, as well as the time and money required to obtain the birth control methods). Motivation to limit fertility only occurs if the supply of children exceeds their demand and the greater the excess of supply over demand, the greater this motivation. But the actual restriction of fertility also depends on the (economic and psychological) costs associated with various birth control methods. A modification in the specification of the demand function compared with the Chicago approach is that Easterlin's model incorporated variable and endogenous preferences, which allowed the explanation of difference in behavior on the basis of opportunities, but also in terms of differences in *tastes*. Furthermore the final dependent variable in Easterlin's model is not children, as much as children surviving to adulthood, thus making not only the supply of children endogenous to the explanatory framework, but child survival as well.

Easterlin contributed another important theoretical proposition to the economic perspective of fertility behavior. This contribution (Easterlin, 1978b, 1980) provided a dynamic element to the analysis of fertility and stands out as the sole fully developed cohort theory in demography. The *Easterlin hypothesis* concerns the adaptivity of fertility preferences (and subsequent fertility behavior) to the realization of a preconceived lifestyle. It asserts that an individual's desired lifestyle is molded by experience during the formative period in adolescence at the parental home. The degree of affluence promised by (male) labor market perspectives during the reproductive period determines the number of children that can be sustained while maintaining the standard of living that was experienced during the formative period. The labor-market or income-earning opportunities, in turn, are assumed to be negatively related to cohort size. This implies that the *tastes* for children or reproductive goals are not given, as assumed in traditional economic theory, but formed during the experience of the income effects caused by the entry of differently sized cohorts on the labor market.

Ní Bhrolcháin (1992) disputes the role of cohort effects in fertility. Although she recognizes the evidence of cohort mortality, which finds convincing foundation in epidemiologic and medical research (e.g., Barker, 1992; see also Caselli, 1990), she is unable to find similar evidence for fertility. Similarly, Wright (1989) has tested the Easterlin hypothesis for 16 European countries but has failed to find a statistically significant correlation between relative cohort size and fertility. From a review of empirical studies, Pampel and Peters (1995) conclude that the evidence for the Easterlin effect proves at best mixed and at worst completely wrong and that the degree of support varies across time periods, nations and level of measurement.

Apart from a number of technical difficulties involved in the measurement of the effect, there are also some conceptual inadequacies. For instance the theory focuses too much on men's roles in the labor market—whereas new home economics emphasizes the role of women—and there is some discussion about whether Easterlin's index of relative cohort size is a good indicator of relative income (Wright, 1989, p. 118). Furthermore, the theory's conceptualization of socialization is rather plain: The influence of personal experience operates from a distant and rather fixed past and neglects the influences of changing social environments apart from cohort size. Exclusive emphasis on the effects of the early socialization experience on a person's aspirations amounts to the neglect of the effect of peer group influences in new environments or experiences in adulthood in general (Freedman, 1987; Namboodiri, 1980). Moreover, there are other lifetime-specific experiences, such as education and labor force participation, which can have decisive impact on (later) considerations in decision making, for instance with regard to goal setting, dependency of others, or the value of children. Lastly, Easterlin's theory needs to specify better the mechanisms through which relative income influences motivation for fertility. Pampel and Peters (1995) suggest that if a number of additional conditions are met, the Easterlin effect still might emerge.

5. Psychological Approaches to Fertility

Compared with the impact of economics, sociology, anthropology, and biology, the contribution of psychology to demographic theory has been very limited (Burch, 1981; McNicoll, 1992b). The encounter between demography and psychology witnessed the application of two main theoretical approaches: the *value-of-children* approach and applications of psychological value-expectancy models.

The first line of thought can be traced back to a Maslowian perspective on motivation. Taking this as a starting point, Hoffman and Hoffman (1973) constructed a conceptual framework that depicted the way in which children could contribute to satisfying a number of material, social, and intrinsic needs. According to this framework, childbearing motivation depends on the evaluation of these satisfactions and the economic and noneconomic costs of children. The associated perceived value of children appears as an intermediate variable in the explanation of the relation between socioeconomic, cultural and gender aspects, and fertility behavior. The framework was elaborated and operationalized in the value-*of-children project* in the early and mid 1970s by James Fawcett and others (Fawcett, 1972, 1983; Fawcett and Arnold, 1973; Fawcett *et al*., 1972). Survey data were gathered in different countries, and subsequent analysis compared data for different countries and regions within countries at different levels of socioeconomic development. In this way the model tried to underpin the propositions of the theory of fertility transition, confirming some of them, but remaining undecided on others (Fawcett, 1983; Bulatao, 1982). It did suggest an evolution during socioeconomic development from economic and material considerations with regard to children, to more emotional rewards and psychological appreciation, which induced the introduction of the concept of the *transition in the value of children*. Whereas most applications of the model were carried out within the international comparative framework of the value of children project, several individual studies also relied on it (e.g., Niphuis-Nell, 1981). The value of children approach produced a substantial body of literature especially in the early 1980s, but has not been pursued much since then. Perhaps this is due to the fact that the research has provided relatively few generalizations about how background variables influence the perceptions of satisfactions and costs of children in order to affect fertility preferences and behavior (Fawcett, 1983).

Value-expectancy models like *expectancy x value* and, notably, the Fishbein–Ajzen model of reasoned action (Fishbein and Ajzen, 1975; Ajzen and Fishbein, 1980) were introduced into demography with regard to the field of fertility, contraceptive use, and female labor market participation (e.g., Bagozzi and Van Loo, 1991; den Bandt, 1982; Fishbein, 1972; Jaccard and Davidson, 1976; Moors *et al*., 1989; Rosenstiel *et al*., 1982; Wijsen, 1994). The Fishbein–Ajzen model states that the intention to perform certain behavior is a reliable indicator of the performance of that behavior. In turn, this intention can be assessed by measuring beliefs with regard to consequences of the behavior and the valuation of these consequences on one hand and perceptions of the opinions of others in combination with the importance attributed to these opinions on the other. An advantage of the model is that it takes into account to a certain extent the influence of the social environment by including a normative component in terms of the opinion of the important others.

To some extent, psychological approaches share the problems associated with micro-economic theories. These concern particularly the volitional character of individual behavior formation and the less than adequate incorporation of the institutional backgrounds determining that behavior. The theoretical framework underlying the value of children framework, and more explicitly the one underlying the psychological value-expectancy models, assumes deliberate choice and purposeful action, which do not always seem to be the most appropriate assumptions given the supply mechanisms of natural fertility, the lack of effective knowledge, the possibility of overriding social pressure in favor of childbearing, and the possibly restricted availability of and access to the means to control it. Ajzen and Fishbein themselves, in fact, recommended their model especially for situations where individuals have strong control over the factors associated with decision making, which is more applicable to developed than to less-developed countries. In this respect, the incorporation of the concept of self-efficacy (Ajzen, 1991; Bagozzi and Van Loo, 1991) may improve the explanatory power of psychological choice models. Other options to increase the relevance of decision making approaches to the situation in developing countries—although at the expense of quantification—relate to a broader definition of the concept of choice: either by extending decision-making analysis to the proximate determinants of fertility or by incorporating the *process* of choice in the sense of processes of attention and (routine and institutionalized) styles of decision making (de Bruijn, 1999; Bulatao, 1984; Shedlin and Hollerbach, 1981; Hull, 1983; Leibenstein, 1982). Such reformulations at least avoid the unjustified distinction between the concept of the person who populates pretransitional societies and who is cast in terms of passive recipients of culture and normative rules and guided by irrational beliefs, and the one who inhabits posttransitional societies and who is viewed as an active, independent decision maker with the capacity for rational thought and behavior (Blake, 1994; Greenhalgh, 1994).

6. Diffusion of Ideas and Technology

Over the years, the theory of demographic transition has incorporated a number of additional ideas to remedy some of its shortcomings. Many of these efforts were related to the failure to define socioeconomic development as the crucial variable of demographic change. The incorporation of some concept of culture—especially perceived as a principle involved in the spread of ideas—seemed to provide a promising alternative. In its wake, the concept of diffusion entered the theoretical edifice of demography (Cleland and Wilson, 1987; Retherford and Palmore, 1983; Watkins, 1986, 1987), or better, was reinstituted as a major explanatory strand.

Diffusion can be understood as the process by which innovations spread from one locale, social group, or individual to another (Retherford and Palmore, 1983). The spread of ideas, behaviors, and techniques has often been found to follow the grooves laid down by sociocultural forces, such as language, ethnicity, neighborhood, and workplace or channels of communication and exchange. Thus, Lesthaeghe's study of fertility decline in Belgium showed a clear demarcation of fertility patterns and levels along language borders for communities, which were otherwise—socioeconomically—very similar (Lesthaeghe, 1977). Kirk attributes the early transition in countries such as Hungary and Bulgaria to their location along the Danube as a prime artery of communication and commerce (Kirk, 1996). Various others point to migration avenues, network channels, and institutionalized lines of communication for the spread and explanation of family planning acceptance (e.g., Bongaarts and Watkins, 1996; Freedman, 1987; Cleland, 1987; Watkins, 1987, 1989). Entwisle *et al.* found evidence of the importance of conversational networks to directing and controlling the flow of information about contraceptive methods in rural communities in Thailand (Entwisle *et al.*, 1996). They associated the variety of method acceptance between communities and the typical predominance of one method within the communities with the structure of largely village-based social networks. The notion of diffusion also focuses attention on the different contextual levels—interpersonal, local, national, and global—involved in the transmission of information (Bongaarts and Watkins, 1996; Hammel, 1990; Montgomery and Casterline, 1996; Retherford and Palmore, 1983).

The reception of diffusion into fertility theorizing brings along its own conceptual and methodologic problems. With respect to diffusion, Greenhalgh cautions against a too reductionistic approach focusing almost entirely on communication about birth control, while neglecting the exchange of a broad scale of perceptions on other issues relevant for reproductive behavior (Greenhalgh, 1995b). To parts of the family planning movement the contribution of diffusion was even restricted to the spread of contraceptive technology (e.g., Ravenholt and Chao, 1974). Pollak and Watkins (1993), like Greenhalgh, argue that diffusion involves more than techniques and mere information. They refer to van de Walle who states that in early 19th century condoms were licit in extramarital liaisons, but not within marriage, and to Bledsoe who reaches a similar conclusion for several African countries. This pertains to the critique that the diffusion approach is problematic in its omission of the context of contraceptive communication, especially with respect to the requirement of its social legitimation and the spread of values (Lesthaeghe and Wilson, 1986; Handwerker, 1986). Related to this critique, many consider the diffusion concept merely a description without notable theoretical content (McNicoll, 1992; Pollak and Watkins, 1993); sometimes it entails just summary statistics that reflect the pattern of spatial and temporal spread of some phenomenon. Hammel's (1990) contribution can be mentioned as an important step to provide more substance to the notion of diffusion, but within demography, of course, Rogers (1962/1983, 1973) must also be referred to, with the work of Montgomery and Casterline (1996), who try to model the social structure of contraceptive diffusion. Still, a fundamental underpinning of the working of the diffusion mechanism—how information is conveyed in the social environment and how the messages are organized and interpreted, and finally lead to behavior—is in the lap of other disciplines such as (cognitive) anthropology, sociology, and, importantly, social learning theory (de Bruijn, 1999).

7. Culture, Structure, and Social Organization

The field of fertility theory covers a large number of interpretations and approaches that are not neatly classifiable as a disciplinary theory. In contrast to, for instance, economic, psychological, and proximate determinants approaches to fertility, they do not have an internally agreed set of variables, concepts, and theoretical propositions nor a strict methodology. Their common feature is the focus on the structural level of society, culture, institutions, or social organization—and often in combination—but otherwise it is a very heterogeneous compilation, its backgrounds largely in the more holistic disciplines of sociology and anthropology. They may involve aspects from theoretical approaches mentioned above, and many of them, in fact, can be interpreted as enrichments or modifications of the theory of demographic transition. Far from claiming to be exhaustive, a list of such approaches to fertility might include system–functionalist ideas derived from Adam Smith's *invisible hand* hypothesis (Wrigly, 1978) and other homeostatic interpretations (Howell, 1979, 1986; Kreager, 1982, 1986; Lesthaeghe 1980), *modes-of-production* paradigms (Boserup, 1970, 1990; Goody, 1976), Lesthaeghe's production–reproduction thesis (Lesthaeghe and Surkyn, 1988b; Lesthaeghe, 1989b), Cain's institutional approach of risk and insurance (1981), Caldwell's wealth flows theory (Caldwell, 1976, 1982), family-oriented analyses (Ariès, 1962; Cain, 1989; Freedman, 1975, 1987; Davis and Blake, 1956; Khan, 1987; Ryder, 1983), the notion of the second demographic transition (Lesthaeghe and van de Kaa, 1986; Lesthaeghe and Verleye, 1992; van de Kaa, 1987) and the recently emerging institutional approaches in the line of Greenhalgh (1988, 1990, 1994, 1995a) and McNicoll (1980, 1985, 1988, 1994).

In disappointment at failing to find the crucial determinants of fertility in socioeconomic indicators, some demographers have turned to culture (Cleland and Wilson, 1987). Research based on the results of the WFS (e.g., Cleland, 1985) and the Princeton study on the European transition experience (Anderson, 1986; Knodel and van de Walle, 1979; Watkins, 1986) signified the importance of cultural factors as the major independent determinants of fertility levels and the onset of fertility decline. These studies, however, did not elaborate on what was exactly meant by *culture*. Greenhalgh (1994) and Hammel (1990), therefore, accuse demographers of a widespread incompetence to conceptualize culture meaningfully. Apart from the work of a small number of researchers, culture has hardly gained any depth; it is usually only grasped in terms of language, ethnicity, or geographic region. Large-scale surveys on which traditional demographic research is based cannot grasp the meaning of culture, and so to many demographers, the concept connotes a *messy bag* (Lesthaeghe, 1989a), which may be assumed to contain all residual explanation. The problem of incorporating culture into theory, however, is not restricted to demographers alone: All social sciences consider culture a notoriously difficult concept, perhaps even more than the concept of social structure (Archer, 1996).

Culture is usually claimed to stand for the shared and intergenerationally transmitted beliefs and evaluations about the world and people's place in it. The role of culture in fertility change is presumed to be particularly located in this feature of transferring values and information within a culturally identifiable group (e.g., Lesthaeghe, 1977). But apart from this communicative feature, culture provides the normative and interpretive or meaning-giving rules with which people consider fertility and its proximate and ultimate determinants. The link between culture as an ideational or meanings system and social organization lies in the common order it provides for the definitions of social relationships and evaluation of individual behavior. Modes of production, intergenerational and gender relations, marriage systems, and so forth are reflected in culture. However, by providing social structure with a meaning, culture also legitimizes and, therefore, (re)produces society. This dualist manifestation has been acknowledged in demographic literature by several exponents of a cultural approach to fertility theory (e.g., Greenhalgh, 1989; Hammel, 1990; Lesthaeghe and Surkyn, 1988a). In the social, political, and anthropologic analysis of fertility, the family is the dominant institution: It is the locus of demand and supply of children, by and large it retains the function of socialization base, and often it constitutes the prime avenue to achieve things that are important in life, such as economic assistance, security, social interaction and status, information, and emotional and political support (Davis and Blake, 1956; Dyson and Moore, 1983; Freedman, 1987; McNicoll 1994).

Several broad lines of thought on the rather elusive concepts of culture and social structure can be distinguished in demography. Most of them are not acknowledged as separate theories, so the discussion here is arranged around the work of the major proponents and publications.

A first mode of thought with social structure as its point of departure is the holistic representation of society as an integrated system of arrangements and mechanisms that are principally geared to the reproduction and maintenance of that system. It can be viewed as a continuation of the Malthusian program, but based on modern research and insights. A milestone publication in this respect is Coleman and Schofield's *The State of Population Theory*. Kreager's work (1982, 1986) may be representative for this approach when he paints an anthropologic vision of demographic regimes as Durkheimian organic solidarities. Population process components—fertility, nuptiality, migration, and mortality—work in a coordinated fashion so as to adjust population size and distribution to the capacities of the environment.

Such studies concentrate on the colorful anthropologic uniqueness of societies, but sometimes tend to over-emphasize the cultural barriers to demographic change (Robinson, 1992; Lockwood, 1995). By their nature they are not infrequently rather static and descriptive, and fail to provide the links of encountered feedback mechanisms to the motivation of individuals to act in line with the long-run societal benefit. Lesthaeghe, for instance, rightly points out that there is no need to assume a latent aim of controlling population growth if other explanations, centering on direct goals, like survival of children or maintaining power relationships, are available to account for it (Lesthaeghe, 1980). On the macrolevel such individual pursuits of goals—importantly shaped by the structure and content of the social environment—may have the effect of maintaining a functional demographic balance in the long run (Blake, 1994).

Explaining demographic patterns only in terms of system needs easily ends in *ad hoc* or tautologic theorizing. The demonstration of the functional quality of certain collective behavior to a population system cannot demonstrate its necessity to be there, at that time and in exactly that form; there may very well be other, functionally equivalent, behavior patterns that could respond to the same motives (McNicoll, 1992; North, 1994). It is easy to interpret some institutional arrangement as valuable if it has found its established place in some situation, but the danger of ex post rationalization is acute: Conceivably under a different arrangement the situation would have been served even better. This reflection led Demeny to his gloomy remark that "the impression is overwhelming that history is a story of unrealised [sic] potentials that could have been within our grasp" (Demeny, 1986, p. 483).

The only line of thought that may claim the status of *demographic theory* and is as yet the only one that can conceptually rival the conventional transition theory (particularly in the setting of contemporary less-developed countries), is Caldwell's wealth flows theory (1976, 1982). Culture, here, is importantly represented by the meaning of kinship and family, traditionally a central issue in the anthropology tradition from which Caldwell originates. The theory states that the level of fertility is primarily imposed by the direction of the net wealth flows between parents and children, which include all the present and anticipated benefits over a lifetime. The outcome of this economic rationale is either maximum or zero fertility, but this is adjusted by the impact of personal, social, and physiological reasons. The commanding principle underlying the direction of intergenerational wealth flows is the social organization of the society, and specifically family structures. Caldwell argues that in all traditional societies the net wealth flow has been from younger to older generations, which means that economic motives promote high fertility. This flow will only be reversed if the economic and emotional primacy is withdrawn from the grip of broader family ties and is focused on the conjugal family. The nucleated family is, therefore, a *sine qua non* for low fertility and the transition from high to low fertility is a product of social change with economic implications, rather than economic change alone.

The primary force behind the transformation of the family is credited to universal education across a nation or cultural group. Mass education changes the values and costs of children within the family and introduces a Western family model into the society. Capitalizing on the general failure to identify critical socioeconomic variables for the onset of fertility decline, Caldwell argues that it is the process of Westernization, rather than economic modernization, which initiates the change toward low fertility (Ryder, 1983). Put to the test (e.g., Dow *et al*., 1994), Caldwell's theory received less support than might have been expected on conceptual grounds. It is not clear to what extent this is due to the severe operationalization and measurement problems—for instance the measurement of wealth flows—that are inherent in the theory's formulation (Schultz, 1983).

A third line of thought, like Caldwell's intergenerational perspective, involves the institution of the family, but with a different nuance. Here, family is primarily the outcome of large-scale historic socioeconomic and cultural processes, rather than the exclusive focus of demographic change. This tradition is most prominently recognized in the work by Lesthaeghe. The gist of his work is best articulated by the attention to the analysis of the first two of Coale's prerequisites for a fertility transition: First that the very deliberation about pros and cons of additional children to the family must be an acceptable form of behavior, and second that perceived social and economic circumstances must make reduced fertility seem an advantage to individual couples (Coale 1973, p. 65). Both preconditions are clearly anchored in the context of ideational systems and social organization, which is formulated by Stamm and Tsui as follows:

> The impact of family-planning technologies on reproductive parameters is a function of the systems of meaning which underlie the reproductive choices and preferences of the individuals comprising a society. Such systems of meaning define both what is and what is not subject to choice and the value of choice options (Stamm and Tsui, 1986, p. 159).

To arrive at reduced levels of fertility, there must be a favorable meaning-giving or ideational environment to direct the preferences and considerations that authorize the legitimacy of individual control over fertility as well as the desirability of smaller family sizes (Lesthaeghe and Wilson, 1986). Falling back on Maslow's notion that, along with development, intrinsic personal needs will become increasingly important, a universal emancipatory tendency of individualization may be assumed to have its effects on fertility behavior (Lesthaeghe, 1983; Lesthaeghe and Surkyn, 1988a). This may lead to a decline in fertility, but only if existing institutions that exert a pronatalist influence lose the legitimacy of their grip on individual decision making, and if socioeconomic conditions are such that the balance of subjective cost-benefit considerations is tipped toward smaller families. Although the complex associations between socioeconomic development and ideational change are explicitly discussed (e.g., Lesthaeghe,1989b; Lesthaeghe and Wilson, 1986), Lesthaeghe stresses the importance of autonomous ideational shifts toward liberal and, especially, secular values. In this respect Lesthaeghe's ideation with social–organization approach is a major modification of the classical notion of demographic transition.

This general scheme has been applied to the situation in sub-Saharan Africa (Lesthaeghe, 1989a, 1989b; Lesthaeghe and Eelensm 1989; Lesthaeghe and Surkyn, 1988b), to historic Western Europe (Lesthaeghe, 1983; Lesthaeghe and Wilson, 1986), and to recent demographic change in Western Europe (Lesthaeghe and Moors, 1992; Lesthaeghe and Surkyn, 1988a), cumulating in the concept of the *second demographic transition* (Lesthaeghe and van de Kaa, 1986; van de Kaa, 1987; Lesthaeghe and Verleye, 1992). Each time, the picture is painted differently, highlighting the specific relevant elements of the historic and institutional background. During Europe's fertility transition this included the nuclear family dominance, the evolution of a capitalistic mode of production, the waning of religious doctrines as guiding principles and general economic growth, fueling individual aspirations (Lesthaeghe, 1983; Lesthaeghe and Wilson, 1986). The second demographic transition can be distinguished primarily on the basis of a marked acceleration of the trend toward self-fulfillment and individual autonomy, bringing about new types of demographic behavior in the sense of new living arrangements and changed timing and prevalence of marriage and childbirth (Lesthaeghe and Verlye, 1992; van de Kaa, 1987). With regard to sub-Saharan Africa, the designation of social organizing principles relies heavily on the intellectual legacy of Boserup (1970) and Goody (1976) with respect to the structuring impact of modes of production on patterns of nuptiality, gender relationships, and progeny; but it also relies on classifications in terms of religious background (especially Islamization and the survival of traditional religions), female education and contraceptive use. The emerging picture reveals the complexity of the effects of interactions between socioeconomic development and social institutions on patterns of starting, spacing, and stopping childbearing (Lesthaeghe and Eelens, 1989).

A promising new line of interpretation is the institutional analysis of fertility. This approach, again, may be viewed as a reaction to the theory of demographic transition. Whereas the classic transition theory searched for general processes (including, at least in its original formulation by Notestein, the role of social institutions) and focused on macrolevel and socioeconomic aspects, the new institutional approach seeks situational and path-dependent specificity, and is sensitive to cultural interpretations and the interaction between structure and agency. The research and analyses of Lesthaeghe and Caldwell clearly largely fall into this interpretive framework. Well-known is also Cain's (1981, 1989) analysis of the value of children as a source of risk insurance in villages in India and Bangladesh, which suggests that the differences between the settings can be largely attributed to institutional elements like labor division between the sexes, patriarchy, legal status, and social security systems. The leading demographers in the field, however, are Susan Greenhalgh and Geoffrey McNicoll. Although Greenhalgh starts out from a political-anthropologic perspective and McNicoll particularly relies on a sociologic and institutional economics background, they are remarkably in unison in voicing the needs for and elaboration of institutional analysis.

Both largely reject the possibility of general schemes of fertility change. Compare, for instance, McNicoll's statement that:

> [F]rom a distance, the process of fertility transition that accompanies social and economic development shows many similarities across major world regions [. . .]. Yet at closer range fertility transitions are idiosyncratic. Their course is influenced by the institutional endowments each society has inherited through its particular historical experience (McNicoll, 1994, p. 2)

with that of Greenhalgh:

> There is no single demographic transition, caused by forces common to all places and all times. Rather, there are many demographic transitions, each driven by a combination of forces that are, to some unknown extent, institutionally, culturally, and temporally specific (Greenhalgh, 1990, p. 88).

A seminal article that contributed much to the attention for the institutional background of fertility and on the micro–macro link of fertility explanation was conceived by McNicoll (1980). Relying on Herbert Simon's concept of bounded rationality, he argued that the options for fertility behavior that are salient to the individual consist of only a selection of all options and that this salience depends on the structure of the information environment that is shaped by social institutions. In McNicoll's perspective, social institutions may be interpreted as the socially constructed (and sanctioned) rules that provide solutions to recurrent problems of individual action and interaction (McNicoll, 1985). This normative character of institutional rules may be complemented with their representational or meaning–giving dimension, which fits better with Greenhalgh's cultural interpretation. Both McNicoll (1994) and Greenhalgh (1995b) view institutions as social constructs that are constantly being made, remade and possibly dismissed in processes of negotiation and individual action. Although neither of them elaborate much on this issue, it may provide a tangible opening toward psychological and economic choice considerations, and thus a unique opportunity to narrow the gap between macro and micro approaches, structure and agency, and context and choice (de Bruijn, 1999).

The identification of interpenetrating local, regional and national institutions reflect the multi-level nature of context. Greenhalgh (1990, 1995) even goes on to the international arena, extending Watkins's remark that in 1870, the relevant community to which behavior pertained was largely local whereas in 1960 it was largely national (Watkins, 1989). Thus, aims of the international community with regard to women's rights and reproductive health as voiced at the 1994 Cairo Conference on Population and Development can be effectuated by supportive legislation at state level and women's organizations at lower levels, but can also be impeded by adverse family and gender systems or local labor market opportunities. Overarching institutions like religion or national family planning programs may be negotiated differently in a rural farming community than in the neighboring fishing community, because of the differences in the local economies (Niehof, 1985). Due to the sustained conjuncture of various institutions in specific social settings, the meaning of the individual institutions may change in the course of time, which is why, for instance Catholicism in Ireland has become different from that in Mexico or Sri Lanka (Handwerker, 1986). An institutional approach finds the understanding of fertility at least partly in the historic evolution of the specific amalgam of institutions: It views them as evolving processes that not only depend on current circumstances, but also, and crucially, on their past history, and, which moreover, evolve at every point in time, rather than only during a transition phase (Greenhalgh, 1995; McNicoll, 1994).

Most of the structural-cultural approaches may be understood as a reaction to the theory of demographic transition as a leading paradigm in demography. This reaction takes shape in various ways, from a reformulation of the central concepts of a transition (Caldwell), via a further specification of particular conditions under which transition is likely to occur (Lesthaeghe), to an outright rejection of a common force of fertility change (Greenhalgh), and further to the adoption of a situational analysis of the specific combination of relevant institutional forms (McNicoll). The theoretical profundity of the study of fertility declines essentially in the same order. Caldwell's approach is a straightforward theory, McNicoll's yields an analytic framework and, hopefully, a methodology or research agenda (McNicoll 1985, 1992).

CONCLUSION

The theoretical orientations presented here provide distinctive angles to view one and the same object of study. The consequence is a corresponding range of different answers to principal questions and requirements with respect to theory building and methodology. On its own, each theoretical approach does not provide a complete picture, but each advances its own propositions that contribute to understanding of fertility behavior. To a large degree, their differences are not complementary, but reflect different interests and assumptions, differences that might be irreducible unless human science in general succeeds in developing an encompassing meta-theory.

Given the state of fertility theory, how is it likely to evolve in the near future? This will depend on a number of factors, such as developments in other disciplines, newly emerging issues—childbearing at advanced ages, new fertilization technologies—and demands with respect to forecasting, policy development, and contributions to intervention programs. With respect to the latter, demographers have long been called upon to contribute their views, but have seemed to lack the appropriate conceptual competence to do so effectively. The demographic transition theory, and in a further distance Malthusian notions, provide a general background for family planning, but have not yet yielded the insight into individual behavior formation nor the specific knowledge about the context of that behavior that is necessary for the design of effective intervention programs. With regard to the interpretation of individual behavior, more contributions might have been expected from psychology, but psychological demography has largely stuck with the value-of-children approach and the 1970s based versions of choice models. It might be useful to consider recent developments in the area of cognitive psychology, and especially learning theory, for instance with regard to information education and communication activities, and, in general, the diffusion of knowledge and ideas. With respect to the situational analysis, demography has made prominent advances. The recently emerged institutional approaches offer good scope to provide an adequate representation of the social, economic, cultural, and political dimensions of the situation-specific context of fertility. Given advances in cognitive anthropology, sociology, and institutional economics, further elaboration and maturation of this field can be anticipated.

Finally, most theoretical approaches to fertility lack a dynamic perspective. Again, institutional analysis, relying on its historic and path-dependent interpretation, might improve this situation with respect to the social context of fertility. At the level of individual time, further development in the area of life course analysis is likely to occur. Although there is substantive literature in this respect (e.g., Birg *et al.*, 1991;

Coleman, 1983; Courgeau and Lelièvre, 1989; Willekens, 1991), it has not yet entered mainstream theoretical thinking in demography.

Acknowledgment

This chapter relies on earlier reviews of fertility theories by the author (de Bruijn 1993, 1999).

SECTION

I

DETERMINANTS OF MORTALITY

Introduction to Volume II

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

Section I of Volume I examined the concept of population dynamics and its mechanisms, and Section II assessed the determinants of one of the three main factors of that dynamic: fertility. In Section I this volume, we consider the determinants of the second factor: mortality. Later sections look at the determinants of migration, the history and future of population settlement, the relations between population and society, the accuracy of population policies and theories, and the methods of data collection and complementary tools of analysis.

By definition, death is the end of a life course, and it often is the result of a shorter or longer process of failing vital energy. Determining the factors of mortality therefore requires examining the process that leads from health to illness and death. This is the subject of Part I (Health, Morbidity, and the Causes of Death), in which the process is considered only in terms of its medical connotations. However, the process resulting in death has a wide range of beginnings. The human organism has an inherently finite life span, and each individual is biologically predestined to die once his or her time has come, but the time of death may be precipitated or delayed by external events or by human behavior. Life and death are the result of a subtle balance between endogenous and exogenous factors, which are considered in Part II (Endogenous and Exogenous Mortality).

No individual is an island. Each person is part of a group whose characteristics predicate the biologic environment and influence behavior. These effects create a wide range of situations between populations and among the constituent groups and subgroups of each population. These differences are difficult to interpret. Evaluation of significant factors, such as gender, social status, and place of residence, is provided in Part III (The Intricacy of Differential Mortality Factors).

Diversity in populations is temporal as well as spatial. Morbidity and mortality rates have changed dramatically since humans first trod the Earth. The conditions of humankind's survival changed with the increasing ability to control the natural world. After millennia of hesitant progress, a sweeping revolution began in the 18th century. The attempts made to explain the dynamics of these changes and the diversity of situations are reviewed in Part IV (Theories and Frameworks of Mortality).

P A R T

I

HEALTH, MORBIDITY, AND CAUSES OF DEATH

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

In purely medical terms, death is usually a multifactorial event, the result of a shorter or longer process of failing vital energy leading from health through the various manifestations of morbidity—acute or chronic diseases, accidents, and other forms of violence—to the medical causes of death. The statistical and demographic approach to analyzing this process is the subject of Part I.

In Chapter 40, Catherine Gourbin and Guillaume Wunsch first discuss the pertinent concepts. Health, illness, and death are simultaneously biologic and cultural events, as well as individual and collective facts of life. Observational designs and data analysis must take these circumstances into account.

In Chapter 41, Catherine Sermet and Emmanuelle Cambois review the methods of collecting and analyzing data on morbidity, the state of impaired health that is curable but that may become a cause of death.

Chapters 42 and 43 address the collection and analysis of cause-of-death data. The first, by France Meslé, paints the general picture in which good records are systematically kept, and in the latter, Vincent Fauveau demonstrates the value of verbal autopsy methods in countries where vital registration is lacking or is deficient.

Cause-of-death analyses often erroneously assume that causes are independent. In Chapter 44, Guillaume Wunsch offers a causal approach that helps clarify cause-of-death interrelationships.

The next two chapters address two particular types of causes of death requiring specific study methods. Maternal mortality is examined in Chapter 45 by Judith Fortney, and the determinants of infant mortality are considered by Godelieve Masuy-Stroobant in Chapter 46.

Part I concludes with the presentation in Chapter 47 of a model by Viviana Egidi and Luisa Frova designed to estimate the unknown prevalence of a disease in a population on the basis of existing mortality data for that disease.

CHAPTER

40

Health, Illness, and Death

CATHERINE GOURBIN AND GUILLAUME WUNSCH

Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

To your health!

Apart from violent deaths due to accidents, homicide, or suicide, among other causes that may result from physical or mental ill health, most deaths are the result of a disease process and health impairment. But what is illness, and what is health? René Dubos defined health as "the circumstances in which an organism reacts by adaptation, at the same time preserving its individual integrity" (Dubos, 1973, p. 245). For Ivan Illich, "health is the ability that every individual has to cope with or assume responsibility for changing his environment" (Dufresne, 1985, p. 989). According to René Leriche, "health is life untroubled by one's body" (Leriche, 1936, p. 6.16.1), and for Jacques Dufresne, "health is not having to think about health" (Dufresne, 1985, p. 985).

I. HEALTH

Health is a concept that varies with time and place. Illness, as "the irrevocable decree of the Olympian gods," was thought to be a tragedy, and in the Judeo-Christian tradition, disease is considered a punishment (Arsenault, 1985). It is reasonable to wonder to what extent this conception still prevails, given the medical profession's reluctance in many Western countries to provide pain relief. In the Baoulé community of Ivory Coast, seers and augurers prescribe what is normal and abnormal—"evil possession to be treated and joyous possession to be preserved"—and these concepts are seen as norms with which to justify the existing social order (Laplantine, 1986, p. 37). In every age and in every society, the dominant models assign causes to diseases, whether ascribed to earth spirits or evil spirits, drinking, smoking, a fatty diet, viruses, or the gene pool.

The World Health Organization (WHO) defines health as "a state of complete physical, mental, and social well-being" and "not merely the absence of disease or infirmity" (WHO, 1958). Although it reflects the multidimensionality of the concept of health, this definition raises other issues. It misreads *health* as *well-being*, but health is only one component of well-being. It also refers to health mainly in terms of the individual's personal experiences, blurring the two dimensions of objective and subjective health. A diabetes sufferer may feel perfectly well as a result of irrefutable medical advances in the control of diabetes, but does that mean he is in good health? By the WHO definition, health is specific for the individual, making it hard to identify a common denominator to use as an aggregate health indicator (i.e., measure of the state of health of a population). For that measure, the society in which the individual lives must have consensus on what is meant by a *state of complete well-being*.

Another approach, exemplified by Christopher Boorse (1977), is to regard health as coextensive with the normal functioning of the individual, with *normal* being a statistical attribute. As pointed out in the literature on this topic, this definition does not accommodate the dynamic interaction between an organism and its environment, and it does not help the medical profession in addressing the demands of patients (with or without physical symptoms). Roberto Mordacci (1995) posited that there are two dimensions to health: adaptation and development. A healthy person can adapt to the physical or mental stressors of the environment, and health is one condition necessary for individual physical and psychological self-realization. Social health (reflecting the WHO definition) arguably refers to the network of social relations (e.g., family, friends, colleagues) that enables the individual to better withstand adversity.

Although the WHO defines health as more than the absence of disease, there is a clear connection between the two. Most people tend to think about health only when faced with illness. It may be, as Roberto Mordacci (1995) argues, that health is a precondition for being ill, but it remains a fact that only through illness (patient's own or that of others) do individuals compass their health. A distinction must be drawn between the *subjective* and *objective* components of health. An individual may feel unwell but not be suffering from any disease detectable by medical science, or a person may feel well but have a latent tumor, functional disorder, or organic condition with no external or perceived signs. In the former case, the individual is considered subjectively ill but objectively well, and the opposite descriptions obtain in the latter case. *Subjective health* is the status perceived by the individual, and *objective health* is the condition diagnosed by the expert (e.g., physician, healer, shaman). In these definitions, we find the components of health mentioned earlier: a properly functioning human organism as described by medical science and the individual's self-rating of well-being.

Most information on subjective health has come from cross-sectional or follow-up health surveys. The oldest was conducted in the 1950s in the United States. Annual health surveys have been done since 1956 in the United States, since 1964 in Finland, and since 1971 in Great Britain (Bowling, 2004). In the surveys, general health is assessed by questions such as *How would you describe your health?* These questions offer a range of answers, such as *very good, good, fairly good, average, poor, very poor*. Although common, this approach is not watertight. As sociologists have shown, using a single question to gauge a self-assessment is open to criticism. What is needed is a scale based on a range of propositions that can be synthesized into a single indicator as proposed, for example, by Likert or Guttman (Babbie, 2004). The question as asked tells nothing about the individual's reference norms. Are they peer-comparative, age-adjusted, lifestyle-referenced (e.g., smoking, diet, sport) standards, or are they referenced to already diagnosed health problems? Can health as a multidimensional concept be described by a single indicator even when multiple attributes are mentioned (Larson, 1994; Bergner, 1985; Boyle and Torrance, 1984)?

To resolve the difficulty of gauging health by a single question, medical sociology has developed a wide range of scales to assess the different components of health. Many measure the individual's self-assessment of health status, and some focus on mental well-being or happiness, defined as the individual's self-rated satisfaction with life. Other scales measure the extent of the social network and support or the individual's physical abilities. An excellent assessment of these scales has been provided by Ann Bowling (2004). These scales often are devised by health professionals, but the criteria articulated by individuals with no diagnosed illness are also significant. Most of the scales are based on closed questions, which may exclude other factors that some individuals may consider relevant. Another drawback is that the indicators used to measure different aspects of health do not necessarily carry equal weight within different cultures or social classes, at different life stages, for different diseases, or for different sexes (Bowling, 1995).

Individuals' subjective assessments of health are bound up with their life histories. Health is a personal concept, but it is also shaped by the individual's cultural environment and adaptability. *Healthy*, *unhealthy*, *abnormal*, and *normal* are concepts that vary with the beliefs and with the values of each society. Health is therefore a composite picture made up of the experiences, values, and information available to each individual and his or her understanding of the information. The medical knowledge that the individual acquires, particularly through the media or contacts with health practitioners, varies with time and place because of advances in medical knowledge, changing value systems, and improvements in information dissemination (Currer and Stacey, 1993). Of particular significance in this respect are the health education campaigns channeled by the medical literature and (mostly women's) mass-market magazines. These publications have revised individuals' subjective assessments of their health and changed their use of the care system, thereby altering the rates of diagnosed diseases. Health is a dynamic concept that differs between individuals and that changes for the same individual with age and circumstance, even when in good health. Health has become inseparable from the concept of well-being and physical and social adjustment to the environment. It includes the concept of improved well-being and quality of life, which may, for example, be expressed through sporting activity, a more balanced diet, or even cosmetic surgery insofar as it helps an individual become more socially integrated and have an improved sense of well-being.

In some Western societies, health has even become a *right*, like the right to education, security, free speech, or work. This concept was embodied in the WHO slogan—*Health for all by the year 2000*—which, however far-fetched, could be envisaged as an aim to be achieved in the remote future. With rights come responsibilities; if individuals have a right to health, they also have the duty to preserve their own and others' health. If health is everyone's business, the issue of individual responsibility for lifestyle choices then arises. An awakening to high-risk behaviors is beneficial in and of itself, but a society in which the right to health is a core precept and health costs are rising may qualify the principle of equal access to health care with that of individual responsibility, such that the cost of accidents sustained in freely chosen dangerous activities may not be picked up by the community. Eric Rakowski (1991) makes the distinction between *brute bad luck*, which is compensated by the social security system, and *option bad luck*, which is the result of a choice and the costs of which the victim (or private insurance) should bear. This kind of approach raises significant ethical questions. To what extent is option bad luck really chosen (Gilain, 1995)? Smoking is a matter of social circumstance as much as individual choice. The worst-off social groups are exposed to a high concentration of risk factors. Are they to be blamed for drug taking, smoking, or excessive drinking because of a harsh life, lack of education, failure to understand the health message, and the risks inherent in their conduct? In a resource allocation context, any health priority setting will come up against ethical problems. *Quality-adjusted life years* (QALYs), for example, attempt to evaluate treatment impacts on adding to life expectancy and quality of life, encompassed within a single measure. This prompts a host of questions. How should we compare the benefits of certain kinds of health care delivered in different care facilities according to different criteria to patients with different characteristics and different severities of illness? Are collective priorities compatible with essentially individual medical ethics? What considerations will apply: those of health professionals or those of healthy individuals? Does a year of healthy life have the same value for everyone? Should we be thinking in terms of health gain or level of health (Williams, 1996)?

Individuals' subjective assessments of their health is inseparable from their life histories. Broadly speaking, each person begins life with a *health potential*, which varies between individuals, improves or declines over the life course, and influences individuals' assessment of their own health. In Chapter 46, Godelieve Masuy-Stroobant describes the causes of heterogeneity in health at the youngest ages. She argues that this potential then increases over the life course in line with factors such as the place of children in each society, the role assigned to parents, vaccinations, lifestyle, a healthy diet, public health, rising living standards, rising educational levels of individuals and in society, and improved health infrastructure. However, these positive factors may be influenced by a series of individual or collective determinants, including an unhealthy lifestyle (e.g., alcohol abuse), an unhealthy environment, or malnutrition[1] due to drought or periods of economic uncertainty. Over time, the adverse factors will outweigh the beneficial ones, producing a gradual decline in health that leads to illness and death. Within this long-term decline, periods of improved health occur, only to be canceled out by new external or internal health stressors.

II. SICKNESS

He's sick, he tells us . . . I bet he is! Sick! So am I sick! What does "sick" mean? We're all sick! You'll be sick too, and not before long what's more! (Céline, 1952, p. 130)

The concept of disease has assumed many guises in time and through history. The *exogenous model* views disease as an accident due to the action of an actual or symbolic element extraneous to the patient. Depending on the time and place, the disease would be thought to originate in the malignity of a supernatural power or in a harmful agent perceived as natural and present in the environment. Disease presented incipient threats to the stability of the social order, which society must bring under control through modern or traditional medicine. It deviated from social norms whereby individuals had functions and duties to fulfill in society.[2] An extrinsic cause of disease had to be met by an equally extraneous cure. Depending on the culture, this might have been by thwarting the lot cast by fate or by administering appropriate medical treatment. The disease, being

[1] The United Nations (United Nations, 1992) estimates that 3% of the world's children are severely malnourished and that 34% of those younger than 5 years have average or moderate malnutrition or are underweight. Severe malnutrition affects children's physiologic and cognitive development.

[2] The purportedly neutral medical model in fact imbues the definition of disease with an ethical and moral dimension. For example, homosexuality was classed for a long time as a psychosis by the American Psychiatric Association (Renaud, 1985).

a foreign body, had to be expelled by ritual purification, bleeding, or antibiotic treatment. In this scheme of things, however, the disease, albeit extraneous to the patient, could nevertheless be caused by the patient's own failure to avoid it by breaking a taboo or adopting a risky behavior.

In the *endogenous model*, disease is caused by a general imbalance in the host organism. In this case, there would be, for example, an infectious agent, but it could develop only in conducive personal conditions. The disease would therefore stem partly from the individual himself. This model is specific to psychosomatic medicine disciplines, such as psychoanalysis and homeopathy. This twin-track model explains why there is no single definition of the morbid state or a single biomedical blueprint, but there are instead multiple concepts of disease and therefore many possible forms of medicine. This model explains why, even in Western societies, modern treatment based on the experimental scientific model is found rubbing shoulders with psychosomatic therapies and with lay healers. Likewise, in African societies, the treatment of disease symptoms may be left to the health clinic or hospital, and treatment of the cause would be the purview of the village shaman and healer (Zempleni, 1991).

For Claude Bernard, the father of modern medicine, health and disease are not two opposing *qualities* but the outcomes of *mere physiologic changes* that are simply stages along the health-disease continuum (Laplantine, 1986). The doctor approaches *health and illness* within the framework of an interpersonal relationship with the patient, whereas epidemiology and demography seek to identify *diseases* within a population group (Jenicek and Cléroux, 1982). Population morbidity research would therefore entail recognizing and evaluating the scale of health disorders within that population, identified from the number of diseased persons and their diseases (see Chapter 41). The demographic or epidemiologic approach is twofold: to measure the incidence of the disease in the population and to identify the determinants or risk factors involved in the occurrence of the disease. Public health epidemiology[3] is more concerned with individual risk factors such as lifestyle, whereas demography puts a greater focus on the impact of the economic and social context on behavioral variables.

Three components must be distinguished in analyzing morbidity. *Perceived morbidity*, also called *subjective morbidity*, enables a population's perceived needs and therefore health care demands to be estimated. However, it only partially reflects the degree of health care demand. Perceived morbidity can be determined through health surveys of a population or a sample population. *Diagnosed morbidity* is the extent of morbidity observed on use of medical provision (e.g., general practitioner, specialist, hospital) or determined in specific epidemiologic surveys designed to identify the scale and causes of a disease in a population, such as a prospective survey of cardiovascular disease. This is the type of morbidity found in hospital statistics or reports from sentinel networks of general practitioners. Both approaches to morbidity—through medical symptoms and by means of epidemiologic surveys—enable diagnosis of one or more disease processes and, if relevant, determination of their severity. The early stages of some diseases, such as Alzheimer's disease, are hard to diagnose because of their multiple, nonspecific symptoms. Alzheimer's disease is diagnosed on the basis of clinical criteria generated using standardized scales and protocols from which only a probability of the disease can be given. Only histopathologic criteria met by biopsy or during a postmortem examination make a certain diagnosis possible. *Objective morbidity* is the degree of morbidity identified by the methods of current medicine. It is measured by routine examinations of a population or subpopulation group (e.g., school students, company employees). The latter two aspects of morbidity initially were classified by the WHO as a cause-of-death classification, a category later extended to the diseases themselves (e.g., tooth decay, myocardial infarction). The WHO's *International Classification of Diseases* (ICD) has undergone adaptations for various medical disciplines, such as for oncology, ophthalmology, and stomatology. The ICD and other possible classifications are considered more extensively by France Meslé in Chapter 42.

As with health, different scales have been developed to measure quality of life during illness in general and especially to evaluate quality of life for those affected by specific diseases, because a cancer patient's quality of life, for instance, must be assessed differently from that of a mental patient. We therefore have tools for measuring general quality of life and various scales more specifically applicable to cancers, respiratory diseases, cardiovascular diseases, psychoses, neurologic disorders, rheumatic disorders, and other disease states. Ann Bowling (2001) has provided a detailed analysis of these scales, making it possible to gain insights into the effects and treatment of a disease.

Determining the incidence of diseases and their causes in a population necessarily involves measuring the phenomenon. In public health, the study of disease

[3] Mackenbach (1995) has provided a more extensive explanation of the distinction between clinical and public health epidemiology.

in a population can be characterized by its incidence and its prevalence. The *incidence* is the number of new (or recurrent) cases of a disease in a given period in a population, whereas the *point prevalence* is the total number of people affected by that disease in a given population at a point in time. As in demography, the following equation can be used in the absence of migratory flows:

$$\text{Prevalence } (t + n) = \text{Prevalence } (t) + \text{Entries } (t, t + n) - \text{Exits } (t, t + n)$$

In this equation, entries are determined by the incidence of new or recurrent cases and exits by the incidence of deaths or cures.

The incidence rate over a given period is calculated as the ratio of new cases observed in the period compared with the population at risk. The measure is similar to that of a death rate (see Volume I, Chapter 11). The prevalence rate is calculated as the point number of ill persons divided by the point population size. This gives a proportion of ill persons similar to that of the single population of marriageable age (see Volume I, Chapter 25).

A disease process may also be characterized by its *severity*, which can be measured by the length of sickness absence, the number of days of bed confinement or hospitalization, or even by severity scoring (Jenicek and Cléroux, 1982). Severity can also be measured by the *lethality* of the disease process, which is the ratio of the number of deaths from a disease to the number of people who contracted that disease over a given period. In certain circumstances, there is a relationship between mortality, incidence, and lethality (Jenicek and Cléroux, 1982). If entries to and exits from the ill population remain time constant, the ratio is determined by the following equation:

$$\text{Mortality} = \text{Incidence} \times \text{Lethality}$$

For example, if the annual incidence of a cancer is 80 cases per 100,000 people in the general population and the mortality is 40 cases per 100,000 people, lethality is calculated as follows:

$$\text{Lethality} = 40/80 = 0.5$$

Cancer will therefore be fatal for one-half of those affected. A health policy focused on reducing mortality may seek to reduce incidence, lethality, or both.

Often, data are lacking to calculate the morbidity indicators detailed previously. Two alternatives are then possible: measure mortality by cause or use whatever data may be available on care supply or demand. In the former case, life tables can be constructed by medical cause of death or life expectancies estimated in the absence of a given cause (see Chapter 42). The value of this approach depends greatly on the relation between the initial cause of death and the underlying disease process. Many diseases, such as osteoarthritis, have little impact on mortality, and an individual may live with a chronic disease for years before dying of it. The changing health landscape, increased life expectancy, and the emergence of chronic diseases have led to the definition of new indices that reflect quality of life more than quantity in terms of duration. At the same time, the WHO's development of the *International Classification of Impairments, Disabilities, and Handicaps* has helped to clarify the concepts. Into the basic sequence of etiology → pathology → manifestation were integrated the *consequences* of diseases that also predicate the demand for health care, generating the following proposed sequence: disease → impairment → disability → handicap. These concepts are defined with more precision by Jean-Marie Robine and Carol Jagger in Chapter 80 along with the newer indicators (e.g., health-adjusted life expectancy, disability-free life expectancy) developed from these ideas.

Another proxy of the measure of morbidity is based on health care supply and demand. For *supply*, health service infrastructure or macroeconomic indicators can be used. The first set of indicators comprises items such as the total number of physicians (e.g., general practitioners, specialists), ancillary medical personnel, dentists, and pharmacists per 1000 people in the general population; hospital provision (e.g., total and types of hospitals, total and types of beds); collective preventative medicine services (e.g., tuberculosis clinics, maternal and child welfare services, cancer screening centers, school and occupational health services); and the availability of home medical care services, nursing homes, home help services, and dependency treatment centers. The second set of indicators refers to items such as the share of gross national product spent on health and the percentage of the population covered by medical benefits insurance. Care *demand* indicators naturally focus on the use of this provision and therefore refer to total consultations of general practitioners or specialists, total hospital admissions and surgical operations, bed occupancy rates, total pharmaceutical consumption (distinguished by the targeted disease), total laboratory tests and clinical examinations performed, percentage of inoculated children, proportion of malnourished children, and type of malnutrition. Several sources provide an overall picture of the type of indicators proposed (OECD, 1996; WHO, 1986; Deliège, 1983). Evaluations of data on the use of private care provision or consumption of medicines not refunded by social security systems are other ways of assessing health care demand.

Factors other than morbidity also influence health care supply and demand (Béresniak and Duru, 1995). Health service funding affects mainly the private provision supply. The financing mechanism also affects demand, because extending health care coverage increases the use of medical services across the board. Supply and demand of health care also are affected by demographic factors; for example, specialist doctors are often concentrated in large towns and cities. A range of socioeconomic factors influences the market. The quantity and structure of supply are dictated by the level of economic development, whereas demand and its characteristics (e.g., uptake of preventative or curative care) vary significantly by the individual's age, sex, and social status (Grandfils *et al*., 1995). Demand and supply are not independent; demand rises as the number of doctors and hospitals and the level of diagnostic and treatment provision expand. There is a pull effect of supply growth on demand growth. For all these reasons, extreme caution must be exercised in using care demand and supply statistics as a proxy measure of morbidity, especially when the data for comparison is from countries with different health care and social security systems.

III. DEATH

All that is upright will be laid low.

(Mandenka proverb, Senegal oral tradition)

You die not because you are sick; you die because you are living. (Montaigne, Essays, Book III, Ch. XIII)

Under French and Belgian civil law, death results in the total loss of physical and legal personality; no other event results in such a total loss. The registrar draws up the death certificate, but as lawyers have pointed out, advances in medical science have complicated the problem of certifying death. Death has ceased to be a single event involving all the vital functions simultaneously, because current medical technologies allow individuals to be kept alive on prolonged life support who in other circumstances or times would have been pronounced dead (Philippart and Stroobants, 1984; Weill and Terré, 1978). The definition of death therefore varies with medical progress, and the same issue arises with euthanasia. According to the *Code of Medical Ethics* drawn up by the National Medical Council of Belgium (1975), the decision to turn off the life support systems of a person in irreversible coma can be made only in light of current medical knowledge (article 98).

The *Petite Encyclopédie Médicale Hamburger* (Leporrier, 1994) defines the end of life according to current medical thinking as brain death in the individual. This event results in a death certificate being issued certifying that irreversible damage has occurred to the central nervous system that is inconsistent with life. A patient whose lungs and heart are still functioning may therefore be clinically dead (Farber, 1988). Brain death may be diagnosed if four clinical conditions are met: total loss of consciousness and absence of any spontaneous activity apart from reflex responses, absence of reactivity of all cranial nerves, absence of spontaneous respiration, and a flat electroencephalographic pattern. All circumstances that may simulate death must be controlled for within a sufficiently long observation period (12 to 48 hours, depending on age) during which the signs of brain death remain unchanged.

The definition of death, like those of health and illness, is spatiotemporally variable. Likewise, humankind's representation of death has changed over the centuries. The conceptions of death and funeral rites partake of the entire sociocultural system. As Louis-Vincent Thomas points out, "Death is a biological occurrence but also a cultural fact for the perceptions that it creates about its nature and origins, the beliefs and representations it gives rise to, and the ways in which it is accepted, denied, or transcended. The funeral rites it brings about are a specifically human practice" (Thomas, 1985, p. 115). Drawing extensively on Philippe Ariès' work, it must be stressed that attitudes about death must be considered relative to the awareness of self and others and to the sense of individual or collective destiny. In the first millennium Christian West, death was prepared for within the family and represented the final rest accepted by people resigned to the fact of their own mortality. Death is also an organized public, albeit nondramatic, ceremony. In the Early Middle Ages (12th century), fear of Judgment Day transformed society's conception of death. It became a more harrowing experience, because the individual's final deeds would weigh more heavily in the scales. It had become what Philippe Ariès (1975) calls "the death of self," at least for the literate, powerful, and wealthy who saw the essence of themselves in their own death and discovered their individuality. In the 18th century, Romanticism changed the idea of death. The Western world dramatized and exalted it; the locus shifted to the death of the other, "the death of the significant you" (Ariès, 1975). Funeral rites had to reflect the grief of the survivors and the depth of their despair.

In the 20th century, death became a matter for shame; society and the family had to be spared the hideous anguish of it. We now die in hospitals, and death becomes a technical fact for the medical profession alone. Medical progress has helped change our conception of death, and we now expect science to postpone death indefinitely. Modern society, ensnared by its own technological progress, wonders about the fitting way to die, and the current debate on death is crystallizing around medical euthanasia. According to Louis-Vincent Thomas (1985),[4] this is likely to result in the loss of symbols, an extreme simplification of rites, desensitization symptomatic of desocialization (e.g., shortened ceremonies, handwritten letters of condolence, discreet mourning), and abnegation of death. However, in a survey conducted in France in 1994, approximately three-fourths of the respondents thought that people were more open about death than in earlier periods. That reaction was probably a consequence of the spread of acquired immunodeficiency syndrome (AIDS), which has claimed a variety of high-profile victims, but it also reflected the fact that death is a big seller for the film industry and other media (de Cacqueray, 1997).

Death in Western countries may be more an individual affair and less one of the family and society, but some writers such as David Armstrong (1987) or Lindsay Prior and Mick Bloor (1993; cited by Lupton, 1994) argue that since the mid-19th century, death has become a public affair. The introduction of death certificates has brought death into the realm of statistics, and the construction of life tables makes it a whole-population phenomenon. Concern has shifted from individual deaths to focus on the mean age at death or the sex- and cause-specific distribution of deaths. Death has become the subject of rational, mathematical representation. The *force* of mortality (i.e., instantaneous death rate) falls under the Gompertz-Makeham law (see Volume I, Chapters 8 and 11).

Each civilization in every era has developed its own strategies for dealing with death and its rituals for transcending this point of separation. In African traditional societies, death is the subject of public representations and ceremonies, because the community takes precedence over the individual. Death is part of life in these societies, and it is a daily presence because of the high incidence and the many songs, tales, and proverbs that feature it. Death is a moment in a process that encompasses life and continues after death. The life force leaves the body to continue in eternity. The dead are still therefore part of time and can be called on to resolve the problems of life. What remains is not a dead body, but an ancestor invested with new functions. The anguish of death is no less present in these traditional societies than in the Middle Ages or the modern Western world, but it is a socially regulated anguish, channeled through ritual and borne by belief: "Death is not freely vanquishable" (Thomas, 1975, p. 310). The fundamental difference between the Western and African traditions may be in the representation of ego:

> The African approach is participative and socially regulated; the West a heightened sense of personhood grappling with the godforsakenness of nothingness. The result is diametrically opposing attitudes to death and the dead: the one refusing the separation of life-death and living-dead; the other emphasizing both points of severance (Thomas, 1982, p. 251).

[4] This section owes much to the writings of Louis-Vincent Thomas (1975, 1982, and 1985 in particular), who was an authority in the field.

CONCLUSIONS

Health, illness, and death are at once biologic and cultural, individual and collective realities. Healthy and unwell individuals self-define themselves as such, but their health and their illness are also dictated by the norms of the society in which they live. Even death is a cultural fact according to whether it leads to the annihilation of ego or the survival of the ancestor in the afterlife. In the Western world, which is rational and ruled by science, the corpses of some wealthy Americans are lying cryogenically frozen, like the traveler in the *Space Odyssey*, in the unrealistic hope that the march of medicine will vanquish old age and disease. The ancient world, traditional Africa, and Western society each has its own way of answering Hamlet's question: "To be or not to be?"

Measuring the State of Health

CATHERINE SERMET AND EMMANUELLE CAMBOIS

Institut national d'études démographiques (INED), Paris, France

Measuring the states of health of a population leads to certain questions: What is health? What do we wish to measure, and for what reason? The responses to these interrogations subsequently will determine the nature of the mechanisms that can be devised.

Health status is a continuum from good health to death by way of disease or any other form of physical or mental change or decline. Definitions concerning states of health therefore depend on the definitions chosen to define good health. The World Health Organization (WHO) employs a positive idea of health ("state of complete well-being") that cannot be equated with "an absence of disease or infirmity" (WHO, 1946). Health is also "a state characterized by anatomic, physiologic, and psychologic integrity; ability to perform personally valued family, work, and community roles; ability to deal with physical, biologic, psychological, and social stress; a feeling of well-being; and freedom from the risk of disease and untimely death" (Last *et al*., 2001) or "an essential dimension in the quality of our lives . . . the opportunity to make choices and to gain satisfaction from living" (CDNHW, 1986). These definitions, which are based on the idea of positive health, are satisfactory on a conceptual level but are often considered barely operational because they are too general (Basch, 1990; Young, 1998). Unlike the positive definition of health, most assessments for measuring the health status are negative; they measure diseases and their consequences rather than health itself (Bergner, 1985). At the individual level, every person has a different view of health. Some think of it in terms of symptoms and diseases, whereas others define health in terms of interference with the normal activities of life, deviation from a norm, or an inability to respond to an environmental aggression. Confronted by a patient, the doctor attempts to make a diagnosis, estimate the need for care, and evaluate the results of treatment.

More collectively—and it is this aspect that we consider here—the approaches to the *health of the population* are equally varied. From the point of view of public health, interest is directed toward epidemic, acute, and chronic diseases; their causes and risk factors; and their distribution among the people. This approach attempts to anticipate diseases, reduce their consequences, and promote health. Those who control the health care system and its policies have other perspectives that reflect their preoccupation with the well-being of the population, the seriousness of handicaps, the costs of diseases, the evaluations of inequalities, and their definitions of priorities. Epidemiologists relate diseases to the individual and the environmental and social factors that are prone to change the frequency, distribution, and evolution of diseases and to define the biologic and environmental determinants of diseases. Demographers approach health matters in terms of the consequences on the duration of life (i.e., mortality rates, causes of death, and life expectancy) and knowledge of the social determinants or epidemiologic history of populations.

We therefore need to address two questions: What do we wish to know, and how should we apply this knowledge? Kue Yung (1998) encapsulated the principal reasons for inquiries into the health status of populations: "*to describe, to explain, to predict, to control*." Studies concerned with the health of populations enable the health status to be described, the causes of diseases to be explained, the individual and collective risks to be anticipated, and solutions for anticipating and controlling health problems to be proposed.

The WHO has listed eight ways of using morbidity statistics: control of communicable diseases; planning for development of preventive services; ascertainment of relation to social factors; planning for provision of adequate treatment services; estimation of economic importance of sickness; research into cause and pathogenesis; research on efficacy of preventive and therapeutic measures; and national and international study of distribution of diseases and impairments (Basch, 1990).

These various measurement targets and the uses that arise from them show that there cannot be a sole indicator for gauging a population's health status. Four large categories may nevertheless be distinguished: demographic data (e.g., age, sex), statistics on vital events (e.g., births, deaths), health statistics (e.g., morbidity, impairments, perceived health), and statistics relating to the health services (e.g., use of the services, indicators of medical supply) (Basch, 1990). To judge the realization of the objective proposed in *Health for All in the Year 2000*, the WHO asked all member countries to provide a series of indicators covering all the following categories: life expectancy at birth; infant mortality rate; proportion of persons aged 65 and older; percentage of gross national product devoted to health; and the number of cases of diseases such as acquired immunodeficiency syndrome (AIDS), poliomyelitis, and measles.

With these indicators, health statistics inform directly about the health status of populations, and the other three categories provide indirect information. These specific health indicators are evaluated in this chapter.

I. HOW TO MEASURE HEALTH STATUS

Until the beginning of the 1960s (Bergner, 1985), death rates formed the principal measure for the health of populations. With the lengthening of life expectancy, it became progressively evident that mortality no longer sufficed for measuring the changes that had come about in health and medical care. It was then that health surveys enabled the collection of numerous indicators of health status, environmental conditions, available health care, biochemical and physiologic measures, and days of inability to work.

In the 1970s, synthetic indicators appeared that were founded, for instance, on the combination of mortality rates and data on the incidence or prevalence of diseases or on distinguishing the years of life expectancy according to their quality. Some indicators of impairment or functional disability were also perfected, and they ranged from simple measures of physical limitations to the inclusion of a much wider field of physical, social, and psychological functions. Although they had been tested and validated before being widely used in many studies, very few had been routinely employed to measure the development of the state of population health over long periods. Indicators of mental health had been developed more quickly, probably because of the greater difficulties in providing precise diagnoses in this domain (Bergner, 1985).

Parallel to the development of general indicators, clinicians perfected their own evaluation tools for their patients. Directed toward diagnosis or surveillance, some of them had then achieved wider employment in more extensive population studies. There has been particular interest in measures of the quality of life, covering a considerable number of physical, social, and psychological dimensions and enabling many of them to calculate synthetic quality of life scores.

As suggested by Mildred Blaxter (1989), the various instruments for measuring the health status can be placed in three categories. The first set is determined according to a medical or biologic model of the disease, which defines the poor health status as a divergence from a physiologic or psychological norm. The second corresponds to a social and functional model in which the poor health status is defined as an inability to fulfill normal tasks or roles. In the third category, the measure of the subjective health status predominates, a model in which individual perception is paramount (Table 41–1). This idea of subjectivity merits clarification. Essentially, what is recorded in the subjective model is the deep feeling of the individual, his symptoms, and his physical or mental identification of health problems. In the medical model, as in the functional model, the account of the information may rest on the declaration of individuals and therefore be partly subjective, but the content of the information has a basis that can be objective, such as a diagnosis of disease or functional incapacity.

This classification system reflects the differences in the three English language terms employed when speaking of worsening of the health status (Blaxter, 1989). *Disease* represents the functional and structural perturbations of the human body that produce clinical signs and symptoms that are labeled as deviation from the norm (Young, 1998). This term generally refers to a biomedical nomenclature, and the diagnosis of diseases is within the province of physicians. It is essentially

TABLE 41–1 Commonly Employed Indicators for Summarizing States of Health

Medical or physiologic and psychiatric model	Social-interaction or functional model	Subjective or illness model
Clinical examination, physiologic or psychiatric screening for abnormality	Test of physical or psychological disability	Self-assessment of health
and/or Medical diagnosis of physical or psychiatric disease	*and/or* Ascertainment of functional status associated with the ill health (e.g., bedridden, not working)	*and/or* Reported experience of physical symptoms of ill health
and/or Self-report of the existence of medically defined diseases or abnormality	*and/or* Inability to perform normal tasks because of diseases, impairments, or illness	*and/or* Reported experience of psychosocial malaise

From Blaxter, 1989.

within the scope of Baxter's medical model. *Illness* represents the subjective experience of diseases, which Mildred Blaxter calls a *subjective model.* It is the perception of a change in the habitual functions or feelings of an individual. Disease can exist without the patient feeling ill, as in cases of hypertension. A person also can feel discomfort that cannot be expressed in diagnostic terms. *Sickness* is the societal response to diseases, and the term expresses the consequences of the latter on the relations of the individual with other people. This term is used more within the functional model, although this does not suffice to describe it completely.

II. THE MEDICAL MODEL: MEASURING MORBIDITY

1. Definitions

a. Morbidity

For *morbidity*, the epidemiologic dictionary offers the following definition (Last *et al.*, 1995): morbidity is "any departure, subjective or objective, from a state of physiological or psychological well-being." This approach covers the whole range of health, and it refers equally to medical diagnoses, functional disabilities, and subjective health.

The same source indicates that morbidity can be measured according to three units: the persons who were ill, the illnesses that theses persons experienced, and the duration of these illnesses. The term *morbidity surveys* makes explicit reference to the frequency of diseases within the population. This measure of morbidity is primarily a medical measure, because ideally, we want to count the diseases that are confirmed by a medical diagnosis and whose denomination necessitates highly encoded nomenclatures. In practice, the assessment is often based on the declarations of individuals, and it is this definition that we employ in this section.

b. Incidence and Prevalence

Incidence and prevalence are the two basic indicators for measuring the frequency of diseases in the population. Strictly speaking, the *prevalence* of a disease is the proportion observed at a given moment of people suffering from this disease. It represents the *stock* of diseases prevailing at a given moment, and it equals the number of sick people recorded in relation to the total population.

Incidence expresses the frequency of *new* cases of a given disease (i.e., persons newly attacked) during a given period within a certain population. It equals the number of *events* commencing during the period under consideration relative to the average population during the period.

When the population is stable, there exists a connection between the incidence (I) and the prevalence (P), which is expressed as follows (Bouyer *et al.*, 1995):

$$P_{t+1} = \frac{I_{t,t+1} \times d}{1 + (I_{t,t+1} \times d)}$$

In the previous equation, d is the average duration of the disease, t+1 is the date on which the prevalence is observed, and t,t+1 is the period of observation of the incidence. In the particular case when the incidence and prevalence are constant and when the prevalence is weak (<10%), the prevalence can be approximated as follows (Freeman, 1980; Bouyer, 1995):

$$P_{t+1} = I_{t,t+1} \times d$$

The prevalence of a disease is therefore a function of its duration, which sometimes makes the interpretation of its variations, in terms of the health status of the population, difficult. Eileen Crimmins (1996) stresses that if life expectancy lengthens as a result of a diminution in the incidence of diseases; it can effectively be maintained that the health status has improved. On the contrary, if it is longer because of an increased survival of the sick, it is not accompanied by an improvement in the health status.

The latter affirmation appears to be open to discussion. Improvement in medical care and therapeutic progress may prevent a certain number of deaths without curing the sick persons. Their survival is therefore prolonged, and prevalence increases. Can it be said that there is a decline in the health status of the population because the number of sick people has increased, or should it be maintained that there is an improvement, because the diseases that were hitherto mortal no longer systematically lead to death (Sermet, 1998)? The reply is subjective and depends on the quality of life experienced by people with the disease. To answer these questions, indicators were devised for healthy life expectancy—with or without chronic diseases, but also with or without disability or in good health as subjectively perceived. The WHO modeled this problem area and presented various possible developments in the health of the populations according to the evolution of the survival curves for the different states of health (WHO, 1984).

2. The Measure of Morbidity

The measure of morbidity of a population encounters two major difficulties: the definition of the disease and the type of morbidity measured. Definition of the disease immediately questions the very concept of normal and pathologic. Where does disease commence, and where does normality end? That which is normal for one population in a given culture is not inevitably so in another. What was normal 10 years ago might have become abnormal at the end of a decade. What is normal at the age of 60 years is not always so at 20 years. A normal clinical state may mask a complaint at a different clinical stage. When does a disease begin and end? When is a patient cured? In reality, there is a continuum between normal and pathologic states at the inception of a disease and at the end of it. Measuring morbidity bears a resemblance to measuring the surface of a field whose boundaries are unknown.

Recognition of a state as constituting a disease is far from being universal, and examples of cultural variations are numerous. For example, the hematuria that accompanies *Schistosoma* infection, a parasitic disease endemic in certain regions of Africa, is seen in certain cultures as a normal phenomenon, not requiring medical attention. In this situation, a record of morbidity based on the declarations of individuals cannot enable this symptom and the disease to be recognized as such. This example leads us to consider the question of the norm. We have become accustomed to consider the biomedical model developed in Western societies as the universal norm, but certain people consider that this model is only a reflection of our culture and that *reality* and *objectivity* are only social constructions (Young, 1998). For this reason, they are difficult to transpose from one society to another.

The role of cultural phenomena is even more important when it concerns the state of mental health. Many authorities emphasize the existence of syndromes that are closely linked to particular cultures. These *culture-bound syndromes* constitute entirely separate diseases in these societies, but they are not found in the models or classifications of other societies. The *mal ojo* of children in the Mediterranean and South American populations attributes sleep problems, crying, or diarrhea to the diabolic glance from a stranger, the evil eye. On the other hand, pathologies such as bulimia and anorexia are accepted in Western countries (Basch, 1990).

The temporal definition of the disease also is subject to discussion. Inasmuch as it is simple to establish the beginning and end of an acute disease such as influenza, it is just as difficult to determine the start and finish of a disease such as cancer. How should we date the commencement of the tumor when it might have been developing insidiously for years without being detected (not even clinically detectable), and how should we date its termination when metastases may occur several years after the treatment of the initial tumor?

The second difficulty to be confronted in the analysis of morbidity data depends on the definition adopted for the type of morbidity being studied. Morbidity based on the declarations of individuals represents only a partial view of the pathology because it is subject to voluntary or involuntary omissions, the possibility of considerable variations in individual perceptions of the disease, and sociocultural and psychological factors. Diagnosed morbidity requires contact with a doctor, and it covers only the pathology that motivated the person to seek treatment or that was revealed during a medical examination.

Three components of morbidity can be described according to the source of information (Fig. 41–1). Diagnosed morbidity, measured morbidity, and self-reported morbidity all exist within the framework of

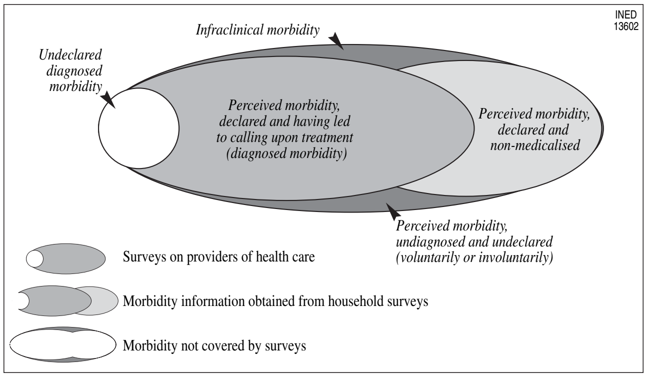

FIGURE 41–1 Types of morbidity. (From Sermet, 1994.)

the medical model described by Mildred Blaxter (1989).

Diagnosed morbidity corresponds to illnesses among individuals who have consulted doctors and been diagnosed and treated by the medical corps. A certain amount of data of this type is routinely recorded in many countries, such as notification of infectious diseases, registers of chronic diseases (particularly cancer), and hospital statistics, diseases, and accidents related to work. Only surveys conducted among doctors can provide pertinent data about diagnosed morbidity.

Measured morbidity can be objectified by clinical or paraclinical health examinations of the population. It forms a subsection of diagnosed morbidity.

Some large demographic surveys on health enhanced by a medical examination have been carried out on the whole or part of the sample. One of the first such surveys, the National Health Examination Survey (NHES), was begun in the United States in 1960. At first, it concerned only a few diseases and enrolled individuals between 18 and 79 years old. It was then extended to become the National Health and Nutrition Examination Survey (NHANES), which has been regularly repeated since 1974. Health examination surveys also exist in Canada (Canada Health Survey) and in various European countries, including Germany, Finland, Spain, and Great Britain. A European Commission study examined these surveys to evaluate the collected data (Koponen and Aromaa, 2001). The report showed that although costly and difficult to set up, this method of collecting data is increasingly used. A health examination will be integrated in the next French, Italian, Norwegian, and Portuguese health surveys.

One of the main difficulties in setting up such studies lies in the complexity at a national level, for example, of a standardized medical examination and of the limited number of diseases whose diagnosis depends on simple, noninvasive, and inexpensive examinations that can be applied to a large sample. Only a few illnesses, such as hypertension, or diseases whose diagnosis is biologic, such as diabetes, are easily measurable.

Frequently, national and regional surveys that include medical examinations confine themselves to a particular pathology, such as mental health in the Netherlands or diabetes in Greece. Surveys of this type have also been carried out on a European or international level; such is the case with the multicentric surveys of cardiovascular diseases (MONICA), osteoporosis (EVOS), or cancers (EPIC).

Self reported morbidity is information that can be obtained directly from individuals. It is also a partial and subjective view of the pathology, because no one can claim to know all the diseases with which he or she is afflicted, particularly those whose clinical presence is not yet detectable, and because of omissions and intentional nondeclarations. By definition, the data are subjective, because all people have their own conceptions of what is normal and pathologic and their own scale of values in ordering illnesses and naming them.

Self-report of morbidity is most frequently carried out through population surveys, commonly called *health surveys*. In France, those that are directed toward the general population include the Decennial Survey on Health and Medical Care of the National Institute of Statistics and Economic Studies (INSEE) and the Health Care and Health Insurance Survey of the Research and Information Institute for Health Economics (IRDES, formerly Centre de Recherhce, d'Etude et de Documentation en Economie de la Sante [CREDES]). Many countries in the world conduct surveys of this type. The European Commission has launched a program listing health interview surveys, which has enabled the compilation of about 40 national surveys of this type in Europe (Hupkens and Swinkels, 2001).

Many factors influence the declared level of diseases without affecting real morbidity. There are the individual factors, with the cultural and social characteristics of the individuals and their level of medical knowledge and their own health status. There also are factors associated with social organization, the environment, and medical development. The development of diagnostic methods, as well as those of the supply and quality of treatment, has enabled certain diseases to be detected more easily and to be identified more precisely. For example, the improvement in detection and the increased use of treatment for elderly people have greatly contributed to the prevalence of hypertension diagnosis in the United States. In France between 1980 and 1991, the number of lipid metabolism disorders reported by individuals was multiplied by three, indicating an increase in medical knowledge and improvement in diagnostic methods (Sermet, 1998). Societal changes also have amplified health-related expectations and requirements, as on the frontier between normal aging and geriatric pathology. Arthritis and dementia, formerly regarded as the signs of normal aging, are now designated diseases (Crimmins, 1996).

The characteristics of the illnesses themselves have influenced their declaration on surveys. Although it may be easy to recognize the presence of an acute disease whose symptoms may be evident and well delimited in time, what should be done in the case of diseases that manifest only sporadically? Sciatica, for example, is characterized by its successions of acute periods and more or less prolonged phases during which the anatomic damage persists but there are no clinical manifestations. The same can be said for other illnesses, such as myocardial infarction, transitory ischemic cerebral accidents, and seasonal allergic rhinitis. In this type of disease, individual attitudes vary considerably; some people declare the diseases, whereas others fail to do so when the diseases are not active.

As evidenced by the European inventory of health surveys, many methods are employed during the surveys to ask people about their diseases. There are questions of a general nature, such as that recommended by the European Office of the WHO within its harmonization program of measuring instruments for surveys by interview (Euro-HIS): “Do you have any long-standing illness or health problem?” Numerous variations of this question are to be found in the various surveys, and a question of this type has figured since 1990 in the United Kingdom census questionnaire. In other cases, to encourage those concerned to make declarations, lists of diseases or disorders are made available during the surveys. The methods employed in gathering the information are not without an effect on the declarations, such as the type of question (open or closed) and the recall period. Mental diseases constitute a particular case in the area of self-reported morbidity, because the disablement they cause and the taboos and misunderstandings of which they are the objects frequently lead to their being under-reported. Rating scales have been developed to enable mental diseases to be traced indirectly through the declarations of symptoms, such as the *Self-Rating Depression Scale* (Zung *et al.*, 1965), or by measuring their functional consequences, as in the *Mini-Mental State Examination* (Folstein *et al.*, 1975).

III. THE FUNCTIONAL MODEL: THE MEASURE OF DISABILITY

Because of the demographic evolutions at work and the increasing proportion of old and very old people, questions relating to the functional state of health have become decisive for public health. The functional model approaches health in terms of the consequences of diseases, accidents, or physiologic aging on the functioning of the individual in daily life. Consequently, the question that arises at the level of morbidity concerning the consequences of increased life expectancy applies equally to the level of functional health. As suggested by the WHO (WHO, 1985), a person must not only be “adding years to life, but life to years.” Authorities should appreciate the burden of disability and dependence that has evolved within the population. Some biomedical models have been developed to provide a conceptual framework for these investigations. They have enabled a precise meaning to be attributed to the terms *disability*, *handicap*, *dependency*, and *impairment* that previously were often confused. Models have placed these concepts within a dynamic process that includes various levels, at which the repercussions of the disease, accident, or aging are expressed in terms of the body’s functioning, daily activities, and social integration.

1. Concepts and Definitions

Saad Nagi (1965) developed the first conceptual works devoted to the disablement process. His aim was for a better definition of these concepts in the areas of functional health. From these activities and a revision in 1976, several important definitions emerged to describe the different levels of the disablement process. *Impairment* was defined as an anatomic, physiologic, intellectual, or emotional abnormality or loss (Nagi, 1976). Nagi then defined the *level of organismic performances*, for which he distinguished three dimensions: physical, emotional, and mental. *Disability* was defined as an inability or limitation in carrying out the activities and social roles related to work, the family, and an independent life. At the same time, the work of Philip Wood and Elisabeth Badley (1978) led to the development of the WHO *International Classification of Impairments, Disabilities, and Handicaps* (WHO, 1980). The WHO approach distinguishes the following levels: impairment, disability, and handicap.

a. Impairment

Impairment is defined (WHO, 1980) as "any loss or abnormality of psychological, physiological, or anatomical structure or function." The abnormalities are of a physical, mental, or sensorial nature, and according to the expression used by the WHO, they are the "exteriorized" form of the disease, malformation, or accident. Sometimes, the disease is assimilated to this exteriorized form, or in other words, to the impairment that it entails. Confusion then arises between the source and its consequences on the psychological, physiologic, and anatomic functions. Macular degeneration is a good example. The name of the disease is nothing other than the impairment it provokes, and it is difficult to clearly define the frontier between the impairment and its cause.

b. Disability

Disability corresponds to "any restriction or lack (resulting from an impairment) of ability to perform an activity in the manner or within the range considered normal for a human being" (WHO, 1980). For the WHO, this limitation of activity is the "objectified" form of the disease, accident, or malformation. For example, macular degeneration can lead to a curtailing of activities, such as reading or driving, that are considered to be essential for the life of individuals, their work, social integration, and leisure activities.

In the first model proposed by Philip Wood and Elisabeth Badley (1978), a distinction was made within disability between functional limitations and activity restrictions. This distinction is related to that which Saad Nagi proposed in his model when defining the performance of the organism on one hand and activities on the other. Later studies based on numerous data collected in this domain have demonstrated that differentiating functional limitations from activity restrictions at the level of disability enables vital public health questions about taking care of the disability and dependence of people to be addressed (Robine *et al.*, 2000).

Functional limitation is situated at the level of the physical, sensorial, or mental body functions. It is the result of a disease, accident, aging, and consequent impairment on the functional abilities of the individual, independently of the environment or available technical aids. Functional limitation is expressed through difficulties in mobilizing body functions to, for example, walk, extend an arm, hear, or remember. In the example of macular degeneration, a functional limitation associated with this impairment would be difficulty in seeing. However, the localizations are not necessarily identical, and impairments linked to brain injuries, for example, may occasion motor, sensory, or mental functional limitations. Functional limitations, whether reversible or definitive, form intrinsic characteristics of individuals and determine their functional state. Environmental factors, personal resources, or technical aids, however, may modify the effect of functional limitations on the performances of the individual for daily activities.

Activity restrictions correspond to the individual's dysfunction in daily activities (e.g., personal care, household activities, work), and they depend on the person's functional status and environment. The WHO definition of disability is related to so-called complex activities. Macular degeneration that entails difficulties in seeing may compel the individual to limit activities such as driving a car or shopping.

In clarifying and ordering these two levels, a distinction can be made between people having functional limitations but who manage to compensate for them and those for whom the functional limitations result in restriction of the activities of daily life. This means that account may be taken of environmental influence and the personal resources of individuals that favor the adoption (or not) of a compensatory strategy. The literature on the subject presents functional limitation as a *preclinical stage* or predictive of activity restrictions (Fried *et al.*, 1996; Lawrence and Jette, 1996). Studies have given prominence to the determinative role of functional limitations in the disablement process (Fried *et al.*, 1996; Harwood, 1998; Lawrence and Jette, 1996; Tager, 1998). Mobility limitations, for example, have proved to be more predictive of activity restrictions than other categories of limitations (Lawrence and Jette, 1996; Manton *et al.*, 1998). They may also generate more recourse to the health services (Wolinsky and Johnson, 1991). Although fundamental, this distinction was not adopted by the WHO in its classification, and it reappeared only in the 1990s through the initiative of the Council of Europe (Council of Europe, 1990) and then on the occasion of later studies.

c. Handicap

Handicap for a given individual results from "an impairment or a disability that limits or prevents the fulfillment of a normal role (depending on age, sex and social and cultural factors)" (WHO, 1980). According to the WHO, handicap is a "socialized" form of disease, accident, or malformation. The WHO proposes six roles according to which handicap may be evaluated, among which are *minimum independence* (i.e., to be independent of someone's assistance for personal care activities), *independent mobility*, and *social* *integration*. The combination of several activities, such as washing oneself, feeding oneself, and going to the toilet, enables these roles to be carried out for the role of minimum independence. For this reason, the frontier between disability and handicap is blurred. Disability is usually measured by the activities that comprise these roles (e.g., personal care, professional activity) and as a consequence, while measuring disability, a handicap is at the same time being suggested.

In a classic scenario, a handicap results from a disability, which is itself provoked by an impairment. However, the WHO classification makes clear that in certain cases this sequence no longer exists or does not exist. In the realm of mental health or malformations, impairment may be the cause of a handicap without inducing a flagrant disability, but general behavior or stigmatization of the disease may form an obstacle to social integration.

The several reference models developed in the 1970s have generated discussion and debate. Newer models and definitions have been suggested for integrating the essential factors involved in the process (e.g., environment) or for defining more accurately the frontiers between the steps, which are sometimes difficult to discern (Robine *et al.*, 1997). In this context, the WHO classification, which served as a reference model for many years, has been revised to address the various criticisms of its original version. The main development to be found in the new version (*International Classification of Functioning, Disability, and Health*, [WHO, 2001]) has been better weighting for the effect of the contextual factors, both environmental and personal, on the functioning of individuals. It no longer rests directly on the principle of the disablement process, but it instead provides blocks of definitions that enable the functioning problems to be classified. As for the classification of diseases, the newer version provides a nomenclature for the problems of functioning:

Impairments are problems in body functions or structure such as significant deviation or loss. *Body functions* are the physiologic functions of body systems (including psychological functions). Body structures are the anatomic parts of the body, such as organs, limbs, and their components.

Activity limitations are difficulties an individual may have in executing *activities*, defined as execution of a task or action by an individual. *Participation limitations* are problems an individual may experience in involvement in life situations.

Environmental factors make up the physical, social, and *attitudinal* environment in which people live and conduct their lives.

The new version of the WHO classification does not explicitly mention the distinction between the functional limitations and activity restrictions. As with *disability* in the previous version, the current level of *activity limitations* covers both of these concepts, and what the WHO now calls *limitation of participation* designates the consequences of these activity limitations in the real life situation.

2. Measuring Instruments

a. Measuring the Various Concepts of the Disablement Process

As for morbidity, the various concepts of functional health may be understood through individual self-reports in interview surveys or by measurement during clinical examinations.

Impairment

Impairment is close to disease and constitutes the first consequence of it. The divide between disease and impairment is blurred, and for that reason, measurement of the latter is not easy. When health is measured through diagnosis, impairments may be approached on the basis of the diagnosed diseases or injuries by questioning about the commonly observed consequences of these diseases or injuries (e.g., altered visual systems, loss of memory). However, when the measurement is based on self-reported health, impairment is a level of alteration that is difficult to identify and evaluate. A number of surveys, such as the French Health Survey or the disability survey (i.e., Handicaps, Incapacités, Dépendance), include questions about disability and impairment, which is considered the source of the disability. These surveys list examples such as motor and auditive impairments, directing the person toward the level of body alteration. It is difficult, however, in this type of questioning to differentiate diseases, impairments, and functional limitations.

Disability

The aim is to measure the ability of individuals to carry out activities in terms of their state of health (i.e., diseases or impairments). For this purpose, scales were employed within the field of clinical research well before development models of disability came on the scene. In 1963, Sidney Katz and others set up the scale of elementary activities in daily life (i.e., activities of daily living [ADLs]), which was based on observing the development of independence in children: feeding themselves, dressing and undressing, showering or bathing, going from bed to armchair, using the toilet, and continence. This scale was later enhanced by Powell Lawton and Elaine Brody (1969) with so-called *instrumental* activities of daily life to measure the ability of individuals to live alone (i.e., instrumental activities of daily living [IADLs]): doing the housework, preparing meals, keeping the accounts, and performing other chores. In 1976, Saad Nagi introduced a scale for evaluating what he called *bodily performance* (i.e., functional limitations). The typical survey questions were about difficulties in activities such as seeing the printed characters of a newspaper, walking 500 meters, and going up and down stairs. The various scales were transformed into questionnaires and used in health interview surveys. Today, most of the health surveys conducted in developed countries include such question modules to evaluate disability and often target the elderly population (Cambois and Robine, 1994; Cambois *et al*., 2000; Wiener *et al*., 1990).

For organizing this field of research and providing the means of comparing the results of surveys, standardized instruments were proposed or recommended by bodies as the Organization for Economic Co-operation and Development (OECD) (McWhinnie, 1981) or the WHO (WHO and Statistics Netherlands, 1996). Certain instruments, particularly that recommended by the OECD, include simultaneously the ADLs, IADLs, and functional limitations such as those suggested by Saad Nagi (1976). Amalgamation of these different scales within one instrument makes the interpretation of the collected information difficult. What can be concluded in terms of the need for aid and care when classified together are a difficulty in *going up and down stairs* and a difficulty in *feeding oneself*? Disentangling the levels of functional limitations and activity restrictions enables prominence to be given to the disablement process; it allows consideration of the possibility that limitations are predictive of activity restriction and then consideration of the possible different needs for help and care associated with these two levels.

Measuring Functional Limitations The functioning of the individual is sought within different categories of functional limitations (e.g., physical, sensory, mental), based on the difficulties expressed (e.g., seeing, walking, remembering), the resort to a technical devices, or the reliance on personal assistance. In a survey based on interviews, the principle is to help the person to self-report possible limitations by suggesting to her or him some gestures or scenarios requiring various functions to figure out possible alterations, such as "bending the arm to shake hands" or "hearing what is said during a conversation." These questions constitute only suggested situations not indispensable in everyday life. Therefore, concerning the formulation of this type of questions, the individual must not be interrogated in terms of effective performance (Do you . . . ?), but should be asked in terms of ability (Can you . . . ?) (Glass, 1998). Different instruments have been suggested on the basis of Saad Nagi's proposals in 1976. A review of these instruments shows that functional limitations can be put into the following categories: physical functional limitations (e.g., balance, mobility, strength, endurance, agility), sensory limitations (e.g., vision, hearing), and mental limitations (e.g., memory, comprehension) (Coutton *et al*., 2000). Each of these categories can be understood on the basis of one or several questions: "Can you go up and down stairs without difficulty? Can you walk 500 meters without difficulty?" These functional limitations can also be tested during a medical examination by asking the individual to carry out certain gestures. This type of test is common in the practice of gerontology. Because of their specificity, mental functional limitations are most frequently tested in such a way, using instruments such as the *Mini-Mental State Examination* (Folstein *et al*., 1975) or small exercises involving reminding about the date of an important event, given the name of the present head of state, or counting backward.

In the interview surveys, the questions may be asked in two stages. The first is to find out the intrinsic functional level of the individual (i.e., excluding an adapted environment and without resort to specific aids or devices). These questions measure the intrinsic functional condition and enable a comparison of the functional state of the population in time or comparison of population groups. Second, by introducing the use of a device, it is possible to measure the effective functional state of individuals (i.e., their intrinsic state corrected by the aids available to them that may prevent further activity restrictions despite functional limitations).

Measuring Activity Restrictions Today, the reference activities for measuring activity restrictions are still those of the ADLs proposed by Sidney Katz (1963) and adopted in the recommendation by WHO Regional Office for Europe (1996). This indicator is generally employed for the older population, for whom it had been developed. Nevertheless, the permanent health survey in the United States, the National Health Interview Survey (NHIS), asks the population from the age of 5 years or older questions relating to activity restrictions of the ADL type. Activity restrictions may also be measured by the IADLs proposed by Powel Lawton to enlarge the ADL approach for assessing the chore daily activities, but what these activities really measure is now debated

(Robine and Jagger, 2000). Some studies suggest that the IADL assessment does more than evaluate the ability to live alone, because activities such as managing accounts or writing checks demand a certain degree of mental lucidity and could be useful to detect restriction due to cognitive functional limitations (Wolinsky and Johnson, 1991). Studies of these indicators have also shown the existence of a veritable hierarchy between the ADL and IADL assessments (Ferrucci *et al.*, 1998; Finch *et al.*, 1995; Lazaridis *et al.*, 1994; Spector and Fleishmen, 1998). A scale of severity of the restrictions can be constructed by ordering these activities. Difficulties in feeding oneself generally reveal the most severe level of disability, and difficulties in showering or bathing (without other difficulties) indicate the most moderate level among the ADLs, therefore a deterioration process can be observed along the scale. In the same way, the IADL assessment can indicate a less severe level of functional deterioration, except for using the telephone, which approaches the severity levels of the ADL type.

Activity restrictions are measured through the interview surveys by using a formulation based on the effective performances of the individual such as, "Do you feed yourself on your own without difficulty?" It is also possible to incorporate the use of a technical aid or the assistance of another person (Cambois *et al.*, 2000). Observation through performance tests, as described for functional limitations, does not furnish reliable information in this field (Kempen *et al.*, 1996; Reuben *et al.*, 1995); simulating activities such as feeding, preparing of a meal, or getting dressed provides more information about functional limitations than about the difficulties encountered in daily life to be independent in these activities in the person's own environment. These tests constitute laboratory conditions, which have very little to do with real life.

The soundness of instruments for measuring disability has been widely studied in relation, for example, to their sensitivity and reproducibility (Fried *et al.*, 1996; Kempen *et al.*, 1996; Reuben *et al.*, 1995; Tager *et al.*, 1998). The choice of items used and the formulation of the questions in measuring the functional limitations and the activity restrictions are important. The information can be refined by employing the quality criteria suggested by these studies.

Handicap or social participation is inferred from the activity restrictions, because the scales used are made up of activities considered to be necessary for ensuring social integration. Restrictions on activities for personal care may indicate the loss of minimum independence; restrictions on instrumental activities reveal difficulties in living alone at home. Handicap is frequently inferred from the restrictions on professional activities. This is most often measured through a synthetic question, and many surveys employ a single question for evaluating activity restrictions or handicap. However, the level of handicap may be studied more specifically. Within the sphere of the current European program, specific questions on social participation are being considered to estimate inequalities in the degree of social integration of persons with or without disability (e.g., work, leisure).

b. Synthetic Questions

Along with the scales, functional health can be evaluated through general questions about limitations in usual activities due to health problems. These questions are to be found in various forms in most health surveys (Perenboom *et al.*, 2000). They sometimes concern short-term limitations occurring during the 15 previous days or consider long-term problems by excluding transient problems. Although the scales presented previously are mostly employed for evaluating long-term disabilities, synthetic questions apply as much to long-term as to short-term problems. The information collected does not have the same use in both cases; the choice of questions depends on what the information is used to measure. The public health concern about care for disability and dependence tends to be evaluated through questions about long-term problems. In this context, a review of the indicators demonstrates that a period of more than 6 months enables transient problems to be screened out. Global questions about limitations in professional activity are also to be found in surveys, and in this case, the interrogations are related to the interruptions of activity because of a health problem or the modifications in the quantity and type of activity because of a health problem.

c. International Comparability

Relying on the international recommendations for disability measurement instruments, health surveys throughout the world have included such instruments in their questionnaires, adapting the formulation of the questions and the number of activities considered or sometimes adapting the type of activities considered according to their needs or to the place available in the surveys. The formulation of the questions and the choice of activities considered are important, and the variation from one survey to another on certain aspects makes the collected information difficult to compare. The European Union is developing research programs for evaluating the degree of comparability between these measures in Europe and concentrating on those that should be improved and recommended to obtain the most precise information. These studies have shown that it is difficult to implement recommendations such as those of the WHO and that the developed questions do not overall necessarily fulfill the quality criteria of such instruments. Proposals have been made in these European programs for promoting instruments that depend on current scientific knowledge (i.e., distinction between functional limitations and activity restriction, formulation of the questions, and hierarchy in the items) (Robine *et al*., 2000).

IV. THE SUBJECTIVE MODEL: PERCEIVED HEALTH AND QUALITY OF LIFE

1. Concepts and Definitions

Perceived health is a subjective measure that conveys the way in which individuals perceive their health status. It reflects the feeling, ideas, and beliefs held by the individuals concerning their health, and it does not necessarily represent the objective state of health. This perception varies according to the person. Two people with the same general state of health may have very different perceptions of it. As for the declaration of the diseases, perceived health is conditioned by the expectations of individuals concerning health, their general medical knowledge, and the information available to them concerning their objective state of health—diagnosed or undiagnosed disease and knowledge of the nature and severity of the complaint. Psychological problems also have an influence on the perception of the disease and may introduce symptoms that reduce the sense of well-being. Psychological problems may also provoke an exacerbation of signs that leads to a belief in a preexisting pathology (Connelly *et al*., 1989).

Perceived health can be measured by various types of instruments, and the data collected informs about its various dimensions, such as quality of life, well-being, and physical and mental symptoms. Synthetic instruments enable wider evaluations to be made.

2. Measuring Instruments

a. Global Approach of Perceived Health

One of the most frequently used instruments for assessing the subjective state of health is the question commonly entitled *perceived general health*. It involves assembling the general feelings of persons about their own state of health in relation to their expectations. It appears that one of the first questions of this type was asked in 1963: "How would you rate your health at the present time? (Excellent—Excellent for my age—Good—Good for my age—Fair—Fair for my age—Poor—Very Poor)" (Heyman and Jeffers, 1963).

A review of the instruments in current use and the investigations associated with them reveals the many formulations existing in the various surveys throughout the world (Sanderson *et al*., 2000). The terms used in the question and the number and type of response items proposed initiate a variety of replies and preclude comparisons between surveys. For the purpose of encouraging comparisons, the European Office of the WHO has suggested a standardized question (WHO and Statistics Netherlands, 1996): "How is your health in general?" It has five levels of response: very good, good, fair, bad, and very bad.

A particular method of response to this general type of question is the analogic visual scale. Individuals must locate their state of health on a thermometer-type vertical scale whose 0 point usually indicates death and the 100-point indicates the best possible state of health.

The interest of this question lies in its simplicity; it is easy to understand and administer, and it is easy to analyze and very informative. It includes all the physical, emotional, and social factors that enable individuals to judge their health status. Studies first revealed the correlation between replies to this type of question and mortality (Kaplan and Camacho, 1983; La Rue *et al*., 1979; Mossey and Shapiro, 1982). Many studies have subsequently confirmed this relationship, while showing a better correlation for men than for women (Idler and Benyamini, 1997). Perceived health is correlated with other health indicators, such as disability, chronic diseases, and symptoms (Kristensen *et al*., 1998) or even the consumption of medical care (Bergner, 1985).

b. Physical and Mental Symptoms

One of the methods used for measuring perceived health, associated or not with averred pathologies, consists of questioning individuals from lists of symptoms or requiring a more or less lengthy account of the symptoms using agenda-type techniques (Blaxter, 1989). Some surveys in Europe have collected symptoms according to one or the other method. The *General Household Survey* in 1977, the *British Health and Lifestyle Survey*, and the survey by the National Institute of Statistics and Economic Studies on living conditions in France in 1987 include questions on physical symptoms, such as fever, constipation, sour stomach, or others pains.

The last Decennial Health Survey in France (1991 to 1992) included a list of symptoms within the sphere of minor mental health problems, such as anxiety, sleep problems, fear of the future, loneliness, and nervousness. These types of symptoms relating to mental well-being have aroused considerable interest, and many indicators have been devised, ranging from simple lists to much more elaborate and validated rating scales. The *General Health Questionnaire* (GHQ) is a self-administered questionnaire comprising 28 questions about psychological symptoms and social insertion, enabling a total score and four subsidiary scores to be obtained (Goldberg and Hillier, 1979). As with the GHQ, there are numerous mental rating scales that inquire about symptoms of this type, and their intention is frequently to detect real pathologies, not just a feeling of discomfort. Some of these are disease specific, and they are about diseases that are very prevalent, incur a risk of prolonged hospitalization, or have a high mortality rate (Robine *et al.*, 2000).

c. Quality of Life

A complete review of health indicators must include the indicators of the quality of life. Their importance has grown in proportion to the increasing need to control the costs of health systems, and they have become invaluable for economic evaluations of costs in health systems. Paul Dolan (2000) describes four applications for these indicators of life quality: in randomized, controlled trials (e.g., to evaluate new therapies or technologies); in individual patient care to improve clinical practice; in describing, monitoring, and predicting overall levels of population health; and in informing resource allocation decision in health care. This latter category is not specific to the indicators of quality of life, but it is often proposed within this framework. These instruments also fulfill a frequently expressed need for synthetic indicators to incorporate diseases, functional state, mental state, and diverse measures of health status.

Various devices for measuring the quality of life have been developed. Alain Leplège (1999) highlights the existence of two types of indicators. The first of these, health-related quality of life indicators, is intended for measuring the effect of diseases on the quality of life. The assumption is that it is possible to separate what affects the quality of life from what does not. For the most part, these instruments combine four main dimensions:

1. The physical state of the subjects
2. Their somatic feelings
3. Their psychological state
4. Their social relations and relationship with their environment

These factors give considerable weight to functional abilities, according to the assumption that a person having difficulties in walking, for example, has a diminished quality of life compared with one who has no difficulties. A certain number of approaches combine life expectancy and health-related quality of life indicators. The *disability-adjusted life years* (DALYs) evaluate the loss associated with disability and premature death in terms of healthy life years. The *quality-adjusted life years* (QALYs) approach attributes a weighting of 0 to 1 for each period, corresponding to the quality of life associated with health status during that time. QALYs measure results in terms of increases in health, whereas the DALYs express them in terms of loss (Dolan, 2000). The *years of healthy life* (YHLs) measure life expectancy adjusted to quality.

The second type of indicator has a wider objective in that it measures the quality of life in general rather than that which is associated with health. As with health, the definitions of quality of life are numerous. The definition of the WHO adopted by Alain Leplège (1999) defines it "as an individual's perception of his place in existence, in the context of the culture and system of values within which he lives, and in relation to his objectives, expectations, norms and anxieties." Marilyn Bergner (1989) introduces the main areas in the quality of life as follows:

1. Symptoms
2. Functional status
3. Activities allied to the social role
4. Social functioning
5. Cognition
6. Sleep and rest
7. Energy and vitality
8. Emotional state or status
9. Perception of health
10. General satisfaction with life

In practice, most of the existing scales are instruments for measuring the health-related quality of life. They may, however, include aspects of the patients' lives that are only indirectly influenced by the state of health, and the frontier with instruments for measuring the quality of life is tenuous.

They may be divided into two groups, depending on the type of measure obtained: profiles and indices. The first group offers a multidimensional measure of life quality, whereas the second group provides a synthetic score (Teeling-Smith, 1988). In the latter case, the question of weighting the different items is essential.

Among the scales currently in use, some (e.g., *Quality of Life Index* [Spitzer *et al.*, 1981]) were initially constructed to measure the well-being of patients suffering from cancers or other serious diseases and receiving palliative treatment, and they can only be used for seriously ill patients (Nelson and Berwick, 1989). Others (e.g., *Nottingham Health Profile* [Hunt *et al*., 1985]) seek to evaluate the effect of diseases and treatments on health. They are not recommended for the general population, however, because they have poor discriminatory power (Leplège, 1999). The dimensions evoked vary according to scales, but physical and social fields are included in almost all of them. The number of questions may vary from about 20, as in the *Psychological General Well-Being*, to almost 140 in the *Sickness Impact Profile* (Bergner *et al*., 1981), and the length and complexity of the questionnaire does deter some people from using it on a routine basis (Nelson and Berwick, 1989). The number of conditions offered for each of these questions constitutes an important differentiation factor of the scales, and some (e.g., *Mos SF-36* [McDowell and Newell, 1996]) are reputed for having a greater sensitivity because of the greater number of response possibilities (Leplège, 1999). In certain cases, the causal link with health problems is explicit. If health problems are not the cause, it can be assumed that the person has no problems, and for certain people, this constitutes an important limit for the instruments (Strawbridge, 1998).

Specific scales of quality of life are supported by many international projects. In Europe, the *European Quality of Life Scale* (EuroQOL) (Brooks, 1996) was developed in the early 1990s. On an even broader level, the *World Health Organization Quality of Life Assessment* (the WHOQOL group, 1998), supported by the WHO, was destined to be used worldwide. This questionnaire provides an examination with six fields: physical health, the psychological domain, level of independence, social relations, environment, and spirituality.

CONCLUSIONS

All the indicators mentioned—morbidity, disability, and quality of life—are in one way or another accurate indicators of health states. Their diversity is a reflection of the multiplicity of possible approaches. The choice of indicator therefore depends solely on the aim of the measure. The indicator depends on the question asked. If the interest is focused on the need for the care of elderly people, it is important to assess disability. If the survey is devoted to the dissemination of diseases, measures of morbidity would be used. The diversity of the instruments enables differentiation and the possibility of covering different health dimensions to be able to reply in the most appropriate way to the questions asked.

Developments enabling reflection on health indicators tend to serve a double purpose in harmonizing and synthesizing the information. This desire to synthesize underlies the construction of numerous indicators. Is it therefore possible to imagine a single health indicator incorporating life expectancy, presence of diseases, functional state, and other health dimensions in such a way that it reflects the contributions of each element? Such an indicator would enable direct comparison of different population groups and follow-up of developments while also providing essential indications on each of the elements in its composition. However, this approach implies that it is possible to describe the continuum from health to disease to death in an unequivocal way and that every combination of factors leads always to a predetermined level of health (Bergner, 1985). Such an indicator still remains to be invented.

Harmonization is no easier to obtain. The proof of this lies in the profusion of scales for measuring disability or quality of life that have been produced in recent decades. International organizations are increasingly engaged, however, in procedures aimed at proposing common tools for the member states. It was in this way that the European Community set up a program for harmonizing the health information system in Europe (i.e., *Health Monitoring Programme*). The European Office of the WHO has been trying to promote the use of common measuring instruments for national health surveys, and from these activities, scales for measuring disability and instruments for measuring the quality of life have come about. Synthetic questions have aimed at providing a global approach to the state of health by covering the three health areas of perception, morbidity, and functional health.

The following three examples are questions proposed in Europe for measuring health:

1. How is your health in general? (Very good, Good, Fair, Bad, Very bad)
2. Do you suffer from any long standing illness or condition? (Yes/no)
3. For at least the past 6 months, have you been limited because of a health problem in activities people usually carry out? (Yes/no)

Acknowledgment

CHAPTER

42

Medical Causes of Death

FRANCE MESLÉ

Institut national d'études démographiques (INED), Paris, France

Whether it is a question of understanding the development of mortality or of explaining the differences between groups, there must be resort to the cause of death. Nevertheless, responses to the question "what did he die of?" are not straightforward. The same death that can be attributed to heart failure, myocardial infarction, angina pectoris, or hypertension also can be related to smoking, working conditions, stress, and diet. Must all these factors be taken into consideration, can some of them be eliminated, or can only one be retained? The first series of causes are the *medical causes* of death, and it is these to which this chapter is devoted. The second series is part of an entire socioeconomic and cultural context that is considered from different viewpoints in Chapters 48 to 52. The boundary between these two groups of causes is not certain; for example, it is not clear how to categorize alcoholism, nutritional problems, suicide, or accidents at work.

From the first attempts at collecting the causes of death to the very elaborate statistical systems employed in the developed countries, the main concern has always been to identify causes that could be prevented or treated. The search for classification criteria has led to the adoption of the *International Classification of Diseases* (ICD), which is used by most of the countries that collect cause-related mortality statistics. With the compilation of a body of strict rules for selecting the cause of death, physicians and statisticians have endeavored to improve temporal and spatial comparability. Attributing death to a single cause, however, remains simplistic in view of the complex succession of pathologic changes that finally lead to death. The study of *multiple causes* permits a better appreciation of the weighting of different pathologies but is still too limited.

The first part of this chapter retraces the path that led to the current system and stresses the difficulties shared by all classification research. After the information has been collected and classified, the analysis of levels and trends in causes of death entails the calculation of indicators that mostly employs classic demographic tools. In the second part, I describe the indicators that are most frequently used and compare their results.

I. COLLECTING, CLASSIFYING, AND CODING

The systems of health statistics in use in developed countries have been progressively constructed by two intersecting processes: setting up a system for collecting the causes of death and elaboration of a classification of these causes. A short history of this twofold process can elucidate the difficulties specific to this area of mortality statistics.

1. History of the Collection of the Causes of Death

As long as the means of combating diseases and death remained rudimentary, collecting the cause of death had little real interest for communities. The first experiments fell within the scope of the struggle against epidemics (Biraben, 1973). The records of causes on which John Graunt based his main observations were carried out after the 1592 plague epidemic in London. Following the example of Graunt, the first cause-related death tables appeared in Europe during the 18th century. In France, the first such table was published in 1767 by Jean Razoux, and it was based on the deaths recorded at the general hospital in Nîmes over 5 years. In 1776, in response to an investigation into the study of epidemics led by the Royal Medical Society, many physicians provided tables of mortality figures. In Denmark, after a plague epidemic, the cause of death was recorded in the town of Copenhagen from 1709 onward (Johansen, 1993). In Berlin, a weekly report on the causes of death was introduced in 1737 to follow the development of infectious diseases (Kintner, 1993).

In the 19th century, the first systematic cause-related mortality records were set up throughout Europe. In England and Wales, the 1837 *Registration Act* introduced, in addition to the registration of vital events (e.g., births, marriages, deaths), listing the cause of death (Fagot-Largeault, 1989). The British system was the first to be extended to the whole territory. In France, registration of the cause of death was first applied to Paris from the end of the 18th century, but it had to wait until 1855 for the system to be extended to towns with more than 10,000 inhabitants and until 1906 for the whole territory to be covered. In Scandinavian countries, the collection of the causes of death was organized at a national level in the middle of the 19th century.

By the early 20th century, the principle of a national registration of the causes of death was established in many European countries. Subsequent changes have essentially been of a qualitative nature. Medical certification of the cause of death has become the rule in Europe (Meslé, 1995a). Suitable arrangements for ensuring confidentiality most frequently accompany it, and these have contributed to an improvement in the quality of the statistics. The World Health Organization (WHO) proposes a standardized certificate, to which a number of countries have conformed more or less faithfully. This certificate enables the physician to declare several causes contributing to the death, and to better define the complex sequence of pathologic processes involved.

Although it has become standard practice in developed countries, statistics for the causes of death in most developing countries are lacking. To counter the shortcomings of the civil registration in these countries, survey methods have been developed to allow non-physicians to collect information from close relations regarding the symptoms and problems that preceded the death (an aspect that is developed by Vincent Fauveau in the next chapter). *Verbal autopsies* have contributed to a better understanding of the causes of death, particularly for children (Desgrées du Loû, 1996; Garenne and Fontaine, 1988, 1990; Zimicki, 1988, 1990). Such investigations cannot, however, replace regular statistics recording deaths by cause.

2. Classification Problems

Collecting the cause of death does not suffice for establishing a statistic. To exploit this information, it must be classified. The choice of classification criteria was at the heart of the discussions that finally produced the first version of the ICD. Successive revisions of this have not basically called into question its primary structure, but they have been responsible for some very unfortunate interruptions in the statistical series. The categorization now used by most of the countries that issue statistics on the causes of death remains organized around several lines of classification, but without any of them spanning it entirely.

a. Origin of the International Classification

The *Bills of Mortality*, on which John Graunt (1662) worked, presented the causes of death in alphabetical order. This type of classification was the one most frequently used in the first statistical collections. The first attempt at a systematic classification of diseases was in the 18th century. Anne Fagot-Largeault, in her work on *Les causes de la Mort* (1989), recorded several dozens of classifications published between 1718 and 1855. The best known was that of Boissier de La Croix, called *Sauvages* (1731), whose nosography in 10 categories was partly adopted by Linnaeus (1763) for the *Genera Morborum* (Vallin and Meslé, 1988).

The first attempt to devise a common classification for several countries appeared at the International Statistical Congress of 1853. Two physicians, William Farr and Marc d'Espine, responsible respectively for the health statistics of England and Wales and the canton of Geneva, were entrusted with "*establishing a uniform nomenclature of the causes of death applicable to all countries*" (Registrar general, 1856). Two years later, each of the two men presented his nomenclature based on different principles. The discussion that then opposed them is still a current one. Marc d'Espine (d'Espine and Farr, 1855) attempted to define a coherent classification according to the *nature of the diseases*. William Farr, more pragmatic, isolated the best-known diseases of the time, such as smallpox, scarlet fever, and tuberculosis, and classified the others according to their anatomic location. A compromise was adopted at the Congress of Paris in 1855, which tended to favor the Farr concept (IIS, 1956). Although revised three times (1874, 1880, and 1886), it was never intended to be used by any national statistical service with each country employing its own nomenclature.

In Paris, notably, a nomenclature, largely inspired by the classification proposed by Philippe Pinel (1797), was used for the cause-of-death statistics from 1802 onward. It was revised nine times during the 18th century, taking regular account of advances in medicine especially concerning progress in bacteriology, with the result that in 1886, the date of the last revision, it was quite modern in conception. When, in 1891, the International Statistical Institute decided to prepare a new international classification, the work was quite naturally entrusted to Jacques Bertillon, head of Statistical Work in the City of Paris. Taking up the nomenclature framework agreed to in Paris in 1886, he proposed, in 1893, a new international classification that was to enjoy rapid success (Bertillon, 1896).

This classification consisted of 14 divisions (Table 42–1), comprising a total of 203 categories (or items) whose precise contents were listed. Bertillon proposed two other, more abridged nomenclatures, one with 116 and the other with 44 items. Several countries and many towns immediately adopted the new classification. It was first revised in 1900 and then revised a total of 10 times during the 20th century. The number of countries using the ICD has not ceased to grow. All the countries with regular cause-related mortality statistics now use the ICD.

b. Successive Revisions

If the chapter headings of the 1893 ICD (Bertillon, 1896) are compared with those of the 10th revision adopted in 1989 (WHO, 1993) almost a century later, the changes appear to be unimportant (see Table 42–1). The number of chapters has increased from 14 to 21, but this results from an expansion of the first two chapters. The *general diseases* have been divided into *infectious and parasitic diseases*, *neoplasms*, *diseases of the blood and blood-forming organs and certain immunity disorders*, and *endocrine, nutritional and metabolic diseases*. Similarly, diseases of the nervous system and sense organs are now divided into four chapters, distinguishing

TABLE 42–1 Chapter Headings of the 1893 International Classification of Disease Compared with Those of the 1989 Tenth Revision

1893 Classification		1989 Classification[a]	
No.	Heading	No.	Heading
I	General diseases	I	Certain infectious and parasitic diseases
		II	Neoplasms
		III	Diseases of the blood and blood-forming organs and certain immunity disorders
		IV	Endocrine, nutritional and metabolic diseases
II	Diseases of the nervous system and sense organs	V	Mental and behavioral disorders
		VI	Diseases of the nervous system
		VII	Disorders of the eye and adnexa
		VIII	Diseases of the ear and mastoid process
III	Diseases of the circulatory system	IX	Diseases of the circulatory system
IV	Diseases of the respiratory system	X	Diseases of the respiratory system
V	Diseases of the digestive system	XI	Diseases of the digestive system
VI	Diseases of the genitourinary system and adnexa	XIV	Diseases of the genitourinary system
VII	Puerperal diseases	XV	Pregnancy, childbirth, and the puerperium
VIII	Diseases of the skin and adnexa	XII	Diseases of the skin and subcutaneous tissue
IX	Diseases of the locomotive organs	XIII	Diseases of the musculoskeletal system and connective tissue
X	Congenital malformations	XVII	Congenital malformations and chromosomal anomalies
XI	Diseases of infancy	XVI	Certain conditions originating in the perinatal period
XII	Diseases of old age	XVIII	Symptoms, signs, and anomalous clinical and laboratory results, not elsewhere classified
XIV	Ill-defined diseases		
XIII	Conditions produced by external causes	XIX	Injury, poisoning, and certain other consequences of external causes
		XX	External causes of morbidity and mortality
		XXI	Factors influencing health status and contact with health services

[a] Tenth revision of the International Classification of Diseases.

mental disorders from different localizations (e.g., nervous system, eye and ear).

The expansion of the chapter on *conditions produced by external causes* into two chapters on *injury, poisoning, and certain other consequences of external causes* and *external causes of morbidity and mortality* relates to another type of reasoning. This distinction, introduced in 1948, recognized the necessity with violent deaths for a double classification according to the nature of the lesion (e.g., wound, fracture) and according to the external cause (e.g., road accident, suicide). The only regrouping concerns the diseases of old age and those that are ill defined, which have constituted a single chapter since 1948. This attests to the increased precision of diagnosis and the desire of the medical community to assimilate senility to an ill-defined cause of death. The last chapter, *factors influencing health status and contact with health services*, was created by the last revision and has a particular status. Its items cannot be used as a principal cause of death.

Despite changes, the structure proposed by Bertillon has stood up well to 100 years of medical progress. It is true that because it depends essentially on the anatomic localization of diseases, it has a lesser risk of losing its relevance than a classification based on more evolutive criteria, such as etiology or avoidability.

This apparent stability of the structure masks the profound upheavals that the ICD experienced during the past century. The items have increased from 203 to more than 10,000. This enormous increase in precision reflected the progress made in the knowledge of diseases and the causes of death, which led those responsible for the nomenclature to refine the medical definitions, but it arose equally through the extension of the fields of use of the classification. When it was created, it was essentially a tool designed to serve the purpose of cause-related mortality statistics, it has been increasingly employed for all sorts of purposes in the realm of health statistics, leading to a not indispensable refinement in the study of cause-related mortality. In this respect, the title of the volumes of the 10th revision is revealing: *International Classification of Diseases and Related Health Problems* (WHO, 1993). The expression *causes of death* has entirely disappeared.

The multiplication of items with each revision would not be very troublesome if it concerned a simple phenomenon of expansion. In reality, the exchanges between the items are much more complex, making it impossible to follow a coherent series of causes of death through the various revisions. At the time of the first revisions, the authors meticulously justified the changes they introduced. This preoccupation has gradually disappeared coincidentally with the nomenclature becoming more complicated. Except in rare cases in which the body responsible for the cause-related mortality statistics has taken the trouble to operate a dual classification with the implementation of a new classification[1], it is necessary to undertake the painstaking task of comparing the contents of the items of the former classification with those of the new to identify the exchanges between items.

This comparison, term by term, of six transitions from one revision to the following one has been carried out by Institut national d'études demographiques (INED). It forms the first step in a method enabling the reconstitution of coherent series of deaths by cause (Vallin and Meslé, 1988, 1998; Mesléand Vallin, 1996). From the correspondence table established, it is possible in a second stage to define elementary associations between the items of the former and the new revision. These associations are constructed in such a way that the medical and statistical content are the same in the two revisions. In a third stage, they provide the necessary safety rail for calculating the coefficients of distribution by sex and age that permit the reclassification of deaths by sex and age from one revision to another.

The method applied to the available French data has enabled the 1925–1999 cause-related mortality series, classified according to the ninth revision of the ICD, to be obtained. For this purpose, it was necessary to deal with six transitions from the third to the ninth revision. Each of these presented particular problems, but the most acrobatic exercise was in the transition from the fifth revision (adopted in 1938) to the sixth revision (adopted in 1948). Despite an increase in precision, the first revisions of the ICD remained broadly influenced by the spirit of Bertillon and the European medical schools, especially that of France. After World War II, this changed. The revision of the International Classification was entrusted to the young WHO, in which the American school of medicine predominated. The nomenclature was overturned, and the number of items increased from 450 to 2000, producing the most detailed level ever offered. Only the structure in chapters remained relatively undisturbed.

c. Different Lines of Classification

As it appears in its most recent version, the ICD is still traversed by different lines of classification. At the most unrefined level, the division into chapters is not according to a single axis. Most chapters refer to an anatomic classification. This reflects a legacy from the

[1] The OPCS (Office of Population, Censuses and Surveys) in England undertook in 1979 a dual classification of a sample of deaths according to the intermediate lists of the eighth and ninth revisions of the ICD, which enabled the reconstruction of statistical series with constant definitions (Meslé and Vallin, 1993).

first Bertillon nomenclature and the influence of William Farr's classification favoring the classification of diseases according to their localization. Some chapters, however, come within the etiologic axis. This is the case in Chapter I for certain infectious and parasitic diseases, in Chapter II for neoplasms, and in Chapter XX for violent deaths. Other chapters refer to a time axis, such as diseases of early childhood, pregnancy, childbirth, or puerperium. The double classification axis introduced in 1948 for violent deaths has remained the exception. No other attempt has been made within the ICD to classify the different diseases according to more systematic criteria.

The diversity of classification criteria can be found at all classification levels, even within the basic items. Besides the detailed list of items and independent of the chapters, the ICD proposes different levels of groupings with a certain number of "intermediate" lists. These lists also are heterogeneous in respect of classification axes.

One of the essential aims in the study of cause-related mortality is to identify homogeneous pathologic groups whose developments may be influenced by common factors on which action may be undertaken. Many investigators have suggested more pertinent classifications than that of the simple anatomic reference. Many of these classifications focus on the concept of *avoidable mortality*. Causes of death may be divided into two groups, according to whether they are *avoidable* or *unavoidable*. This enables effective health policies to be determined, which are relevant to the first group.

The well-known distinction drawn by Jean Bourgeois-Pichat between endogenous and exogenous mortality (see Chapter 48) originates from this concept. He aims at identifying the causes of avoidable mortality that may be eliminated to reach as closely as possible the "hard core" of completely resistant causes. Working first on infant mortality, he relies more on age-specific mortality than on causes of death that are considered to be too imprecise at that age (Bourgeois-Pichat, 1951a, 1951b). In seeking to quantify a biologic mortality limit, he also distinguishes the deaths arising from exogenous causes (i.e., infectious diseases, respiratory diseases, and accidents) that it would be possible to eliminate from deaths arising from endogenous causes related to a weakening of the organism (Bourgeois-Pichat, 1952).

Employing the same idea, Erica Taucher proposed a division of avoidable deaths into several groups according to the type of intervention that could prevent them (Taucher, 1978). In this way, she distinguishes four categories of avoidable deaths (i.e., by vaccination or preventive medicine, by early diagnosis or medical treatment, by improvement in sanitary conditions, and by mixed actions) and three other categories (i.e., difficult avoidable deaths, those where the cause is ill defined, and other cases).

The concept of avoidable mortality enjoyed great popularity in the 1980s, and a European atlas of avoidable mortality was published by the European Community (Holland, 1988). It contained cause-specific mortality maps for a certain number of categories, assembling diseases that were recognized as avoidable within the framework of current medical knowledge. The limitations of such a classification are evident, however, in that revisions become continually necessary as medical knowledge advances. Although of practical use for establishing a health policy, the idea of avoidable mortality is ineffective in analyzing future developments.

The ideal solution would be to discover keys to a classification that would enable the cause of various diseases to be identified. This was the idea supported by Marc d'Espine at the International Statistical Congress in 1855, when he proposed distinguishing diseases solely according to their nature. A perusal of the classification that he had then established (Table 42–2) shows how utopian the idea was at a time when the nature of the pathologies was little understood. It is a pity, nevertheless, that the attempt declined in the mid-19th century has never subsequently been retried, except for the timid double classification of violent deaths.

After various attempts (Vallin and Nizard, 1978; Baloche and Nizard, 1973) in the area of reconstituting coherent cause-of-death series for France subsequent to 1925, we proposed the reclassification of deaths

TABLE 42–2 Nomenclature Proposed by Marc d'Espine at the 1855 International Statistical Congress

1st division:	stillborn
2nd division:	death from congenital malformation
3rd division:	death from old age or senile marasmus
4th division:	violent death or from an external accident
5th division:	death from morbid accident
6th division:	death from acute diseases, subdivided into three classes:
I.	Acute generalized or local inflammation
II.	Specific or general inflammation
III.	Inflammation allied to certain physiologic conditions
7th division:	death from chronic diseases, subdivided into two classes:
I.	Chronic inflammation or chronic diseases of local origin
II.	Chronic diseases resulting from various defects or chronic generalized diseases
8th division:	death from undetermined cause

according to an etiologic axis comprising seven major categories:

Infection
Malnutrition, intoxication (including drugs), allergy, and immunologic disorders
Accidental traumas and homicides
Neoplasms
Hereditary and congenital conditions
Degenerative disease
Suicide
Diseases of unknown origin and ill-defined or undeclared causes of death

The content of all the items in the eighth revision of the ICD was redistributed according to this axis. Most of the items only corresponded to a single etiologic category. Sometimes, however, it was necessary to distribute their contents among several causes. We then cross-referenced this etiologic dimension with an anatomic axis, which served as a safety device, having regard to the essentially anatomic character of the ICD. This type of exercise does not escape criticism that may be leveled at the fragile nature of such a classification and the arbitrary nature of certain etiologic groupings. The degenerative category, especially, is far from satisfactory. Above all, it hides our ignorance of the factors concerned with the origin of certain pathologic processes.

Nevertheless, the analysis of the evolution of mortality from this angle is not without interest. It enables, for example, more light to be cast on the real importance of infectious mortality, which is largely underestimated in the case of the ICD chapter on infectious diseases. Numerous items containing infectious diseases can be found in other chapters (e.g., influenza in diseases of the respiratory system, appendicitis in diseases of the digestive system), and the content of certain items even mixes infectious diseases with other conditions that relate to other causes. In the case of France, infectious mortality as estimated in 1925 was about 70% higher than that attributed to it in the single ICD Chapter I, and in 1978, it represented more than double of ICD Chapter I mortality (Vallin and Meslé, 1988).

It could be thought that in carrying out *ad hoc* regroupings of the items, the ever-increasing precision of the ICD enables the most pertinent classification axis to be selected. This is partly true, but it still remains for the authors of the ICD to rethink a more coherent and better-adapted classification for the cause-of-death statistics. One solution may be to develop a more systematic interlacing with an anatomic axis, unavoidable with an axis designed to define the etiologic process as precisely as possible.

3. Choice of Cause

A death results from the succession of a certain number of pathologic processes whose appearance or development may have been encouraged by other preexisting conditions. Nevertheless, most of the studies carried out on the causes of death make reference to a single cause. Identification of this so-called *initial* or *underlying cause* is decisive. With the changes in the structure according to age and cause of death that have come about over the past 50 years, this identification has become increasingly delicate, with the majority of deaths occurring among old people most frequently suffering from several chronic pathologies intertwined one with another. To ensure the coherence of statistics from one country to another, the WHO recommends a standard medical certificate of cause of death and a body of fairly strict rules for coding.

a. Rules of the World Health Organization

The death certificate has two parts (Fig. 42–1). The first is intended for a summary of the succession of the various processes that led to the death. The physician reporting the death must specify chronologically the various conditions that played a part in the occurrence of death. There is space, with three lines for three possible stages. On the first line (Ia), the physician states the condition immediately responsible for the death, entitled *direct cause*. The following line (Ib) is provided for the *intervening cause*, and on the third line (Ic), the *underlying cause* (i.e., primary or initial cause) is given. To verify the order of appearance of these various conditions, a column enables the interval between the appearance of each morbid process and the death to be recorded. The second part is reserved for the reporting of conditions that were not directly responsible for the death, but which could have contributed to it. The cause or causes appearing in this second part are the *contributory causes*. Most countries have adopted certificates quite similar to the international model.

In formulating strict coding rules, the WHO was aiming at a maximum guidance in the practice of national statistical institutes. Coding of the cause of death depends on a general rule, three selection rules, and six modifying rules (WHO, 1995).

The General rule stipulates that "if more than one condition is entered on the certificate, select the condition entered alone on the lowest used line of part I unless it is highly improbable that this condition could have given rise to all the conditions entered above it."

This principle is inapplicable if, on the last line of part I, several conditions are stated or a single condition that appears completely unlikely to have given rise to all the conditions mentioned in the previous

CAUSE OF DEATH		Approximate interval between onset and death
I		
Disease or condition directly leading to death *	*(a)* . . . . due to (or as a consequence of)	. . . .
Antecedent causes Morbid conditions, if any, giving rise to the above cause, stating the underlying condition last	*(b)* . . . . due to (or as a consequence of)	. . . .
	(c)	. . . .
II		
Other significant conditions contributing to the death, but not related to the disease or condition causing it	. . . .	. . . .
	. . . .	. . . .
* This does not mean the mode of dying, e.g., heart failure, asthenia, etc. It means the disease, injury, or complication which caused death.		

FIGURE 42–1 International form of a medical certificate of cause of death proposed by the World Health Organization.

lines. In this case, if it is impossible to obtain further information from the reporting physician, one of the first two rules of selection is to be applied.

Rule 1 stipulates the following: "If there is a reported sequence terminating in the condition first entered on the certificate, select the underlying cause of this sequence. If there is more than one such sequence, select the underlying cause of the first-mentioned sequence."

If no sequence is present, Rule 2 must be applied: "If there is no reported sequence terminating in the condition first entered on the certificate, select this first-mentioned condition."

Rule 3 may apply in addition to one of the above: "If the condition selected by the General Rule or Rules 1 or 2 can be considered a direct sequel of another reported condition, whether in Part I or Part II, select this primary condition."

In certain cases, however, the application of one of the above rules leads to the retention of an underlying cause that is of little interest from a statistical or epidemiologic point of view. The modification rules permit, for example, the choice of a different underlying cause when that which arises from the principal rules is senility, an ill-defined state, a nonserious condition, a cause allied to other conditions mentioned, a condition whose nature may be determined by other elements of the declaration, a condition comprising several stages or a late effect.

The WHO also gives a certain number of coding instructions for particular ICD items. However rigid the body of rules, the assessment of the sequences and links between various conditions remains very difficult. It may vary from one period to the next and from country to country. In addition, the obligation to select a single cause considerably reduces the information that could be analyzed. That is why attempts are increasingly being made to take account of the whole information provided by death certificates by analyzing the principal cause and all the conditions certified by the physician.

b. Analysis of Multiple Causes

The attractive path of analysis of multiple causes nevertheless encounters complex methodologic problems. The propensity of physicians to attribute the death to the concurrence of one or several causes varies considerably from one country to another or from one period to another, and this makes comparisons in space and time very difficult. In France, for example, the proportion of deaths for which the certificate contains more than one condition increased from 25% in 1955 to 67% in 1996 (Désesquelles and Meslé, 2000, 2004). Rather than a real complication in the pathologic phenomena, this must be seen as the result of a growing desire by certifying physicians to attempt a complete definition of the whole process leading finally to death.

The absence of comparability also arises from statistical practices that may evolve with the passage of time or vary between countries. In France, the National

Institute for Medical Research (INSERM), which until then had retained senility if it was mentioned on the death certificate as a contributory cause, decided in 1983 to no longer code this condition. The profile of multiple causes at mature ages was completely upset. The number of registered causes may also vary according to the statistical rules of each country (Meslé, 2000). In France, the statistics for the causes of death only include a maximum of four causes of death: an underlying cause, a direct cause, and two contributory causes. If the death certificate includes more, the coders must make a choice according to criteria that are not completely explicit. In the United States, the whole information (up to 20 conditions for a single death) contained on the death certificate is coded and may be analyzed. In practice, the custom in France is especially toward retaining a direct cause in addition to the principal one and nothing else. Death certificates only rarely contain contributory causes, and the INSERM in any case only includes two at the most. In the United States, the consideration of all the information to be found on the death certificate, and a more complete contribution by the physicians provides much more information. In any case, comparison of the two statistics based on such widely differing selection criteria could not be relevant.

Despite these difficulties, the analysis of multiple causes at a given time and in a given country may contain valuable information. Two principal paths are followed. On one hand, the number of times a condition is mentioned may be totalled, irrespective of its level of appearance. This type of approach has the advantage of highlighting the role played in mortality by certain pathologies (e.g., alcoholism, diabetes) that appear more rarely as a main cause. In a study conducted into the cause of death of people older than 60 years in France, it was shown that the proportion of deaths mentioning an endocrine disease or mental disorders was tripled when the registered causes as a whole were considered rather than the sole underlying cause (Désesquelles and Meslé, 2000, 2004).

A more precise interest may be taken in the most frequent associations in an attempt to identify the sequences of typical diseases in certain pathologic processes. In France, an association is unsurprisingly to be found between alcoholism and violent deaths, or more unexpectedly, between skin diseases and mental disorders. The problem with such analyses lies in the fact that significant associations can only be identified by using a very delicate level of detail. It is therefore very difficult to formulate a general picture, but it does nevertheless permit a very precise study of certain pathologies.

Analysis of the multiple causes of deaths is still in its infancy. Nevertheless, it will constitute an important challenge for the study of cause-related mortality in the future. The next step will entail the formulation of common rules for choosing and classifying the multiple causes, such as was done by the WHO for choosing the underlying cause of death. It is only in this way that it will be possible to really profit from this type of study.

II. ANALYTIC INSTRUMENTS

After collection and classification, the development of cause-related mortality may be analyzed by means of several indicators that generally assume the hypothesis of independence between the causes (discussed in Chapter 44). In reality, the hypothesis of independence between causes of death is most probably unsatisfactory. It constitutes, nevertheless, a useful simplification for carrying out a first description of cause-related mortality. The introduction of dependence between causes would entail the ability to dispose at the very least of a good recording of all the causes contributing to death, or better still, information on the cause of the disease.

1. Rates by Age and Standardized Rates

The use of rates (age-specific or standardized rates) is common in describing trends. Age and cause-specific rates are a simple way of measuring cause-related mortality with the advantage of being additive: the sum of death rates by cause equals the death rate from all causes. Table 42–3 gives the standardized male mortality rates in 1970 and 1992 in England and

TABLE 42–3 Standardized Mortality Rates per 100,000 Men for Seven Groups of Causes in England plus Wales and in Russia in 1970 and 1992

Causes	England and Wales		Russia	
	1970	1992	1970	1992
Infectious diseases	10	5	57	25
Neoplasms	328	322	313	361
Cardiovascular diseases	851	550	999	1098
Diseases of the respiratory system	299	142	228	134
Diseases of the digestive system	39	34	48	56
Other diseases	95	104	61	73
Violent deaths	62	46	245	300
All causes	1684	1203	1951	2047

Wales and in Russia for seven major groups of causes. The use of a standard population, in this case the European standard population proposed by the WHO, enables a comparison of cause-related mortality levels in time and space, independent of the differences in the age structure of the population. It is possible in this example to compare the cardiovascular mortality trends in England and Wales and in Russia. Starting at a slightly higher level, the Russian mortality from this cause increased between 1970 and 1992, whereas in England, it showed a net reduction, with the result that in 1992 the first was twice as high as the second.

Because this concerns an additive measure, it is possible also to measure the share of a cause of death in the total mortality. In the two countries, cardiovascular mortality accounted for 51% of the total mortality in 1970. In 1992, its share had reduced to 46% in England and Wales, whereas is reached almost 54% in Russia.

It is often forgotten, however, that the standardized mortality rate (see Chapter 15 of Volume I) is not an absolute measure of mortality. According to the standard population chosen, with the same age-specific death rates, the value of the standardized rates may vary and the relation between the two measures become reversed. This may be the case if comparison is desired for countries or causes in which the age structure of mortality is very different. Let us take the example of Russia and England and Wales once more. Figure 42–2 provides two versions of the annual evolution of the standardized rates of mortality in the two countries for three large groups of causes: neoplasms, cardiovascular diseases, and violent deaths.

The first was obtained through the WHO European standard population (see Fig. 42–2A). It shows a fairly classic hierarchy of causes of death in the two countries: cardiovascular diseases, then neoplasms, and finally violent deaths, at a very low level in England and Wales, but very close to neoplasms in Russia. The same divergence in the development of cardiovascular mortality is found as that described above, whereas the deaths from neoplasms are very close—slightly falling in England and rising in Russia, with the two curves intersecting in the mid-1980s.

Figure 42–2B presents, for the same causes and the same countries, the trends in the standardized rates calculated this time according to the world standard population that is also proposed by the WHO. At first sight, this new picture appears to be similar to the previous one. It differs from it, however, in a certain number of respects. The level of the standardized rates is much less high, irrespective of the cause. The younger age structure of the world population gives more weight to the ages where mortality is low. This difference between standardized rates according to the standard population adopted is all the more important when the cause of death especially affects advanced ages. In the case of Russia, employing the world standard population reduces the rates of mortality from cancer more than those for violent death; with this reference population, violent mortality occupies second place for almost the whole period.

Between Russia and England and Wales, at the level of these big regroupings of causes, the change in the reference population does not seriously change the commentary suggested by the reading of Figure

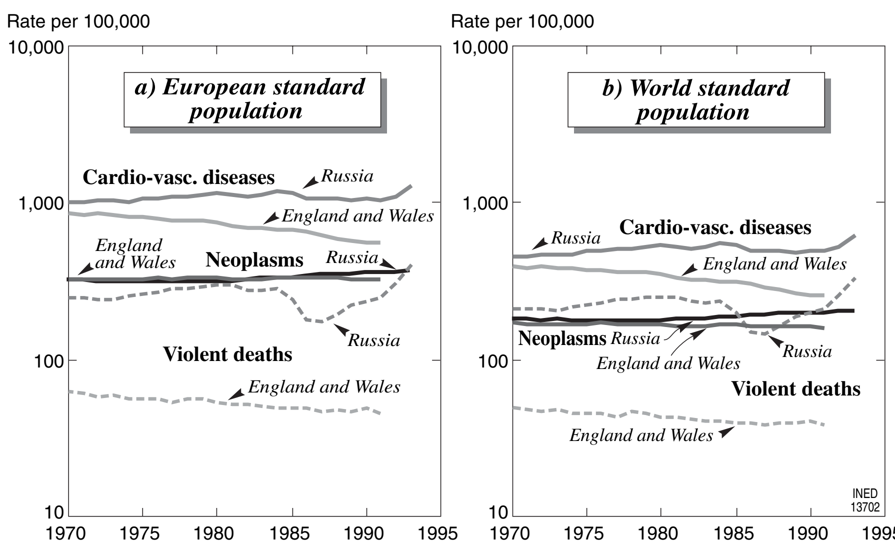

FIGURE 42–2 Annual trends of standardized mortality rates by neoplasms, cardiovascular diseases, and violent deaths in Russia and in England plus Wales according to the type of standard population employed.

42–2A. Nevertheless, a greater divergence is to be noted for neoplasms. The Russian cancer mortality, at the same level as the English one until the 70s, then rises above it very markedly. Cancers weigh more heavily on the young ages in Russia than in England and Wales. The use of a younger standard population penalizes the former.

2. Cause-Related Life Tables and Cause-Elimination Life Tables

Although, despite these reserves, the standardized rate remains a pertinent indicator of the trend and level of cause-related mortality, it does not enable cause of death and expectation of life to be directly related.

It is possible from the age- and cause-specific death rates to calculate the probabilities of dying by age for a given cause and to establish cause-related life tables (Monnier and Nizard, 1985; Baloche and Nizard, 1974; Schwartz and Lazar, 1961; Elveback, 1958; Berkson and Gage, 1950) (see Chapter 9 of Volume I). From these tables, the average or median age at death for a given cause can be calculated. The average age of death or expectation of life resulting from the effect of a single cause is not a very interesting indicator. In France, for example, life expectancy resulting from the action of cancer mortality changed, between 1925 and 1991, from 92.9 years to 87.7 years for men and from 91.5 years to 94.4 years for women. It certainly indicates the increase in male mortality and the decline in female mortality, but these figures do not tell us very much—what is the relevance of life expectancy related to the effect of a single operative cause? It would have to be possible to compare it to life expectancy in the absence of any cause other than the inevitability of death (i.e., a sort of maximum possible life expectancy), and this assumes the resolution of a very controversial question (see Chapter 48). The median age at death from a given cause informs more about changes in the age structure of cause-related mortality. Graziella Caselli (1993) showed how this median age at death had risen during the century for death from all causes. She cites, for example, the case of infectious diseases in Italy, for which the median age had increased from the 10–14 age category in 1930 to that of 75–79 years in 1985. At the same time, this median age varied little for accidents, from only 50–54 years to 55–59 years. This is an indicator that bears witness faithfully to the greater or lesser precociousness of a cause of death.

Nevertheless, if life expectancy resulting from a single cause is in itself not significant, and it is possible to ask what the expectation of life would be if one succeeded in completely suppressing certain causes of death. From the early 19th century, Emmanuel Duvillard had attempted to measure the increases in life expectancy anticipated from the elimination of smallpox, which it was then hoped to eradicate by means of a vaccine (Duvillard, 1806). Other authors have subsequently been interested in this question (Benjamin and Overton, 1981; Vincent, 1966; Greyville, 1954). It was also the idea supporting the work of Jean Bourgeois-Pichat when he differentiated endogenous and exogenous mortality to determine the anticipated gain from the complete suppression of mortality allied to external agents (see Chapter 48).

By calculating the difference in life expectancy from all causes and life expectancy obtained by removing one cause of death, we obtain a measure of the impact of a specific cause of death on life expectancy (Table 42–4).

At first sight, we have here a clear response to the question asked: what gain, in terms of life expectancy, can be anticipated by the removal of such and such a cause of death? According to the example proposed, in 1925, it was the eradication of infectious diseases that would have enabled the most effective gains in life expectancy (11.6 and 10.9 respectively according to sex). In 1978, suppression of this pathology did not contribute more than an additional year to life expectancy. On the other hand, the disappearance of deaths due to cancer enabled a gain of 3.9 years for men and 3.0 years for women, and that for degenerative disease (basically due to diseases of the circulatory system) was a gain of 6.4 or 6.7 years according to the sex.

The response is in reality not so simple. If the gains anticipated by the elimination of each cause are added

TABLE 42–4 Gain in Life Expectancy at Birth (Years) Anticipated by the Elimination of Certain Causes of Death in 1925 and 1978 in France

Cause of death	1925		1978	
	Men	Women	Men	Women
Infectious process	11.6	10.9	1.0	0.9
Neoplasms	1.1	1.6	3.9	3.0
Hereditary process	2.8	2.4	0.8	0.7
Degenerative disease	6.1	7.2	6.4	6.7
Malnutrition, intoxication	0.9	0.9	1.0	0.6
Diabetes	0.1	0.1	0.1	0.2
Accidents and homicides	1.4	0.8	1.8	1.0
Suicides	0.5	0.1	0.6	0.3
Total	24.5	24.0	15.6	13.4

From Vallin and Meslé, 1988.

up, the difference between the expected and maximum supposed life expectancy are not to be found. For the results presented earlier, the supposed maximum expectation of life was 101.5 years. In other words, to close the life tables, the life expectancy at 100 years was fixed at 1.5 years. The sum of expected increases in 1978 amounted to 15.6 and 13.4 years according to sex. If these gains in life expectancy in 1978 are added up, we obtain 85.4 years and 91.3 years, which is well short of the maximum of 101.5 years, which would logically be obtained if all the causes were removed.

This arises because the calculation takes account not only of the mortality due to the particular cause, but also of the mortality due to other causes. The results presented in Figure 42–4 were obtained by calculating the anticipated gain thanks to the elimination of one cause, all other causes remaining unchanged. If we now proceed successively to eliminate all the causes, the effect of each cause on life expectancy will depend on the rank order of elimination of the cause. The later this is eliminated, the greater will be the anticipated gain.

This gain is not directly related to the level of cause-related mortality. In 1978, women would have gained 3 years' life expectancy from the elimination of cancer, but in 1925, the difference was only 1.6. However, female mortality due to cancer was higher in 1925 than in 1978. There again, this paradox arises due to the fact that the elimination of this cause comes about in a certain context in which all the other causes of death intervene.

The simplicity of this indicator is only superficial. It must be handled with care, and does not, in any case, give a clear picture of the relations between life expectancy and causes of death.

3. Contribution of Each Cause to Differences in Life Expectancy

To have a measure of the weighting of each cause of death in life expectancy, several researchers have developed methods enabling differences of life expectancy between two populations to be allocated according to age or cause (Pressat, 1985; Arriaga, 1984; Andreev, 1982; Pollard, 1982, 1988, 1990) (see Chapter 16). Devised at approximately the same time, these various methods give very similar results (Toulemon, 1996).

They possess the enormous advantage of providing an additive decomposition of the life expectancy differences. According to the question we wish to answer, the basic elements of the decomposition can be regrouped over a certain interval of ages or according to the different causes of death.

It is therefore possible to quantify the contribution of the different causes of death in trends of life expectancy at birth (Table 42–5). Even if expectation of life at birth increases, certain causes of death may act negatively in hindering the progress. This is the case for the French example in Table 42–5. Over the last 4 decades, average duration of life has constantly increased, thanks primarily to the decline in mortality from infectious diseases and diseases of the respiratory system, then, more recently, to the fall in cardiovascular mortality (i.e., cerebrovascular diseases and other cardiovascular diseases). Between 1952 and 1991, male expectation of life has gained 8.5 years, for which infectious diseases and respiratory diseases account for 3.1 years and cardiovascular diseases as a whole for 2.8 years. Other causes, however, have hindered the increase in life expectancy. This is the case for cancers

TABLE 42–5 Contributions of Eight Major Groups of Causes to Variations in Life Expectancy in France during the Past 4 Decades

(–0.39 years) and violent deaths over the first 2 decades.

The contribution of the causes of death to the differences in life expectancy between the sexes can also be calculated (Table 42–6 and Fig. 42–3). Table 42–6 may be read in two ways. Adding up the lines gives the participation of the different ages to these differences, and that of the columns the participation of the main causes. It is also possible to analyze which cause of death plays a major role at a certain age or even which is the age for which the contribution of a cause is most important.

With the difference in life expectancy between the sexes observed in France in 1990, it is violent deaths that play an overwhelming role from 15 to 29 years: 83% of the total contribution of this age group. Conversely, it is from 30 to 59 years that the contribution of violent deaths is greatest in absolute value: 0.71 per year as against 0.59 per year between 15 and 29 years, and much less for the other ages. The graphical representation of these contributions by age and cause is equally striking (see Fig. 42–3).

In the search for an indicator of the weighting of causes of death in life expectancy, decomposing the differences in average duration of life provides a tool that is interesting but remains relative, because it is always necessary to quantify the contribution of a cause of death within a difference between two life expectancies. An extension of this method (Vallin and Meslé, 1988) makes possible to measure the weighting of pathology in life expectancy at any given time, and for a given year to calculate the contribution of a cause to the difference between the life expectancy with all causes calculated for that year and the anticipated

TABLE 42–6 Contributions by Age Groups of the Major Causes of Death to Differences in Life Expectancy between the Sexes in France, 1990

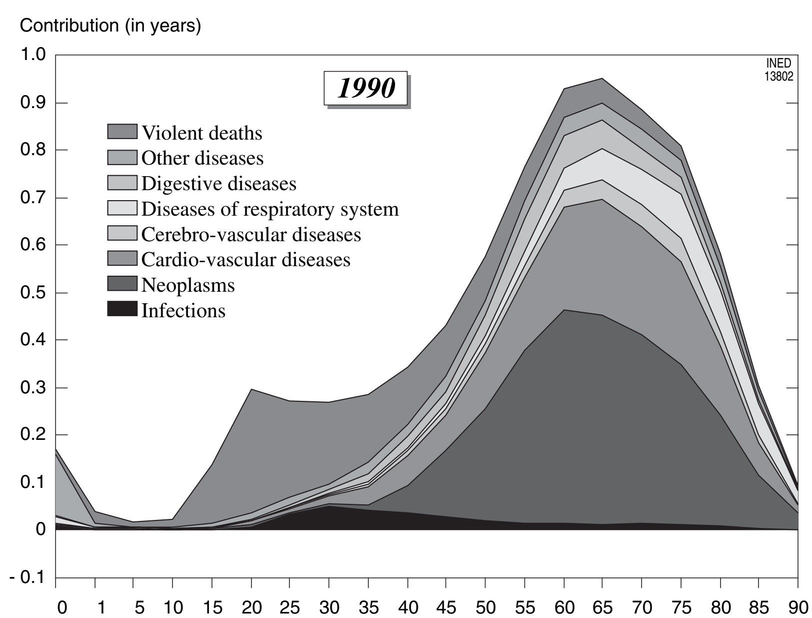

FIGURE 42–3 Contributions by age groups of the major causes of death to differences in life expectancy between the sexes in France, 1990. (From Meslé, 1995b.)

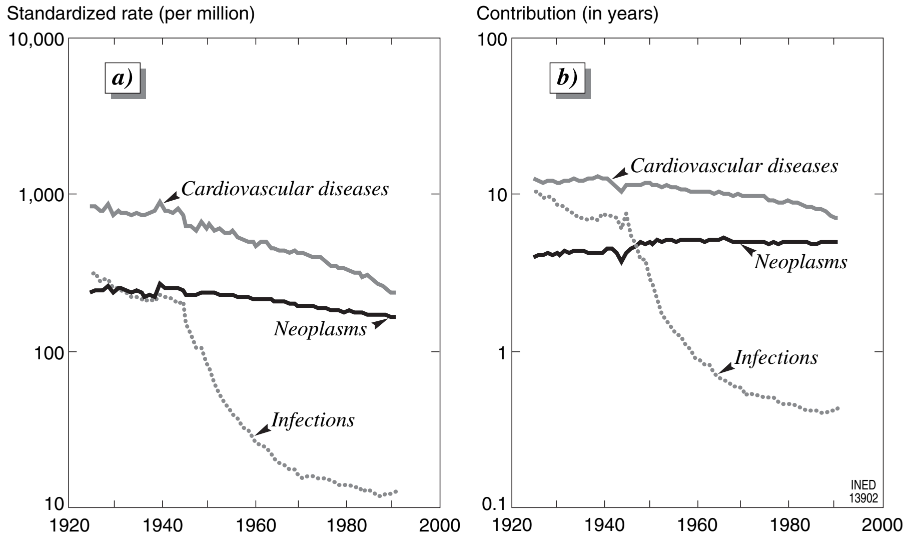

FIGURE 42–4 Comparison between the trend of the standardized mortality rate **(A)** and the trend of the contribution to the difference in life expectancy at birth and the maximum of 101.5 years **(B)** for three large groups of causes. Data are for females in France.

maximum life expectancy in the absence of all mortality before 100 years and with an average of 1.5 years of life to be lived after that age. The comparison between the trend of this contribution and that of the standardized rate is interesting (Fig. 42–4).

These two measures of the impact of infectious mortality develop in a very similar way—the lessening of the contribution of this pathology to the difference between life expectancy and 101.5 years faithfully follows the decline in the standardized rate of mortality. In the case of cardiovascular diseases, trends follow the same direction, but the decline in contribution is much slower than that of the rate. For certain periods, the movement is even contrary—during World War II, the standardized rate of cardiovascular mortality augmented, whereas the contribution of this cause to the limitation of life expectancy was diminishing. The paradox is even more evident for cancer mortality. Seen from the viewpoint of the standardized mortality rate, mortality was falling, whereas from the viewpoint of contributions, it was rising; at least until the end of the 70s.

The change in the standardized rate takes account of the evolution of the risk of death from a cause, independent of other causes. On the other hand, in the development of the contribution of pathology to the difference between life expectancy and a maximum of 101.5 years, changes in the structure of cause-related mortality also intervene. The contribution of cardiovascular diseases decreased during the war, because the increase in mortality due to this cause was relatively less important than that due to infections, and especially to violent deaths. Similarly, the increased contribution of cancers in a period where cancer mortality was diminishing is due to the fact that this reduction occurs at a much slower rate than the reduction in other conditions (infectious or cardiovascular diseases). This indicator therefore depends both on the level of mortality due to a cause and on the weighting of the cause in the total mortality.

4. Potential Years of Life Lost

Epidemiologists often use another measure of cause-related mortality: *the potential years of life lost* (Jenicek and Cléroux, 1982; Romeder and McWhinnie, 1978). This indicator quantifies the number of years that will not be lived because of premature deaths, occurring before a certain age (e.g., 70 years). The more a cause produces death at early ages, the more important will be the potential years of life lost.

The use of such an indicator presupposes, therefore, that an age is chosen at which death would subsequently be accepted as normal, whereas it would be considered premature if it happened earlier. In France, cancers were responsible in 1990 for a standardized rate of potential years of life lost between 1 and 70 years that was much higher than from other causes (Table 42–7). They were followed by cardiovascular diseases and by violent deaths. In this case, we have an indicator of the precociousness of a cause of death, rather than a real level of mortality due to this cause.

TABLE 42–7 Potential Years of Life Lost (Standardized Rates and Proportions) between 1 and 70 years and between 1 and 75 years in France, 1990, for Both Sexes

Groups of causes	PYLL, 1 to 70 yr		PYLL, 1 to 75 yr	
	Rate (per 100,000)	Proportion (per 100)	Rate (per 100,000)	Proportion (per 100)
Infectious diseases	655	3.0	797	2.8
Neoplasms	9008	41.7	11933	41.2
Cardiovascular diseases	3374	15.6	5070	17.5
Cerebrovascular diseases	958	4.4	1497	5.2
Diseases of respiratory system	780	3.6	1196	4.1
Diseases of digestive system	1453	6.7	1835	6.3
Other diseases	1609	7.4	2222	7.7
Violent deaths	3812	17.6	4385	15.2
All causes	21649	100	28935	100

PYLL, potential years of life lost.

The main problem arising from this indicator lies in the arbitrary nature of the fixed age limit. Table 42–7 compares the results obtained when the age limit is increased from 70 to 75. The integration of a supplementary group of ages quite clearly increases the standardized rate of potential years of life lost. The relative increase is not the same for all causes, and this means that the distribution of these lost years of life is modified. In the current example, the proportion of neoplasms varies little, but that of cardiovascular diseases increases appreciably, and the contribution of violent deaths diminishes.

To limit the arbitrariness of the choice of age limit, certain authors have proposed adopting expectation of life as the reference age (Estève *et al.*, 1993). In this way there is an estimate of the number of years lost in relation to the average number of years theoretically remaining to be lived. As the study authors themselves stress, the comparison in the time and space of the results obtained is not of great significance, because the calculations were based on different life expectancies.

CONCLUSIONS

Whatever the imperfections of the methods for measuring and the difficulties of ensuring comparability of the data in time and space, a thorough analysis of the causes of death has become indispensable for understanding the changes in mortality and for predicting its future developments. Throughout the 20th century, identification of the cause of death has continually improved due to progress in medical knowledge and the development of increasingly standardized tools for collecting and classifying. With ever-increasing concentration of deaths in older age groups, improved understanding about the morbidity processes leading to death will require perfecting newer analytic methods that take account of the multiplicity of causes and their interactions.

The Assessment of Causes of Death in Developing Countries

VINCENT FAUVEAU

United Nations Population Fund, New York, United States

The importance of collecting and analyzing causes of death for demography and public health has been much emphasized (Lopez, 1990; Vallin and Meslé, 1988; WHO, 1987, 1994). The concept of mortality by cause has become predominant in the analysis of the evolution of general mortality and the mortality of particular groups (e.g., infants, children, women of child-bearing age), in comparing the mortality of different groups (e.g., rural–urban, boys–girls, rich–poor) or evaluating the effect of public health interventions (e.g., vaccinations, mass treatment, hygiene). Health ministries of every country now have a medical statistics department responsible for publishing the main causes of death, often relying on the famous World Health Organization (WHO) International Classification of Diseases (ICD), which was adopted for the first time in 1893, or on variants adapted to local conditions.

If most developed countries fulfill the main condition for this analysis (i.e., good quality of collected data) because of their rigorous medical tradition and the generalization of deaths in medical environments, the same is not true for developing countries. In situations where most deaths occur outside of a medical context, it has become necessary to find alternative solutions to the problem of establishing causes, either in experimental and limited conditions (on sample groups or in certain pilot zones) or preferably as a routine practice. In this latter case, the first issue is to ensure that all deaths in the population sample are recorded, despite the absence of a reliable civil registration system. To consider only deaths occurring in a hospital environment does not guarantee representation and is therefore not suitable for any satisfactory statistical analysis from a public health point of view.

This chapter provides the historical background of the origins of alternative methods of establishing causes of death in developing countries, before introducing a detailed description of the practice of *verbal autopsy*, its applications and its limitations. Other possible techniques are also mentioned. The chapter ends with a discussion of the conditions of extension for the use of these alternative methods of collecting causes of death.

I. BACKGROUND

Arab doctors were the first to perform autopsies in an attempt to understand causes of death. In medieval Europe, autopsies were rarely performed, and if so, they were done illegally. It was not until the beginning of modern medicine at the end of the 18th century that this technique was officially accepted, which is now well codified.

As France Meslé described in Chapter 42, medical certification and its corollary, the classification of the causes of death, became widespread in France during the 19th century, eventually leading to the development of the international terminology that has been several times revised by WHO (Vallin and Meslé, 1988; WHO, 1977).

Regarding the establishment of causes of death in countries with incomplete statistics, in 1956, Yves Biraud published the first article recommending the use of information supplied by a deceased person's family to estimate the cause of death. In 1978, WHO started publishing lists of causes of death for the use of nonphysicians working in developing countries.

The first demographic studies aimed at collecting information on causes of death in the general population were conducted in Khanna, Northern India, between 1955 and 1960 (Wyon and Gordon, 1971) and in Companiganj, Bangladesh, between 1975 and 1978 (Chowdhury and Khan, 1980). In the same period, a team from Johns Hopkins University were starting work on a longitudinal study of a health program in rural Punjab in Narangwal, India. Among those researchers, Arnold Kielmann and colleagues (1983) were the first to coin the term *verbal autopsy*, a questionable expression but one which is now universally used.

Shortly after and in parallel, other researchers worked on the same subjects in large longitudinal population study laboratories, which were run by demographers and physicians in Matlab, Bangladesh (Zimicki *et al*., 1985; D'Souza, 1981), Niakhar, Senegal (Garenne and Fontaine, 1988, 1990), Kenya (Omandi-Odhiambo *et al*., 1984), and Gambia (Lamb *et al*., 1984). Verbal autopsy methods were gradually theorized, discussed and refined, particularly in Matlab (Fauveau *et al*., 1994; Zimicki, 1988, 1990).

The first international seminar organized to share different experiences of verbal autopsies took place in Baltimore in March 1989 at the Johns Hopkins University School of Public Health (Gray *et al*., 1990). During this meeting, the issue of multiple causes and that of putting verbal autopsies into algorithms, particularly those concerning infant mortality, were discussed for the first time. In 1994, a second seminar was organized by the WHO at the London School of Hygiene and Tropical Medicine, focusing on the use of the verbal autopsy for the causes of female deaths and particularly for maternal deaths. Once more, the debates were focused on the analysis of multiple causes, the design of algorithms, and on validation problems (WHO, 1995).

Since then, the verbal autopsy method has been widely used, particularly on samples from some demographic and health surveys, and numerous publications report its use in several developing countries. The Department of Reproductive Health and Research of the WHO included the methodology of verbal autopsy in their publication on maternal deaths, *Beyond the Numbers* (WHO, 2003).

II. THE VERBAL AUTOPSY METHOD

Verbal autopsy can be defined as "a technique of using the information acquired from a recently deceased person's entourage to reconstruct the events and the symptoms that preceded the death so as to deduct a medically acceptable cause or causes of death" (Fauveau, 1995). This definition (every word counts) contains the limitations of the method, particularly concerning the validity or the official recognition and the medically acceptable aspect. Its advantage remains its capacity to compensate for the absence of a medical certification in regions where that is not available. Of the six successive stages of the method and their potential variations described hereafter, the most difficult is the first, the stage that affects the statistical validity of the entire procedure.

Stage 1: Gathering and Recording Death Information

To begin the procedure, all deaths occurring during the considered period in the relevant age group (or if necessary, in all age groups) must be counted and recorded. The information should include the date and place of death, sex, age (date of birth if known), and name and address of the deceased person. This very basic but precise task, which does not require any medical knowledge, is generally undertaken by a representative of the demographic surveillance system or of civil registration. Using only deaths occurring in a hospital environment must be avoided as in most cases, these deaths constitute a biased group, and they are certainly not representative of all deaths.

Stage 2: Interview on the Cause of Death

The information gathered on the deaths is transmitted to a health agent (or health worker) who visits the family or friends of the deceased, ideally within a period of 1 to 3 months, to interview them about the circumstances of death in the local language. This interview, which must not under any circumstances be perceived as a police interrogation, consists of two parts. First, a free narration of the illness is recorded with emphasis on the chronologic order of events. Second, the important elements are revisited for details of the patient's observed symptoms or at least those symptoms perceived and described by the family. It is recommended that this interview is conducted in the presence of two or three people who were present during the progression of the illness to be able to optimize the details by cross-checking. The interviewer must be very knowledgeable in the local pathology and in the locally used names and explanations, but she or he must not be responsible for the diagnosis.

Stage 3: Interpretation by a Physician or an Experienced Health Worker

The reported facts are then interpreted by a public health doctor, an experienced nurse, or a community health worker experienced in the interpretation of local symptoms to make a diagnosis of the cause of death: first the *principal cause*, which was responsible for the original illness or the sequence leading to the death; then the *immediate cause*, which directly caused death; and finally, the *associated causes*, ailments that were not responsible for the patient's death but which contributed toward the chain of events leading up to death. The health professional notes his or her conclusions and then compares the causes with existing lists consisting of the categories of causes that are being investigated and prepared by the public health authority. In the most rigorous variant of this process, the reported facts are given to three health professionals who independently write their conclusions. A fourth person then compares the diagnoses by applying the rule of simple majority. If all three readers have reached the same conclusion, it is accepted; if only two have come to the same conclusion, a second reading takes place before the conclusion is accepted; and if none of the three readers is in agreement with the others, the case is filed in the *impossible to attribute* category.

Stage 4: Returning to the Field for Incomplete Cases

When the readers indicate that they have been unable to make a diagnosis in the absence of precise information, they must list on the form the missing information required to proceed. The visiting health agent (or field worker) must return to see the deceased person's family to try to collect the necessary information before resubmitting the completed forms into the system.

Stage 5: Coding and Classifying

There are many classification and coding systems. After a system has been selected, it is important to adhere to it in the long term to be able to follow the evolution of the causes of death over the years or compare the development of certain causes over a certain period. WHO's detailed ICD list is not directly useable for verbal autopsies because it is too complex and detailed, and it is too often based on precise medical diagnoses, relying greatly on anatomic-pathologic information. However, it is useful to refer to its main categories by allocating the first number of a three-digit code according to large categories (e.g., respiratory diseases, diarrheal diseases, accidents). It is also often useful to add certain codes according to a combination of pathologies or frequently observed local causes. For example, for a death attributed to a complication of measles, three different codes can be used: one for death due to an immediate neurologic complication of measles (i.e., during eruption), another for a death due to a late respiratory complication, and a third for a death due to a late digestive complication (i.e., an invasive type of diarrhea). During the analysis, this cause of death could therefore be classified as neurologic, respiratory, digestive, or infectious (measles) according to the chosen orientation. It could also be useful to add a prefix or a suffix to indicate the diagnostics confirmed by a paraclinical examination (e.g., laboratory, radiology), even if these cases are rare. Special procedures are recommended for certain categories of causes, representing three cases in particular.

a. Deaths in the Neonatal Period

Deaths in the neonatal period are great in number but difficult to attribute using information collected by verbal autopsy and particularly so in regions where supernatural explanations persist (e.g., magic, linked to the "evil eye"). To better process the causes of these deaths, particular attention must be paid to the chronology of events with regard to the birth. For example, on the basis that it is biologically nearly impossible to die of neonatal tetanus before the fourth day of life and that these deaths are rare after the fourth week of life, the diagnosis of neonatal tetanus can be refined by differentiating it from neurologic complications due to anoxia, obstetric trauma, or other neonatal infections. By trying to determine the length of the child at birth rather than the weight (which is rarely measured), knowledge of deaths linked to prematurity and intrauterine growth retardation can also be improved (Fauveau *et al*., 1990c). If a special questionnaire is used for all neonatal deaths, it would be of no use for any other deaths (Srivastava *et al*., 2001).

b. Deaths from Malnutrition

During an interview on infant death, particular attention should be paid to symptoms of malnutrition and their chronology. Except for certain cases of acute malnutrition, these symptoms appear progressively and are not immediately noticed by the mother. In general, neither the traditional growth chart nor measurement of weight can be relied on. It is often remarks made by family members who only see the child occasionally that draw attention to the condition. Moreover, coding and classification of malnutrition will be different according to whether it is to be presented as one cause of death amongst others or as an underlying cause, which is more plausible and more useful from a public health point of view (Fauveau *et al.*, 1990a).

c. Deaths of Women of Child-Bearing Age

Regarding maternal mortality, as in the previous case, and especially in those regions where the attitudes and roles concerning female health problems are very distinct (in particular when men have little access to information concerning obstetrics and gynecology), it is highly advisable to entrust the verbal autopsy questionnaire to a female health worker who is respected in the local community and who is knowledgeable in local practices and beliefs. To detect the specific role of the complications of an induced abortion, a sensitive questionnaire should be used to determine the presence and regularity of menstrual periods, the respondent's (or her family's) awareness of pregnancy in the early stages, her attitude and comments regarding her wish to carry the pregnancy to term, contraceptive practices and methods used, and social, economic, or marital problems (Fauveau *et al.*, 1988, 1989) (see Chapter 45).

Stage 6: Analysis and Publication

An initial analysis can be produced simply with a spreadsheet (EPI-INFO type) which is capable of calculating the exact age of the person at the time of death from the dates of birth and death (when known). The results are presented in tables organized by age group, sex, and categories of causes of death. When several years of observation are available, they can be grouped in the same table, thereby neutralizing the effect of annual variations (especially if the number of cases is very low); otherwise, the annual results can be presented to analyze the trends. Obviously, aggregating the causes of death for a whole population, including all age groups, should be avoided because of the differences in cause of death according to age and the variations of age structure. The classic table includes the absolute number of deaths by each category of cause in one column and the percentage of each category with regard to all deaths in the group in another column. In this way, the *proportional mortality rate* is obtained. This is the most frequently used indicator in publications concerning these types of data. However, if denominators are available, represented by the mid-year population or the population of the middle of the period under scrutiny, a third column of *cause-specific mortality rates* per 1000 or 100,000 persons at risk by age group and sex can be introduced. Table 43–1 gives an example of both indicators.

Probabilities of dying for 1000 live births can also be constructed, particularly for infant and child mortality. It is interesting to compare causes of death between years (or periods before and after a program), between regions (e.g., a control zone with a case zone), and between sexes using appropriate statistical tests (i.e., comparison of rates or proportions).

III. USES OF THE VERBAL AUTOPSY

A first use of the verbal autopsy method is to show the comparative importance of the main causes of death in a given population and in a given age group, either in a relative way by ranking them, or in an absolute way using cause-specific mortality rates. This application can be made at a local level in a population laboratory (Hoj *et al.*, 1999; Marsh *et al.*, 1993; Chowdhury *et al.*, 1991; Fauveau *et al.*, 1991d; Fauveau *et al.*, 1989; Omandi-Odhiambo *et al.*, 1984) or at a national level from a representative sample, such as a demographic and health survey (MSP, 1990) or by following the evolution of specific causes.

The verbal autopsy technique also is used in guiding the decision-making process that precedes the implementation of a specific intervention or set of interventions, such as the targeting of nutritional programs (Fauveau *et al.*, 1990a) or the choice of an optimal age for vaccination (Fauveau *et al.*, 1991a).

A third category of use is in evaluating the effect of specific programs on the corresponding cause-specific mortality. One of the classic objectives of public health is to evaluate the effect of interventions (preventative and curative) by a comparative examination of mortality rates. In developing countries, analyses were usually limited to crude death rates or restricted to certain age-groups and sex, such as infant or childhood mortality and mortality of women of child-bearing age (Lamb *et al.*, 1984). However, under pressure from international organizations and in connection with the establishing of large-scale vertical programs to fight epidemics or endemic diseases, it quickly became apparent that it was necessary to refine the presentation of mortality rates by subdividing them into cause-specific rates. In the same way, analysts can combine the cause-specific mortality rates with those by age and sex to further refine the evaluation. This difficult exercise was used to evaluate measles and tetanus vac-

TABLE 43–1 Proportional Mortality Rates and Cause-Specific Mortality Rates by Sex for Ages 1 to 4 Years According to Verbal Autopsy in Matlab, Bangladesh, 1986 to 1987

Causes of death	Boys (n = 24,219)			Girls (n = 22,652)			Difference between rates
	N	CSMR (per 100)	PMR (%)	N	CSMR (per 1000)	PMR (%)	
Acute watery diarrhea	12	0.5	4.7	22	1.0	5.2	0.5

cination programs (Koenig *et al.*, 1991; Aaby *et al.*, 1988), programs to reduce maternal mortality (Fauveau *et al.*, 1991c), programs to reduce mortality from acute respiratory infection (Fauveau *et al.*, 1992a; Bang *et al.*, 1990), and programs to reduce mortality caused by acute diarrhea (Fauveau *et al.*, 1992b) or malaria (WHO, 1991). Verbal autopsy has also been used in therapeutic tests on tropical pathology (Pacque-Margolis *et al.*, 1990).

A fourth category of the use of verbal autopsy applies to the selection of strategies or *packages of health interventions* with specific objectives, such as to reduce the excess mortality of girls compared with boys in certain communities (Fauveau *et al.*, 1991b) or to optimize the cost-effectiveness of a health program (Attanayake *et al.*, 1993).

Verbal autopsy techniques also can be used to make international comparisons. For instance, in the case of the International Study Group on Diarrhoeal Mortality (Victora *et al.*, 1993), in a coordinated multicenter study, a common methodology was applied to several sites around the world and comparative results were then produced.

IV. PROBLEMS AND LIMITATIONS OF THE VERBAL AUTOPSY

Several issues relative to the methodology appear in publications reporting the use of the verbal autopsy: coverage of deaths, the quality of the interview and the aptitude of the interviewers, coding and classification, processing of undetermined causes and multiple causes, use of algorithms, validity and validation, cost and continuity, and particular cases of diseases with nonspecific symptoms.

1. Coverage of Deaths

To maximize the value of interpretations of the results of verbal autopsy analysis, it is necessary to avoid selection bias and to ensure that *all* deaths in the relevant age group occurring in the community have been recorded and have been subject to the necessary investigations. For example, a selection of deaths recorded by a hospital or a community clinic would be of no value in producing usable statistics in public health in most developing countries. However, the verbal autopsy method has been used for deaths in hospitals in validation studies (Chandramohan *et al.*, 1998; Snow *et al.*, 1992). The same problem applies to verbal autopsies conducted on samples at the time of demographic and health surveys if the samples are not representatively weighted.

2. Quality Control of the Interviews

In the case of an issue as sensitive as that of the death of a relative, the interview should take place as soon as possible after the event, which means that it will often take place during the period of mourning. It requires subtlety and tact to be comprehensive and precise while respecting local customs and cultural sensitivity. The need for the interviewer to be respectable and respected in the local community, to be preferably female when a woman's death is under review, to speak the local language, and to guide the progression of the interview without interpreting or speeding events has been emphasized. It would not be appropriate for the interviewer to be the same health worker who had treated the deceased person before death. It is essential to pay attention to the chronology of events. A supervisor should revisit a certain number of interviews at random to check their validity.

3. Algorithms

Taking into account the diversity of agents involved in collecting information in this process and in a concern for standardization, use can be made of decision trees or algorithms (Quigley *et al.*, 1996; WHO, 1995; Chandramohan *et al.*, 1994; Snow *et al.*, 1992). This procedure is useful to standardize interviews, but it does require careful development and thorough validation because an erroneous branch could be used that would lead to an absurd conclusion. Standardized questionnaires and simplified algorithms have been used, particularly since 1992, for the Demographic and Health Surveys (notably phase III, Macro International, 1992). An example is given in Figure 43–1.

4. Coding and Classification

WHO's ICD cannot be applied in its initial state to verbal autopsies because it is too complex and based on anatomic-pathologic factors. A simplified classification is therefore needed (Chandramohan *et al.*, 2001). Classifications are too frequently based on symptoms because of the nature of the collected information, and systems based on causes would be of better use in public health care. Marie-Hélène Bouvier-Colle and colleagues (1976) and Jacques Vallin and Alfred Nizard (1978) proposed a more coherent classification based on causes to be applied to developed countries (Meslé, 1999; Vallin and Meslé, 1988; Meslé and Vallin, 1984). However, no standardized simplified classification has been adapted for use with verbal autopsy.

5. Multiple Causes

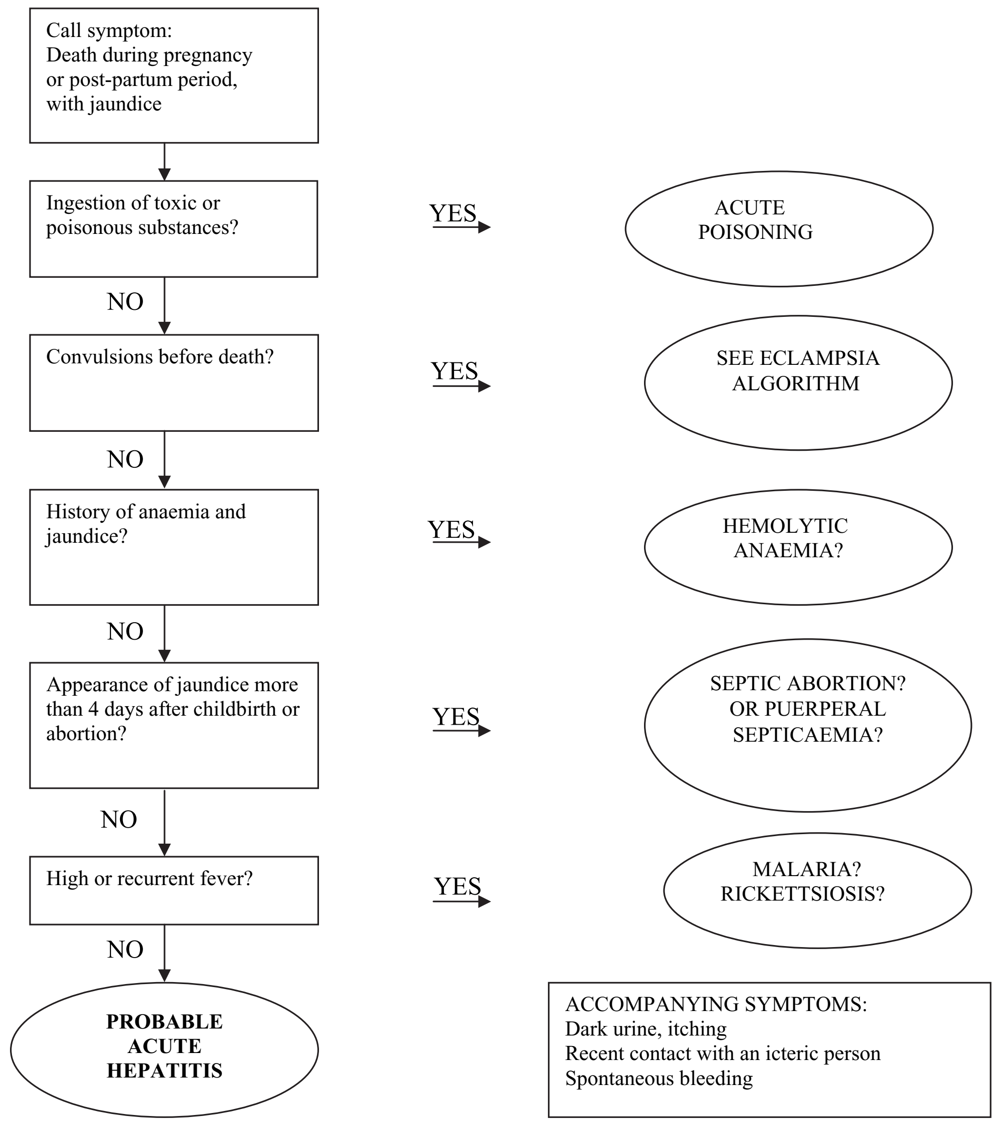
If, as for the ICD, the practice has been spread to code a *principal* cause (which initiated the sequence of events leading to death, such as abortion), an *immediate* cause (which directly caused the death, such as genital hemorrhage), and an *associated* cause (which contributed to the death, such as anemia), the standardization of directives to attribute these codes remains incomplete and the comparability of the studies subject to caution. Several large categories of causes present difficult coding problems: trauma or violent causes, diabetes, alcoholism, malnutrition, and acquired immunodeficiency syndrome (AIDS).

Moreover, it has often been recommended in public health to consider the sociobehavioral causes of death to shed more light on avoidable factors by approaches that are not exclusively medical, such as "contraceptive failure," "illegal abortion," or "refusal of medical assistance" (Fauveau and Blanchet, 1989). The famous classification of "the three delays" has been proposed as an explanation for maternal mortality: a delay in the decision to refer the parturient in difficulty, a delay due to transport time, and a delay in treatment once the patient has arrived at the referral centre. It is clear that this presentation leads to a proposal for preventive action of a behavioral nature rather than medical intervention.

6. Undetermined Causes

The recognized proportion of causes impossible to determine by verbal autopsy, without counting those for which the information is not available, varies significantly according to different studies. High proportions (>20%) raise doubts about the interpretation of the results provided, but recognition of the impossi-

FIGURE 43–1 Example of an Algorithm for the Logical Progress of the Diagnosis by Verbal Autopsy of Puerperal Hepatitis



From WHO, 1995.

bility of attributing causes generally guarantees greater credibility of the presented results.

7. Validation

The issue of objective validation of the results of verbal autopsies was raised from the first tests of the method (Mobley *et al*., 1996; Kalter *et al*., 1990; Dutta *et al*., 1988), only to run into the problem of the gold standard. In theory, validation can be made only by comparing verbal autopsy results with results from medical certificates made by qualified doctors using complete medical case records. Snow and colleagues (1992) tested this comparison by administering a verbal autopsy on a sample of 303 Kenyan children's deaths, the diagnoses of which had been established in a hospital. They obtained a good specificity (between 80% and 95%) for measles, neonatal tetanus, and trauma but an insufficient sensitivity (less than 50%) for malaria, anemia, acute respiratory infections, gastroenteritis, and non-epidemic meningitis. Quigley and colleagues (1996), using the same series, showed that for the diagnosis of malaria, a sensitivity greater than 70% could be obtained by using an algorithm more adapted to the local symptoms. Validation studies were applied to neonatal deaths (Marsh *et al*., 2003).

8. Particular Cases of Certain Pathologies

Simple cases in which the presence of a pathognomonic sign indicates an indisputable cause without any ambiguity are rare. Cases with nonspecific symptoms, for which the analyst must be satisfied with a group of indicators (e.g., malaria, AIDS) are more common.

a. Malaria

Numerous researchers have underlined the difficulty of diagnosing malaria in endemic regions because of the weak specificity of symptoms and clinical aspects and the rarity of biologic confirmation (Todd *et al*., 1994; Snow *et al*., 1992). The classic combination of fever, headaches, shivers, and seasonal anemia remain most common, but this profile is rarely complete. Validation studies have shown sensitivity below 50%. Clinical aspects of pernicious malaria are often impossible to distinguish from those of meningitis, except in the case of a typical epidemic.

b. Acquired Immunodeficiency Syndrome

In some countries or population groups, AIDS has emerged as a major, if not principal, cause of death. Knowing that AIDS sufferers generally die of interrelated infections or neoplasms and often of multiple complications, it has become necessary to develop a set of criteria that can lead to this diagnosis or at least indicate a strong likelihood (Doctor and Weinreb, 2003; Okongo *et al*., 1998; Kamali *et al*., 1996; Dowell *et al*., 1993). Among the principal criteria are belonging to a group most at risk (e.g., young adult, sex worker) and the presence of characteristic symptoms (e.g., cough or recurring diarrhea, weight loss, buccal mycosis, appearance of particular tumors). The diagnosis is even more difficult in the case of the AIDS-tuberculosis combination and AIDS in children.

V. OTHER TECHNIQUES

The objective of this chapter is not to detail the innovative techniques intended to determine and record all deaths occurring in a population. However, an alternative method of investigating the causes of death, the *medical audit*, should be mentioned. This method was developed to improve patient care in hospitals, particularly for perinatal (Edouard, 1985) and maternal mortality (Anonymous, 1992). The method consists of closely examining all elements of patient care from arrival at the hospital or even from the decision to transfer the patient to hospital. Factors such as decision-making delays, errors in orientation, errors in diagnosis, treatment errors, and lack of surveillance are analyzed by an external investigator or, more frequently, by the hospital or clinic staff, always with a view toward improving care by insisting on extra training to prevent a future recurrence. Details of these newer techniques applied to maternal deaths are found in the WHO's *Beyond the Numbers* (WHO, 2003).

CONCLUSIONS AND PROSPECTS

The increase in publications by public health organizations concerned with developing countries and using alternative methods to establish causes of death, notably the verbal autopsy, indicates a growing interest in these methods. Most authors express reservations about the absolute validity of the results, but they recognize that in the absence of an universal, and universally reliable, medical certification, these methods have acquired legitimacy. Several authors stress their weak sensitivity, especially in the context of endemic diseases with nonspecific symptoms. Nonetheless, numerous organizations, health ministries, and research institutes are still unable to respect the criteria for reliability in the use of these methods and run the risk of lessening their credibility.

Under what conditions can the extension of use of the verbal autopsy be recommended?

1. *The demographic surveillance system should be independent from the service provider system*. The neutrality and objectivity of determining causes of death are not guaranteed if we ask the physicians and nurses concerned by these deaths (which are perceived as failures of the system) to provide explanations for them. However, maintaining two parallel systems at the same time does require a large budget.
2. *The quality of the procedures* depends on training, initial and continuous, of the agents involved and on the constant and constructive supervision of these agents. Combined with the logistic needs, maintaining quality involves high costs.
3. *Consistency, sustainability, and continuity* of quality, essential conditions for studying chronologic series, involve high maintenance costs that are often incompatible with the resources of a developing country.
4. *Validation* by comparison with reliable hospital data, when available, should be an integral part of the

procedure. However, hospital data too often include only the diagnosis made on admission, which is not reviewed on release after (or before) death. This can lead to wrong conclusions.

5. International consensus does not exist in *the standardization of procedures*, making regional or international comparisons difficult. Several decision trees and algorithms have been published, showing that the best combinations of sensitivity, specificity and replicability can only be applied to a small number of distinct pathologies (e.g., tetanus, measles, meningitis, epidemics of cholera). Sometimes, even algorithms have been shown to be a source of confusion.

6. *Standardization of classifications* suffers from a lack of consensus, even though it seems more feasible. Only the WHO can propose appropriate lists. The processing of principal, immediate, and underlying associated causes, as well as multiple causes, remains subject to debate. A certain amount of caution should also be applied when processing causes that are impossible to determine.

Dependence and Independence of Causes of Death

GUILLAUME WUNSCH
Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

The problem of competing risks and the assumptions of *independence* and of *continuity* are discussed in Chapter 9. In this chapter, much of the same ground is covered in relation to the possible dependencies between causes of death or, more specifically, between the risks of dying of these causes. Consider a group of persons with ischemic heart disease followed over time to determine age at death or, more generally, their *failure-time*. In this situation, other causes of death compete with heart disease in addition to loss attributed to follow-up because of, for instance, out-migration. All these events censor the observation, but one cause of censoring—heart disease—is itself the topic of the study. The question is not in this case what would have been the result if there had been no censoring effects but what would have been the probabilities of dying of heart disease if there had been no competing events and, in particular, no other causes of death. The question is especially acute when computing probabilities by cause of death. Because everybody dies from one or another cause of death, some deaths (e.g., heart disease) have not been observed because persons ill from this disease have died of another disease (e.g., stroke) or an accidental cause (e.g., car crash).

I. PROBLEMS WITH THE CLASSIC APPROACH TO PROBABILITIES OF DYING

The probability of dying from one cause (e.g., ischemic heart disease) is usually estimated demographically by using the formulas of Elveback (1958) or Berkson and Gage (1950) (see Chapters 9 and 42), assuming independence between causes of death. This approach to evaluating probabilities of dying by cause of death is not without problems. First, because most deaths in countries with low mortality are due to chronic diseases, with often a long lag of time between the onset of a disease (e.g., heart disease, cancer) and death, it is often incorrect to assume, for example, that if someone had not died of heart disease between ages x and x + 5, he or she could have died of cancer. This assumption becomes less valid as the age interval decreases, because the chance of getting ill and dying of the competing disease decreases with the length of the period. Because a person has to be ill with cancer to die of the disease, either the person could not possibly die of cancer during the age interval considered if she or he did not have cancer or (s)he already suffered from both diseases. The single decrement approach would not be correct in the first situation, and the methods used commonly in this approach (e.g., Berkson or Elveback formulas for estimating the net probability) would therefore not be plausible. Multistate morbidity-mortality tables are required instead (see Chapter 47).

II. INDEPENDENCE OR DEPENDENCE AMONG CAUSES OF DEATH

Consider the assumption of *independence*. Is the risk of death from ischemic heart disease independent from, for example, the risk of death from cancer? Smoking has a negative impact on the incidence and lethality of lung and breast cancers and heart disease. For smokers, the probabilities of dying of heart disease or cancer are therefore not independent, because these effects have a common cause (i.e., smoking). Probabilities of dying from ischemic heart disease should therefore be computed among the nonsmokers, because in this case cancer and heart diseases cannot be associated through smoking behavior, although other known or unknown common causes can still play havoc with the results. The common causes of death should be controlled for when computing probabilities of dying by medical cause of death. The same can be said for the probabilities of becoming ill. For example, it is necessary to distinguish breast cancer incidences among female active smokers, passive smokers, and those not exposed to smoking. In this case, for the population of Geneva between 1992 and 1993 (Morabia, 1996), the following incidence rates were obtained for 100,000 women: 276 for active smokers, 252 for passive smokers, and 114 for the nonexposed subjects. These differences point to a possible impact of smoking (active or passive) on the incidence of breast cancer.

In the previous example, smoking behavior was a common cause of cancer and heart disease. Other common causes inducing dependencies between medical causes of death can be of a genetic nature. It has been shown, for example, that variations in the *APOE* gene are associated with variations in the risks for ischemic heart disease and Alzheimer's disease (Ewbank, 1997). These medical causes of death or disease processes are not independent in a causal sense, because they have a common genetic origin. When speaking of causes, it must be understood that what is meant is not a *sufficient* cause. There are few sufficient causes in the social sciences. A weaker causal relationship is assumed in our view of a causal structure, "such that the truth of the antecedent statement would at least give some support to the truth of the consequent" (Karhausen, 1996) or, in other words, that the occurrence of the cause increases the probability of the effect.

What *types* of competing events can be distinguished? As discussed in Chapter 8, an event such as migration competes with death for the censoring of the individual life line in the geographic region concerned. In a closed population, migration would not be problematic.[1] In an open population, migration perturbs the observation of mortality. Risks of dying can then be corrected for the occurrence of migration, using the Berkson method, for example, and assuming independence between mortality and migration in the absence of better information (Leridon and Toulemon, 1997). In the case of death, diseases may compete among themselves as the cause. An interesting discussion in the case of cancer is provided by Estève and colleagues (1993). According to these authors, probabilities of dying of cancer and those for other causes could be positively correlated, because being ill from cancer or being treated for cancer can increase the probability of dying of other causes. The opposite situation also can happen according to Estève and colleagues (1993), because cancer patients are medically monitored and adopt less risky lifestyles. In this case, probabilities of dying of other causes may be lower than in the general population.

What causal structures can be assumed among causes of death? Suppose an individual suffers from two lethal disease processes or causes of death, X and Y. The occurrence of death due to X prevents the occurrence of death due to Y, and vice versa, but the occurrence of one or the other would lead to life's end. X or Y are, in this case, *disjunctive causes* of death, although there can be *interaction effects* between X and Y. In this latter case, if death due to X occurs before death due to Y, death would not be due solely to X but also to the XY interaction effect between both disease processes. The same holds for Y happening before X. As an example of *interaction*, smoking and carrying the *APOE4* allele are separate risk factors for Alzheimer's disease, but it seems that smoking has a beneficial impact for those who have the *APOE4* allele and smoke (Breteler *et al*., 1999).

In another situation, both causes, K and L, lead to death in *conjunction*. Death occurs because of both K and L (e.g., acquired immunodeficiency syndrome and tuberculosis), and attributing death solely to K or to L would not be relevant.

In still another case, it is possible to have a situation in which M causes N. If someone who has terminal cancer (M) commits suicide by poisoning (N), cancer should be considered the true cause of death, and cancer would then be the initial or *underlying cause* of death and suicide the *immediate cause*, because taking the poison was intermediate in this case between cancer and death.

The single decrement approach is not a very satisfactory model in most of these circumstances, and demographers should make more use, in a causal perspective, of the medical information available on the lethal disease processes they are studying, taking into account among others the underlying, immediate, and associated causes of death as stated on the death certificate (Manton and Stallard, 1984). They should also develop multistate morbidity-mortality models or stochastic compartment models if the necessary data are available (see Chapter 47). For example, Manton and Stallard (1984) compute multiple decrement life tables for chronic diseases based on the underlying cause and on all medical conditions mentioned on the death certificate (i.e., the underlying, intermediate, immediate,

[1] Some countries have been closed in the past for political or geographic reasons. A small population size can lead to inbreeding, and genetic consequences can include health problems and death (see Chapter 79).

and associated causes of death); the definitions are provided in Chapter 42. They obtain the so-called pattern-of-failure life tables better suited to multiple pathologies than the classic tables by underlying cause alone, because the former take into account patterns of dependent conditions and the latter does not. According to these life tables, Table 44–1 compares for the United States (1969) the proportion of white males eventually dying of various chronic diseases (i.e., cancers, ischemic heart disease, stroke, diabetes mellitus, and generalized arteriosclerosis) with the proportions derived from the underlying cause life tables.

Pattern-of-failure life tables lead to higher proportions of deaths than the underlying cause life tables, because the former are based on the additional mentions of chronic disease in the multiple-cause data, whereas the latter take only the underlying cause into consideration. The difference between the two approaches is small for cancers but large for generalized arteriosclerosis.

Mortality by cause can also be studied using statistical methods, such as event-history analysis (see Chapter 23), based on individual life courses. The advantage of this approach is to take account of population heterogeneity and of the past and present individual risk factors. However, these methods require longitudinal individual data that are rarely available in the field of mortality for the whole population. Although statistical methods based on individual data are used in the field of fertility research (see Chapter 23) because of the wide availability of retrospective surveys, they are still not of common usage in mortality studies requiring costly and cumbersome prospective longitudinal surveys (Alderson, 1983), or individual data linkage between census results and vital registration data (Wunsch *et al*., 1996). As Courgeau and Lelièvre (see Chapter 23) rightly point out, although these methods are used in the field of clinical tests and epidemiology, they have not had great success in demography due to the nature of the data required.

TABLE 44–1 Proportions of White Males Dying from a Specific Chronic Disease According to the Underlying Cause and Pattern-Of-Failure Life Tables (United States, 1969)

Chronic disease	Underlying cause life table (%)	Pattern-of-failure life table (%)
Cancer	16.49	19.30
Ischemic heart disease	39.25	45.71
Stroke	9.54	15.12
Diabetes mellitus	1.47	5.74
Generalized arteriosclerosis	1.73	15.39

Manton and Stallard, 1984.

As an example, Zhu an colleagues (2000) used a Cox *proportional-hazard model* (Collett, 1997) to examine the possible relation between cognitive impairment and mild dementia or stroke, controlling for various confounders such as age, sex, education, and systolic blood pressure. The data were obtained from a population-based, prospective, longitudinal survey conducted in Kungsholmen (Stockholm); subjects were 75 years old or older at the baseline date (October 1, 1987), and the data were linked to the Stockholm inpatient hospital register. Results of this research demonstrate a significant positive relation between cognitive diseases and stroke, probably because of a common cause such as small cerebral lesions not detected at the clinical stage. The study covered 1551 individuals followed during a 3-year period. Because of the high cost involved, such a study could not be carried out on the whole population of Sweden. Demographers can nevertheless take advantage of this approach in the mortality field if they are looking for an answer to a specific question that does not require following a large sample of the whole population of the country considered.

Continuing reflection on the possible relations between causes of death, it was stated in Chapter 8 that a condition of *continuity* was required when evaluating fertility rates or frequencies in the absence of competing risks. Continuity supposes no causal relation between competing processes, such as fertility not changing the probability of dying. The problem is more complex in the field of mortality. Suppose there are only two causes of death or lethal disease processes, A and B, and no common causes. The condition of independence due to the absence of common causes is therefore satisfied. A person may be affected with A, with B, or with A and B, or the person may be in good health during the time interval considered. Being ill with A, however, may change the lethality of process B or vice versa, as in the cancer case given previously. Suppose the analyst is interested in mortality by cause A; cause B is therefore the disturbance or competing risk. In this case, for individuals suffering from both A and B, suppose that having contracted illness B modifies the probability of survival due to A (i.e., introduces a *discontinuity*). For example, the presence of syphilis modifies the risk of developing arterial aneurism. In this situation, both diseases are dependent, not because of a common cause but because of a causal relationship between them.[2]

[2] From a causal viewpoint, dependence between two (or more) risks can result from common causes or from a causal relation between the risks themselves. It can be shown that *statistical independence* of the cause-specific ages at death is a sufficient condition for *risk independence* (Manton and Stallard, 1984, chap. 4).

Probabilities or rates should take account of this factor and compute one probability of dying due to A conditional on the fact that the person is ill with A alone and compute a second probability of dying of A conditional on the fact that the person is ill with both A and B, with the presence of B possibly modifying the lethality of A. The population in good health or suffering only from B cannot die of A during the time interval considered because they are not ill with A. We may conclude that demographic analysis requires a thorough understanding of the processes involved and that, in this case, methods such as causal analysis (see Chapter 130), multistate increment-decrement models (see Chapter 47), and event-history modeling (see Chapter 23), would be better suited to the study of complex phenomena such as mortality by cause of death than the single decrement approach.

CONCLUSIONS

Because populations are *heterogeneous*, it must be remembered (see Chapter 10) that individuals with the higher risks of dying are on average excluded earlier from the population than those with lower risks. The *frailty* of the population therefore changes over time due to this selection effect in favor of those in better health. Without appropriate information, it is therefore not possible to distinguish the situation in which the age-specific heterogeneous probabilities of dying are constant for each individual from the situation in which probabilities decrease by age for a homogeneous group of individuals, because both cases lead to declining average probabilities over time. In the field of mortality by cause, this means that those who become ill with the most deadly diseases die first, leaving behind those with less severe conditions. This selection effect can explain, for example, the possible crossover in age-specific death rates between groups of different mortality levels and the fact that those who survive until old age can still be in quite good health on average.

Measurement and Levels of Maternal Mortality

JUDITH A. FORTNEY

Family Health International, Research Triangle Park, North Carolina, United States

Only 50 years ago, maternal mortality in Europe was as high as it is in parts of the developing world today, and it had a significant demographic and dynastic impact. Maternal mortality has changed the course of history and has resulted in untold suffering for the mothers themselves and their bereaved husbands and children. Princess Charlotte's death in 1817, after 48 hours of mismanaged labor (Dewhurst, 1980), began the chain of events that led to Queen Victoria's place on the British throne and her amazing impact on European history (Potts and Potts, 1995).

In a less spectacular way, the relentless loss—one per minute—of women in childbirth affects families throughout the developing world. Today, 99% of maternal deaths occur in developing countries, and the disparity between the developed and developing world is the greatest of any public health indicator. Estimates put the loss (in 1990) at 585,000 deaths per year (WHO and UNICEF, 1996). Apart from these maternal deaths, only 25% of their babies born alive survived their first year (Koenig *et al*., 1988). Although data are scarce, older children (especially girls) whose mothers die often terminate their education to care for the younger siblings, and many street children are motherless (Piraino, 1991).

After discussing current definitions of maternal mortality, this chapter describes measurement issues, means of estimating maternal mortality, and levels of maternal mortality in the world today and in the past.

I. DEFINITIONS

The definition of a maternal death is surprisingly contentious. Although the World Health Organization's (WHO) *International Classification of Disease*, 10th revision (ICD-10), definition of maternal mortality (Table 45–1), and acknowledgment of "pregnancy-related death" is an improvement over the ICD-9 version, some researchers think it does not go far enough. There are two contentious issues. Maternal mortality, like infant mortality, is partly defined by time. Infant mortality is universally accepted to be deaths of infants younger than 1 year of age from any cause. In the case of maternal mortality, however, both the period and the significance of cause are disputed.

Traditionally, a death is defined as maternal when it occurs during pregnancy or within 42 days of termination of pregnancy, although there are variations on this period. In the ICD-10, WHO acknowledges the need for an extended period and refers to "late maternal deaths," which occur after 42 days and up to 1 year after delivery. The call for extending the relevant period comes mainly from the developed countries where modern medicine can delay death beyond the traditional 42-day period. This is not the case in developing countries. Research in Bangladesh, using a 90-day definition, found that only 5% of maternal deaths in that country occurred 43 to 90 days after delivery (Koenig *et al*., 1988). Excluding the deaths after 42 days

TABLE 45–1 World Health Organization's ICD-10 Definitions of Maternal Mortality

Maternal death: The death of a woman while pregnant or within 42 days of termination of pregnancy, irrespective of the duration and site of the pregnancy, from any cause related to or aggravated by the pregnancy or its management but not from accidental or incidental causes.

Pregnancy-related death: The death of a woman while pregnant or within 42 days of termination of pregnancy, irrespective of the cause of death.

ICD-10, International Classification of Disease, 10th revision.

TABLE 45–2 Variations in the Period for Defining Maternal Mortality

Organization	Period
WHO, ICD-10	42 days
FIGO	42 days (follows ICD-10)
CDC	12 months
ACOG	Indefinite if cause is maternal
RCOG	42 days (follows ICD-10)

ACOG, American College of Obstetrics and Gynecology; CDC, U.S. Centers for Disease Control and Prevention; FIGO, Fédération Internationale de Gynaecologie et Obstétriques; ICD-10, International Classification of Disease, 10th revision; RCOG, Royal College of Obstetrics and Gynaecology (UK).

reduced the maternal mortality ratio from 550 to 520 per 100,000 live births.

Researchers must take care when making comparisons that the data are comparable with regard to the period used in the definition, as well as other variations. Occasionally researchers use unconventional periods; for example, Bardet and colleagues (1981) use 60 days. Even international organizations may use different periods (Table 45–2). This is unsatisfactory because it discourages comparability.

There is another problem in comparative research in addition to the period used for calculations. Traditionally, maternal deaths have been divided into direct obstetric, indirect obstetric, and accidental, and incidental types (i.e., apparently not caused by the pregnancy or delivery, such as accidents, homicides, suicides), with the last category excluded from the maternal mortality ratio statistic. Because it is sometimes difficult to distinguish between the last two categories in classifying a death, the maternal mortality ratio may be underestimated because of misclassifications into the accidental or incidental category.

There is growing recognition that what the ICD-10 definition refers to as "accidental or incidental" causes may not be incidental to the pregnancy. Vincent Fauveau and Thérèse Blanchet (1989) working in Matlab, Bangladesh, report that 20% of deaths of pregnant unmarried women were caused by suicide compared with 5% for married women. Kleiner and Greston (1984) and Frautschi and colleagues (1994), in reviewing the literature, found that suicide precipitated by pregnancy is not an uncommon occurrence. Several investigators (Gazmararian *et al*., 1995) report that domestic violence in the Unites States, regardless of whether it results in death, may be triggered by pregnancy, especially if the pregnancy was unintended. Some pregnant, unmarried women are killed by their families because of the pregnancy.

Some accidents may be pregnancy related. Fildes and his colleagues (1992) refer to trauma as the leading cause of maternal death in the United States. In the state of Maryland, approximately 10% of pregnant women are hospitalized for accidental injury during pregnancy (Greenblatt and Dannenberg, unpublished observations). Reviewing the literature on accidental injury during pregnancy, Sherer and Schenker (1989) ask, "Is the pregnant woman accident prone? Ever changing physical dimensions, increasing abdominal girth, continuous weight gain combined with physiologically compensatory lordosis create a change in the pregnant woman's center of gravity. Affected are both her maneuverability as well as her ability to react to approaching dangers. Neufeld *et al*. state that as pregnancy progresses, the incidence of minor trauma increases and by the third trimester will occur more frequently than at any other time during female adulthood." This question is still debated. Some studies show the opposite relationship, with pregnant women being less accident prone than others (Ronsmans *et al*., 2001).

Pregnancy affects immune status and therefore susceptibility to infections. Several infectious diseases are more severe during pregnancy and are more likely to cause death than in nonpregnant women. The most important of these (in terms of numbers) are malaria, tuberculosis, hepatitis, and measles. A study in Kenya reports that there is an 11-fold decrease in recovery from malaria infection among pregnant women (Brabin, 1983). Kwast and her colleagues (1986) report that 15.5% of maternal deaths in Addis Ababa, Ethiopia were caused by hepatitis. For measles, there is an excess female mortality, which peaks during the reproductive years of 15 to 44 and lasts until age 50 years. In Senegal, for example, excess mortality during the reproductive years is 43% (Garenne, 1994).

Breast cancer has a worse prognosis when diagnosed during pregnancy because it is usually in a more advanced state at the time of diagnosis. Whether this is because the hormonal environment causes it to grow more rapidly during pregnancy or because diagnosis is delayed because of other changes in the breast due to the pregnancy is unknown (Petrek, 1996). Regardless of the cause, pregnancy contributes a higher level of mortality from breast cancer.

For the reasons previously cited, many of the leading researchers in maternal mortality prefer a definition that includes *all* deaths of women who are pregnant or within 1 year of termination of pregnancy, regardless of the cause of death. Although this definition will doubtless include deaths that are not attributable to pregnancy or delivery, the resulting overcount is less problematic than the previous undercount, and it has the advantages of being conceptually simple, having a precedent in infant mortality, and being far simpler to implement than the present ICD definition.

II. MEASURES OF MATERNAL MORTALITY

Several indicators of maternal mortality are used in the literature, and investigators should be aware of their differences in comparative studies.

1. Maternal Mortality Ratio

The most frequently used measure of maternal mortality is the following ratio:

$$(\text{number of maternal deaths} \,/\, \text{number of live births}) \times 100{,}000$$

Although 10,000 or 1000 live births is sometimes used, 100,000 is increasingly the preferred denominator, especially because ratios in the developed world drop below 10 per 100,000 live births. For example, 8 maternal deaths per 100,000 live births is more easily interpreted by nontechnicians than 0.8 per 10,000 or 0.08 per 1000. Use of the 1000 live births denominator is largely a holdover from times and places with much higher maternal mortality rates. Although developing country researchers often (for good reasons) still use the 1000 live births denominator, the 100,000 denominator is recommended in the interests of comparability.

Why use live births as denominator? It has been suggested (Thuriaux and Lamothe, 1984) that the number of all pregnancies is a more correct denominator. This suggestion has not received serious attention because of the impossibility of implementing it. Few countries are able to count or even recognize all pregnancies.

Any period can be used as a reference as long as it is identical for both numerator and denominator. Periods longer than 1 year are often desirable because larger numbers of deaths make for more stable estimates.

The term *maternal mortality ratio* began to be used in the mid-1980s. Before that (and still by some writers), it had been called the *maternal mortality rate*. It is not, however, a true rate because the numerator is not a subset of the denominator. The misuse of the word *rate* can be confusing to the beginning investigator of maternal mortality.

2. Maternal Mortality Rate

The *maternal mortality rate* for a defined period is calculated as follows:

$$(\text{number of maternal deaths} \,/\, \text{number of women aged 15 to 45 years}) \times 100{,}000$$

In this case, the numerator (i.e., maternal deaths) is a subset of the denominator (i.e., women between 15 and 45 years old), and it is therefore a true rate.

Despite its usefulness and conceptual importance, the maternal mortality rate is not widely used. Although the ratio measures the risk to a woman *once she becomes pregnant*, the rate measures the risk that a woman *will become pregnant* and *that she will die after she has become pregnant*. It is strongly affected by the level of fertility in the region of interest. The ratio is influenced by the quality and availability of health services, but the rate is influenced by the quality and availability of family planning as well as health services.

3. Lifetime Risk

The lifetime risk measures the risk that a woman entering adulthood will die at any point from maternal causes. The more frequently she becomes pregnant, the more frequently she is exposed to the risk. The lifetime risk is written as "1 in N" risk of experiencing a maternal death, and a smaller N represents a greater risk. It is actually 1 minus the probability of surviving all pregnancies.

For example, using age and parity-specific mortality data from Matlab in Bangladesh (Chen *et al.*, 1974) and assuming a TFR of 6, with one birth before age 20, two births at age 20 to 29, two births at age 30 to 39, and one birth at age 40 to 49, the following probabilities of survival by age and parity are obtained (Table 45–3) multiplying the survival probabilities:

$$0.9912 \times 0.9964 \times 0.9964 \times 0.9975 \times 0.9975 \times 0.9920 = 0.9713$$

This is the probability of surviving six births at those ages in that place and time. The probability of

TABLE 45–3 Probabilities of Female Survival by Age and Parity: Statistics from Matlab, Bangladesh, in the Early 1970s

Age	Probability of surviving (1 − probability of dying) at each specified age and parity			
	1	2–3	4–5	6+
10–19	0.9912	—	—	—
20–29	—	0.9964	—	—
30–39	—	—	0.9975	—
40–49	—	—	—	0.9920

Adapted from Chen *et al.*, 1974.

maternal death given that reproductive pattern is calculated as follows:

$$1 - 0.9713 = 0.0287$$

This is equal to about 1 in 35 (1/0.0287 = 34.8). In practice, however, the calculation can be made without access to such detailed data (i.e., parity-specific risks are rarely available). The maternal mortality ratio found in the study shown above was 570 per 100,000 live births or 0.0057 for each individual birth, or $0.0057 \times 6 = 0.0342$ (i.e., about 1 in 29, a close approximation to 1 in 35).

4. Proportional Mortality

Proportional mortality refers to the proportion of all deaths of women of reproductive age that are maternal deaths (i.e., that occur during pregnancy or within 42 days [or 12 months] of the termination of pregnancy). In developing countries, it is typically 20% to 25% and the leading cause of death in this age group, whereas in developed countries, it is usually less than 1%.

III. MEANS OF ESTIMATING MATERNAL MORTALITY

Adult mortality generally is not well measured in the developing world. Maternal mortality, a subset of adult mortality, is also not measured well.

There are several ways of estimating maternal mortality and, for a variety of reasons, none is entirely satisfactory (WHO, 1987). Even where maternal mortality is very high, deaths are relatively rare in any one community. For example, with a maternal mortality ratio of 500 per 100,000 live births, a crude birth rate of 30 per 1000 population, and a community population of 5000, the number of births per year is 150, and the number of maternal deaths per year is 0.75, or an average of three deaths every 4 years. Surveys designed to identify maternal deaths must cover a very large population base or extend over many years (or both) to identify enough deaths from which to estimate any measure with some degree of stability.

1. Vital Registration

Maternal deaths can be identified from several sources. In principle, vital registration is the ideal source of information on maternal death. However, experience has shown that underestimation is usual (Dye *et al*., 1992; Bouvier-Colle *et al*., 1991; Benedetti *et al*., 1985; Speckhard *et al*., 1985). An extensive review of deaths of women of reproductive age in France (Bouvier-Colle *et al*., 1991) resulted in an increase in the maternal mortality ratio from 10 to 22 per 100,000 live births. In the United States, several states have added pregnancy status to the death certificate or link birth and death certificates. These efforts have increased the maternal mortality ratio in those states by 30% to 153% (Berg *et al*., 1996).

Few developing countries have systems of vital registration. Even where vital registration is of good quality, there is underestimation of maternal mortality, most often because the person certifying the cause of death fails to mention the pregnancy status. The risk of this occurring increases as the time after termination of pregnancy is extended. For example, a woman who experiences eclampsia (i.e., convulsion resulting from hypertension induced by pregnancy) develops kidney failure as a result of the eclampsia; she dies weeks (or months) later from kidney failure, and her death takes place on the medical rather than the obstetric ward. The physician who is treating her is concerned only with the kidney failure (because that is what requires treatment), not its underlying cause, and does not mention eclampsia or pregnancy on the death certificate.

In another example, a woman with obstructed labor (i.e., because the baby is in the wrong position, the baby is too big, or the pelvis is too small) has a cesarean section and dies because of an anesthetic accident. The physician who certifies the death reports it as an anesthetic or surgical accident without mention of cesarean section or pregnancy.

A physician certifying the death of a woman from postpartum hemorrhage may write hypovolemic shock on the death certificate. Research from developed and developing countries has repeatedly shown that the contribution of pregnancy to a death is omitted from death certificates. Few developing countries have functional systems of vital registration, and even where registration is virtually complete, the cause of death reporting is usually incomplete for maternal deaths. For example, in Egypt, the deaths of women who died of postpartum hemorrhage are often reported on their death certificates (death certification and recording of adult deaths is virtually complete in Egypt) as hypovolemic shock (Grubb *et al*., 1988). Although technically correct, postpartum hemorrhage is more informative and permits designation as maternal death, which the former designation does not. In most developed countries, unexplained deaths are usually investigated by autopsy, but in developing countries, autopsies are most often reserved for situations in which violence is known or thought to have occurred (even where the cause of death is obvious, such as a motor vehicle accident).

2. Hospital Data

Hospital data are commonly used in developing countries where other data are lacking. They are, however, virtually impossible to interpret when some births or other pregnancy terminations take place outside of hospitals. Deaths from spontaneous or induced abortions or ectopic pregnancies are most likely to occur outside of hospitals, and in most developing countries, many births occur at home. It can be safely assumed that hospital births are not representative of all births in this situation. However, are they more representative of complicated deliveries, births to wealthier women, or births to urban women? In any case, it is not possible to infer anything about the population in general. Although hospital death rates are indicative of conditions in hospitals and can be useful, they should not be referred to as maternal mortality ratios or rates.

3. Population-Based Surveys

Several population-based surveys are considered to be of reasonably high quality (Boerma and Mati, 1989; Bhatia, 1988; Fortney, 1986). In these surveys, the families of women who died are interviewed to determine the circumstances surrounding the death and to determine the cause of death. This has been called the *verbal autopsy* method (WHO and LSHTM, 1995) (see Chapter 43). This approach has yielded useful information about the circumstances surrounding maternal deaths and for verifying that the deaths were maternal. Deaths of young adults are relatively easier to diagnose because they are more likely (than deaths of children or older people, for example) to be caused by accidents or acute conditions, and the deceased is likely to have verbalized her symptoms. Nevertheless, for some proportion of deaths, it will be impossible to assign a cause.

Identifying the deaths being investigated can be done by several means: vital registration, reporting by community leaders, and reporting by multiple informants (Boerma and Mati, 1989; Measham *et al*., 1981). If all deaths of women of reproductive age are investigated, they are sometimes called *reproductive-age mortality surveys* (RAMOS), a term coined by James Shelton of United States Agency for International Development (USAID) in 1979.

One limitation of population-based surveys is that deaths are often unreported or misreported if they are an object of shame (e.g., after an illegal abortion, if the mother was not married); are unrecognized (e.g., ectopic pregnancy); are forgotten (e.g., when the mother has low status or has no surviving or nearby relatives); occur to women who live in remote areas; or involve illegal activity (e.g., abortions, homicides, suicides). Other limitations include the large population that needs to be covered (and therefore the high cost) and the need for sensitive and expert interviewing, although families are often willing to discuss the circumstances despite their grief.

4. Sisterhood Surveys

The *sisterhood method* (Graham *et al*., 1989) of estimating maternal mortality was developed because of the difficulty and expense in getting such data in other ways. It involves asking just four questions, which can be added relatively easily to an ongoing survey of an appropriate population, thereby reducing costs. Because of its relative ease of data collection it has been widely adopted and is routinely added to many surveys, including the Demographic and Health Surveys (DHS). The four questions cover the number of sisters the respondent has (had), the number of sisters who reached reproductive age, the number who are still alive, and the number who died a maternal death.

An important limitation of the method is that it cannot be used to measure short-term change because it estimates mortality for an extended period (10 to 12 years) preceding the survey. Work in modeling estimates of maternal mortality (Stanton *et al*., 1995) has suggested that the sisterhood method consistently underestimates, by about one-third, mortality due to maternal causes. This claim is supported by work in Bangladesh (Shahidullah, 1995a, 1995b) and Burkina Faso (Garenne and Friedberg, 1997; Garenne *et al*., 1997).

5. Modeling

The numerous difficulties in estimating maternal mortality and identifying maternal deaths have led to increased interest in indirect estimation through modeling. Modification of the 1990 global estimate is a result of modeling, and the numbers provided in the next section are based on this model. There has been only one published report of a model to estimate maternal mortality (Stanton and Hill, 1996). This model was based on indicators known to influence maternal mortality.

An earlier model by the same authors was abandoned because it was based on life tables. Although a model based on actual life tables would be acceptable, for most developing countries, actual life tables have not been calculated, and only model life tables exist. All countries using the same model life table would have the same estimated level of maternal mortality, regardless of variations in availability and quality of health services. Model life tables are strongly influenced by levels of infant mortality. This results in maternal mortality being estimated from infant mortality, and they are believed to be only moderately associated.

Garenne and colleagues (1997a, 1997b) used a simulation model with real data from Burkina Faso to evaluate the direct and indirect methods of sisterhood estimation. The use of models to estimate maternal mortality remains controversial. The WHO and UNICEF 1996 estimates were hotly contested by many countries whose estimates were increased. Nevertheless, other methods also have their limitations, and an increased role for models in the future is both likely and desirable.

IV. LEVELS OF MATERNAL MORTALITY

Table 45–4 shows levels of maternal mortality for selected countries. All these estimates are taken from the WHO and UNICEF (1996) estimates for 1990 based on a model. The disparities between the developed and the developing world are large, 300-fold when comparing the highest (Sierre Leone: 1800) with the lowest (Canada or Norway: 6; two small countries, Iceland and Luxembourg, have an estimated ratio of 0). The developed world as a whole has a maternal mortality ratio of 27, compared with 480 in the less developed regions, almost a 20-fold difference.

What do these numbers mean in terms of demographic impact? In Afghanistan, with a maternal mor-

tality ratio of 1700 and a total fertility rate (TFR) of 6.9, a woman has a 1 in 8 or 9 chance of dying a maternal death—a significant demographic impact. In Sri Lanka, where the maternal mortality ratio is 140 and the TFR is 2.6, a woman's likelihood of dying a maternal death is only 1 in 275—a relatively small demographic impact.

1. Decline in the Developed World

In historic times, maternal mortality in the developed world was at least as high as it is in the developing world today. Tables 45–5 and 45–6 show data from some European countries for which historical data are available. Table 45–5 presents maternal mortality ratios, and Table 45–6 shows what is assumed to be close to a maternal mortality rate. The existence of relatively complete records for England, Sweden, France, and for the aristocracy in several countries makes estimates possible (Högberg *et al*., 1986; Wrigley and Schofield, 1983; Peller, 1965).

Elsewhere in Europe, the ratio in Geneva was 1470 in the 1600s, 1511 in the 1700s, and 1333 in the 1800s (Perrenoud, 1981). In the United States, the ratio in the year 1900 was about 600, which was quite similar to that in Europe at about the same time (Högberg and Broström, 1985). Between 1975 and 1982 in the United States, a religious group that refused all medical care had a maternal mortality ratio of 874 (Kaunitz *et al*., 1986).

Högberg and Broström (1985) attribute the decline in the number of maternal deaths in the 1700s in Sweden to a decline in fertility rather than an improvement in obstetrics. This trend is partly evident also in

TABLE 45–6 Average Maternal Mortality per 100,000 Fertile Women from the Ruling Families of Europe Who Were Married in the Specified Years

Age	1500–1699	1700–1799	1800–1849	1850–1899
20–24	3100	5540	3400	2610

Table 45–6, which shows rates (not ratios) from European ruling families.

Several events caused the decline of maternal mortality in the developed world beginning in the 19th century. In interpreting the data in this section, it is necessary to understand that most (roughly 80%) of maternal mortality can be attributed to the following five causes:

Infection
Hemorrhage
Eclampsia (i.e., convulsion resulting from hypertension induced by the pregnancy)
Obstructed labor (i.e., because the baby is in the wrong position, the baby is too big, or the pelvis is too small)
Abortion

The first major breakthrough in obstetrics came with discovery of the contagiousness of puerperal or childbed fever. This appears to have been discovered by Alexander Gordon in Scotland around 1790 and independently in the 1840s by Oliver Wendell Holmes in the United States and Ignaz Semmelweiss in Austria. The discovery was resisted, perhaps as late as the 1930s, by some obstetricians (Loudon, 1992), but the idea was adopted by many others. Högberg and his colleagues (1986) show that the incidence of puerperal sepsis in Sweden dropped from 5263 per 100,00 deliveries in 1881 to 220 in 1900. Obstetric forceps were used by some obstetricians from about 1740 on (Loudon, 1992), but they were a carefully guarded secret and available only to wealthy patients. Although they represented obstetric progress, they had little impact on maternal mortality in general. The development in the 1840s of anesthesia was not sufficient to make cesarean section widely available, but toward the end of the century, surgical techniques also improved, averting many deaths from obstructed labor (Loudon, 1992). Sulfonamides became available in the 1930s, as did penicillin in 1945, providing the means to treat puerperal sepsis. In Britain, more than 80% of the decline in total maternal mortality between 1934 and 1940 resulted from the decline in (non–abortion-related) sepsis (Loudon, 1992).

A rapid decline in maternal mortality occurred in the developed world between 1934 and 1950. In Britain, these 16 years saw a drop from 440 deaths per 100,000 live births to 87. Loudon attributes this dramatic decline to the following factors:

Introduction of sulfonamides and penicillin

A decline in the virulence of *Streptococcus* (which causes puerperal sepsis)

Introduction of ergometrine, blood transfusion on a large scale, and the growth of obstetric flying squads, all of which played a major role in reducing deaths from obstetric hemorrhage

Improvement in the standard of living and the nutrition of the population (reducing, for example, the prevalence of rickets which cause pelvic deformity)

Improvements in obstetric training

More than most issues of public health importance, the reduction in maternal mortality was a function of medical intervention rather than prevention; the important exception was the belated and reluctant introduction of infection control, mainly by handwashing (Fig. 45–1). With the exception of rickets, the role of nutrition is difficult to document and far from clear. Historical fluctuations in maternal mortality could have been attributed to variation in food availability or to variations in obstetric customs. Food availability is unlikely to have affected ruling families, however, and great fluctuations are also evident in this population.

The role of transport in reducing maternal mortality in the developed world has yet to be studied, but the improvement of roads and the development of mechanical transport undoubtedly improved

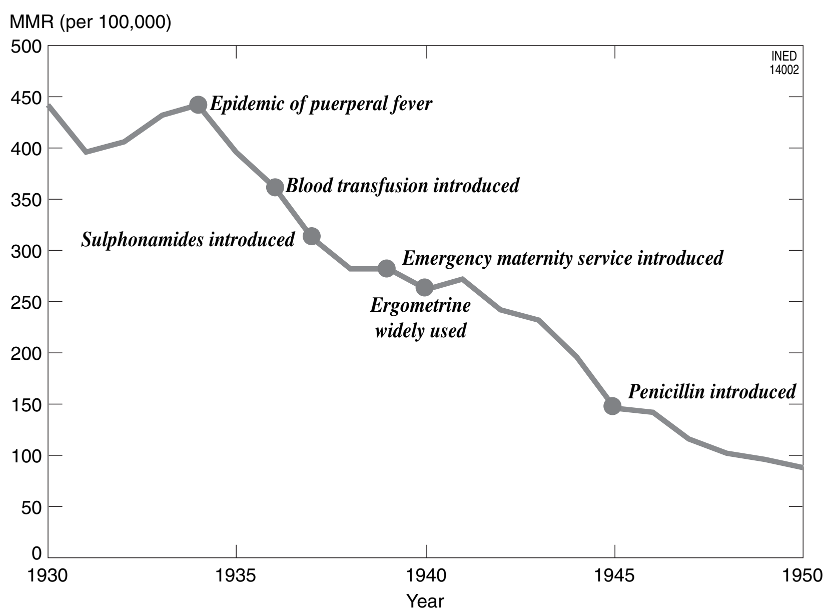

FIGURE 45–1 Maternal mortality ratios (MMRs) in England and Wales from 1930 to 1950 associated with advances in medicine.

women's access to medical care when it was necessary. The midwife on her bicycle and the doctor making house calls by car were common long before most women delivered in the hospital.

2. Decline in the Developing World

The situation of maternal mortality in the developing world is fundamentally different from that in the developed world in the early 19th century. In 1800, there were no antibiotics, no barbiturates, no anesthesia, and no blood transfusions. All of these are now technically feasible, not technically difficult, and not especially expensive, even in the developing world. Why then do women still die in childbirth?

The reasons are many and complex, and they go far beyond medical technology. In the developed world, medical technology became available as economies were burgeoning; charities often countered poverty; educational opportunities expanded; and transport improved. Although some of these changes are occurring in the developing world, it is often at a slower rate and with more frequent setbacks than during the periods of economic expansion in the West. Desertification, war, anticolonialism, government inefficiency, corruption, interrupted transport, structural adjustments, and the brain drain all contribute to reducing availability of health care. Where developing countries (e.g., Sri Lanka, Costa Rica) have made public health a national priority, maternal mortality is relatively low.

The last 15 years of the 20th century saw great strides in understanding the factors that contribute to high maternal mortality in developing countries. Although the developed world expresses its interest in helping the developing world address the issue and many developing countries have stated their desire to address it, neither has yet made the necessary political and financial commitment to achieve the goal. Although medical and technologic advances of the past century have given us the means to reduce persistent high levels of maternal mortality in the world's less developed regions, the medical infrastructure is not always in place, services are not always geographically and financially accessible, and the training, accountability, and commitment of providers are sometimes limited.

The Determinants of Infant Health and Mortality

GODELIEVE MASUY-STROOBANT

Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

Starting from a level of potential health capital at birth, which can be roughly estimated through indicators such as birth weight, gestational age, or the presence of a congenital handicap, an infant's capacity to maintain or restore this potential, if necessary, depends on a whole series of factors on which the newborn has almost no means of action. These are referred to by demographers and epidemiologists as *determinants* of perinatal, infant, or child health and mortality.

I. DETERMINANTS OF WHICH INFANT MORTALITY?

Infant mortality, which is defined as the probability for a live-born child to die before its first birthday, is a multifaceted phenomenon that needs to be placed in its historical, geographic, and social contexts. This particularly frail year in the life of a human being is, at the individual level, part of a process that from conception to death could potentially last more than 100 years. Being born alive presupposes having escaped fetal death, and the study of the first year of life is a recognition of its specific nature, resulting primarily from the very high mortality risks observed therein compared with succeeding ages. In very-low-mortality countries, equivalent mortality risks are only reached at 60 years of age. In situations of high mortality, only old people are exposed to risks higher than those for small children, and going beyond the stepping stone of the first birthday is but one stage in the race for survival because child mortality (from 1 to 4 years) is still far from negligible (see Table 46–3), whereas it is mainly due to accidents in low infant mortality countries.

In a historical context, the rapid and continuous decline in infant mortality in countries where it has reached current in low levels was accompanied by a concentration of deaths at even younger ages. Between 40% and 50% of the deaths that occur during the first week of life are mostly children born preterm (less than 37 weeks' gestation) or with low birth weight (less than 2500 g or even 1500 g). It is therefore not surprising that research is increasingly focusing on the cause of late fetal deaths, which are deaths immediately preceding the early neonatal period, of which it is conceptually and chronologically the extension (see Chapter 32). In these situations, the concept of *perinatal mortality* (grouping late fetal deaths or stillbirths and early neonatal deaths) tends to supersede that of infant mortality, even if there is regained interest in the post-neonatal period in the context of prevention of the sudden infant death syndrome. In situations of high mortality levels, attention is focused on the already born child, and the concept of infant mortality is completed by that of child mortality (1 to 4 years), because mortality risks remain high until the age of 5.

Today, we are faced with two mortality systems that differ fundamentally in their levels, timing (age at death), structure of medical causes, measurement, search for determinants, and identification of priorities for action. Through these differences, a certain number of regularities are observed, such as the well-known phenomenon of social inequality, which persists irrespective of mortality levels, or the series of measures applied toward their elimination.

At the global level, the most recent estimates produced based on civil registration for developed countries, on retrospective surveys such as the Demographic and Health Surveys (DHS), or generated by indirect methods from census or survey questions on the survival status of children for developing countries, show that infant mortality varies from 195‰ in Sierra Leone to 4‰ in Japan (Lévy, 1999). The levels by large regions are shown in Table 46–1. Europe was still characterized by differences in risks of such magnitude in the early 20th century, with an infant mortality rate of 80‰ in Norway from 1901 to 1905 (Masuy-Stroobant, 1997) and perhaps more than 300‰ in Russia (Zakharov, 1996) at the same period.

As much as available data permits, the high mortality levels of the past show some similarities with what is observed in many poor countries today. Mortality remains high beyond the first year of life, and the causes of death were mostly of infectious origin. It is paradoxical that we have civil registration data for medical causes of infant mortality in 19th century Europe, that, although containing a high proportion of ill-defined causes of death, give a good idea of the situation at the national level. In Belgium between 1895 and 1900, enteritis and diarrhea were leading causes, followed by infectious diseases (e.g., measles, smallpox, whooping cough, scarlet fever, diphtheria) and then by acute respiratory diseases (Masuy-Stroobant, 1983, p. 32). Concerning early neonatal mortality, Iceland showed very high levels of mortality due to tetanus in the 18th century (Vasey, 1997).

TABLE 46–1 Infant Mortality per 1000 Live Births in the World in 1999

Region	Rate (‰)[a]	Region	Rate (‰)[a]
Africa	**88**	**America**	**28**
North	51	North	7
West	86	Central	34
East	105	South	35

South Central	74	North	6
South East	46	West	5
East	29	East	13
		South	7
Oceania	**24**	**World**	**57**

[a] Most of these figures are the results of estimates made by the Population Reference Bureau based on available statistics in different countries. In low-mortality countries, they come from civil registers, and in high-mortality countries, they come from retrospective surveys.

From Lévy (1999).

For developing countries and especially for countries with very high infant mortality, these sources of data do not exist, and it is often necessary to rely on intensive surveillance systems, which are generally not representative of the countries in which they function, or on highly selective hospital data concerning predominantly urban populations. In these cases, the major causes of death in childhood (0 to 5 years) are mainly infectious or parasitic: "They are mostly severe respiratory conditions, diarrhoea and enteritis, malaria, measles and tetanus" (Hill and Hill, 1988, p. 75). Undoubtedly, we must include today the devastation caused by the acquired immunodeficiency syndrome (AIDS) epidemic that directly, by transmission from mother to child, or indirectly, by the greater risk of becoming an orphan, increases the risk of mortality in childhood, especially in urban areas of Central and Eastern Africa (Rossi-Espagnet *et al*., 1991).

At the other extreme, the main causes of infant deaths in low-mortality countries are perinatal conditions, among which those related to immaturity are most common, followed by congenital anomalies and the sudden infant death syndrome, which in certain countries belongs to the larger category of "ill-defined symptoms and morbid states". If perinatal causes are concentrated in the first month of life and cot death appears after the first month, infant deaths due to congenital anomalies, especially frequent during the first month, may also occur later. These three large groups represented 73% of infant deaths in Belgium and in Great Britain in 1994.

The fact that measles, enteritis, diarrhea, and other infectious diseases, considered preventable today by vaccination or easily cured and rarely lethal in low-mortality countries, are such terrible killers in poor countries no doubt evokes the nutritional hypothesis proposed by Thomas McKeown (1976) to explain the general mortality decline in Europe since the middle of the 19th century. According to him, the reduction in lethality of disease was brought about by an improved resistance of the host (in this case, children) because of improved living conditions in general and better nutrition in particular. Other authors invoke the advantages of public health measures, which by the end of the 19th century provided cities with sewage systems and drinkable water distribution services, when domestic and personal hygiene practices became more popular. As much as it is possible to understand and explain *a posteriori* events that belong to the past, these two hypotheses have been confirmed by facts.

Infant feeding however, shows some specificity, and if the medical corps had already noticed a higher weight gain among breast-fed newborn babies compared to bottle-fed babies (Bouchut, 1878), artificial feeding of the newborn could not yet be carried out safely. Pasteur's discoveries were applied on a large scale only at the end of the 19th century by methods of industrial pasteurization of milk and by the diffusion of Pasteur's recommended hygiene rules and pediatric care (through well-baby clinics) and by the sterilization of milk and feeding bottles at home, hygiene, and care of babies. These rules are still practiced today, and their spread and the measurement of their effects by regular medical check-up of children (e.g., weight, height, monitoring of changes in feeding habits, general vaccination) are the basis of the European organization of preventive medicine, which has since spread all over the world.

The observed past interaction between malnutrition and infectious diseases is quite similar to morbidity and mortality by infectious diseases among children in the Third World today. It is estimated that malnutrition is associated with 60% of deaths in childhood for developing countries (Blanc, 1991). Measles among malnourished children is frequently associated with other infectious diseases such as pneumonia or diarrhea. Children who survive this severe episode remain weakened for a long time, and various studies show a delayed effect of measles on the children's survival, particularly in sub-Saharan Africa (Clements *et al.*, 1992). Maternal malnutrition is also partly responsible for the high proportion of low-birth-weight children reported in some estimations (Kramer, 1987). These children, already weakened at the onset, will show lower resistance to subsequent infectious diseases.

Pasteur and the improvement in infant nutrition are not the only factors responsible for the steady decline in infant mortality, which for developed countries constitutes one of the most important achievements of the 20th century. This decline was accompanied by a general economic and social development that seems to have been particularly favorable to women and children; the generalized access to education and the development of effective contraception gave rise to an unprecedented improvement in women's status in these societies. Equally important was the considerable development in medical care during pregnancy and delivery and the fight against infectious diseases by means of vaccination or antibiotics.

Medically assisted procreation and the care of increasingly preterm and low-weight babies have since the mid-1980s gradually reshaped the context of health and infant mortality in rich countries. An increasing number of children, who otherwise would not even have been registered because of their extreme immaturity, can be now be cared for and saved. There is an increase in low-birth-weight births (less than 2500 g) and of very low birth weights (less than 1500 g) in most developed countries with the access to intensive neonatal care techniques. This phenomenon may cause an apparent stagnation in infant mortality levels, but the increasing possibility saving babies of very low weight does not exclude the risk of handicap for those who survive (Topp *et al.*, 1997). The question for these countries is that of the consequences of this decrease in mortality on the health of children, especially children being born with a very low birth weight.

II. A COMPLEX PHENOMENON TO BE ANALYZED AT DIFFERENT LEVELS

The determinants of infant mortality, which are generally different from medical causes of death, can be analyzed, explained, or acted on at different levels. The coexistence of very different mortality systems is generally interpreted at the macro-societal level in terms of the level of economic and social development. The association between national or regional levels of infant mortality and level of development, measured according to various indicators, is so systematic that infant mortality is generally considered to be one of the most sensitive indicators of a country's level of development. At the individual level, the extent of social inequality in infant mortality could also serve as an indicator of equity in the distribution of resources within a country.

The determinants of infant mortality have been traditionally identified by simple comparative analyses of available data. The term *determinants* was then attributed each time a variable shows a recurrent significant association with infant mortality in various situations.

At the national level, political choices made by governments are likely to improve female literacy and education of young girls, increase access (physical and financial) to health care, and improve living conditions (e.g., through reclamation of swampy land, installation of sewage systems, extension of drinkable water distribution, collection and treatment of waste). They may also promote access to employment with a view to ensuring better living standards for all.

At the community level, the quality of water for domestic use or the availability of drinking water; access to electricity and to a sewage system; a healthy environment; adequate housing; and climatic conditions have been major determinants of the mortality decline in Europe until the early 20th century and are still important factors in poor, high-mortality countries. Access to health services (preventive and curative) at the local level is also a part of this group of determinants. Generally, the urban or rural nature of the area determines access to such collective services.

The household's composition where a child is born and the importance given to each member in the division of tasks or the distribution of available resources (e.g., food, health care, education) may be promising research themes, as well as the status of women and girls in particular and the relation of children to adults in general. Beyond the analysis of the bargaining power between generations or between spouses, an analyst has to consider the help and the affective or psychological support the household members, relatives, and friends can provide in sharing childcare.

At the individual level, the position of the infant's family in the social hierarchy affects in various ways access to resources needed to maintain good health and coping strategies for everyday life conditions. This position is often measured by the father's income and occupation or the mother's level of education. The legal nature of the union, the nationality, and the ethnic group are other social status criteria.

The mother's biologic characteristics, such as her own weight at birth, her pregestation weight, and weight gain during pregnancy, are other nutritional indicators that enable us to predict a child's birth weight and, consequently, its frailty.

1. Preventative Behavior

The fertility scheme (i.e., age at child birth, number and spacing of births, and in particular, the last birth interval) adopted by the mother is part of the numerous recommended preventive behaviors to carry her pregnancy to term and maintain her child in good health. The identification of risk factors in her past pregnancies history, such as miscarriages, preterm births, or infant deaths, is part of the standard anamnesis during pregnancy because of their predictive power on the outcome of the current pregnancy.

Prevention can start before conception by the search for hereditary defects likely to be transmitted to the child. It may continue during pregnancy by early prenatal care and the search for signs of acquired immunity by the mother (e.g., tetanus, rubella, toxoplasmosis, sexually transmitted diseases, testing for human immunodeficiency virus) against a certain number of infectious or parasitic diseases (malaria) and the existence of maternal pathologies (e.g., diabetes, heart disease) that could endanger the life of the mother, the fetus, or the newborn.

The early detection of congenital anomalies can lead to the decision to undergo a so-called therapeutic abortion, thereby reducing the infant mortality level but mostly reducing the prevalence of handicapped children in the population. Beyond this medical type of prevention, there is also the adoption of daily preventive behavior, which can be summed up as living a healthy life: not overtiring oneself, avoiding stress and heavy or tedious work, having a balanced diet, and when necessary, using vitamin supplements to manage preexisting deficiency (i.e., anemia) or deficiency caused by the pregnancy itself, avoiding alcohol but especially smoking or taking drugs. Childbirth should, if possible, take place in a hospital equipped to cope with dystocic pregnancies and high-risk births.

As soon as the child is born, prevention should be continued by providing the baby with adequate nutrition (especially in the case of artificial feeding and during the delicate weaning period), ensuring the newborn's body hygiene, remove sources of infection or accidents, and give it the attention and love enabling it to grow well. From a medical point of view, vaccinations should be done according to a recommended schedule, and attention is paid to the baby's growth by regular visits to well-baby clinics or health centers. It is also necessary to have the capacity to identify early symptoms of illness to seek adequate care in due time (e.g., water diet or use of oral rehydration salts in the case of diarrhea, evaluation of the severity of episodes of fever).

2. Psychological Factors

Already identified in 1955 by J. Morris and J. Heady (1955), the concept of mother's capacity, which indicates an active rather than passive psychological profile when facing difficulties, is a research theme that is being developed (Kronenfeld, 1997).

3. The Child's Characteristics

Besides birth weight, pregnancy duration, and the presence of anomalies, the male mortality disadvantage is the rule, at least until the first birthday, which in high-mortality situations may give way to a female disadvantage that can last until the ages of 14 to 15 years (Tabutin and Willems, 1996). These trends, duly reported at the end of the 19th century in Europe, where they gradually disappeared during the early 20th century, are still observed in several high-mortality countries today. Twin births represent an increased risk because they are often preterm births. The spread of medically assisted procreation in low-mortality countries has triggered an unprecedented increase in multiple and very multiple (triplets and more) births in the past 2 decades (Masuy-Stroobant, 1994).

This already long list is far from exhaustive, but it reflects the importance of research on the cause of death in infancy, the complexity of its causality, and its analysis because of the interdependence of the different levels of explanation.

The often mentioned theme of maternal education (see Chapter 56 on theories and explanatory frameworks on child mortality) can be analyzed at several levels. Its mode of operation and the status it confers to a woman depend on the political context.It no doubt affects the choice and place of residence and lifestyle, and the educational level, if high enough, gives rise to better living standards, which gives people access to more comfortable, better furnished, and easier to maintain housing, as well as to financial access to adequate health care. The status it confers to a woman and mother in the household empowers her to better negotiate the distribution of resources in favor of better care for her child. It is also generally associated with behavior more attuned to anticipation, investment in the future, and prevention, and it gives a woman the cognitive means and the rationality to find solutions to the difficulties she might encounter.

Most of the determinants discussed here rarely exist in isolation, and they may have an effect on child health or mortality only in the presence of other determinants, making it difficult or impossible to isolate a totally independent effect. This is the case, for example, for smoking, which is the object of numerous studies. Smoking often appears to exert a direct effect on birth weight by producing intrauterine growth retardation. Studies have shown that the smoker's diet during pregnancy is of less good nutritional quality than that of nonsmokers, nutritional deficiency in itself contributing also to fetal growth retardation (Trygg *et al*., 1995). The social and behavioral profile of female smokers also is significantly different from that of nonsmokers in many ways. How then can we isolate the specific effect of smoking?

III. CAUSES, DETERMINANTS, AND DIFFERENTIAL RISK

In an overview of research conducted by demographers in the area of mortality, Eileen Crimmins (1993, p. 589) wrote the following:

> Mortality research remains largely descriptive, as was the fertility research of 30 years ago. Because no "theory" of mortality currently exists, this area is likely to undergo considerable theoretical development in the coming decade. Currently, the emphasis is placed on describing differences according to race, ethnicity, and social class. New independent variables, such as social support, are suggested regularly as possible explanatory variables for mortality differences, but the mechanisms through which these variables might work often remain unspecified.

This comment adequately summarizes the situation of field research in this area, even if some recent attempts to test the effect of maternal education (Sandiford *et al*., 1995) or the evaluation of the respective effects of contextual determinants (collective services such as water or electricity supply) and individual determinants (socioeconomic and behavioral characteristics) are interesting in explaining, for example, rural-urban differentials in child mortality in Brazil (Sastry, 1997).

Research on the determinants or causes of infant mortality is confronted to the relative scarcity of data on the phenomenon and the highly complex interrelations of its factors at several levels of observation and analysis demonstrated by demographers and by epidemiologists.

Developed countries generally have civil registration or medical birth registry systems that ensure complete coverage (almost exhaustive coverage for medical registers) of births and deaths. Organized for administrative or medical purposes, these information systems enable research to at least associate the sociodemographic characteristics of a child's parents (e.g., occupation, nationality, education) and certain biologic variables (e.g., mother's age, parity, last birth interval, twin status, sex of the child) with the risk of infant mortality or the risk of low birth weight or preterm delivery (Table 46–2).

In many cases, the possibility of calculating differential infant mortality risks or risks of low-birth-weight or preterm births depends on being able to match death records having less information with the corresponding birth records (Gourbin, 1996; Gourbin and Masuy-Stroobant, 1995). Medical birth registers are generally limited to recording early neonatal deaths, and if they contain other medical data (e.g., maternal pathologies, parity, gestation period, child's

TABLE 46–2 Social Inequality, Fetal Mortality, and Infant Mortality per 1000 Births in Europe

Data from civil registration, published statistics (England and Wales, Hungary), available records (Austria, Portugal, Romania), and from analysis of private data by the author (Belgium).

birth order, precise circumstances of birth, baby's situation at birth, care of the newborn), social data are often absent. In certain countries and especially in most northern European countries, these data are systematically matched with those of civil registers making it possible to analyze data from both sources. The systematic recording of the individual identification code of the population register on each administrative document makes different types of cross-tabulations possible in most northern European countries. Consequently, it is by matching data from medical registers with census data that measurement of the joint effects of parents' level of education on infant mortality became possible in Norway (Arntzen *et al.*, 1993).

If these databases are available to researchers, they enable them at most to measure very precisely, for total populations, the differential risks associated with the several available variables, to establish the possible interactions between fertility behavior, past pregnancies' outcomes, and social identification variables, or to measure the net effect of these individual variables (after controlling for confounders) on mortality or on the indicators of child health at birth (e.g., weight, gestational age). They are, however, strictly limited to an individual level of analysis and can only rarely test hypotheses regarding the mechanisms (of prevention) explaining how the mother's education could protect or even improve the health of children.

In developing countries, those for which most of the theories and explanatory frameworks were developed (see Chapter 56), most studies on infant and child mortality are based on retrospective data from secondary analyses of surveys (initially the World Fertility Surveys, then the successive waves of Demographic and Health Surveys), whose primary aim was to measure and analyze fertility. Numerous studies were therefore based on the fertility history of women and the results of successive pregnancies and then, depending on available data, went on to develop valid estimates of infant and child mortality before measuring its differentials (Table 46–3). If the statistical rarity of death forced them to conduct mortality analysis on the 5 or even 10 years preceding the survey, they however present the undeniable advantage of providing different levels of analysis: individual, household and community or contextual levels (as in the example of Brazil cited earlier).

To the question about what are the determinants of infant mortality or at least what are the proven determinants, which are significantly related to the risk of infant mortality in several contexts (as far as confounders are taken into account) and for which a plausible mechanism for action could be described (if not tested in the field), the answer remains difficult. An impressive number of risk criteria have been published and are regularly updated, but, for instance, only a vague response is available to the question concerning the pathways through which early prenatal

consultations can reduce infant mortality or the incidence of preterm births, especially when maternal education and place of residence considerably reduce net effects. We are faced with the situation described by Kenneth Wolpin (1997, p. 532) "The result of the absence of theorizing is that researchers are unrestricted in the choice of factors that are simultaneously considered," which makes systematic and comparative analysis particularly difficult.

IV. FROM MORTALITY TO HEALTH: A QUESTION OF WEIGHT, HEIGHT, AND GESTATIONAL AGE

Mortality is most often preceded by a worsening of health or even a state of frailty at birth. Pediatricians have for a long time recognized birth weight as an indicator of a child's frailty. If it is less than 2500 g, it is identified as *low birth weight*; if it is less than 1500 g, it is *very low birth weight*. If weight is not actually a valid measure of maturity for a newborn (e.g., a baby can be born at term, or 37 weeks' gestation, and weigh less than 2500 g, describing a case of intrauterine growth retardation), it is at least more accessible and easier to measure, irrespective of place or conditions of birth–you only need a scale.

Taking birth weight into account in the measurement of infant mortality in low-mortality countries ensures a considerable improvement in spatiotemporal comparability of the phenomenon. This is because of the effect on the overall level of infant mortality of the increasing incidence of differences in legal criteria for birth reporting in civil registers and of the growing and varying tendency to declare very low birth weight births, for which survival chances have improved dramatically because of advances in neonatal intensive care (Masuy-Stroobant and Gourbin, 1995).

TABLE 46–4 Early Neonatal Mortality (0 to 6 Days) per 1000 Live Births by Categories of Birth Weight in Some European Countries in 1990

Weight (g)	Austria	Belgium	Czech Republic	Hungary	Poland[a]
500–999	397.1	387.5	609.3	718.8	754.4
1000–1499	95.2	134.9	257.7	236.6	304.5
1500–1999	41.1	33.9	71.6	48.6	101.7
2000–2499	11.4	11.0	16.4	14.9	24.4
2500–2999	2.3	1.7	3.6	2.8	4.9
3000–3499	0.8	1.1	1.6	1.7	2.2
3500–3999	0.5	0.7	0.9	1.5	1.7
4000–4499	0.9	1.3	1.4	1.4	1.9
4500+	2.6	1.9	2.5	4.4	6.2
Total	3.3	3.4	5.8	8.7	12.4
Infant mortality	7.8	8.0	10.8	14.8	19.4

[a] Including "nonviable" live births. For Poland, the weight categories do not correspond exactly to international recommendations. The figures presented here refer to the following categories: 601–1000 g; 1001–1500 g; 1501–2000, and so on.
From Civil Registration statistics. Unpublished data except that for Poland.

A close relationship is systematically observed between birth weight and the risk of mortality (Table 46–4), including in developing countries. McCormick (1985, cited in Kramer 1987, p. 664) stated the following: "In both developed and developing countries, birth weight is probably the single most important factor that affects neonatal mortality, in addition to being a significant determinant of post-neonatal infant mortality and of infant and childhood morbidity." There are many similarities between the determinants of low birth weight and those identified for infant mortality.

The choice of the risk of low birth weight has the advantage of partially solving the problem of the statistical rarity of death faced by researchers (i.e., the incidence of births weighing below 2500 g is at least 10 times the risk of death in low-mortality countries) and, in the case of developed countries, save time spent in matching births and death records. The disadvantage, however, is that it excludes maternal behavior after delivery. An example is given by the mother's smoking habits, infant feeding practices, and sleeping positions in the study of the determinants of cot death. In developing countries, this indicator of intrauterine growth can be generalized by a measure of its nutritional status at different ages, as suggested by Henry Mosley and Lincoln Chen (1984) (see Chapter 56). The choice of birth weight as an indicator of health at birth offers a much wider range of research themes going far beyond those restricted to mortality. One example of this is a case-control study in Sudan comparing individual and community characteristics of families with low-birth-weight children with families whose children weighed 2500 g or more (Taha *et al.*, 1995).

Relationship between Morbidity and Mortality by Cause

VIVIANA EGIDI AND LUISA FROVA

Università degli Studi di Roma "La Sapienza," Rome, Italy

Instituto Nationale di Statistica (ISTAT), Rome, Italy

I. KNOWLEDGE GAINED BY MONITORING THE MORBIDITY PROCESS

When mortality is high, particularly due to infectious and acute diseases, the life table and its indicators constituted quite efficient tools for evaluating the population's state of health. Increased life expectancy and the growing impact of chronic or degenerative diseases impose the need for a more in-depth evaluation of the current trends. Attention is shifting from the considerable progress made in quantitative terms over the past few years, particularly with regard to survival in adult and senile age, toward an analysis that investigates the quality of the years that have been added to the mean life duration. The possibility of monitoring the entire morbidity process from a theoretical and statistical point of view rather than only its terminal event (death) substantially increases knowledge and the possibilities to evaluate differentials and trends as well as allowing the formulation of more appropriate public health policies.

This chapter presents an overview of the available data sources for the evaluation of the health status of a population and the concepts and methods that take into account the relationships between mortality by cause and the incidence, prevalence, and lethality of diseases. We consider the methods of evaluation of survival by health status based on morbidity-mortality life tables and their corresponding healthy life expectancies. The latter refer to different concepts and definitions of health and can be computed according to different methods, taking into account the basic assumptions and the availability of data on incidence or prevalence of diseases.

II. MONITORING MORBIDITY

1. Hypotheses about Longevity and the Quality of Survival

Numerous hypotheses have been put forward concerning the consequences of increased longevity on the quality of survival in adult and senile age. Certain theories maintain that an improvement of therapeutic capability, leading to the lengthening of a patient's life, has not been accompanied by an equally efficient action in the field of disease prevention. The decline in mortality therefore would be the result of a decrease in the probability of death (or lethality) from chronic diseases rather than a reduction in their incidence and would therefore hide a worsening of survival in qualitative terms. This is the *theory of pandemic morbidity* (Gruenberg, 1977, 1980; Kramer, 1980). Partially correcting this hypothesis, Olshansky (1991) maintains that the fall in mortality has merely changed the balance of morbidity processes from fatal to nonfatal ones, observing that the diseases that mostly affect the quality of survival are not necessarily those associated with the highest risk of death.

On the contrary, many experts (Day, 1991; Robine and Colvez, 1991; Fries, 1980, 1983, 1987, 1989) believe that, thanks to a more suitable diet, less tiring lifestyles, greater attention to physical exercise, more widespread awareness about prevention and well-known risk factors (e.g., smoking, alcohol, sedentary habits, high-fat food intake), the state of health remains at good quality levels up until an advanced age and that the morbidity process tends to be more and more concentrated in later life This is the *theory of the contraction of morbidity*.

In between these two extreme viewpoints, a theory called *dynamic equilibrium* has been advanced (Manton, 1982). According to this theory, the increase in life expectancy can be partly explained by a slowing in the rate of progression of chronic diseases. For patients, this produces a longer mean duration of the state of disease, with a subsequent increase in the prevalence of chronic diseases that would remain at less serious levels for longer periods. According to another hypothesis, the dynamic equilibrium could be produced by means of a reduction in the mean duration of disease accompanied by an increase in the mean level of seriousness of the disease itself (Olshansky, 1987).

2. Disease as a Process

According to the state of health, a survival analysis requires the availability of both conceptual and methodologic tools capable of monitoring the entire process from the onset of the disease until the death of an individual or his or her eventual recovery. Numerous efforts have been made to complement traditional indicators of mortality with measures capable of indicating the population's state of health. There are several difficulties involved, for the most part linked to the very nature of the phenomenon, for which even the definition poses a problem. This chapter does not address the question of the wider debate about the different objective and subjective approaches to study the state of health. The goal of describing the relationship between morbidity and cause-specific mortality leads to adoption of an objective approach, according to which the attribution of a state of ill health depends on the presence of a specific disease, which is identified by reference to the International Classification of Disease (ICD), used for the classification of causes of death.

Despite the simplification introduced whereby ill health is identified with a state of disease, the conceptual and methodologic problems that remain are considerable. Disease is not an event that can be identified as taking place at a given time and age of an individual with the same degree of certainty normally encountered when identifying a precise event. The passage from a condition of health to one of disease is rarely evidenced by one precise event. Generally, it can be represented as the beginning of a process–not necessarily completely evident–that goes through a number of phases, developing over the course of time and with reference to the age of the individual concerned, leading to different outcomes (e.g., recovery, chronic state, death). The course of the disease, its duration and outcome, depend on the type of disease and on endogenous factors, such as sex of the individual and age at which the disease was contracted, and exogenous factors, such as the health care facilities available to the individual and his or her ability to use them effectively. During the process, the individual may go through different phases of severity of the disease, both in terms of the risk of death connected with it and in terms of limitations of autonomy and impact on the quality of life. At an advanced age, it is difficult to attribute the state of disease to one specific morbidity process. More often than not, several processes accumulate and interact in the same individual, creating even more complex situations.

III. MORBIDITY PROCESSES AND CAUSES OF DEATH

1. Disease, Death, Lethality, and Recovery: From the Individual to the Population

The concepts and models necessary to evaluate the impact on a population of a particular morbidity process are substantially different from those used in clinical or epidemiologic microanalysis. The objectives of the two types of study are also very different: the former tends to highlight the consequences rather than the causes of particular trends and characteristics of the state of health, often placing the accent on aspects such as the evaluation of the impact of morbidity and its dynamics with respect to health resources available and associated costs. The latter objectives are aimed at describing and interpreting the causal mechanisms underlying morbid states to provide indications regarding the possibilities to intervene in the processes themselves. For instance, an important element in microanalysis is the exact determination of the *moment of onset* of a disease for an individual, an occurrence that often precedes the first manifestations of the process and its diagnosis by a long period (Fig. 47–1).

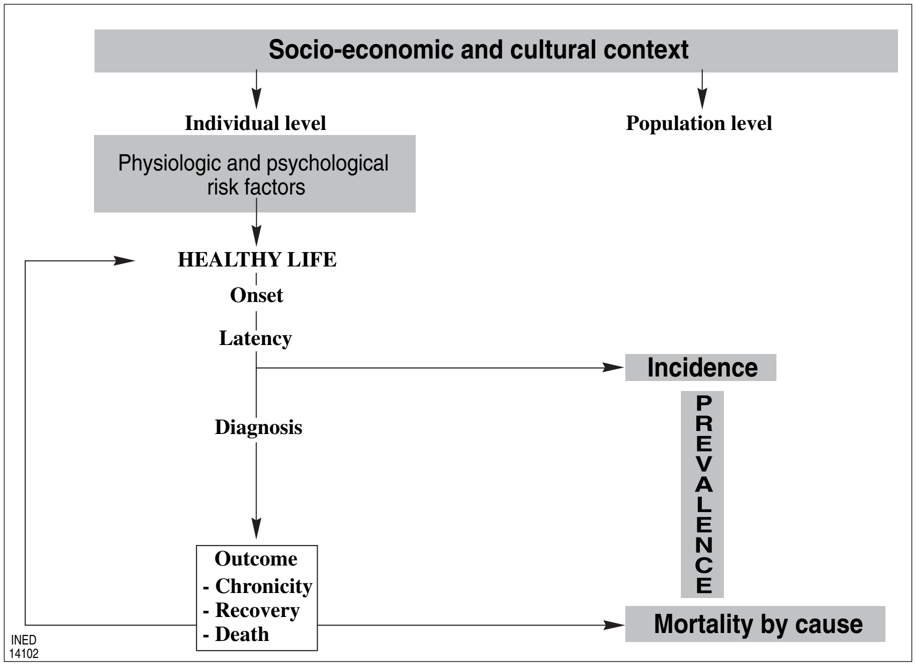

FIGURE 47–1 The morbidity process: context, individual events, and statistical measures.

This element cannot be overlooked, but it is less critical in macroanalysis, especially concerning the economic and social impact of the disease, as the period during which an individual is affected by a disease but is not conscious of it and is not harmed can be ignored because it does not exert any particular demands on society. It becomes important to monitor the latent period with greater accuracy by macroanalysis when the need is to evaluate dynamics of morbidity over time or differentiate its effects between population groups. The earlier age of contraction of a disease and an increase of its duration can be explained by an improvement in diagnostic capabilities and by an increase in health education, which today allows for the identification of a disease much sooner than in the past and in a differential manner in the population. *Recovery*, the transition from a state of disease to that of health, poses considerable problems when determining the exact point in time because it is difficult to establish when a patient ceases to be sick and returns to a healthy state. In this case, however, the macroanalysis approach allows for simplifications that can be used for estimating purposes. For instance, the survivors of a cohort of patients, all of whom contracted the disease at the same age and therefore, at a certain date, exhibit the same duration of the disease, can be considered "statistically recovered" when their relative survival curve becomes parallel to the axis of duration, expressing the nullification of the excess death risk of patients when compared with the general population.

a. Models of Disease-Death Processes

In an attempt to govern the complexity of disease-death processes in the population, models are designed to monitor the numerous elements coming into play. A set of *states*, each referring to a particular state of health, and *transitions* between states, regulated by specific transition probabilities, are assumed to represent the aging process of a cohort exposed to the risk of becoming ill and dying. The two models described subsequently illustrate the logic used, and reference is made to them to illustrate the procedure for constructing morbidity-mortality tables. Before examining the assumptions and characteristics underlying each model, it is useful to briefly discuss the symbols used:

$\alpha(x)$ is the overall mortality rate at age x in the general population.

$\gamma(x)$ is the cause-specific mortality rate at age x in the general population.

$\mu(x)$ is the hazard rate to contract the disease at age x for healthy people (i.e., the incidence rate).

$\lambda(x,\tau)$ is the recovery rate at age x for an individual who contracted the disease at age τ.

$\beta(x,\tau)$ is the mortality rate at age x for an individual who contracted the disease at age τ.

$\delta(x,\tau)$ is the cause-specific mortality rate at age x for an individual who contracted the disease at age τ.

$\xi(x)$ is the mortality rate at age x from causes other than the specific disease in the general population.

When a number of morbidity processes affect the population, rates $\gamma_i(x)$, $\mu_i(x)$, $\lambda_i(x,\tau)$, $\beta_i(x,\tau)$, and $\delta_i(x,\tau)$ are specified with respect to disease i, and $\beta_{i,j}(x,\tau,\rho)$ is the death hazard rate at age x for those having contracted disease i at age τ and disease j at age ρ.

Model A (Fig. 47–2) represents the simplest and most frequently used case, in which the process of elimination of the cohort is described by means of disease-death process and a death risk due to all *other causes* than the specific disease, acting in an instantaneous manner on the healthy and diseased population. A healthy individual at age x is exposed to the risk of falling ill or dying from other causes. Only when an individual is ill is he exposed to the death hazard from the specific cause.

Model B (Fig. 47–3) represents a more complex situation in which the process of elimination of the cohort is broken down by two disease-death processes and an instantaneous risk from other causes. The individual is exposed to the death hazard due to a specific cause only in the case that he is already ill and suffering from the corresponding disease.

The complexity of Figure 47–3 emphasizes the difficult conceptual and operative points of view in generalizing morbidity models to monitor a greater number of diseases. For n diseases, 2^n life states and $n+1$ death states must be contemplated together with all of the corresponding probabilities of transition between them.

Moreover, with regard to the availability of basic information, numerous problems exist. Only for a few illnesses, characterized by high social costs, have research instruments been set up that enable the estimation of incidence, recovery, and lethality rates. Many countries now have registers in which information related to tumors or serious illnesses of the circulatory system is collected. In just a few of these nations, the registers cover the entire national population; most refer to specific subpopulations, often geographically bounded. It is almost impossible to obtain the information required to estimate the probabilities of falling ill from a specific illness in the presence of others, the cause-specific mortality and recovery rates for those that have caught more than one disease. For this reason, it is necessary to introduce a hypothesis, often unrealistic (see Chapter 44), of independence between illnesses, whether it is during the initial stage, the subsequent stages, or the result of the morbidity processes.

IV. RELATIONSHIPS THAT LINK INCIDENCE, PREVALENCE, AND MORTALITY IN A COHORT

The overall incidence, prevalence, and mortality rates for the general population and for patients within the same cohort are very closely linked. In the case of incurable diseases or those having a high fatality rate, for which the probability of the patient returning to a healthy state can be hypothesized as being null

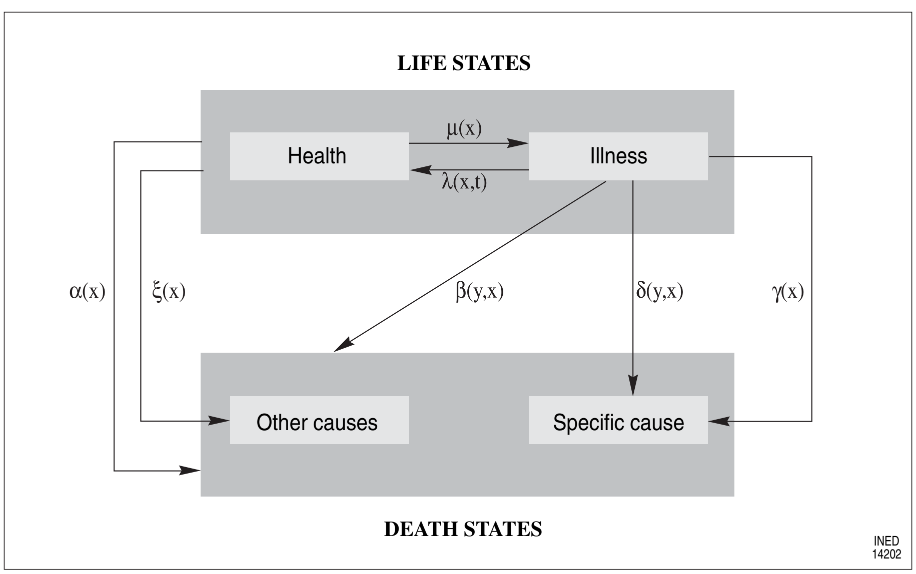

FIGURE 47–2 Model A: one disease-death process and one cause of death.

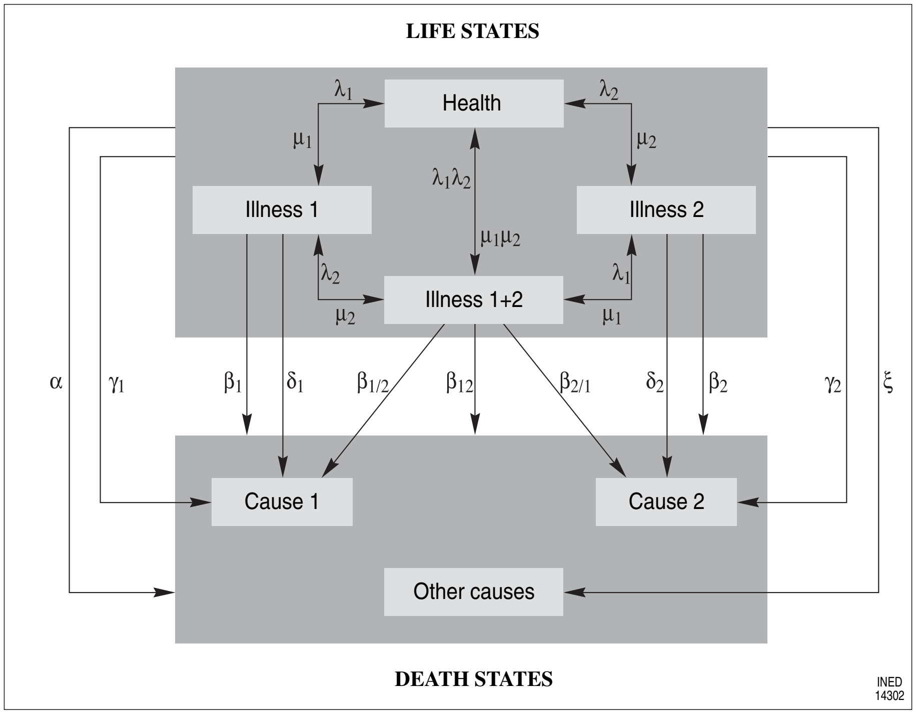

FIGURE 47–3 Model B: two disease-death processes and one cause of death.

or extremely low, knowledge of the relative survival curve for patients with respect to the general population allows the transition from incidence to prevalence to be appraised in a relatively simple manner (Verdecchia *et al*., 1989). With reference to the symbols used in Figure 47–2, the following can be said:

$$\nu(\mathrm{x}) = \int_0^x [1-\nu(\tau)]\mu(\tau)\mathrm{s}(\mathrm{x},\tau)\mathrm{d}\ \tau \qquad (1)$$

In Equation 1, for a selected disease,

$\mu(\tau)$ has been previously defined.
$\nu(x)$ is the prevalence rate at age x (or probability of being sick at age x, conditional on survival until age x).
$s(x,\tau)$ is the probability for an individual, having contracted the disease at age τ, of surviving the additional risk of death between ages τ and x. This is the relative survival function, which is the probability of survival up until age x of an individual who contracted the disease at age τ, $\beta(x,\tau)$, related to the same probability of survival of the general population, $\alpha(x)$.

This information can be expressed as follows:

$$\mathrm{s}(\mathrm{x},\tau) = \exp\left\{-\int_\tau^x [\beta(\mathrm{u},\tau)-\alpha(\mathrm{u})]\,\mathrm{du}\right\}$$

Another important relationship links the instantaneous mortality rate from a specific cause of death in the general population to the incidence, the prevalence, and the death hazards in the general population and in patients:

$$\gamma(\mathrm{x}) = \int_0^x [1-\nu(\tau)]\mu(\tau)\mathrm{s}(\tau,\mathrm{x})\delta(\mathrm{x},\tau)\mathrm{d}\ \tau \qquad (2)$$

The previous equations completely describe the morbidity-mortality process in a cohort, and knowing $\gamma(x)$, $\alpha(x)$, $\delta(x,y)$, and $\beta(x,y)$, they can also be used to estimate the incidence and prevalence of the disease on the basis of complete cohort mortality data. (Verdecchia *et al*., 1989).

The principal assumption of these relationships is the irreversibility of the morbidity processes. However, for practical applications, this assumption is acceptable for many chronic degenerative diseases, reflecting the idea that a patient with a history of a severe disease (e.g., cancer, ischemic heart disease) is expected to make greater use of health resources for the rest of his or her life.

It is evident that these equations are valid within a same birth-cohort. In a population, the past dynamics of the elements in play and the structure of the population, both general and the sick, would prevent the establishment of such precise relationships, except under the hypotheses of population stationarity and risks of illness and death. Despite this, the sense of relationship remains, as is clear from Table 47–1, created from data of incidence, prevalence, and

TABLE 47–1 Incidence and Prevalence Rates Estimated from Patient's and Population Mortality in Italy, 1990

Cancer sites	Males				Females			
	Relative survival[a]	Mortality by cause	Incidence	Prevalence	Relative survival[a]	Mortality by cause	Incidence	Prevalence
Lung	0.08	87.8	105.1	135.4	0.12	13.8	15.6	18.9
Larynx	0.65	8.2	19.3	187.5	0.71	0.4	0.9	10.1
Colon-rectum	0.38	29.0	61.5	237.3	0.40	24.7	53.3	250.0
Stomach	0.19	26.5	35.1	86.7	0.21	16.0	21.7	62.7
Breast					0.72	34.1	112.2	280.9

mortality in Italy for the years 1970 and 1990. The wide gap between incidence and prevalence characterizing cancers with the highest relative survival rate is evident. For cancer of the larynx, which allows for survival after 5 years of about 70% for women and 65% for men, the ratio between incidence and prevalence is 1 : 10. For lung cancer, the ratio is very close to 1 (1 : 1.3).

V. SPECIFICATION OF SURVIVAL ACCORDING TO STATE OF HEALTH: THE MORBIDITY-MORTALITY TABLE

Among the synthetic indicators summarizing morbidity that have obtained most success in recent years are life expectancies specified with respect to state of health which integrate information on mortality and morbidity. The *health expectancies*, as these indicators are generally called, can be referred to different concepts and definitions of health, and they can be calculated by various methods. The *perceived life expectancies* are very widely used and constitute a family of measures that use data on perceived health status, the best known of which is the *healthy life expectancy*, namely, the average number of years an individual is expected to live in a state of health defined as good or very good if current patterns of mortality and self-rated morbidity continue to apply. On the basis of the objective approach adopted here, the *disease-free life expectancies* can be estimated; this term refers to the average number of years an individual is expected to live free from one or more specific diseases.

The estimate of these indicators is based on specific morbidity-mortality tables that act as an integrating mechanism of information derived from several sources and studies regarding the morbidity and mortality of the population, including them in a model based on a cohort and life course perspective such as that presented in Figures 47–2 and 47–3. Substantially, the tables are made up of a set of life table survival curves related to the different morbidity processes being examined. When longitudinal data are available, the model can be used as a model of survivorship to describe the elimination process of a cohort of healthy individuals due to disease and death. When longitudinal data are not available—and this is the most frequent case—an assumption of stationary population dynamics can be adopted to construct a period morbidity-mortality table based on the disease and death risks observed in a certain period, which is a different and complementary way of evaluating the impact of a disease on a given population. Like a traditional period life table, the period morbidity-mortality table reflects the cross-sectional experience of individuals who belong to different cohorts. The table makes it possible to obtain measures summarizing morbidity and mortality of a population, to show the net effect of the age-structure, and to evaluate the impact of such morbidity on the quality of survival at that moment.

Comparisons of period morbidity-mortality life tables can show more rapidly and vividly period-specific effects, such as a better accuracy in diagnostic procedures or the development of new therapies; on the other hand, cohort influences (i.e., the cohorts' modification in life styles, smoking habits, or physical activity) are more clearly evident in comparisons of cohort morbidity-mortality tables.

For construction of morbidity-mortality tables, it is theoretically possible to use various methods that can generally be distinguished according to two main principles: prevalence methods and incidence methods. The conventional method, or Sullivan method, belongs to the former, whereas the multistate morbidity-mortality tables are an example of the latter.

1. The Sullivan Method

The Sullivan method (1971) is certainly the simplest and most widespread method for constructing a morbidity-mortality table and, as a result, of indicators of life expectancy by state of health. It can be applied in under the most diverse conditions because it requires only a life table of the population referring to a period in which prevalence rates by age are available (whether objective or subjective in nature). In this regard, it must be emphasized that this type of method is the only one that can be used when health data definitions are based on individual perception and on self-evaluation for which the basic information is represented by prevalence rates of states of health perceived as being "not good," gathered by means of interview surveys conducted directly with individuals themselves. In these cases, concepts such as disease-specific incidence and curve of survival of patients, necessary when using incidence methods, have no meaning at all.

The prevalence method is based on the distribution of the years lived from a life table, which is the $l(x)$ column of the table, into the different states of health in proportion to the rates of prevalence of the disease (or condition), $\nu_i^*(x,x + \Delta x)$, surveyed at a specific moment regarding a specific population, and belonging to a specific age bracket. The years spent in a state of illness (or with a condition) between the age x and $x + \Delta x$ can be calculated using the following equation:

$$L_i(x, x+\Delta x) = \int_x^{x+\Delta x} L_i(u)du = \nu_i^*(x, x+\Delta x) \times \int_x^{x+\Delta x} L(u)du$$

The years spent in a healthy state can be determined as follows:

$$L_h(x,x + \Delta x) = L(x,x + \Delta x) - L_i(x,x + \Delta x)$$

From the $L_i(x,x + \Delta x)$ term, it is easy to calculate synthetic measures such as *healthy life expectancy* or *disease-free life expectancy*. The parsimonious nature of the method and the extreme simplicity of the calculations necessary for the estimates are discounted by a rather strict system of assumptions (i.e., stationarity of risks of mortality and morbidity of the population) and by the inevitable approximation brought about by the fact of operating with prevalence rates (i.e., stock rates) that may, especially for processes with a shorter duration, greatly underestimate the real diffusion of the disease in the population and, as a consequence, the person-years spent in unhealthy conditions (Alho, 1992; Freeman and Hutchison, 1980; Keiding, 1991; Preston, 1987). Moreover, in the case of long-term pathologies, the hypothesis of stationarity is unacceptable because it relates to long periods due to high rates of survival. The cross-sectional prevalence data used by this method imposes serious limits due to the influence of the current states of morbidity and of those of previous years (Brouard and Robine, 1992).

2. Multistate Life Tables for Chronic Diseases

With incidence methods, the morbidity-mortality table is calculated following the logical evolution of the morbidity process from its onset to its final outcome, favorable or unfavorable, through competition with other morbidity processes and other risks of elimination to which the population is exposed. These methods make it possible to evaluate the consequences of the dynamics that in the past few years have affected the different aspects of the morbidity process: disease onset, its duration, and its lethality. The same logic on which these methods are based assumes the adoption of the definitions of objective health based on the absence of certain diseases or specific disabilities or handicaps for which it makes sense to assume a morbidity process that, arising or diagnosed at a specific moment, develops over the course of time toward the three possible outcomes (i.e., death, recovery, chronic state) (see Fig. 47–1).

One of the essential limits of application of these methods is imposed by the availability of adequate data. They assume the availability of very detailed information concerning the probability of transition of individuals between the various states of health, deducible only by means of continuous longitudinal surveys (e.g., follow-up studies, registers), and they are therefore difficult to have available except for certain important diseases and in countries that are very advanced in the field of collecting health information.

Let us suppose that the transition rates between all states comprising the model are available. The multistate multiple-decrement life table proposed by A. H. Pollard (1980) extends the concepts of the aggregate life table to cause-specific mortality and foresees that the healthy individual can leave this state for reasons of disease or death. This model, similar to that illustrated in Figure 47–1, consists of two double-decrement tables: Individuals remain in the disease-free group or depart from the disease-free group by contracting a disease or by dying from causes other than the disease under study. Those who contract disease cannot recover and remain ill until they die of the disease or die of other causes. Only the group of patients is exposed to the risk of death from the specific disease, whereas both of the groups are exposed to the same risk of death from all other causes of death (the process of disease-death and the death hazard from other causes are considered to be independent of each other).

This method of constructing the morbidity-mortality table undoubtedly constitutes a considerable step forward compared with the previous method based on prevalence rates, even though it does not take into account the possibility of recovery from the disease and return to a healthy state. However, this possibility is considered in the multistate increment-decrement model that provides for the monitoring of all possible states of transition when entering and leaving the different states (Duchêne 2002; Pollard J. H. 1990; Rogers 1989; Haberman 1983, 1984; Golini and Egidi, 1982; Chiang 1968). In these models, modifications of the state of health are represented by means of the transitions between the various states regulated by specific probabilities. The probability each individual has to transit from one state to another in a determined period is assumed to be independent from the transitions made previously and is conditioned by the last state in which the individual was found. These processes are principally based on Markov chain models to calculate transition matrices describing all transitions between states that may occur throughout an individual's life span.

To consider a greater number of interfering variables, methods for estimating probabilities of transitions are becoming more and more sophisticated. For example, to take into account the duration of the disease (i.e., the period of stay in a given state), semi-markovian models have been developed.

The incidence methods make it possible to construct a morbidity-mortality table and to estimate all of the analytic and synthetic variables and indices associated with it. To explain the relations existing within the morbidity-mortality tables, reference is made to Model A and Model B and to their respective symbols, assuming for simplicity the irreversibility of morbidity processes ($\lambda_i = 0$, for all i). It is assumed that mortality rates from other causes are independent of the morbidity process and that both the healthy and the ill are exposed to the same risk $\xi(x)$ of death from other causes. In Model A, this relationship is calculated as follows:

$$\xi(x) = \alpha(x) - \gamma(x)$$

In Model B,

$$\xi(x) = \alpha(x) - \gamma_1(x) - \gamma_2(x).$$

a. Model A

The set of survivors, $l(x)$, in the morbidity-mortality table at each age is obtained as the sum of the healthy survivors, $l_h(x)$, and diseased survivors, $l_i(x)$:

$$l(x) = l_h(x) + l_i(x)$$

In this case,

$l_h(x) = l_h(0) \times \exp\left\{-\int_0^x [\mu(u) + \xi(u)]du\right\}$ are the healthy survivors at age x

$l_i(x,\tau) = l_h(\tau) \times \mu(\tau) \times \exp\left\{-\int_\tau^x \beta(u,\tau)du\right\}$ are the patients who, having contracted the disease at age τ, are still alive at age x

$l_i(x) = \int_0^x l_i(x,\tau)d\tau$ are the diseased survivors at age x, whatever the duration of the disease.

The morbidity-mortality table therefore provides the structure of the population by state of health (healthy or diseased) for each age. On the basis of the survivors specified according to the state of health, the specific life expectancies can be calculated. This also makes it possible to assess the healthy survivors to obtain two other interesting indicators: the life expectancy and the disease-free life expectancy for healthy individuals at age x. The first indicator is estimated using the following equation:

$$e_h^T(x) = \frac{\int_x^\omega l_h^T(u)du}{l_h(x)} \quad \text{where}$$

$$l_h^T(u) = l_h(x) \times \exp\left\{-\int_x^u \alpha(s)d(s)\right\}$$

The second is obtained as follows:

$$e_h^h(x) = \frac{\int_x^\omega l_h(u)du}{l_h(x)} = e_h(x) \times \frac{l(x)}{l_h(x)}$$

In the previous equation, $e_h(x)$ is the disease-free life expectancy at age x.

Table 47–2 shows, as an example, total and "disease-free" life expectancy for two important diseases, cancer and major coronary events. Morbidity-mortality tables, based on Model A, are elaborated for each disease. Because Italy does not have incidence data, incidence was estimated by means of Equations 1 and 2 applied to overall and cause-specific cohort mortality data and patients' relative survival observed in existing local registers.

The increase in life expectancy seen in Italy between 1970 and 1990 of 5.3 years for men and 6.2 years for women should be scaled down considering the cancer-free life expectancy of 4.3 and 4.9 years, respectively.

TABLE 47–2 Life Expectancy, Cancer-Free Life Expectancy, and Major Coronary Events–Free Life Expectancy in Italy, 1970 and 1990: Model A

Age	Years	Males			Females		
		Total life expectancy	Life expectancy free from		Total life expectancy	Life expectancy free from	
			Cancer	MCE		Cancer	MCE
Birth	1970	68.8	67.4	67.5	74.5	72.3	74.0
	1990	74.1	71.7	73.1	80.7	77.2	80.5
65 years	1970	13.3	12.1	12.2	16.0	14.3	15.5
	1990	15.5	13.4	14.7	19.3	16.7	19.1
80 years	1970	5.8	5.0	5.0	6.6	5.6	6.2
	1990	7.4	5.8	6.8	8.6	7.0	8.5

MCE, major coronary event.

Moreover, the life expectancy advantage of women is considerably reduced: of the 6.6 years that on average a woman lives more than a man, only 5.5 years are cancer free. On the contrary, the dynamics over the last 20 years regarding major coronary events has been favorable, and the increase in disease-free life expectancy is greater than the overall value (i.e., 5.6 years for men and 6.5 years for women). At 80 years of age, as much as 92% of the additional 5.8 years of life expectancy of men is free of major coronary events (99% for women), whereas only 78% (81% for women) is free of cancer.

b. Model B

The set of survivors in the table is obtained from the sum of the survivors generated by four distinct processes:

1. Healthy survivors, $l_h(x)$
2. Patients with disease 1, $l_{i1}(x)$
3. Patients with disease 2, $l_{i2}(x)$
4. Patients with both diseases, $l_{i1,2}(x)$

These terms are added as follows:

$$l(x) = l_h(x) + l_{i1}(x) + l_{i2}(x) + l_{i1,2}(x)$$

From the previous equation,

$$l_h(x) = l_h(0) \times \exp\left\{-\int_0^x [\mu_1(u) + \mu_2(u) + \xi(u)]du\right\}$$

$$l_{i1}(x,\tau) = l_h(\tau) \times \mu_1(\tau) \times \exp\left\{-\int_\tau^x [\beta_1(u,\tau) + \mu_2(u)]du\right\}$$

$$l_{i2}(x,\rho) = l_h(\rho) \times \mu_1(\rho) \times \exp\left\{-\int_\rho^x [\beta_2(u,\rho) + \mu_1(u)]du\right\}$$

$$l_{i1,2}(x,\tau,\rho) = l_{i1}(\rho,\tau) \times \mu_2(\rho) \times \exp\left\{-\int_\rho^x [\beta_{1,2}(u,\tau,\rho)]du\right\}, \quad \text{if} \quad \tau < \rho$$

$$l_{i1,2}(x,\tau,\rho) = l_{i2}(\tau,\rho) \times \mu_1(\tau) \times \exp\left\{-\int_\tau^x [\beta_{1,2}(u,\tau,\rho)]du\right\}, \quad \text{if} \quad \rho < \tau$$

In the previous equations, $\tau(x)$ and $\rho(x)$ are, respectively, the age at onset of disease 1 and of disease 2. Details of the formulas are not given, but they are nothing more than extensions of those developed in Model A.

A worthwhile comment can be made with regard to the example shown in Table 47–3 regarding life expectancy for the overall and healthy-only Italian population for 1970 and 1990 calculated using this model. When considering the two morbidity processes (i.e., cancer and major coronary events) acting together, disease-free survival is reduced to 70.8 years for men and to 77.0 years for women, a lower number of years than estimated separately for the two processes (see Table 47–2). By reaching 65 years of age in a healthy state, a man's life expectancy increases from 15.5 years to 17.3 years (from 19.3 years to 21.1 years for a woman). For a woman 80 years old, who can look forward to a further 8.6 years, being in a healthy state leads to a life expectancy of more than 10 years, and of these, as many as 8.4 are free of cancer and major coronary events.

3. Other Indicators Derived from Morbidity-Mortality Tables

Morbidity-mortality tables constitute an extremely important tool for the evaluation of the impact of incidence and prevalence of specific diseases or states of health perceived as "not good" on the quality of survival. Besides the calculation of the traditional summary index representing life expectancy by state

TABLE 47–3 Life Expectancy and Cancer and Major Coronary Events–Free Life Expectancy Calculated for Total and Healthy Individuals in Italy, 1970 and 1990: Model B

Age	Male life expectancy				Female life expectancy			
	l(x)		$l_h(x)$		l(x)		$l_h(x)$	
	Total e	Disease-free e_h	Total e_h^T	Disease-free e_h^h	Total e	Disease-free $_h$	Total e_h^T	Disease-free e_h^h
Birth								
1970	68.8	66.2	68.8	66.2	74.5	71.8	74.5	71.8
1990	74.1	70.8	74.1	70.8	80.7	77.0	80.7	77.0
65 years								
1970	13.3	11.1	14.7	12.3	16.0	13.8	17.3	15.0
1990	15.5	12.5	17.3	13.4	19.3	16.4	21.1	18
80 years								
1970	5.8	4.3	7.5	5.6	6.6	5.3	8.0	6.4
1990	7.4	5.3	9.9	7.2	8.6	6.9	10.4	8.4

of health, other indicators such as the mean duration of disease, mean age of disease onset, and the probability of being "healthy" at a given age, can be calculated. Variables such as the structure of patients by age and duration of disease and net of the age structure of the population can be considered as useful information, which is especially necessary to better guide actions of health policies and to evaluate their impact on health conditions of the population.

A morbidity measure of particular interest when considering specific diseases is the probability that an individual will reach a specific age x without contracting the specific disease:

$$p_h(x) = \frac{l_h(x)}{l(0)} = \exp\left\{-\int_0^x \mu(u) + \xi(u)du\right\}$$

Another is the disease-free life expectancy at birth:

$$e_h(0) = \int_0^\omega \frac{l_h(x)}{l(0)}dx$$

Another measure is the probability of survival after a given period of duration of the disease, x, for an individual who has been diagnosed at age τ (i.e., the proportion of cohort members who survive all risks of mortality from diagnosis to duration x):

$$_x p_\tau^i(\tau + x) = \frac{l_i(\tau + x, \tau)}{l_i(\tau)} = \exp\left\{-\int_\tau^{\tau+x} \beta(u,\tau)du\right\}$$

The case fatality-rate is the proportion of the cohort of individuals who have been diagnosed at age τ who succumb to the disease as an underlying cause of death:

$$CF_\tau = \frac{\int_\tau^w l_i(u,\tau)\delta(u,\tau)du}{l_i(\tau,\tau)}$$

These relations are verified within a cohort but may be generalized for a population through a suitable system of hypotheses and the availability of information collected on two successive occasions that permits estimation of growth rates in the population with or without a disease by duration since diagnosis or by age (Preston, 1987).

When measures of prevalence according to age are available (certainly the most common case of availability of cross-sectional surveys), it is possible to estimate, for example, the probability that an individual will reach a specific age x without contracting a specific disease:

$$p_h^*(x) = \frac{H(x)}{B} \times \exp\left\{\int_0^x r^H(j)dj\right\}$$

In the equation, $H(x)$ is the number of individuals who are free from a specific disease at age x; B is the number of births, and $r^H(j)$ is the growth rate of the number of persons of age j without the disease. In this case,

$$e_h^*(0) = \int_0^w \frac{H(x)}{B} \times \exp\left\{\int_0^x r^H(j)dj\right\}dx$$

This equation provides the disease-free life expectancy at birth.

In a stationary population, duration-specific rates of growth in the number of cases must be zero, and the period probability of not developing the disease and the disease-free life can be derived directly from observed data on disease-free persons and on the annual number of births. When the population is not stationary, a simple growth correction is required. The growth adjustment, $r^H(j)$, can be estimated from two disease prevalence surveys.

CONCLUSIONS

Even the brief review of relationships between morbidity and mortality developed in this chapter demonstrates that there is a vast interpretative and analytic potential offered to demographic study by examining the morbidity process, besides the obvious benefits it affords to epidemiologic and clinical studies. It is necessary to delve deeper into this complex field, but continued study can provide a wealth of information, if one wishes to abandon the merely descriptive viewpoint of an analysis of mortality, of its evolution, of its differentiation between population groups, and the possibility of its further future reduction. Every phase of the process that precedes the event of death is influenced by endogenous and exogenous factors that condition its evolution, modifying the duration and outcome and influencing the consequences the disease produces on the autonomy of the individual and the possibility to conduct an acceptable life.

A fundamental problem for the development of these studies is in many countries still represented by the lack of availability of statistical data capable of accounting for the diverse and numerous aspects of the morbidity process, a lack that can be justified by the complexity of the instruments that must be used to correctly collect this type of information, from both theoretical and conceptual viewpoints. The diffidence shown for a long time by medical science with respect to the possibilities offered by analyses conducted on very large population groups and the similar reluctance shown by statisticians and demographers with regard to analyses of a predominantly qualitative nature have represented considerable obstacles to cooperation, without which it is difficult to make the qualitative jump that can lead to an improvement in understanding the complex individual and social mechanisms that influence the quality of human survival and the possibility of further extending the life span.

Much progress has been made in gathering adequate statistical information and in creating methodologic tools that are better adapted to representing the complexity of the phenomena. The road ahead is long in conceptual and methodologic terms. It involves the exploration of new dimensions in the state of health, the study of the relationships with lifestyles and changes in lifestyles, and the identification of interdependencies among the different diseases and conditions that may favorably influence the outcome.

II

ENDOGENOUS AND EXOGENOUS MORTALITY

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

The process resulting in death has a wide range of beginnings. It can be posited that the human organism has an inherently finite life span and that each individual is biologically predestined to die once his or her time has come. However, the time of death may be precipitated or delayed by external events or by human behavior itself. Life and death are the result of a subtle balance between endogenous and exogenous factors, which the next five chapters will endeavor to take stock of.

Jean Bourgeois-Pichat was among the earliest demographers in the early 1950s to differentiate endogenous and exogenous causes of death. The former were hereditary characteristics and so were not readily curable, whereas the latter were environmental and could be acted on. The concepts and approaches have evolved greatly since then, and the changes are reviewed by Jacques Vallin and Giovanni Berlinguer in Chapter 48.

Endogenous mortality is grounded on genetic makeup. In Chapter 49, Lamberto Soliani and Enzo Lucchetti outline the main genetic factors that predispose to good or ill health, reviewing the genetic diseases that may lead to below-average life spans and discussing what can be done about them.

Exogenous causes of mortality can be broadly categorized as those attributable to natural environmental threats, possibly as a result of human action, and those resulting from individuals' behavior in response to such threats or to changes in their own bodies. Francis Sartor reviews environmental factors in Chapter 50, and Jacques Vallin, Graziella Caselli, and Pierre Surault assess behaviors, lifestyles, and sociocultural factors in Chapter 51.

Modern medicine's efforts to deliver on public demands for care and prevention are examined by Paolo Vineis in Chapter 52.

CHAPTER

48

From Endogenous Mortality to the Maximum Human Life Span

JACQUES VALLIN AND GIOVANNI BERLINGUER

Institut national d'études démographiques (INED), Paris, France

Università degli Studi di Roma "La Sapienza," Rome, Italy

The medical approach to causes of death, a subject that has been extensively discussed in previous chapters and particularly so by France Meslé in Chapter 42, has always maintained a close relationship with diseases that physicians endeavor to cure but that can also lead to death. Consequently, the method of classifying causes of death has always been closely linked to the method of classifying diseases because of the need, as Charles Nam (1990) wrote, "to examine morbidity in conjunction to mortality and to become cognizant of morbid conditions contributing to the mortal state." It has been this way since antiquity. However, since the beginning, the idea of classifying causes of death has gone hand in hand with research into the fundamental principles common to diseases and causes of death. Often, this led to emphasis on dichotomous criteria such as "internal or external," "natural or violent," "essential or accidental," and "predisposed or dissociated." The supposed explanatory capacity of such fundamental distinctions, reflecting the ideas of the time, stimulated etiologic research, with one theory being replaced by another, but they have, by imposing presuppositions on a whole era, also occasionally led to some epistemologic roadblocks, restraining the progress of ideas. In this way, the miasmatic interpretation of numerous fever-type lethal syndromes confused the understanding of their microbial origin and even the concept of infectious disease until the latter half of the 19th century. In its turn, the germ theory, which after the work of Louis Pasteur was finally maintained at the beginning of the 20th century and which advanced the view that behind each disease was the *presence* of a microbe, delayed the onset of research on the explanation of disease due to the *absence* of certain agents (e.g., vitamin deficiency) or to other causes. The progress of etiopathogenic knowledge and its preventive or therapeutic properties has periodically challenged the successive inclinations to enclose causes of death within a simple principle of fundamental etiologic classification (Vallin and Meslé, 1988).

By echoing the historical evolution of demographic thinking in this area in this chapter, we are concentrating on the question of whether certain causes are inescapable because they are inherent to the nature of human beings, whereas others are avoidable, resulting from the action of external agents or from a deleterious controllable process. The main interest of such a distinction is to steer us toward reflection on the maximum human life span, a consideration that, far from reaching definite answers, is leading to a very open debate: Are we now, with a life expectancy of 80 years or more at birth, near to the end of the *health transition* (see Chapter 57) as biologists such as James Fries or demographers such as Jay Olshansky are claiming? Or on the contrary, can we expect to encounter new battle fronts against death that will in the future open the way to substantial progress of a different kind to what has preceded?

In an era when life expectancy at birth did not reach 30 years, Condorcet, in his splendid *Esquisse d'un Tableau Historique des Progrès de L'esprit Humain*, wrote the following:

> One feels that the progress made in medicine, having become more efficient thanks to the advance of reason and social order, must in time eliminate transmittable and contagious diseases, as well as general diseases due to climate, food and working conditions. This should logically be the case for all the other illnesses the distant causes of which we will one day know. Would it be absurd to suppose that this perfecting of the human race should be expected to go on indefinitely, that there must come a time when death would only be the result of either extraordinary accidents or of the progressively slower destruction of the vital forces and that finally the average length of time between birth and this destruction has no specifiable duration? There is no doubt that man will not become immortal; but is there no reason to believe that the interval between the moment when his life begins and the time when, naturally and without the intervention of an illness or an accident, he usually finds it difficult to go on living, continually increase? (1795, translation from French to English by Paul Belle).

Although absolutely prophetic, this vision nevertheless contained one fundamental contradiction: while rejecting in advance the idea that humans could one day attain immortality, this philosopher of the French Revolution imagined no less than that human life could "increase continuously." Current theories continue to confront this contradiction. Condorcet's text also contains the beginnings of the two fundamental hypotheses that separate immortality from the existence of an absolute limit to a human life. According to him, with progress, death could in effect only be the result of "exceptional accidents" or the slow destruction of "vital forces." If death only occurred because of exceptional accidents, it would open the way to immortality to a small number of individuals. If death only occurred in cases of accident and therefore was independent of age, it would strike only a constant fraction of each generation at random each year. It would suffice therefore that this fraction be low enough and the generation be large enough to enable at least a few individuals to live for an almost infinite period. If death occurred as a result of a slow degeneration of the vital forces, at the end of this process, all individuals would die. By slowing down the process, life could be prolonged, but without stopping this process completely, humans will never be immortal. Acknowledging the existence of an intrinsic process of degeneration is to acknowledge death as inevitable, resulting directly from the biologic aging of the organism, and the existence of an imperative maximum human life span, an intrinsic limit to the species.

The concept of *endogenous mortality*, as opposed to that of *exogenous mortality*, which results from external factors, brings together causes of death that are intrinsic to the organism but do not coincide entirely with the concept of biologic aging for two reasons. Even if the endogenous factors of mortality are conceived implicitly as those that command the degeneration of the vital forces (Rose, 1991; Kirkwood, 1990), random endogenous factors, independent of age and which provoke death while by-passing the aging process, can be imagined. Above all, an aging process that is not entirely endogenous but, on the contrary, results in an interaction between the human organism and its environment can also be imagined (Finch and Kirkwood, 2000).

From a demographic point of view, there are two real types of limits on the life span within a species: *maximum longevity* or the maximum age that even the most fortunate individual could not exceed, and the average age at which all individuals in the best possible health conditions die, which Jean Bourgeois-Pichat called *the maximum biologic life expectancy limit*. If this second limit depends on the first, it is not entirely reduced to maximum longevity because it is just as dependent on the distribution of individual life span this side of maximum longevity. In the assumption of biologic aging, a very simple model takes into account both these aspects of the maximum human life span: Gompertz's law. It is from this model that Jean Bourgeois-Pichat and Paul Vincent tried to measure the maximum human life span. However, today's debate is about the extent to which this law applies to the human species.

I. GOMPERTZ'S LAW: MEASUREMENT FOR BIOLOGIC AGING

1. The Force of Mortality and the Aging of the Human Organism

As early as 1825, Benjamin Gompertz put forward a formula for defining the probabilities of death according to "*the progressive deterioration of the human being*" with age (see Chapter 11). He estimated that the force of mortality, μ_x, followed an exponential function of age:

$$\mu_x = Bc^x$$

In the equation, B and c are constants. He saw in this mathematical model a description of "two generally co-existing causes; the one, chance, without previous disposition to death or deterioration; the other, a deterioration, or an increased inability to withstand destruction" (Gompertz, 1825, p. 517).

This formula does not require any preconceived idea on the maximum life span. If the values B and c are fixed, μ_x tends toward infinity, and it is easy to imagine that the chances for survival are minute beyond a certain age. Strictly speaking, when the force of mortality tends toward infinity, the probability of dying, ${}_1q_x$. tends toward 1, without ever completely reaching it. This therefore makes the survival of at least a few rare individuals beyond any limits possible in theory. Nevertheless, the exponential constraint is such that for this probability to have the slightest chance of occurring, it would have to be in the presence of a population of an immeasurable size, which means that for a given value of the B and c parameters, the model fixes an age limit on the survival of a generation. However, for this age to vary, new values for this parameter are all that are needed. In this sense, the model does not impose a precise limit. This adjustment is based on the idea that, in a given context, mortality is essentially an exponential function of age that translates into the idea that the human organism is doomed to age, which leads unavoidably to death.

2. The Gap between the Model and Reality: External Causes

Gompertz's model gives a good description of reality only beyond a certain age. This is why other authors have tried to refine Gompertz's model to bring it closer to real data. William Makeham (1860, 1867) believed that some causes of death were independent of age and proposed to extrapolate the force of mortality at old ages on the basis of a modified version of Gompertz's law:

$$\mu_x = A + Bc^x$$

In the equation, the parameter A represents the risk of dying for all causes that are independent of age (Thatcher *et al*., 1998).

The hypothesis of causes of death being independent from age is questionable, and numerous authors have tried to suggest other refinements to better account for the complexity of the existing relationship between risk of death and age (Duchêne, 1980). Adjustment of the mortality curve using Gompertz's formula always comes up against the fact that causes of death do not always vary in the same way with age and that certain causes do not follow the exponential schema at all.

Can it not be imagined that mortality is a combination of at least two components: a fundamental component, intrinsic to the process of degeneration (i.e., biologic aging), which the exponential model describes perfectly, and one or several complementary components of external causes that might or might not be linked to age but in a nonexponential way? Jean Bourgeois-Pichat volunteered to divide the endogenous and exogenous causes to attempt to answer this question.

II. JEAN BOURGEOIS-PICHAT: SEARCH FOR THE "HARD ROCK"

If statistics on deaths from sufficiently reliable causes are available, it should be possible to distinguish those related to degeneration of the organism and those related to external surroundings.[1] In measuring mortality due to the first causes, it should be possible to simultaneously obtain a measurement of the biologic limit of human life. Acknowledging the fact that the approach by declared causes, often subject to caution, was most frequently insufficient, especially with regard to infant mortality, Jean Bourgeois-Pichat also extended Gompertz's idea of a mathematical link between mortality and age to infants to specify the border between endogenous and exogenous factors.

1. From Endogenous Infant Mortality to the Maximum Biologic Life Table

a. Endogenous and Exogenous Infant Mortality

Bourgeois-Pichat's work initially revolved around the first year of life, establishing what he called *the biometric analysis of infant mortality* (Bourgeois-Pichat, 1951a, 1951b).

Some infant deaths clearly result from the physical constitution of the newborn (i.e., congenital deficiencies) or from conditions of childbirth, reputed to be unavoidable at that time (e.g., obstetric trauma); both are cases of endogenous mortality. Others result from external aggression or inadequate care (e.g., infectious diseases, malnutrition, violent deaths); these are cases of exogenous mortality. Using statistics from medical causes of death, it is possible to separate the two groups. Most frequently (and even more so before the 1950s), the results are not satisfactory because there is a great margin of uncertainty (undeclared or ill-defined causes) and because endogenous causes tended to be overestimated for a long time, especially during the period when the idea of congenital deficiency was very fashionable. This is why Jean Bourgeois-Pichat proposed to define the proportion of endogenous deaths in infant mortality using a mathematical adjustment of deaths by age. His method is based on a double hypothesis:

1. The (cumulated) distribution by age of exogenous deaths between 1 and 12 months is a simple mathematical function of age.
2. All endogenous deaths occur before the age of 1 month.

[1] This paragraph draws largely on a previous contribution to an INED publication (Vallin, 1993).

Several trials in countries with relatively reliable mortality statistics enabled the investigator to establish that the number of cumulated exogenous deaths (E_n) between birth and age n (in days) responded well to the following type of function:

$$E_n = b \cdot \log^3(n + 1)$$

This corroborates the first hypothesis.

He also established that the same function fits beyond the age of 1 month, except for one constant, the total D_n of deaths from all causes:

$$D_n = a + b \cdot \log^3(n + 1)$$

This verified the second hypothesis. Thereafter, the parameter a is no less than the number of deaths attributable to endogenous causes.

Transformed into a graph with an adequate age scale, $\log^3(n + 1)$, the cumulated number of deaths by age between 1 and 12 months easily lends itself to a line adjustment whose intersection with the axis of deaths gives the number of endogenous deaths (Fig. 48–1).

From the start, Jean Bourgeois-Pichat was aware that endogenous mortality defined in this way was not immutable. He ascertained that it was not the same everywhere and that it had a tendency to decline, although significantly slower than exogenous mortality. It was therefore not completely impervious to health improvement; it was merely much more rebellious. Whereas it was conceivable that exogenous mortality could be eradicated one day, it seemed to him impossible not come up against an endogenous life span limit that would be difficult to overcome. It is this notion of a limit that Jean Bourgeois-Pichat (1952) endeavored to specify in his work on infant mortality while widening his field of research to mortality as a whole.

b. The Maximum Biologic Life Table

Is it possible to establish a life table that in some way constitutes the insuperable limit, at least according to current medical knowledge? For infant mortality, this seemed to have been the case. In Norway, the country that was in the lead, the process of decline of endogenous mortality seemed to be nearing its end. To obtain an estimate of this near-insuperable limit, it was enough to extrapolate this tendency. In this way, Jean Bourgois-Pichat retained the limit of infant mortality rate at 13 per 1000 for boys and 9 per 1000 for girls. These limits have been easily surpassed in several countries since then, but at the time, in a country such as France, where the infant mortality rate was 50 per 1000, they seemed far in the future.

What about the other ages? Still drawing on data from Norway, a country where mortality was particularly low and the causes of death relatively well recorded, and by separating deaths that appeared to be essentially exogenous (i.e., infectious diseases, respiratory diseases, and accidents) from those which seemed essentially to occur with the normal wear of the organism (all other causes), Jean Bourgeois-Pichat ascertained that between 30 and 90 years, the quinquennial mortality rate of this second group adhered absolutely to Gompertz's law (i.e., a line on a semi-logarithmic graph). Knowing that it concerned a country

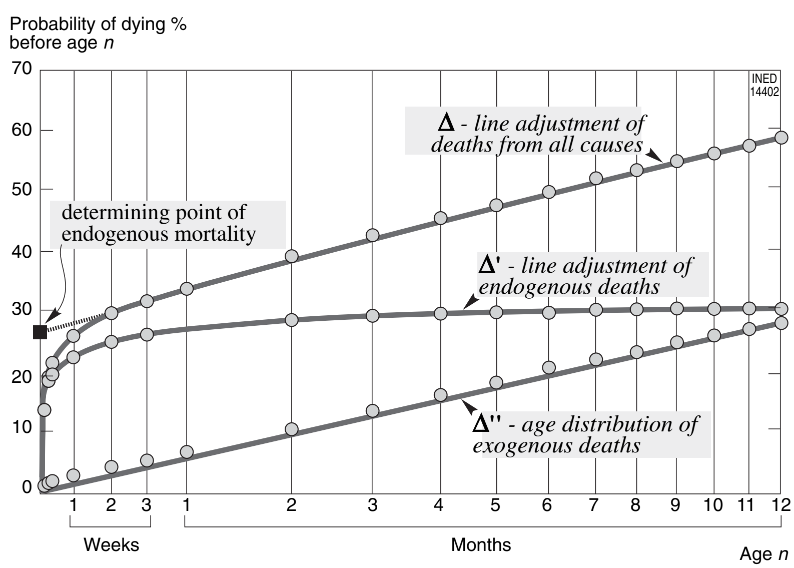

FIGURE 48–1 Separation of endogenous and exogenous infant mortality, according to Jean Bourgeois-Pichat (1951).

with the lowest rates, he assimilated these rates to the endogenous mortality limit at these ages, presuming that beyond the age of 30, noninfectious or nonaccidental mortality in that country reflected the natural consequences of the deterioration of the organism. Between 1 and 29 years, separating the endogenous from the exogenous declared causes of death seemed too risky to him, even in a country such as Norway, whereas it was very difficult to measure beyond 90 years, taking into account the risks of small numbers and problems with data quality. However, taking into account the extremely accurate observations between the ages of 30 and 90, it was enough to retropolate the line adjustment obtained for endogenous mortality downward for these ages to obtain the rate between 1 and 30 years and extrapolate the same upward, beyond 90 years, to complete the life table. At very old ages, for which all mortality is endogenous, he verified that his adjustment coincided with the results obtained by Paul Vincent (1951) on the mortality of the very old.

In terms of life expectancy, the limit fixed in this way was 76.3 for men and 78.2 for women. One-half century later, these figures may make us smile because this theoretical maximum for women has already been exceeded in several countries, with female life expectancies superior to 80 years and the figure for men now on the way to exceeding his estimate. Nevertheless, at the time, this left a wide margin for future progress, because in France, for example, according to the most recent life table (1946 to 1949), French women could hope to gain 10.8 years and French men to gain 14.4 years, according to this "law."

To get across the significance of his research, Jean Bourgeois-Pichat (1952) concluded his *Essay on the Maximum Biological Human Life Span* with a geologic comparison. One can, he wrote "compare mortality to a piece of ground composed of two unequally friable rocks. The process of erosion takes place to begin with, on the more tender, leaving bare the profile of the hard rock."[2]

2. The Hard Rock Is Not Unassailable

The hard rock is not unassailable. Neither are the methods.

a. Biometric Analysis of Infant Mortality Confronted with the Facts

Paradoxically, the contradictions exposed in Bourgeois-Pichat's law by the facts are without doubt, the most interesting contributions of this "law," which is now obsolete. It is these exceptions that have given meaning to a rule, which has been inept at predicting the limit of infant mortality decline.

Late Exogenous Excess Mortality

As early as 1957, Jean-Noël Biraben and Louis Henry showed that in some Mediterranean populations, the graphical adjustments proposed by Jean Bourgeois-Pichat could not be obtained with one single line, but with two. The points corresponding to the first months aligned themselves with a lower slope than the points corresponding to the last months. They attributed this contradiction to the Bourgeois-Pichat law to a particularity in the health situation of the Mediterranean countries. Because milk is more difficult to preserve in hot temperatures than in cool ones, infant excess mortality from diarrhea after weaning occurred during the summer. In other words, exogenous mortality increased abruptly after weaning, thereby breaking Bourgeois-Pichat's line at around the third month (Biraben and Henry 1957).

The same phenomenon was observed in Senegal by Pierre Cantrelle a short time later, thanks to the creation of one of the first *demographic surveillance systems*[3] in the districts of Niakhar and Paos-Koto (Cantrelle, 1969). This time, because weaning occurred later, the break in the alignment occurred after the sixth month. Excess exogenous mortality was prolonged to beyond the first birthday, and the risk of death was still very high during the second year. This phenomenon, confirmed by surveys of seasonal mortality (Cantrelle and Leridon, 1969), is now well known and characterizes the profile of mortality in several developing countries where infant and child mortality is, at equal levels of life expectancy, very much higher than in the European-type schema. The exception to Bourgeois-Pichat's law is particularly interesting because it provided an improved interpretation of observations that up to then tended to be held in doubt because of the poor quality of the data.

Better still is the fact that in this type of situation the respective proportions of *normal exogenous mortality* and *late excess exogenous mortality* essentially linked to nutritional problems can be measured through the break in alignment shown by comparing the two lines of adjustment. This characteristic was revealed to be particularly useful in the analysis of infant mortality by sex in some countries. In Algeria in 1969 to 1970, the infant mortality rate was 142 per 1000 boys and 141

[2] "Comparer la mortalité à un terrain composé de deux roches inégalement friables. L'action de l'érosion s'exerce d'abord sur la plus tendre, mettant à nu le profil de la roche dure."

[3] This is one of the terms used for permanent observation systems in which births, deaths, migrations etc within a population are continuously recorded after an initial survey (see Chapters 121 and 124).

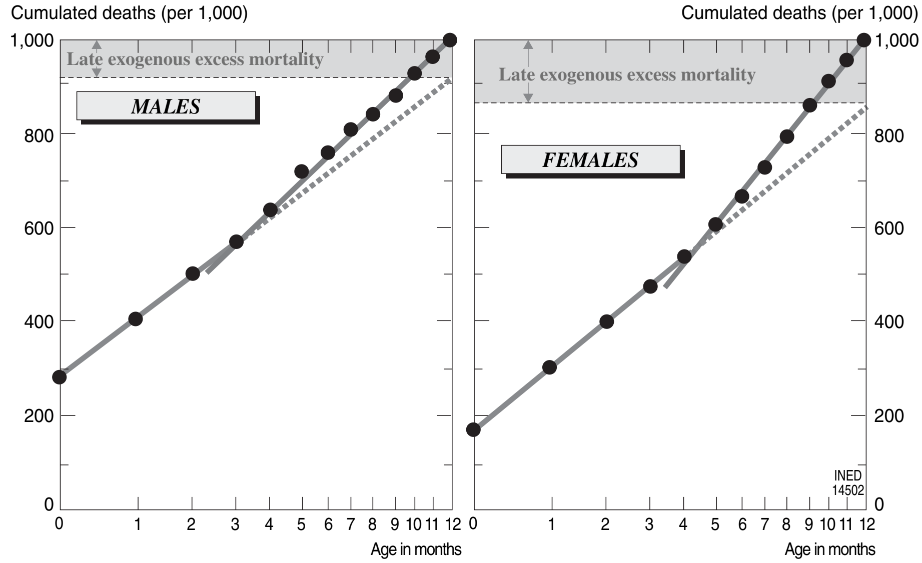

FIGURE 48–2 Biometrical analysis of child mortality: Algeria, 1969 to 1970. (From Vallin, 1975.)

per 1000 girls. Meanwhile, thanks to the Bourgeois-Pichat method, it was possible to establish that endogenous mortality was 40 and 24 per 1000, respectively. The excess male mortality was 67% while normal exogenous mortality was 89 per 1000 and 97 per 1000, and the surplus exogenous mortality associated with weaning was 13 and 20 per 1000, and the excess female mortality was 10% to 50% (Fig. 48–2). In this way, it became apparent that excess mortality in small girls, observed beyond 1 year, took effect from the first year and that it was entirely exogenous and affected particularly by late excess exogenous mortality linked to weaning and therefore to family behavior (Vallin, 1975).

Early Exogenous Excess Mortality

Other types of exceptions to the Bourgeois-Pichat law have been revealed. For example, for ancient Europe, Louis Henry and Yves Blayo observed a different break in the alignment, the adjustment line of the first points having a stronger slope than the line adjusting the last points, here again, the exception is interesting as it allowed the researchers to put forward a hypothesis of early exogenous excess mortality associated with certain respiratory diseases, particularly active in winter (Henry and Blayo, 1967). This same phenomenon was observed in France in certain administrative regions (particularly in Normandy) between the two world wars (Prioux and Vallin, 1976).

These two types of exceptions, whether they concern early or late exogenous excess mortality, only affect the principle of alignment of exogenous deaths, Jean Bourgeois-Pichat's first hypothesis. The second hypothesis (i.e., no endogenous deaths beyond 1 month) remains intact, and the principle of determining endogenous mortality by a (wisely chosen) adjustment line persists.

Postponement of Endogenous Deaths

The same does not apply to the exception of recently characterized populations with very low infant mortality. A break in the alignment can be seen (Fig. 48–3), but the higher slope of the first line cannot be interpreted as a reflection of early exogenous excess mortality. It is due to the fact that endogenous mortality is no longer specific to the first month. In a significant number of cases, newborns who previously would have died very early survive some extra weeks or months, and the second hypothesis of Jean Bourgeois-Pichat is no longer verified. The law no longer applies at all.

b. Causes of Death, Endogenous Mortality, and Avoidable Mortality

Beyond the biometric analysis of infant mortality, measuring the maximum biologic life span according to Jean Bourgeois-Pichat depends entirely on the manner in which the causes of death indexed by number of deaths are distributed between causes considered endogenous and those considered exogenous. This is the most perishable aspect of Jean Bourgeois-Pichat's calculations. Retaining all diseases of the respiratory systems, for example, as exogenous, whereas

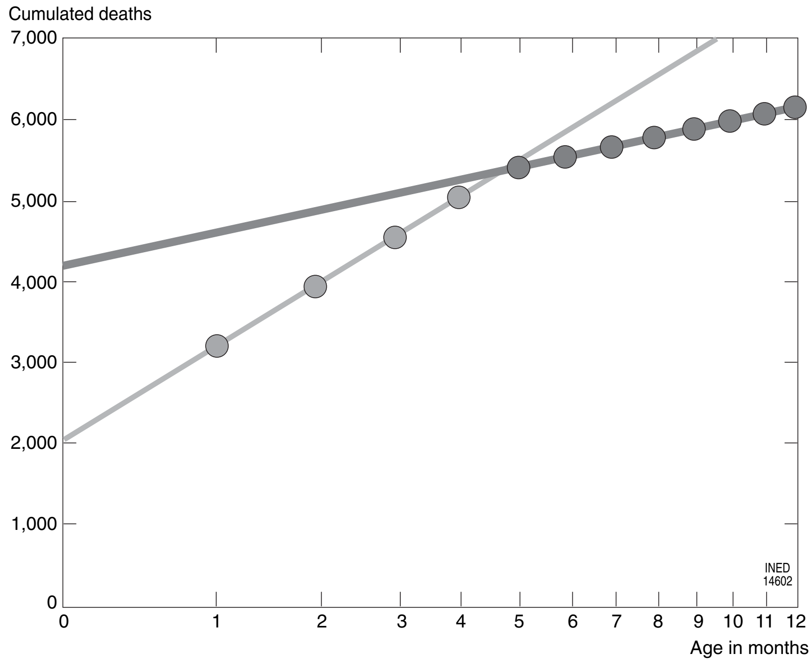

FIGURE 48–3 Biometrical analysis of child mortality: France, 1988. (Source: Vallin, 1993.)

several of them are chronic diseases not necessarily originating from a process of external aggression, is obviously not ideal. Inversely, retaining all cancers and cardiovascular diseases as endogenous, whereas some of these diseases are largely caused by smoking or alcoholism, without adding the henceforth-acknowledged influence of dietary habits or lifestyle, becomes problematic. What about all the other nonaccidental causes, all classified as endogenous? It is at the very least a very rough approximation. The author was aware of this, but he thought that one way or the other, the opposite effects would cancel out and be sufficient to save the approach. In reality, there is no guarantee of compensation effects and imbalance can obviously vary.

There is worse than this. Beyond this approximation, unfortunate but perfectible, there is a slide from the notion of *endogenous* deaths toward the notion of *avoidable* deaths. In trying to define a maximum biological life span, Jean Bourgeois-Pichat relied on the idea that all exogenous deaths, caused by external aggressions are avoidable and that all endogenous biologic deaths are unavoidable. However, it is not certain that we will be capable one day of avoiding all exogenous deaths (because the difficulty in eliminating the significant remainder of infectious diseases or coping with new diseases such as acquired immunodeficiency syndrome shows), and it is becoming more apparent that truly endogenous causes, such as genetic diseases, can be overcome.

c. Hard Rock and Limits: Where Does the Inevitable Come In?

We should acknowledge Jean Bourgeois-Pichat for having always stated that he was reasoning "according to current medical knowledge." The *hard rock* was not unassailable. It merely needed to be processed differently to the *soft rock*, and it required new medical discoveries. This is why Jean Bourgeois-Pichat published an update of his results in 1978, to measure the evolution of the hard rock under the effects of medical progress. To this end, he repeated the same calculations, with the same hypotheses, using data from Norway and more recent statistics. The result was at the very least surprising: new limits of life expectancy were establishing themselves, 80.5 years for women and 73.8 years for men, instead of 78.2 and 76.3 according to the 1952 calculation. Even more surprising was the researcher's comment: "During the last 25 years, while the soft rock has been disappearing, the level of the hard rock has risen for men and crumbled for women."[4] The idea that the increase of 2.3 years in the average maximum life expectancy for women was a result of the erosion of the hard rock under the influence of new medical technology could possibly be accepted, but how could medical discoveries and their spread explain the reduction observed in men?

[4] Durant les 25 dernières années, alors que la roche tendre disparaissait, le niveau de la roche dure s'est élevé pour les hommes et s'est effondré pour les femmes.

Has erosion ever been seen to increase the size of mountains?

In reality, Bourgeois-Pichat's maximum biologic life span included certain completely avoidable causes of death "according to current medical knowledge," but these were on the increase during the period under consideration. The author himself mentioned the increase in male mortality from cancers and cardiovascular diseases. This obviously did not result from an evolution in medical knowledge, but from increase in smoking and increase in the consumption of animal fat and some other social phenomena that did not fulfill a "biologic necessity." This is the major limitation of Jean Bourgeois-Pichat's work. However, is it not more a limitation in form than in essence? Bernard Benjamin (1982), for example, in taking up Jean Bourgeois-Pichat's idea and trying to improve the translation in terms of causes of death, came up with a life expectancy limit of 81.3 for men and 87.1 for women in 1982. These figures are themselves very close to the life expectancy obtained in France in 1978 by looking only at the deaths by "degeneration" resulting from an etiologic reclassification of causes of death: 80.9 for men and 85.7 for women (Vallin and Meslé 1988). Criticism of the quantitative results should not make us lose sight of the essential: the idea of the existence of a hard rock, an unassailable limit according to current medical knowledge probably is true, as is the hope that technologic progress can reduce this hard rock. However, if the hard rock is assailable, how far can we go?

III. IS THERE A LIMIT?

Since the 18th century, it seems that medical progress has barely enabled the average length of life (i.e., life expectancy) to approach the theoretically possible maximum (i.e., longevity). A greater proportion of each generation survives to increasingly older ages, with most deaths occurring in an increasingly older, but also limited, age range, without significantly changing the maximum age at death. This is called the *rectangularization* of the survival curve, a phenomenon that is supposed to set an unassailable limit on life expectancy at birth. However, two questions are far from answered. Is human longevity really intangible? If it evolves, will it be with or without calling Gompertz's law into question?

1. The Limits of Rectangularization

Figure 48–4 illustrates the phenomenon of the rectangularization of the survival curve from French female life tables of the 18th century (Blayo, 1975) and of the present day (Vallin and Meslé, 2001b) with a projection up to 2100 (Vallin and Meslé, 2001b). Starting as a concave, the curve becomes more and more

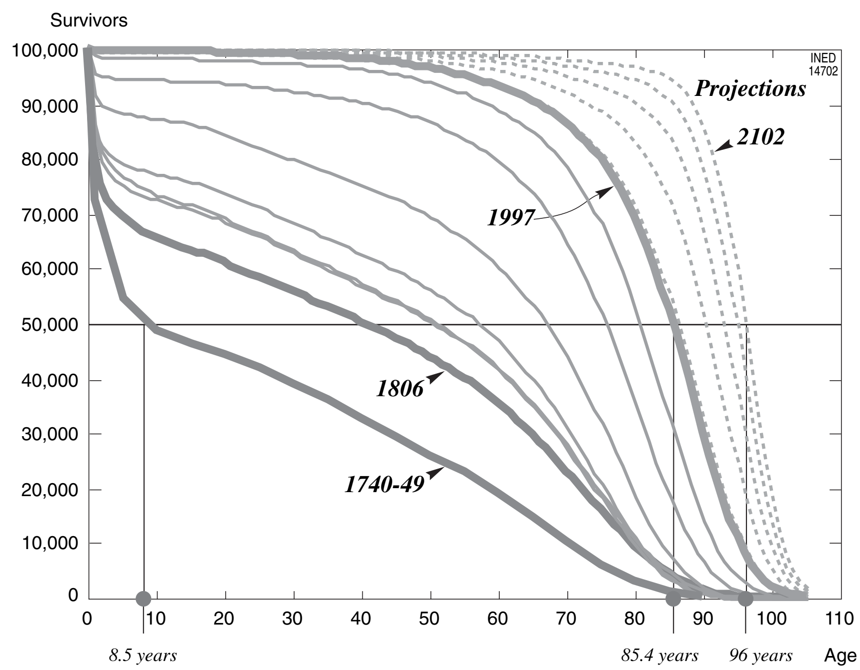

FIGURE 48–4 Rectangularization of the survival curve: plot for females in France since the 18th century and projections up to 2100.

convex with time. An amazing fact is that the median age at death, the age at which 50% of the initial number of an imaginary birth cohort under the conditions of the life table of the period (see Chapters 4 and 20) would survive, increased from only 8 years in 1740–1749 to more than 85 years in 1997. In France at the end of the 20th century, very few women died before the age of 60; on the contrary, most died between the ages of 75 and 95 years. If the recent trend of mortality decline continues in the same pace until the end of the century, the median age at death will reach 96 years in 2100.

Various researchers have proposed different indicators to measure more precisely this phenomenon of rectangularization of the survival curve and numerous reviews of these indicators have been published. Table 48–1 lists the available indicators drawn up by John Wilmoth and Shiro Horiuchi (1999) and completed by Jean-Marie Robine (2000, 2001) to include more recent research by Vaïnö Kannisto (2000a, 2000b).

John Wilmoth and Shiro Horiuchi, after having inventoried and tested ten indicators, recommend using the interquartile range (*IQR*) for its pertinence and ease of interpretation (Wilmoth and Horiuchi, 1999). Vaïnö Kannisto recommended using a new indicator that he named *C*50: the smallest age range necessary to regroup 50% of deaths. Figure 48–5 compares the evolution of these two indicators for French females from the middle of the 18th century until today and prolongs the comparison on the basis of projections up to 2100 (Meslé and Vallin, 2002).[5]

TABLE 48–1 Principal Indicators Proposed for Measuring the Dispersal of Life Spans and the Rectangularity of the Survival Curve

Indicators Inventoried by Wilmoth and Horiuchi (1999)
Proportion occupied by the surface of a fixed rectangle under the survival curve
Proportion occupied by the surface of a moving rectangle under the survival curve
Maximum decline in numbers of the survival curve between two ages
Maximum acceleration in the decline of the survival curve from one age to another
Maximum deceleration in the decline of the survival curve from one age to another
"Prolate" indicator (Eakin and Witten, 1995)
Interquartile range
Standard deviation
Gini's coefficient
Keyfitz's H (Keyfitz and Golini, 1975)
Other Indicators Inventoried by Jean-Marie Robine (2001)
Coefficient of variation (Nusselder and Mackenbach, 1996)
Numerator of Keyfitz's H (Nusselder and Mackenbach, 1996)
Age at various centiles of the distribution of deaths (Manton and Stallard, 1996)
Standard deviation of ages at death below the mode (Kannisto, 2000a, 2000b)
Standard deviation of ages at death of the last quartile (Kannisto, 2000a, 2000b)
Smallest age range assembling a given proportion of deaths (Kannisto, 2000a, 2000b)

The *IQR* and *C*50 have both declined rapidly during the first half of the 20th century, reflecting the scale of the phenomenon of rectangularization of the survival curve observed during this period. However, Figure 48–5 shows the superiority of Kannisto's *C*50 over the *IQR*, insofar as the latter overestimates the speed of rectangularization by measuring the concentration of deaths over too wide an age range while the rectangularization is still relatively modest. This results from the fact that the *IQR* does not, contrary to *C*50, necessarily identify the smallest age range that assembles 50% of deaths. On the other hand, neither *C*50 nor *IQR* are capable of measuring the phenomenon of rectangularization of the survival curve already perceptible in the 18th and 19th centuries. Not only are these two indicators almost stable from 1820 to 1880, except for annual fluctuations, but they also greatly increase from 1740 to 1820, and this latter phenomenon is even more apparent with Kannisto's *C*50 than with the *IQR*.

This disadvantage reflects the important role played by the decline in infant and child mortality in the initial improvements in life expectancy. In the case of *IQR*, while infant and child mortality remained high, the second quartile begins at a very early age, and the *IQR* is relatively short. From 1740 to 1820, the *IQR* rose as infant mortality declined. Then followed a period in which the *IQR* related to a relatively flat portion of the survival curve, with a slope that had hardly varied since the 19th century, which explains the relatively high level of the plateau observed between 1820 and 1900. In the case of *C*50, the influence of child mortality is stronger still because research on even the smallest age range involves the inclusion of infant mortality itself as soon as it goes beyond a certain threshold, and the higher the level of infant mortality, the smaller the *C*50 which includes it, as we can see in the tables for the 18th century.

This gravitation of both *C*50 and *IQR* toward infant mortality attracts attention toward a part of the mor-

[5] The calculation is based on completed annual life tables for the period 1806 to 1997 and for the 1997 to 2100 projection (Vallin and Meslé, 2001b) and summarized decennial tables between 1740 to 1749 and 1800 to 1809 (Blayo, 1975).

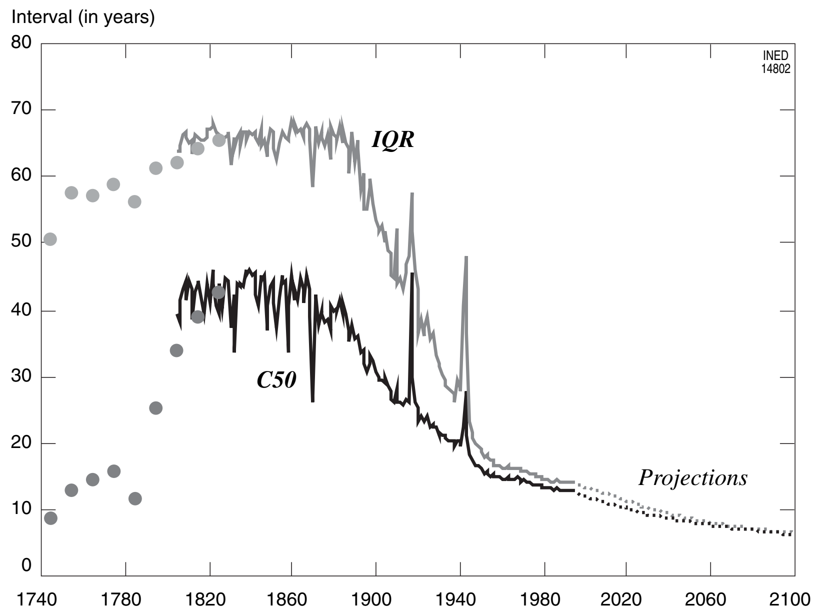

FIGURE 48–5 Evolution of the interquartile range and of Kannisto's *C*50 for females since the 18th century in France and projections up to 2102. (From Meslé and Vallin, 2002.)

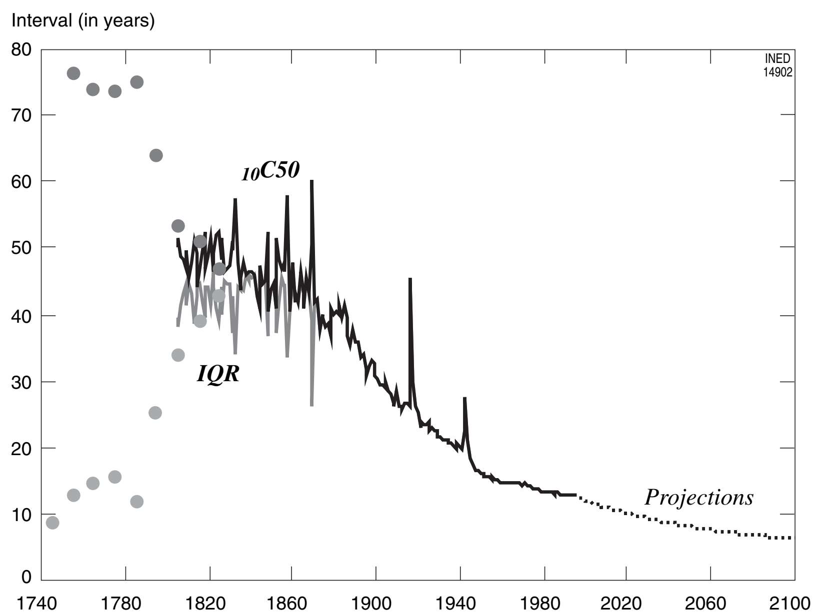

FIGURE 48–6 Evolution since the 18th century and projections up to 2102 of $_{10}C50$ compared with Kannisto's *C*50 for females in France. (From Meslé and Vallin, 2002.)

tality curve that has nothing to do with the phenomena that they are supposed to measure; the evolution of mortality at ages where the risk of death increases with age is what is of interest in the rectangularization of the survival curve. When we need to measure the age range that assembles 50% of deaths, this inconvenience can be overcome by limiting research on the smallest age range that assembles a given proportion of life table deaths to ages of more than 10 years, where the lowest point of the mortality curve is generally situated, thereby creating a new indicator called $_{10}C50$ (Meslé and Vallin, 2002).

Figure 48–6 compares the evolution of $_{10}C50$ with that of Kannisto's *C*50 and illustrates the advantage of $_{10}C50$ over the preceding one (and *a fortiori* over the *IQR*). It also calls to mind that the advantage in relation to *C*50 is valid only when mortality before 10 years is high enough to impose a lower boundary inferior at this age. In all other cases, $_{10}C50$ is, by construction, equal to Kannisto's *C*50.

However, $_{10}C50$ is itself not totally independent of the level of childhood mortality. In some cases in which more than 50% of deaths occur before the age of 10 years, it simply does not exist. Nevertheless, this is hardly an inconvenience because during the whole historical period that corresponds to health transition in France, it appears only once, in the 1740 to 1749 life table, a period of severe food shortages. It is therefore possible to say that in studying the highest concentration of 50% of deaths, this indicator monitors the process of rectangularization entirely.

The difference between $_{10}C50$ and Kannisto's *C*50 is interesting in the sensitivity to infant mortality. In Figure 48–6, it is established that during the 19th century, the fluctuations of both indicators are almost symmetrically opposed. Because *C*50 has the age of 0 as the lower boundary, each point of infant mortality is translated by a narrowing of the age range because most of the deaths are concentrated in the first ages. On the contrary, these same peaks of infant mortality produce a widening of $_{10}C50$ because the increased proportion of childhood deaths reduce those of deaths after 10 years by the same amount, and all other things being equal, a larger age range is required to embrace 50% of deaths. This phenomenon is particularly visible in 1834 with the cholera epidemic and in 1871 with the *Paris Commune*. This difference argues once more in favor of $_{10}C50$ to the extent that when *C*50 escapes the gravitation toward childhood mortality, it behaves exactly like $_{10}C50$. The same is true of the infant mortality crisis of 1918 (i.e., Spanish influenza) or that of 1944 to 1945 (i.e., bombings and food crisis).

Since the 18th century, in 3 centuries of health transition, the progression in the phenomenon of rectangularization has not ceased (except for historical accidents, which have sometimes severely disrupted the trend), a phenomenon that goes hand in hand with constant elevation of the modal age at death: Death always occurs later in an increasingly declining age range. This is clearly seen in the French data, but an international comparison shows that the French case is by no means exceptional (Fig. 48–7).

There is no indication of an imminent reopening of the age range at death. On the contrary, the mortality projections obtained for France by extrapolating the recent trends of decline in the probabilities of dying by age over a century indicate the possibility of a new phase of rapid rectangularization in which $_{10}C50$ could drop for French women, from a little less than 12 years in 1997 to slightly more than 6 in 2012 (see Fig. 48–6). However, it is only a projection based on the hypothesis of a constant life expectancy of 105 years. Other scenarios can be imagined in which mortality declines more and more rapidly at very old ages, opening the way for a new expansion of ages at death and therefore to a derectangularization of the survival curve. However, in the case of a projection (Brutel, 2001), assuming that beyond 100 years mortality becomes

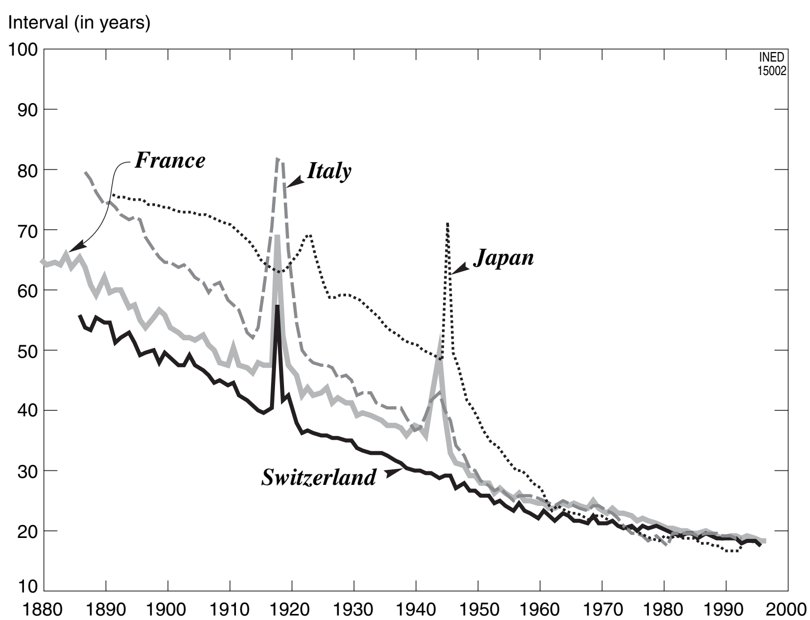

FIGURE 48–7 Trend of $_{10}C50$ for females since the end of the 19th century in four developed countries. (From Meslé and Vallin, 2002.)

independent of age and lowers with time, ${}_{10}C50$ continues to drop for French women during the whole of the 21st century (Meslé and Vallin, 2002). Even with a strong hypothesis of a re-expansion of ages at death after 100 years, the phenomenon of rectangularization could still continue for a long time, and we are no doubt a long way from seeing it appear through indicators such as ${}_{10}C50$. To be capable of perceiving a possible future expansion of ages at death, indicators based exclusively on very old ages (100 years and older) would have to be used; it is precisely at these ages that it quickly becomes impossible to measure mortality for want of data of sufficient quality.

Secular trends give the impression that the progress of life expectancy is constrained by the impossibility of exceeding a certain level imposed by the maximum human life span: The nearer this maximum life span is approached, the more the potential for future progress is exhausted. At the extreme, supposing that nonmeasurable human longevity was effectively characterized by an intangible life expectancy of 1.5 years at age 105. Supposing we had succeeded in eliminating all mortality before this age, life expectancy could reach 106.5 years, but it is not only about an absolute, totally unassailable limit; it is also about a completely illusory objective, because the total eradication of all mortality between 0 and 105 years is doubtless beyond reach.

Some biologists and demographers believe that life expectancy should come up against a nearly unassailable limit before 105 years, or even 100 years. Irreducible mortality by senescence begins much earlier and progresses exponentially with age. The average age at death, or life expectancy at birth, therefore cannot equal the maximum life span. Biologically, it is obliged to remain significantly less. At the beginning of the 1980s, James Fries (1980) and Jay Olshansky and Brian Ault (1986) estimated that this limit should be about 85 years. It is also approximately at this level of life expectancy that United Nations experts have put a ceiling on all future trends for their world population projections, country by country (see Chapter 77). This point of view appears today to be excessively pessimistic, because current life expectancy, for women at least, is already approaching this limit in several countries, nearing 84 years in France and 85 years in Japan, and this progress does not seem to be running out of steam. In a later article, Jay Olshansky appreciably changed his attitude and is now trying to estimate the time it would take for life expectancy to reach 85 or even 100 years in various countries. Japanese women probably will reach the limit of 85 years in about 2005, French women in 2014, French men in 2052, and Japanese men in 2060, but American women will reach it in 2152 and American men in 2239 (Olshansky *et al.*, 2001). A life expectancy of 100 years could be attained by French women in 2106 and even by American men in 2577. It is therefore only a matter of time! If the remaining perspectives for the simple rectangularization of the survival curve remain open, what is the case for the fundamental constraint of a fixed longevity?

2. Fixed or Evolutionary Longevity?

The measurement of human longevity is, alas, a field dominated by much uncertainty. It is also the fundamental crux of the debate on the future of mortality: Does an endogenous biologic limit to the human life span exist?

a. First Attempts to Estimate the Maximum Human Life Span

Convinced of the existence of a limit for the human life span, Paul Vincent tried to estimate it at the beginning of the 1950s. It was also on this issue that he developed the method called *the extinct generations* (see Chapter 11) to measure the mortality of the old (Vincent, 1950). Having through this method calculated as carefully as possible the risks of death at very old ages in four European countries (i.e., France, Sweden, Netherlands, and Switzerland) and based on Gompertz's principle (although without referring to it at all), he adjusted the age-specific probabilities of death observed between 98 and 104 years and prolonged the exponential upward, presuming that the age corresponding to the point where the line extrapolated from the logarithms of these probabilities reached unity was a precise estimate of the extreme limit of life. No one can survive at a probability of dying of 1. Using cumulated data from these four European countries, the author estimated the current limit of the human life span to be a little less than 110 years (Vincent, 1951), not really leaving any chance for Jeanne Calment to become famous.

However, 20 years later, Françoise Depoid (1973) repeated the same operation on the same countries with later data and found a limit of 117.3 for men and 119.3 for women. Did this mean that human longevity had increased?

At the root of these studies, there is a calculation problem. By extrapolating the line from the logarithms of the probabilities of dying, Paul Vincent neglected the fact in Gompertz's law that an exponential increase with age applies to the force of mortality and not to the probabilities of death. When the force of mortality tends toward infinity, the probability of dying tends toward 1 (see Chapter 11). There is therefore not an age (if not infinity) where the probability of dying can precisely reach unity or any justification for a linear extrapolation of the adjustment line of the logarithms of the probabilities of death (Le Bras, 1976; De Finetti, 1953). It is true that the practical range of this difference between instantaneous force of mortality and annual probability of dying is minimal when we look at ages with low probabilities of death, but at old ages, the values of the probability of dying are high enough for it to grow in size. The slope of the line adjustment of logarithms of death probabilities therefore is likely to decrease if more calculations are based on empirical mortality data at the oldest ages. This is one of the possible reasons for the difference of 9 years between the age limit measured by Paul Vincent and that estimated by Françoise Depoid 20 years later. This does not remove from the fact that measuring a maximum age in this way is illusory and if a limit does exist, this method is incapable of indicating its possible trend.

This does not however invalidate the existence of a maximum human life span nor answer the question of a possible postponement of this limit in the last decades, as several recent observations like the emergence since the 1980s of a non-negligible number of "supercentenarians", individuals who have reached the age of 110 years, might suggest (Thatcher, 2001; Meslé *et al*., 2000).

b. Biologic Aging and Longevity

Assuming there is a biologic limit to human longevity, can it evolve with time? If longevity constitutes a biologic characteristic of the species, its evolution is based on the principles of Darwin: the probabilities of mutations at the time of reproduction and a selection of favorable mutations (or the elimination of unfavorable mutations) by mortality (Kirkwood and Rose, 1991; Rose, 1991; Kirkwood, 1990). According to James Carey (2000), human longevity increased significantly during the evolution of *Homo* and since the appearance of *Homo sapiens*. Although it did not exceed the age of menopause by more than 7 to 11 years for *Homo habilis*, it did by 15 to 18 years for *Homo erectus*, with the selection process retaining the favorable aspects of survival well beyond the age of menopause (notably for the rearing of children and grandchildren). In this way, longevity reached 60 to 63 years for *Homo erectus* before reaching more than 70 years among the first *Homo sapiens*, which leads to the conclusion that it has increased again in our species, because it is now situated around the 122 years of Jeanne Calment.

We know that the mechanisms of evolution at the origin of this lengthening of the maximum human life span can take effect only in the long term, with the succession of generations. Not only is the reproductive cycle of mankind long, but for 2 centuries, by greatly reducing fertility and mortality, people have considerably reduced the field of action of their own evolution. How can we imagine at this precise moment that the process liable to increase human longevity has accelerated to the point where change is visible in a few decades of statistical observation, as the results of Paul Vincent and Françoise Depoid would suggest? It is extremely doubtful.

There may be another explanation. Human longevity may not be a biologic characteristic directly determined by genetic heritage; it may result mainly from a balance, albeit ephemeral, between the potential of this heritage and environmental constraints. Is it not possible to draw on recent biologic breakthroughs in the field of aging to shed light on demographers' questions on longevity? This question will be asked more specifically in Chapter 49 about the genetic factors of mortality, but as Graziella Caselli, James Vaupel and Anatoli Yashin (2000) wrote:

> Ageing and longevity are very typical questions on today's agenda. The two processes are closely intertwined. Biologists and geneticists who study the mechanisms implied and try to establish at what stage one is old as well the real possibilities of further extending longevity, have come up with about 300 or so theories on ageing. According to Medvedev (1990) these can be grouped under four main theories: programmed genetic ageing; age associated changes; primary damage; evolutionary theories (Marigliano, 1995). Some of these theories focus on "*how we age*", i.e., on the mechanisms of free-radical damage, telomere shortening, errors in cell division, hardening of arteries, etc. that characterize aging. Other theories focus on *why we age* (i.e., on the fundamental evolutionary forces that underlie the fact that humans and other species are not immortal) (Finch and Kirkwood, 2000; Rose, 1991; Kirkwood, 1990; Williams 1957). Demographers are interested in *when we die*. That is, demographers want to know why some people die at age 60, others at 80, and a few at 100 and why the number of people dying at older ages is rapidly increasing. The theories of how we age have not yet shed much light on this kind of question. The current theories of why we age are so abstract and general that these theories shed virtually no light at all on the age-patterns of mortality and changes in these patterns over time.

For the time being, we should be satisfied with believing that human longevity is possibly gifted with a certain elasticity according to the evolution of the environment. What global change, such as climatic modifications, have produced indirectly in the long term in the species through selection, humans' own actions are in the process of doing, at least on an individual level, by modifying his relationship with his environment. In other words, could not progress in health have prolonged not only the average life span (i.e., life expectancy), but also its maximum span (i.e., longevity), without invoking an evolution of the genetic heritage of humanity, at this stage?

c. *Indicators of Recent Trends*

It is possible to assert that important changes are being produced at the level of mortality at old age.[6] Cases of extreme longevity have always been fascinating. According to the Bible, Adam, the first man, lived 930 years, and others after him lived even longer, such as Enoch, who died at 965 years, and Methuselah, the champion of champions, who died at 969 years! Logically, the ages at procreation were also much higher than today. According to Genesis, Adam was 130 when he "knew" Eve to give her Seth, her third child, and he knew her many more times after that. All this is no more than legend. The Bible is full of epic images, and the age of the patriarchs from before the flood was meant to strike the imagination, rather than to recount reality. For the successors after the flood, the estimates are much more reasonable: 275 years for Abraham, 180 for Isaac, 147 for Jacob, and 110 for Joseph.

In the more recent era, the centenarians of the Caucasus and those from several Andean valleys have been in the news, without mentioning the American Georgians. If they appeared credible for some time, we know today that they did not represent reality. They are three examples of a classic phenomenon: In many societies, the very old inspire deference and respect, and when the civil status of individuals is not well recorded, the ages declared for the very old are most of the time overestimated. For a legend to be born, all that is required is an argument to render the facts plausible (e.g., the effects of living on a high mountain or eating yogurt, the hypothesis of a genetic heritage specific to an isolated people). The longevity of the Georgians of the Caucasus was very flattering to Stalin, who did his utmost to maintain the myth (Bennett and Garson, 1986). It has also been shown that the first information from the Indians at Vilcabamba largely overestimated the ages (Mazess and Forman, 1979). As for the American Georgians of 120, 130, and even 140 years, this is simply a reflection of imprecision in census age declaration particularly in the black population among whom, at the end of the 19th century, it was rare for births to be recorded.

It is extremely improbable that until recent decades, anyone could have lived much longer than 100 years. It was even rare for this age to be reached. On the contrary, centenarians today are counted by thousands, and we are almost certain that at least one woman, Jeanne Calment,[7] lived for 122 years (Robine and Allard, 1999). Does this mean that human longevity is increasing?

It could initially be believed on reading about the secular evolution of the maximum age of death observed in a country such as Sweden that has for a long time had an excellent system for registering births (Fig. 48–8).

The oldest age at death observed in a year necessarily fluctuates. It is an extreme performance, an event, which cannot be established each year at the same level. Nevertheless, despite the very strong fluctuations observed in Figure 48–8, as much for men as for women, the trend is very clearly rising: in the middle of the 19th century, the maximum age at death oscillated between 100 and 105 years for women and between 97 and 102 for men, whereas over the past 20 years, it has been approximately 107 to 112 years for women and 103 to 109 years for men. This phenomenon has recently accelerated; the slope of the regression line obtained for the 1970 to 1997 is significantly higher than that obtained for the 1851 to 1969 period (Wilmoth *et al.*, 2000).

This does not necessarily mean that human longevity is increasing. There is a simple statistical game linked to the evolution of the number of elderly people, itself partly associated with medical progress, at the root of this phenomenon. The greater the number of people living to 90 years, the greater, with equal chances of survival, the probability of at least one person reaching 95, 100, or 105 years. For a very long time, human populations increased only very slowly as a result of the small surplus of a very high fertility over an equally high mortality. The population pyramid was very pointed at the peak; those older than 60 years represented barely 5% of the total population. The very old were rare, and the probability of a centenarian emerging was extremely low.

From the end of the 18th century, Europe's population went through a period of exceptional population growth, which in itself would have been sufficient for the emergence of an increasing number of very old people. This increase went hand in hand with aging of the population, which widened access to very old ages. Initially, the simple reduction of infant mortality that occurred 60 years earlier significantly increased the number of the generations entering old age. Better still, in the 1960s, survival beyond 60 years greatly

[6] This section uses extensive passages from an article that appeared in *Population et Sociétés* (Vallin and Meslé, 2001a).

[7] Doyenne of humanity, probably of all time, Jeanne Calment, born February 21, 1875, and died on August 4, 1997, having spent all her life in Arles. No one has lived to her age since. On the men's side, the validated record is that of Thomas Kristian Mortensen, born August 16, 1882, and died April 25, 1998, at the age of 115 years.

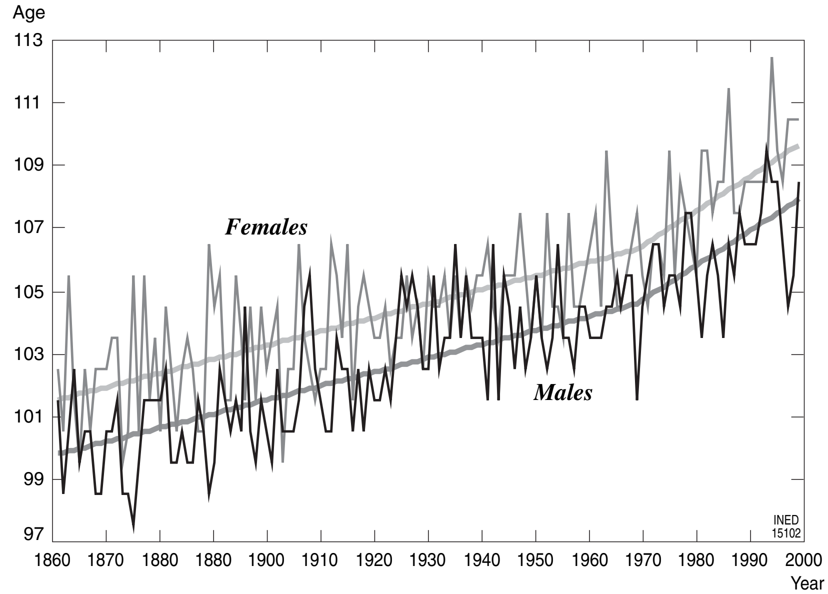

FIGURE 48–8 Evolution according to sex of the oldest age at death observed in a year since 1851 in Sweden. (From Wilmoth *et al.*, 2000.)

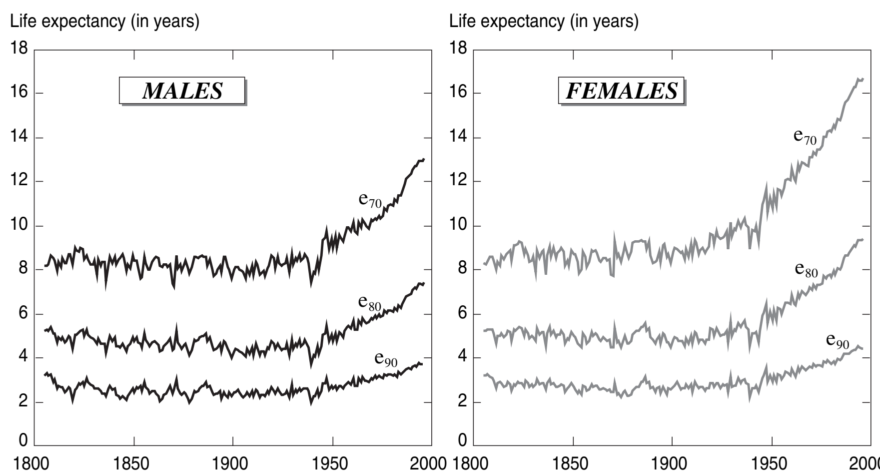

FIGURE 48–9 Evolution according to sex of life expectancies at 70, 80, and 90 years since 1806 in France. (From Vallin and Meslé 2001a.)

increased, thereby increasing the numbers at 70, 80, and 90 years by as much again and increasing the possibility of survival of a person to an age never previously reached. Since 1969 in Sweden, the mortality decline after 70 years has been responsible for 95% of the increase in the maximum age at death (Wilmoth *et al.*, 2000).

The more mortality decline settles at older ages, the more the question begs to be asked whether, beyond the effect of numbers, there is not also a real increase in the maximum life span due to a new phase in medical progress.

The increase in life expectancy at 70, 80, and 90 years has been spectacular since the 1950s, whereas it was previously nil, especially for men (Fig. 48–9). In France, the life expectancy of men at age 70, which had consistently oscillated between 7 and 9 years from the beginning of the 19th century up to the Second World War, exceeded 13 years in 1997. For women, progress started a little earlier, between the two wars, when the level was more or less a constant of 8 to 10 years, to nearly 17 years today. The same change in the maximum life expectancy can also be observed at 80 and 90 years, and if at these ages recent developments

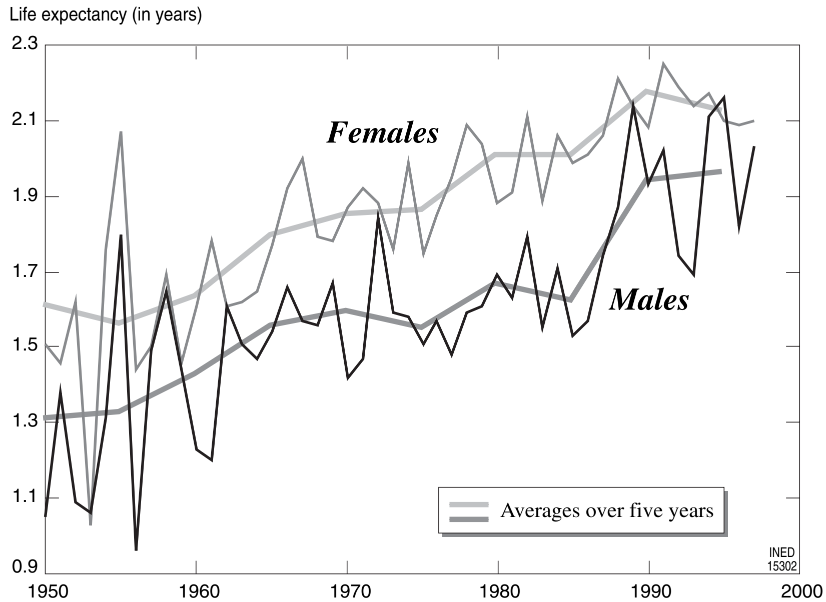

FIGURE 48–10 Evolution of life expectancy at 100 years since 1950 in France. (From Vallin and Meslé, 2001a.)

seem slower than at 70 years, it is only because of the arithmetic scale of the graph. The relative increase is just as important: an increase of more than 60% for men and nearly double for women.

Even at a 100 years, life expectancy has been noticeably increasing for several decades (Fig. 48–10). At this age, the annual figures fluctuate much more because they are based on reduced numbers, and only recent years are shown here to accompany the annual results of moving averages over 5 years. Nevertheless, the trend is clearly on the increase. At 1.1 year at the beginning of the 1950s, increased life expectancy for men at 100 years is 2 years. At the same time, women's life expectancy has increased from approximately 1.4 to 2.1 years.

This sudden increase in survival at very old age is an enigma. Does this mean that medical progress will henceforth affect the maximum human life span (i.e., longevity) and not only the average life span (i.e., life expectancy at birth)?

IV. DOES GOMPERTZ'S LAW APPLY TO THE OLDEST AGES?

The double assumption of an extreme intangible maximum human life span and an exponential growth in mortality by senescence well before this limit, is frequently being strongly contested. One of the first to do this was the biologist, Roy Walford who, in *The Maximum Life Span* (1984), suggested that initially life expectancy would approach the current maximum life span, but that soon, due to a technologic jump provoked by biologic progress, this limit could be pushed back and that it was not absurd to imagine that life expectancy could reach 150 years at the end of the 21st century. Other researchers believe that certain living beings (e.g., queen bees, some species of flies, sequoias) are escaping from the communal rule of the exponential increase of risk of death with age and would be nearly immortal were they not subjected to the risk of violent death (Klarsfeld and Revah, 1999). Better still, the massive experiments carried out on the fruit fly during the last 15 years have shown that beyond a certain age, mortality declines with age (Carey 1997; Vaupel and Carey, 1993), which incites a demographer such as James Vaupel to ask the following question: "Shall we soon witness a situation where certain individuals of the human race, as in the case of these flies, live long enough to reach a stage where mortality declines with age?" (Vaupel *et al*., 1998). A lucky few could then dream of immortality.

Even if it seems premature to judge the concrete reality of lengthening human longevity, let us say that this could occur in two quite different ways, only the second of which calls Gompertz's law into question.

1. Is the Curve Shifting to the Right?

Gompertz's law, if it can be interpreted as a model of characteristic biologic aging of humans, does not prejudice the fixity of longevity or place a limit to mortality decline. The fixity of longevity, which constrains the rectangularization of the survival curve, assumes that because all the mortality curves should converge toward the same force of mortality at the extreme age, mortality decline will be accompanied by an increase in the slope of the curve. For the limit to be constantly pushed back, it therefore suffices that the mortality decline does not modify the slope of the mortality curve, with the latter shifting entirely toward the right. Figure 48–11 shows the evolution of the French female mortality curve since the beginning of the 19th century. As mortality previously declined, the slope of the mortality curve increased. Between 1810 to 1814 and 1950 to 1954, mortality very clearly declined much more for those younger than 70 years compared with those older than 70 years, and the slope of the probabilities of death increased considerably. This evolution seems to corroborate the existence of an intangible maximum life span. On the contrary, since 1950, mortality has been declining rapidly for older ages. The rate of decline remains a little less than for younger ages, and the slope of the mortality curve continues to increase, although less so than previously, whereas anyone would logically have expected this phenomenon to entrench itself.

This assessment is not enough to prove a real lengthening of longevity, but the trend firmly supports such a hypothesis. However, we would have to be able to show that it not only occurs between 70 and 100 years as is seen in Figure 48–11, but also beyond 100 years. Here, we come up against the rarity of reliable data on mortality after 100 years. We are only now beginning to have access to some acceptable measurements, and there is a desperate lack of experience to judge the evolution in the shape of the curve beyond that age.

2. Is Progress with Aging Slowing Down?

Certain researchers believe that mortality curve is shifting toward the right and that Gompertz's law no longer applies beyond a certain age. Shiro Horiuchi and John Wilmoth (1998) showed that the increase of mortality with age tends to slow down and even stop

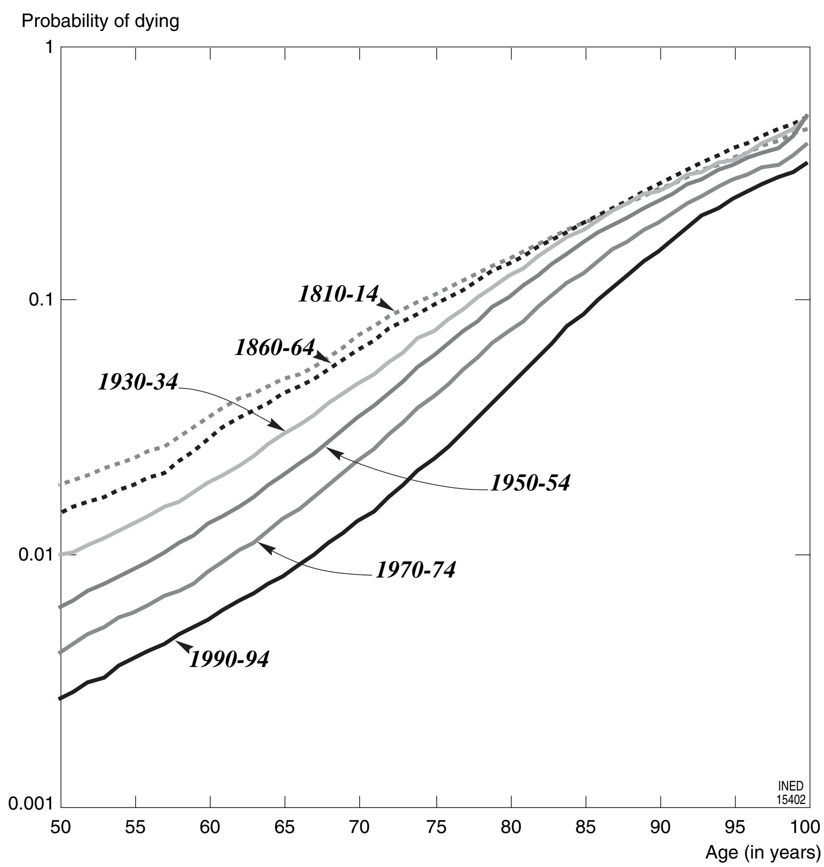

FIGURE 48–11 Modification of the mortality curve between 50 and 100 years since the beginning of the 19th century. (From Vallin and Meslé, 2001.)

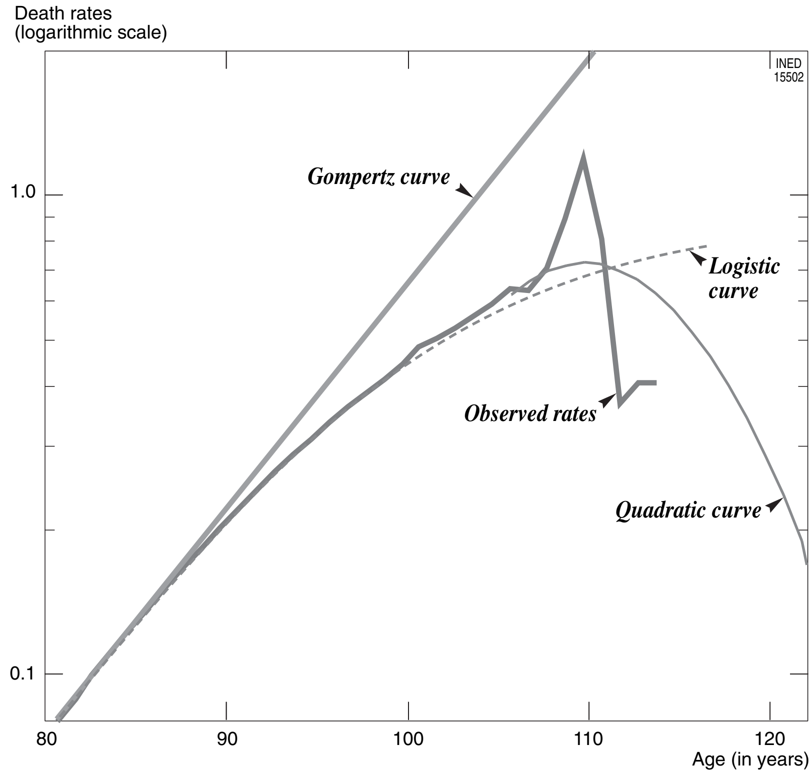

FIGURE 48–12 How do we adjust the risks of death observed at very old ages? Possible alternatives to Gompertz's law, according to James Vaupel (2001). The *bold solid line* indicates rates observed in cumulated data from Japan and the 14 European countries.

at very old ages. Is this a real phenomenon characterizing the force of mortality, or is it a result of bias, increasing with the risk of mortality at these ages, in the estimate of this instantaneous force based on discontinuous measurements? If this phenomenon is real, is the rapid reduction of heterogeneity in the survivors exposed to a very high mortality enough to explain this deviation from Gompertz's law, with each homogenous subgroup remaining subject to this law? Jean-Marie Robine (2001) has proposed two other hypotheses that could explain the interruption in the increase of mortality with age: the general improvement in the environment and in living conditions that has occurred during the last half century in industrialized countries and the fact that if elderly people are very fragile, they are also more frequently being placed in a protective environment, like crystal jewels carefully kept away from any risk of damage. Nevertheless, the available data are too tenuous to give definite answers to these questions. The door is wide open to the imagination of extreme scenarios. Based particularly on the example provided in the experiments performed on flies, James Vaupel (2001) has put forward the hypothesis that the mortality curve might be expected to turn around at very old ages for humans, too (Fig. 48–12).

The current data are too fragile to enable a choice between these extreme models of adjustment. This is why the development of research on centenarians and supercentenarians, those rare individuals who have life spans that exceed 110 years, has begun (Robine and Vaupel, 2001; Thatcher, 2001; (Meslé *et al*., 2000).

CONCLUSIONS

With Jean Bourgeois-Pichat's attempts, we have seen how difficult and even inaccessible is the definition of endogenous mortality linked essentially to human biology. Most causes demonstrate endogenous and exogenous aspects, and it is rarely possible to make a distinction between them to define the biologic life span limit of humans. Can we at least rely on a genetically determined fixity of longevity to estimate, in accordance with the principle of rectangularization of the mortality curve, what could be the unassailable rectangle or another way of defining the maximum human life span? It is possible that even this framework, about whose dimensions there is a great incertitude, could explode under the effect of the relatively new phenomenon of mortality decline among the very old. It is not certain that Gompertz's law can hold the road indefinitely at very old ages.

Perhaps the biologic material of which living organisms are made does not necessarily define, as it is believed, the vital process whose progressive deterioration leads ineluctably to death. Endogenous factors cannot, by their very nature, be dissociated from the environment with which they interact. Moreover, is this not what we learn from the laws of evolution? When a mutation changes an element of genetic heritage, its own environment determines whether it is retained for transmission to its heirs.

What do biologists have to say today about death? Contrary to what we have believed for so long, biologists think that death is not a biologic necessity but that evolution simply did not choose immortality because it was not essential to the survival of the species (Klarsfeld and Revah, 1999).

Genetic Factors in Mortality

LAMBERTO SOLIANI AND ENZO LUCCHETTI

Università degli Studi di Parma, Parma, Italy

I. METHODS AND PROBLEMS IN HUMAN GENETICS

Does having long-lived parents increase the probability of living longer? Although the idea is widely accepted, there is neither proof of the connection nor a clear consensus on the mechanisms of this relationship. What is the fundamental factor determining long life? Is it the absence of hereditary pathologies, whose presence reduces the length of life, or is longevity inherited as a characteristic in and of itself (Vandenbroucke *et al*., 1984; Glasser, 1981; Hammond *et al*., 1971)?

Comparisons between ethnic groups using epidemiologic and demographic data produce similar conclusions. In Florence, for example, deaths from lung cancer are less common, and life expectancy is longer among immigrants from the south of Italy, especially those born in Sicily (Buiatti *et al*., 1985); in Australia, Italians have lower rates of coronary diseases than other national groups (Armstrong *et al*., 1983). In England, numerous differences in cause-specific mortality have been identified among people originating from different Commonwealth countries; analogous observations have been made in Israel between Jews of different provenance. Interesting correlations, often independent of socioeconomic and environmental conditions, have been uncovered in the United States by comparing the territorial concentration of national origin groups to the geographic distribution of principal causes of death (Mason *et al*., 1981; Morin *et al*., 1984). It is easy to assume the existence of hereditary factors that influence or determine the average life span, but in all these examples, it is difficult to separate biologic components from cultural components.

By 1918, before the development of modern genetics, Ronald Fisher (1890–1962) had interpreted observed correlations of certain individual characteristics within families as an indication of their hereditary character. Classic models of the study of hereditary pathologies are based on analysis of a family group (i.e., presence of the disease among ancestors, descendants, or collateral relatives) or of a population (i.e., distributions between groups of individuals as a function of the family ties that unite them). These methods have led to the identification of a number of hereditary diseases and the discovery of their modes of transmission.

Developments in biology over past decades have opened the way for a more precise exploration of the symptoms and modes of transmission of pathologies and for identification of the genes responsible for the diseases and the biochemical mechanisms at work: the precise location of genes, the mechanisms of expression, the genetic anomalies affecting the mutated alleles, and the process by which diseases occur. Cytogenetics has provided detailed descriptions of the morphology and structure of chromosomes, the physical seat of genes. Molecular biology has identified the biochemical underpinnings of numerous hereditary diseases. Understanding the structure of DNA, the process of genetic decoding, and the sequencing of DNA has made it possible in many cases to trace the alteration of genetic information behind the appearance of the disease. Genetic engineering introduces the possibility of direct intervention to replace or repair genes that carry anomalies.

Medical science has been enriched by diagnostic techniques that take information directly from the fetus (e.g., amniocentesis, culture of amniotic cells from the fetus) in addition to ultrasound methods that allow observation of the fetus during pregnancy. Genetic consultation has moved beyond primitive probabilistic diagnosis, based on analysis of the family tree and family memory, to the certainty of direct observations of the fetus and its genetic makeup. The fine tuning of methods that are inexpensive and only moderately invasive has made it possible in many countries to begin systematic programs of complete neonatal examinations for the diseases that are the most common and that have the most serious pathologic and social consequences.

II. GENETIC DISEASES

Diseases with genetic origins can be divided into three principal groups: pathologies caused by anomalies in the number or structure of chromosomes; pathologies stemming from mutation (i.e., variation in the informative contents) of a gene; and pathologies or predispositions to disease due to multifactorial inheritance. From the demographic point of view, the most important genetic diseases are those with a high frequency of occurrence, those that cause death at young ages, and those that are geographically diversified. We therefore limit this discussion of the genetic aspects of mortality to factors that have a significant influence on life expectancy and that can explain a non-negligible proportion of mortality differences between families and between ethnic groups.

1. Chromosomal Disorders

The karyotype of human somatic cells is made up of 46 chromosomes; it is produced by the union of two haploid cells, one from the egg and one from the sperm, with 23 chromosomes each. The resulting diploid cell contains 23 pairs of chromosomes; the elements of each pair (i.e., homologous chromosomes, one from the mother and one from the father) have the same structure and carry information on the same characteristics. All individuals therefore carry two pieces of information for each trait. The pair of chromosomes labeled sexual (the 22 other pairs are called autosomal) is an exception. In men, the pair contains a larger chromosome called the X chromosome and a smaller chromosome called the Y chromosome, and in women, the pair is made up of two X chromosomes. Among men, the X chromosome necessarily comes from the mother and the Y chromosome from the father; among women, one X chromosome comes from the father and the other from the mother.

Meiosis, the process of formation of the gametes, guarantees that each germinal cell (*gamete*) carries 23 chromosomes, exactly one element of each homologous pair; the union of two gametes (i.e., fertilization, formation of the *zygote*) reestablishes the number of 46 chromosomes. Chromosomal disorders result from anomalies in the number or structure of chromosomes. Incidents during the course of meiosis can produce gametes with an abnormal number of chromosomes. The zygote may, for example, contain an extra chromosome (i.e., *trisomy*, or three copies of one chromosome) or one chromosome too few (i.e., *monosomy*, or only one copy of a chromosome). More significant variations can involve several chromosomes, but in general, these defects do not reach the point of manifestation because they cause alterations that are incompatible with further zygotic development.

The chromosome's structure can also be altered by insertions (i.e., repetition of a section of DNA), deletions (i.e., missing sections of DNA), inversions (i.e., section rotated 180 degrees), and translocations (i.e., section transferred to another chromosome). Organisms can adjust for some structural modifications because the information contained on one section of DNA is present and even active if it was transposed onto another chromosome, allowing normal phenotypes to be expressed. Gametes produced by a healthy carrier can nevertheless contain abnormalities, because a chromosome may be missing a piece or possess extra copies, with effects analogous to those produced by monosomies and trisomies.

Alterations in the number of chromosomes usually result from accidents during the formation of gametes; they do not generally have a genetic component and are rarely repeated for the same progenitor. They appear more frequently as the progenitor's age increases. However, chromosomal anomalies of a structural nature can be repeated during the production of germ cells and can produce the same pathologies among several children of the same parent, even if the anomalies are compensated for and have no effects on the healthy carrier.

Chromosomal anomalies, even when they are compatible with the zygote's development, inevitably lead to very serious and complex illnesses. These anomalies are common at the moment of conception, but most malformations are eliminated during the earliest phases of development of the fertilized egg.

By combining data from numerous analyses, it has been estimated that about 15% of confirmed pregnancies end in spontaneous abortion, and that in almost one-half of these cases, the fetus carries a chromosomal anomaly. For the earliest miscarriages, occurring before 4 weeks' gestation, the frequency of chromosomal anomalies is between 90% and 100%; it falls to 60% for terminations in the fifth through eighth week and to 32% for terminations in weeks 9 through 12. Trisomies (52%) constitute the most common type of anomaly. Spontaneous abortions at 16 to 18 weeks' gestation show karyotypes with trisomy of chromosome 21 (i.e., Down syndrome) or with trisomy 18, which most often results in normal karyotypes. Autosomal monosomies are rarely observed in miscarriages. Their effects appear to be so serious that they make it impossible for the embryo to develop, and the embryo is eliminated at a very early stage, probably before implantation.

In 7% of couples who are sterile or who have had several miscarriages, one of the partners is a carrier of a chromosomal rearrangement that has been compensated for; the individual is healthy but produces abnormal germinal cells. This frequency is 20 times higher than that observed among couples who have not experienced spontaneous abortions.

Among infants born alive, the frequency of chromosomal anomalies is on the order of 1%. According to epidemiologic analyses, which normally exclude deaths in the first 24 hours, 1 birth in 160 to 200 presents an abnormal karyotype. Clinical manifestations are observed in 35% of cases; the most common are autosomal trisomies, certain variations in the number of sexual chromosomes (notably Klinefelter's syndrome and Turner's syndrome), and noncompensated transpositions.

The best known syndrome, Down syndrome, is caused by trisomy of chromosome 21. It appears once in every 450 to 750 births. It leads to a complex pathology, causing increased infant mortality or premature aging, and persons with Down syndrome require lifelong medical treatment. As in almost all syndromes of chromosomal aberration, there is variation in the expression of the various pathologies associated with the anomaly. Cardiac effects are common, and the risk of acute leukemia is 20 times higher than in individuals with normal karyotypes.

Chromosomal anomalies appear more frequently as the mother's age increases. It has been estimated that in the absence of voluntary abortion, clinically significant chromosomal anomalies would appear in about 0.5% of births to mothers age 35 years, 1.5% of births to mothers age 40 years, and 5% of births to mothers age 45 years.

Among live births, chromosomal anomalies are relatively uncommon. Their frequency is declining in developed countries with the spread of regular examinations and therapeutic abortion.

2. Single-Gene Disorders

Single-gene disorders are caused by mutations of genes or modifications in the nucleotide sequence of DNA. Insertions and deletions or substitutions of one nucleotide for another that modify the sequence can change the information contained in the gene; the related function (i.e., synthesis of a structural or functional enzyme or protein) may then be carried out incorrectly, leading to the appearance of a pathology. These point-specific mutations can be sex-linked or autosomal, depending on whether the gene in question is situated on a sex chromosome. Mutations are further distinguished by whether they are dominant (i.e., manifestation of disease when only one of the two alleles is mutated) or recessive (i.e., disease appears only when both alleles are mutated).

The catalog of mendelian inheritance among humans established by Victor A. McKusick in 1988 included 1443 dominant autosomal characteristics, 626 recessive traits, 139 traits linked to the X chromosome, and 2000 traits that has not been completely identified or validated. Great progress has been made during past decade in mapping the human genome, notably by the Human Genome Project, which was dedicated to complete identification of the human genome. The hereditary diseases most important for mortality include Tay-Sachs disease, cystic fibrosis, sickle cell anemia, hypercholesterolemia, and phenylketonuria; we provide a brief profile of these conditions to illustrate the diversity of their modes of genetic transmission, their symptoms, and their diffusion.

Tay-Sachs disease was first described by the English ophthalmologist Warren Tay in 1881 and the American neurologist Bernard Sachs in 1887. It is common among Ashkenazi Jews, established in northeast Poland, southern Lithuania, and parts of European Russia, but it is rare among Sephardic and Asian Jews. In the United States and in Canada, Tay-Sachs disease has an incidence of 1 case in 5000 births among Jews, as opposed to 1 case in 550,000 among non-Jews. Caused by a recessive autosomal trait, the disease is characterized by the accumulation of a particular type of lipid, gangliosides, in the neurons and the brain. Children with the disease have normal reactions at birth, but they deteriorate rapidly starting in the first year of life. By age 18 months, children can become blind, gradually lose hearing, have serious difficulties in digesting food, develop macrocephaly, or develop general paralysis. Most victims lose mobility by their second year. Death, often by respiratory infection, follows between the ages of 3 and 4.

Cystic fibrosis is one of the most common childhood diseases among whites, but it is extremely rare among other racial groups. It is caused by a recessive mutation of a gene on chromosome 5. This disease, like Tay-Sachs disease, is expressed only in homozygotes. It affects 1 newborn in 2500 in the general population; the frequency among healthy heterozygotes is 1 in 25. The disease leads to respiratory complications; in the absence of treatment, 95% of people with the disease die within 5 years. With treatment, life expectancy rises to 12 to 15 years for women and 15 to 20 years for men.

Among blacks, the most common autosomal recessive disease is *sickle cell anemia*, caused by the mutation of a gene on chromosome 11. This gene directs the production of hemoglobin, which becomes defective with the genetic mutation and is no longer able to transport oxygen. Red blood cells tend to cluster in the narrowest capillaries, preventing the transport of blood to tissues and organs. Homozygotes usually die between ages 15 and 30 years and rarely live past age 45. In West Africa, one child in 100 has the disease, and 1 person in 6 is a carrier. In the whole of the African continent, it is estimated that about 100 000 people die annually from sickle cell anemia.

A Mediterranean form, thalassemia major or Cooley's anemia, is common in malarial zones of that region. Heterozygotes (i.e., thalassemia minor) have overall advantages relative to healthy individuals, because they have a lower susceptibility to malaria. In the homozygote state, the allele produces serious anemia, which until recently was fatal in early childhood. The allele is still common in several formerly malarial areas, including the Po delta and several regions of southern Italy, Sardinia, and Greece, although the elimination of malaria there has removed the conditions favoring heterozygotes and suppressed the mechanism of conservation of the allele. In Asia Minor, the disease affects 1% of Armenians and Syrians, among whom one person in six is a heterozygote.

Familial hypercholesterolemia is an example of a disease linked to a dominant autosomal allele. Affecting an average of 1 in 500 individuals, it is responsible for 5% of all heart attacks before age 60. It is particularly common among Lebanese, South Africans, and French Canadians, isolated populations exhibiting evident founder effects. In adulthood, heterozygotes have a predisposition to heart attacks that is 25 times greater than that of normal individuals; among carriers, 50% of men and 35% of women die before age 60 years.

Phenylketonuria is a hereditary metabolic disease with strong biochemical and genetic heterogeneity, caused by an unknown number of DNA mutations. In Western industrialized countries, the incidence of the disease ranges from 1 case in 6000 to 1 in 20,000 newborns. For some time, a simple, inexpensive diagnostic test has been part of the examinations normally carried out at birth; the test permits a straightforward and effective intervention, starting in the first week of life, involving the adoption of a specific dietary regimen that can neutralize the risk of irreversible brain damage.

3. Multifactorial Diseases

Most phenotypic characteristics (e.g., height, bodily proportions, shape of the face and physiognomic characteristics, skin color, blood pressure), like much pathology, do not have a simple genetic origin but rather are determined by the interaction of several genes with each other and with the environment. Multifactorial heredity is usually expressed as a predisposition toward a disease whose phenotypic manifestation also depends on environmental context or behavior (e.g., diet, environment, lifestyle). Analyses of multifactorial heredity aim both to separate genetic factors from environmental determinants (to evaluate their relative weight) and to identify the genes involved and their modes of interaction. For diseases, analysis also seeks to identify people or groups at risk who may benefit from an intervention.

Coronary atherosclerosis, for example, recurs in families; its frequency in case families is two to six times higher than in control families, suggesting the presence of a hereditary component. Family affinity is stronger when the onset of the disease is early (i.e., the strength of the correlation increases as age at onset falls); the hereditary component is most marked in the most serious or earliest forms. The hypothesis is confirmed by the presence of a strong genetic component in specific pathologies (e.g., hyperlipidemia, hypertension, diabetes) associated with coronary diseases. The fact that family affinity is more marked when the victim is a woman suggests that sex plays a role, but this may just as well come from behavior as from biologic sex (see Chapter 53). The complex genetic-environmental interaction is confirmed by the fact that, even in the family of origin of spouses of a case family, disease frequency is stronger than in control families. In the absence of shared genetic makeup, family affinity may arise from a simple commonality of habits, behaviors, lifestyles, and diet (factors that also influence marital choice) and, from there, shared environmental conditions likely to provoke the disease.

Comparison of twins historically has constituted an elegant method of evaluating the genetic component of measurable characteristics. Monozygotic twins come from the duplication of the same zygote and share the same genetic makeup. Any differences between monozygotic twins are therefore due to environment and not to genes. Dizygotic twins are equivalent to ordinary brothers and sisters and, like them, share only 50% of their genetic makeup; the only difference between dizygotic twins and other siblings is that twins are born at the same time and undergo more strictly similar environmental conditions.

Family analyses and twin studies have uncovered a large number of multifactorial genetic diseases. Among the most common are schizophrenia, several forms of diabetes, hypertension, and cardiovascular diseases. Age is an important cofactor; its role is clearer for cardiovascular and neoplastic disease and for endocrine and metabolic disorders. With age and accumulated exposure to environmental factors—ranging from tobacco consumption to radiation and pollution—the immune system loses capacity. This results in rapid growth of the risk of disease.

The association between disease and the various modes of phenotypic expression of the same characteristic (i.e., polymorphic characteristics such as blood type or the human leukocyte antigens [HLA] system) is another promising instrument for classifying multifactorial pathologies. Groups of infectious diseases (e.g., plague; cholera; chronic infections like tuberculosis and syphilis; intestinal infections, particularly among children; infantile and juvenile tropical diseases), still important today in certain countries, strike less frequently or are less lethal for those who belong to certain phenotypic groups. For the most part, these are statistical observations whose biochemical mechanisms are not known.

The HLA system, an ensemble of several highly polyallelic genes situated on chromosome 6, regulates individuals' capacity for immune defense. Several hundred cases of strong statistical association between diseases and specific alleles of the HLA system are known, including ankylosing spondylitis, psoriasis vulgaris, rheumatoid arthritis, juvenile diabetes mellitus, and multiple sclerosis. Even allergies, autoimmune diseases, and immunodeficiencies (including severe combined immunodeficiency, which is inherited as a recessive monosomy in 50% of cases and leads to death by bacterial, viral, or mycotic infection as early as the first months of life) are understood as the consequences of antigen-antibody reactions that depend on the functioning of the HLA system. These diseases should not be confused with acquired immune deficiency syndrome (AIDS), which causes its complicated activation of vital cells in the immune system under the effects of a retrovirus, not from direct causes or from genetic predispositions.

Several generalizations can be made based on current knowledge of human tumors. Mendelian inheritance is rare, although it is suggested in the case of certain types of observed frequencies, such as for neurofibromatosis, multiple polyposis, and various neoplastic endocrine syndromes. The probability of a neoplastic transformation may be correlated with turnover of the somatic cells involved; we know from the biology of carcinogenesis that neoplasms increase with age. Chromosomal anomalies are common in cancerous cells but rarely specific; in certain cases, the risk of neoplasm is associated with a higher frequency of chromosomal ruptures, especially if these involve the systems of control of cellular division. When tumors appear, somatic cells are more often involved than germinal cells. Simple or polygenic heredity is a cause in 20% of tumor cases. For the most part, there is a general interaction of environmental agents, and the precise relations of cause and effect are unknown.

4. Mitochondrial DNA and Degenerative Diseases

Extranuclear genetic information (DNA) is contained in the mitochondria, cytoplasmic organelles that control the process of oxidation and energy metabolism, furnishing close to 90% of the energy necessary for cells and for the organism as a whole. Mitochondria contain their own DNA (mtDNA), and the structure, organization, and genome sequence of human mitochondrial mtDNA, as well as certain associated structural and regulatory functions, are known. The tissues and organs most often affected by a shortage of cellular energy are the central nervous system and, in decreasing order of the seriousness of symptoms, cardiac and skeletal musculature, kidneys, and endocrine tissues.

Mitochondria are inherited exclusively from the mother in the ovum, which contains an abundance of them. Mitochondria in the sperm are rare, degrade rapidly, and usually do not penetrate the oocyte during fertilization. The genetic information contained in the mitochondria of every cell of every individual comes from the mother. Because of the transmission method, there can be notable variation in the number and type of mitochondria among children of the same woman; as a result, even among siblings, the pathologies associated with the mitochondrial genome can have very different symptoms and levels of seriousness.

The list of diseases that can be provoked by mutations of mtDNA or that are at least are related to mitochondrial functioning continues to grow (Wallace *et al*., 1997). Among the diseases that are the most widespread and the most likely to be associated with mutations in mtDNA are Alzheimer's disease (i.e., progressive loss of cognitive capacity), chronic progressive external ophthalmoplegia (i.e., paralysis of the ocular muscles and mitochondrial myopathy), Leber's hereditary optic neuropathy (i.e., permanent or temporary blindness, provoked by the deterioration of the optic nerve), and Leigh's syndrome (i.e., progressive loss of motor and verbal capacity, with degeneration of basal ganglia, potentially lethal in childhood).

III. THEORIES ON AGING AND THE LIFE SPAN

Aging and death can be seen as biologically programmed phenomena, just like development after conception and growth during adolescence and up until maturity. Hormones, enzymes, and antibodies change during the individual's life, both in response to the environment and in reaction to genetic programs. Changes interact and accumulate, causing cellular anomalies, cell death, tissue dysfunction, and degeneration of the organism, resulting in senescence and death (Hayflich, 1965, 1980). There is no shortage of examples of biologically programmed death being activated at a given stage of development of the human organism. Around the seventh week of fetal life, for example, mullerian-inhibiting substance stimulates the degeneration of the primitive female reproductive system in boys; similarly, certain specific functions, such as the functions of genes that code for the synthesis of various types of hemoglobin, disappear or are activated at different ages.

The idea that aging and the individual's natural death depend on characteristics inscribed in cells dates from the end of the 19th century. The zoologist August Weismann wrote, as early as 1891, that death takes place to the extent to which worn tissue can no longer renew itself, and the capacity for growth through cellular division is limited and not eternal. In the early 20th century, Alexis Carrel's experiments on somatic cells in chickens, which seemed to subdivide infinitely, gave credit to the hypothesis of *potential immortality* of cells cultivated in vitro. In the 1960s, Leonard Hayflick showed that normal diploid fibroblasts (i.e., embryonic mesenchyme cells that later become the fundamental amorphous substance) in mammals are capable of only a finite number of mitoses (i.e., divisions); this number is estimated at 50 ± 10 for the human embryo. Other observations seem to confirm the hypothesis that the duration of cellular life is biologically programmed. When donors are old, their cells cease to divide; the species with the shortest life spans enjoy a lower number of divisions, although the relationship is not proportional; and the cells of individuals affected with forms of premature aging have reduced capacity for division (Schneider and Mitsui, 1976; Martin *et al*., 1970; Epstein *et al*., 1966).

The idea of being able to predict a person's life span has fascinated researchers. Recall Raymond Pearl's assertion (1928, p. 151): "The length of life depends inversely on the rate of living," in which *rate of living* is used to mean the rhythm of energy consumption. Others, including Charles Rose and Benjamin Bell (1971), have found a positive correlation between the length of life and the rate of activity.

Two principal groups of hypotheses address the molecular and genetic mechanisms likely to determine aging and death. The regulation of the dynamics of mitosis (i.e., duplication of somatic cells) depends on the mitotic clock, and cells lose their capacity for division because of the accumulation of errors, meaning that mitosis is no longer possible after a certain level is surpassed. Somatic mutations likely contribute to the process of natural aging, in the same way that they contribute to carcinogenesis, which also depends on age. The mechanisms and interactions with other cellular processes are still unknown; even the causes to which the errors should be attributed are not clear (Flodin, 1984).

In recent years, it has been proposed that "the hour of death" can be estimated from the length of telomeres; the ends of chromosomes, the telomeres, may regulate the capacity for cellular duplication. Although it is not known whether the phenomenon is a cause or an effect of aging, the telomere does shorten over the course of an individual's life. Various research projects have tried to quantify the observed relationship between the length of the telomere (easily measurable in a cellular culture) and the length of life remaining for an individual. The passage from cells to organism raises scientific objections, because not all cells in the organism have the same capacity for replication. However, by cloning an individual from cells whose telomeres have been elongated, some researchers believe that an individual may inherit greater longevity. It may be possible to positively affect the length of life by replacing sick organs with healthy new organs derived by culturing cells with the capacity for longer life.

In an article published in *Science* with the very promising title of "Extension of Life-Span by Introduction of Telomerase into Normal Human Cells," Andrea G. Bodnar and colleagues (1998) extended the telomeric theory of aging to the point of completion by demonstrating that an enzyme, telomerase, can prevent degradation of the telomere. In young cells, telomerase is abundant, and telomeres renew themselves rapidly; in aged cells, in which telomerase is scarcer or absent, the telomeres become progressively shorter, and the cell stops dividing and dies. Scientists have been able to clone telomerase extracted from the sperm and the egg and introduce it into human cells from different tissues; this procedure has resulted in an increased number of mitotic divisions.[1] Stéphanie M. Cascio (2001) wrote:

> Normal somatic cells have a finite life span due in part to their inability to maintain telomere length and chromosome stability. Immortalization strategies based on recent advances in telomere biology and aging research have led to the creation of genetically stable, nontumorigenic immortalized cell lines. Reversible immortalization, using the Cre-lox recombination and excision system, has been developed for the expansion of primary cells for cell based clinical therapies. Immortalized human hepatocyte cell lines with differentiated liver functions would find broad applications in biomedical research, especially for pharmacology and toxicology, artificial liver support, and hepatocyte transplantation.

In presenting these results, some members of the press have regarded telomerase as a veritable fountain of youth—a label that is scientifically misleading but strongly appealing to the sensitive cord of expectations aroused by discoveries in the biotechnology industry. Another promising aspect of this discovery relates to cancerous cells, whose high capacity for division may be related to a high concentration of telomerase. Useful therapeutic developments may be generated by reducing the quantity of telomerase in tumor cells, causing them to age and die after a few divisions.

Another theory of aging, which does not necessarily contradict the other theories, is based on mitochondrial functioning. The process of energy production in cells can generate free radicals, which may increase the frequency of mutations of mitochondrial DNA. The accumulation of mutations may reduce the capacity for energy production and accelerate aging. It has been shown that the production of energy declines with age as somatic mutations linked to mitochondrial DNA increase, especially in the brain, skeletal and cardiac muscle, skin, and liver (Wallace, 1992). Proponents of this hypothesis have demonstrated that laboratory animals submitted to a restrictive diet producing a lower amount of free radicals accumulate fewer damages in their mtDNA, staying healthier and living longer than controls allowed to eat freely.

Free radicals attack all cellular structures: the nucleus, the mitochondria, and especially the membrane. The cellular membrane protects the cell, regulates the exchange of substances between environments inside and outside the cell, and activates numerous, vital biochemical reactions. Free radicals, which are produced during normal metabolic processes, can multiply under the effects of environmental factors (e.g., pollution), lifestyle factors (e.g., tobacco use, high-calorie diets that are rich in toxic residue), and disease (e.g., inflammations, medications). They reach elevated levels in cancerous cells. Their action can be counteracted by antioxidants, substances usually found in a diet rich in polyunsaturated fats that may also block the growth of cancerous cells. Pharmaceutical companies propose a number of multivitamins and minerals that are expected to reduce free radicals and their aging effects. This hypothesis demonstrates the importance of environment, both external and internal to individuals and their cells, in the biologic determination of the life span.

IV. SEX

In societies in which the effect of environmental factors on mortality has been reduced, we have seen a long period during which women's life expectancy has grown more rapidly than men's (see Chapter 53). Explanations for this difference have been sought in the factors differentiating the behavior and characteristics of the two sexes (Vallin, 1993 and 1999). At the biologic level, there are four types of sexual differentiation among humans: chromosomes (XX or XY), gonads (ovary or testicles), phenotype (internal and external sexual traits), and psyche.

Women and men differ in their chromosomal makeup. For women, the pair of sex chromosomes contains two identical elements, X chromosomes; in men, a single X chromosome is paired with a smaller chromosome, called Y. The primary function of genetic factors determining sex is to produce the gonads, which spur the development of other sexual organs and secondary sexual characteristics. Unlike other species, in humans it has been shown that the presence of a Y chromosome, not the absence of an X, determines the development of the testicles; it is not the lack of a "feminine" chromosome that determines the male but the presence of a specific "masculine" chromosome.

[1] The authors specify (p. 352) that biotechnologic applications of this phenomenon may promote the extension of human life: "Cloned normal diploid cells could replace established tumor cell lines in studies of biochemical and physiological aspects of growth and differentiation; long-lived normal human cells could be used for the production of normal or engineered biotechnology products; and expanded populations of normal or genetically engineered rejuvenated cells could be used for autologous or allogenic cell and gene therapy. The ability to extend cellular life-span, while maintaining the diploid status, growth characteristics, and gene expression pattern typical of young normal cells, has important implications for biological research, the pharmaceutical industry, and medicine."

More than 100 genes are attributed with certainty to the human X chromosome. These genes control various characteristics and functions: red blood cells, vision, hearing, the nervous system, the muscular system, teeth, skin, and the metabolism of glucose. Pathologies caused by recessive alleles located on the X chromosome have different probabilities of expressing themselves according to sex. Because men are hemizygous, the allele carried on the unique X chromosome is necessarily expressed; among women, the effects of a harmful or lethal allele can be counteracted by the presence of a normal allele on the second X chromosome. A heterozygote woman carrying a harmful or lethal recessive allele will not develop the associated disease (i.e., healthy carrier), but one-half of her male children will be affected by the disease. Her daughters will all be healthy, but one-half will be carriers of the damaged allele.

The best-known example of recessive sex-linked heredity is that of hemophilia A, a disease affecting the male descendants of Queen Victoria and carried by her daughters, healthy carriers, into many European royal families. A simple numeric example suffices to give the order of magnitude of the difference between male and female risks of developing the disease. A damaged allele with a frequency of 1 in 1000 will be expressed once in every thousand male births and only once in a million female births. Even if the disease is lethal and no affected individual can reproduce, the population will carry about 2 per 1000 female healthy carriers, and one-half of their children will receive the lethal gene (and be automatically sick if they are male or healthy carriers if girls).

As early as the 1920s, despite the still imprecise definition of pathologies at that time, it was observed that there are more men than women among individuals showing mental retardation. Since the late 1970s, it has been known that a form of mental retardation is linked to the X chromosome. This is the most common form of hereditary mental retardation after Down syndrome. However, the biochemical mechanism is not known.

Men's greater risk of developing hereditary diseases or dysfunctions linked to the X chromosome has often been invoked to explain lower male life expectancy. Errors in the duplication of DNA accumulate in somatic cells over time. When these errors involve genes on the X chromosome, they are always expressed in men, because of their hemizygous condition, but they can remain silent among women thanks to their second X chromosome. Women therefore benefit from a greater resistance to anomalies that occur over the course of life. The hypothesis is not disproved by the theory of random inactivation of one of the female's two X chromosomes (i.e., the female, despite possessing two X chromosomes, would have the same number of active genes as the male as the result of a compensation mechanism inactivating one of the two X chromosomes).

The X chromosome shows less polymorphism than other autosomes. It seems to be better preserved over the course of evolution, possibly by the greater intensity of selection to which it is subjected among males, in whom abnormal mutations are always expressed.

Based on numerous clinical and experimental observations, it is clear that sexual hormones have a strong influence on the metabolism of lipids and lipoproteins and on atherosclerotic diseases; this influence produces health advantages in women of reproductive age, especially in more developed countries. This would explain the lower mortality of women, as well as the smaller social and geographic differences in mortality observed among women. From the psychological or behavioral point of view, women often show greater concern for their health.

V. BIOMETRIC MODELS

In the early 20th century, Ronald Fisher (1918) proposed a method for estimating coefficients of heritability, based on the variance and correlation coefficients between parents and children, between brothers and sisters, or between spouses. Relative to historical methods based on biometrics, modern genetics has the advantage of identifying the biochemical causes of hereditary diseases, providing clear indications for diagnosis and treatment. Knowing the substance whose absence (or excess) leads to the disease is an extremely important piece of operational information; administering (or reducing) the substance makes it possible to eliminate the symptoms of the disease. Being able to identify the genetic defects behind the shortage (or excess) of the incriminating substance also leaves open the possibility of eradicating the cause itself. Nevertheless, neither the genealogic or mendelian approach nor biometric methods of inquiry among families and populations have lost their value; they are still the most appropriate methods for evaluating the relative weight of genetic and environmental components in the case of multifactorial characteristics or pathologies, especially for preliminary analyses.

In the early 1950s, Jean Bourgeois-Pichat (1952) proposed a graphical method for dividing infant mortality into portions attributable to "endogenous" deaths (i.e., deaths from hereditary defects, congenital malformations, obstetric trauma, or similar causes) and "exogenous" deaths (i.e., linked to external factors) (see Chapter 48). This method remains one of the most elegant demographic models for evaluating the biologic and environmental components of mortality. In this method, a logarithmic function of age in days is plotted along the x-axis of a system of cartesian axes, and the cumulative number of deaths occurring by each age is plotted along the y-axis. This produces a curve that has a logarithmic shape for the first months of life and then becomes rectilinear up until age 1 year. This curve can be interpreted as the result of the rapid drop-off in endogenous deaths after the first month of life combined with the linear distribution of exogenous deaths (as a function of transformed age) over the course of the following months. The trend line of the graph at age 1 month can then be extended back to the y-axis to estimate the number and the relative incidence of endogenous deaths (see Figure 48–1 in Chapter 48). The evolution of these two components of infant mortality illustrates their different sensitivities to medical progress. Exogenous mortality diminished rapidly with the development of modern medicine and the improvement in sanitation and nutrition conditions, whereas endogenous mortality was more resistant and seemed to be heading asymptotically toward a limit below which it is very difficult to drop. The decline in infant mortality and the resulting increase in life expectancy come largely from declines in exogenous mortality; there has been a concomitant increase in the relative proportion of endogenous deaths, on which the influence of medical progress has been much lower.

Demographic analysis of mortality rates by age can be used to measure differences between populations and to evaluate the effects of genotype. The standard population method of calculating standardized or normalized rates eliminates the effects of differing age structures (see Chapters 15 and 42). By applying this method separately by sex to different ethnic groups with similar socioeconomic characteristics, it is possible to evaluate the total effect of ethnic difference, a largely hereditary factor (Kitagawa and Hauser, 1973; Kitagawa, 1964).

The existence of a hereditary component in the determination of life span implies that populations with similar socioeconomic and environmental conditions would maintain relatively constant mortality differences at older ages and that these differences would be correlated with the distance between their genetic makeups. Italy, thanks to its geographic configuration, the historical separation between regions, and its migratory flows, presents optimal conditions for a territorial analysis. As early as the 1940s, Livio Livi (1941) held that territorial differences in mortality at older ages were the result of biologic differences between populations showing significantly different patterns of longevity. Based on the same idea, Corrado Gini predicted with great foresight a longer life expectancy for southern regions once infant mortality was reduced to the level then prevalent in the northern regions. The strong regional correlation between genetic distances and the slope of the mortality curve for older ages in Italy furnishes direct demonstration of this thesis (Soliani, 1984).

These correlations are necessary but not sufficient to demonstrate that ethnic or territorial differences in mortality are solely attributable to heredity (Caselli and Egidi, 1980, 1988). Within the nuclear family and across the family tree, values and behaviors that surely influence both cause of death and survival, such as nutrition and lifestyle, are transmitted along with genes.

VI. PERSPECTIVES

Despite scientific progress in formal and molecular genetics and in medicine, it must be recognized, as Albert Jacquard (1980) observed, that the commonly accepted role of biology in the determination of human longevity has never been conclusively demonstrated.

Knowledge about many biologic and genetic aspects of specific diseases has increased. It is now possible to counteract the effects of many causes that reduce longevity by means of medication or by acting on environmental factors. With the recent transfer of research from universities to industry (and more generally, from the public sector to the private sector), capital investment, and the organization of groups, there has been a significant increase in the implementation of practical and marketable solutions. Medicine, biotechnology, and biodemographic research have opened highly promising paths. One approach using gene therapies seeks to eliminate the negative effects of hereditary defects and acquired illnesses and to identify and to provide genes that are positively advantageous for survival. A second approach, building on the reconstitution of personal genealogies in regions with good health data, allows the identification at birth of people at risk of diseases that are at least associated with family predispositions (i.e., prevalence determined by culture or environment) if not fully hereditary (i.e., prevalence determined by genetics).

In medicine and biotechnology, a historical change is presaged by the announcement of the possibility of direct action to cure or treat hereditary or acquired diseases using genetic information carried by the individual. The conceptual phase is almost complete, although the development of applications in humans is still in the early stages (Brenner, 1995). In principal, it is possible to replace a defective gene with its normal version; in practice, the desired insertion is not yet feasible in humans. Certain genes are useful only if their expression is regulated such that the specified protein is produced in an exact quantity, at the right moment, and for the necessary period. Happily, in many cases, such precise regulation is unnecessary; in these cases, the solution may be more straightforward.

Genetic research is primarily directed at pathologies caused by gene mutations in the germline, but its discoveries also apply to many acquired diseases that have a genetic component (i.e., predisposition) or result from mutations in information at the level of somatic lines. Research can then attempt to correct or eliminate the harmful effects of these diseases. For instance, more than one-half of the clinical experiments in genetic therapy deal with cancer, which is only partially hereditary. Many of these approaches have not yet gone beyond preliminary clinical tests, but the medical research world considers their future developments to be very promising (Rosenfield and Curiel, 1996).

Biotechnology applications to correct genetic information are still limited to intervention in somatic cells. These techniques cannot be applied to germ cells until there is more complete information on their consequences for future generations. It is already possible to produce twins by cloning, although this is not done in humans for bioethical reasons. In theory, gene therapy affecting the germline could correct pathologic alterations in all of the children of a couple and in all their descendants.

It is important not to confound the cell and the organism. For example, it would be possible to prevent the aging of certain cells by intervening in the key genes coding telomerase, thereby treating certain diseases and lengthening the average life span, but we would not have discovered the key to aging and to longevity. The human organism is a unique and extremely complex whole. Genetics should make it possible to understand the phenomena of aging better and to delay them selectively or to accelerate them (e.g. to hasten the death of cancerous cells). These gains would result in increased life expectancy, comparable to that which is obtained by successively replacing the defective parts of an automobile, but we would still not be able to extend the biologic limits of the life span.

Bioengineering holds out the prospect of discovering and using genes to guarantee a better use of actual vital potential and to increase longevity. Protection against the formation of atherosclerotic plaque, the obstruction that blocks blood flow, is carried out by a genetically controlled element regulating blood levels of a coagulation agent called factor VII. The action of this protective element can go so far as to reduce the risk of cardiovascular disease by a factor of 15. The lower incidence of cardiovascular diseases in Italy relative to the countries of Northern Europe may result from the higher allelic frequency of synthesis of this protective element (20% in Italy). Epidemiologic studies have already shown that a reduction in blood levels of factor VII obtained by the administration of low doses of an anticoagulant similarly diminishes the risk of cardiovascular incident. We now understand the basic genetic structures, and we can foresee, at least in theory, the recourse to genetic engineering to insert protective alleles in the genetic makeup of individuals.

In April 2000, the theory of telomeres was unexpectedly relaunched by an article in *Science* on the results of a new cloning method applied to six calves. Among the first animals cloned, such as the famous sheep Dolly, starting at a young age, cells in the clones were the same age as the donor cells (Shiels *et al*., 1999). Their telomeres were short, and they benefited from fewer replications than normal for an individual of the same age.[2] This posed a problem of a metaphysical nature: "Are her cells older than she is?" (Vogel, 2000). With the cloning of six calves from the nucleus of an adult cow, the results were contrary to all expectations. These calves had telomeres that were not only longer than the donor's, but also longer than those of ordinary bovines of the same age and even longer, in some cases, than those of calves at birth (Lanza *et al*., 2000). The cause is unknown (possibilities include random variations, different species, different types of cells, and different methods of nuclear transfer), but the researchers involved spoke of cellular rejuvenation: In these clones, cells divided an average of 93 times, whereas in a normal fetus, they divide an average of 61 times. In the journal's editorial, Gretchen Vogel (2000) cites Robert Lanza's remark underlining the importance of the discovery: "If this increased lifespan extends to the whole animal, there is a real possibility that cloned animals might live as much as 50% longer than their normal counterparts, up to 180 to 200 years in the case of humans."[3]

[2] The authors specify: "Recent veterinary examination of the nuclear-transfer animals has confirmed that they are healthy and typical for sheep of their breeds, despite having a shorter mean TRF (terminal restriction fragment) length."

[3] The authors add (p. 665): "Here we investigate whether the production of live offspring is possible by nuclear transfer of late-passage somatic cells and whether the epigenic changes seen in the donor cells, such as telomere shortening and loss of replicative lifespan, are reflected in the resultant organism."

Moving from animals to humans, the possibility of regenerating telomeres and "rejuvenating" cells is important not for cloning new individuals, which is ethically forbidden, but for replacing diseased or aged cells and organs with young and healthy cells. These results make it possible to imagine creating a clone that in 6 or 7 days would become a cluster of multifunctional cells at a relatively early stage of life, able to develop into any organ or tissue—from the brain to the heart—after transplantation into the failing organ of a sick person. Three methods of forming such omnipotent cells are known, starting from the union of a woman's ovum and a human cell, the union of an animal ovum and a human cell, or human cells that have not yet specialized.

The first technique, known as human-human, consists of emptying an ovum of its nucleus and replacing it with the nucleus of an adult cell. Even if the objective is only to form a pre-embryo (in medicine, the word *embryo* is used only after 14 days of gestation) to use cells that have been alive several days for exclusively therapeutic goals, many fear that the next step will be to create a human clone; more radically, this ensemble of still-undifferentiated cells is already seen as an individual. This situation invokes universal law and the laws of numerous countries that forbid the deliberate creation and destruction of a human being for the benefit of another. With the second method, called human-animal, for which it is an animal ovum whose nucleus is withdrawn and replaced with the nucleus of an adult human cell, the resulting cells adapt too slowly in the diseased human organism. The third path takes progenitor cells called *stem cells* from adult tissues (in this case, from the blood) and transforms them into mature cells that can be reprogrammed according to the patient's needs. This method is more complex than the first two, but it seems to many to be the only method that can reasonably be applied.

The laws in many countries have been overtaken by the rapid evolution of techniques for which we now lack clear and coherent norms. Even the sentence "The creation of human embryos for research purposes is prohibited" (article 18, paragraph 2) in the European Bioethics Convention of 1996 can be interpreted in different ways. For some, it forbids all use of pre-embryos, even for medical purposes, whereas for others, it forbids only the formation of embryos or individuals through cloning. Future scientific and medical results depend on the outcome of this political debate and the more precise guidelines on human cloning that will be provided by ethics committees.

Developments in computing have opened new horizons for personal biodemographic research, allowing applications that have until now been inconceivable. Reconstitutions of individual histories can be extended to large populations and, most importantly, enriched by automatic linkages with different cause-of-death databases from hospital, clinical, and pharmaceutical data. Demographic history, genealogic history, and medical history can be brought together to identify people at risk. In the United States and in Canada (Bouchard *et al*., 1991), linking millions of data on the populations of entire regions has made it possible to identify people at risk and have them tested for genetic predispositions to cardiac diseases, depression, osteoporosis, obesity, asthma, and different types of cancer. This is an example of mass testing that may become current practice in the near future. Thanks to now-classic statistical techniques, it should soon be possible to measure the heredity of biologic and genetic factors of other characteristics that we do not yet know with precision, such as the length of life.

CHAPTER

50

The Environmental Factors of Mortality

FRANCIS SARTOR

Institut Scientifique de la Sante Publique, Brussels, Belgium

The International Council for the French Language proposed the following definition for the term *environment*: "the group of physical, chemical, and biologic elements and the social elements liable, at a given time, to have a direct or indirect, immediate or long-term effect on living beings and on human activities" (Aguesse, 1971). In the broadest sense, the environment combines three elements: a socioeconomic component, a psychosocial component, and an ecologic component. The first governs human activities aimed at the production, distribution, and consumption of goods and wealth. The second influences attitudes and individual behavior in various areas such as diet and addiction (e.g., tobacco, alcohol, drugs). The ecologic component refers, among other things, to the physicochemical qualities of the environment surrounding people's homes. From all the evidence, exogenous deaths are caused by the environmental characteristics of a population.

Neither the influence of the three environmental components on mortality nor *a fortiori* their interactions are studied in this chapter. The discussion is limited to an inventory of the physical, chemical, and biologic elements that are causes of avoidable deaths. The influences of the social component and lifestyles on exogenous mortality are studied in other chapters, notably Chapter 51. Every year, earthquakes, volcanic eruptions, hurricanes, avalanches, and landslides cause many premature deaths on a global scale. The impact on exogenous mortality of these natural disasters associated with structural elements of the environment is not considered in this chapter.

The influence of the environment's harmful physicochemical elements on mortality can be quantified by estimating the absolute number of premature deaths or the reduction in life expectancy attributable to these risk factors, or both. An impact study of this kind would also define the contribution of the elements in question to exogenous mortality. For that purpose, we need reliable data concerning the scale of the risks and the size of the populations exposed to the risk factors under consideration. This fundamental information is lacking for most of the risk factors discussed in this chapter, and projecting any kind of estimate using our current information is unrealistic.

The qualitative study of causes of exogenous deaths associated with the physicochemical factors of the environment also poses methodologic problems. In this chapter, we establish that mortality increases particularly in cases of severe environmental pollution. Excess mortality generally occurs in the most vulnerable population groups: young children, the elderly, and fragile people (e.g., invalids). In a population exposed on a single occasion or over a prolonged period to harmful environmental factors, we observe a sequence of biologic effects of different types, ordered according to the increasing gravity of the effects. At the beginning of the process, we find signs of biochemical changes measurable at cellular levels among a large number of people. The significance of these early effects is sometimes difficult to establish. The reversible symptoms, such as coughs, that are observable in the population at a lower frequency follow in this hierarchy. The established cases of illnesses that do or do not necessitate hospitalization, define the next terms of the sequence, and they concern an even smaller number of persons. Death constitutes the final effect of the process. The frequency of each of these effects in the population is therefore assumed to vary in inverse relation to their seriousness. In some conditions of exposure, only morbidity may be affected without any immediate effects on mortality. However, even a temporary increase in morbidity can be the source of a decrease in life expectancy.

Establishing the link between an environmental factor and such a diluted and delayed excess mortality proves to be a very difficult task within the framework of classic demographic methods. Moreover, the causes of death do not clearly reflect the initial causes of illness, especially when the period of latency is very long, as is the case for cancer. To analyze the causes of such illnesses, it is necessary to have individual data, whereas demographers generally use aggregate data. The link between air pollution and lung cancer, for instance, can be studied by examining the evolution of the mortality rates of lung cancer in several towns according to risk indicators such as the degree of urbanization and industrialization of those towns. Some sources of systematic error inherent in such an approach cannot be avoided, even if the populations studied are comparable from the point of view of smoking frequencies. The influence of individual risk factors, such as duration of residence, exposure to carcinogenic elements in the work environment, mobility, and characteristics of the housing, are not easy to assess using aggregate data. Analytic epidemiologic studies using individual data collected during case-control or cohort surveys can better assimilate confounding elements. From a methodologic point of view, the difference between analytic epidemiologic studies and demographic studies is that the former rely on population samples, whereas the latter usually study entire populations. Theoretically, it would be possible to carry out demographic studies using individual data as long as it is possible to match information contained in different data sets, such as national registers, cancer registers, and computerized social security records. Nevertheless, this approach remains problematic in many countries because of issues such as data confidentiality and the protection of privacy. In many public health problems related to physicochemical environmental elements, the possibility of a reduction in life expectancy with an increase in morbidity cannot be excluded. It is for this reason that the influence of environmental pollution on mortality is in many cases examined by means of morbidity.

The structure of the chapter is based on the essential ecologic components: the physical, chemical, and biologic elements. This may be questionable, particularly because these elements usually do not act independently. Moreover, the distinction between physical elements and chemical elements is not always clear; radon which will be considered as a physical factor and a chemical factor, is an example of this lack of distinction, which can be confusing. As a product affiliated to uranium and radium, radon can be classified as a physical agent with radioactive properties, but when it is found in the air in a dwelling, it can be considered a chemical pollutant of a gaseous state emitting radioactive particles. Other subdivisions could have been used to write this chapter.

The chapter title suggests that we could first study the influence of the natural environment on human health, followed by the effects of human-induced environmental changes on morbidity and mortality. This method is not necessarily the most interesting, and even though it helps to fill certain gaps inherent in the approach used in this chapter, it can cause other problems. In the first place, we stumble over the difficult problem of defining the meaning of natural environment. Then there is the inevitable overlap due to the interaction of elements. In what context should the problem of excess mortality be treated when it is due to heat waves if the temperature is considered as a factor of the natural environment and air pollution from ozone caused by traffic is responsible for the high temperatures and exacerbate the effect of the same temperature on health? In health problems linked to the environment, there will always be a conjunction or an interaction between various elements of the ecologic component to which socioeconomic and psychosocial influences must be added. The main characteristic of health problems linked to the environment is the contribution of complex phenomena of different types. A global vision of these phenomena is therefore necessary to evaluate the scale of these problems and to measure the impact of each of the various risk factors. The principal objective of studying environment and health relationships is to identify these risk factors, not to make a systematic classification of the nature of these elements.

I. PHYSICAL FACTORS

1. Climatic Conditions

The extent of daily deaths from all causes varies according to outside temperature according to a V- or U-shaped curve (Kunst *et al.*, 1993; Kilbourne, 1990).

The *optimal temperature*, also called the *comfortable temperature*, at which the risk of death is minimal depends on geographic location. For daily deaths from all causes recorded in St. Louis, Missouri (Kilbourne, 1990), the optimal temperature is about 25°C, whereas it is 17°C according to mortality data collected in the Netherlands (Kunst *et al*., 1993). This difference suggests the existence of a phenomenon called *acclimatization*. The same phenomena, the U-shaped curve and geographic variations of optimal temperatures, have also been observed to affect cardiovascular and cerebrovascular diseases (Pan *et al*., 1995; Rogot and Padgett, 1976). Cardiovascular and cerebrovascular excess mortality in extreme temperatures can be explained by the phenomenon of the body's adaptation to cold and heat. Cold and heat trigger different mechanisms that increase blood pressure, heart rate, and the blood's ability to clot. The number of deaths caused by respiratory diseases increases during the winter months, and this constitutes a second factor that contributes to excess mortality from all causes at low temperatures. In the latter case, it is the reduction of the body's resistance to microbiologic elements and the increase in contagiousness due to a greater propensity for confinement, which increases the risk of death.

Death by hyperthermia (i.e., death due to increased body temperature after severe dehydration) is the second cause of death during heat waves, after deaths caused by cardiovascular and cerebrovascular diseases. Death by hyperthermia generally affects isolated people and invalids who cannot feed or take care of themselves (although air conditioning is a factor that protects from hyperthermia). Death by hyperthermia can also be the result of negligence (e.g., children abandoned in a car). The share of excess mortality attributable to hyperthermia nevertheless varies considerably according to each heat wave and does not seem to exceed 50% of total excess mortality (Kilbourne, 1990). Daily mortality appears to be influenced by other meteorologic factors, such as wind direction, humidity, rainfall, and snow (Kunst *et al*., 1993; Rogot and Padgett, 1976). Contrary to common belief, an increase in humidity during heat waves may be a protective factor in temperate regions (Kunst *et al*., 1993). Studies of the effect of global warming on mortality suggest a possible decrease in cardiovascular deaths during the winter among the elderly living in areas with moderate winter weather.

Deaths from skin cancer in the United States and Canada, an indirect method of measuring exposure to solar radiation, vary inversely with latitude; an increase of 10% in the annual intensity of irradiation by ultraviolet rays could therefore be linked to an excess mortality from skin cancers of 4% at 50° and 9% at 30° latitude (IARC, 1992; Elwood *et al*., 1974). Mortality data recorded in Australia and New Zealand for European immigrants, numerous studies relating to geographic variation of mortality, and incidences of these illnesses, as well as experimental data from animals conducted at the International Agency for Research on Cancer (IARC), have concluded that solar radiation is carcinogenic for humans (IARC, 1992). Between 65% and 80% of melanoma cases can be attributed to overexposure to sunlight (Rivers, 1996; Koh, 1995). The incidences of skin cancer and certain other ocular diseases such as cataracts may increase during the decades to come because of more intense irradiation of the earth; part of the ultraviolet rays are absorbed by the stratospheric ozone layer, whose depth is diminishing (Armstrong, 1994).

The degree of humidity and the temperature are the principal factors governing the proliferation of microscopic fungi (i.e., mold) likely to produce natural toxins, called *mycotoxins*, on certain foodstuff. One of these, aflatoxin B_1 can contaminate corn, wheat, barley, oats, rye, rice, sorghum, groundnuts (i.e., peanuts), and cotton plant seeds. Several studies, carried out mainly in Africa, have showed an increase of primary cancer of the liver in humans in accordance with the level of food contaminated by aflatoxin B_1 (WHO, 1980).

Desertification is the main cause of famines, which contribute greatly to mortality. The Sahel is a zone 300 to 500 km wide that borders on the south of the Sahara and forms the transition between the desert and the tropical forest on the west coast of Africa. In this semiarid zone, the soil needs to be humid during 2 months of the year for seeds to germinate and for roots to form. Otherwise, the entire harvest is delayed until a more favorable period. In the Sahel, rainfall has been decreasing for more than a century, with periods of extreme drought occurring, notably between 1915 and 1918 and between 1968 and 1972. The decrease in rainfall partly explains the encroachment of the desert by 100 km observed between 1900 and 1975 in the Sudan (Holdgate *et al*., 1982). In recent decades, overgrazing and the increase of agricultural land through deforestation have favored soil erosion and increased desertification. Certain regions in Australia, Brazil, Iran, Pakistan, Afghanistan, the Middle East, Northern Africa, and Libya are also affected by this phenomenon. In 1982, it was estimated that the food supply of 80 million people living in the regions recently affected by desert encroachment was insufficient as a result of the decline in agricultural production (Holdgate *et al*., 1982).

2. Radioactivity

Uranium and radium are two radioactive elements that naturally occur in soil, rocks, and water. Through their disintegration, the inert gas radon is formed, which is itself radioactive and has a life span of 4 days. Radon emits α particles, which are responsible for its carcinogenic action. In the 16th century, Agricola, in his book *De Re Metallica*, stated that exposure to radon was one of the causes of lung cancer among miners in central Europe. Between 1970 and 1980 in many countries, air pollution from radon inside dwellings was the main source of exposure to ionizing radiation; the radon was generated by radium in the soil and the rocks of the land on which the dwellings were built, or it came from the radium in some of the building materials, such as plaster. The extrapolations obtained from the risks observed in miners exposed to radon suggest that between 11% and 13% of all deaths from lung cancer each year of people living in single-family dwellings in the United States can be attributed to radon exposure (Lubin, 1994). A case-control study carried out in Sweden has confirmed that this radioactive element is an important risk factor for lung cancer (Pershagen *et al*., 1994). The results of this survey were not, however, corroborated by an independent study carried out at the same time in Canada (Látourneau *et al*., 1994). A definitive response to this important public health problem is expected in the coming years as at least 19 case-control studies on the effects of radon have been undertaken in recent years (Lubin, 1994). A preliminary meta-analysis carried out on eight case-control studies suggest that the risk of lung cancer increases by 14% for levels of radioactivity usually found in a significant number of dwellings. About 6%, 28%, and up to 40%, respectively, of dwellings in the United States, Stockholm, and in some regions of Finland are affected by this problem (Lubin and Boice, 1997).

Pollution of the environment by radioactive substances around nuclear power plants and factories can also be a risk factor for ill health. In England, geographic analysis of mortality statistics revealed abnormally high incidences of leukemia in children living in a village near the Sellafield nuclear power plant, which from 1952 had been producing plutonium and processing radioactive waste from nuclear power plants all over the country (Gardner and Winter, 1984). A possible relationship between radioactive pollution of the environment and leukemia was then confirmed by the results of a study of two cohorts of children (Gardner *et al*., 1987a, 1987b). A case-control survey later suggested that the appearance of leukemia in these children resulted from their fathers' exposure to ionizing radiation in the workplace before conception (Gardner *et al*., 1990). The increase in cases of leukemia in the areas surrounding nuclear plants continues to be problematic, because several studies carried out in France and the United States have not been able to reproduce the association observed in England (Gardner, 1992; Hill and Laplanche, 1990; Viel and Richardson, 1990).

Serious nuclear accidents can have disastrous consequences for the environment, as the example of Chernobyl shows. One of the plant's reactors exploded on April 25, 1986, and it caused a fire that lasted for 10 days. This accident caused serious soil pollution in the area around the plant by the fallout of nonvolatile radioactive elements such as strontium and plutonium. The air, greatly polluted by the radioactive isotopes of iodine and cesium and aided by the wind, contaminated the soil of most European countries. In the Netherlands, for example, the activity of cesium 137 in milk was 10 times higher in 1986 and 1987 than it was between 1980 and 1985 (WHO, 1995). Iodine 131 was only detected temporarily in the air because of its short life span. The immediate and long-term consequences of this catastrophe on morbidity and mortality are not precisely known. The size of the population still irradiated by weak doses varies according to estimates between 8 and 17.5 million people living mainly in the Ukraine, Byelorussia, and Russia (Ginzburg and Reis, 1991). A million people probably received a higher dose of radiation: the 135,000 people living within a 30-kilometer radius of the plant and evacuated the day after the catastrophe; the 100,000 people evacuated in the year after the fire; the 10,000 people still living in radioactive zones; and the 400,000 people and an unknown number of military personnel who participated in the clearing operations without any protection against ionizing radiation.

The initial explosion caused the death of 2 workers, whereas the deaths due to irradiation and burns of 30 firemen and workers participating in the clearing operations were recorded in the 3 months after the fire. In 1990, the number of deaths directly attributed to irradiation was put at 250 (WHO, 1995; Ginzburg and Reis, 1991). According to experts from the U.S. Department of Energy, the radioactive contamination of the planet caused by this accident is likely to result in 28,000 new cases of cancer (Ginzburg and Reis, 1991). A sharp increase in the cases of thyroid cancer in Ukrainian and Byelorussian children was observed in the 5 years after the passing of the radioactive cloud over these two regions and has been attributed to the presence of radioactive iodine in the cloud (Weinberg *et al*., 1995; WHO, 1995). This increase may nevertheless be artificial as a result of the improvement in the recording of epidemiologic data after the accident.

This argument appears to be corroborated by the negative results obtained during the clinical and radiologic examination of the thyroids of the people living in villages at distances of 30 to 300 km from Chernobyl that were carried out in 1990 (Mettler *et al*., 1992). Significant variations in the incidences of congenital malformations and leukemia in children have not been recorded in most European countries where radioactive fallout was observed. The immediate public health problem seemed to be the psychological consequences of the evacuation of populations; the number of voluntary abortions also increased in certain European countries after the disaster. According to the World Health Organization (WHO, 1995), it will probably not be possible to evaluate the long-term impact of this accident on morbidity and mortality.

II. CHEMICAL FACTORS

1. Soil Quality

Most elements of the stratosphere interact in the soil; water, air, climatic and geologic elements, and living organisms participate in the elaboration of the soil. Vegetable species that develop in soil transform solar energy into living matter using chlorophyllous photosynthesis. The physicochemical composition of these vegetable species, the first link in the earth's food chain, is influenced by the nature of soils. Water infiltration in soils also affects their physicochemical qualities.

In certain cases, soil type can be the primary cause of a disease. Humans and animals need certain food components to stay in good health. These components are indispensable to the functioning of the organism and are referred to as *essential*. Among these essential components are several amino acids, some fatty acids, vitamins, and 14 minerals, also called *trace elements*. The minerals include iron, iodine, fluoride, copper, manganese, zinc, cobalt, molybdenum, selenium, chromium, nickel, tin vanadium, and silicon. To meet the organism's needs, the daily dose of each of these elements should be well defined, because an insufficient dose is a cause of deficiency diseases and an overdose can transform these essential elements into toxic substances.

The variations of geochemical conditions and an unequal distribution of these trace elements all over the world are responsible for large differences in the doses of essential elements found in the human diet. The health consequences of an insufficient supply of these elements, which is directly linked to soil type, are well known for at least three trace elements: selenium, fluoride, and copper. In the Kesham region of China, an endemic cardiomyopathy that particularly affects children has existed since the beginning of the 20th century. It was discovered that this disease, which has a lethality rate of about 50%, is caused by a deficiency of selenium in the diet, which is a result of the extreme penury of this metal in the soil. Excess selenium also has deleterious effects. Toxic effects have been recorded in workers exposed to aerosols containing selenium in its elementary state and in people having eaten foods rich in selenium (WHO, 1987b; Högberg and Alexander, 1986). Fluoride is well known for its capacity to prevent carries and tooth decay. In some tropical and subtropical regions, where the water and the soil are rich in fluoride, there are zones where skeletal fluorosis, caused by excessive doses of fluoride, is endemic (WHO, 1985). This bone disease is also a serious problem in certain areas of several developing countries, where it causes serious disability in a substantial proportion of the population. Iodine is a component of thyroid hormones, and the iodine content of food varies according to the composition of the soil from which it is derived. Severe iodine deficiency causes simple goiter, cretinism, a decrease in fertility, and an increase in perinatal and infant mortality (Delange, 1994). In Europe, it is estimated that between 50 and 100 million people living mainly in mountainous regions are affected by this deficiency. Iodism indicates poisoning due to a prolonged absorption of iodized medicines; environmental factors do not seem to play a decisive role in the cause of this disease.

Soils are also contaminated by various chemical substances that are not essential components for living organisms. Some pollutants can last for several years, even several centuries, and will slowly be accumulated in the earth's food chain. This bioaccumulation can become a health threat by increasing the risk of diseases such as cancer. The substances in question are pesticides, organic components such as PCBs and dioxins, some inorganic components such as nitrates, and some heavy metals such as cadmium. For most of the population, these substances are absorbed through ingestion of food and water. Nevertheless, inhaling these substances can be a supplementary source of risk for certain categories of people; the air in some rural zones can contain measurable quantities of pesticides as a result of spraying and as a consequence of the evaporation of the pesticides deposited in water, vegetation, and the soil. Only one association of a causal nature has been established: between exposure to arsenic-based pesticides and pulmonary cancers (WHO, 1995). PCBs belong to a complex group of aromatic chlorinated hydrocarbons, which have a number of uses as thermal transfer fluids, organic dilutants, plasticizers, lubricating inks, flame retarders for fireproofing, paint additives, liquid plugs, immersion oils, dielectric adhesives, and fluids for condensers and transformers. PCBs are concentrated in the fat of marine and land animals because of their high solubility in lipids. The possibility of an increased risk of liver cancer associated to exposure to PCBs has been evoked in workers exposed by their occupation and in populations accidentally exposed to PCBs. In contrast to PCBs, dioxins have never been synthesized for any use. They are by-products that appear during the synthesis of other chemical substances (i.e., PCBs, chlorinated phenol and their by-products, and especially herbicides). Dioxins do not exist naturally but are present everywhere in the environment. A small increase in the risk of some cancers has been recorded among workers exposed to dioxins. Nevertheless, it is estimated that there is hardly a measurable risk incurred by the general population as they are exposed to quantities of dioxin of between two and three times lower than doses absorbed by workers exposed by their occupation.

Nitrates and nitrites are groupings of atoms that are part of the nitrogen cycle, and they exist naturally. Their accumulation in the environment, particularly in the soil, is the result of massive uses of nitrogenous fertilizer in agriculture, the increase in quantities of nitrogenous waste originating from the production of cattle and poultry, and from the treatment of urban waste. Vegetables are usually the main source of nitrates. The concern associated to this type of soil pollution comes from the fact that nitrates and nitrites can form nitrosamines in the presence of amines. The formation of these derivatives can take place in the digestive tract or in the environment. Most nitrosamines have proved to be carcinogenic in animals. Moreover, studies have shown that the geographic distribution of deaths from gastric cancer is linked to the presence of nitrates. Because they are based on the analysis of aggregate data without excluding the influence of confounding factors, the relation of cause and effect remains controversial.

The toxic effects caused by the absorption of large doses of cadmium through the food chain are an example of the possible repercussions of soil pollution by heavy metals on human health. In Japan at the end of the Second World War, certain bone diseases were more common among people living in several villages in the Jinzu river basin (Toyama region). This disease is characterized by intense pain in the bones, from which was derived the name Itai-Itai (i.e., ouch-ouch in Japanese). The pain was the result of a weakening of the bones, which was likely to cause multiple, spontaneous fractures in the most serious cases (Kjellström, 1986). The kidney function of most of those affected with the disease was also damaged. This disease affected mostly multiparous menopausal women. According to an epidemiologic survey carried out in 1967, the prevalence of the Itai-Itai disease was approximately 7% in a total population of 6700 residents older than 30 years who lived in the Jinzu basin zone. Approximately 100 deaths were attributed to this disease. Organs of the autopsied patients contained very high quantities of cadmium, lead, and zinc. The cadmium content of rice cultivated in the region was also very high. The cause of Itai-Itai disease was the major pollution of soil and water from waste produced in a zinc and lead mine upstream from the villages where the cases of this disease had been recorded.

2. Water Quality

The expansion of industrial activities and certain modern agricultural practices, such as heavy use of fertilizers and pesticides, have in the last few decades modified the quality of water as much in rivers, natural lakes, and dams (i.e., surface water) as in superficial or deep aquifer layers (i.e., underground water). The level and complexity of this universal problem was exposed in a WHO publication that recommended a guideline value (WHO, 1996).[1]

Noncarcinogenic pollutants present in small quantities in drinking water accumulate slowly in the targeted organs of the body. For example, lead accumulates in the bones, and cadmium accumulates in the kidneys and the liver. In this way, very small doses can cause minor biochemical modifications, which can be measured with the help of specific biologic tracers. Enzymatic inactivity has been observed for small environmental exposures to lead, but the physiologic-pathologic significance of these effects is still not clearly established. When there is an increase in the dose absorbed, preliminary symptoms (sometimes unspecific) are observed, such as neuropsychological disorders or mild anemia in the case of exposure to lead in the surroundings, followed by chronic poisoning for which the prognosis is not necessarily fatal. It is therefore improbable that trace amounts of noncarcinogenic pollutants account for a substantial difference in the risk of deaths from all causes or from specific pathologies in the general population, provided the intensity of the exposure does not reach

[1] A guideline value represents the concentration of a constituent that does not result in any significant risk to health of the consumer over a lifetime of consumption (WHO, 1996).

exceptional levels and that the exposed population is not large.

The quality of diagnosis and medical data recorded in the medical certificate can also be an important factor in the observation of this type of problem, as the following example shows. Using biologic tracers, an overload of lead was found in 40% of the inhabitants of a well-defined region in the east of Belgium, where the drinking water was severely contaminated by lead piping (Sartor and Rondia, 1980 and 1981; Sartor *et al*., 1981). This situation had existed since the beginning of the 20th century, and the volume of the overload suggested that numerous cases of lead poisoning, also known as *saturnism* in the medical literature, must have occurred in the region. An excess mortality from renal diseases was not excluded. A survey that would enable the registration of cases of saturnism could not be carried out because of a confidentiality issue with the medical records and the polymorphism of the symptoms of poisoning which could affect the exactitude of the medical diagnosis and possibly the cause of death. The number of deaths from all causes was not higher than in other bordering regions after several confounding factors were taken into account (Sartor, 1979). Infant mortality in particular did not seem to be affected, even though this is the group most vulnerable to the effects of lead. Only male cerebrovascular mortality appeared to increase (Sartor and Rondia, 1983). It was in 1987, after an autopsy, that the first fatal case of lead poisoning of a young child living in this region was reported; the child had initially been hospitalized for acute encephalopathy attributed to another cause (Heinrich *et al*., 1987).

It is sometimes possible to observe an increase in the cases of a disease specifically caused by a pollutant without the mortality related to that disease being affected. In a region in the center of Slovakia that had major pollution of water, air, and soil by arsenic, the incidence of skin cancer, with the exception of melanoma, was twice as high as in other Slovak regions between 1975 and 1984 (Plesko, 1989). Because of the low lethality of this type of cancer, there was no geographic variation in the mortality rates for skin cancer. In effect, in situations such as this, the number of deaths attributed to a particular disease is independent of the number of cases of the disease. The site of the tumor provoked by the ingestion of arsenic is relatively specific to this pollutant, but this is not the case for other carcinogenic substances in the environment. The potential confounding factors must first be taken into consideration, followed by the dose to which the population has been exposed and the relatively long period of latency that separates the beginning of the process of carcinogenicity and the tumorous propagation. From all evidence, death certificates, which provide the classic data used to study mortality, do not provide information that is precise enough on this subject. It is therefore difficult to univocally establish possible links between the level of environmental pollution and certain long term effects such as cancer based on mortality studies of the general population.

Moreover, the ecologic nature of mortality analyses (i.e., use of aggregate data) can be a source of premature causal interpretations. In the 1970s, the results of about 50 ecologic surveys carried out in various countries suggested that the extent of cardiovascular mortality was inversely correlated to the level of mineralization in drinking water (Neri *et al*., 1974). Two major hypotheses have been proposed to explain this association: the protective role of calcium, magnesium, or lithium, which are more abundant in water with high mineral content, and the toxicity of elements present in water pipes, such as lead and cadmium, which are often more abundant in water low in minerals. Because surveys based on individual observations have proved to be more convincing than ecologic surveys in showing a cause-effect link, a longitudinal study and two case-control studies were undertaken. The results of these three surveys, based on individual data, invalidated the link observed in the ecologic studies (Comstock, 1988).

In Japan, a major pollution of water by mercury salts proved to be an indisputable cause of avoidable death. From 1953 to 1956, numerous cases of poisoning occurred in a fishing community on the bay of Minamata. The cause was attributed to the consumption of fish contaminated by methyl mercury formed by liquid waste from a factory producing vinyl chloride. In 1985, 2758 cases of the Minamata disease were recorded, 656 (25%) of which were fatal. Deaths from all causes, from liver cancer, and from liver and kidney diseases in the exposed population (50,000 inhabitants) for both sexes were found to be higher than those recorded in the two neighboring sample regions (Tamashiro *et al*., 1985 ; Tamashiro *et al*., 1987).

Pollution of underground water by nitrates as a result of massive use of fertilizer is another example of an environmental factor liable to provoke avoidable morbidity and possibly avoidable mortality. The quantity of nitrates, particularly in artesian well water, can easily exceed the guideline value recommended by the WHO (WHO, 1996). Ingestion of large quantities of nitrates, especially by infants, can be the source of a sometimes-lethal asphyxia called methemoglobinemia, which is caused by a denaturation of hemoglobin. In the United States, 278 cases of methemoglobinemia attributable to the pollution of drinking water, of which 39 were fatal, were recorded between 1945 and 1950 (Walton, 1951). Because reporting of this disease was not obligatory and the declarants were volunteers, the incidence of this disease was obviously underestimated. In Hungary at the beginning of the 1970s, 200 to 300 cases of methemoglobinemia were reported annually in zones with low-quality drinking water (Rudnai, 1992). At the end of the 1980s, only about 30 cases were recorded as a result of the preventive measures that had been put in place. Nomadic populations seem to be those most at risk for this condition; between 1987 and 1992, the Slovakian authorities recorded 129 nonfatal cases of methemoglobinemia, most of which had occurred in Gipsy camps using unregulated wells. As with most health problems linked to environmental factors, the effect of water pollution by nitrates on morbidity and mortality is difficult to quantify as a result of the varying reliability of the collected data (e.g., methods of recording and declaring cases of illness or deaths, rate of coverage of the exposed population, accuracy of diagnosis).

3. Air Quality

Certain meteorologic conditions can constitute an environmental factor capable of causing a disastrous incidence of air pollution. Thick fog associated with an increase in temperature with altitude (i.e., an inversion of the thermic gradient), lack of wind, and temperatures slightly below 0°C prevent the dispersal of atmospheric pollutants and promote their accumulation in the surrounding air. Atmospheric conditions such as these were behind three serious occurrences of air pollution during which an increase in mortality was observed. The first incident, reported by Batta and colleagues (1933), occurred in December 1930, in the industrial zone of the Meuse Valley in Belgium, where 27 different types of factories (e.g., coking plants, steelworks, zinc industry, production of sulfuric and phosphoric acid, glassworks, crystal manufacturers) were located over a distance of 30 km. The quantity of sulfur dioxide and sulfuric acid in the surrounding air, estimated using simple dispersion models, seemed to have been between several multiples of 10 and 1000 mg/m^3 of air. The crude death rate observed in this region during this period of pollution was at least 10 times higher than the expected rate, and pulmonary necrosis was discovered during autopsies carried out on persons in good health who died suddenly during this episode.

Historically, this was also the first study that suggested that air pollution is an environmental factor liable to increase the risk of death. In 1948, a similar incident occurred in Donora, a small industrial center near Pittsburgh, Pennsylvania, during which the mortality rate increased 10-fold (Lipfert, 1994). The third episode occurred in London in December 1952, and it was the most documented case for the volume of exposure and for public health indicators (Lipfert, 1994). Instruments for the continuous measurement of the quantity of dioxide and sulfur in the breathable particles in the surrounding air were available at the time. The average daily quantities of these two pollutants, commonly found in London during the winter, amounted to 0.5 mg/m^3. During the first half of December 1952, they increased 10-fold to between 4 and 5 mg/m^3. In the London agglomeration, where the average number of deaths per fortnight was a little over 4000 (100,000 per year), more than 8000 deaths were recorded during the first half of December 1952, which corresponds to a standardized mortality ratio of 200% for a population of 10 million, whose usual mortality rate was 1%. This phenomenon affected all age groups, although it was more intense among children and elderly people (Ministry of Health, 1954). Respiratory and cardiovascular diseases stood out as the main causes of excess mortality. An increase in the daily rate of hospitalizations and the requests for refunding medical services indicated a significant rise in morbidity during this period. Because burning coal rich in sulfur in a hearth was a fairly widespread method of domestic heating at the time, the degree of pollution of the indoor air was probably comparable to that of the outdoor air. This supplementary argument supported the likelihood of a cause-effect relationship between air pollution and excess mortality.

Various legislative measures have progressively been put in place in most industrialized countries to avoid the harmful effects of air pollution. Their aim is to reduce the sulfur content in fossil fuel used in the production of electricity and for domestic heating, improve the conditions of dispersal of pollutants (increasing the height of chimneys), purify gaseous emissions, inspect individual boilers, and possibly cease the production of electricity when critical levels of air pollution have been exceeded. Producing electricity from natural gas and nuclear plants and instituting measures to save energy have significantly reduced pollution by sulfur dioxide and breathable particles in most countries in Western Europe and in North America. The quantity of these two pollutants in the air of these countries is, on average, 100 times lower than the quantities recorded in London in 1952. Several surveys based on ecologic analyses of prolonged time series have nevertheless suggested that an increase in the degree of air pollution by sulfur dioxide and fine particles (i.e., particles that can be physically assimilated to spherical particles of a diameter of

10 μm and that are capable of reaching the pulmonary cells), at the low levels currently measured, could provoke a significant increase in deaths from all causes, particularly from respiratory and cardiovascular diseases (Katsouyanni *et al*., 1997; Schwartz, 1991, 1993; Dockery *et al*., 1992; Schwartz and Dockery, 1992a and 1992b; Pope *et al*., 1992). An increase in air pollution by fine particles of 0.1 mg/m^3 could therefore be the cause of a daily excess mortality of between 4% and 16%. Meanwhile, the causal nature of this combination remains controversial (Sartor, 1998; Gamble, 1998; Gamble and Lewis, 1996; Moolgavkar and Luebeck, 1996).

From the 1970's onward, public health problems linked to air pollution by motor vehicle exhaust fumes became a source of concern. These gases contain significant quantities of toxic agents such as lead, nitrogen dioxide, carbon monoxide, and some volatile organic compounds such as benzene and some hydrocarbon by-products. It is estimated that one-half of the nitrogen oxide emissions come from motor vehicle exhaust fumes (Stanners and Bourdeau, 1995). During the summer, as a result of strong sunshine, nitrogen oxide and the volatile organic compounds become precursors in the formation of tropospheric ozone. The increase in air pollution from the latter also can be a cause of excess mortality (Sartor *et al*., 1995 and 1997; Touloumi *et al*., 1997; Moolgavkar *et al*., 1995; Kinney and Ozkanyak, 1991).

The fact that the connection between the presence of certain toxic substances and mortality is generally difficult to establish has already been emphasized in this chapter. This is particularly true for carcinogenic effects caused by the inhalation of substances such as benzene, aromatic polycyclical hydrocarbons from motor vehicle traffic, and coal combustion. It has been known for a long time that mortality from bronchial cancer is higher in urban or industrial areas than in rural areas, and an often repeated hypothesis is that this difference is attributable to the presence of larger quantities of carcinogenic substances in the air of cities. At the end of the 1970's, by extrapolating from mortality data collected from workers exposed to such substances, it was estimated that the combined effect of all these carcinogenic pollutants present in the air in cities could only be translated into the occurrence of five cases of lung cancer per 100,000 inhabitants per year (Doll, 1978). Several case-control and longitudinal epidemiologic surveys have corroborated this estimate by showing that the carcinogenic substances in the air can, independently of other risk factors and in a worst-case scenario, double the risk of lung cancer in the general population (Cohen and Pope, 1995; Barbone *et al*., 1995; Engholm *et al*., 1996).

Serious air pollution can also be caused by a major chemical accident that generates a massive emission of a toxic substance into the environment as a result of a serious technical breakdown. The accidents in Seveso, Bhopal, and Chernobyl are the three most famous examples of modern industrial disasters that caused serious pollution of the environment, particularly of the air. The dioxin liberated in the region of Seveso on June 10, 1976, did not have an immediate effect on mortality and caused an epidemic of chlorinated acne in children younger than 15 years, which was observed a few days after the accident (Caramaschi *et al*., 1981). A longitudinal study of the exposed population continues to look for any carcinogenic effects due to this exposure to dioxin (Bertazzi *et al*., 1989, 1992, 1993; Pesatori *et al*., 1993). The latest data analysis shows an excess mortality from diseases of the circulatory and respiratory systems, probably due to a combination of exposure to dioxin and the psychosocial consequences of the accident. Deaths from diabetes are also higher, but a connection to the dioxin exposure remains to be established. The increase in deaths from gastrointestinal cancers and cancers of the lymphatic and hematopoietic tissues are indisputably attributable to the exposure to dioxin (Bertazzi *et al*., 1998).

During the night of December 2, 1984, the air in the region of Bhopal, India (900,000 inhabitants), was severely polluted by the volatilization of 27 tons of methyl isocyanate, which was stocked in the tank of a chemical factory. Two hundred thousand people were poisoned by this gas, which is a serious irritant for the respiratory, ocular, and cutaneous mucous membranes. The official assessment of this catastrophe, an underestimate according to some Indian experts, is at least 2500 immediate deaths (Dhara, 1992). According to the local authorities, the mortality rate for the exposed population remained higher than that for a neighboring population that was not exposed until 1990; the number of deaths attributable to this air pollution in the 5 years after the disaster rose to 1100 supplementary deaths, mainly caused by respiratory complications. At the end of the 1980's, the prevalence of respiratory, ocular, and gastrointestinal symptoms in the exposed population was also much higher than in a neighboring sample population. The fire in the Chernobyl nuclear plant, mentioned earlier in this chapter, further illustrates the cross-border nature of air pollution. Air can play the role of a vector in transporting harmful substances to regions far from where the emission occurred.

The quantity of pollutants measured in the outdoor air, in the specimens taken from outside dwellings, has been used as an indicator of exposure in most ecologic surveys showing the effects of air pollution on morbidity or mortality. However, a large proportion of the population of industrial countries spends most of their lives inside work premises and dwellings, where the air quality is not necessarily the same as that of the outdoor air. The degree of air pollution from outside pollutants found inside work premises depends on the rate of infiltration of the outdoor air, the size of particles, and the chemical reactivity of the pollutants with the materials for constructing and furnishing the walls in the premises. The rate of infiltration can vary considerably according to the type and the use of premises. The finest particles penetrate the interior of premises more easily and can remain suspended in the air for a long time (Lipfert, 1994). Sulfur dioxide and ozone are gases capable of great chemical reactivity, and they therefore disappear rapidly, whereas carbon monoxide can remain for a long period because of its chemical stability.

It is not easy to estimate inside dwellings the degree of exposure to pollutants present in the outdoor air. Indoor air can be more polluted by certain substances than outdoor air. This is the case for carbon monoxide, nitrogen oxide produced by gas cookers, tobacco smoke, and household dust (i.e., coal burning residue). Other substances that pollute indoor air are not normally present in the outdoor air. These are mainly organic solvents found in building materials, paint, aerosols, and cleaning products. Sources of biologic pollution, such as dust mites, hair from domestic animals, and allergenic plants, are found inside dwellings. Thermal insulation and the use of air conditioning are also factors in the problem of air pollution inside buildings. Even though the agents likely to pollute indoor air and the levels of pollution that they can cause are known, the statistics of morbidity and mortality are only available for certain pollutants, such as radon (discussed earlier) and carbon monoxide. Between 1978 and 1988, the number of deaths attributed to carbon monoxide in the United States (total of 11,500 deaths) represented one-fourth of deaths due to accidental poisoning; for comparison, heroin overdose caused the deaths of approximately 6000 people during the same period (Cobb and Etzel, 1991). Carbon monoxide caused by vehicle exhaust fumes was responsible for 57% of these deaths, and the toxin produced by faults in domestic heating appliances were responsible for 20% of these deaths; accidental poisoning was not recorded as a cause in 20% of the death certificates studied.

The various varieties of asbestos are derivatives of fibrous silicate. Asbestos was abundantly used for its insulating properties from the beginning of the 20th century by the building industry. These fibers are carcinogenic agents reputed to be the only known cause of mesothelioma of the pleura, a rare cancer that affects one or two people per million in the general population per year; this form of malignant tumor cannot be attributed to smoking, even though it can exacerbate the carcinogenic effects of asbestos. The mortality rate from mesothelioma of the pleura is considered to be the best indicator of past exposure to asbestos. Numerous experts expect to see an increase in mortality from this cancer over the next 20 years, particularly among construction workers (Price, 1997; Peto *et al*., 1995). Excess mortality from mesothelioma of the pleura has also been observed in Turkish villages where dwellings were built using silicate materials similar to asbestos (Baris *et al*., 1992).

The role of exposure to asbestos in the development of mesothelioma of the pleura was discovered during epidemiologic surveys on industrial toxicology. These surveys look at occupational intoxication, mainly caused by air pollution of the workplace by the chemicals used or produced industrially. The number of substances that may cause occupational poisoning is impressive. More than 1500 chemical compounds are listed in the index of Robert Lauwerys' reference book (1990). Despite the existence of occupational hazards, mortality from all causes in the population of workers (age standardized) is generally inferior to that of the general population (Table 50–1).

The healthy worker effect comes from a selection, based partly on medical criteria, of subjects in good health; it seems to be greater for nontumorous diseases than for cancers. The observation of cohorts of workers more particularly exposed to certain substances has nevertheless indicated that mortality attributable to certain types of cancer has revealed itself as being significantly higher than in the general population (see Table 50–1). In this way, surveys on mortality have helped to reveal the carcinogenic effects on humans of substances such as benzene, nickel, arsenic, vinyl chloride, and tar.

III. INFECTIOUS DISEASES LINKED TO THE ENVIRONMENT

In this section, we discuss only the pathogenic germs that can be transmitted to humans as a result of environmental conditions and that can therefore be eliminated with appropriate measures. On a global level, the number of deaths caused by these infectious diseases is much greater than for those that can be attributed to the physical and chemical factors discussed earlier in this chapter.

The principal health risk linked to the pollution of drinking water comes from the contamination of the

TABLE 50–1 Deaths from All Causes and Specific Mortality in Some Cohorts of Workers Exposed to Specific Toxic Substances

Industrial activity	Standardized mortality ratio (%)[a]			
	All causes	From all cancers	From specific cancers	Site
Rubber	83 (5079)	93 (986)	129 (55)	Bone marrow
Vinyl chloride	75 (352)	102 (79)	412 (7)	Liver
			280 (7)	Brain
Steelworks	82 (4716)	92 (1008)	283 (40)[c]	Lungs
Nickel (Scotland)	90 (67)[b]	320 (38)	1600 (16)	Lungs
			1100 (11)	Nose
Nickel (Canada)	80 (245)	130 (54)	220 (19)	Lungs
			3680 (7)	Nose
Arsenic	111 (324)	147 (69)	300 (32)	Lungs

[a] The numbers of deaths observed are given in parentheses.

water supply by bacteria, viruses, protozoa, or parasites. The presence in drinking water of germs pathogenic to humans is always caused by fecal contamination, except in the case of the guinea worm, which is responsible for dracunculiasis. The eradication of these diseases depends on sanitation, the sanitary evacuation of excreta and the purification of domestic used water. The infectious diseases transmitted in water include diarrheal diseases, cholera, viral hepatitis, and salmonellosis. However, water is not the only channel of transmission; these diseases can also be carried by contaminated food. Some diseases can be transmitted by the inhalation of water (e.g., legionnaire's disease) or by skin contact (e.g., bilharziasis). On a global level, mortality from water-transmitted diseases remains a major public health problem. In 1985, noncholeraic diarrheal diseases in children younger than 5 years caused 3.5 million deaths in developing countries, which was about 10% of the total 39 million deaths in that year (Lopez, 1990).

Deaths from cholera remain fewer than deaths from diarrheal diseases. In 1991, more than one-half million cases of cholera, of which 16,000 were fatal, were reported by 52 countries (Siméant, 1992). The lethality rate of cholera decreased on a global level during the seventh pandemic, decreasing from 50% in 1960 to 3.3% in 1991. Several factors have contributed to this development: improvement in notification of cases (i.e., more exhaustive recording of the benign cases which previously escaped notification), the reduced virulence of the El Tor biotype, improved knowledge about the disease, and rapid implementation of effective means of combating it (Siméant, 1992). It is nevertheless difficult to specify the portion of deaths from diarrheal diseases and from cholera directly attributable to the bad bacteriologic quality of water because of the lack of available epidemiologic data. In industrial countries, bacteriologic water pollution remains a public health problem, although the effect on mortality cannot be compared with that in developing countries. In the United States for example, 291 epidemic outbreaks of water-transmitted diseases were recorded between 1981 and 1990, causing four deaths (Craun, 1992).

Pathogenic germs can also be transmitted to humans through other organisms living in water or air, which serve as intermediary hosts or media. The two most frequently occurring diseases in tropical and subtropical zones are transmitted in this way: bilharziasis and malaria. Bilharziasis is a parasitic disease caused by the presence of a worm, the *Schistosoma*, in certain veins of the host organism. It is transmitted through skin contact with water containing larvae that developed in intermediary hosts, which in this case are certain types of aquatic snails. This parasitic disease is endemic in the rural regions of 74 countries, where 250 million people are infected. Given the diversity of the organs infested with the parasite, it is difficult to evaluate the level of mortality attributable to this parasitosis. After a latent period of 5 to 15 years, those suffering from bilharziasis develop serious diseases of the bladder, brain, liver, spleen, intestines, and lungs as a result of the parasitic activity of *Schistosoma*. Moreover, presence of the parasite in the bladder causes a particular type of cancer of this organ, which is the main cause of death in young adult Egyptians.

Malaria, an Italian word that means "bad air," is an infection with the *Plasmodium*, a parasitically living, unicellular species transmitted to humans through a mosquito bite. The regions where endemic malaria still exists or where no antimalarial campaign has ever taken place contain up to 500 million inhabitants (9% of the world's population) and are mainly situated in Africa. According to estimates by the WHO (1992), more than 80% of the clinical cases and 90% of the carriers of the parasite are in tropical Africa. However, only very incomplete and erratic information on deaths attributable to malaria is available. The WHO's African Region declared 800,000 children's deaths per year in 1991, but child mortality had declined in certain zones as a result of widespread use of antimalarial drugs and of progress in education and social development.

Behavior, Lifestyles, and Sociocultural Factors of Mortality

JACQUES VALLIN, GRAZIELLA CASELLI, AND PIERRE SURAULT

Institut national d'études démographiques (INED), Paris, France

Dipartimento di Scienze Demografiche, Università degli Studi di Roma "La Sapienza," Rome, Italy

Groupe d'études sur démographiques, economiques et socials, Université de Poitiers, Poitiers, France

Although health and mortality depend partly on the natural or humanly adapted environment in which individuals live, people can also encourage or curtail the incidence of diseases and death by their behavior and living habits (Stanley and Joske, 1980). However, this behavior is largely determined by attitudes generated by cultural inheritance, living conditions, and policies directed at local and national levels, especially in the realm of health. In the following sections, we examine the different elements in individual behavior that have a bearing on health and then concentrate on the influence of surroundings, living conditions, and collective action on the expression of attitudes that stimulate this behavior.

I. BEHAVIOR THAT INFLUENCES HEALTH AND MORTALITY

The preservation and deterioration of current and future health are affected by every activity of daily life, such as washing, smoking cigarettes, eating pasta and fruit, crossing the road, working in a chemical factory, heating the house, having unprotected sexual relations, practicing a sport, having social relations with other people. The list of individual behaviorals having an effect on health and mortality is long, but we shall try to identify the most significant aspects by distinguishing within the individual activity the care devoted to the body, sexual behavior, organization of the living and professional environment, and relations with other people.

1. Bodily Care and Leisure Pursuits

A certain number of human activities are directed expressly to the care of the body. The same clearly applies to using health services, whether in an attempt to cure a disease or to prevent its development. Care of the body necessitates eating, drinking, resting, and exercising, actions that, although designed to keep the body in good working order, may also cause the state of health to deteriorate.

a. Resort to Medical Services

The behavior most immediately allied to health and survival is the resort to care in the case of sickness. The individual decision to seek treatment may often determine a cure and the preservation of future chances of survival. Although recovery from benign or even serious diseases may occur without any treatment, resort to care increases the chance of a faster, more complete cure with fewer complications. In addition to immediate survival, recourse to care also preserves the capacity for later survival.

Resort to care is not enough. The treatment must be effective. Generally, the result will not be the same if the sick person resorts to traditional forms of healing or to modern scientific medicine, although there is a margin of uncertainty. Sometimes, there has been a tendency to age-old solutions that had merit and instead to regard modern medicine, which remains an art that is subject to error, as sacred. In some cases, sick people given up for lost by the medical faculty have been cured by turning to alternative or complementary forms of medicine, such as homoeopathy, acupuncture, and phytotherapy. It is also true that certain elements of the pharmacopeia are far from having proved themselves, and studies have shown that the placebo effect is sometimes as important as the medication itself (Shapiro and Shapiro, 1997). Nevertheless, the healing of sick people depends on their attitudes about the resources that health services place at their disposal, whether in visiting a physician or in following a prescribed treatment. This does not mean that sick persons should display blind confidence in their physicians, but rather that their ability to discuss their symptoms with them to establish a diagnosis obtain a prescription play an important part in the success of the procedure.

What is valid for the treatment of a disease applies equally to its prevention. Although prevention within a population is largely the concern of those in charge of public health, it also depends on individual behavior. Vaccination campaigns can be organized and the most useful of them can even be made obligatory, but the vaccine coverage of a population depends very much on individual behavior. However, vaccination is one of the preventative measures mostly easily imposed from above. In the area of cardiovascular diseases, cancers, and vehicular accidents, individual intervention is even more conclusive, because preventative techniques require the vigilance of the patient (e.g., prevention of breast cancer) and because successful prevention necessitates a change in behavior (e.g., food regimen, wearing a car seat belt).

The effects of resorting to medicine, however, are not always beneficial. Many types of harmful effects may injure health and cause death. Analysts must take account of the iatrogenic effects of care given, such as secondary effects of medication or treatment or a surgical or anesthetic accident. Some cases of deleterious effects, such as that of thalidomide, are well known (Lenz and Knapp, 1962), but others doubtlessly have had more discreet consequences (e.g., harmful effects of chemotherapy, unwise use of cortisone) (Meyler and Herxheimer, 1972). There is sometimes even a risk involved in crossing the threshold of a hospital, where it is difficult, especially in developing countries, to ensure perfect asepsis; some infectious diseases, such as certain forms of hepatitis, are rarely contracted other than in a hospital. The transmission of malaria and of acquired immunodeficiency syndrome (AIDS) through the transfusion of contaminated blood also occurs in such medical centers. Individual behavior clearly is at work in the abuse of drugs, including those sometimes designated as comfort drugs (Meyler and Herxheimer, 1972). The most flagrant case is that of "psychopharmacy."

b. Individual Hygiene

Situated on the frontier between infectious diseases and bodily comfort are all the practices of individual hygiene. Following the discoveries of Louis Pasteur, there is no need to stress the merits of soap and detergent in keeping the body and clothes protected from pathogenic agents. Progress in hygiene has contributed to the decline in infantile and maternal mortality and in diseases such as typhus and tuberculosis.

The same action that in most cases is favorable to health may be harmful in others. Certain types of soap may have been factors in propagating cholera (Jean-Noël Biraben, personal communication, 2001). More common, however, are the effects of excessive zeal in matters of hygiene, consisting of overuse of certain practices (especially cosmetics) or using without adequate protection certain chemical products that are too aggressive, such as the case of skin diseases caused by domestic detergents (Leung and Greaves, 2000; Little, 1977).

c. Food Habits

Although a person must eat to survive, eating is also a pleasure that can easily lead to excesses. Health depends on the quantity of food consumed, the quality of the food, and the balance of the diet.

Quantity

For thousands of years, humans have faced the threat of famine. Avoiding famine was little concerned with individual behavior but was much more affected by systems of agricultural production and storage, the distribution of food resources, and disturbances in obtaining food because of climatic or political events.[1] This problem remains to some extent that of certain disadvantaged populations because they inhabit regions or countries that are very poor and economically fragile or because they are at risk for famine because of political struggles or military aggression.

In more developed countries, quantity may be a problem at the margins of society, especially for those

[1] In the Ukraine, for example, life expectancy at birth fell to 7 years for men and 10 years for women during the great famine of 1933, provoked by Stalin's "deculakisation" campaign (Vallin *et al.*, 2002).

who have no access to adequate resources. This situation does not usually depend directly on individual behavior.

Two types of individual behavior may seriously damage health through the quantity of food consumed: anorexia and bulimia. Taken to extremes, these types of behavior are diseases in themselves. Without going as far as the extremes of pathologic cases, insufficiency (especially among certain old people) and increasingly excessive food consumption lead to consequences that are harmful to health. Obesity is recognized as a major risk factor for cardiovascular diseases, diabetes, and other diseases (Bender *et al.*, 1998; Solomon and Manson, 1997; Truswell, 1982), and it is a scourge of modern, developed nations.

Quality

Although gradual reduction in the risks of food shortage or famine has greatly contributed to the extension of life expectancy, going beyond a certain threshold of food sufficiency, without there necessarily being an excessive quantity, has sometimes led to the emergence of new health problems. A traditional diet consists of a small number of basic elements, but access to increasingly abundant supplies has been conducive in some cases to excessive consumption of certain ingredients that favor certain pathologies. In the 1950s, there was a rise in mortality from cerebrovascular diseases coincident with a rise in the living standard in countries such as Portugal, Scotland, and Japan, where salt plays an important part in traditional food. In Hungary, access to more abundant food supplies led rapidly to excessive consumption of fats and a consequent rise in cardiovascular mortality (Meslé and Vallin, 1992; Shigematsu and Yananawa, 1985). Another type of adverse effect arising from reduction in scarcity may perhaps be illustrated by the case of Northern Italy in the 19th century. The introduction of maize on a large scale enabled people to eat more abundantly by making polenta the national dish, but this was to the detriment of other elements in the traditional diet, and this excessively monotonous regimen gave rise to a veritable epidemic of pellagra (Livi-Bacci, 1986). Subsequently, knowledge about the connection between diet and health has greatly advanced food behavior and plays an increasing role in the level of life expectancy.

The part played by vitamins in a healthy diet was established from the late 19th century onward. Scurvy, a disease rife among seamen living exclusively on preserved foods, was remedied by the consumption of lemons rich in vitamin C (Davidson *et al.*, 1979; Lind, 1753). It was a lack of tryptophan or niacin (i.e., nicotinamide, vitamin B_5, or vitamin PP) that caused the outbreaks of pellagra in Northern Italy and in South Carolina (Goldberger *et al.*, 1920). In the 20th century, the part played by vitamins came to the forefront in the prevention of certain cancers and in protection from the effects of free radicals (Holmes *et al.*, 1992; Cutler, 1984). Equally positive is the case of foodstuffs containing vegetable fiber in the prevention of certain cancers, especially of the colon (Modan and Lubin, 1980). The public is increasingly attentive to the presences of vitamins, fiber, amino acids, and other components of food, and individual life expectancy may be influenced by such behavior.

The consumption of animal fats (i.e., saturated fatty acids) encourages the development of cardiovascular diseases (Stamler, 1973; Keys, 1970) and some cancers. This relationship is, with rare exceptions, apparent in almost all developed countries (Artaud-Wild *et al.*, 1993). In the United States and in central and northern Europe, where the basic diet is very rich in animal fats, cardiovascular mortality is traditionally higher than in the Mediterranean countries, where there is a greater focus on the consumption of vegetable oil and fish (Pica and Uemura, 1982). In France, the consumption of olive oil seems to have a protective effect against cancer of the colon (Meslé, 1983). Consumer habits concerning sugar also have a strong influence on health and mortality, especially through obesity (Truswell, 1982) and diabetes (Sokolov, 1997; Wunderlich, 1982; Power *et al.*, 1971).

Methods of preparation and eating are also important. Cooking over charcoal favors certain cancers (McBean and Speckmann, 1982); frying in oil causes digestive conditions, especially stomach cancers (Ji *et al.*, 1998); and the ingestion of maté (South America) or of boiling hot tea (China, Japan) cause cancers of the esophagus (Kinjo *et al.*, 1998; Day, 1982).

Balanced Diet

Beyond the harmful character of certain nutrients or the positive effects of others, the general balance of the diet has to be taken into account. One poison may neutralize another, and variety of culinary ingredients may introduce positive synergies. This explains the success of the Mediterranean diet (Kushi *et al.*, 1995; Keys *et al.*, 1986) and elucidates the French paradox (Criqui and Ringel, 1994; Renaud and de Lorgeril,1992; Hegsted and Ausman, 1988; Tunsdall-Pedoe, 1988; Richard, 1987; Saint-Leger *et al.*, 1979), even though certain investigators consider that this paradox results from a later increase than elsewhere in the consumption of saturated fatty acids (Law and Wald, 1999) or even believe that it does not exist (Ducimetière and Richard, 1992). How else can the fact be explained that cardiovascular mortality, which is already exceptionally low at a national level in France, is even lower in the southeast, the region known for cassoulet (i.e., traditional dish based on fatty pork and duck), conserve of duck, foie gras, and good wine?

Food Safety

In addition to quantity, quality, and general balance, healthy eating requires vigilance in matters of hygiene (i.e., food safety). Although food safety is of current interest, especially because of the occurrence of bovine spongiform encephalopathy (not to mention *Listeria* or the possible effects of Genetically Modified Organisms or GMOs), it is far from new. The fear of food poisoning (e.g., poisonous mushrooms, ergot, botulism, saturnism) has occupied an important place in the preparation of food. Although the invention of the feeding bottle enabled certain unweaned infants to be saved, its general use was at first the cause of much infant mortality. It was only with the practice of sterilization that these deaths were avoided. Some important progress is still needed in developing countries as breast-feeding declines.

d. Use of Alcohol, Tobacco, Stimulants, Narcotics, and Tranquilizers

Within the realm of food hygiene comes the consumption of alcohol and that of various substances having antidepressive, stimulant, or tranquilizing effects. Although these substances at first may satisfy physical or psychological needs, they quickly can become the object of excessive consumption and harmful to health.

Alcoholism

The consumption of alcohol, especially of wine, which forms part of the diet in many societies, is not *a priori* a danger to health. A number of studies have shown that regular but moderate consumption of wine may have a protective effect against certain cardiovascular conditions, particularly myocardial infarction (Renaud and de Lorgeril, 1992; Poikolainen, 1982; Saint-Leger *et al.*, 1979). Abuse of alcohol can cause severe harm (Sournia, 1986). Certain countries, such as France (Nizard and Munoz-Perez, 1993; Alderman, 1956, 1964) or Poland (Meslé, 1991; Okolski, 1985a, 1985b) are particularly affected; the most extreme case is that of Russia (Shkolnikov and Nemtsov, 1997; Meslé *et al.*, 1994).

The effects of alcohol vary according to the type of consumption. In a country such as France, there is the practice of regularly consuming excessive quantities of drinks with a low alcohol content, which progressively degrades certain organs, especially the liver, generating an excess mortality due to cirrhosis of the liver. In a country such as Poland or Russia, alcohol is mostly consumed in draughts of strong alcohol absorbed in high quantities and mostly causes death by acute alcoholism and alcoholic psychosis. In all cases, alcoholism has serious repercussions in the area of cardiovascular diseases (Koskenvuo *et al.*, 1986; Leclercq *et al.*, 1979) and certain cancers (e.g., esophagus, upper respiratory tract, digestive tract) (Tuyns, 1982).

Indirectly, alcohol kills through violent deaths. Vehicular accidents are frequently the result of loss of vigilance and diminished reflexes caused by the consumption of alcohol (Got *et al.*, 1984; Norman, 1962). Alcoholism equally encourages suicide and homicide (Ritson, 1977). Alcohol ingestion during pregnancy also compromises development of the fetus (Lee and Leichter, 1982).

Tabacism

Unlike alcohol, the consumption of tobacco is harmful to health from the very first cigarette (Peto, 1986). Tobacco may sometimes contribute to a sense of well-being, but it is always at the price of health risks (Guignon, 1994; Lopez, 1993; Peto *et al.*, 1992; Hill, 1988; Masironi and Rothwell, 1988; Benjamin, 1982). According to the U.S. Surgeon-General (1979), in the early 18th century, J. J. Holland and, then in 1795, S. T. Soemerset drew attention to the relationship between tobacco use and cancer of the lip. At the beginning of the 1950s, following the clinical studies of Frans Mueller (1939), Ernst Wynder Evarts Graham (1950), and Richard Doll and Bradford Hill (1950, 1952, 1954), the relationship between tabacism and lung cancer was firmly established. The effects of tobacco on cancer of the lungs, together with hypercholesterolemia and myocardial infarction, was an example chosen by Daniel Schwartz (1989) to illustrate the epidemiologic approach in causality research.

Although it is known that the consumption of tobacco affects life expectancy through many causes of death, bronchial and lung cancers are most commonly linked to tobacco use and are the dominant tobacco-related causes of death in many populations (Doll and Peto, 1981). In Europe and the United States, tobacco-related deaths became widespread during World War I, when tobacco was systematically distributed to the soldiers in trenches, until the period between 1960 and 1970, when anti-tobacco policies were at last developed (Vallin and Meslé, 2001; Caselli *et al.*, 1999). In addition to bronchial and lung cancer, the use of tobacco products greatly increases the risk of developing cancers of the upper respiratory and digestive tracts, bladder, prostate, and breast (Rosenberg, 1987; The Surgeon General, 1982); certain cardiovascular (especially ischemic heart diseases) or cerebrovascular diseases (Kaprio, 1984; The Surgeon General, 1983; Garfinkel, 1979); and chronic diseases of the respiratory tract (Wilhelmsson *et al*., 1981; Weill and Diem, 1978).

Tobacco is a drug in the strong sense of the term, in that it creates dependence (Ravenholt, 1984). To start smoking is to accept the risk of creating an irrepressible need, an addiction that leads to smoking more and more and prevents the consumer from ceasing to smoke through severance crises. Most frequently, the smoker wishing to abandon tabacism must resort to medical and psychological assistance.

Tabacism also harms nonsmokers forced to inhale the smoke from their neighbors in confined areas (Helsing and Comstock, 1987). Smoke from tobacco may be particularly dangerous for the young children of smoking parents (Poswillo and Alberman, 1992) and for the fetus within the womb of smoking mothers (Oakley, 1989; Sachs, 1987).

Alcohol-Tobacco Synergy

Already harmful individually, alcoholism and tabacism are even more harmful when combined. The synergy produced increases the risks of cancers of the upper respiratory and digestive tracts (Austin, 1982; Mahboubi and Sayed, 1982; Tuyns, 1982; Wynder and Bross, 1961). The synergistic effects of alcohol and tobacco explain the high death rate from carcinomas observed for French men (Nizard and Munoz-Perez, 1993).

Stimulants

To a lesser degree, the abuse of fortifying and stimulating drinks such as coffee may engender health problems (Debry, 1993, 1994; Garattini, 1993; Saint-Arroman, 1845, 1846). These substances are particularly inadvisable for persons suffering from cardiovascular and other illnesses.

Narcotics

Narcotics include heroin, cocaine, and synthetic drugs such as crack and ecstasy (Solanto *et al*., 2001; Harvey and Kosofsky, 1998; Inciardi and Harrison, 1998; Karch 1996; Malizia *et al*., 1993; Ellinwood and Kilbey, 1977). These so-called hard drugs are dangerous for physical and mental health; they can cause death, especially in the case of an overdose. Even more than tobacco, they create dependence on the part of the consumer that can be severed only by detoxification and rehabilitation (Carton *et al*., 1994; Cohen, 1990).

The so-called soft drugs (e.g., hashish, marijuana, quat) are more controversial. These drugs do not immediately appear to be dangerous to health, and their likelihood of encouraging a shift to harder drugs has been challenged (Nahas, 1976; Berke and Hernton, 1974). Even if they are not as dangerous as alcohol or tobacco, soft drugs have serious indirect effects, such as respiratory tract irritation and an increased risk of vehicular accidents (Roques, 1999).

Drug taking by intravenous injection is indirectly a cause of death because it is one of the major avenues for the introduction of human immunodeficiency virus (HIV), the AIDS virus (De Rossi *et al*., 1988), and hepatitis viruses (Bortolotti *et al*., 1986).

Tranquilizers

Tranquilizers are substances that may help in overcoming difficult stages in life and thereby favor survival. However, they still are drugs, and making use of them without strict medical control can cause serious health disorders (Bish *et al*., 1996; Hughes *et al*., 1994).

e. Leisure and Physical Activity

Rest for the body and mind is essential for the preservation of health, but leisure time can be misspent. Increasingly productive machines have freed people from the burden of work and have enabled long periods of rest and leisure. In relying too much on energy-saving devices, people can deprive their bodies of the exercise necessary for good functioning and create opportunities for new pathologies.

Has there ever been a finer discovery than that which enables the control of electricity? Did not Lenin define communism as "socialism plus electricity"? However, in almost eliminating the difference between day and night, this marvelous invention has opened the door wide to the disturbance of the activity-rest cycle imposed by the earth's rotation. Management of sleep has become the object of individual or collective living behavior, and the alterations can have consequences on health.

Another invention, an extension of the first, is the loudspeaker, which adolescents have adopted to enjoy the excitement arising from the excess of decibels in hard rock music, a practice associated with a high risk for deafness (Tubiana and Amadio, 2000).

Behavior concerning exposure to the sun is of considerable importance in preventing certain conditions. Solar radiation facilitates the fixation by the organism of indispensable substances such as iron and calcium. Exposure to sunlight promotes the synthesis of vitamin D, essential for calcium fixation. Lack of exposure to the sun is one of the well-known causes of rachitis (Paunier, 1984), and it may be encouraged by too much protection from solar radiation. However, too much exposure provokes skin cancers (Dubertret *et al.*, 1995; Blum, 1959; Dubreuilh, 1907). The incidence of all types of skin cancers has greatly increased among northern populations due to their infatuation with sun tanning (Scotto and Fraumeni, 1982), and the incidence varies with latitude (Lee, 1982).

Even though the Olympiads were a Greek invention many centuries before our time, sport can be considered as the modern antidote for the reduction of physical activity in work. In this sense, the practice of sport is largely beneficial to health (Surault, 1989, 1996; Paffenbarger *et al.*, 1978). It is an important factor in the prevention of cardiovascular diseases (Paffenbarger *et al.*, 1986; Kannel, 1967; Morris *et al.*, 1953a, 1953b) and osteoarticular diseases, especially osteoporosis (Daniels, 2000). However, sporting activities may have serious consequences, even leading to death. The risk is even greater when the sport is practiced intermittently and without adequate training; skiing accidents are typical. Professional athletes, with or without doping (Yesalis, 2000; Clark, 1990), incur accidents at work and sports-related diseases, to the extent of generating a new medical specialty: sports medicine (Magnin and Cornu, 1997).

2. Sexual Behavior

Sexual activity, primarily necessary for the reproduction of the species but also useful for individual development, encompasses a panoply of risks that largely depend on behavior. The most prominent risk is that of sexually transmitted diseases, such as syphilis, gonococcemia, blennorrhagia, yaws, and AIDS. In a strictly monogamous society, these diseases would not qualify for mention, at least those for which other ways of transmission are insignificant.

Diffusion of these diseases largely depends on sexual behavior. In the case of AIDS, the reason for the very rapid transmission of the virus among homosexual populations was the frequency of multiple partnerships and the high renewal rate of partners (Konings and Caraël, 1997; Caraël, 1995; Anderson *et al.*, 1990; Anderson, 1988). If in sub-Saharan Africa the epidemic quickly spread among the heterosexual populations, it was because they widely practiced multiple partnerships and frequently changed partners (Brouard, 1987, 1994). Behavior regarding the choice of partners also affects the spread of disease. Nicolas Brouard (1994) has shown that the dynamism of the African epidemic is largely a result of the diversity of age differences between partners; a strictly constant difference would in the end entail the disappearance of the disease.

As with the spread of disease, prevention depends greatly on sexual behavior, whether of contaminated persons avoiding transmission of the disease or of healthy persons avoiding contraction of disease. In both cases, two types of elementary precautions may be very effective: abstinence (or at least observation of strictly reciprocal monogamy) and systematic protection of the relationship (i.e., condom or pessary). Both cases entail a general change in behavior, which is often difficult to attain.

Sexually transmissible diseases are not the only area of sexual life for which behavior may have an effect on health and mortality. Certain practices in traditional societies, allied or not to initiation rites, may be disastrous for health. These extend from more or less serious sexual mutilation imposed on women, ranging from the excision of the clitoris to the ablation of the major and minor labia, and to the even more barbarous practice of infibulation, which is extensively practiced in the countries within the Horn of Africa. Besides the suffering and deprivation of pleasure that they cause, these practices increase women's risks for infection, gynecologic diseases, and obstetric difficulties (Locoh, 1998; WHO, 1997, 1998).

Modern contraception under medical supervision has a positive effect on health (Rosenberg, 1991). Consultations concerning adoption or the follow-up of contraceptive methods have enabled progress to be made in many countries in the prevention of uterine and breast cancer, for which early detection is decisive (Wingo, 1993; La Vecchia, 1990; Hatton *et al.*, 1985a, 1985b). Abortion, depending on whether it is practiced officially in a hospital environment or clandestinely in more or less questionable venues, involves very different risks for the health and survival of the mother (Abou-Zhar and Royston, 1991; Measham *et al.*, 1981). In the words of Axel Mundigo (1996): "The legal status of the abortion determines to a large extent whether it takes place under safe or unsafe conditions."

3. Life Setting and Professional Activity

Other areas in which lifestyles may influence health include habitat, transport, work, and migration.

a. Habitat

It is unnecessary to dwell at length on the importance of housing conditions. From the prehistoric cave to the apartment block of modern times, the average conditions of comfort and quality of life settings have greatly evolved, but there remain an immense variety of situations. Access to a certain type of accommodation is not solely a matter of individual behavior (we return to this topic later), but it may have a pronounced effect on health.

Certain elements of comfort are of great importance. In urban housing in northern countries, the lack of ventilation, insufficient exposure to sunlight, and overcrowding formerly played major roles in the development of tuberculosis (McDougall, 1949; Greenwood, 1926), and improved standards have considerably contributed to a decline in unhealthy living conditions. In Sweden, the introduction of double-pane windows, leading to air-tight enclosure, probably played a part in propagating tuberculosis (Greenwood, 1924). The widespread adoption of central heating systems and the use of polyvalent vaccines have probably contributed to the decrease in great influenza epidemics. Nevertheless, the precariousness and unhealthiness of some housing remains a major factor in public health (Burridge and Ormandy, 1993), especially in developing countries. On the margins of society, the extreme situation of those with no fixed abode involves serious health problems (Barow *et al*., 1999).

b. Transport

Whatever means of transport is employed, traveling involves risk, but it varies from one form to another and depends how the chosen means is used. Generally, travel by rail is less dangerous than by air or sea, which are themselves less dangerous than traveling on roads (Vallin and Chesnais, 1975). On the road, the pedestrian, cyclist, car driver, motorcyclist, and public transport user have different risks. All of them, especially those holding handlebars or a steering wheel, run risks more or less consistent with their behavior. It is in the attempt to minimize these risks that highway rules and regulations have been developed and safety measures increased. The most marked differences in behavior essentially concern respect for these rules. Obeying speed limits (Vallin and Chesnais, 1975) and wearing a seat belt appear to be most important (Chesnais and Vallin, 1977; Nelson, 1974). It is quite significant that in all the European countries, in a surprisingly simultaneous way, the ascending curve of road deaths reversed around 1974, the year of the first oil crisis (Vallin and Meslé, 2001). The sudden rise in fuel prices aroused awareness in most people of the value of speed limits that could spare human lives and their pockets. Moreover, alcohol use by drivers considerably increases the risk of vehicular accidents (Got *et al*., 1984; Norman, 1962).

c. Work

Working conditions are an important factor in public health (Costa and Segnan, 1988; Volkoff, 1987; Cassou *et al*., 1985; Chesnais, 1985a, 1985b; Duclos, 1984; Dejours, 1980; Vallin, 1979a). This situation became a public health issue with the advent of industrialization (Haines, 1991; Dublin, 1917), and in this area, where industry (Goldsmith, 1982) or agriculture (Laurell, 1982) are concerned, there is an immense diversity of situations. Occupations that correlate with serious risks include building, chemical manufacturing, and mining, not to mention the police or the army in time of war. For the same type of employment, there is an immense variety of situations because of diversity in the state of economic development, the social surroundings, and respect for the standards in force (by the employer and by the employee himself). Industrial injuries (Héran-Le Roy, 1999; Davis and Friedman, 1989; Molinié and Volkoff, 1984; Leplat and Cuny, 1974) and officially recognized professional diseases (Couturier, 2000; Martin, 1975) are often only the visible part of the iceberg. Apart from the appearance of specific diseases, working conditions contribute in various ways to the progressive deterioration in the state of health. The rhythm of work, cleanliness of the working area, difficulty of the tasks, and stress may cause premature weakening of the body (Surault, 1995a; Vachon, 1987; Wolf and Finestone, 1986). However, safety at work and appropriate sanitary provisions are factors in conserving health, and part of a balanced life is achieved by good social integration through work (Baldge and Krieger, 2000). Unemployment has a negative effect on health (Valkonen and Martikainen, 1995; Gélot, 1992; Smith, 1987; Platt, 1984; Bungener *et al*., 1982).

d. Migration

Migration has an effect on health and survival. It is quite often motivated by the desire to improve living conditions and, in the case of refugees and asylum seekers, even to escape from life-threatening situations. The act of migrating itself often involves an important part of the risk, especially in the case of forced (refugees) or clandestine migration. The risks undertaken are sometimes enormous, whether they concern long journeys plagued with difficulties (e.g., drama of *boat people*), the horrible destiny of the 58 Chinese found dead in a container in Dover in June 2000 (e.g., see *Le Monde*, 23 June), or the amazing adventure of the young Senegalese who traveled for 5 hours in the undercarriage compartment of an Airbus[2] between Dakar and Paris in January 1999, in a temperature of –50° C.

[2] Unfortunately, he did not profit from his incredible exploit and was expelled without further consideration (*Le Monde*, March 16, 1999).

At the place of arrival, migrants usually encounter health conditions that are better than those from which they came. Admittedly, the extent of this phenomenon is difficult to measure, because although the death rate of migrants is lower than at the place of departure, it partly results from the fact that migration attracts individuals in good health and capable of "making the journey" (Trovato, 1998; Courbage, 1996). In the case of South-to-North migration, health conditions are better in the country of arrival than that of departure. This does not necessarily mean that they are the same for the migrant as for the native of the country of refuge (Rice, 1999; Trovato, 1991). Most frequently, the migrant accepts less favorable living conditions and accepts work that is rejected by the native inhabitants (Piore, 1979) and that is riskier (Travato, 1991).

South-to-North migration is not the only model. Internal migrations have sometimes produced (in northern countries) or still produce (in southern countries) various effects on health. At a certain stage of economic and social development, urbanization attracted people in search of employment to cities, where they were crowded in unhealthy conditions worse than they had known in their country districts. In 19th century Europe, this resulted in marked urban excess mortality (Williams, 1989; Rödel, 1988; Robert, 1988; Davis, 1973). Today, this situation is partly compensated in southern countries by the existence within cities of minimum health provisions, which are not found in outlying country districts (Vallin, 1989, 1992), and mortality is often much higher in the rural environment (Mozumder *et al.*, 1997; Gichuhi, 1993).

Migration is sometimes a decisive factor in transmitting diseases (McNeil, 1980). It has played a big part in the spread of AIDS in Africa (Lalou and Piché, 1994).

4. Relationships

Personal relationships influence health and survival. We provide three examples in the following sections.

a. Raising Children

It is well known that the behavior of mothers and more generally of parents toward children from birth to the beginning of adult life is decisive for the physical and mental health of their offspring. From the stage of pregnancy onward, the maternal and family environment may be favorable or otherwise for the unborn child (e.g., medical follow-up of the pregnancy, type of activity of the mother, maternity leave, consumption of alcohol, tobacco, or drugs) (Inciardi *et al.*, 1997; Klerman and Johnson, 1991). The type of feeding (i.e., breast-feeding or other forms) (Palloni and Tienda, 1986), weaning conditions (Beverly, 1982; Cantrelle and Leridon, 1980), quality and quantity of nourishment, resort to medical care, hygiene, and accident prevention depend very much on the family environment and especially on the mother. Some studies show, for example, that within the same family, different treatment may be given to children according to their sex, especially in societies in which the preference for boys is very strong, resulting in excess mortality for girls. This has been especially demonstrated in Bangladesh (Chen *et al.*, 1981), in Algeria (Vallin, 1979b), and in China (Calot and Caselli, 1988, 1989). This phenomenon was formerly evident in Europe (Pinnelli and Mancini, 1992, 1999; Tabutin, 1978).

Children also may be treated differently according to other characteristics. In sub-Saharan Africa, twins are often treated differently from single children, whether for worse or better, according to whether they are culturally venerated or cursed (Pison, 1989, 1992).

It was recently discovered that the sudden death of infants, for a long time unexplained, depended to a large extent on how the babies were put to sleep. It sufficed to lay them on their back or side instead of on their stomachs for this phenomenon to decline decisively (Becroft *et al.*, 2001; Flick *et al.*, 2001; Gessner *et al.*, 2001; Sullivan and Barlow, 2001). It is also known that exposure to nicotine, another factor depending on the attention of the parents, favors the sudden death of the infant (Milerad *et al.*, 1998).

The failure of families to provide for the rearing of children obviously endangers the life of the newborn. In the extreme case, abandonment (*exposure* as they formerly called it) is a flagrant cause of excess infant mortality. This occurrence was formerly well known in Europe (Rollet, 1997; Buccianti, 1993; Corsini, 1991) and still is today in certain developing countries (Seboui, 1990; Mehta, 1982). It has recently been dramatically aggravated by the spread of AIDS, which has increased the cases of abandonment and made the lives of abandoned children even more precarious (Anonymous, 1999). Even when the collective responsibility for abandoned children is suitably assumed, the children continue to have higher than average risks for disease and death. In certain developing countries, the solution has been adopted of entrusting the children to another family for a longer or shorter period. This system may, according to the context, give the child better or worse chances of survival (Bledsoe and Brandon, 1989). The practice of putting an infant out to be nursed may also have positive and negative effects. In 19th century Europe during the course of industrialization, families of workers were frequently led to do this under terrible conditions, which in France were the main cause of the upsurge in infant mortality between 1850 and 1880 (Rollet, 1990).

Beyond infant health and mortality, maternal and family behaviors also have an influence on survival to adulthood, especially through hygiene and by means of health education. All sorts of events experienced in childhood may have repercussions in terms of survival into adulthood (Marmot, 1995; Caselli, 1995; Menahem, 1994; Wilmoth *et al*., 1989, 1990; Horiuchi, 1983).

b. Violence

Violent behavior has an influence on health and mortality. Domestic violence is often little publicized, but it is present everywhere, in all societies and social groups: ill-treated children (Kashani and Allan, 1998; Ariffin *et al*., 1997; Burgess, 1978) and violence toward women (Taylor, 1997; Nowrojee and Manby, 1995), including sexual violence (which is not limited to the mutilation rites described earlier) and physical violence.

Even in the absence of war or major political unrest, homicide is a cause of death that occupies a highly variable place from one country to another and from one epoch to another (Chesnais, 1976). In certain countries, death rates from homicide are very high. This is especially the case in the United States (Lester, 1993; Iskrant and Joliet, 1968) and even more so in Russia (Meslé *et al*., 1994).

Collective violence is also a factor. Victims sometimes number in the millions or tens of millions (Lancaster, 1990; Chesnais, 1976; chap. 33, p.314–340). Evaluation of the excess mortality of war in the Ukraine between 1941 and 1945 produced an estimate that life expectancy fell to 14 years for men and 21 years for women (Vallin *et al*., 2002)!

c. Importance of Relational Networks

Although the family circle is of prime importance for the health and survival of children, the family and the operation of all kinds of relational networks have parts to play at all ages and especially for older people. Loneliness and abandonment are well-known factors in the decline of health and hastening of death (Sabin, 1993), whereas the quality of intergenerational cooperation helps to maintain good health and prolongs life (Avlund *et al*., 1998; Steinbach, 1992; Rogers, 1996; House *et al*., 1988; Pous *et al*., 1988).

In the extreme case, the resort to suicide, an eminently individual act, is rarely unrelated to the family circle. Integration within a sound network of family and social relationships is a determining factor in the prevention of suicide (Besnard, 1997; Surault, 1995b; Lester, 1994; Baudelot and Establet, 1984; Durkheim, 1897).

5. Synergies

This long list of behavioral factors affecting health and mortality is inadequate for summarizing the situational diversity. Although, in theory, each of these factors can act negatively or positively in isolation while all the others remain neutral, most frequently, many factors combine in the same or in opposite directions. When several factors operate together in the same direction, a synergy may develop in which the result exceeds the simple addition of the expected results of each factor acting in isolation. Mention has been made of alcohol-tobacco synergy responsible for the tumors of the upper respiratory and digestive tracts. The numerous examples of this type include speed and alcohol while driving and tobacco use and silicosis among miners. The accumulation of risk behavior is often the cause of great differences in mortality observed between social or family groups (Das Gupta, 1990).

II. SOCIOCULTURAL FACTORS AND ATTITUDES REGARDING THE BODY AND HEALTH

Discussion of behavioral factors in the preceding sections must not allow the fact to be overlooked that health and survival are determined by more than these behaviors. Health and survival depend on processes that are largely determined by the context. Individual behavior is derived from general attitudes regarding the body and health, which are themselves allied to culture. These attitudes are expressed according to the resources available to the individuals, and they are largely conditioned by the place people occupy in society. Sanitary and social policies affect behavior, whether directly through awareness campaigns or indirectly through improvements in the services and their accessibility.

1. Attitudes Regarding the Body: A Question of Culture

Attitudes regarding the body, health, disease, death, and medicine influence lifestyles and behavior in very diverse areas, particularly that of prevention and resort to the health care system. These attitudes are allied to representations that are primarily social.

Although the body has an anatomic and physiologic reality, it is also, as David Le Breton wrote in 1985, a social construction "both in its involvement in the collective scene as in the theories that explain its functioning or the relations it maintains with the person that it embodies. Biomedical knowledge, and official knowledge of the body in our Western societies, is one representation of the body among others, and effective in the practices that it supports" (Le Breton, 1992).[3] There exist as many representations as there are societies and cultures, with as many different actions based on these different representations (Loux, 1979).

The functions of the body, its uses, its image, and the attention paid to it vary according to societies (Bouchard, 1982) and according to regional and ethnic cultures or social class within the larger societies (Surault, 1983). Values and standards lead to the development of "a sort of code of correct behavior toward one's body" (Boltanski, 1971)[4] and "the bodily experience of every person is penetrated through and through by other people and by society, as the source, organ, and support of all culture" (Bernard, 1973).[5] Ethnologists have frequently stressed the extreme variety in the conception of the body from one society to another.

Lucien Sfez (1995) compared conceptions of the body in the United States, Japan, and France, showing how the differences explained the diversity of behavior and attitudes with regard to health. In the United States, for example, the search for "perfect health" justifies development of a new attitude concerning, among other things, food (without cholesterol), sexual practices with a single partner (danger of AIDS), and struggle against tabacism (safety for oneself and for others), as well a priority given to biotechnologies and extensive programs such as the worldwide Genome project for mapping and sequencing human genes (in favor especially of predictive medicine) and the Biosphere II project, a reduced model of the terrestrial biosphere, in which four men and four women sequester themselves for 2 years (1991–1993).[6]

Representations and uses of the body determine the representations of disease and health, as well as the attitudes concerning them. Disease and health, beyond their biologic aspects, are also social facts: their recognition is allied to the cultural values and standards of a given society or social group; depending on the case, a biologic state is perhaps determined but not regarded as a disease (Foucault, 1972).

In industrialized countries, the increasing attention paid to the body explains the demand for perfect health and even for immortality, and it justifies the means of achieving these goals, such as increased health expenditures and public health policies. The more health improves in terms of longevity, disability, incapacity, or handicap, the greater is the extension of the field of disease and the power of the medical disciplines, such that organic or psychological manifestations are increasingly being classified as morbid symptoms (Lachaud, 1975).[7] In France, for example, the average number of diseases declared per person (i.e., prevalent morbidity) doubled in 20 years from 1.6 in 1970 to 3.3 in 1991 (Sermet, 1994), whereas the rate of persons declaring themselves to be in perfect health (i.e., feeling no discomfort in their daily life) is decreasing (19% in 1980 to 15.8% in 1993) (Bocognano *et al.*, 1994).

Health and longevity are increasingly becoming objectives in themselves and no longer just the means for a better quality of life. The more uncommon disease becomes, the more distant the foreseeable horizon of death, the greater the fear of disease and death,[8] and the greater the requirements for medicine and medical technology. This accounts for the growing medicalization of social, family, and psychological problems and of all that arises from discomfort or merely fatigue, increasing the dependency on medications (Reynaud, 1984) and explaining the success of "happiness pills."

This information points to an astonishing paradox. Although the effectiveness of medical interventions is undeniable, it is also possible to imagine that medicalization and the development of preventive practices pushed to extremes can become a constraint, having negative effects on health through an increase in stress and anxiety, which can help to generate serious conditions, including cancers (Amiel-Lebigre

[3] "Tant dans ses mises en jeu sur la scène collective que dans les théories qui en expliquent le fonctionnement ou les relations qu'il entretient avec l'homme qu'il incarne. Le savoir bio-médical, savoir officiel du corps dans nos sociétés occidentales, est une représentation du corps parmi d'autres, efficace dans les pratiques qu'il soutient."

[4] "Une sorte de code des bonnes manières d'être avec son corps."

[5] "L'expérience corporelle de chacun est pénétrée de part en part par autrui et la société, comme source, organe et support de toute culture."

[6] Lucien Sfez defines *perfect health* or *full health* as an already unified bio-eco-religion, a 21st century utopia, armed with all its symbolic power. In France, *prevention biology* encounters active resistance (Agora and CREMMS, 1994; Malet, 1993).

[7] A quarter of a century ago, Ivan Illich (1975) was speaking of "the elimination of the status of health by unlimited multiplication of the roles of sickness" ("l'élimination du statut de santé par la multiplication illimitée des rôles de malade").

[8] In France, according to the annual CREDOC investigations, the fear of serious illness is constantly increasing. It has become the primary worry (before drugs, insecurity, and unemployment), representing the nonacceptance of what it might bring: death.

and Gognalons-Nicolet, 1993; Dutot and Lambrichs, 1988).

A number of studies in industrialized countries have revealed significant differences according to social environment and education level in the representations of and attitudes toward the body, pain, disease, health, and medicine (Adam and Herzlich, 1994; Aiach *et al*., 1992; d'Houtaud and Field, 1989; Surault, 1984; Aiach and Cebe, 1983; Loux, 1983; Aballea, 1982; Letourmy ad Pierret, 1982; Aiach *et al*., 1980; Zborowski, 1972; Herzlich, 1970; Zola, 1966). In less favored circles and for a given pathology, there is a reduced capacity for identifying with the morbid condition, a less intense reflexive relationship with the body, a greater resistance to pain, and a reduced degree of medicalization, leading to a reduced perception and identification of the disease than among better-educated groups and, consequently, a lower rate of declared morbidity. Similarly, a reduced level of resort to care correlates with an equally declared morbidity, less confidence in medical techniques, a broader definition of health,[9] and fear of incapacity (allied to a real or imaginary experience of the disease and to the level of social protection and resources). The same social differences may be observed in preventive practices (Aiach *et al*., 1992).

In the Western world, since the 18th century, the improvement in health and decline in mortality have changed attitudes toward disease, health, and death and reciprocally, according to a circle that remains up to the present "virtuous," without our knowing what development preceded the other. Previously, disease and death, including high mortality among young children, were accepted with resignation. Analysis of death and disease remained almost absent from the literature until the 20th century. According to Philippe Ariès (1971), death appeared "neither as an accident that a procedure of attention and technique might avoid or postpone[10] nor as a subject of individual affliction. It was a matter of destiny that had to be accepted, even assisted, and also appropriately surrounded by ritual ceremony."[11] The preoccupation was not to avoid the end, but to be aware of its coming. The mere idea of a struggle against death was considered to be sacrilegious, as if to oppose divine will.

It was more or less at the time when deaths began to decrease essentially as a consequence of economic development and its effects that attitudes changed. The child was increasingly seen as a completely separate being (an idea almost absent from earlier literature), and the possibility and desire to act on its destiny emerged. In France, with the dissemination of the ideas of 18th century philosophers and the loss of influence of the Catholic Church (recorded especially by Alfred Sauvy [1960]), attitudes changed more rapidly, as evidenced by an early decline in fertility—because happiness, according to Jean-Jacques Rousseau (1782), was no longer to be sought exclusively in the hereafter, but also on Earth.

This process cannot be applied today to countries with a high death rate, especially because they constitute a cultural ensemble that is much more heterogeneous than in the former European countries,[12] even though the spread of Western culture and ideas occurred there long ago, at least among the elite. Nevertheless, the decline in mortality, especially among very young children, has increased the desire to have control over one's own life and that of others, as can be seen by the general tendency to control fertility.

Attitudes toward medicine are also conditioned by the sociocultural context, which explains attitudes about the body, disease, and death (Adam and Herzlich, 1994; Augé and Herzlich, 1983). For most of the population, the body is an instrument for work, and as long as it is as able to function as such, the person is not considered to be ill. Consequently, as Henry Mosley (1985a) points out, more attention is paid to prevention than to therapeutic measures: "Every stage of life and frequently almost every daily activity is accompanied by rituals and actions designed to ensure health and welfare. Furthermore, life may be filled with all sorts of taboos, many of them related to diet, to avoid sickness" (p. 130).

Mosley, in attempting to analyze the effectiveness of programs for primary health care, stressed the influence of attitudes toward disease and traditional systems of belief; taking them into account or ignoring them may influence the programs' effectiveness. On the contrary, problems sometimes encountered in the

[9] As long as somatic symptoms, diagnosed or not, did not prevent work, a person did not consider herself or himself to be ill. Essentially, health had a market value; it enabled work and the income arising from it to be realized. To this can also be added a nonmarket value, because it enabled optimization of nonworking time, particularly that devoted to leisure pursuits (Letourmy and Pierret, 1982).

[10] For centuries, the practice of medicine remained restricted to a very limited circle, that of the Court, nobility, Princes of the Church, and the prosperous middle class.

[11] "Ni comme un accident qu'un effort d'attention et de technique peut éviter ou reculer, ni comme un sujet d'affliction individuelle. C'est un arrêt du destin, qu'il faut admettre et même aider, qu'il convient aussi d'entourer d'une pompe rituelle."

[12] François Laplantine (1986) speaks of "the infinite variety of reactions toward disease according the societies and epochs" ("la variation infinie des réactions à la maladie selon les sociétés et les époques"), even though the etiologic and therapeutic models are those, very limited in number, that were not exclusive from one another in the same society or even with the same individual.

application of medical techniques that have proved their worth in Europe or North America may result from the fact that modern medicine "also incorporates many popular beliefs and folk practices of Western culture" that are often very far removed from those of developing countries (Mosley, 1985a).

Dominique Tabutin and Eliwo Akoto (1989, 1992) have shown that ethnic membership has a great influence on the mortality of children in sub-Saharan Africa, which confirms the importance of cultural variables that affect the care given to children. "The ethnic group, in their estimation, may influence the mortality of children through a whole series of variables, such as the attitude toward disease, death and care services, beliefs relative to the etiology and therapeutic art, practices in the feeding of children, the care given them (Hill and Randall, 1984), family structures, age at delivery . . ."[13] (p. 61). A number of studies provide similar results (Fassin, 1995; Gbenyon and Locoh, 1989, 1992; Pison, 1989, 1992; Raynaut, 1992; Soumoy and Thiltges, 1992; Vallin, 1989).

Despite the progress made in the epidemiologic transition (see Chapter 57), attitudes concerning the body, disease, death, health, and medicine remain extraordinarily varied, just as varied as the cultures are that underlie them. From the denial of death, symbolized by the American practice of presenting the deceased sitting in an armchair with every appearance of life, to the almost impatient desire for it (i.e., the *tamed death* of Philippe Aries [1977]), as evidenced by the lack of concern of certain populations regarding AIDS; from *perfect health* as the guide to life and subject of all conversations to survival-motivated health practices; from disease that is destructive to that which is liberating (Herzlich, 1992), there are an infinite number of representations and intermediate attitudes, all of which influence preventive behavior,[14] resort to treatment, and death.

In a country such as France, the frequency and importance of alcohol consumption is explicable by a culture rooted in history from the Gallo-Roman epoch, when wine production was introduced. Made sacred by religion, wine has also become a socializing agent, a means of social relationships, which furthers a status-enhancing image of the "social utility, relaxation, and ritual conviviality"[15] factor (Chapuis, 1989), handed down from generation to generation.

Death from a vehicular accident provides a good example of the influence of behavioral differences allied to specific cultural characteristics. Whichever indicator is used, mortality in Europe is lower in the countries of the North. Jean-Claude Chesnais (1985a, 1985b) considers that "the high degree of safety there corresponds to a cultural trait shared by the people of the North—supportive societies where tolerance is higher, collective discipline stronger, and prevention consequently easier."[16] The most stringent policies in Europe for the repression of alcoholism at the wheel were developed in Norway and Sweden. In most Latin countries (including France), this mortality, although declining, remains higher; their inhabitants are more individualistic, tend to favor their own interests rather than that of the majority, and therefore adapt themselves less easily to preventive measures. Especially among men, the automobile is not used solely as a means of transport; it is also a symbol of power, virility, and social prestige (Baudrillart, 1976).

Many examples from traditional societies can be cited, such as in the Sahel environment, where red urine (one of the symptoms of bilharziasis) is associated with virility (i.e., small boys playing in the backwaters are more exposed to it than girls), or the theory of the evil eye in certain Mediterranean populations, leading to the confinement of babies to the interior of the poorly lit and badly ventilated dwellings to avoid exposing them to another person's view.

Measles merits particular mention. For a long time, the synergy between malnutrition and infection was conceded to be the sole factor explaining the highly lethal effect of measles in southern countries and especially Africa, whereas it remains a benign disease in northern countries. The undernourished child is less resistant to the virus, and the sick child in losing its appetite creates a situation that transforms measles into a mortal disease (Solimano and Vine, 1992; Mosley, 1985a, 1985b). The contention was that children did not die directly from the measles but from its serious complications when children were undernourished. In 1980, Peter Aaby demonstrated that such was not the case. The lethal effect of measles in Africa results from lifestyle. Children who live in the overcrowded dwellings, where all or most of the family members sleep confined to a single room, are exposed

[13] "L'ethnie, estiment-ils, peut agir sur la mortalité des enfants à travers toute une série de variables telles que l'attitude face à la maladie, à la mort et aux services de soins, les croyances relatives à l'étiologie et à l'art thérapeutique, les pratiques d'alimentation des enfants, les soins qui leur sont accordés (Hill et Randall, 1984), les structures familiales, l'âge à l'accouchement...."

[14] During a recent conference, professor M. Tubiana cited the results of an American investigation, according to which the Seventh Day Adventists, whose religion forbids them to smoke and drink alcohol, benefit from a cancer morbidity rate that is less than 50% of that of the other inhabitants in the same districts.

[15] "D'utilité sociale, de détente, de rituel de convivialité."

[16] "La grande sécurité y correspond à un trait culturel des peuples du Nord: sociétés solidaires où la tolérance est plus grande, la discipline collective plus forte et, par conséquent, la prévention plus aisée."

to and die of measles. A child contaminated under these conditions effectively receives a strong viral dose that increases the risk of having a fatal disease, whereas the same child catching measles when playing outside with his or her friends develops a benign form of measles (Aaby, 1989, 1992). Measles is more often fatal in West Africa, where polygamy is more widespread and the co-spouses and their children sometimes sleep in the same room, than in East Africa, where there is less polygamy and cohabitation of the co-spouses is rare. Culture and living conditions can strongly influence lifestyle, which may directly affect mortality (Wunsch, 1981).

2. To Know and To Act: A Question of Means

Although attitudes regarding the body and health vary according to the cultural context, involving different ways of representing and perceiving disease, and consequently a greater or lesser disposition to prevent or treat health problems within the same country or culturally homogeneous ethnic group or region, the behavior that arises from these attitudes can also greatly vary according to the means at the disposal of the individuals or families. Mortality can be differentiated by three types of means: education and access to information media, material wealth (income or fortune), and existing health services and their availability.

a. Education

Knowledge is one of the primary resources for encouraging the adoption of behavior conducive to health. There is a close link between mortality and the level of education (Kunst and Mackenbach, 1994). All the investigations carried out on social mortality, especially in industrial countries, fully demonstrate this principle[17] (see Chapter 54). It may partly depend on selection by education of the healthiest individuals (i.e., mentally deficient or sick children are less able to undertake studies) or on the indirect relationship between education and health through contextual variables (i.e., persons belonging to disadvantaged social categories are subject to unfavorable health conditions and have difficultly accessing higher levels of education). Increasing levels of education have increasingly positive effects on health. Education provides knowledge about what is logically beneficial for health, and it is in many ways a means of accessing the power and resources necessary for carrying out preservative or recuperative health activities.

Although all people can, because of their education, act directly on their own health, the education of a family member or household may also influence the health and survival of other members. This is particularly true for the mother in relation to her children. In France, for example, infant mortality entered a very rapid and enduring downward phase in the late 19th century. It was largely a result of the new approach to infectious diseases (especially those of infants) after the discoveries of Louis Pasteur, but the decline in infant mortality also reflected the spread knowledge through general public education after the laws of Jules Ferry on compulsory schooling were enacted.

In developing countries, the education of mothers has been recognized by demographers as one of the prime factors in lowering infant mortality (Caldwell and McDonald, 1981; Behm, 1979; Caldwell, 1979; Behm and Primate 1978). Similar to a number of investigators, Henry Mosley (1985a, 1985b) stressed the importance of the educational level of women in generating a social synergy that enabled a change in attitudes toward disease, its prevention, and treatment and, more generally, toward the child and its survival. In particular, observations in Kenya and other African countries showed that maternal education and income level (or poverty) are related to infant survival.

Dominique Tabutin and Eliwo Akoto (1989, 1992) observed that in sub-Saharan Africa, there is a positive relationship between the educational level of the mother and the survival of the children. The intensity of the relationship varies considerably among countries, and it is more apparent for mortality between 1 and 5 years than before 1 year. The effect of the father's educational level is less clear, but it complements that of the mother.

b. Wealth and Economic Affluence

Economic affluence is an obvious factor in the access to health resources. With incomes that are just enough to satisfy the most elementary daily needs, the treatment of a disease may appear all the more superfluous in that it is not always assured of success. The expense entailed in prevention constitutes a gamble that may not seem urgent to undertake.

The effect of income in terms of health behavior is often less than that of education. At an individual level, the priority for health expenditures does not change much according to income. The higher the income, the greater the increase and diversification of needs, and this is not always to the advantage of health expenditures, even though these increase with income.

[17] The recent synthesis study carried out by Kunst and colleagues (2000) for the European Union confirms this fact.

At an equal collective level of income, resort to medical care depends greatly on the accessibility of heath resources. According to the health policies applied and the system of assuming responsibility (e.g., social security) in force, revenue differences will have a greater or lesser influence on the resort to preventive care (Bell, 1985a, 1985b).

c. Accessibility of Health Services

It does not suffice to pay attention to one's health, to be informed about the means of proceeding, or even to have sufficient resources to pay for care. Effective care must exist (e.g., for infectious diseases), and the services must be available. However, we have seen the time required by medical research to arrive at a treatment, largely insufficient, for AIDS. The example of AIDS is symbolic of the difficulty of making an existing treatment accessible in poor countries (Mann *et al*., 1992). As the French Minister of Health Bernard Kouchner declared in 2001, "90% of the medicaments are in the north, whereas 90% of the sick are in the south."[18] Even though the conflict between the big pharmaceutical companies and the governments in southern regions, such as India, Brazil, or South Africa (who wish to produce cheaper medications by freeing themselves from the licenses) is being resolved, treatments for diseases such as AIDS remain beyond the economic reach of most sick persons.

The distribution of the health services and the price of the medication or treatment are not the only issues. Concerns exist for the whole chain of prevention and assumption of responsibility, including the identification of risks, detection and diagnosis of cases, treatment, follow-up, and responsibility for the sick person at health, social, psychological, and even economic levels. Although AIDS is one of the most striking examples of the important part played by the availability of services, the same applies for many of infectious endemics in southern countries, especially Africa, whether it concerns tuberculosis, measles, malaria, or other tropical diseases.

What remains true for infectious diseases in a number of developing countries is everywhere evident for diseases against which the struggle has only more recently been effectively engaged: cardiovascular diseases and cancers. One of the most striking illustrations is the introduction of emergency intervention services (SAMU in France), which are particularly decisive in the treatment of myocardial infarct. With equal attitude and behavior, the chances of a sick person being treated in time and of being able to recover depend on the presence and effectiveness of such services. Similarly, the arrival of scanners (e.g., computed tomography, magnetic resonance imaging) created a fairly marked disparity in the quality of diagnoses and therefore in the adoption of appropriate treatments according to the ease or difficulty (geographic or other) of access to this type of apparatus.

[18] The declaration of "90% des médicaments sont au nord alors que 90% des malades sont au sud" was made for the first time in the *Journée Mondiale du Sida* on December 1, 2000 and repeated many times since (e.g., see *Le Figaro* of January 30, 2001 or *Le Monde* of July 7, 2001).

3. Social Conditioning

a. Social Categories

Attitudes toward the body and behavior in health matters are largely conditioned by the social surroundings (Valkonen, 1987). This issue is addressed in detail in Chapter 54. It suffices here to stress that social adherence influences almost all of the aspects of health previously described. Each social group has its own culture that affects the attitudes and behavior of its members, and adherence to a social group affects access to the means of action, like education and economic resources. However, the relationship between social class and mortality considerably exceeds the limits of the behavioral mortality factors alone. Some of the differences in mortality observed between social categories arise from selection according to health, which influences access to other social categories. For example, health problems may compromise access to good training, which compromises access to good professional qualifications and therefore to interesting and well-paid employment. Deficient health makes upward social mobility more difficult, and in this way, membership in the higher social categories itself depends on the state of health. However, social categories are largely founded on professional activity, which itself greatly affects mortality through the conditions of work and other profession-related risk factors. This complexity of the relationship between social membership and mortality is addressed in Chapter 54.

b. Sex

Similar relationships exist for death, sex, and gender. Although the differences in mortality between sexes is to a large extent a question of gender—of "socially constructed sex" that engenders specific masculine and feminine behavior—they also introduce other factors, including biologic factors, which will be treated in Chapter 53. Part of the difference results from cultural distinctions that prevail between men and women, especially in their attitudes about the body and health, but also from the diverse conditions of life imposed on men and women because of the role and status assigned to them by society.

c. Marital Status

The fact of belonging to a group and of having a status, whatever it may be, has consequences on lifestyle that may be important for health. An example is provided by the variations in mortality according to marital status. Almost universally, married people have better chances of survival than people who are celibate, widowed, or separated. Reasons for the difference are complex (Vallin and Nizard, 1977). As for migration and social ascent, marriage selects individuals according to their health; sick or handicapped people find it more difficult to find mates. In certain cases, divorce may act in the same way, especially when the law authorizing it is very restrictive and the procedure is so difficult that a solid physical and mental state of health is necessary for bringing the process to a conclusion. This was the case in France when the law forbade divorce if the spouse was suffering from serious illnesses or mental disease (Vallin and Nizard, 1977). When divorce is freely obtained and if all separations (legal or otherwise) are taken into consideration, deaths are higher among persons who are separated, widowed, or single than among those who are married. Apart from the effect of selection, the difference can be explained at two different levels. Status affects lifestyle, and from this point view, marriage protects health by imposing certain elements of lifestyle and behavior that are favorable to health. At an equal age, tabacism, alcohol abuse, and vehicular accidents are more common among single people or persons living alone than among married people. Similarly, eating behaviors, living conditions, and resort to medical care are better among married people than those living alone. However, the change of status may constitute a shock or trauma that worsens health and decreases mortality among widowed or separated persons (Thierry, 1999; Vallin and Nizard, 1977). According to a study by Valkonen and colleagues (2001), these differences in mortality between types of marital status have tended to increase in European countries.

d. Urbanization

Urbanization may have an influence on health because the city at a certain stage of development may be dangerous (e.g., unhealthiness of accommodation, human concentration encouraging the spread of epidemics, social disintegration encouraging the development of violence) or because, at another stage of development, it is favorable to health activities (e.g., human concentration favoring the advantages of health services close at hand, spread of knowledge about health matters). Urbanization also may be influential because the town or city is a modernizing factor of behavior. In Africa, sanitary progress has come first to the towns. All the differential mortality studies recognize this fact, regarding it as an obvious truism on which it is unnecessary to dwell (Tabutin and Akoto, 1989, 1992; Cantrelle *et al*., 1986; Ewbank *et al*., 1986). As confirmed by the authors of a case study published by the United Nations (Cantrelle *et al*., 1986), of all the demographic, socioeconomic, cultural, and environmental factors, living in an urban environment contributes most to the reduction in mortality. In the town itself, the mortality is not the same for those who have been living there for a long time as for the new arrivals. At Pikine in Senegal, the mortality rate for children born in the agglomeration of Dakar is two times below that for children who arrived after their birth (Antoine and Dough, 1988).

This urban advantage can only partly be explained by the great socioeconomic differences that distinguish the town from the rural world. When argument is founded on equal conditions of income, education, or social or professional category, the degree of advantage often declines but almost never disappears. It is stressed that the city usually encompasses the essential medical resources and that the urban environment facilitates health activities. This is undoubtedly the main source of difference in the 19th century, which was immersed in a medicosanitary context unfavorable to towns.

> But beyond these well known characteristics, one should inquire into the part played by the town, more particularly in Africa, in mixing together populations of various origins, pouring them into a common mould and involving them in more modern ideas, especially through education. Not only is the latter more developed in the town, but it also finds a greater justification there through the economic activities of an urban type less indebted to traditional practices than agriculture. Faced by the very considerable differences in African ethnic cultures, the town offers an alternative that is more open to effective medical and sanitary practices, and doubtlessly constitutes, in Africa more than elsewhere, the veritable crucible for modernization[19] (Vallin, 1989).

[19] "Mais, au-delà de ces caractéristiques bien connues, ne doit-on pas s'interroger sur le rôle que la ville joue plus particulièrement en Afrique en brassant des populations d'origines diverses et en les coulant dans un moule commun empruntant davantage aux idées modernes, notamment par le biais de l'instruction. Non seulement cette dernière est plus développée en ville, mais elle y trouve davantage sa raison d'être dans les activités économiques de type urbain moins redevables des pratiques traditionnelles que l'agriculture. Face aux différences culturelles ethniques, très fortes en Afrique, la ville offre une culture alternative davantage ouverte aux pratiques médicales et sanitaires efficaces et constitue sans doute, en Afrique plus qu'ailleurs, le véritable creuset de la modernisation."

d. Religion

Religion is a social conditioning factor that may affect health and mortality. For example, religious ideas affect the consumption of alcohol and the consumption of tobacco products. Within the same population, membership in different religious groups may lead to differences in mortality (Räsänen *et al*., 1996; Akoto, 1990). Moreover, many wars, massacres, and persecutions have been and still are motivated by religious fanaticism.

4. Health Policies

With equal behavior, mortality depends on the current and past health policies in the broadest sense (Vallin *et al*., 1985a, 1985b), and behavior may vary according to the health policies in effect. Some chapters (Chapters 106 to 109) are devoted to health and social policies and their effects on mortality. We limit this discussion to examples of how policies may influence behavior.

a. Availability of Means

Healthy behaviors depend on the means available for their expression. Health policies can improve the provision of health services, whether through treatment or prevention, by maximizing proximity, quality, and effectiveness of health care (Abbasi, 1999).

This is equally true for the development of collective resources that do not have health as its sole object (McKeown and Lowe, 1966). One example is the provision of water. With equal attitudes and propensities, the most elementary rules of hygiene are followed according to the facilities for access to water. Uses include drinking, food preparation, bathing, washing laundry, and cleaning the premises. The construction of networks for drinking water, extended by the systematic installation of running water in houses, has contributed greatly to the progress of hygiene, even though it continues to vary according to individual behavior. Similarly, since antiquity, the installation of sewage networks and of water treatment has increasingly transferred individual to collective responsibility for the protection of the environment through the treatment of domestic waste and eradication of the causes of unhealthy housing.

In an even wider sense, the economic and social development policies that contribute to a diversification in the supply of goods and services tend to widen the choice of consumers and therefore the possibility of expressing behavior and attitudes (favorable or not) about health. One of the most significant examples is that concerning the diversification of available food products. The choice of products now available in developed countries bears no relation to what was formerly available. Because of this abundance, the diet has developed, for better or for worse, according to individual behavior. Globally, it may be assumed that this diversification has moved in the direction of a more balanced and healthier diet. In parallel with this progress, there is concern, sometimes extreme, about food safety by the public and by public health authorities.

b. Orienting Behavior

Policies may also aim at orienting behavior, whether indirectly by acting on the prices of certain products or directly by developing information and awareness campaigns. Governments may go so far as adopting strict regulations on the use of certain products or of prohibiting them.

Two examples can illustrate the effects of price. In France, in 1957, the Pinay-Rueff plan for *economic and financial stabilization*, which caused a sharp rise in prices and a reduction in salary adjustments, led to a decrease in household consumption, a unique phenomenon in France during the whole second half of the 20th century. Paradoxically, this effect found expression in a sudden increase in life expectancy in 1958, which gained more than one year of life expectancy in a single calendar year, compared with an average of less than 6 months gained between 1947 to 1957 and even less afterward. Analysis of the causes of death showed that this exceptional increase was caused entirely by the decrease in the consumption of table wine after the sharp rise in the price of a liter of red wine (i.e., increased in Paris from 92 centimes to 1.4 francs) (Meslé and Vallin, 1993).

Another striking example is provided by the influence of the price policy carried out by the Organization of the Petroleum Exporting Countries (OPEC) on the behavior of motorists. In most European countries, the ongoing tendency for a rise in driving-related deaths was reversed in 1974, which coincided remarkably with the explosion in oil prices. Higher prices engendered an interest in moderating speed to save money, and the slower speeds reduced the number of fatal accidents (Vallin and Meslé, 2001).

Conversely, the price policy for medical products may affect the resort to preventive treatment. In countries having social security systems, it is more often the collective responsibility for medical expenses that limits the price (or even abolishes it) for the consumer and encourages access to treatment and prevention. Development of these institutions since the Second World War has caused a great expansion of health expenditures, which probably has contributed to the increase in life expectancy. Social mortality studies have nevertheless shown that this policy has not reached its primary target of reducing inequality in respect to death, because social differences in mortality continue to increase. Mortality has fallen for all categories, but it is, *grosso modo*, the most favored categories of people who have profited most. Although reduction in the individual's health costs has enabled better expression of favorable behavior, behavioral differences remain important, and their effects may increase precisely because resources are more available.

Health policies may also act directly on behavior through health education campaigns that explicitly encourage certain changes in behavior. Education may concern long-term work, such as the development of health instruction programs in schools or within the area of adult training. Health education may also act through campaigns that are more directly targeted at specific public health problems, such as vaccination, antismoking, and road safety campaigns. Many studies have shown the important effects of antismoking campaigns on deaths from lung cancer (The Surgeon General, 1989, 1990; Blanc, 1985a, 1985b) or from diseases of the coronary arteries (Puska *et al*., 1983).

Policies may go so far as attempting to restrain behavior through regulation or even prohibition. One of the most important areas for health protection regulation is that concerning the production and use of medications. Each product undergoes a very demanding series of tests and quality controls before being authorized for sale, but the use itself is more or less strictly regulated according to the nature of the product. This is one of the current means of curbing medical overconsumption, which is dangerous. It is also one of the means for combating suicidal behavior, and for the prevention of malicious acts.

Another example of regulation aimed explicitly at protecting health and life is that of road safety, including regulations determining highway codes, drivers' licenses, speed limits, and wearing of helmets or seat belts. Many measures aim at controlling the behavior of those using a dangerous means of transport. Similarly, regulations on the use of tobacco are becoming more and more restrictive, with more and more public places prohibited to smokers.

In certain cases, the regulations go as far as a total ban of a product and of its production, marketing, and use. In most countries, this is the case with certain narcotics, even though the health advantage of such extreme measures in restricting behavior is the object of controversy. Experience shows that governmental policies are never enough for eradicating the needs or curbing consumption, and in raising prices, they encourage illegal production and trafficking. Despite the problems with regulation, it is tempting to consider that deaths from lung cancer would never have reached the same high proportions if tobacco had been treated as a hard drug since the late 19th century.

All measures for alcohol prohibition have failed. The famous attempt at prohibition in the 1920s in the United States, which encouraged fraud and crime more than sobriety, was a fiasco. The immediate effect of the campaign carried out by Mikhael Gorbachev in the last hours of the Soviet Union was to cause an appreciable rise in life expectancy,[20] but prohibition measures were too easily avoided (e.g., fraud, resort to nonalimentary alcohols), and the attempt was quickly abandoned, after which life expectancy fell to even lower levels than before the campaign[21] (Shkolnikov *et al*., 1995, 1996).

CONCLUSIONS

Although health and survival depend primarily on the balance between genetically programmed vital resources and the resources and dangers arising from the environment, they also depend on the way in which men and women control this balance, individually and collectively. Individuals and society in their relationship with the environment have a large measure of freedom, which may lead to great differences between the state of health and the probabilities of survival.

The Medical Response: Medical Technologies and Public Expectations

PAOLO VINEIS

Dipartimento di Scienze Biomediche e Oncologia Umana, Università di Torino, Turin, Italy

Conservative estimates suggest that medical treatment can be scientifically proved effective in only 20% of cases.[1] This fact was behind the major impetus given in recent years to what is known as *evidence-based medicine* (EBM), although the failure of scientific research and medicine to live up to users' expectations is not new. As far back as 1900, the *San Francisco Chronicle* was leading with articles on biomedical issues that are still headline news today, such as baby gender selection, life extension technologies, and new cancer treatments.

After Mary Shelley's *Frankenstein* (1818), the late 19th and early 20th centuries were a time of intense cross-fertilization between science and literature, and the collective imagination centered on the *ambivalence of effects*, an issue extensively explored by contemporary bioethics, particularly by Hans Jonas (1985) and Daniel Callahan (1999). Marshall Berman (1983) argued that Goethe's *Faust* (1790) was an early demonstration of how the noblest ends may spawn the most dreadful deeds.

Examples of the creation of expectations that far exceed the real capacity to deliver practical responses to patients' needs and health problems abound. Jacques Loeb (1912) of the Rockefeller Institute of New York, for example, was in 1910 claiming the ability to recreate life from organic molecules, just as biotechnology developer Craig Venter (2000) was doing very recently. Press reaction to Jacques Loeb's pronouncements varied from enthusiasm to concern. Scientists and academics stressed the benefits and potentials of its clinical application, and the British Association for the Advancement of Science meeting in 1912 was given over to Jacques Loeb's discoveries under the banner of *life per recipe* (Turney, 1998).

Various examples of "technology assessment" are found in Harry Collins and Trevor Pinch's book, *The Golem at Large* (1998), which seeks to analyze the complex relationships among technologic developments, the public image of them, and their real quality-of-life effects. Examples include the Challenger shuttle disaster, the aftermath of the Chernobyl accident, economic forecasting abilities, acquired immunodeficiency syndrome (AIDS) research, and the role of gay self-help groups. The latter is particularly telling as one of the very first examples of a group of biomedical technology users being set up by singularly qualified individuals really able to influence scientific research strategies. The activists of Act-Up have successfully called into question the traditional model of the randomized clinical trial (i.e., phase III studies), thereby prompting the U.S. Food and Drug Administration to authorize the use of a treatment for which no phase III study evidence was available. John Turney (1998) and Harry Collins and Trevor Pinch (1998) assert that the promises of science, their interpretation by the media, and the role of the public have been

[1] This does not mean that such treatments are only 20% effective. They are very likely much more effective, but the proof is lacking.

indissociable for at least a century. The authors of *The Golem at Large* argue that there is no special insight, as claimed, for example, by the leading scientist Richard Feynman (cited in Collins and Pinch, 1998) with reference to the Challenger space shuttle accident, that would enable any technical problem to be foreseen and solved "by a scientist who is smart enough" (p. 151). Harry Collins and Trevor Pinch showed that there was no such thing as an exclusively technical problem; they demonstrated that every situation contained a component of randomness and subjective assessment. They also looked at risk analysis. The skills normally employed in risk analyses are highly specific and sectorial, and they have regard neither to the subjective aspects nor any assessment of risk *acceptability*. The fact that we find 10,000 deaths widely dispersed in space and spread out over time (e.g., road deaths in a year) more acceptable than 10,000 deaths concentrated in a short period in a specific place (e.g., a war) is surely not a technical problem. For Harry Collins and Trevor Pinch, "to give them unconditional respect is to make science and technology a fetish" (p. 153).

I. MEDICAL TECHNOLOGY'S CONTRIBUTION TO MORTALITY DECLINE

How has therapeutic progress helped improve Western public health? Thomas McKeown (1990) showed that most of the remarkable infectious disease mortality decline achieved in the West from the 19th century onward resulted from improved living and working conditions. McKeown estimated that in England between 1854 and 1971, 74% of the mortality gains resulted from a decrease in infectious disease–related mortality. His premise was that most of the decrease occurred even before effective drugs like sulfamides and antibiotics (developed in the 1940s) came in and therefore can only be attributable to other causes, such as improved hygiene and diet. Only 3% of tuberculosis deaths were prevented by treatments between 1848 and 1971, argues McKeown, but the proportion rises to 51% in the period from 1948 to 1971. In the health conditions that now prevail in the developed world, medical treatments are decisive in keeping mortality low, but their role in the rapid mortality decline since the turn of the 18th century was much more limited.

Infectious diseases aside, what share of current mortality improvements can be attributed to medical treatments? Indirect estimates have been done from available health statistics, especially in the Scandinavian countries. In Finland, for example, Kari Poikolainen and Jaakko Eskola (1986) estimated the health services impact on curable diseases between 1969 and 1981. The authors of the study selected the curable diseases (i.e., "amenable to intervention") from a list that included enteritis, tuberculosis, syphilis, other infectious and parasitic diseases, diabetes, hypertension or high blood pressure, and duodenal ulcer. They excluded all malignant tumors (including cervical carcinomas, which are treatable if diagnosed at a sufficiently early stage), the most serious and most frequent cardiovascular diseases (e.g. myocardial infarction, strokes), and sublethal accidents. Mortality from these curable diseases was compared with other-disease mortality. The study showed that mortality for curable diseases fell by approximately two-thirds in 12 years, compared with just one-third for incurable-disease mortality. Most of the decrease in incurable-disease mortality results from the blurred dividing line between curable and incurable diseases and, to a lesser extent, from effective primary prevention measures for nontreatable diseases. The main curable diseases that registered mortality improvements are tuberculosis, hypertension, gallstones, and causes of neonatal deaths. The Finnish authors conclude from this that health services were probably responsible for approximately one-half the curable-disease mortality decline over the review period. Other studies reached highly comparable conclusions. In an international comparison of 10 curable diseases (almost identical to those of the Finnish study), very similar decreases were observed in a set of industrialized countries, including Italy and France (Charlton and Velez, 1986). Table 52–1 shows a marked drop in curable-disease mortality across all countries, from 51% in England to 72% in Japan. Japan is a case apart because curable-disease mortality started from a much higher level, especially for tuberculosis, maternal mortality, and cerebrovas-

TABLE 52–1 Mortality Improvements from Avoidable Causes and Mortality from All Other Causes in Six Industrialized Countries, 1956 to 1978: Comparative Annual Rates per 100,000 People

Country	Curable causes		All other causes	
	1956	1978	1956	1978
England	68.6	33.4	327.2	313.0
United States	74.7	24.6	398.6	364.0
France	69.4	25.0	385.1	311.6
Japan	177.6	49.2	355.3	201.9

cular diseases. That notwithstanding, incurable diseases were the primary cause of death in the review period, with annual rates of approximately 300 to 400 per 100,000 people compared with 60 to 80 per 100,000 for curable diseases (except in Japan).

II. RISKS OF CLINICAL PRACTICE AND MEDICAL UNCERTAINTIES

Clinical practice remains beset by risks that to some extent highlight the shortcomings in mechanisms for *transferring research outcomes into practice*. At a workshop held in the San Giovanni Hospital in Turin, a group of doctors were asked in a series of simple questions about current clinical situations: whether they thought vitamin C helped heal scabs; whether they gave vitamin C to prevent or treat a cold; what drug they thought most effective in treating rheumatoid arthritis and which had least side effects; and whether they thought that surgical patients with serious trauma (e.g., femoral fracture) should be preventively treated for deep vein thrombosis (DVT) with heparin or a physical method (e.g., lower limb compression) (Vineis and Canavese, 1999). The respondent doctors were not a representative sample of the entire hospital, but they were not specially selected either. As expected, the doctors' replies were not entirely uniform. For rheumatoid arthritis, for example, 48% gave corticosteroids as the treatment of choice, and 34% opted for antimalarials. For 41%, their choice was based on information about randomized trials or other scientific evidence, and for 50%, the choice reflected their knowledge of the mechanisms of action (i.e. physiopathologic considerations). Although 19% reported using drug treatment alone to prevent DVT, 75% preferred combination therapies. The effectiveness of heparin was significantly overestimated; 88% of respondents thought it cut the risk of thrombosis by 5 to 10 times, whereas reduction established in trials is about twice; 95% thought that heparin cut the risk of pulmonary embolism by more than 25% and reduced mortality.

Having canvassed the clinical practitioners' views, we jointly consulted on each question the *Cochrane Library*, a database of systematic reviews of studies of clinical trials. The aim was not to look for answers but to see what relationship might obtain between what practitioners thought and a good source of updated knowledge. For example, we checked the number of results referenced for prevention of DVT. We found approximately 90 randomized trials to be accessible on the prevention of different forms of thromboembolism in patients with fractured femurs. Of these, however, only 26 were considered relevant and acceptable by the Cochrane Library review groups' criteria. The final outcome of the consultation was that heparin reduces the incidence of DVT, but it increases the risk of nonfatal pulmonary embolism and, paradoxically, the probability of dying. Physical methods (e.g., lower limb compression) present a somewhat different case. For an equal effect on DVT, there is also a preventative effect on pulmonary embolism deaths. Surprisingly, far fewer studies were found on the effectiveness of physical methods (4) than on heparin (19), perhaps because of the different commercial interests involved.

Rheumatoid arthritis is a much more clear-cut example. Treatment of acute cases with injectable gold salts and treatment with corticosteroids are about equally effective (measured as the difference between the average number of inflamed joints in treated patients and a control group), but gold salts have clearer and much more severe side effects.

The broad findings from these few examples could be demonstrated for many other clinical practices, including widely varying opinions and attitudes among doctors and scientific results that overall are hard to evaluate and to condense and that are often anything but compelling and clearly transferable into practice. The risks of clinical practice do not result from doctors' ignorance or inefficiency. Rather, choosing the best treatment is often a complex procedure of sifting through mountains of information that includes research outcomes and subjective aspects such as patient acceptance of treatment.

The need to address this problem was behind the founding of the *Cochrane Collaboration* (named after one of the inventors of randomized clinical trials) some years ago and the more general movement of EBM. Its main purpose is to facilitate transfer of information into practice through the preparation and dissemination of systematic literature reviews (e.g., the Cochrane Library). EBM has the merit of signaling which medical treatments have proved valid and which are useless or harmful. However, it has been criticized on the ground that not all medical activity is fitted to randomized, controlled trials, especially complex ones such as prevention practices; EBM also disregards the interpersonal and subjective aspects of the doctor-patient relationship.

III. BRIDGING NATURAL SCIENCE AND ANTHROPOLOGY

The relationship between biomedical science and public expectations has always been difficult (Turney, 1998). The role of biomedical technology often has been overestimated at the macro level (e.g., mortality decline in the West from the 19th century and onward) and the micro level (e.g., daily clinical practice). Broadly, the issue is one of transferring research outcomes into clinical practice. The main emphasis here has been on the objective aspects, such as how to facilitate the preparation and dissemination of clear and usable abstracts of medical research to update clinical practices (e.g., Cochrane Library), but the subjective aspects of the doctor-patient relationship—or more generally, those between biomedical research and public expectations and images—should not be disregarded. The doctor-patient private consultation is often a fragmentary and frustrating dialogue, but is it right to class patients' beliefs as superstitions or as short of the scientifically evidenced mark? Evidence shows that the problem is much more complex, as suggested, for example, by the work of the leading anthropologist Byron Good, who demonstrates that the doctor-patient dialogue must be looked at in the whole context. This means looking at the substance of the communication, as well as turns of phrase, the form of the discourse, and even the punctuation. It is to Byron Good's credit that he has illuminated how the doctor-patient narratives are distinguished not only by "high" versus "low" knowledge, but also by "knowledge" versus "belief" (Good, 1994). It is highly valid and significant that a trend toward dissemination of proven scientific knowledge (i.e., EBM) has developed within clinical medicine, but we also hope that doctors assimilate at least two lessons of anthropology. First, the significant improvements in Western public health in the 19th century were more the result of demographic and anthropologic than technologic factors. Second, the transfer of medical knowledge into clinical practice must deal with patients' own cultures, which should be respected.

III

THE INTRICACY OF DIFFERENTIAL MORTALITY FACTORS

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

Mortality varies widely (as will be seen more in detail in Volume III, on the history of population settlements), not least by level of national economic, social, medical or cultural development. Patterns differ not just between countries, but also between national subpopulations—be they regional or local—as well as subgroups within a population defined by membership criteria like gender, social status, marital status, educational level, occupation, etc. In fact, any criterion of differentiation used, provided it has a social, economic, psychological, cultural, or other significance for health and mortality, is highly likely to reveal mortality differentials.

These inter-group mortality differentials may have three very different but complementary origins. First and most obvious is belonging to a group. If, for example, femaleness is biologically propitious to survival, then femaleness guarantees a longer life than maleness. Likewise, being married, educated, or in a higher social status group generally entails category-specific behaviors that improve probabilities of survival. Secondly, where the criterion is not based on a genetic, unchangeable characteristic like sex, for example, the change of state may itself add a further differential to the category-specific one. So, widowhood, unemployment, loss of social status, etc., may be a time-specific factor of excess mortality. Finally, health-specific entry into a category may create a selective inequality. Married people's lower mortality than single people may in part be due to less healthy individuals' greater difficulty in finding a marriage partner and tendency to remain never-married. Likewise, at the normal economically active ages, there is a significant excess of nonworking over working population mortality, often due to ill-health keeping or driving them out of the labor market.

The factors that predicate these three grounds of differentiation are themselves varied and complex. There is an intricate number of explanations for each difference observed. An examination of all possible dimensions of differential mortality is clearly outside the scope of this treatise, so it was thought preferable to confine the analysis to three significant examples, striving for as comprehensive as possible an outline of each.

In Chapter 53, Jacques Vallin discusses the relationship between mortality, sex and gender. In Chapter 54, Tapani Valkonen will consider the mortality gap by social status. Finally, in Chapter 55, Graziella Caselli and Jacques Vallin will examine geographical mortality variations.

53

Mortality, Sex, and Gender

JACQUES VALLIN
Institut national d'études démographiques (INED), Paris, France

Girls are fewer in number at birth and live longer than boys. It appears that these two "laws of nature" biology impose on the human race complete one another to ensure the presence of men and women in almost identical numbers at reproductive ages. However, these are two laws that psychological attitudes and social behaviors can profoundly modify to the detriment of one or the other sex. The topic of the sex ratio of births is discussed in Chapter 4. This chapter analyzes the causes of excess male mortality, which is prevalent in most countries.

Life expectancy among women is higher than among men almost everywhere today (Table 53–1). In the United States in 1995–2000, the difference was 6.7 years; in France, it was 7.8 years. In some cases, the difference is much higher, as in Russia, with a difference of more than 12 years, but in other cases, it is much smaller, as in Iran (1.5 years), India (0.6 year), or Bangladesh (0.1 year), to mention only countries with more than 50 million inhabitants (systematically included in Table 53–1).

This diversity indicates that the difference is not merely a biologic effect. It is unlikely that the genetic distance between large human populations is enough to bring about such differences in a purely biologic parameter. The difference in mortality between men and women is not only a question of biologic sex; it is mainly a question of "socially constructed sex," or a question of gender.

The range of mortality situations is the result of historical evolution, which brings into play an even greater diversity, the examination of which makes it possible to understand the factors determining the difference in life expectancy between men and women. From the outset, it seems plausible that women have a biologic advantage. In the past and in certain cases today, the social conditions imposed on women deprived them of the benefits of this advantage, which women eventually regained through improved social status. Regaining this lost advantage led to widening the gap in life expectancy between men and women far beyond the strictly biologic difference. Is this because of the development among men of specific behaviors harmful to health? Alternatively, does it have more to do with a greater ability on the part of women to make the most of improved health conditions? Both successively made a difference.

I. A PLAUSIBLE NATURAL ADVANTAGE

Part of excess male mortality, which according to different investigators varies in degree, has always been considered as the expression of the biologic difference between the sexes. Some authorities even consider the XY pair of chromosomes, which determines the male sex, a lesser version of the XX pair of the female sex, perceiving males as having got the short end of the stick (Federici, 1950; Lenz, 1940).

1. An Obvious Genetic Advantage

If a mutation affects one of the genes of the X chromosome in women, it does not cause a disease or disorder in most cases because the second X chromosome

compensates for the loss of function (see Chapter 49); in men, all genes on the single X chromosome express themselves, even if they are deleterious. This is why genetic diseases such as hemophilia or myopathy mostly affect males. More than 1000 diseases are linked to the X chromosome. Not all of them specifically affect males, because the Y chromosome can sometimes compensate for a defective gene on the X chromosome, but in the end, a female advantage is evident. The female advantage is derived from more than protection from genetic diseases. Certain specifically female functions also are associated with greater life expectancy, and the genetic difference between the sexes generally seems to be associated with better resistance to biologic aging. In this chapter, only a few selected factors and their possible link with life expectancy are discussed.[1]

The female body must have food reserves for pregnancy and breast-feeding. According to some biologists, this capacity in women to store and eliminate food reserves without damage to the body allows them to deal with changes in living conditions with greater ease, to endure overfeeding, and to more efficiently eliminate excess food (Seely, 1990).

Folliculine-stimulating hormone (FSH) is secreted until menopause. FSH facilitates dilatation of veins and protects against circulatory diseases. Male and female hormone profiles are very different. The estrogen-to-testosterone ratio is approximately 10 in women and 0.1 in men. Estrogen in women enables them to eliminate more easily the bad low-density lipoprotein cholesterol and to afford them greater immunity against cerebrovascular diseases. At the same time, testosterone, the hormone of aggressiveness, tends to incite men to violence and to taking risks.

In addition to the effect of FSH, the female circulatory system has other advantages. For equal physical effort, women have lower increases in arterial pressure and greater elimination of lipids, which protects them against ischemic heart diseases (Nygaard *et al.*, 1990). Female cardiac muscle, which functions in a more complex way, is more flexible than male cardiac muscle (Ryan *et al.*, 1994).

The pair of X chromosomes plays an important role in defending the body against oxidizing lesions caused by free radicals by ensuring the replication of repair enzymes, a function that a single X chromosome is much less able to fulfill. If a gene on the X chromosome is defective and unable to code for the correct repair enzyme, men are unprotected, whereas women can retain the repair capacity because the corresponding gene on their second X chromosome is functional (Hollyday, 1987). Jean-Claude Chesnais (1998) described other genetic mechanisms that may underlie the greater life expectancy of women. There are many other examples, but apart from the fact that these phenomena and their effects on life expectancy

[1] The factors are among those mentioned by Jean-Claude Chesnais (1998) in a review on the subject presented at an Association internationale des démographes de langue française conference.

have not yet been entirely elucidated (Magnami and Accorsi, 1993), the part played by all of the genetic factors in the difference in life expectancy between men and women is very difficult to isolate from the effects of nonbiologic factors.

2. An Advantage That Is Difficult to Measure

It is difficult and perhaps impossible to measure the part played by genetic factors and that played by sociocultural factors in the differences in mortality observed between groups of human beings. How can we isolate the effect of the genotype from that of the sociocultural context when, from a genetic standpoint, differences between individuals are often much greater than differences between groups? How can a demographer interpret the differences observed between groups when, in many cases, the constitution of these groups itself has an influence on mortality through selection? These are only two of many difficult questions to solve for the analysis of differential mortality. We are at least certain that sex divides the population into two distinct groups on the basis of a genetic difference, the famous Y chromosome, and because it constitutes for each individual a constant characteristic from conception until death, it can induce no selection effect.

Is there an "admissible reference that will make it possible to sort out what is attributable to biologic factors from what is linked to social and behavioral factors in excess male mortality"[2] (Pressat, 1973)? It is very unlikely, because sex in itself is a support for sociocultural differences, the effects of which are extremely difficult to isolate to evaluate those of biologic difference.

Some demographers have presented very different arguments to demonstrate that the difference in life expectancy and its recent evolution almost entirely resulted from women's purely biologic advantage over men. For example, in trying to understand the reasons for the constant increase in excess male mortality, which at the time gave an advantage of up to 6 years in life expectancy to American women, Francis Madigan wrote in 1957: "Not only sociocultural pressures *[are]* less important than biologic factors in relation to the mortality differentials of sexes, but they are of comparatively small importance in this respect." He reached such an extreme conclusion by making a comparison between two groups of religious communities of different sexes that obeyed exactly the same monastic rule and that he therefore assumed had the same living conditions. The slight excess female mortality observed at the beginning of the century had in the space of 50 years given way to increasing excess male mortality, similar to that prevailing in the total population. Considering that between these two religious populations, the biologic difference linked to sex was the only intervening element, he therefore concluded that for the whole of the population, as for the religious communities, the evolution of excess male mortality could be explained almost entirely by the sharp decline in infectious diseases, against some of which (i.e., tuberculosis) women supposedly were less well armed than men, and by the increasing weight of cancers and cardiovascular diseases to which they were less susceptible than men. This did not take into consideration a major difference, admitted by the author himself, that existed between the two religious groups: the consumption of tobacco.[3] This approach also denied the fact that sociologic sex, or gender, could more generally induce different sociocultural behaviors, even within the framework of similar monastic rules. While avoiding the thesis of the total prevalence of biologic factors that was very much in vogue at the time, other investigators attempted to measure the proportion of excess male mortality that might be attributed to it.

In an attempt to generalize the distinction he had made between *endogenous* and *exogenous* mortality in infancy (Bourgeois-Pichat, 1951a, 1951b), Jean Bourgeois-Pichat (1952) built a *table de mortalité biologique limite* (i.e., table of maximum life expectancy), attributing to women a life expectancy greater than that of men by 1.9 years: 78.2 years compared with 76.3. The concept of *endogenous* mortality is not, however, understood here in the strictly biologic sense (and even less in the genetic sense of the term). It covers more of the morbid processes that, at a given stage of knowledge, medical science is more or less powerless to counteract (see Chapter 48). Jean Bourgeois-Pichat took into account future progress in medical science that would push this limit back. Twenty-five years later, in making the same calculations with the same concepts, he obtained a considerably greater difference in mean life expectancy between the two life tables:

[2] "Référence admissible pour démêler ce qui dans la surmortalité masculine tient aux facteurs biologiques et ce qui revient aux facteurs sociaux et de comportement."

[3] It is true that at the time the harmful effects of tobacco were not as well known as they are today, but as Roland Pressat stressed at the time (1973) in a criticism of Francis Madigan's work, according to a contemporary study by the American Cancer Society, male excess-mortality beyond the age of 35 in 54% of cases among cigarette smokers was due to smoking, with the harmfulness of this habit principally increasing mortality from cancer and cardiovascular diseases: exactly the diseases to which Francis Madigan thought that women were more biologically resistant.

80.3 years for women and 73.8 years for men, corresponding to a difference of 6.5 years (Bourgeois-Pichat, 1978). During this period, what Jean Bourgeois-Pichat referred to as the "hard rock" was largely eroded in the case of women, whereas for men, it was reinforced. This cannot have been the result of increased biologic differentiation between the sexes; it must instead reflect improved health measures or changes in behavior that may have evolved differently according to sex. The main reason for the apparent decline in maximum life expectancy among men is linked to increased smoking, which provoked during that period an explosion in the number of lung cancers, which Jean Bourgeois-Pichat included with all other cancers in his calculations of endogenous mortality. Measured in this way, maximum biologic mortality gives only an approximation by excess of the biologic difference between the sexes.

In a different way, Roland Pressat calculated the biologic advantage of women to be 2 years of life expectancy at birth. In the absence of efficient health practices, a difference of this amount seems to be almost totally attributable to biologic factors. This assumption seems to be confirmed by the fact that "currently, in the first year of life, when no outside influence is likely to cause a mortality differential according to sex, at least in the West, mortality among boys exceeds by 25% to 30% that of girls" and that "the continued difference during the whole of life would be such as to result in a moderate difference of approximately [. . .] 2 years [in life expectancy at birth]"[4] (Pressat, 1973). Although a modern demographer may have some doubts concerning the historical argument (i.e., the biologic advantage of women was masked by the negative consequences of their social status), the second argument based on infant mortality is one of the most convincing (Pressat, 1987). Extrapolating this information to other ages remains risky. Although there is an advantage for females at the start, the advantage most likely lessens with age. However, certain elements in the biologic difference may lead a person to believe that it increases at very old ages through improved resistance to aging. At this stage, there is a certain convergence of opinions concerning the existence of a female biologic advantage, probably a rather small one, even if it must be acknowledged that it cannot be measured accurately. Let us assume that God made women a little stronger than men.

[4] "Actuellement, dans la première année de vie, quand ne joue aucune influence extérieure de nature à différencier la mortalité selon le sexe, au moins dans l'univers culturel occidental, la mortalité des garçons surpasse de quelques 25 à 30% celle des filles . . . le maintien de cet écart tout au long de la vie serait de nature à entraîner une différence modérée, de l'ordre de [. . .] deux ans [espérance de vie à la naissance]."

II. ADVANTAGE THAT IS REDUCED OR INVERSED BY UNFAVORABLE SOCIAL STATUS

The first in a series of paradoxes in the analysis of mortality differentials between the sexes in past populations or more recently in populations with high mortality is the fact that an almost equal chance of survival (i.e., combining excess female mortality in adolescence and the beginning of adulthood with excess male mortality at older ages) or even a more global excess female mortality, which leaves women with a life expectancy inferior to that of men, usually is observed when measurement is possible. In certain circumstances, corresponding in all likelihood to a given state in social and economic development, nature's generosity to women has been thwarted by the actions of men (having for a long time confined women to an inferior social status) or of nature itself (reserving for women most of the risks linked to reproduction). Despite of the biologic advantage of women, past populations and some modern populations in developing countries have been marked by certain forms of excess female mortality.

1. Maternal Mortality

Excess female mortality at reproductive ages is well known. It has been abundantly documented in Europe in the past (Tabutin, 1978) and measured in France, thanks to the analysis of the representative sample of parish registers conducted by Louis Henry in the 1960s. In the 18th century and at the beginning of the 19th century, between the ages of 25 and 45 years, the probability of women dying was higher than that of men, between 5% and 20% according to the age group and the period (Blayo, 1975). In developing countries, the same pattern was seen until very recently (Potter and Volpp, 1993).

Excess female mortality is linked essentially to maternal mortality. It could therefore be qualified as biologic because only women are exposed to this risk because of pregnancy, childbirth, and postpartum complications. It is therefore partly nature that took back from women some of the advantage it had conferred on them. However, beyond the purely biologic risks, maternal risks also depended on the economic and social conditions of women's reproductive lives, which were closely linked to their status and level of fertility, which in itself is closely linked to the cultural and social context of females. It is therefore also (male) society that partly eroded women's natural advantage. In 18th century France, women's overall life expectancy at 25 years of age was slightly less than that of men, because male excess mortality observed after the age of 50 years was not enough to compensate for excess female mortality between the ages of 25 and 45 years.

2. Mortality at Young Ages

The role of women's status is even more obvious concerning excess female mortality at young ages, which can be explained only by differences in behavior toward children according to their sex. In the past, female excess mortality was manifest in Europe, where it seemed to have been especially pronounced in the 1- to 4- and 5- to 9-year-old age groups. The degree of female excess childhood mortality seemed to worsen in the 19th century (Tabutin, 1978). In France, more precise statistics from 1899 show that the issue of excess mortality was still a concern for all girls between 4 and 17 at the beginning of the 20th century and that it disappeared only during the Second World War after gradually becoming limited to a declining number of age groups (Vallin, 1983; Tabutin, 1978). Dominique Tabutin stressed the essential role played by infectious diseases, notably tuberculosis, in this excess mortality among little girls, which was sufficiently high to overtake excess male mortality due to accidents or violence, which was already high in these age groups. For Tabutin, the excess female mortality due to infectious diseases was directly linked to the unfavorable conditions imposed on girls at the time, who were more often deprived of health care and food, under the influence of an antifeminist ideology[5] that attributed little value to girls compared with boys.[6]

This lack of value of the female sex is at the origin of excess mortality among girls today in many developing countries. The most glaring examples come from the Indian subcontinent (Das Gupta, 1987; Chen *et al*., 1981). In Bangladesh, mortality among girls between the ages of 1 and 14 years was 50% higher than that of boys at the end of the 1970s. Inequality between food rations and health care for boys and girls was the cause (Chen *et al*., 1981). In India, the burden on the parents of female children imposed by the dowry system often means that the birth of a female is a catastrophe for the family. The phenomenon has been observed in most cultural regions. In addition to Bangladesh, these practices continued until recently in most Moslem countries (Adlakha and Suchindran, 1985), including in the Maghreb (Haffad, 1984). In Algeria, for example, excess mortality among little girls from the third month of life constitutes exclusively the *exogenous* component of infant mortality, whereas the *endogenous* component is marked by high excess male mortality (Vallin, 1979). As in Bangladesh, the phenomenon seems, to be closely linked to the fact that less attention is given to the female sex (Ferry, 1979; Vallin, 1979). Even in sub-Saharan Africa, for which statistics are too imprecise to isolate the different components of infant mortality, it may be that despite a cultural context that is less unfavorable to women, the absence of an infant mortality differential between the sexes is linked to unfavorable treatment of little girls, who should otherwise have a lower infant mortality rate than boys (Gbenyon and Locoh, 1989, 1992).

The relation between women's social status, the value of the female sex, and excess mortality among little girls stands out in China, where there is evidence of the survival of the old practice of female infanticide, which the governmental policy of the single child has probably revived (Calot and Caselli, 1988, 1989). In the province of Anhui, where the probability of dying before the age of 1 year for females is more than 12% higher than for males, Wangsong Zhang (1983) estimates that infanticide, which may responsible for almost 60% of infant deaths, is the main cause of this exceptional excess female mortality. This prejudice against female babies also is found in the practice of discriminatory *feticide*, which consists of eliminating female embryos after having an ultrasound scan (Miller, 1996).

The biologic advantage women theoretically have in terms of life expectancy has been all or partly masked by the unfavorable influence of women's social status for a long time in Europe and in many developing countries, where prejudice against females continues to this day. In India (Ragavashari *et al*., 1974), in Bangladesh (Bean and Khan, 1967; Yusuf, 1967), in Pakistan (Afzal, 1973; Yusuf, 1967), and in Sri Lanka (Sri Lanka, 1974), the accumulation of the different aspects of excess female mortality from young ages to the ages of maternity was so high that up until the end of the 1960s, it led to a much shorter mean life expectancy for women than for men. In Algeria at the beginning of the 1970s, excess male mortality in the

[5] Developed, as Dominique Tabutin (1978) reminds us, by great minds such as Jean-Jacques Rousseau, August Comte, Balzac, and even the Socialist Proud'hon, who had "scientifically calculated" that the value of a woman was only $^{8}/_{27}$ of that of a man!

[6] To illustrate to what extent this ideology prevailed in the past, André Armengaud (1973) mentioned two anecdotes drawn from *Histoire Morale des Femmes* by Legouvé (1842): "Question a peasant about his family, and he will answer: 'I have no children; I only have daughters.' And the Breton farmer, whose wife gives birth to a daughter, still says today: 'my wife had a miscarriage.' "

first months of life and beyond the age of 50 years just counterbalanced life expectancy at birth for both sexes, and the phenomenon persists today. In France in the 18th century, at a time when the absence of health care made mortality less sensitive to social inequalities, low excess male mortality in the first year applied to a very high overall rate was enough to produce a shorter mean life expectancy for the male sex. However, from the age of 1 year, life expectancy, combining excess female mortality before the age of 45 and excess male mortality beyond that age, was equivalent for the two sexes or slightly lower for women. Although "God made women" a little more resistant than men, for a long time, men took away from them the benefits of this natural advantage.

III. FROM REGAINING THE ORIGINAL ADVANTAGE TO OBTAINING A NEW PRIVILEGE

Everything changes. Extraordinary economic and social progress from the 18th century was accompanied by a reduction in social differences between the sexes and a radical lightening of the weight of maternities. Early on, demographic transition led to greater life expectancy among women. In improving their status, women might have been merely regaining the lost benefit of their natural advantage.

If so, it would not be enough to account entirely for the comparative evolution of women's status and the mortality differential between the sexes. The life expectancy of women depends on many social factors beyond the biologic difference that is responsible for the substantial mortality differences between the sexes. While pursuing improved social status, women have continued to benefit from the protection resulting from their biology. This partially explains why everywhere in Europe since the beginning of the 19th century, excess male mortality has continually increased.

In the past 2 centuries in Europe and more recently (and much faster) in developing countries, women have acquired a new social status that will soon compare favorably with that of men. Moreover, the attitudes of adults toward children have changed completely during this period, attributing to them value that is increasingly independent of their sex (Vallin and Lery, 1975, 1978).

Having obtained equality in food, health, and cultural terms, there no longer was any reason for little girls to die younger than little boys, and they could recover the full benefit of their biologic advantage. With the decline in fertility rates and with the improvement of conditions for women during pregnancy and childbirth, the only specific health disadvantage for women disappeared. However, the recent change in mortality has gone far beyond that of recovering women's original advantage to creating a new and even greater advantage for them.

1. Disappearance of Excess Female Mortality and the Development of Excess Male Mortality

In France, even under the *Ancien Régime*, women's life expectancy at birth has never been lower than that of men. According to research by Louis Henry, from the 1740s to the 1860s, the female advantage remained small, shifting rather irregularly between 0.6 and 2.4 years, and generally remaining less than 2 years, which according to Roland Pressat, corresponded to the female biologic advantage. It was therefore not entirely canceled by the unfavorable status given to women, unless we also take into account the nonbiologic factors of excess male mortality that at that time were added to the biologic factors: violence and accidents. Since then, in 1 century, the difference between life expectancy at birth has increased substantially, going from 1.7 years between 1865 and 1869 to 8 years between 1984 and 1986 and reaching a level four times higher than the assumed 2-year female biologic advantage. However imprecise estimating their biologic advantage may prove to be, it is evident that women have done much more than simply recover it, or men have lost much more than strict equality of treatment would have produced for them in terms of life expectancy. These facts are not limited to France. Even if there are great disparities today between industrial countries concerning excess male mortality, everywhere the tendency has been the same. Although it was very limited in the 19th century, the difference in life expectancy increased and even accelerated in the 1950s and 1980s (Table 53–2). Although the difference remains smaller in the most advanced developing countries, it already exceeds 2 years.

An investigator becomes even more clearly aware of the extent of women's progress when examining the evolution in ratios of male excess mortality by age. Figure 53–1 provides an illustration for France. To evaluate this ratio, a demographer may use, for exploratory purposes, Roland Pressat's two assumptions. First, excess male infant mortality essentially results from biologic factors. Second, without the intervention of other factors, the same excess male mortality is observed at other ages. At less than 1 year, since the beginning of the 19th century, excess male mortal-

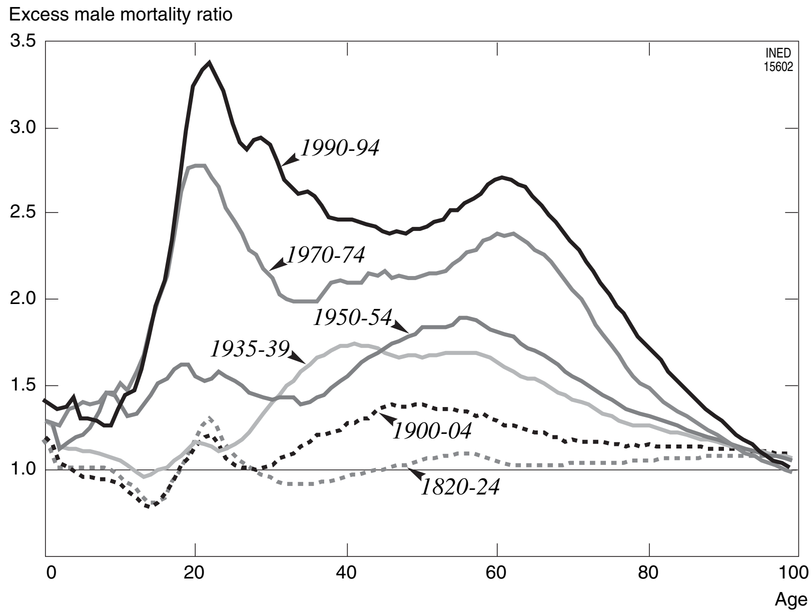

FIGURE 53–1 Evolution in excess male mortality ratios by age in France since the beginning of the 19th century.

TABLE 53–2 Life Expectancy by Sex in France since the 18th Century and in Russia, the United States, and Japan in the 20th Century

Period	Life expectancy		Difference between sexes
	Men	Women	
France			
1770–1779	28.2	29.6	1.4
1820–1824	38.2	39.5	1.4
1865–1869	39.9	41.6	1.7
1909–1913	48.6	52.5	3.9
1950–1954	64.0	69.9	5.9
1990–1994	73.1	81.3	8.2
1997	74.2	82.1	7.9
Russia			
1896	30.9	33.0	2.1
1938	40.1	46.0	5.9
1958	63.0	71.3	8.3
1994	57.7	71.3	13.6
1997	61.0	73.0	12.0
United States			
1900	46.3	48.3	2.0
1950	65.6	71.1	5.5
1979	70.0	77.8	7.8
1990	72.0	78.8	6.8
1995	72.5	79.3	7.2
Japan			
1900	37.5	38.0	0.5
1950	57.5	60.8	3.3
1994	76.6	83.0	6.4
1996	77.0	83.6	6.6

ity has remained almost perfectly constant, ranging between 25% and 30%, and this excess can be attributed to the male biologic disadvantage. Today, there is no difference in attitudes toward children according to sex,[7] and despite the marked prejudice in the past, this difference has had only a small impact on mortality in the first year of life. However, the situation is very different at other ages for which radical changes have occurred.

At the beginning of the 19th century, excess female mortality was clearly demonstrated in childhood and adolescence (5 to 18 years) and in at reproductive ages. Around 1900, there remained excess female mortality at young ages, but excess male mortality was already high after the age of 35 years, exceeding the level reached for men approximately 50 years of age at less than 1 year of age. Just before the Second World War, excess female mortality at young ages had almost disappeared (except at 13 and 14 years), but the ratio of excess male mortality remained at all ages clearly below that observed in the first year of life, suggesting that unequal treatment of young girls probably still had a negative effect on their survival. At the same time, excess male mortality considerably increased in adulthood, reaching 60% between the ages of 40 and

[7] A precise analysis of substantial excess fertility after the loss of a child shows that in the 1960s, the desire to replace the child expressed by the parents bears no relation to the sex of the deceased child (Vallin and Lery, 1975, 1978).

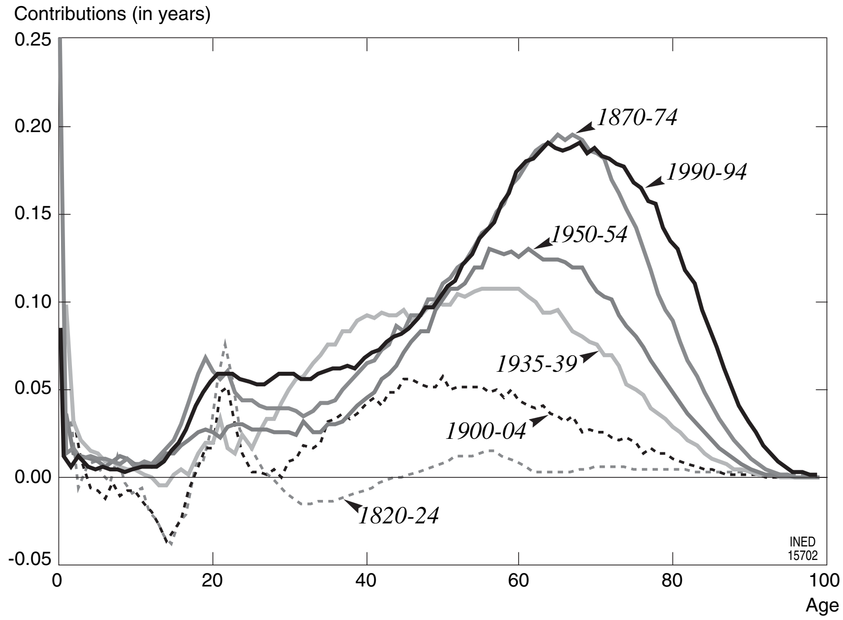

FIGURE 53–2 Evolution of the contribution of the differences in mortality by age to the difference in life expectancy at the beginning of the 20th century.

60. Just after the war, excess male mortality was almost the same as at birth until the age of 35 years, suggesting that women had probably fully recovered their biologic advantage at these ages, whereas at older ages, men were still losing ground. From the 1950s, excess male mortality continued to worsen and even accelerated at older ages, and a second upsurge in excess male mortality harshly affected a few years around 20 years of age.

At the beginning of the 1970s, the excess male mortality ratio exceeded 200% from 18 to 70 years, reaching as high as 240% between the ages of 60 and 70 and even 270% at 20. Since then, the relative situation of men has worsened again, with a peak of 350% at 20 to 22 years and very wide coverage, with a rate of more than 250% at adult ages. At all ages, this is 10 times the reference level of 25% to 30%!

This vision of the mortality difference between the sexes given by the ratio of the age-specific death rates does not, however, take into account the very great variation in death rates according to age and their weight in the difference in life expectancy at birth. Using a method of decomposition of the difference in life expectancy between the sexes (Pollard, 1988, 1990) (see Chapter 16), it is possible to measure the contribution of each year of age to this difference (Vallin, 1993a). Although excess male mortality at less than 1 year of age has remained almost constant, its weight in the difference in life expectancy between the sexes has greatly declined. At the beginning of the 19th century, it alone explained almost all of the difference in life expectancy between the sexes (i.e., 1.4 years of a total of 1.5 years between 1820 and 1824). Between 1900 and 1904, it still accounted for almost one-half of the difference (i.e., 1.4 of 3.4 years). However, in the middle of the 1970s, it accounted only for 3% (i.e., 0.26 of 7.9 years). The decline in absolute figures (from 1.4 to 0.26 years) stems entirely from the decline in infant mortality, but the marginalization of its weight (from more than 90% to 3%) is accounted for by the great increase in excess male mortality at the other ages (Fig. 53–2).

Even reduced in this manner, the contribution of excess male mortality at less than 1 year of age remains higher than the contributions by the other age groups taken individually. The case of infant mortality is isolated, and it is the combination of the contributions of all of the contiguous age groups from roughly 50 to 75 years that now make up the greater part of the difference between mean life expectancies. The exceptional peak in the ratios of excess male mortality observed at approximately the age of 20 carries a weighting factor of only secondary importance because of the very low mortality at these ages.

2. Increasing Predominance of Environmental and Behavioral Factors

It is possible to measure with the same decomposition method (Pollard, 1988, 1990) the weight of the different medical causes of death in the difference in life expectancy between the sexes and in its worsening.

This was done 15 years ago for France, based on a reconstitution of mortality by cause that made it possible to follow its evolution from 1925 to 1978 (Vallin and Meslé, 1988). This approach allowed several assessments that, without being entirely conclusive, showed interesting trends (Vallin, 1993a). The fact that a large fraction of current excess male infant mortality is closely linked to hereditary or congenital processes substantiates the theory of a genetic origin for this difference. The greater susceptibility of boys to infectious pediatric diseases, remarkably stable for the whole period, does not contradict this idea. It is only because of its collapse that infectious pediatric mortality plays a moderating role in the aggravation in the difference in life expectancy between the sexes. Today and since the 1920s, the fight against infectious diseases seems to have been well managed in France, independently of the child's sex, and little boys are therefore almost constantly at a disadvantage due to their genetic handicap.

Findings were not the same at other ages. Although for a long time the role of infection in young girls masked their biologic advantage, the statistical disadvantage results more from their unfavorable social status than from any specific susceptibility to certain diseases. As soon as women's social status improved for any length of time and at all ages, infectious diseases resulted in excess male mortality. The latter situation goes well beyond the male fragility observed among babies. A more detailed analysis shows that at adult ages, susceptibility concerns mainly infectious respiratory diseases that are strongly linked to the consumption of tobacco and to industrial pollution, two exogenous factors that, until recently, affected men much more than women.

It might be said of degenerative diseases, which are the consequence of the body wearing out, that they affect men more because they are less resistant. However, it would be just as plausible to attribute the effect to a lifestyle that is more harmful to men's health. The second interpretation is more realistic insofar as excess mortality linked to this type of cause has greatly increased in the past 50 years.

The case of tumors, which play an extremely important role in increasing excess male mortality, is even clearer because tumors of the respiratory system closely linked to smoking and industrial pollution and tumors of the esophagus linked to alcoholism are first among the causes for excess male mortality. Behavioral and environmental factors clearly play a role.

The same factors lead to very strong excess male mortality rates linked to accidents, suicide, alcoholism, and cirrhosis of the liver, which are sufficiently strong that, despite the secondary part they play in overall mortality, they contribute substantially to the difference in life expectancy between the sexes and in its increase over time.

IV. FROM THE NEGATIVE EFFECTS OF MALE BEHAVIOR TO THE POSITIVE EFFECTS OF FEMALE BEHAVIOR

All of these observations perfectly coincided, at least at first sight, with the idea that was prevalent for a long time: Beyond a slight biologic advantage for females, excess male mortality and its spectacular increase in industrial countries resulted from the emergence of typically male "man-made diseases."[8] Work-related risks in industrial activity, alcoholism, smoking, and car accidents were the main factors contributing to excess male mortality. Their unprecedented expansion from the beginning of the 20th century, which was barely interrupted during World War II and which has continued to grow since the end of the 1940s, provided an obvious explanation for the continued increase in excess male mortality. However, this explanation has a limit.

1. They Smoke, They Drive, They Work—But Women Still Die at Older Ages

Although differences in behavior or living conditions are the main factors of excess male mortality, what can explain the continued increase at a time when, especially since the end of the 1960s, these differences have considerably declined?

In recent decades, most male and female behaviors have become greatly similar. Whereas smoking has been greatly reduced among men—the success is such that in England, for example, bronchial and lung cancer mortality has begun a spectacular decline (Meslé and Vallin, 1992)—it has greatly increased among women. In the same way, alcoholism, previously thought to be a very male condition, has declined in France since the beginning of the 1960s (Vallin and Meslé, 1988). Road accidents have been declining since the oil crisis in the 1970s, but they are increasingly less specifically associated with men because women now drive in almost equal numbers. Women's participation in economic activity has increased to a level close to that of men, which at the same time has perceptibly declined.

These changes already seemed rather likely to occur or were already clearly taking shape in the 1960s for the authors of life tables to assume in the construction

[8] "Man-made diseases" as described by Omran (1971).

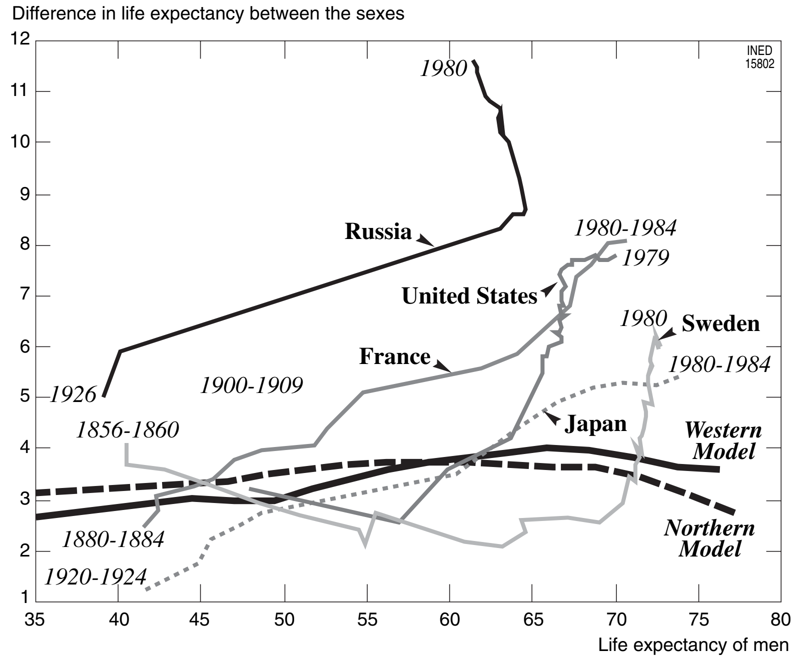

FIGURE 53–3 Correlation between the level of life expectancy and the difference between the sexes according to the models of Coale and Demeny and according to the real situation in some industrial countries from the end of the 19th century to the 1980s.

of their models that there would soon be a decline in the difference in life expectancy between the sexes and therefore a reversal in the constant trend toward an increase that had been observed until then (Coale and Demeny, 1966). The subsequent evolution entirely contradicted a projection that seemed certain at the time. The difference between the sexes continued to increase everywhere while life expectancy was reaching higher levels, and instead of slowing down, this trend tended to accelerate, as cruelly demonstrated in Figure 53–3 (Vallin, 1983). Despite contradiction of the facts, the authors of the tables did not modify their models when they republished them in the 1980s (Coale and Demeny, 1983).[9]

Although behaviors have become more similar for men and women, they are not identical. Men continue to smoke and drink more than women, they drive more often, and they have higher rates of economic activity. Although this may be enough to explain continued excess male mortality beyond the initial biologic advantage of women, it in no way explains the increase observed.

There has always been a tendency, concerning excess male mortality, to highlight the causes of death likely to increase mortality, in the belief that they are the result of social vices men are more likely to engage in. This approach does not acknowledge the fact that the exceptional increase in excess male mortality has emerged at the same time as the equally exceptional development of health care. Beyond the negative behavioral and environmental factors that have more adverse effects on men's health than on women's health, is it not likely that there is a more fundamental difference in lifestyle that enables women to benefit more from improved health care than men?

2. Being Female: An Art of Living?

a. Inherited Aspects

From the socially inferior status that was their lot for so long, women reaped more than disadvantages. Although they were treated as slaves and as means of production and reproduction, they were also reputed to be weak and fragile, and women benefited from a certain degree of protection. Machismo and politeness toward women have often gone hand in hand. Denied access to power by a patriarchal system, women were also preserved from the most dangerous tasks involved in war and hunting. Is it not customary to cry out in case of danger, "Women and children first!"? During the industrial age, to such customs were added many laws forbidding women access to certain dangerous jobs (in mines) or arduous work (night shifts),

[9] A correction has been published since, but it is only for the Western and Northern models (Coale and Guo, 1989, 1990).

limiting the length of their working day and protecting their fertility (e.g., monitoring of pregnancies, maternity leave). At the beginning of the century, they were almost excluded from many factory jobs and relegated to activities more "in keeping with their nature," such as domestic work. In the same way as for war and military service, they were for the most part spared from the inhuman working conditions imposed by heavy industry. It is also essentially because of their status and social pressures that women were denied the dangerous male privileges of consuming alcohol and tobacco or of driving automobiles, not to mention that of sexual freedom and its associated health risks (formerly syphilis and more recently AIDS).

Although mainly a thing of the past, this heritage of protection has not completely disappeared. In addition to having gained greater social equality and substantially reducing the risks of reproduction, women have managed to preserve some of the positive aspects of their former status in the form of a different approach to life and to societal interaction.

b. Female Form of Development

The fact that women are attaining equal status with men does not mean that female behavior is becoming increasingly male, nor does it signify that women's relation to modern society increasingly resembles that of men. Fundamental differences remain, some of which may explain why, until now, women have gained greater benefit from improved health care than men.

It is true that modern women have access to alcohol, tobacco, and cars and that excess male mortality linked to the causes of death directly related to these factors has tended to decline in recent years. Many of the consequences of closing this gap between behaviors remain to come insofar as some harmful effects emerge only later (e.g., those linked to smoking). It seems, however, that the way women behave in these areas is less dangerous than that of men. For example, among younger generations, the proportion of women who smoke is almost equal to and sometimes greater than that of men; however, the average number of cigarettes smoked each day by regular smokers is lower today (Blanc, 1985a, 1985b). In the same way, women drivers are on average more careful, and they drive more slowly and take fewer risks. The first aspect is probably minor compared with the two other characteristics.

Female participation in economic activity has been massive during the last three generations (Lévy and Labourie-Racapé, 1983), but it remains fundamentally different from that of men (Vallin, 1995). It is often pointed out that women have less access to the positions of highest responsibility. Less often mentioned is the fact that they are generally more qualified and that they often hold less degrading jobs. In France from the beginning of the 1980s, the census showed that 40% of jobs were held by women, and this proportion has remained stable since, as the 1996 employment survey revealed (INSEE, 1996). Women now participate almost as much as men in economic activity. However, their participation in the different professions is very unequal (INSEE, 1996; Vallin, 1995).

Jobs with the greatest share in decision-making are seldom held by women (in 1996, only 16% of corporate chief executive officers were women), and this is even more the case for technical jobs (female engineers: 13%), but the same applies for manual jobs (i.e., industry, crafts, and agriculture), whether qualified or unqualified (20%), especially if the jobs involve the responsibility of management (female foremen: 9%). Intermediate-level jobs are considered feminine (77%) in the ancillary professions of health and social care, in civil service (80%), and in companies and the service industry (83%). The proportion of these jobs compared with the total number of jobs held by women is huge (70%), whereas among men, manual jobs are prevalent (more than 40%).

I cannot help but relate this difference in the distribution of men and women in the workplace with the even greater difference observed concerning social inequality in death (Vallin, 1995). Among men, risks of death vary greatly according to socioprofessional category. In France, between senior executives and the professions on the one hand and manual workers on the other, the difference in life expectancy at 35 years of age is 9 years (Desplanques, 1976, 1984). Among women, the variation is very slight (Desplanques, 1984). Not only is female economic activity essentially concentrated in professions in which health risks are low (e.g., schoolteachers) or average (e.g., office workers), but even when they work in sectors that are more dangerous for men, women seem to enjoy better protection. Detailed analysis clearly reveals this trend (Vallin, 1995). The two most dangerous jobs in peacetime (i.e., policemen and drivers) are among the least often held by women (8% and 6%, respectively). Almost as active as men and even more so if domestic activity is taken into account, women take part in activities that generally are less harmful to health, and they manage their affairs in a fashion that is kinder to their health.

A third aspect to be highlighted here is that the attitude women generally have concerning their body, their health, and their lifestyle is very different from that of men. Here again we find that initially, this is a consequence of the reproductive function and of its evolution. At the same time that control of fertility lightened the weight of maternities, maternal and infant protection, gynecology, and obstetrics have mobilized an increasing share of medical resources, an area exclusively reserved for women. Development of this specific area of health care has done much more than compensate for the risks of pregnancy. It has contributed to improving overall female health, making women more accustomed than men to contacts with medical services and more concerned about health issues. Screening for tumors of the uterus during visits to gynecologists, the principal reason for the reduction in mortality from uterine cancer, is just one example of improved health care for women (Hatton *et al.*, 1985a, 1985b).

Women's special relation to health is not just a consequence of their reproductive function. For the human body, the culture of femininity is a very different constraint than that imposed by the exaltation of virility. At the risk of caricaturizing, it can be said that the search for beauty is in opposition with the search for power. In the first instance, the body must remain young and healthy as long as possible; in the second, the body is subjected to risk very early on. The fact remains that women seem to be much more attentive than men to their body and to their health needs. They use health services more often, and they often talk with the practitioner with greater ease and openness.

More inclined to temperance, practicing less harmful activities in a manner probably more respectful of their health, more inclined to care for their bodies and to preserve their lives, women have quite naturally drawn greater benefit from medical and social progress. Since the turning point of the 1960s, they have reinforced their advantage in all of these areas thanks to education. In France, for example, during the 1960s, the proportion of girls in a same birth cohort succeeding at the *baccalauréat* (end of secondary examination) exceeded that of boys (Lévy, 1981). Although fewer women than men have access to the most advanced levels of higher education, on average they have a higher level of general education—another major asset in their favor.

3. Women: Champions in the Second Phase of the Health Transition

Women had all the described assets in hand at the time of the health transition. During the 1960s, at the end of a spectacular convergence of all industrial countries toward the life expectancy of countries formerly more advanced (i.e., Japan, Russia, or the Mediterranean countries catching up with the countries of Northern and Western Europe), progress slowed down almost everywhere. The maximum benefits from the fight against infectious diseases had been attained thanks to the distribution of vaccines and antibiotics. Mortality due to these diseases, especially at very young ages, had become so low that a continuation of its decline was no longer likely to produce a significant increase in life expectancy. Cardiovascular diseases and cancer, against which medical science remained essentially powerless, ranked first among causes of death, far ahead of infectious diseases, and economic and social changes also had brought about an unprecedented increase in negative phenomena such as alcoholism, smoking, and road accidents. This explains the stagnation or even reversal in life expectancy observed in industrial countries during the 1960s, spawning pessimism about returning to improvement in the trend.

It is in such a context that Abdel Omran (1971) formulated his theory of epidemiologic transition, which brought humanity from "the age of pestilence and famine" to that of "degenerative diseases and man-made diseases" (see Chapter 57). Because the huge benefit of the victory over infectious diseases was a thing of the past, there was no more hope of a return to sustained improvement in life expectancy. However, this improvement is a reality. The 1960s were nothing more than a transition crisis from a first phase of improvement, which Abdel Oman called *epidemiologic transition*, to the second phase of the *health transition* (Vallin, 1993b). The health transition was founded on the success made in treating and preventing man-made diseases and cardiovascular diseases and cancers. In France, improvements in life expectancy resumed in the 1970s (Meslé and Vallin, 1993). One after the other, increases in man-made diseases were curbed. The trend began to reverse from 1965 for alcoholism, from 1974 for road accidents, and near the end of the 1980s for lung cancer, but it was the spectacular decline in cardiovascular diseases that was key to this new phase of improvement. What happened in France also happened more or less rapidly in most Western industrialized countries. In Japan, the transition was so rapid and so successful that the improvement in life expectancy did not even experience a slowdown in the 1960s. Eastern countries, particularly Russia, have failed to introduce this transition, and life expectancy has been in stagnation or decline since the 1960s (Shkolnikov *et al.*, 1995, 1996).

This East-West divergence has been much written about, and the causes of the failure in the former Communist countries are as complex as the reasons for the success of Western countries. However, one of the fundamental reasons for the difference lies in the fact that whereas the fight against infectious diseases might have resulted essentially from a policy of dissemination for the benefit of the greatest number of simple and efficient techniques such as vaccines and antibiotics, success in the area of cardiovascular diseases or cancer requires much more sophisticated medical techniques and the active participation of each individual in the preservation of his or her own health. Man-made diseases can be checked only by individual awareness and changes in behavior. The transition to this new health strategy is naturally easier for societies founded on individual responsibility than for countries where for many decades the state was omnipresent and discouraged individual initiatives.

Mutatis mutandis, the acceleration of the divergence observed during the 1960s and 1970s between female and male life expectancies, can therefore be explained. For all of the reasons previously given, women were initially much better prepared than men to succeed in the second phase of the health transition. Whereas the crisis of the 1960s in Western countries was marked in almost all of the industrialized nations by a substantial slowdown, stagnation, or even decline in male life expectancy, women's life expectancy everywhere continued to increase, sometimes without the rate even slowing down. In many cases, the decline in cardiovascular mortality for women seamlessly took over from the decline in infectious diseases, whereas men needed a much longer period of adaptation. Subsequently, the 1970s and 1980s were marked by a much faster decline in cardiovascular mortality among women than among men (Meslé and Vallin, 1992). Women took better advantage of this new phase in the transition to improved health much more quickly than men.

With this background, it is easier to understand how the difference in life expectancy between men and women could continue to grow at the same time the behaviors of men and women came to resemble one another as they increasingly shared "masculine vices." The more fundamental virtues of women enabled them to embark much faster and much more effectively on the second phase of the health transition.

V. WHEN GEOGRAPHY CONTRADICTS HISTORY BUT CONFIRMS THE PREVIOUS HYPOTHESIS

It is the dual aspect of the role of behaviors in mortality differences (i.e., the harmfulness of certain practices and the capacity to take advantage of improvements in health care) that makes it possible to elucidate a third paradox concerning excess male mortality. Over the centuries, as life expectancy has increased, so too has the mortality difference between the sexes. However, when considering the geographic variations in a country such as France (and many other countries), it is clear one observes that the greater the life expectancy, the smaller is the difference between the sexes (Vallin, 1990).

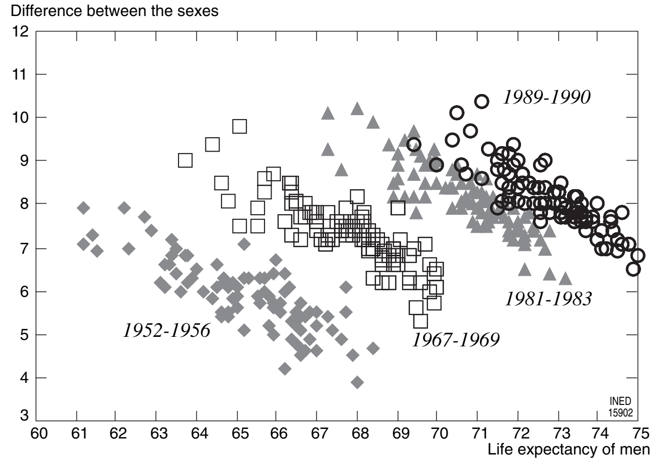

FIGURE 53–4 Correlation between the variations in male life expectancy and those of the difference in life expectancy observed between the French departments in 1952–1956, 1967–1969, 1981–1983, and 1989–1990.

1. The More Life Expectancy Increases, the More the Difference Increases, but the Greater the Life Expectancy, the Smaller the Difference

Figures 53–4 and 53–5 illustrate the paradox as it may be observed in France: Variations between *départements* show a very strong negative relation between life expectancy at birth among men and the difference in life expectancy between the sexes[10] (see Fig. 53–4), whereas the evolution over a century (see Fig. 53–5) reveals a positive correlation between the two indicators that is just as clear.

This phenomenon, which also is observed in many other countries (Vallin, 1990), is based on the fact that geographic variations are mainly linked to the action of different types of male behavior harmful to health (e.g., alcoholism, especially in the case of France) that shorten male life expectancy and increase the difference between men and women, whereas the evolution over time is essentially linked to improved health that,

[10] As demonstrated in Figure 53–4, this phenomenon is constant over time. The increase in life expectancy shifts the cluster of points without modifying its orientation.

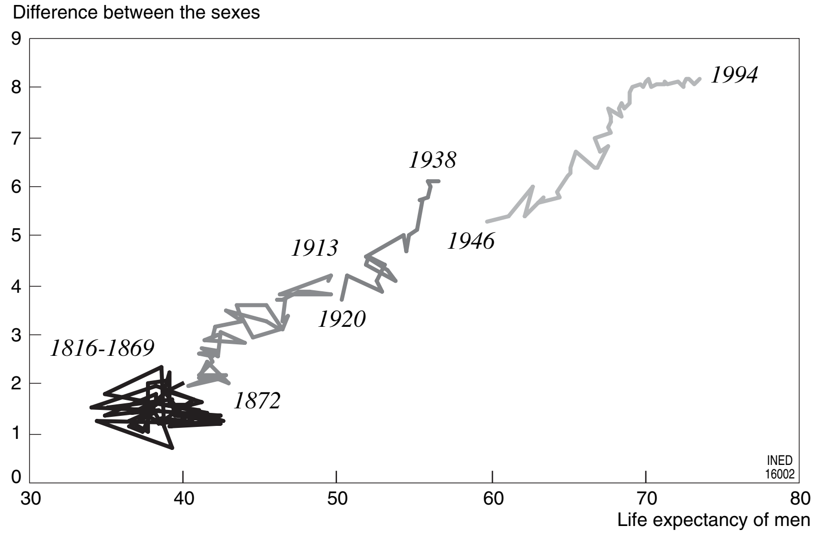

FIGURE 53–5 Correlation between annual variations in male life expectancy and those of the difference in life expectancy between the sexes observed in France since the beginning of the 19th century.

although it increases life expectancy of both sexes, increases the life expectancy of women more because they are able to draw greater benefit from it.

Social inequality in mortality exhibits the same sort of paradox. In past decades, the difference between manual workers and senior executives increased as life expectancy increased. Regional variations also show an inverse relationship because regions where excess mortality among manual workers was greatest were those where life expectancy was lowest (Vallin, 1995). The reason for this is that for social differences and for differences between the sexes, the same causes produce the same effects. Whereas regional differences are very sensitive to behaviors harmful to health (i.e., more widespread among manual workers than among executives), evolution over time is much more sensitive to the capacity to benefit from improved health (i.e., more widespread among senior executives).

This third paradox takes on a special characteristic in Eastern countries, especially in Russia (Meslé and Vallin, 1998). Although geographic variations show that in these countries, as almost everywhere else, a negative correlation exists between the life expectancy of men and the difference between the sexes, in Russia, Hungary, and Poland, the historical evolution only demonstrates a positive correlation until the 1960s. Since then, the correlation has been reversed, with the difference between the sexes continuing to widen while increased life expectancy has stalled or declined. In Russia and elsewhere before the crisis of the 1960s, geographic variations dominated by man-made diseases specifically affecting men contrasted with the historical effects of rapid progress in health conditions, which were more favorable to women. Eastern countries—Russia in particular—completely missed passage to the second phase of the health transition, and their inability to curb the spread of man-made diseases or to fight cardiovascular diseases has resulted in a stagnation or decline in life expectancy and in an increase in the difference in life expectancies between men and women. In Russia, for example, the difference in life expectancy between men and women went from 8.7 years in 1964 to 13.6 years in 1994, whereas male life expectancy fell in the same period from 64.6 years to 57.7 years.

2. Different Roles Played by Different Causes of Excess Male Mortality

The third paradox, far from confusing the issue, substantiates the explanations and examples previously presented. Beyond the biologic differences between the sexes, excess male mortality correlates with two types of causes of death. Certain diseases that may be designated as man-made diseases, whether they are related to individual behaviors harmful to health (e.g., alcoholism, lung cancer, road accidents, suicide), or to risks associated with certain economic activities (e.g., accidents and diseases linked to work), affect in a highly discriminatory manner certain categories of population (i.e., men, when distinguishing the sex, and manual jobs when distinguishing economic activities), and these diseases make up the major part of the geographic variations in mortality within a given country. The evolution of mortality over time is affected more by other causes; in the past, these deaths were caused by infectious diseases, and currently, mortality is affected more by cardiovascular diseases and cancers. Because infectious diseases were initially more unfavorable to women, especially at younger ages and at reproductive ages, their decline since the end of the 19th century had already increased the difference in life expectancy between the sexes. Success since the 1970s in the fight against cardiovascular diseases and to a more modest degree against cancers has mainly benefited women, resulting in an unprecedented difference in life expectancy between the sexes despite a homogenization of behaviors and a reduction in the differences linked to man-made diseases. In countries such as Russia, where man-made diseases (i.e., alcoholism and violence) have a greater impact than anywhere else and where passage to the second phase of the health transition has not yet occurred, both phenomena penalize men much more than women and push excess male mortality to new heights, resulting in a negative reconciliation of history and geography.

VI. THE FOURTH PARADOX: WILL EXACERBATION OF EXCESS MALE MORTALITY ACCOMPANY A REDUCTION IN DIFFERENCES IN LIFE EXPECTANCY?

It would be rash to conclude that an endless increase in the difference in life expectancy between the sexes is inevitable. A fourth paradox suggests that the phenomenon will soon halt. The fourth paradox is that an extreme exacerbation of excess male mortality may accompany a reduction in the difference in life expectancy between the sexes. In France, this is what was brought to light by extrapolating over a period of 100 years recent mortality trends by age and by sex (Vallin and Meslé, 1989). The decline in female mortality was at all ages faster during the last 20 years than that in male mortality, and it is not surprising that the extrapolation led to higher and sometimes quite extravagant excess male mortality ratios at all ages. In this analysis, the ratio of male rates to female rates would exceed 10 against 1 at approximately 50 years of age and would be close to 15 against 1 at approximately 20 years of age, compared with the current figures of 2.5 against 1 and 3.5 against 1, respectively. Despite this incredible increase in excess male mortality, the difference in life expectancy between the sexes would quite quickly reach a peak of 9 years (without ever reaching the current real level in Russia) and drop back at the end of the projection to 7 years, definitely less than the current 8 years. This paradox is explained by the fact that the extrapolation brings the female rates to levels so much lower than male rates that they would require a stronger relative reduction to produce the same effect on life expectancy. Male rates can therefore continue to decline less quickly than female rates (and to worsen excess male mortality) while producing a progression of life expectancy markedly higher than that obtained by females. Except if the extreme age limit were to be pushed back (an assumption that is rarely made in this type of projection) and even if female mortality continued to decline faster than male mortality, the difference in life expectancy between the sexes could no longer increase, and it would tend to decline. The same projection in a country like Russia leads to a completely different result. With increasing male mortality, there is no close limit to the increase in the difference in life expectancies. The facts speak for themselves because the difference is already more than 13 years.

This fourth paradox is not the only reason to hope for a decline in the difference in life expectancy between the sexes, nor is it the main reason. English-speaking countries and Scandinavian countries, which are often ahead in terms of improved health, especially when health status relies on a massive effort in terms of individual prevention, have very clearly shown for a number of years that the difference in life expectancy between the sexes can be reduced by new increases in life expectancy (Fig. 53–6).

In Australia, Sweden, and Norway, the increase in male life expectancy from 70 to almost 75 years during the 1980s and 1990s led to a reduction in the difference between the sexes of approximately 1 year of life expectancy. The same phenomenon has been observed in the United States, albeit at a lower level of life expectancy. Male behaviors harmful to health play a diminishing role, and in these countries, men have partially succeeded in copying the positive behaviors of women in terms of disease prevention and accessing health care. There is no reason why the experience of English-speaking countries and Scandinavian countries should not become generalized, enabling men in most places to eventually regain some of the ground they lost during the 20th century.

At the beginning of the 1960s, to build their model life tables, Ansley Coale and Paul Demeny, made (and lost) the bet that women would increasingly imitate men. Maybe it would be enough today to bet the other way to win and say that men will increasingly imitate women. Will they go so far as to reduce their disadvantage to the strict minimum imposed by biology? That is more difficult to say.

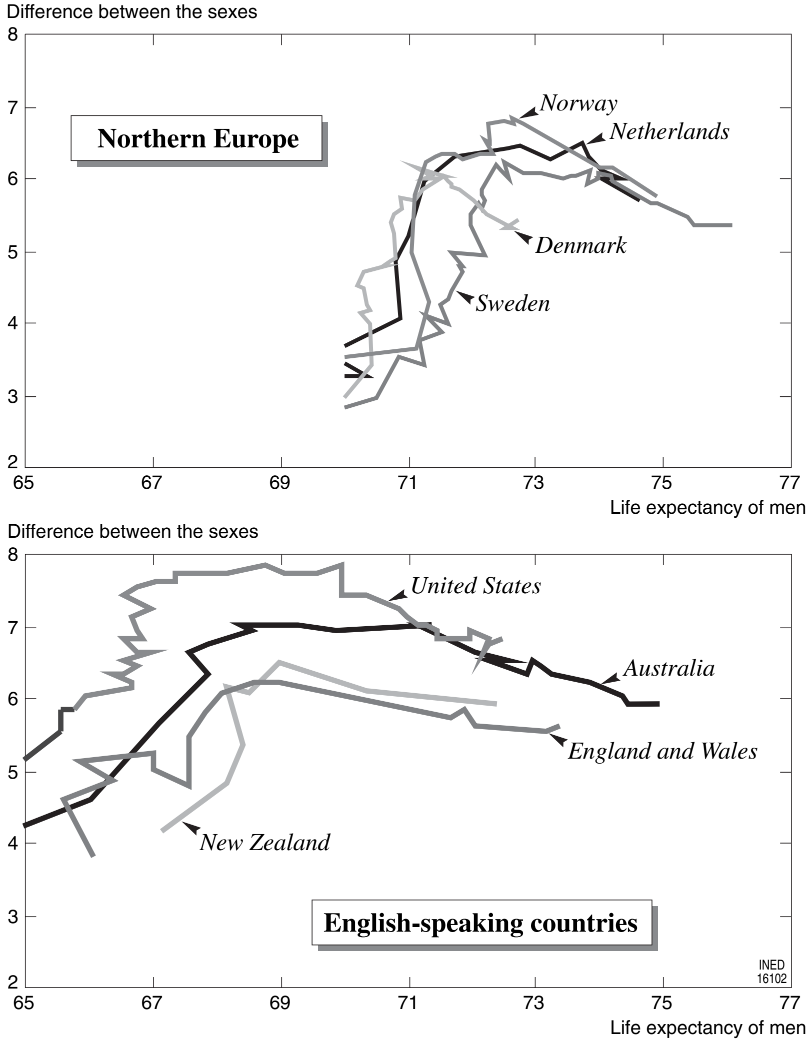

FIGURE 53–6 Relation between the level of life expectancy and the difference in life expectancy between the sexes during recent decades in some English-speaking and Northern European countries.

Social Inequalities in Mortality

TAPANI VALKONEN

Département de Sociologie, Université de Helsinki, Helsinki, Finland

Persons in lower socioeconomic positions die on average younger than those in higher positions. This social inequality has been observed in almost all studies of different populations and using different indicators of socioeconomic position, such as social or occupational class, socioeconomic status, educational attainment, income, and housing characteristics.

Research on social inequalities in mortality has long traditions. In his early 20th century monumental work, *Die Lehre von der Mortalität und Morbidität*, Harald Westergaard (1901) reviewed a large number of studies on mortality by wealth, social class, and occupation carried out in Europe in the 19th century. The classic study on the length of life by Louis Dublin, Alfred Lotka, and Mortimer Spiegelman (1949) dealt with social differences in mortality on the basis of British and North American studies. Antonovski (1967) wrote a review of the studies carried out on social classes, life expectancy, and mortality. According to him:

> Despite the multiplicity of methods and indices used in the 30-odd studies cited, and despite the variegated populations surveyed, the inescapable conclusion is that class influences one's chance of staying alive. Almost without exception, the evidence shows that classes differ on mortality rates.

Research on social inequalities in mortality attempts to answer several questions. To what extent are there differences in the length of life and in death rates between social groups? What causes the existence of such differences? Are these differences lessening or rather increasing? How and why does the size of the differences change? Does the size of the differences vary from one country to another?

There are several reasons for studying these questions. They are important from the point of view of demographic research, because socioeconomic differences are often more discriminatory than other differences between sub-groups of the population. Studies contribute to a better understanding of the determinants of mortality levels and trends. For epidemiologists, social mortality differences provide clues to the causes of diseases. Mortality differences are also important from a social and health policy perspective, because they indicate inequalities in health and well-being.

I. NATIONAL STUDIES ON SOCIAL MORTALITY DIFFERENCES AND METHODS USED

Statistics on mortality by social category do not usually feature in regular statistics. The regular exploitation since 1911 of the British data published by the Registrar General since 1851 provide the only regular time series of mortality by occupation and social class (Fox, 1979; OPCS, 1978). The death rates in these statistics are calculated by relating the deaths, classified according to the last occupation recorded on the death certificates, to the population classified in the same way on the individual census forms. Deaths are usually grouped in a period of 3 to 5 years focused on the census. Social class is based on the classification of occupations into six categories. The three classes ranking highest in the social scale include nonmanual occupations at different levels, and the others include manual occupations.

Figure 54–1 shows age-standardized death rates for men between the ages of 15 and 64 by social class in England and Wales between 1970 and 1972. The death rates are based on two sources; deaths registered between 1970 and 1972 by the age and social class of the deceased person provide the numerator, and a 10% random sample of the population recorded in the 1971 census (mean population) by age and social class provides the denominator.

Mortality increases with decreasing social class. The age-standardized mortality of the 15- to 64-year-old class V (i.e., unskilled manual workers) is 80% higher than that of class I (i.e., professional).

This classic method has been used in other countries as well as in the United Kingdom (Mielck and do Rosário Giraldes, 1993). In many countries, however, it cannot be used, because the death certificate does not indicate the social category of the deceased person. Another serious limitation is that the results are likely to be biased, because the information on the occupation of decedents and persons in the risk category comes from different sources. Even though the same question is asked in the census and on the death registration form, the accuracy of the information may differ. There is evidence that this bias (often called numerator/denominator bias) can be substantial (Lévy and Vallin, 1981; Fox 1979). Because of this increased bias, the results on social mortality presented in the Registrar General's Decennial Supplement for mortality in the 1981 census (OPCS, 1986) are considered to be less reliable than those preceding them (Thatcher, 1986).

To avoid problems associated with the use of unlinked records, other methods are employed. These are usually based on the linkage of death records registered by the civil authority with population records. As early as 1865, Chapin (Antonovski, 1967) had compared death rates among taxpayers and nontaxpayers using linked records. He assigned every person who died in 1865 in Providence, Rhode Island, to the taxpayer or nontaxpayer group on the basis of census and tax records, and he calculated the death rates for both groups. He found the rates for the nontaxpayers to be more than double those of the taxpayers.

The idea of linking individual death records to census records was applied on a large scale for the study on differential mortality in the United States carried out by Evelyn Kitagawa and Philip Hauser (1973). About 340,000 of the deaths that occurred during the period of May to the end of August 1960 were matched with the 1960 census records to obtain social and economic characteristics of decedents as reported in the 1960 census. Death rates were calculated by occupation, level of education, and income. According to the investigators, the collected education data are more reliable indicators than those concerning occupation and income. The approach of death does change the occupational system and income

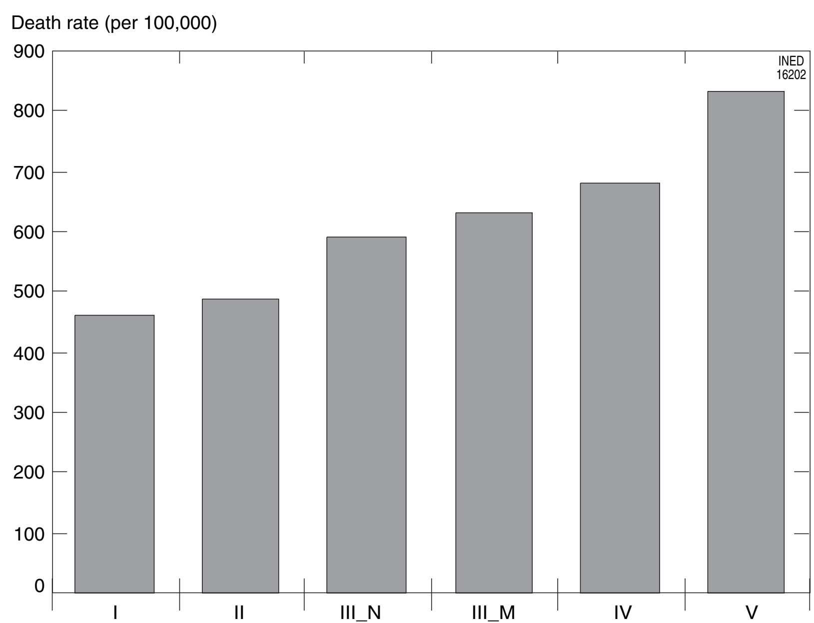

FIGURE 54–1 Age-standardized death rates (per 100 000) by social class of men between the ages of 15 and 64 years in England and Wales, 1970 to 1972.

situation, but the educational level is unaffected by it. As anticipated by the authors of the study, mortality varied inversely with level of education. For example, among white persons between the ages of 25 and 64 years, men with 4 years or more of college education had 30% lower mortality than the whole age group. Among women, the difference was 22%.

Another version of linking records back to census records involves following a sample of persons from the census, as in the longitudinal prospective studies common in epidemiology. An early example of this approach was the study carried out in France by the National Institute of Statistics and Economic Studies (INSEE), in which a sample of 800,000 persons from the 1954 census was followed for mortality (Desplanques 1976). The data made it possible to measure mortality by social-occupational group, level of education, and marital status. Another longitudinal study of 800,000 persons from the census was undertaken in 1975 (Desplanques, 1984). Table 54–1 shows the probabilities of death for men between the ages of 35 and 60 years during first 5 years after each of these two studies.

Results for the two periods show the expected gradients: lowest mortality in the group for administrators and professionals and highest mortality among unskilled workers. The ratio between the two extreme social categories was 2.8 : 1 between 1975 and 1980.

The ranking of the social-occupational categories by mortality remained almost constant during the 20-year period separating these two studies. Nevertheless,

TABLE 54–1 Probabilities of Dying in France for Men between the Ages of 35 and 60 Years by the Main Social-Occupational Categories for 1955 to 1959 and for 1975 to 1980

Social-occupational category	Probability of dying (%)	
	1955–1959	1975–1980
Administrative and professional groups	12.7	9.1
Teachers	12.0	10.1
Foremen	15.9	11.6
Technicians	15.0	11.8
Farmers	15.3	12.0
Middle-level administrative groups	15.7	12.4
Employers in industry and commerce	18.2	13.6
Non-manual workers	19.4	13.9
Skilled workers	20.8	17.2
Semi-skilled workers	21.3	18.7
Agricultural workers	21.8	20.2
Unskilled workers	27.7	25.4
All economically active	19.0	15.0

From Desplanques, 1984.

although mortality declined in all categories, the effect was most evident in the most favored social groups. Differences in social mortality increased. Between 1975 and 1980, life expectancy at the age of 35 for male teachers was 43.2 years, but for unskilled male workers, it was 34.3 years (i.e., a difference of 8.9 years), whereas between 1955 and 1959, the difference was 8 years.

Although France had been one of the first countries to produce reliable statistics on social inequalities in mortality, work on measuring and following the development has remained sporadic (Leclerc *et al*., 2000).

Another example of a longitudinal study based on linked records is the longitudinal study for England and Wales, based on a 1% population sample (about 500,000) from the 1971 census. Data on deaths, as well as some other demographic events occurring in this population, have since been linked to the sample records. Detailed studies on different aspects of socioeconomic mortality differences have been carried out using this data set (Harding *et al*., 1997; Goldblatt 1990).

Studies based on linked records offer better possibilities for analyzing social differences in mortality than cross-sectional unlinked studies, but they still have limitations. Manual linking of census and individual death records is a time-consuming and very expensive process. The costs involved make the study of large populations impossible, and samples must be used. Although the samples used in the three studies described here were large enough for a statistically satisfactory analysis of differences in total mortality, the possibilities for detailed analysis by cause of death and in subgroups of the population are limited. Moreover, because of problems in linking the census and death records, the quality of data is not always very good. In the Kitagawa and Hauser study (1973), for example, 23% of the decedents could not be linked to any census record.

Longitudinal linked records of a population sample can best be carried out in countries in which a system of personal identification numbers makes the computerized linkage of records possible. Mortality studies (Borgan, 1996; Vågerö and Lundberg, 1995; Valkonen *et al*., 1993; Andersen, 1985) have been carried out in Denmark, Finland, Norway, and Sweden. Practically all registered death records can be linked to census records. In Finland, for example, only 0.3% of all deaths between 1986 and 1990 could not be linked to the 1985 census records (Valkonen *et al*., 1993). An additional advantage of the system of personal identification numbers is that information from other registers, such as tax and pension registers, can also be used.

Table 54–2 shows comparative death rates by occupation-based social class in Finland, on the basis of death records for 1986 to 1990, linked to the records of the 1985 census (Valkonen and Martikainen, 1997). For the purposes of calculating death rates by social class for the economically active population, only those who were employed in 1985 were assigned to social classes. All economically inactive persons and persons who were unemployed were excluded. For the purpose of calculating the death rates by social-occupational category for the whole population, retired, disabled, and unemployed persons were classified on the basis of their former occupation obtained by record linkage to the 1970 census. Nonworking family members (mainly housewives) were classified on the basis of the occupational category of the head of the household. The *All* column in Table 54–2 shows mortality differences for the whole population, not just for those who were employed in 1985.

The results for the economically active and the whole population are clearly different, particularly among women. Mortality in each social-occupational class is lower for the economically active, because the mortality of retired and other non-employed groups is, at an equal age, much higher than that of employed persons. More importantly, the differences between classes are clearly smaller among the economically active than in the whole population, because the proportion of economically inactive persons is higher in the manual classes. Among economically active women, class differences are much smaller than those among men.

This difference between the economically active population and the whole population is significant. Findings on social mortality have often only represented the economically active population, because access to information on the former occupations of non-employed persons is more difficult than for the employed. Such findings, however, underestimate the real magnitude of social differences. The amount of bias diminishes when the follow-up time becomes longer (Lévy and Vallin, 1981; Valkonen and Martikainen, 1979).

Different approaches have been used in countries where, for legislative or other reasons, studies based on the linkage of records on individuals were not possible. One example is ecologic research, in which death rates in particular geographic areas are correlated with

TABLE 54–2 Age-Standardized Mortality and Relative Age-Standardized Mortality for 1981 to 1985 by Social Class for the Economically Active Population in 1980 and for the Whole Population, with Distributions of Persons by Social Class for Men and Women between 35 and 64 Years Old in Finland

Social class	Age-standardized mortality rates (per 100,000)		Relative age-standardized mortality (upper white-collar employees = 1)		Population distribution (%)	
	Econ. active	All	Econ. active	All	Econ. active	All
Men						
Upper white-collar employees	595	768	1.00	1.00	15.3	13.0
Lower white-collar employees	709	1062	1.19	1.38	17.0	16.3
Skilled workers	781	1229	1.31	1.60	40.1	39.8
Unskilled workers	944	1744	1.59	2.27	7.1	9.8
Farmers	702	1068	1.18	1.39	13.1	13.8
Other self-employed persons	843	898	1.42	1.17	7.4	6.2
Others	391	2724	0.66	3.55	0.0	1.2
All	749	1176	1.26	1.53	100.0	100.0
Population (in 1000s)					2990	3839
Women						
Upper white-collar employees	242	344	1.00	1.00	9.0	9.3
Lower white-collar employees	267	393	1.10	1.14	38.4	32.5
Skilled workers	280	444	1.16	1.29	24.6	27.0

socioeconomic indicators and other characteristics of those areas (Wilkins *et al.*, 1989). This method is inexpensive and generally feasible, but it suffers from the usual weaknesses of ecologic analyses. The results of ecologic studies are therefore not comparable with those of studies in which data on individuals are used. The aggregate-level relationship between the socioeconomic status and mortality of populations in specific areas may be quite different from individual-level association between the same variables.

II. MORTALITY DIFFERENCES BY AGE

All examples of social mortality differences presented have dealt only with the working-age population. The extent of differences between social classes varies considerably with sex and age. Figure 54–2 shows excess mortality by age of men and women of different social-occupational groups in relation to that of upper-class nonmanual employees in Finland (Valkonen *et al.*, 1993). For the youngest age groups, the social classification is based on the social-occupational category of the head of the household.

With few exceptions, the order of occupational classes is the same in all age groups for both sexes. Mortality is highest among manual workers, second highest among farmers, and third highest in the lower nonmanual class (Table 54–3). It is always lowest in the upper nonmanual class, which is set at 100 in Figure 54–2. The relative differences are the smallest among children and elderly people and most pronounced among young adults 25 to 45 years old. The differences even exist in the much older groups. Among females, the age pattern of mortality differences is similar to that among males, but the relative differences are clearly smaller in all age groups, as shown in Table 54–2 for women between the ages of 35 and 64 years.

Age-specific death rates can be used to calculate life tables by social class. The difference in life expectancy at birth between upper nonmanual employees and manual workers was about 6 years for males and 3 years for females in Finland in between 1986 and 1990 (Valkonen *et al.*, 1993). The extent of the differences depends on the classification used. A more detailed classification of manual workers would show larger differences than the 6 years in male life expectancy at birth.

In England and Wales, the difference in life expectancy at birth between the social classes I/II (i.e.,

TABLE 54–3 Life Expectancy at Birth and at 30 Years of Age by Social Class and Sex in Finland, 1986 to 1990

Social class	Men		Women	
	e_0	e_{30}	e_0	e_{30}
Upper nonmanual employees	75.3	46.6	81.1	51.9
Lower nonmanual employees	73.0	44.4	79.9	50.8
Manual workers	69.2	40.9	78.1	49.1
Farmers	71.6	43.3	78.5	49.6
Total	70.8	42.4	78.8	49.8
Difference between the extremes	6.1	5.7	3.0	2.8

From Valkonen et al., 1993.

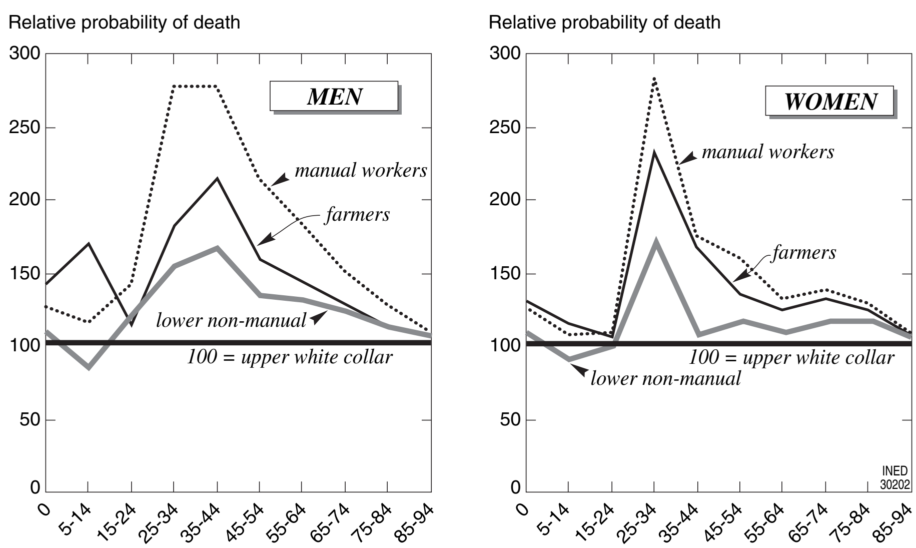

FIGURE 54–2 Relative probability of death by age (10-year age groups) and occupational class between 1986 and 1990 for men and women (upper white-collar employees taken as base 100).

upper nonmanual employees or self-employed technicians) and classes IV/V (i.e., manual workers) was estimated at 5 years for men and 3 years for women in between 1987 and 1991 (Hattersley, 1997). No recent estimate of life expectancy by social category is available for other countries.

III. MORTALITY BY CAUSE OF DEATH

The first step toward a better understanding of social inequalities in mortality is to study them by cause of death. As an example, Table 54–4 shows the higher mortality ratios of manual workers to upper white-collar employees of 35 to 64 years old in Finland in the 1980s for selected causes of death.

Among men, mortality is higher among manual workers than nonmanual workers for all causes of death except cancer of the intestines and rectum. Although the direction of the difference between the social classes is practically the same for all causes of death, the extent varies. Male manual workers have at least 2.5 times higher mortality than upper nonmanual employees due to alcohol poisoning, diseases of the respiratory system, and lung cancer. As for males, female manual workers also have higher mortality for almost all causes of death, except for cancers of the intestine and rectum and, in this case, breast cancer.

Table 54–5 shows the contribution of the most common causes of death to the difference in life expectancy at the age of 35 years between workers and upper nonmanual employees in Finland at the end of the 1980s. The total difference is 5.5 years for males and 2.7 years for females. For both sexes, the main causes of differences are ischemic heart disease and other cardiovascular diseases. These account for 46% of the male difference and 68% of the female difference in life expectancy. Among males, lung cancer, respiratory diseases, and accidents provide marked contributions to the inequality of life expectancy between social classes.

TABLE 54–4 Ratio of Age-Standardized Mortality Rates by Cause of Death of Manual Workers to that of Upper Nonmanual Employees by Sex for Ages 35 to 64 Years in Finland, 1981 to 1990

Cause of death	Men	Women
Malignant neoplasms	1.54	1.00
Stomach cancer	1.54	1.48
Cancer of intestine and rectum	0.97	0.88
Lung cancer	2.93	1.82
Breast cancer	—	0.68
Other cancers	1.14	1.09
Circulatory diseases	2.01	2.10
Ischemic heart disease	2.02	2.37
Cerebrovascular diseases	1.90	1.73
Other diseases	2.15	1.81
Respiratory diseases	3.58	2.06

Accidents and violence	2.53	1.44
Road accidents	1.68	1.31
Alcohol poisoning	3.89	—
Suicide	2.33	1.15
All causes	2.01	1.40

From Valkonen *et al*., 1993.

IV. WHY ARE THE SOCIAL DIFFERENCES IN MORTALITY LESS AMONG WOMEN THAN AMONG MEN?

In all countries for which reliable data exist, the social differences in mortality are less among women than men. Seppo Koskinen and Tuija Marelin (1994) tried to understand this phenomenon by using data for men and women 35 to 64 years of age in Finland. They showed that the results did not depend on the indicator chosen to define the social-occupational status. For each of the four social-occupational indicators used in the study, the inequalities between women were much less than those between men.

Analysis of the differential mortality by cause of death showed that for cardiovascular diseases, women's relative socioeconomic differences were slightly higher than those of men. For other diseases affecting both sexes, the relative social mortality differences are practically the same, except for respiratory diseases, for which the mortality differences are higher

TABLE 54–5 Contribution in Years of Selected Causes of Death to the Difference in Life Expectancy between Upper Nonmanual Employees and Manual Workers by Sex in Finland, 1986 to 1990

Cause of death	Men	Women
Lung cancer	0.68	0.05
Breast cancer		–0.12
Other cancers	0.19	0.16
Ischemic heart disease	1.75	0.91
Other cardiovascular diseases	0.79	0.91
Respiratory diseases	0.50	0.18
Other diseases	0.50	0.34
Accidents	0.55	0.15
Alcohol poisoning	0.21	0.04
Suicide	0.36	0.08
All causes	5.53	2.73

From Valkonen *et al*., 1993; for method, see United Nations, 1988.

among men. The differences are also more marked among men for accidents and violence.

The fact that the social range of total mortality is much greater among men than among women is partly explained by this steeper social gradient for violent death among men. The main reason, however, is that the distribution of deaths by causes varies according to sex. Cancer of the breast, which according to the data employed by Seppo Koskinen and Tuija Martelin is responsible for 9% of female deaths, is practically nonexistent among men. Deaths from breast cancer also fall with social-occupational status, and this significantly reduces the social range of female mortality. Cancers other than those of the stomach, intestines, lungs and breast, whose social gradient is very slight, account for at least one-fourth of the deaths of women and only one-tenth of those of men. If the same distribution of deaths by cause among men is applied to women, the social gradient of mortality among women becomes quite similar to that of men. According to these Finnish data, the big difference in social range between men and women mainly results from the difference in structure by cause of death. We do not know to what extent this result can be applied to other populations and age groups.

V. EXPLANATIONS OF SOCIAL INEQUALITIES IN MORTALITY

The most frequently used explanatory framework for social mortality differences is that which appeared in the *Black Report*, set up in Great Britain in 1980 by a task force presided over by Sir Douglas Black (Townsend and Davidson, 1982). This framework distinguishes four main types of explanation: statistical artefact, natural and social selection, material and structural causes, and cultural and behavioral factors. These explanations, which had already been put forward by other authors (Behm and Vallin, 1982; Vallin, 1979), were also the object of further developments (MacIntyre, 1997; Vågerö and Illsley, 1995; Davey Smith *et al*., 1990).

Social and mortality differences could only be a *statistical artifact* if they were viewed as mere measurement errors. Admittedly, such errors may effectively bias the extent of the observed differences, but there is considerable proof that the differences are quite real. Problems of measurement tend more frequently to underestimate rather than overestimate them.

According to the *selection hypothesis*, the association between social position and mortality is in line with the reasoning that personal health determines social position and not *vice versa*. People are not in poorer health because they belong to disadvantaged social categories; they belong to these social categories because their health is less good than the health of people in other categories. Young people in poor health have greater difficulty in completing their studies, and adults with health problems move down the social scale. Although direct measurement of the role of health in this selection bias is difficult, most investigators have concluded that social mobility due to health reasons is not a highly determinant factor in social mortality differences (Davey Smith *et al*., 1994; Wilkinson, 1986; Fox *et al*., 1985).

Another type of selection, sometimes called *indirect selection*, may contribute to social mortality differences because some *confounding factors* are capable of affecting the social-occupational status of persons and their health and mortality. High social status of the parents, good school performance, and certain psychological and physical characteristics, for example, may favor access in adulthood to a socially privileged status. The inherited lifestyle model (especially behavior in health matters) may also contribute to health and chances of survival. Consequently, a part of the relation observed between social status and adult mortality may not depend on the status itself. Unfortunately, no recent empirical study enables us to appreciate these distinctions.

The materialistic/structural and behavioral/cultural explanations are two additional elements in an interpretive outline that stresses—through the risk factors involved—the effects of social position on a person's health. It explains why those benefiting from a higher social status are also less exposed to the risks of death than those of a lower status.

In the *materialistic/structural* view, persons of a disadvantaged status suffer from health problems inherent in material living conditions, such as precarious living conditions, difficult working conditions, and insufficient income for ensuring correct nutrition and health care. This type of explanation seems plausible for the past and for less-developed countries, but it is less certain that poverty and precarious living conditions are pertinent factors today in developed countries. Results for all countries indicate that differences in mortality are not solely between the poor and the rest of the population, but that there are also stepwise differences within the middle and upper classes. Working conditions are more discriminatory and, even though they tend to become homogeneous, their role in social mortality differences persists in the most advanced societies.

According to the *cultural/behavioral explanation*, socioeconomic mortality differences result from differences in the prevalence of risk behaviors, such as smoking, alcohol abuse, lack of exercise, and unhealthy dietary habits. For example, class differences in the prevalence of smoking may account for a substantial part of the socioeconomic differences in mortality from lung cancer and from coronary heart disease, because smoking is a risk factor for both diseases and because there are differences in smoking habits among social classes in most countries.

Literature on the subject has suggested hypotheses to explain social mortality differences other than those put forward by the *Black Report*. One of these concerns the effects of biologic programming that is set up *in utero* or during infancy (Barker, 1991). According to this hypothesis, differences in present social mortality differences may correlate with conditions prevailing in a previous generation. These conditions would have influenced maternal health, which would have influenced the growth and development of the fetus and child and the probability of suffering from a disease or of dying prematurely at an adult age. Because adults in a disadvantaged social category have experienced precarious living conditions since their childhood, their higher mortality could be attributed to the conditions prevailing during their first years of life. The validity of this hypothesis has yet to be established.

Another hypothesis is that the higher mortality of persons forming part of a disadvantaged social category reflects psychosocial factors, particularly those relating to work, and is more frequent in the categories from the lower part of the social spectrum (Marmot *et al*., 1997). Differences in access to health services and their use also contribute to social inequalities in mortality (Keskimäki *et al*., 1997).

The theories and hypotheses about the causes of social differences in mortality are numerous, but few empirical investigations have verified the validity and measured the role of the risk factors evoked. Of all the studies aiming to explain the social differences in mortality, the one most frequently cited is the so-called Whitehall investigation, carried out with about 17,000 British civil servants (Marmot *et al*., 1984). According to this study, only one-fourth of the considerable differences in mortality by coronary diseases observed among five grades of civil servants could be attributable to those involving smoking, physical activity, blood pressure, or cholesterol level. Of all the risk factors, only smoking varied significantly from one category to the other, and the explication for differences in mortality must essentially be attributed to other risk factors and behavior.

The authors of the study also suggested another possible explanation. Exposure to specific risks favoring specific causes of mortality, such as those of the Whitehall study, cannot take account of all the observed differences in mortality. The great similarity of social differences for most of the causes of death in many national studies cannot be explained by employing a list of specific risk factors. Michael Marmot and his colleagues (1984) think that social inequalities in mortality are largely attributable to "general risk factors" that concurrently influence most causes of death. Psychosocial stress could be one of these factors (Williams, 1990). A new follow-up study (Whitehall II) is being carried out in an attempt to find a better explanation of the differences in morbidity and mortality observed between different categories of civil servants in Britain (Marmot, 1996).

According to some other studies, a greater share of the social inequalities of mortality by coronary diseases appears attributable to some disparities in the prevalence of risk factors. In most cases, a large part of the difference remains unexplained (Kaplan and Kiel, 1993).

The empirical studies seeking an explanation of the social-occupational differences are generally inconsistent and do not reach any firm conclusion. The poverty of these results may reflect the nature of the problem—that the explanation of the differences varies from one cause of death to another, from one country to another, and according to the era.

The persistence and even worsening of social-occupational mortality differences have preoccupied a number of governments and the World Health Organization (WHO). A very complete British report (Independent Inquiry into Inequalities in Health, 1998) included 10 pages of recommendations for health policies and programs aimed at reducing the inequalities of health and mortality. Some of these recommendations are aimed at a global level of society (e.g., reduction in the inequality of incomes), but others are very specific (e.g., improvement in access to therapy for replacing nicotine). No study exists, however, for measuring the effectiveness of the policies for reducing the social differences in mortality.

VI. INTERNATIONAL COMPARISONS

Although the level of mortality is everywhere higher among persons in the most disadvantaged social positions, it is not clear to what extent the size of this difference varies from country to country. International comparisons of social-occupational mortality differences are difficult to carry out. Reliable data exist only for a few countries. Even when data do exist, there are differences between studies in terms of time periods and age bands covered, social-occupational indicators used, coverage (e.g., exclusion of economically inactive persons), measures of mortality, and quality of data. There is no generally agreed method for measuring the magnitude of the differences even if the data problems are resolved. A large number of inequality measures have been constructed, and the choice of these may substantially influence the results. It is therefore not surprising that the results of attempts to compare the sizes of socioeconomic mortality differentials have been inconsistent (Kunst and Mackenbach, 1994c).

The diversity of the results observed from one country to another was studied in an ambitious project covering 11 countries in Western Europe, the United States, and three socialist countries in Central and Eastern Europe, for which representative mortality data were available at national level, according to educational and social-occupational categories (Kunst, 1997; Mackenbach *et al*., 1997). These data were collected between 1980 and 1990, and generally were for male adults between 30 and 64 years old.

In the 14 countries where this information was available, the death rate among manual workers was higher than that for nonmanual workers, and the relative excess mortality of the manual workers was remarkably similar from one country to another. Nevertheless, some larger differences were observed in France, the Czech Republic, Finland, and (especially) Hungary than in other countries (Kunst, 1997).

It has been possible to measure these differences in the cause of death in 11 West European countries and in the United States. The excess mortality of manual workers is manifest for each of the nine groups of mortality causes employed, except for one notable exception: ischemic heart diseases. No excess mortality can be observed for this group of causes in France, Switzerland, Italy, and Spain. In Portugal, the mortality rate for ischemic heart diseases was even lower among the manual than the nonmanual workers. It is possible, however, that this exception is only an apparent one. Many of the deaths from ischemic diseases are confused with other cardiac causes, or they remain ill defined (Meslé and Vallin, 1988). This problem of data quality is often more acute for the most disadvantaged social categories. The social differences in causes of death other than ischemic heart diseases were more marked in those of the southern countries than in those of the north of Europe.

In an attempt to explain the weak social discrimination of ischemic heart diseases in southern Europe, Anton Kunst (1997) has suggested that some specific factors have contributed to protecting people there against these diseases, such as a traditional diet comprising a high consumption of fish and vegetable oil and a traditionally moderate consumption of alcohol. These factors particularly have favored the most disadvantaged social categories.

Differences in mortality by social class are higher in Finland and France than in other countries of Western Europe. In both countries, alcohol-related mortality is a contributing factor. In France, death by cancer of the digestive system or cirrhosis of the liver—for which the consumption of alcohol is the main risk factor—is seven times higher among unskilled workers than in the higher social-occupational categories (Desplanques, 1984). Similarly, accidental and violent deaths in Finland, which play an important part in the mortality differences for all causes, are closely linked to the Finnish drinking habits; according to the information available on death certificates, one-half the Finnish adult men who died a violent death were inebriated (Mäkelä, 1998). In Finland, alcohol-related deaths account for one-fourth of the difference in life expectancy between manual and nonmanual workers (Mäkelä *et al*., 1997).

VII. TRENDS IN SOCIAL MORTALITY DIFFERENCES

The problems encountered in studying trends in mortality differences are similar to those in making international comparisons. It is difficult to obtain comparable data, and even when data exist, the conclusions may depend on the population groups covered and the indicators of inequality used.

Anton Kunst (1997) compared some evaluations of the extent of differences in mortality by education level and social class for men between the ages of 50 and 59 years in Finland, Norway, France, and Italy (Turin) during the first and second halves of the 1980s. In all these countries, the differences have tended to increase. An increase in the differences for men 40 to 54 years old in the United States has also been observed. The Kunst results do not only apply to a limited age group. Other data clearly show that, since the 1980s, the relative differences in social mortality have increased in all developed countries where measurement was possible. This increase in the social range of male mortality at working ages was already apparent in Sweden and Spain in the 1970s (Diderichsen and Hallqvist, 1997; Regidor *et al*., 1995) and since the 1960s in France (Desplanques, 1984).

Figure 54–3 illustrates the increase in differences between educational levels observed in Finland since 1971 for life expectancy according to sex at the age of 35. Men with a higher education had a life expectancy in 1970 that was 4.3 years more than those with a lower one. The difference remained almost the same until the

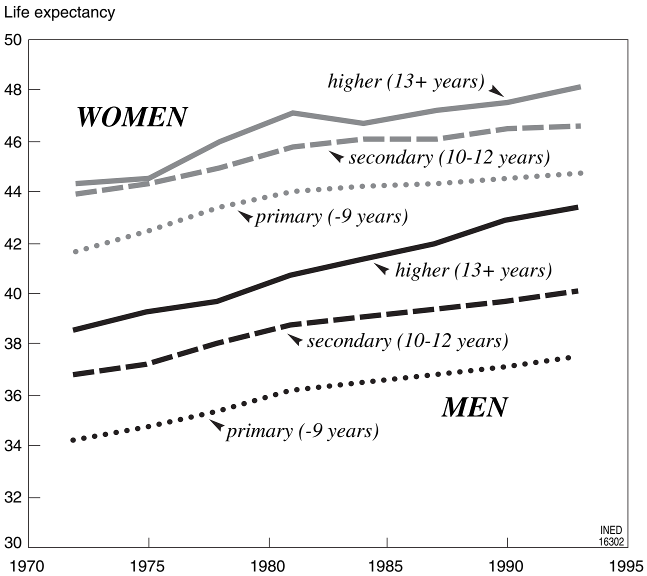

FIGURE 54–3 Life expectancy (years) at age 35 according to sex and level of education in Finland between 1971 and 1993.

end of the decade, but since the early 1980s, it has grown rapidly, reaching up to 5.9 years in the early 1990s. Among women, the difference grew in the same period from 2.7 to 3.4 years. Differences by occupational category have followed similar trends.

Some data for the trend of life expectancy by social class are available for England and Wales. They show that the difference in life expectancy at birth between the classes I/II (i.e., professional, managerial, and technical occupations) and IV/V (i.e., partly skilled and unskilled occupations) increased by almost a year between 1979 and 1981 and between 1987 and 1991 among men and women (Hattersley, 1997).

This increase in social mortality differences contradicts the objective advocated in 1985 by the Regional Bureau for Europe of the WHO: "By the year 2000, the actual differences in health status between and within countries should be reduced by at least 25%" (WHO, 1985). The reasons for this failure have not been analyzed in detail, but it has been suggested that the increase might reflect the general increase in social inequalities and income differences (Carrol and Davey Smith, 1997). Although this explanation is valid in certain cases, it does not provide a sufficient explanation. Differences in mortality have increased in countries where income differentials have increased (e.g., Great Britain) and in countries where they have decreased (e.g., Finland).

The principal common factor in the increased social mortality differences is the decline in cardiovascular deaths and especially in deaths from ischemic heart diseases—a decline that has been more rapid among persons with the highest education or employed in nonmanual occupations. In the Nordic countries and the United States, death rates from heart diseases probably have not always been higher among manual than nonmanual workers. In the United States and in England and Wales, this has been recognized only since the 1950s or 1960s (Kunst, 1997; Marmot *et al.*, 1978), and it has been true for Sweden and Norway only since the 1960s and 1970s (Diderichsen and Hallqvist, 1997; Borgan, 1996). Similarly, scarcely any social differences in mortality due to ischemic diseases were observable in France, Switzerland, Italy, or Spain in the 1980s, and even the reverse is the case in Portugal. In all the countries for which data are available, a more rapid decline in deaths from cardiovascular or ischemic heart disease has been observed among men of working age from the upper, rather than the lower, socioeconomic groups. This is the major reason for the increase in social inequalities in mortality.

This increase in social mortality differences, largely due to greater deviations for cardiovascular diseases, does not necessarily imply that social-occupational inequalities in mortality will increase in the future. The rapid decline in deaths from cardiovascular diseases in the socially privileged classes shows that this type of death has become avoidable and that substantial advances are still possible. Although the most favored social categories have benefited most from this advance, this is probably because they have changed their health behavior more rapidly (e.g., diet, smoking, physical activity) and because they have had better access to new medical treatments, such as coronary bypass and angioplasty (Keskimäki *et al.*, 1997). Doubtlessly, the most disadvantaged classes will eventually adopt the same behavior in health matters and benefit from the new medical techniques when these have become routine treatments.

Cardiovascular diseases are not the only conditions that have contributed to an increase in the differences. The data concerning the part played by other causes are not always available, and it is difficult to generalize. It appears, however, that there is no uniformity between countries in the trend of the mortality profiles other than for cardiovascular diseases. For example, although death through lung cancer has contributed to accentuation of the social mortality differences in certain countries, this was not the case in Finland between 1980 and 1990. Although death through alcoholism was one of the major causes for the increase in mortality differences in Finland during the 1980s and, to a lesser extent, during the 1990s (Valkonen and Jalovaara, 1996), there is no information concerning such processes in other countries. Changes in differences in mortality result from a complex combination of different and even opposite trends for various causes of death, which may vary by sex, class and period. It is most unlikely that a single explanation could account for this.

Geographic Variations of Mortality

GRAZIELLA CASELLI AND JACQUES VALLIN

Dipartimento di Scienze Demografiche, Università degli Studi di Roma "La Sapienza," Rome, Italy

Institut national d'études démographiques (INED), Paris, France

Mortality varies according to sex (see Chapter 53), to social background (e.g., social class, social-occupational category, level of education; see Chapter 54), to a variety of individual characteristics (e.g., weight, height, marital status), or to collective criteria (e.g., religion, ethnic origin). Mortality also varies according to geographic location. This statement may seem obvious, given the differences between situations observed throughout the world, but such differences also can be observed within a single country. The finer the territorial division, the more we find differences; geographic diversity exists within a single region or a single province and at all levels in the hierarchy of administrative territorial divisions.

In this chapter, we first provide an overview of this diversity.[1] Later, we demonstrate that geographic variations are not necessarily the same for different components of mortality. For example, the patterns of child mortality may be different from those of adult mortality, whereas cause-specific mortality patterns may sometimes show striking contrasts. In the same way, geographic variations of mortality may depend on sex, social class, or other factors.

Geographic variations of mortality are partly linked to the particular history of each country, region, or other geographic entity. For this reason, geographic patterns of mortality necessarily change over time, even if they do show some constant features. In some cases, we observe the persistence of specific patterns over long periods, whereas in other places, the situation may undergo a complete reversal.

We examine the different factors that can explain geographic variations of mortality and see to what extent they can be attributed to variations in the composition of the populations of different geographic units, to geographic factors in the strict sense of the term (e.g., climate, altitude), or to socioeconomic, cultural, and environmental factors (e.g., occupation, eating habits, smoking, industrial pollution).

I. A GREAT DIVERSITY OF SITUATIONS

1. Inequalities on a World Scale

The most noticeable geographic difference in mortality is that which can be established between different world populations. This can be observed by referring to differences between countries. Over the past several decades, the United Nations has regularly published estimates of life expectancy at birth for country.[2] Figure 55–1 and Table 55–1 provide data for the 1995–2000 period; the life expectancy data are for both sexes taken together. The map was obtained

[1] A more detailed description of geographic variations of mortality and health can be found in numerous specialized atlases (Britton, 1999a, 1999b; Salem *et al.*, 1999; Jozan and Prokhorskas, 1997; Merenne *et al.*, 1997; Dorling, 1995; Potrykowska and Clarke, 1995; Plane and Rogerson, 1994; Peters et Larkin, 1993; Holland, 1988, 1991, 1993; Bähr *et al.*, 1992; Decroly and Vanlaer, 1991; Union géographique internationale, 1990, 1991; Clieff and Haggett, 1988; Yue Lu, 1987; ISTAT and ISS, no date).

[2] Some of these estimates may be criticized. Nonetheless, we provide them here as they are given, because this set of data has the advantage of being complete and is sufficient to support our point in this chapter.

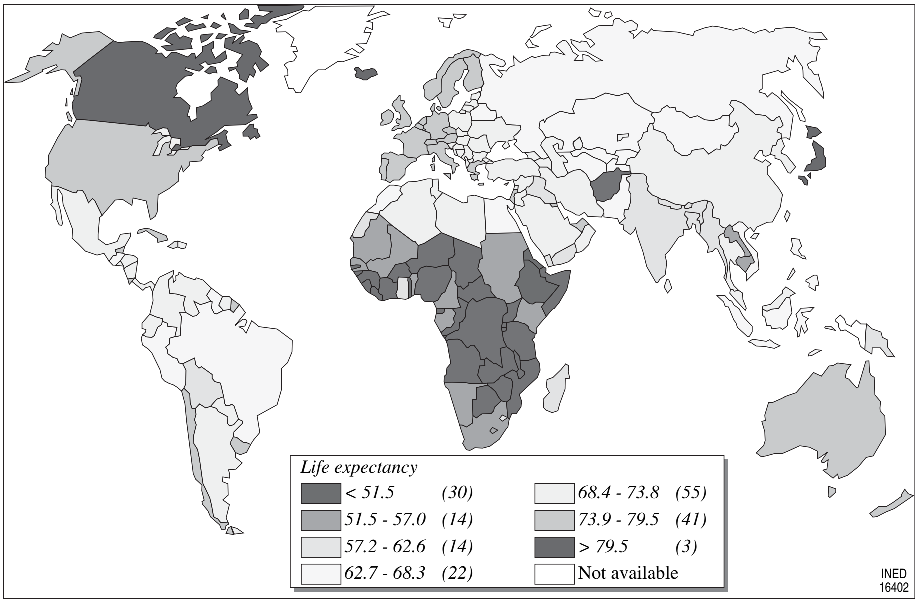

FIGURE 55–1 Life expectancy at birth for both sexes between 1995 and 2000: inequalities between different countries of the world. (From United Nations, 2001.) (Figure 55–1 also reproduced in color plate section.)

by distinguishing seven classes of life expectancy defined on the basis of the simple average, *m*, and the standard deviation, σ, of the 189 values observed.[3] The central class covers $m \pm \frac{\sigma}{4}$, and on either side, each class represents one-half of a standard deviation.

According to these estimates, at the end of the 20th century, life expectancy ranged from 37.2 years in Sierra Leone to 80.0 years in Japan. On the map, we can see a clear opposition between a region of low life expectancy covering all the countries of sub-Saharan Africa and (in a less homogenous way) a substantial part of Southern or Southeast Asia and Oceania (from Afghanistan to Papua New Guinea) and a region of very high life expectancy, occurring mainly in the most developed countries (i.e., Japan, North America, Europe, Australia, and New Zealand) but also extending toward less developed countries (i.e., Central America, northern and southern parts of South America, Middle-East, China, and neighboring countries). Each of these two regions forms a relatively continuous expanse, highlighting the clear-cut division of the planet in terms of health status. Between these regions, for different reasons, we find the center of Latin America (e.g., Brazil, Peru), which is less advanced in the health transition, and most of the territory of the old USSR, whose health status has been declining for more than 30 years.

[3] Whereas the life expectancy calculated for the world population taken as a whole is 65.4 years, the simple average of life expectancies per country is 65.5 years. This may be surprising because of the wide diversity of population counts (i.e., several thousand for some microstates to more than a billion for China). This finding probably means that the distribution of the diversity of population counts is not related to life expectancy levels. The variability is quite high because the standard deviation represents 11.2 years, almost 20% of the average.

2. A Matter of Scale

The world map of life expectancy raises a few problems of interpretation, particularly in terms of scale, prompting comments about heterogeneity of geographic distribution and disproportion of population numbers.

a. Heterogeneity of the Geographic Division of the Planet

The political division of the planet into separate states is far from ideal for the observation of geographic variations of mortality. Indeed each state has its own policies and observes a certain consistency in health regulations and behavior, and from this point of view, international comparisons are extremely useful. However, due to differences in size among countries, such a world map can easily mask the internal discrepancies existing within certain countries; internal lines of separation are as important as national borders, which sometimes have little impact. This type of situation is common when the focus shifts from

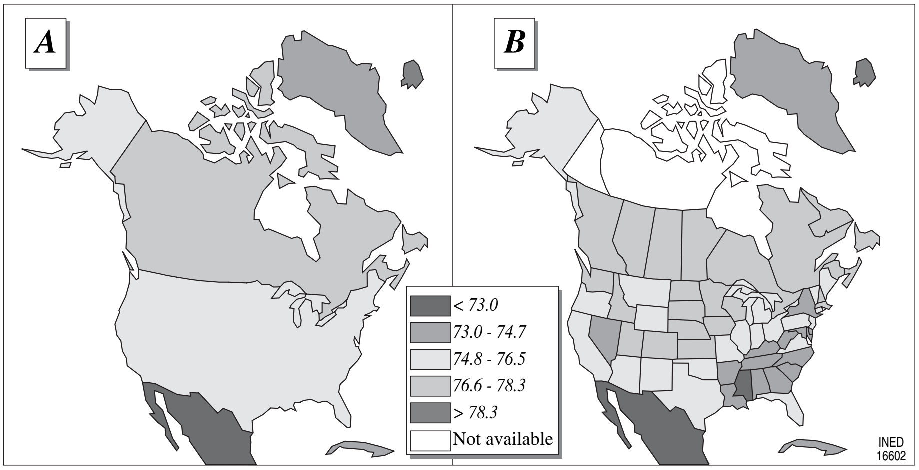

FIGURE 55–2 Life expectancy at birth for both sexes in North America in 1990, without **(A)** and with **(B)** state or province borders within the United States and Canada. (Figure 55–2 also reproduced in color plate section.)

large countries such as the United States or China to smaller neighboring countries.

Figure 55–2 illustrates the case of North America compared with its closest neighbors in Latin America (e.g., Mexico, Cuba) and in Europe (e.g., Iceland). If we follow national borders, nothing particular can be observed, except that Canada does better globally than the United States (see Fig. 55–2A). However, if we establish distinctions between the different states or provinces that make up these two federations, we see that the situation of the north-central part of the United States resembles that of the Canadian provinces, whereas that of the southeastern part of the United States bears a closer resemblance to Cuba or Mexico (see Fig. 55–2B). The fact that these states have large African-American or Latin American minorities probably plays a role. In any case, it appears that neither the border between the United States and Canada nor the Rio Grande have any more significance in terms of health than the line separating the U.S. southern states from the northern states.

Another striking example is that of China compared with its neighbors (Fig. 55–3). Like the United States, China is an enormous expanse, apparently homogenous, in the middle of a diversity of smaller countries, among which is Japan, which holds the record of highest life expectancy, and Burma, whose life expectancy is one of the lowest in the world (see Fig. 55–3A). We refer to figures from the early 1980s to be able to use the life expectancy estimates for every Chinese province established on the basis of the 1982 census (Calot and Caselli, 1989).

If we look separately at the Chinese provinces, about 10 of which have populations larger than those of France, Italy, or the United Kingdom, we can see how they are divided in relation to the surrounding countries. The situation of the far-western provinces resembles that of South Asia (e.g., Pakistan, India, Nepal, Bhutan, Bangladesh, Burma, Laos, Vietnam), whereas the maritime provinces (e.g., Formosa) are colored blue and are closer to Japan (see Fig. 55–3b).

This problem, which is obvious in the case of the United States or China, exists at all levels, even within countries or smaller geographic units (Decroly and Grimmaud, 1991; ISTAT and ISS, 1988). Heterogeneity is common, and the finer the territorial division, the more precisely this heterogeneity can be defined.

In the case of Italy, as we move down in the territorial hierarchy from the 20 regions to the 95 provinces or 8100 communes,[4] we obtain a better picture of the true situation, although a complete description of geographic variations can never be obtained. In this case, to perform such a comparison, given the insufficient data, we had to replace life expectancy by a comparative index of relative mortality, but the result is about the same.

The three maps shown in Figure 55–4, which represent the variations of male mortality, reproduce globally the same well-known profile of excess mortality in the northern region and low mortality in the southern region. However, this picture is considerably qualified when we divide the regional map into smaller areas. On the regional map, we observe a striking contrast between the regions situated north of the Po River (i.e., Aosta Valley, Piedmont, Liguria, Lombardia, Veneto, Trentino-Alto-Adige, and Friuli-

[4] According to the communal boarders in force in 1991, the year of the census, on which the analysis of mortality for 1991 to 1993 is based.

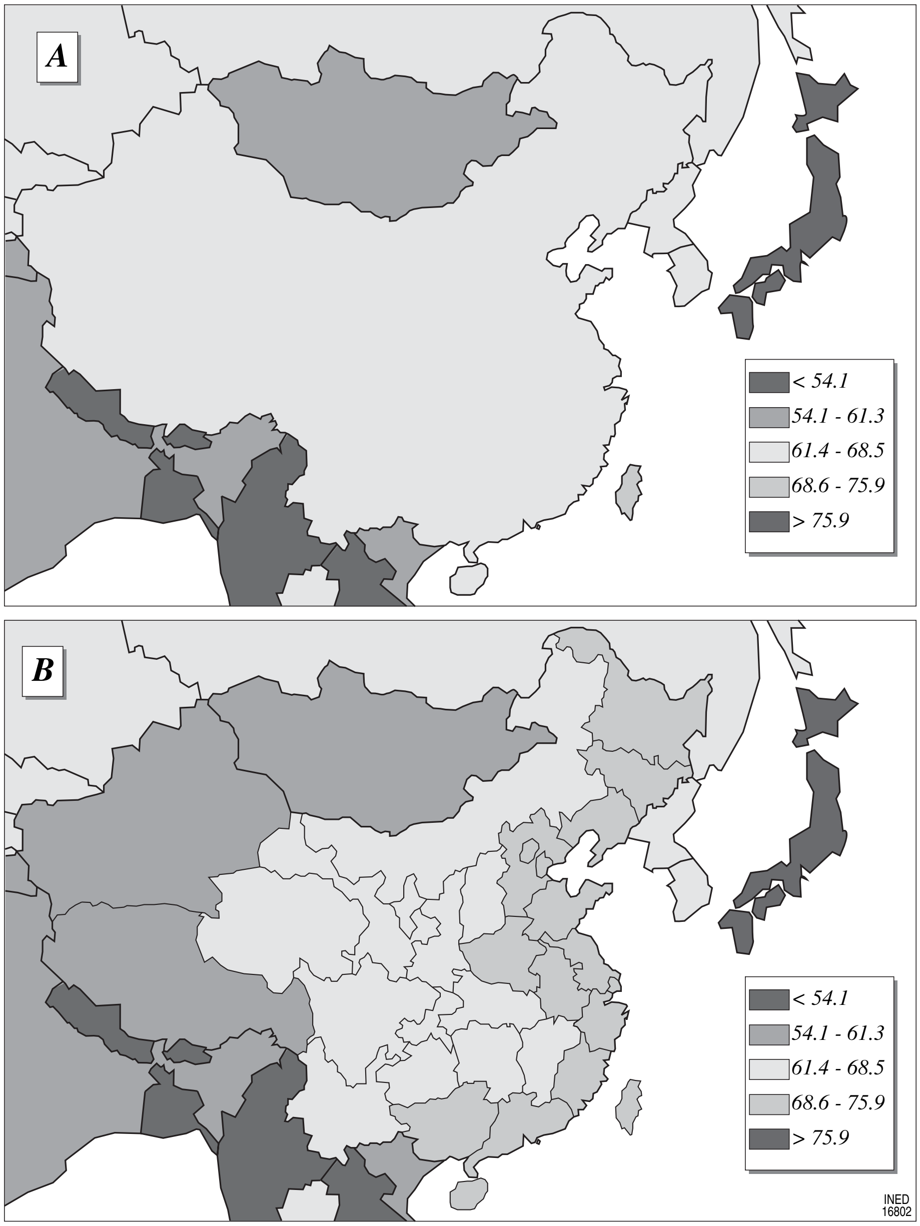

FIGURE 55–3 Life expectancy at birth for both sexes in eastern Asia in the early 1980s, with **(A)** and without **(B)** borders between Chinese provinces. (Map based on data from Calot and Caselli [1989].) (Figure 55–3 also reproduced in color plate section.)

Venezia-Giulia), which have a higher mortality, and the regions closer to the Adriatic Sea (i.e., Marches, Umbria, Abruzzi e Molise, and Puglia) and the Ionian Sea (i.e., Basilicata and Calabria), where mortality is lower. Between these two regions, there is an intermediate zone with mortality rates close to the national average, which includes the islands (e.g., Sardinia, Sicily), Emilia-Romagna, Tuscany, and Latium. The only exception to this apparently clear-cut division is Campania, colored red on the map, in the middle of blue or yellow regions.

If we look at the map of provinces, the situation appears more complex. We observe that excess mortality does not affect the area north of the Po as homogeneously as it first seemed. Piedmont and Liguria, for example, contrast with the provinces close to Lombardia, especially in the northeast Piedmont (i.e., Novara and Vercelli) and in the eastern part of Liguria (i.e., Genova), where male mortality is high, and all the western provinces, where mortality is close to the national average. Similarly, the region of Veneto includes only several high-mortality provinces (e.g.,

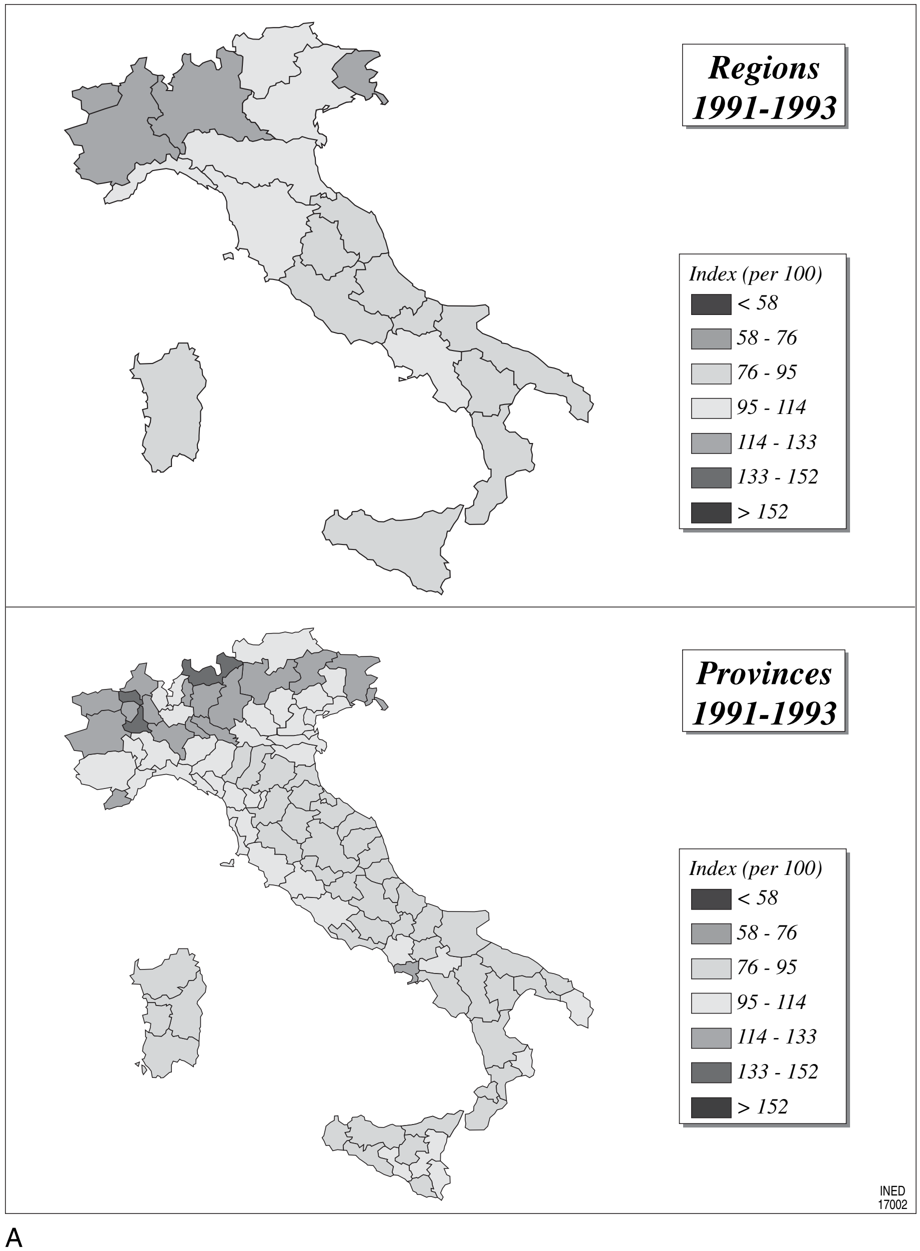

FIGURE 55–4 Geographic variations of Italian male mortality according to three levels of administrative territorial division: regions, provinces, and communes, in 1991–1993. **A:** Relative mortality index (per 100) by region and province. (Maps based on data from ISTAT [2000], Caselli [2002], and Caselli *et al*. [2003].) (Figure 55–4 also reproduced in color plate section.)

Belluno, Vicenza, Rovigo), whereas mortality in the others is about average.

In Tuscany, where mortality seemed to be average for the country, only three provinces (i.e., Grosseto, Livorno, and Lucca) are on average level, whereas the northernmost province (i.e., Massa-Carrare) has the excess mortality of northern Italy; all the other provinces, which are more eastern, have low mortality rates.

However, the most interesting case is that of Campania, identified as an exception. Whereas this region, taken as a whole, presents moderate excess mortality, it is made up of four provinces, two of which have very high mortality (i.e., Naples and Casertae), two of which have very low mortality (i.e., Benevento and Avellino), and a fifth province (i.e., Salerno) that has average mortality.

When we shift from the regional to the provincial level, excess mortality rates are located in smaller zones, whereas the lower mortality rates are spread over wider expanses, overflowing into Emilia, Tuscany, Latium, and Campania, as a continuation

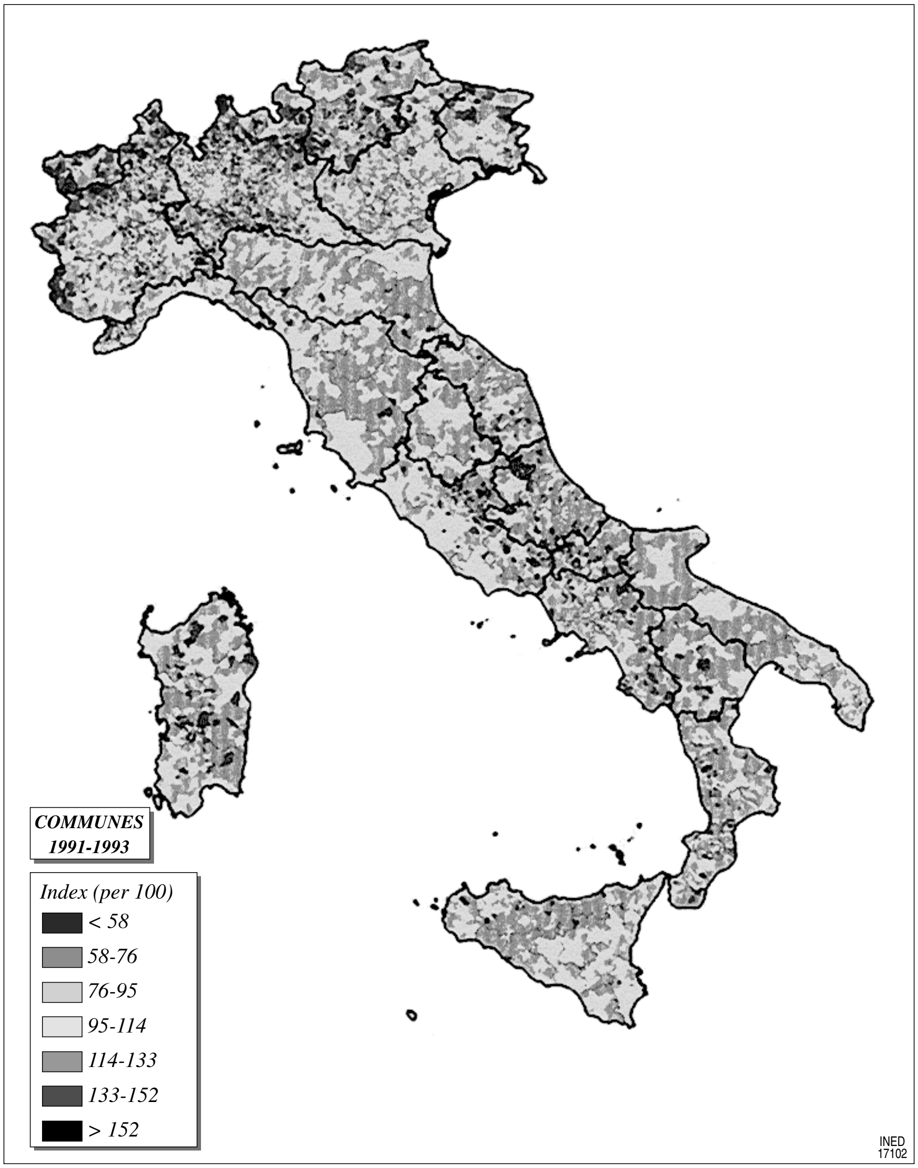

FIGURE 55–4 (*Continued*) **B:** Relative mortality index (per 100) by commune in 1991–1993. (Maps based on data from Cislaghi [2000].) (Figure 55–4 also reproduced in color plate section.)

of the regions where levels are low everywhere. Conversely, only four provinces (i.e., Tarente, Brindisi, Reggio-Calabria, and Aquila) are excluded from the low-mortality area, but some provinces of Sicily and Sardinia can be included. In shifting from the regional to the provincial level, the weight of some cities draws some provinces toward higher mortality rates, whereas the more rural provinces tend to have lower mortality levels.

The next step, the shift to the *commune* or municipal level (see Fig. 55–4B), allows still greater precision in defining the complexity of the division between high and low mortality. Some municipalities located in northern regions with high mortality have very low mortality, such as some communes of the Aosta Valley or other Alpine provinces and some communes of Liguria. Conversely, a few communes in low-mortality regions of central or southern Italy show excess mortality levels.

Figure 55–5 is a close-up view of the Campania region, showing the contrast between the communes that are the cause of the region's global excess mortality rates and those whose health conditions are no worse than elsewhere in the country. We see how the city of Naples contrasts with the communes located at the region's periphery, close to surrounding regions

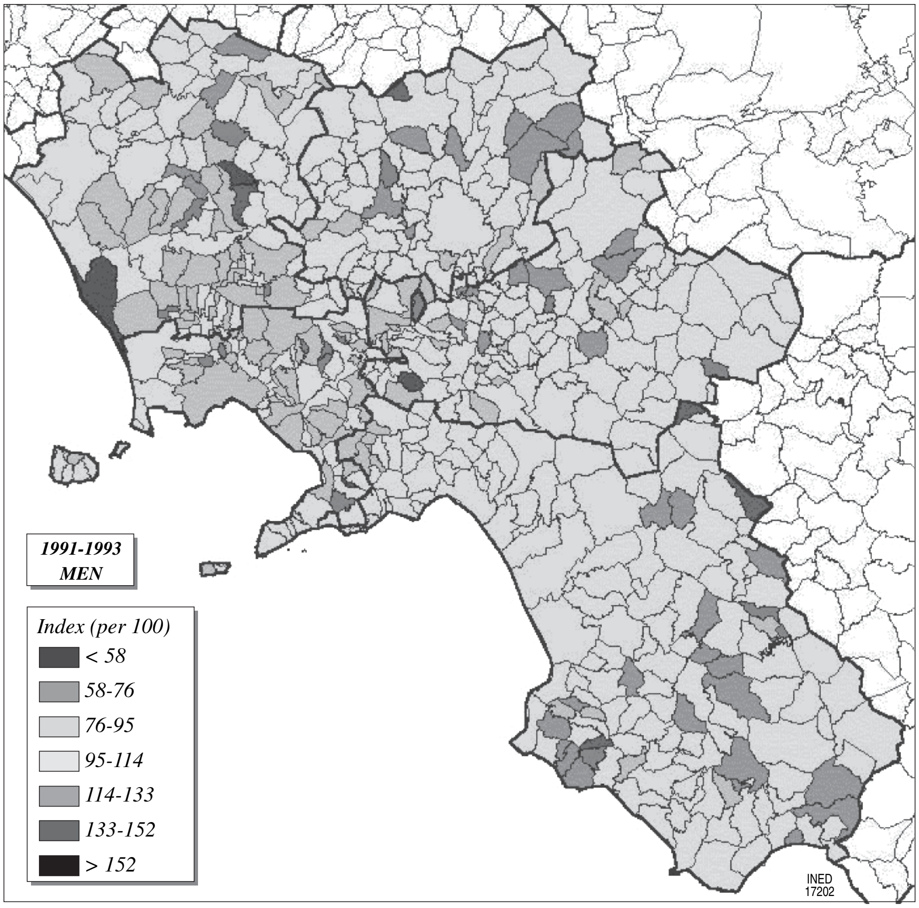

FIGURE 55–5 Closer view of the geography of mortality in Campania: provinces and communes. (Maps based on data from Cislaghi [2000].) (Figure 55–5 also reproduced in color plate section.)

that have low mortality rates. Besides the province of Naples itself, which is made up almost exclusively of communes with high mortality, the four other provinces of Campania are divided, in various proportions, into an area of average to high mortality closer to Naples and an area of low mortality closer to the neighboring regions.

If the division into smaller units plays an important role in the image we get of reality, that image also depends on the lines along which divisions are made. This was demonstrated in the cases of North America and China, where the difference in size of the areas can be a problem; however, defining borderlines is not a simple matter. The administrative limits of a city, for example, do not necessarily separate zones that suffer more or less from urban pollution. For this reason, geographers suggest dividing a given territory into geographic units of constant shape and size (see Chapter 70). The available data cannot be applied to such an operation. An analyst would have to use complex adjustment methods. In this case, such adjustments would be all the more relevant if the basic data were obtained on the smallest possible scale. To study mortality in a country such as Italy, the demographer would have to reach below the communal level.

b. Disproportion in Population Numbers

However, even analysis of populations below the communal level is not enough to solve the problem of unequal territorial division (i.e., inequality in the size of the areas covered or in the determination of area limits). It is difficult, when analyzing geographic variations of mortality not to address the issue of the size of the populations concerned.

In the geographic representations provided earlier, the same visual importance was given to two territories covering the same area, even if one of them had a population of a hundred million and the other had a population of only several million. In Figure 55–3, for example, the Chinese province of Szechwan, which according to the 1982 census had a population of 100 million, covers a smaller area than the Xinjiang

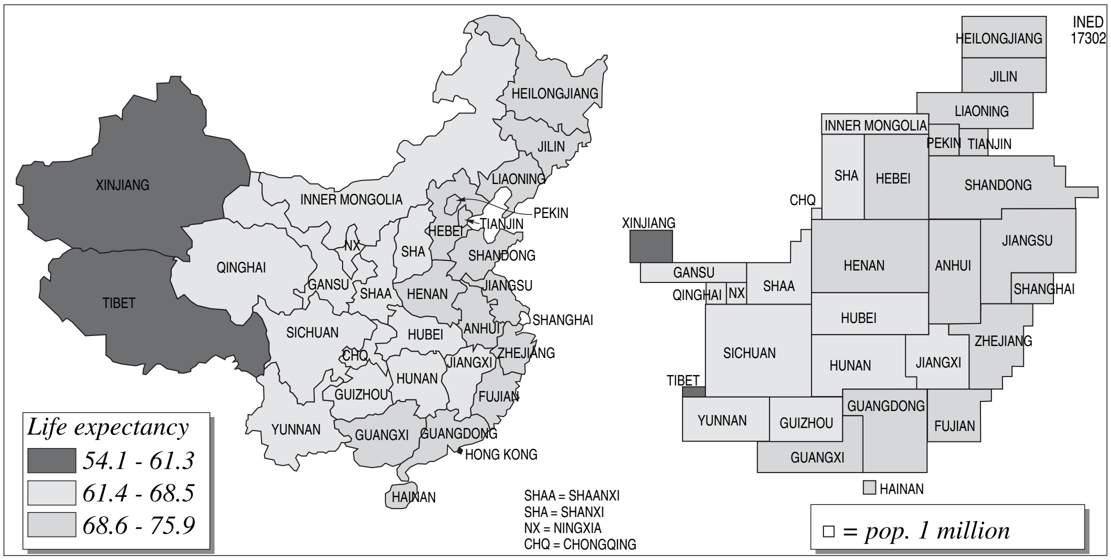

FIGURE 55–6 Geographic variations of life expectancy at birth in China in 1981: traditional representation and representation in proportion with population numbers. (Maps based on data from Calot and Caselli [1989] and from the United Nations [1999b].) (Figure 55–6 also reproduced in color plate section.)

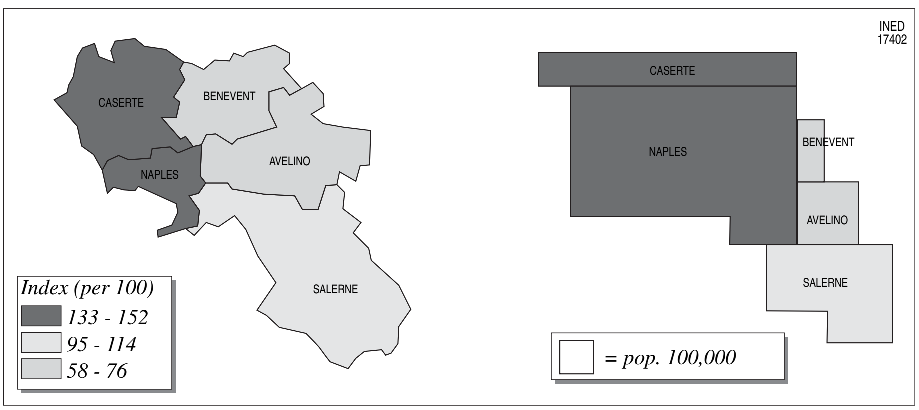

FIGURE 55–7 Geographic variations of the relative mortality index for males in the five provinces of Campania: traditional representation and representation in proportion with population numbers. (Figure 55–7 also reproduced in color plate section.)

province or Tibet, which had populations of 4 and 2 million, respectively. This means that the weight of the mortality levels observed in the latter provinces is exceedingly high compared with that observed in Szechwan.

To overcome this obstacle, we can draw schematic maps in which the area of each geographic unit is proportional to its population. Figure 55–6 isolates China's provinces as they appear on Figure 55–3 and compares them with a map of this type. The result is striking: The blue zone of low mortality is much larger than the rest; the orange zone of excess mortality is quite limited in size.

What is obvious for Chinese provinces is also true for more ordinary situations and much more widely so than often thought. There are no deserts in Italy, but we can observe the same phenomenon. For example, of the 5.6 million people of Campania, more than 3 million live in the province of Naples and 800,000 in the province of Caserte, the two provinces with high mortality, whereas only 400,000 live in Avellino and 200,000 in Benevento, both provinces with low mortality. The extension of the low-mortality zone, which was the result of the shift from the regional to the provincial level, was in part an optical illusion (Fig. 55–7). From a demographic point of view, what is most important is that the most-populated area is a high-mortality zone.

c. The Cities

A similar problem of scale occurs systematically when dealing with cities. Most often, the apparent map of mortality changes when a demographer calculates separately the mortality index of cities and that of the administrative units they belong to. One example is the case of mortality due to cancer in Baltic countries (Krumins *et al*., 1999). In these countries, the mortality due to cancer observed in cities is almost systematically higher than that of the corresponding administrative territorial unit. It is possible that this difference may be an observational problem (i.e., deaths due to cancer happen more often in cities because that is where the hospitals are located). Whether the phenomenon is real or artificial, the chosen system of representation changes our perception of the phenomenon. For most geographic units that include a city, the mortality index for cancer decreases if the city is accounted for separately (Fig. 55–8).

For greater precision, the cities could be represented by areas proportional to their population, which is not the case in the maps of Figure 55–8. However, this would be no more than an unsatisfactory half-measure if the other administrative units were still represented according to their real borders, without any indication of population size.

II. COMPONENTS OF GEOGRAPHIC INEQUALITY IN MATTERS OF MORTALITY

The previous example concerning mortality due to cancer prompts us to take a new look at the whole of our analysis of geographic variations of mortality. The differences in life expectancy or standardized mortality rates that we have accepted until now provide only an overall measurement. Within the same area of geographic observation, the mortality map can vary greatly depending on sex, age, causes of death, or other components. With the use of Italian data, we assess the roles played by these three basic components.

1. Reversal of the Geography of Mortality from Male to Female

Figure 55–9 shows to what extent the sex-specific mortality maps differ for Italy. The classic opposition between northern and southern areas, already illustrated in several ways in Figure 55–4, concerns mainly

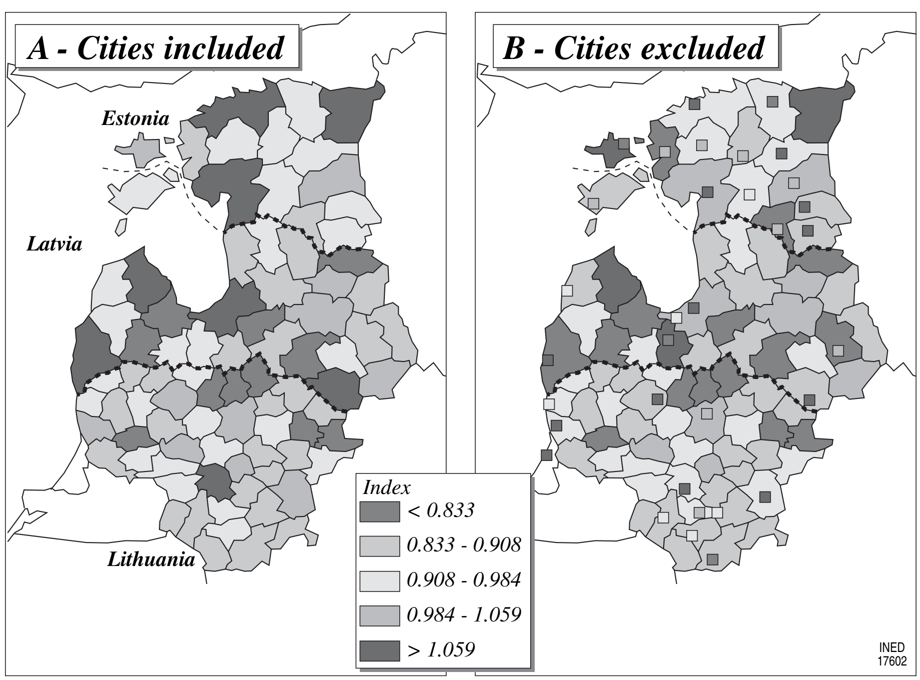

FIGURE 55–8 Variation of the index of comparative mortality due to cancer in Baltic countries for 1987–1990, depending on whether the cities are included **(A)** or considered separately **(B)** from the administrative territorial division to which they belong. (From Krumins *et al*., 1999.) (Figure 55–8 also reproduced in color plate section.)

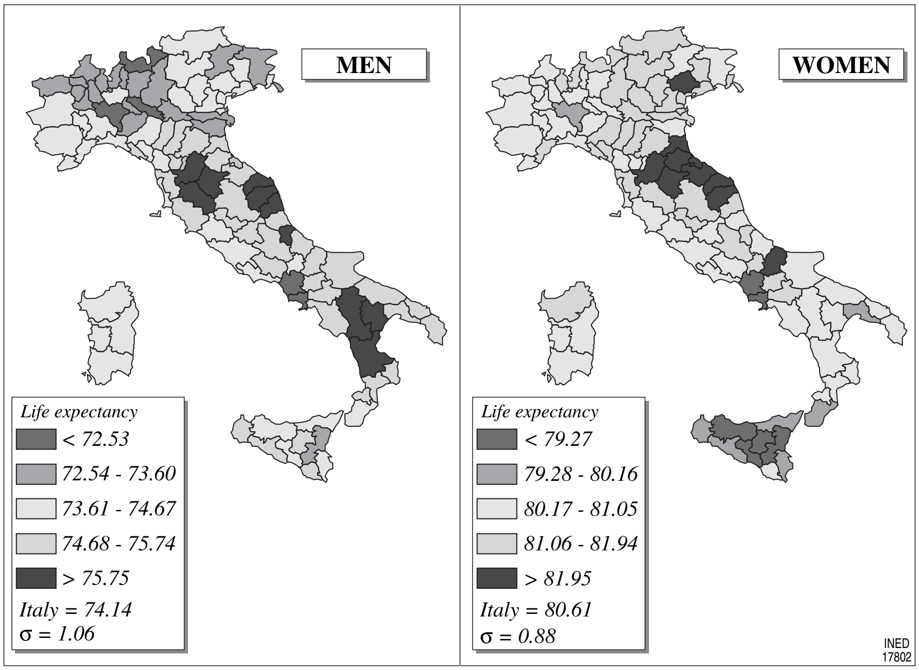

FIGURE 55–9 Geographic variations of sex-specific life expectancy at birth in Italy for 1991–1993. (Maps based on data from Caselli [2002].) (Figure 55–9 also reproduced in color plate section.)

male mortality. The situation for female mortality is completely different. We do observe a privileged area where the life expectancy at birth of both sexes is much higher than the national average; this area includes mainly the Marches, Umbria, and parts of Tuscany and Emilia. Similarly, both sexes have high mortality rates in Naples and Caserte. For the remaining areas, almost everything points to an opposite case. In southern Italy (e.g., Calabria, Puglia, Basilicate), male life expectancy is very high, whereas it usually is less than average for females. Sicily has the lowest female life expectancy, whereas male life expectancy figures are somewhat higher than average (at least in the southern and western provinces of the island). Conversely, in the northern provinces of Italy, where male life expectancy is usually low, women's life expectancy is at least equal to the national average and often higher (with the exception of Pavia). This major contrast between the distribution of male and female mortality in Italy is the result of complex combinations of multiple factors (Caselli *et al.*, 2003; Caselli, 2002). However, we may say, even though it is a slight simplification, that men suffer more than women from industrial pollution in the north of the country, whereas women suffer more than men from the state of underdevelopment in the southern area, particularly as concerns health care services (Vallin, 1981). The geographic map underscores the differences in life expectancy between the sexes and illustrates the changes that occur over time (Meslé and Vallin, 1998) (see Chapter 53).

2. Reversal of the Geography of Mortality from Infants to Adults

The reversal of the geographic map is even more spectacular when we shift from small children to adults. Although, as concerns the mortality probability between the ages of 40 and 65 years for males (Fig. 55–10, second map), the map is almost an exact replica of the map of life expectancy variations, the map of infant mortality is its complete opposite (see Fig. 55–10, first map). The northern region almost systematically has the lowest probability, whereas the southern region has the highest. Even more clearly than for the male-female difference, this reflect the fact that infant mortality is closely linked to the quality of health care, which is better in the northern region than in the southern region, whereas male adult mortality is much more affected by industrial pollution in the north. Geographic and other variations are most sensitive at adult ages (Van Houte-Minet and Wunsch, 1978).

The geography of mortality at older ages (65 to 84 years) is a little more complex. It bears more of a resemblance to adult mortality than to infant mortality. Similar to the rate for persons between the ages of

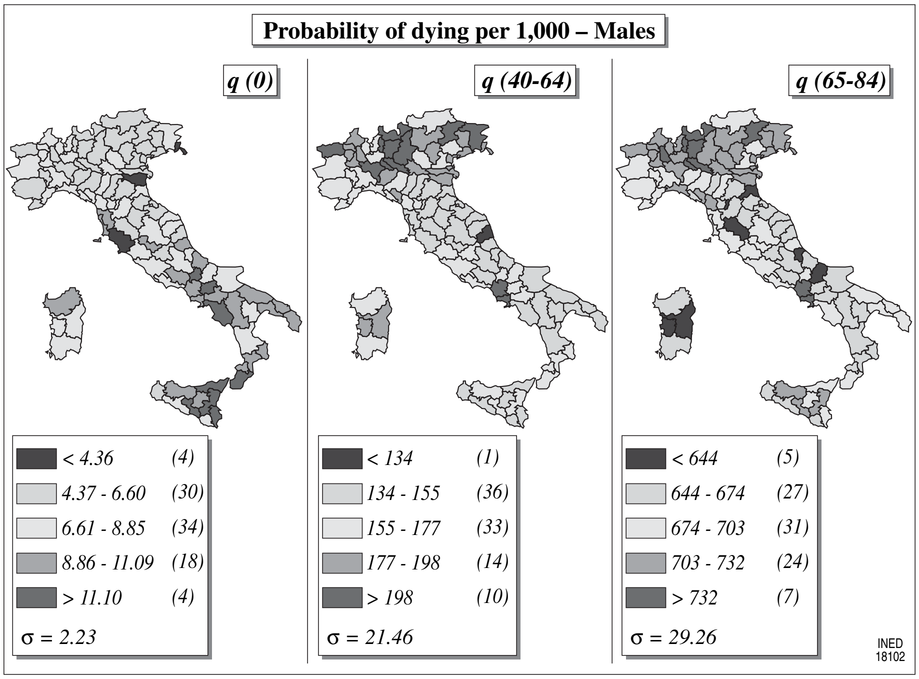

FIGURE 55–10 Geographic variations of the male probability of dying before the age of 1 year, between 40 and 64 years, and between 65 and 84 years in Italy for 1991–1993. (Maps based on data from Caselli [2002].) (Figure 55–10 also reproduced in color plate section.)

40 and 64 years, excess mortality can be found by far mostly in the northern part of the country, but low mortality is less frequently observed in other regions in the country than for the previous age groups. Almost all of the provinces of Italy or Sicily that are near the Tyrrhenian Sea, along with Puglia, are at or above the national average. Conversely, mortality is low in all of Sardinia, even though the rate is relatively poor at adult ages. The factors behind these specific aspects of mortality at advanced ages are complex. In the northern region, industrial causes play a negative role, but there are other causes in certain central provinces (e.g., urban pollution) and in the southern region (e.g., poor health care services, emergency care in particular).

3. Reversal of the Geography of Mortality from One Social Category to Another

The weight of social class in geographic variations of mortality is high. In a country such as France, for example, regional differences in mortality are for a large part explained by differences in the distribution of the population per social-occupational category. Social inequalities in terms of mortality are more or less pronounced, depending on the region. Whereas the Paris region has one of the highest life expectancy levels in France, the mortality of the poorer social groups is higher there than elsewhere. In other words, it often happens that the geography of mortality is different, even reversed, for different social classes (Desplanques and Nizard, 1978).

4. Reversal of the Geography of Mortality from One Cause to Another

The various regional contrasts reflect geographic variations in the cause of death, and we can observe complete reversals in this area as well. In Italy, the pattern of male mortality due to diabetes at age 40 to 64 years is almost the exact opposite of that of mortality due to bronchial and lung cancer (Fig. 55–11). Although bronchial and lung cancer affects mainly the northern part of the country, diabetes affects the southern part. The northern regions suffer from high levels of air pollution, with a combination of industrial emissions and frequent fogs, whereas the southern area is spared these two factors. Even more important is smoking, which is much more widespread in the northern region than in the southern region of Italy. Conversely, there are more factors favoring diabetes in the southern area (particularly sugar consumption), along with insufficient health services to control mortality due to this cause.

The geographic opposition between lung cancer and diabetes can be found in almost identical form for

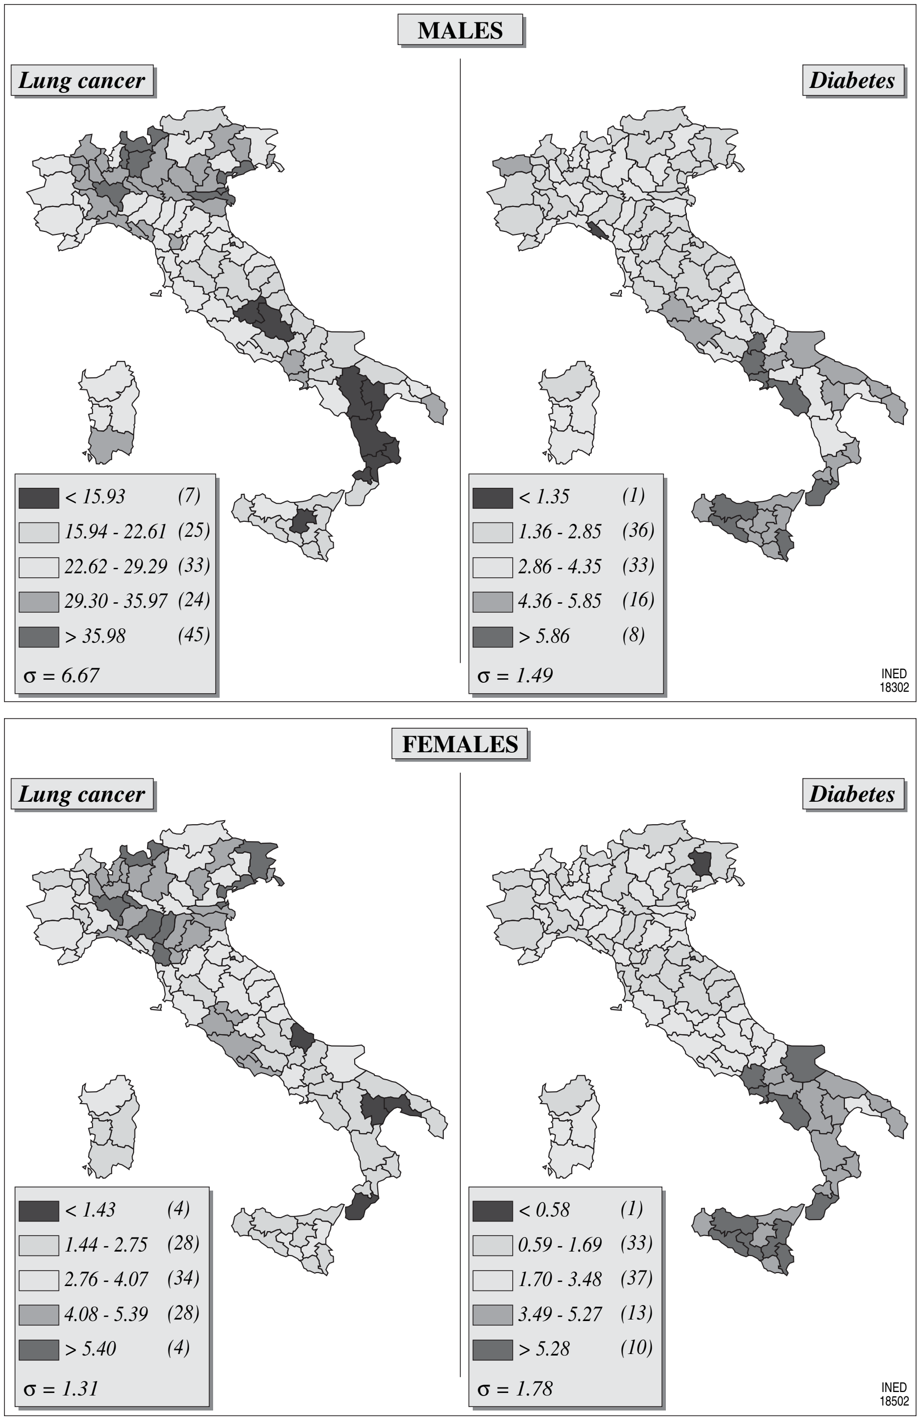

FIGURE 55–11 Geographic variations of the probability of dying of lung cancer or diabetes between 40 and 64 years of age in Italy for 1991 to 1993. (Maps based on data from Caselli [2002].) (Figure 55–11 also reproduced in color plate section.)

females (see Fig. 55–11, lower part), which is not surprising. Nonetheless, the difference in mortality for these two causes plays a role in the larger geographic opposition in mortality for males and females. Whereas diabetes kills about equal numbers of men and women, bronchial and lung cancers kill almost 10 times as many men than women. If these were the only causes, they would be enough to account for the male-female geographic contrast, but there are many other causes of mortality. Most of them, including ischemic heart disease (Fig. 55–12), have similar geographic profiles for both sexes, and the geographic contrast between males and females for mortality due to all causes is mainly the result of intensity differences.

However, for some causes, the geographic profile changes according to sex. This is particularly true for mortality due to "other diseases of the circulatory system" (mainly cerebrovascular diseases). For both sexes, there is excess mortality for this cause in the south, whereas most of the central regions have low mortality. However, if this mortality is very high for males in the northwestern regions, it is much less so for females, who enjoy rather low mortality rates due to this cause in the north. The negative situation in the south may be caused by certain eating habits that may favor cerebrovascular disease, but it is probably also affected by the lack of adequate emergency health care. This phenomenon can be observed for both sexes, but the negative factors prevalent in the north, which are mainly of industrial origin, affect mostly men. This contrast observed for the other diseases of the circulatory system is all the more important in the sex-specific mortality pattern in that this group of causes affects women much more than ischemic heart diseases, whereas the latter cause of death is more frequent among men.

III. PERMANENCE AND CHANGE

An analysis[5] of mortality trends in Europe since 1950, conducted under the aegis of the Council of Europe, has made it possible to bring together all the existing data and to provide estimates of life expectancy for all the European countries according to their current borders (Vallin and Meslé, 2001). We compared the situations observed in 1950, 1965, and 1995. In the mid-1960s, large gains in life expectancy were made thanks to the reduction of mortality due to infectious diseases and to advances in the treatment of cardiovascular diseases (Meslé and Vallin, 1993). What were the consequences for European mortality? To answer this question, Figure 55–13 was composed on the basis of statistical classes common to the three maps.[6] We can see how the maps are modified while keeping track of trends from one date to the next. What we observe is a radical transformation. In the early 1950s, there was a small group of Nordic countries (e.g., Scandinavian countries, Iceland, Netherlands) with life expectancies considerably above average. These countries, along with the United Kingdom, Belgium, Germany, and Switzerland, which were also above average, represented a north-northeastern corner spreading toward the center of Europe and bringing together the more prosperous countries. In striking contrast with this group, there was Eastern Europe (i.e., the entire Communist bloc except for the Czech Republic and Bulgaria) and a large part of southern Europe, the Iberian Peninsula, Yugoslavia, and Turkey. France, Italy, and Greece held an intermediate position. These different positions on the map show the stage reached at the time by each country in the first phase of the health transition, the phase during which most infectious diseases are eradicated (see Chapter 57). The northern countries were far ahead of those in the east and south, for which the transition occurred much later and which remained behind.

By 1965, the picture had completely changed. Progress had slowed down in the most advanced countries and accelerated in those that were behind, and in 15 years, the gap had narrowed. Only Turkey, Portugal, and two or three Yugoslav republics remained a little behind. The homogenization process was considerable, and most of the contrasts prevalent in 1950 had disappeared in a context of overall improvement of the situation.

In 1995, however, a new contrast emerged, more striking than that of 1950, with a clear opposition between East and West. All the western countries are colored blue. All those of the former USSR are colored brown or red, with the exception of the Transcaucasian republics, where we know that mortality is underestimated.[7] Between these regions, there are the former

[5] Analysis was based on previous work (Caselli *et al.*, 1999; Vallin, 1998; Caselli and Egidi, 1981a; van Poppel, 1979; Vallin and Chesnais, 1974).

[6] To do this, we calculated the average and the standard deviation for all the figures used for these three periods, and we created seven classes from a central class of one-half standard deviation centered on the average.

[7] This is not so much due to the under-registration of deaths, which is relatively moderate, as to the overestimation of the population. After the collapse of the USSR, the massive departure of nonlocal populations (especially Russians) was only partially taken into account in official population estimates (Badurashvili *et al.*, 2002; Yeganyan *et al.*, 2001).

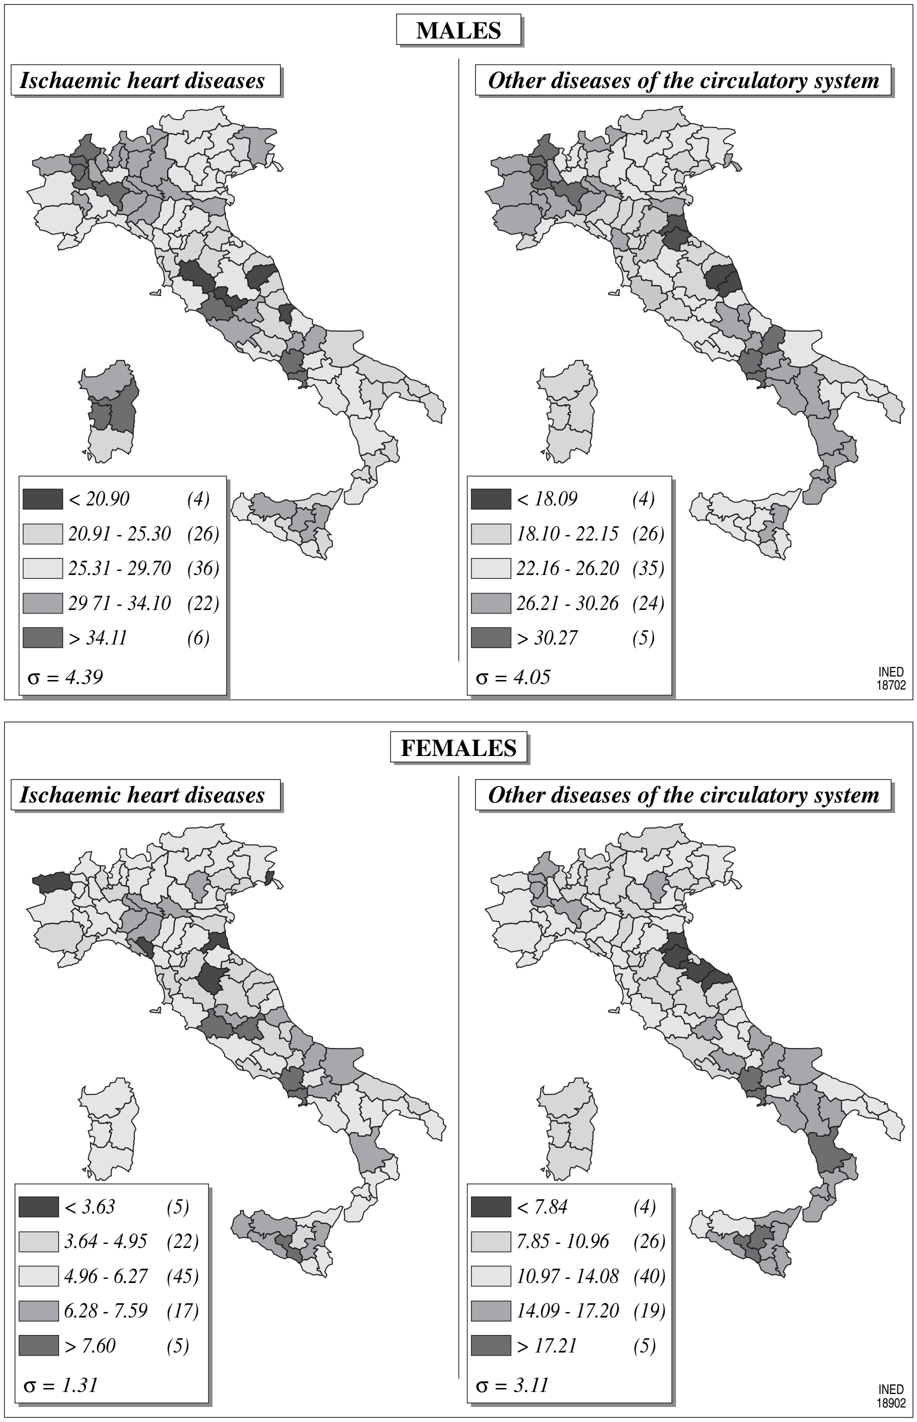

FIGURE 55–12 Geographic variations of the probability of dying of ischemic heart disease or other diseases of the circulatory system between 40 and 64 years of age in Italy for 1991 to 1993. (Maps based on data from Caselli [2002].) (Figure 55–12 also reproduced in color plate section.)

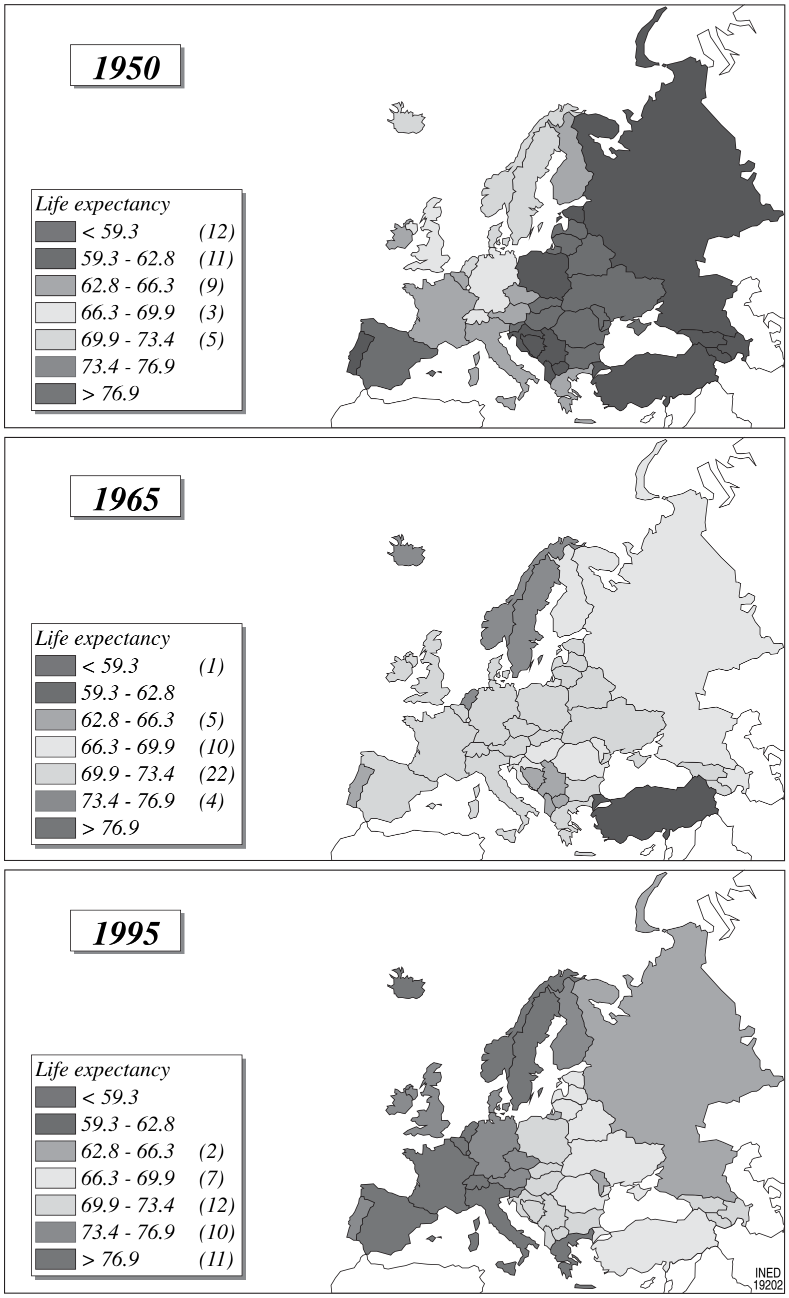

FIGURE 55–13 Life expectancy at birth for both sexes in Europe for 1950, 1965, and 1995. (Maps based on data from Vallin and Meslé [2001].) (Figure 55–13 also reproduced in color plate section.)

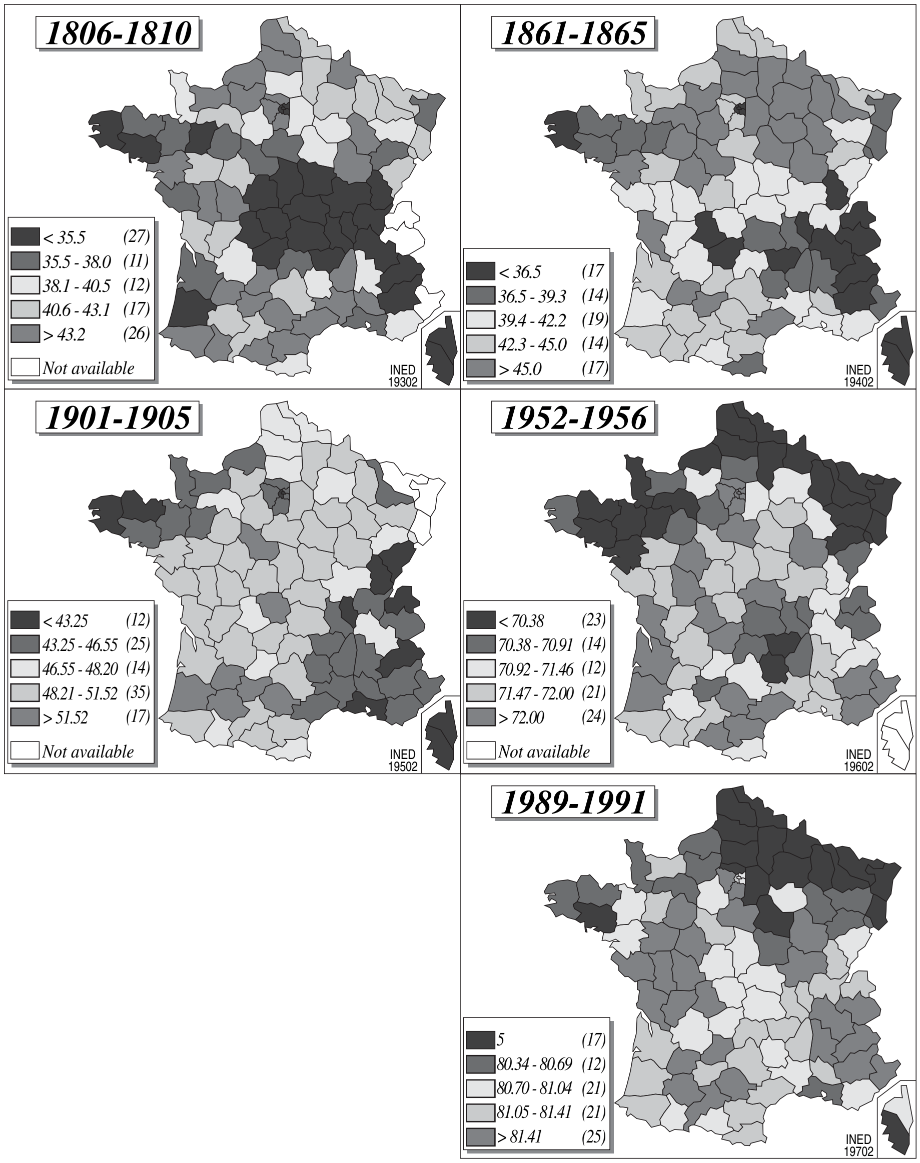
satellite countries of the USSR, the countries of the former Yugoslavia and of Turkey. Since the end of the 1960s, Western countries have succeeded in gaining more years of life expectancy thanks to advances made in the field of cardiovascular disease and some forms of cancer (i.e., the second phase of the health transition). However, the formerly Communist countries are experiencing a crisis. They have not succeeded in entering the second phase of the health transition, and certain social ills, such as alcoholism or violent deaths, have increased while health services have deteriorated, leading to an increase in the number of causes of death, which previously had been almost under control (Meslé *et al*., 1998; Meslé, 1991).

The example of Europe shows that strong political differences can have a great impact on the overall state of health in a country. Once the question of infectious



A

FIGURE 55–14 **A:** Trends by department in variations of life expectancy at birth of French women between 1806 and 1810 to between 1989 and 1991. (Maps based on data from Bonneuil [1997] for the 19th century and INSEE for the 20th century and on data from Isnard and Lavertu [1995] and INSEE [1964].) (Figure 55–14 also reproduced in color plate section.)

diseases—mainly a question of simple technical means—has been solved, overall progress in health issues depends on economic and social progress and on cultural changes leading to a modification in behavior and lifestyles that are detrimental to health (Vallin and Meslé, 2001; Caselli and Egidi, 1981d). Such factors are powerful enough to create a health gap between countries undergoing different political and economic trends, while leading to greater homogeneity between countries belonging to the same geopolitical group.

What can be said about internal variations within a single country? Usually, the trends move at a slower pace (Tonnelier, 1991), but they are no less significant. The map of life expectancy at birth for French women, for example, has completely changed in 2 centuries[8] (Fig. 55–14A).

[8] The comparison over 2 centuries is possible only for females. This was made possible by reconstitution of data for each département by Noël Bonneuil (1997) for the 19th century, and this research was carried out only for females.

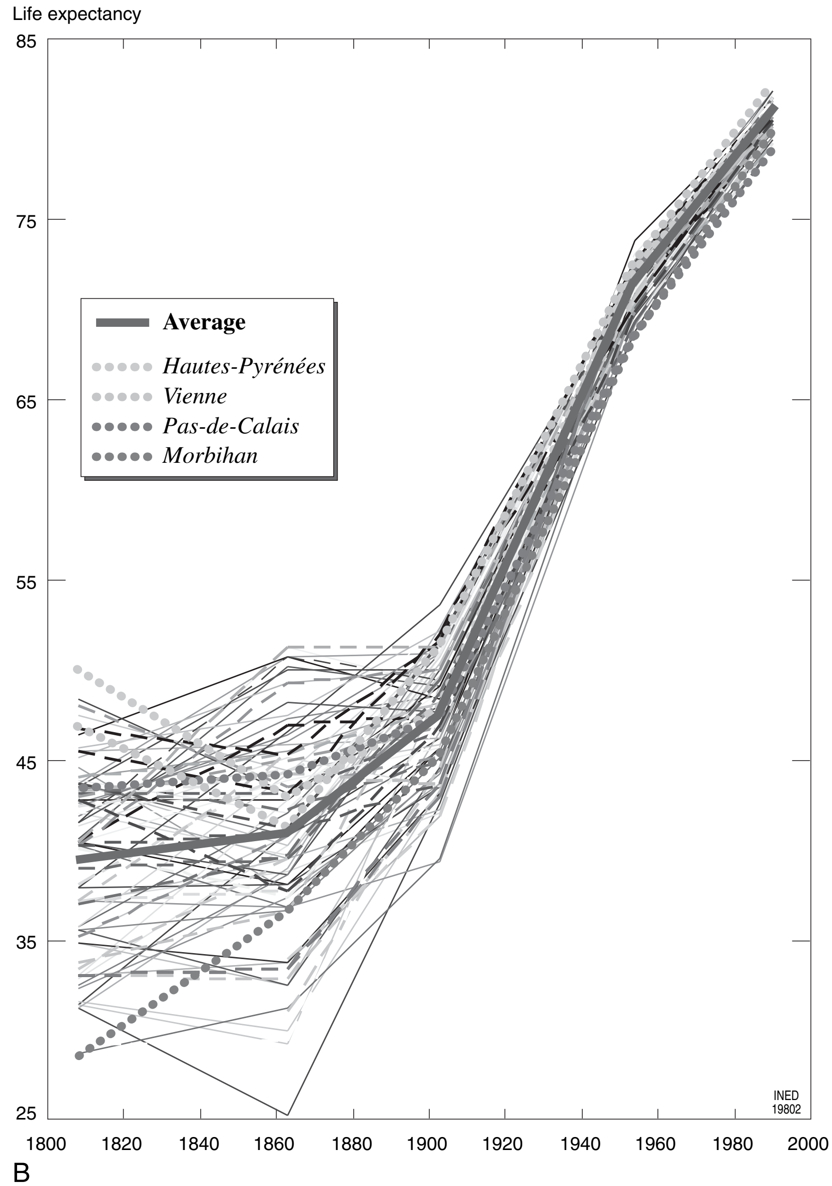


FIGURE 55–14 (*Continued*) **B:** Trends in female life expectancy by department in France since the beginning of the 19th century. (Data from Bonneuil [1997], INSEE [1964], and Isnard and Lavertu [1995].) (Figure 55–14 also reproduced in color plate section.)

In France at the beginning of the 19th century, in 1806–1810, there were two vast zones of low mortality in the northeast (i.e., Normandy, Nord-Pas-de-Calais, Picardy, Ile-de-France, Champagne-Ardennes, Lorraine, Alsace, Burgundy, and Franche-Comté) and in the southwest (i.e., Poitou-Charentes, Lot, Tarn, Pyrenees, and Languedoc), separated by a vast area of excess mortality in the center (i.e., Berry, Limousin, and Auvergne), with extensions into the Alps on one side and into Brittany on the other.

Fifty years later, in 1861–1865, excess mortality had declined in some parts of the center and become specific to the Alps and Brittany; in the north, however, the low mortality zone extended over the Paris basin (except for Paris itself and the suburbs), but it no longer included the Alsace region. In the early 20th century, the excess-mortality zone covered the entire southeastern part of France (from the Jura mountains to the Cévennes and Provence) and the Brittany-Normandy region, whereas mortality was low in the center and the southwest.

In 1952–1956, excess mortality had for a large part disappeared in the southeast, but had returned to the north and northeast areas. In those years, there appeared a pattern that was to remain for the next 50 years, with an opposition between the north, which had poor health conditions (from Brittany to Alsace, through Normandy and Pas-de-Calais, Picardy and Lorraine) and nearly all of the remainder of France (except Savoie and two or three *départements* of the Massif Central region). At that time, the dominant factor in geographic mortality variations was alcoholism (Meslé, 1990; Nizard and Prioux, 1975; Ledermann, 1956, 1964), even when taking into account specific regional factors, such as infant mortality in the Nord-Pas-de-Calais or industrial pollution in the north and northeast (Caselli and Egidi, 1988; Caselli 1984).

The years 1989–1991 show a change in this familiar pattern. Normandy in particular is no longer included in the excess mortality zone, which then ceases to be a continuous expanse. The zone of excess mortality covers several *départements* of the central region (i.e., from Yonne to Creuse, through Nièvre and Allier).

If we compare the first map with the last, the geography of mortality completely changed over 2 centuries, in large part because of economic and social changes. In the past, the areas with very high mortality were situated in the traditionally poor regions of Brittany, the Massif Central, and the Alps; the southwest was rich farming country, whereas the north and east areas were entering the economic development process tied to the industrial revolution. At the end of the 1980s, excess mortality was still a fact in Brittany, but it was especially marked in the north and the east of France due to the consequences of heavy industrialization.

At the same time, the geography of mortality also changed in terms of the inequality between regions. In the early 19th century, the average life expectancy of French women was 39.4 years; it was only 28.4 years in the Morbihan (Brittany), but it reached 50.0 years in the Hautes-Pyrénées, a difference of nearly 22 years and a relative gap of 76% between both extremes (Table 55–2). This difference does not result from extreme values, because the standard deviation was 5.1 years. In the mid-19th century, inequality increased still more; with just about the same life expectancy (41 years), the absolute gap was 26 years, from 25.2 years in the Hautes-Alpes to 51.2 in Yonne (i.e., standard deviation of 5.6 years). In the early 20th century, inequality strongly decreased. For an average life expectancy of 47 years, the absolute difference was only 14.2 years, from the Finistère (39.3 years) to the Loir-et-Cher (53.4 years). However, the differences were dramatically reduced during the 20th century, and by 1952 to 1956, the average life expectancy had greatly increased, reaching 71.2 years; the gap between extremes had

TABLE 55–2 Statistical Characteristics of the Variations in Life Expectancy at Birth of French Women at Different Times in History

Characteristics	Periods				
	1806–1810	1861–1865	1901–1905	1952–1956	1989–1991
Average	39.35	40.77	47.22	71.24	80.92

dropped to only 4.9 years (between Morbihan, with 68.3, and Alpes-Maritimes, with 73.2 years), with a standard deviation of 1.08. Between 1989 and 1991, the average life expectancy reached almost 81 years. There was a difference of only 3.7 years between Pas-de-Calais (78.7 years) and Vienne (82.4 years), and the standard deviation had dropped to 0.68 years.

Figure 55–14B illustrates this spectacular decrease in the geographic inequalities of French mortality. The trends observed in the different *départements* are extremely varied in the 19th century, but their differences suddenly fade during the 20th century, and life expectancy rapidly increases. To make our table easier to read, we have indicated the average value in bold red type, whereas the two *départements* with extreme values between 1805 and 1810 are in bold blue type, and those with extreme values between 1989 and 1991 are in bold green.

Changes in mortality patterns are even more striking in Italy. Figure 55–15 shows that the current pattern of excess mortality for males north of the Po River compared with low mortality in the center and south (with the remarkable exception of Campania) is the opposite of the situation observed in the beginning of the 20th century, when excess mortality was specific to the south, and the situation was better in the north (the center, however, already had a very privileged situation). The explanation is simple. In the past, when mortality mainly was attributed to infectious diseases, the low level of development of the south represented a greater disadvantage than the industrial pollution in the north. Today, the main causes of mortality are cardiovascular diseases and cancer, and industrial pollution in the north has a greater impact than the persistent underdevelopment of the south. The advantage of the central region, which has been spared the industrial pollution of the north but is very developed,

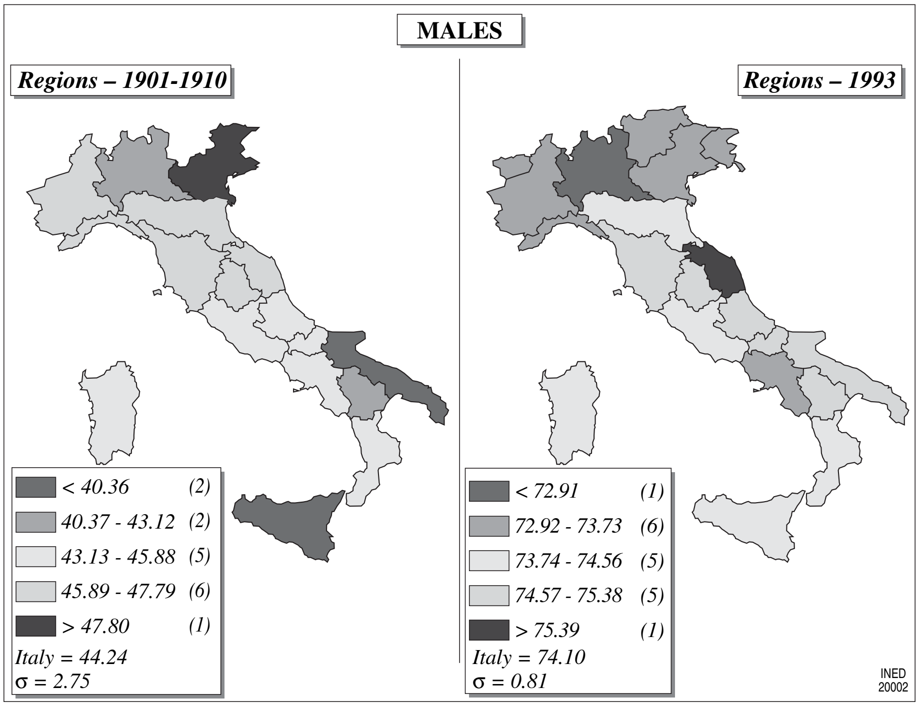

FIGURE 55–15 Trends in regional variations of male life expectancy at birth in Italy from 1901 to 1910 and in 1993. (From ISTAT, 1996a; Caselli, 1990.) (Figure 55–15 also reproduced in color plate section.)

remains permanent (Caselli *et al*., 1993; Caselli and Egidi, 1981b, 1981c).

This complete change of pattern mainly results from the near disappearance of child mortality. Child mortality had always been high in the southern region, whereas very early on, adult male mortality was higher in the north than in the south. At the beginning of the century, child mortality was still high in Italy (more than 100 deaths per 1000 children) and had a large impact on life expectancy, with a considerable advantage for the north. Today, it has decreased 10-fold (less than 10 deaths per 1000 children), and although it remains higher in the south than in the north, the consequences in terms of life expectancy are negligible. The difference in life expectancy now reflects adult excess mortality in the north (Caselli and Reale, 1999).

IV. FACTORS BEHIND GEOGRAPHIC INEQUALITIES

What can be said of these maps of mortality and causes of death? Overall mortality maps can be compared with of this or that variable that is thought to play a role in mortality differences. One example is provided by the two maps shown in Figure 55–16. The first is a map of male mortality at ages 25 to 54 years in each Italian province, and the second illustrates the proportion of the working population employed in mining and manufacturing industries. They are extremely similar, which suggests a strong correlation between male adult mortality and the harmful effects of these industries. There is also a surprising coincidence in France between the geographic distribution of olive oil consumption and that of the lowest rate of mortality due to colon cancer (Meslé, 1983). Although we could provide many such illustrations, this type of comparison remains very limited due to the number of factors involved, the necessity of comparing a large number of maps, and the difficulty of drawing meaningful conclusions on the basis of an intuitive reading of them.

Different methods of statistical analysis, such as principal components analysis, correspondence analysis, canonical analysis, hierarchical analysis, and regression models, can lead to more objective interpretations. With geographic interpretations based on areas that are small enough to be homogenous in terms of mortality, it is possible to identify more precisely high and low mortality zones and to verify or determine more precisely the relationships that exist between different mortality levels (as well as profiles by age, sex, and cause) and the environmental factors

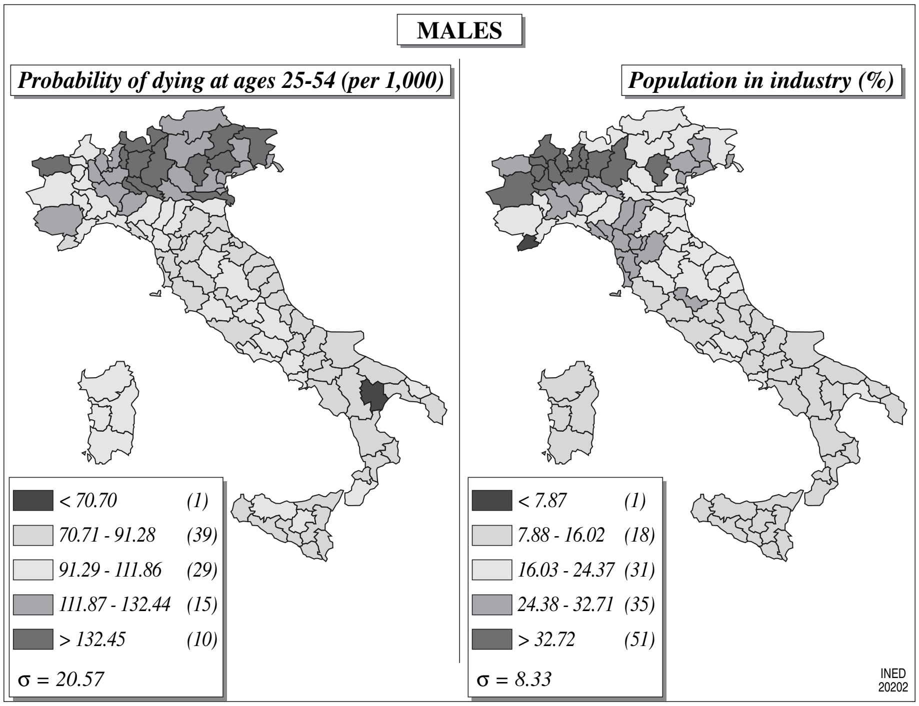

FIGURE 55–16 Geographic variations of male mortality at ages 25 to 54 years and of the proportion of the working population employed in mining and manufacturing industries in Italian provinces between 1971 and 1973. (From Caselli, 2002.) (Figure 55–16 also reproduced in color plate section.)

that may explain these differences. This approach, based on observations that were aggregated for a geographic area and not for individual data, does not enable us to establish any causal relationships between external variables and mortality, but it can suggest their existence and provide assumptions to explain observed differences; such assumptions can be verified only through in-depth epidemiologic studies based on individual data.

To illustrate how this type of analysis can contribute to the interpretation of geographic variations of mortality, we refer to the main conclusions of a principal components analysis carried out on the geographic variation of male mortality in Italy between 1971 and 1972 for two age groups representative of the adult (25 to 54 years) and elderly population (55 to 79 years) (Caselli and Egidi, 1981c). At that time and for these two age groups, the mortality maps were about the same as those in Figure 55–10 for the 40 to 64 and 55 to 84 age groups between 1991 and 1993, with the same striking contrast between northern and southern parts of Italy. In this study, the cause-specific geographic differences in mortality (Table 55–3, 16 groups) observed in the 94 Italian provinces were compared with 38 indicators, including socioeconomic and environmental indicators, indicators pertaining to eating behavior, and other behavior indicators than can be linked to health[9] (Table 55–4).

Thanks to the image obtained by projection of the 94 province-points on the factorial plane, the proximity of the provinces, in terms of analogy of behavior pertaining to the variables, becomes significant. The projection of the 16 + 38 variables makes it possible to attribute a significance to the proximity of the

[9] Briefly recall that the principal components analysis is a method of factorial analysis that makes it possible to reduce the dimensions of the data matrix with the use of synthetic variables (factors) obtained through linear combination of the initial variables. This analysis is based on a geometric interpretation of the data matrix, according to which each of the n (94 for Italy) provinces is assimilated to a point whose coordinates are the p (16 + 38) variables (causes of death and external variables). Similarly, each variable can be interpreted as a point whose coordinates are the n values taken from the provinces. The provinces and the variables are elements belonging to two Euclidian vectorial spaces whose dimensions are, respectively, p and n. The procedure consists in projecting the cloud of 94 points-provinces, as well as the 16 + 38 variables, on a subspace of fewer dimensions but that guarantees the lowest possible distortion of the initial image (see Bouroche and Saporta, 1980). The first two or three factors almost always suffice—especially in the field of demography—to explain most of the total dispersion of points, and the first factorial plane (formed through the first two factors) reflects most of the dispersion.

TABLE 55–3 Groups of Causes of Death Used for the Principal Components Analysis of the Geography of Italian Mortality

No.	Code	Group of causes	ICD code[a]
1	MIP	Infectious and parasitic diseases	000–139.9
2	TMD	Malignant neoplasm of digestive organs and peritoneum	150–159.9
3	TMR	Malignant neoplasm of respiratory system	160–163.9
4	TMU	Malignant neoplasm of genito-urinary organs	180–189.9
5	AT	Other malignant neoplasms	140–149.90; 164–179.9; 190–239.9
6	D	Diabetes mellitus	250
7	AGN	Other diseases of endocrine glands, nutritional and metabolism disorders	240–249.9; 251–279.9
8	CI	Ischemic heart disease	410–414.9
9	AAC	Other diseases of circulatory system	290–409.9; 415–458.9
10	B	Acute bronchitis and bronchiolitis; bronchopneumonia, unspecified; chronic bronchitis; emphysema and asthma	466; 485; 490–493.9
11	AAR	Other diseases of respiratory system	460–465.9; 467–484.9; 486–489.9; 494–519.9
12	MAD	Diseases of the digestive system	520–577.9
13	MAU	Diseases of genitourinary organs	580–629.9
14	SEM	Symptoms and ill-defined conditions	780–796.9
15	AET	Accidents, poisoning, and traumas	E800–E999.9
16	AM	Other conditions	280–289.9

[a] International Classification of Diseases: detailed list of the eighth revision.
From Caselli and Egidi, 1981c.

provinces in terms of correlation: The nearer each other on the plane, the better correlated are the distributions of two variables, all the more so as they are distant from the origin.

The proximity of the points (provinces or variables) shows their homogeneity, but in this analysis, the demographer cannot project simultaneously the province-points and the variable-points, because they do not belong to the same cloud or to the same space. However, it is possible to compare the respective positions of two or several provinces with the total group of variables and *vice versa*.

To interpret the results, it is particularly important to attribute a meaning to factors, because they are linear combinations of the initial variables. To this end, we used the coordinates of the variable-points that express correlations between variables (i.e., cause-specific death probability and external variables) and the factorial axes.

An initial analysis, conducted with only the external variables, enabled us to show the relationships between variables and to divide the territory into geographic areas according to their dominant characteristics. We observed that the first factorial axis opposes variables linked to economic zones at a lower stage of development to those pertaining to the most developed zones. The provinces all follow this axis, from south to north according to the well-known social economic division of Italy. This dichotomy, as we have seen, can be found in the pattern of adult and elderly mortality, although in a form contrary to what might have been expected, because adult and elderly mortality is higher in the wealthier regions of the north and lower in the poorer regions of the south. The second factorial axis, which is tied mainly to the geographic distribution of the population, establishes an opposition between the populations of the sparsely populated rural and mountainous regions (i.e., Alpine and Apennine regions) and the large urban centers such as Rome, Milan, and Naples.

If we apply the principal components analysis to the entire group of 16 + 38 variables, the joint study of the territorial distributions of causes of death and external variables suggests interesting considerations for the research of factors underlying the observed geographic differences. For the sake of brevity, we do not show the projection of the provinces on the first factorial plane; we instead concentrate on the projection of the variable-points (Figs. 55–17 and 55–18), while calling attention to the specificities of the geography of different causes of death, as well as the meaning given to the two main axes of the analysis of external variables.

Between the ages of 25 and 54 years, the first factorial axis of this joint analysis (which explains 27% of the variance) offers two pieces of information: one concerning economic development, especially in the industrial sphere, and the other the high rate of mortality, closely tied to the high probability of dying of

TABLE 55–4 External Variables Used for the Principal Components Analysis of the Geography of Italian Mortality

Number	Code	Variable
Use		
1	Activity	Rate of activity
2	Salaried	Proportion of salaried workers
3	Construction	Proportion of the working population salaried in construction and civil engineering
4	Indupop	Proportion of the working population salaried in mining and manufacturing industries
5	Induprov	Proportion of working population working in mining and manufacturing industries among those working in the province
6	Dimind	Average dimension of the industry
Geographic mobility of workers		
7	+1 h	Proportion of persons commuting 1 hour or more to get to work
8	Commute	Proportion of commuters who drive to work every day
Risks at work		
9	Malprof	Incidence of diseases contracted at the workplace in industry
10	Accind	Incidence of accidents at the workplace leading to death or permanent invalidity in industry
Environment and demographic density		
11	Density	Population density per km 2
12	Size/household	Average number of persons per household
13	Urban	Proportion of persons living in communes with population >20,000
14	Agglom	Proportion of persons living in an urban environment
15	Mountain	Proportion of persons living in the mountains
16	SO_2	Emission of SO_2 air pollution indicator
17	Pollwater	Estimate of degree of water pollution
18	Radiac	Basic radioactivity
Climate		
19	Precip	Annual average precipitation in millimeters
20	Excuther	Thermal excursion
Housing		
21	<1919	Old housing (proportion of private dwellings built before 1919)
22	Bath	Proportion of private dwellings with running water, bathroom, or water closet (WC)
23	Heating	Proportion of private dwellings with central heating
24	Persons/room	Average number of persons per room
Medical and hospital infrastructure		
25	Physicians	Average number of practicing physicians for 1000 inhabitants
26	Beds	Number of beds for adults available for 1000 inhabitants
27	Assistance	Public expenditure for assistance
Consumption		
28	Bread	Consumption of bread and pasta
29	Sugar	Consumption of sugar
30	Fat	Consumption of vegetable and animal fats
31	Meat	Consumption of meat and fish
32	Milk	Consumption of milk and cheese
33	Non-food con.	Non-food consumption
34	Smoking	Consumption of tobacco
Income and standard of living		
35	Income	Net income per capita
36	Car	Average number of privately owned cars per capita
Education		
37	Instruction	Proportion of persons 15 years old or older having had at least 8 years of education
Marital status		
38	Marital status	Ratio of unmarried and widowed persons 15 years old or older to married persons

From Caselli et Egidi, 1981c.

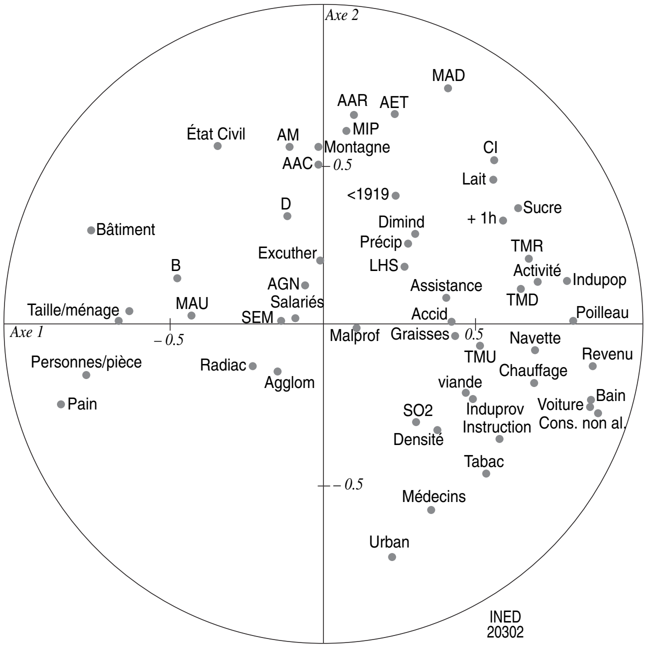

FIGURE 55–17 First factorial plane in the principal components analysis of male mortality between the ages of 25 and 54 years that is associated with the external variable matrix for Italian provinces between 1971 and 1972. See Tables 55–1 and 55–4 for causes of death and external variables. (From Caselli and Egidi, 1981c.)

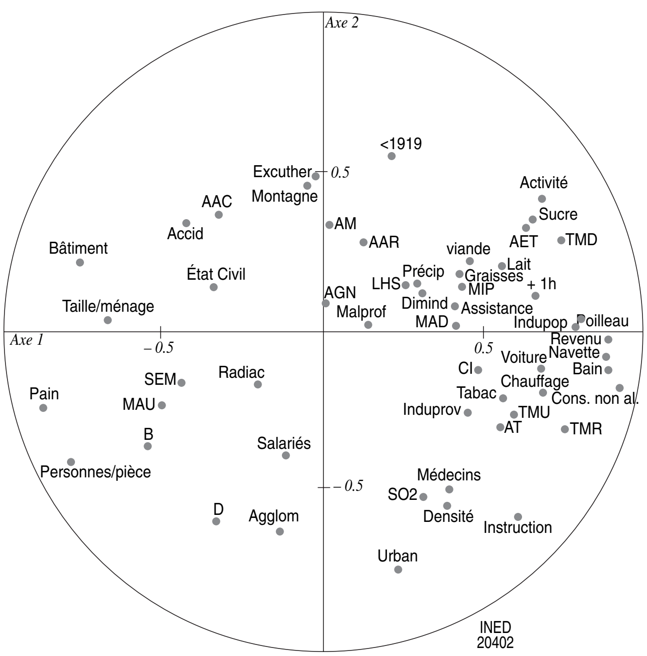

FIGURE 55–18 First factorial plane in the principal components analysis of male mortality between the ages of 55 and 79 years that is associated with the external variable matrix for Italian provinces between 1971 and 1972. See Tables 55–1 and 55–4 for causes of death and external variables. (From Caselli and Egidi, 1981c.)

cancer or ischemic heart disease. The second factorial axis (12% of the variance), which tells us about the spatial distribution of the population, does not play a discriminating role in terms of cause-specific mortality structure. Overall, the correlation of mortality causes with the first factorial plane is low.

The external variables taken into account have little impact on the explanation of the territorial differences in mortality due to diseases of the endocrine glands and the metabolism (D and AGN), diseases of the genitourinary organs (MAU), or poorly defined causes (SEM). We also observe the low level of relevance of the variables linked to climate conditions and the variables taken as indicators of environmental degradation, most often typical of urban zones. The latter variables (i.e., density and SO_2) are rather correlated with the third factor (not represented here), which establishes an opposition between malignant tumors of the respiratory system (TMR) and malignant tumors of the digestive system (TMD). The latter are frequently associated with high-protein and high-fat diets. The main results, listed in Table 55–5, demonstrate several of the relationships between cause-specific mortality and these variables. We see that ischemic heart diseases and cancers are common in the most highly developed and wealthiest areas of the country. Diseases such as diabetes (which, thanks to medical advances, are rarely fatal today) continue to cause death in regions that are economically underdeveloped and where health services are still deficient.

Between the ages of 55 and 79 years (see Fig. 55–18), the general structure of the projection of points on the first factorial plane (29% of the variance) is in large part similar, but some interesting differences are revealed. The correlation between external variables and factors seems generally higher. As a result, the variables that seem to have an impact on the territorial distribution of mortality at that age are more numerous.

The first axis, the development indicator, correlates more with mortality due to malignant tumors of the respiratory system (TMR) or the digestive system (TMD) and mortality due to violent causes (AET). This axis also correlates, negatively this time, with mortality due to acute infectious diseases of the respiratory system (B) and to diabetes (D).

The second axis (11% of the variance), linked to urbanization, takes on a significant role in the description of mortality between the ages of 55 and 79 years. This axis establishes an opposition between the characteristics of mortality in urbanized regions, with a greater frequency of diabetes (D), acute diseases of the respiratory system (B), and cancers, and the characteristics of mortality in the mountainous

TABLE 55–5 Correlations between the Geographic Distribution of Causes of Death and Selected External Variables, with Reference to the First Factorial Plane of the Principal Components Analysis

Ischemic heart diseases	Malignant tumors of the respiratory system	Malignant tumors of the genitourinary organs	Malignant tumors of the digestive system	Diseases of the digestive system	Accidents, poisonings, and trauma	Bronchitis, bronchopneumonias, and similar diseases
For age 25 to 54 years

See Table 55–4 for an explanation of the external variables.

regions of the Apennines, where other diseases of the digestive system (AAR), violent deaths (AET), and malignant tumors of the digestive system (TMD) are prevalent.

The influence of urbanization on ischemic heart disease seems entirely different from what we observed in the previous age group. Between the ages of 25 and 54 years, mortality due to ischemic heart disease is higher in the northern provinces, which have a lower density (even if they are more industrialized), whereas between 55 and 79 years, this type of mortality is high mainly in the large, industrial cities.

Several strong relationships between variables and cause-specific mortality are modified by age. For example, the influence of certain variables pertaining to individual behavior (e.g., smoking) on mortality due to malignant tumors of the respiratory system or the genitourinary system and on mortality due to ischemic heart disease grows stronger after the age of 55 years (see Table 55–5). The fourth factorial axis (not shown here) reveals a specific dimension, because it positively correlates with other diseases of the respiratory system and with public health expenditures, the number of physicians per capita, and altitude. This factor appears as the axis illustrating the situation of some provinces of the Alps and the Ligurian Riviera, where the climate and the availability of adequate medical services attracts elderly persons suffering from respiratory diseases.

Among young and older adults, there is a coincidence between the geography of mortality due to malignant tumors of the respiratory system or genitourinary organs and the geography of air and water pollution, as well as the level of industrialization. However, a significant correlation with smoking appears only at older ages. At these ages, the variables that play a part in the geography of cancers also play a considerable role in the geography of ischemic heart disease, whose geographic distribution at younger ages seems very much linked to that of high-protein and high sugar diets, as well as stressful lifestyles.

The differences between the death probability due to malignant tumors and diseases of the digestive system are also linked to eating habits, but in this case, especially among older persons, the high consumption of fatty foods and animal protein seems to have a very negative impact.

Beyond permanent patterns, the specific trends of certain causes of death are responsible for changing the Italian geography of mortality. Another study (Caselli, 2002), which focuses precisely on the more sensitive causes, shows that such changes are still taking place, particularly in relation to modifications in eating behavior (which are increasingly homogenous), in the nature of industrial activities (which are increasingly diversified), or in health prevention practices (for which the north-south divide has grown deeper).

CONCLUSIONS

Like all variables that divide a population into different subgroups, geography brings to light mortality variations that underscore one aspect of the population's heterogeneous nature. The concept of geography in itself requires explanations, which partly explains the global heterogeneity of the population in terms of risks of dying. However, geographic differences in mortality can also help show the relationship between mortality and other socioeconomic or cultural variables, to the extent that the latter also vary according to geographic location. The study of multiple correlations between variables in the realm of geographic differences can be very useful in this respect.

If studies on geographic variations of mortality more often focus on developed countries than on developing countries, it does not mean that the phenomenon is less important in the developing countries (Verhasselt and Pyle, 1993). The paucity of studies indicates only that the necessary data are much harder to obtain in some countries.

PART

IV

THEORIES AND FRAMEWORKS OF MORTALITY

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

Morbidity and mortality have changed beyond all recognition since man first trod the Earth. The conditions of humankind's survival changed with their ability to control the natural world, and after millennia of hesitant progress, a sweeping revolution began in the 18th century. Nevertheless, vast differences remain between the situations of populations and between the constituent groups of populations, as was stressed in earlier chapters.

The efforts to account for the dynamics of these changes and the diversity of situations are reviewed in the next two chapters from two very different but complementary angles. Many tentative theories have been formulated about the very high infant and child mortality in the least-developed countries. Godelieve Masuy-Stroobant critically reviews the main frameworks of infant and child mortality trends and differentials in Chapter 56.

In Chapter 57, France Meslé and Jacques Vallin look at attempts to find a paradigmatic explanation for health gains since the 18th century, from Abdel Omran's *epidemiologic transition theory* to the broader concept of *health transition*.

Theories and Frameworks for the Study of Child Mortality

GODELIEVE MASUY-STROOBANT

Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

Thus although we may know in how many studies has infant mortality been found to slope downwards with increasing education of the mother, and in how many cases the relation is presumably not affected by disturbing factors, we know little about the theories and frameworks that led to the study of the association. . . . It is no wonder then that one of the most common findings in the literature—that mother's education exerts a negative effect on infant mortality—is also one of the least understood.

(Palloni, 1987, p. 31)

The importance given to the mother's education at the individual level and the development of horizontal health policies in developing countries—of which access to education is one of the main components—at the collective level, were of central importance in the development of theories and frameworks on infant and child mortality in the demographic literature in the late 1970s.

This chapter does not discuss the respective advantages and limits of theories and frameworks; the former are usually considered as more rigorous but too limited, and the latter are often too ambitious in trying to integrate all known risk factors, whatever the level of observation or the nature of the relation (direct, indirect, or only contributing through other factors) with infant and child mortality. Nor should the testability of the proposed hypotheses be evaluated. Theories and frameworks are presented here as part of a theorization process in the sense defined by Hubert Gérard: "a process of critical systematization of acquired 'knowledge,' in an appointed body of qualified proposals resulting in hypotheses likely to be subjected to empirical testing verification" (Gérard, 1989, p. 271).

The theoretical hypotheses concerning mortality in the general process of demographic transition are not considered here because they are presented in later chapters. Such developments usually refer to the historical decrease of overall mortality (and incidentally, of infant and child mortality) and consider it a social process, observed and measured at a macrosocietal level and analyzed jointly with the dynamics of fertility decline.

This synthesis is limited to the tentative theorization and understanding of the mechanisms of infant mortality (i.e., from birth to the first birthday) and child mortality (i.e., between the first and the fifth birthday) observed at the individual level. Because of the diversity of mortality levels, research focuses on infant mortality (including fetal mortality) in the developed countries and on infant and child mortality in the developing countries. Because they are still closely dependent on the cultural, socioeconomic, political, and temporal contexts they refer to, such theorizing attempts have not yet resulted in a general theory, although a number of potentially common elements can be derived from them. The theorizing process is under way but still poorly developed: “Mortality is the theoretically under-developed area of demography which will probably incur the greatest evolution in the next 30 years” (Crimmins, 1993, p. 589).

I. FROM HYPOTHESES TO THEORIES

Several attempts have been made, in developed and in developing countries, to understand and produce frameworks or even theories on the universal or quasi-universal (negative) relationship observed between mortality in early infancy and the mother’s education. A similar relationship is observed at the aggregate level (i.e., country, region, or other geographically defined unit of analysis) between the level of infant or child mortality and women’s education and, at the individual level, between a child’s risk of dying and its mother’s educational level.

1. In the Developed Countries

Long before demographers, sociologists have tried to uncover the mechanisms behind this relationship by proposing hypotheses very similar to John Caldwell’s theories for Nigeria (1979).

When trying to understand the biologic and social factors of infant mortality in England and Wales from 1911 to 1950, J. Morris and J. Heady (1955, p. 558) suggested three ways of accounting for persisting social inequality: “The first is concerned with time-lag in the improvement of health as a result of social improvements; the second approach deals with the changing composition of the social groups; the third emphasizes that the whole question—a crucial one for contemporary social medicine—is still open.”

The time lag in the dissemination of the effects of social improvements may be cultural, because the influence of grandmothers and traditions are a socially variable obstacle to change and to the adoption of new health behaviors. The investigators further suggest that long-term capital assets such as education could well be more effective than income as far as maternal and child health are concerned.

The second approach deals with the hypothesis of selective social mobility upheld by Raymond Illsley, based on the 1954 Aberdeen survey of women having their first child. Illsley said, “The moves from one social class to another are frequent between generations. . . . It is possible to show that moves of this type are selective not only on the social and the educational level, but also where health is concerned. . . . Disparities will usually be all the greater as the (social) mobility was more significant and/or linked to the level of education, the child’s development, growth or death” (Illsley, 1987, p. 51).

Luc Boltanski (1969) develops the same hypothesis of a superposition of the social and temporal distances in the acquisition of the knowledge and of the health and childcare behaviors:

> The dissemination of medical knowledge occurs faster and more easily among the upper classes than in the lower ones. This is first of all because the patient-doctor . . . communication pattern varies according to the patient’s social class—he is more familiar with them when they belong to the upper classes, and more authoritarian when they are working class. Another reason is that members of working classes, having a low educational level, do not have a critical view on their knowledge or “prejudices” because they lack that “examination mind” which is a consequence of the formal education. . . . The implementation of the newest rules, those that best comply with (childcare) norms, requires less the acquisition of any particular knowledge than taking up an overall attitude to knowledge (Boltanski, 1969, p.12, 72–79).

The attempts to describe the mechanisms of the action of a mother’s education on the health (and survival) of her child were all developed in reference to the Western European context. At that time, child mortality was very low in those countries, with infant mortality levels ranging from 27 deaths for every 1000 live births (England-Wales, 1951 to 1955) to 32 per 1000 (France, 1956 to 1960). Compulsory education was already introduced for several decades, and all Western European countries benefitted from national maternal and child health systems. Social security systems, including compulsory health care insurance, had been organized immediately after the Second World War. Although infant mortality today reaches well levels well below 10 per 1000, the gap between social groups still persists (Masuy-Stroobant and Gourbin, 1995); such inequalities are also observed in fetal mortality, even in countries, such as Sweden, experiencing the lowest mortality rates (Cnattingius and Haglund, 1992).

2. In the Developing Countries

John Caldwell’s research on Nigeria (1979) played a leading role in the renewed interest demographers took in a more explanatory approach to child mortality in Third World countries. He first establishes the fact that the level of education (specifically, the mother’s education) is the most discriminating socioeconomic characteristic as far as children’s survival is concerned: “Maternal education is the single most significant determinant of these marked differences in child mortality . . . maternal education cannot be employed as a proxy for general social and economic change but must be examined as an important force in its own right.” He adds, “Furthermore, in Nigeria, as doubtless in much of the Third World, education serves two roles: it increases skills and knowledge as well as the ability to deal with new ideas, and provides a vehicle for the import of a new culture" (Caldwell, 1979, p. 408–409).

John Caldwell then suggests three hypotheses of growing importance:

> The first explanation is usually given as the only reason. That the mothers and other persons involved break with tradition or become less "fatalistic" about illness, and adopt many of the alternatives in childcare and therapeutics that become available in the rapidly changing society. The second explanation is that an educated mother is more capable of manipulating the modern world. She is more likely to be listened by doctors and nurses. . . . She is more likely to know where the right facilities are and to regard them as part of her world and to regard their use as a right and not as a boon. There is a third explanation, which may be more important than the other two combined. . . . That is, that the education of women greatly changes the traditional balance of familial relationships with profound effects on child care.

Most of the studies subsequently published, including the explanatory frameworks on child mortality, refer to this series of hypotheses, even though they were not systematically verified on the field. The tentative theory centered on the mother's education was subsequently refined or even expanded by considering it within a more general context of generalization of the schooling of the population (Palloni, 1985a, 1985b) and in its dynamics from one generation to another (Ware, 1984).

To Alberto Palloni, the effect of a mother's educational level should be considered with reference to the population's general education level: The higher it is at collective level, the less significant its effect will be at individual level. For him, this is a sign of greater equity in the distribution of national resources, and he suggests the following hypothesis: "In countries with socially integrated populations and higher levels of participation, the beneficial effects of an individual's education are less important since access to the basic resources and services is less constrained by individual assets and characteristics" (Palloni, 1985b, p. 474).

The effects mentioned here are measured in absolute terms, but relative differences persist in very-low-mortality countries.

With reference to Bangladesh, Helen Ware mentions an transgenerational dimension of the health-education interaction: "Educated mothers may be taller and fitter, not only in cases where their parents were also educated and lived in comfortable circumstances, but also in cases where poor parents selected the healthiest and brightest of their children to go to school and then strengthened their investment with preferential treatment in the allocation of food and medical services" (Ware, 1984, p. 195).

3. Similarities of Hypotheses

There are many similarities between the hypotheses concerning developing countries and those on developed ones. When Luc Boltanski argues in 1961 that the effect of education has proved to be more significant than any specific training in childcare, he is later echoed in observations made in Africa by Helen Ware (1984, p. 194). The hypotheses made by Luc Boltanski and John Caldwell on how education results in an increase in maternal autonomy are very much alike, whether such autonomy is shown in mothers breaking with tradition or in their feeling more comfortable in using modern medicine and communicating with it. The hypothesis of selective social mobility and of health-education transmission of girls from one generation to another, such as made by Raymond Illsley, turns out to be relevant in observations made in Bangladesh and Nepal (Ware, 1984). The idea that the acquisition of a certain level of education by the general population, especially by mothers, act as a "long-term investment" (Morris and Heady, 1955) in health is further expanded on by people who believe in social, rather than economic, development and in horizontal and basic policies, rather than in vertical health interventions, to secure the mortality decline and the health of Third World children.

This information shows that a theory of child mortality focused on mothers' education is still being developed. When taking the different levels of action (i.e., individual, family, and societal) into account, its temporal dimension, through the transgenerational transmission, may make it possible to turn it into a more universal theory. The formal education mentioned here, like medical technologies and preventive health behaviors, was exported from the developed into the developing countries. The former and the latter are probably inextricably linked. But how?

II. FRAMEWORKS FOR CHILD MORTALITY

Frameworks for child mortality appear by the early 1980s in the demographic literature, several decades after the well-known fertility framework suggested by Kingsley Davis and Judith Blake in 1956. Although theories on demographic transition, of which mortality is an essential component, were developed in the meantime, few or no attempts at systematic approach to mortality have been made. How can such delay be accounted for, and what triggered the emergence of the numerous frameworks on child mortality in the early 1980s?

The understanding of mortality seems more complex than that of other demographic phenomenon, partly because of its biologic component; its variable, sometimes unknown, latent period between exposure to or origin of the disease; its clinical manifestations; and its fatal issue. Setting aside the identification of what epidemiologists call risk factors of infant or even child mortality, multivariate analysis of mortality is strongly limited by the fact that deaths are a statistically rare event (even in situations of high mortality), whereas it is widely acknowledged that the analysis of its causality is multifactorial.

Demographers, as social scientists, and epidemiologists, belonging to the biomedical sciences, share a common interest in the study of infant and child mortality. Social sciences, including demography, focus mainly on its measurement, the social and economic determinants of its historical decline at a collective level, and in showing how mortality differences are an indicator of persisting social and economic inequalities at the individual level. The biomedical sciences have analyzed the biologic process of diseases, attempting to identify how to prevent diseases (mainly by vaccination), or to cure them, according to the classic epidemiologic model of infectious diseases, by intervening on one of the three elements of the agent-exposure-host triad. In doing so, demographers found it difficult to access the mechanisms (which were partly biologic, but also related to health behaviors) that would enable them to establish a link between social class and early death in childhood, whereas physicians and epidemiologists often neglect the social factors about which they felt helpless. There was also the widespread feeling that mortality, especially mortality in childhood, was supposed to continue decreasing as the poorer countries experienced process of economic and social development. This belief was reinforced by the fact that medical technology was then considered efficient and able to control infectious diseases by means of mass vaccination, securing a clean environment (e.g., in the case of malaria), or educating mothers to practice oral rehydration when their infant suffer from diarrhea. However, such beliefs were completely upset by the fact that the rate of decrease reportedly slowed down in high-mortality countries and that health conditions worsened in others (Gwatkin, 1980). Theses linked to the very conception of development were then confronted, resulting in the idea that vertical interventions, usually punctual health interventions, such as mass vaccination programs and targeting specific diseases, could only have a limited effect. Children who escape dying of the targeted disease would die of another one. Reaching a certain level of economic development, measured, for example, by means of the gross national product growth is not enough to improve the population's health; the wealth acquired must benefit the majority, which implies that social policies are set up to ensure that the results of economic development are redistributed: "Major barriers to good health are social and economic; more attention should therefore be given to such activities as education of women and community development" (Mosley, 1985, p. 189). Alberto Palloni, referring to Latin America, gives primary importance to making chances equal: "Equally relevant is the presence of broad social developments as reflected in equalization of access to material resources and health services, active participation in community and national life by all groups in society, and suppression of traditional, locally based norms of behavior which are detrimental to the health of some individuals (excess fertility, short birth intervals, sex discrimination in the treatment of children, child rearing practices, traditional resistance to adoption of modern medical services)" (Palloni, 1985a, p. 449). To vertical interventions meant to have an effect over specific diseases using specific technologic means are opposed horizontal interventions that "are designed to deal with generic conditions producing high prevalence of a wide variety of diseases by providing egalitarian and better access to medical services, improving sanitation and water supply, supporting dietary and nutritional campaigns and engaging individuals and families in campaigns for the prevention and treatment of common diseases" (Palloni, 1985a, p. 449). How successful such horizontal interventions can be depends on the development of social policies such as previously mentioned.

The emergence of the nutritionist movement resulted on the medical side in the development of a more general approach to children's health conditions, using simple anthropologic measures in which their age, weight, and size are combined. The underlying logic was based on the observation that, except in cases of strictly accidental causes, children do not die of any single disease, but rather of the combined effect of repeated infectious attacks, from which a child recovers with even greater difficulty because it was suffering from malnutrition from the start or was weakened by a previous disease. Various measurements of nutritional status have been developed with a view to evaluate some transitory or chronic deficit, but what matters is that the concept makes it possible to establish a link between the social and biomedical approaches to mortality, because the child's nutritional status (including its weight at birth) is closely linked to its parents' social and economic conditions and because measuring nutritional status is not specifically linked to any particular disease, as is the measurement of overall mortality, with which demographers are more familiar.

1. In Developing Countries

The frameworks of child mortality have been developed by referring to contexts in which infant and child mortality rates are still very high (along with very high fertility rates). They were also largely inspired by the fertility framework developed by Kingsley Davis and Judith Blake (1956), drawing clear distinction between intermediate and proximate variables of mortality, which have direct effect on a child's chances of survival, and other variables whose indirect effect is felt through intermediate variables.

Beyond aiming at giving some order and coherence to the series of risk factors and to the alleged causes of premature death in early infancy or during childhood hitherto identified in scientific literature, such frameworks also aim at reconciling or even bringing together the social and biomedical approaches by "identifying a set of proximate determinants that can link social processes in populations to biological outcomes in individuals" (Mosley, 1985, p. 202). At the same time, the different levels of influence (and analysis) were deliberately taken into account. In some cases, these range from the macrosocietal political system to the genetic factors at the individual level, the ecological environment, the community infrastructure, household composition, and other levels.

What matters about these frameworks is the identification and enumeration of determinants, as well as their classification into broad categories, rather than the complex relations between each of the elements within each category or with those of other categories. Along with the frameworks, a presentation of and justification for the consideration of each of their constituents are usually given but no hypotheses are offered that could be confronted with reality. That was not part of the authors' objectives. For some, "the task . . . is the identification of those characteristics of individuals, households, and communities that need to be maintained, altered or eliminated by means of health interventions and social development" (Palloni, 1985a, p. 457) and consequently to help developing an efficient health policy, whereas for others, it was "to provide a construct that can assist researchers in reexamining the assumptions underlying their work in order to better identify the relevant questions to ask" (Mosley, 1985, p. 202).

The frameworks suggested by Sriniwasa Meegama (1980), Michel Garenne and Patrice Vimard (1984), Henry Mosley and Lincoln Chen (1984), and Alberto Palloni (1985a, 1985b) are presented here as illustrations. The field experiences of the authors cover the three major developing regions—Asia (Meegama, Mosley, and Chen), Africa (Garenne and Vimard), and Latin America (Palloni)—and they allow us to trace their thinking process and to identify what was at stake in the health and development policies with regard to children's health and mortality.

Instead of suggesting a single pattern that would be applicable *mutatis mutandis* to the deaths of all children before their fifth birthday, Sriniwasa Meegama draws radical distinction between neonatal deaths and post-neonatal and children's deaths. Rather than integrating the paradigms of social and medical sciences, his approach consists of enlarging the traditional epidemiologic model of infectious diseases. For example, post-neonatal and children's mortality is broken down into groups of major causes of death (e.g., respiratory diseases, digestive system disorders, illnesses due to malnutrition, anemia); in the next stage, the exposure vectors (e.g., the air, water, environment, inadequate nutrition) and the contributing causes are identified. For example, inadequate clothing or housing may lead to exposure to adverse weather conditions, which may cause respiratory diseases that may lead to death; the lack of prenatal or postnatal monitoring, insufficient information, or the mother's economic activity may result in early weaning or insufficient feeding of the infant, which may cause malnutrition or anemia that, in interaction with infectious disease, may be direct or indirect causes of a child's death.

The same reasoning applies to neonatal deaths. Sriniwasa Meegama's approach offers a synthetic vision of the biologic determinants of mortality in childhood, grouping together infectious diseases and identifying their causes, which are mainly linked to social and economic conditions. The proposed causal process, however, remains specific to each group of causes of death and to age at death. Malnutrition appears as a direct cause of death and as contributing to it when combined with infectious diseases. The framework, however, is strictly limited to the individual level, whereas most of the frameworks subsequently published achieved a much larger scope.

The framework designed by Michel Garenne and Patrice Vimard (1984) goes beyond the individual's social and economic conditions to the political and ecological contexts (Fig. 56–1). Infant and child mortality is considered as a whole, as is the case in most frameworks designed for developing countries. Their framework has a rather modest objective: "It is not meant to

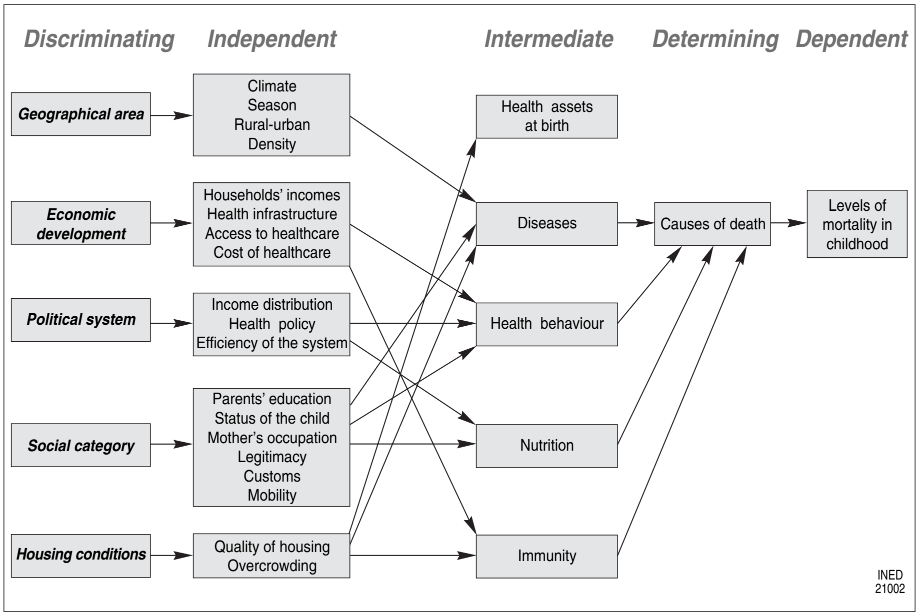

FIGURE 56–1 Analytic framework for the study of child survival, first example. Derived from the framework developed by Michel Garenne and Patrice Vimard (1984).

be exhaustive in any way, only to situate things so as to clarify the discussion" (Garenne and Vimard, 1984, p. 306). The authors distinguish five groups of variables, corresponding to different levels of causality:

1. The discriminating variables "should not have any direct effect over mortality, but refer to the classical studied differential mortality: geographic characteristics, economic development level, political system, social categories, and housing conditions.

2. The independent variables describe in detail the different dimensions of the variables collectively defined at the previous level; they are "likely to have an effect on mortality through one or several intermediate variables." Geographic characteristics therefore are broken down into categories of climate, season, residence (rural or urban), and population density and the political system into "distribution of income," "health policy," "efficiency of the system," and other categories. Maternal education is mentioned as one dimension of the social category, but the status of the child, the mother's occupation, the customs, and other factors are also included.

3. The intermediate variables are those through which most of the independent variables are likely to exert their influence and "their action over the survival of the child or the cause of its death"; here, the chain of causes is much more complex than Sriniwasa Meegama's (there is no specific path to each cause of death), and the authors have proposed five groups of variables (i.e., the health status at birth, diseases, health behaviors, nutrition, and immunity).

4. The determining variables are medical causes of death. No cause or disease is explicitly mentioned; the authors mention that it is not the result of any simplistic medical diagnosis "because the death of a child is often the result of a complex process that can seldom be summarized in any single cause of death."

5. The dependent variable is the overall level of mortality.

Michel Garenne and Patrice Vimard provide a classification of the variables by the nature of their relationship with the risk of death. What they refer to as *levels* do not necessarily cover the level of observation or analysis of the variables taken into account. The levels are defined from a functional point of view. From an operational point of view, the variables pertaining to a specific category are not necessarily observed at the same levels—independent variables that correspond to such aspects of economic development such as "households' income," "health infrastructure," "access to health care," and "cost of health care" should be observed at the household's or at the community level. The independent variables belong to the "social category," and discriminating variables are observed at the individual level (e.g., the mother's and the father's education) or at the household level (e.g., status of the child) or a more aggregate level (e.g., mobility of the population).

Henry Mosley and Lincoln Chen (1984) keep the idea of a distinction between independent and intermediate variables, but they classify the independent variables by level of observation or analysis into household-related individual variables and community variables. The authors state that they mean to suggest a framework integrating the social and biomedical sciences approaches. They do it in two ways. First, they combine the nutritional level of growth faltering (nutritional status) of the survivors with the level of mortality of the respective birth cohort into a more general health index for the dependent variable. In doing this, the authors go beyond the usual deceased-survivor dichotomy, classifying the survivors by their health levels, with death being considered an extreme situation of ill health. The point was to consider child mortality "more as a chronic disease process with multifactorial origins than as an acute, single-cause phenomenon" (Mosley and Chen, 1984, p. 41). Second, they select proximate determinants (or intermediate variables) in which "clinical" relevance with regard to the risk of malnutrition or death is combined with their being observable or measurable in studies made at the population level. The intermediate variables or proximate determinants are categorized into five major groups: maternal factors linked to reproductive behavior, environmental contamination, nutrient deficiency, injury, and personal illness control (Fig. 56–2).

Independent (or underlying or socioeconomic) determinants, which are operating through the proximate determinants, are grouped into three broad categories corresponding to three levels of observation:

1. Individual-level factors include productivity or the capacity of producing a surviving, healthy child, such as can be measured by the father and mother's education, their health condition, and their time availability; the norms, traditions, and attitudes likely to change economic choices and practices related to health (as measured by the power relations within the household); the value of the child; beliefs about disease causation; food preferences; and taboos.
2. Household-level factors include availability of food (including water), clothing, bedding, housing, fuel or energy availability, transportation, access to health care (both preventive and curative), and access to information.
3. Community-level factors are related to the characteristics of the context, such as the ecologic setting and political economy, including the stability of the political institutions and the degree to which individuals participate in local and national decision-making, and are related to health system variables.

The studies by John Caldwell (1979) concerning individually measured independent variables are used as references, and most importantly, Henry Mosley considers the mother's educational level as a key factor: "Because of her responsibility for her own care during pregnancy and the care of her child through the most vulnerable stages of its life, her educational level can affect child survival by influencing her choices and

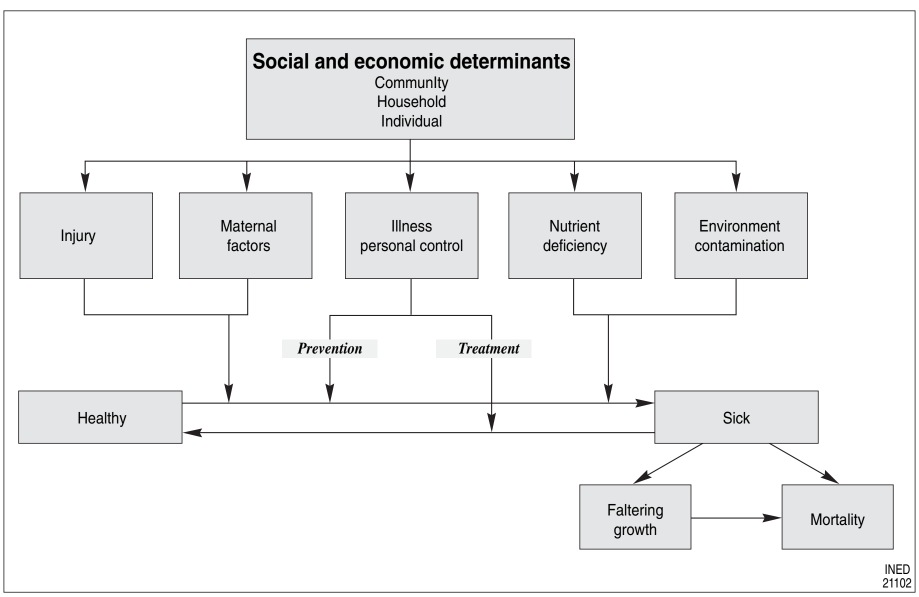

FIGURE 56–2 Analytic framework for the study of child survival, second example. Derived from the framework developed by Henri Mosley and Lincoln Chen (1984).

increasing her skills in health care practices related to contraception, nutrition, hygiene, preventive care, and disease treatment. In fact, so many proximate determinants may be directly influenced by a mother's education to radically alter chances for child survival, that one of the authors [Mosley] was prompted to label the process 'social synergy.'" (Mosley and Chen, 1984, p. 35).

Whereas Henry Mosley and Lincoln Chen's objectives were to suggest a framework for research and action, Alberto Palloni (1985a, 1985b) is more oriented toward action. He strives to prove the necessity to develop social policies and the so-called horizontal health interventions (Fig. 56–3).

Palloni states that "the excess of infant and child mortality and the anomalous structure of causes of death are clues about the nature of the comparative failure of the health policies implemented up to then" (Palloni, 1985a, p. 455). His framework was intended to help formulate a health policy, and its elements were selected with reference to their vulnerability to a social policy action. It includes three levels of action:

1. The policy level emphasizes social policies and horizontal interventions (i.e., education campaigns and socialization of health care).

2. The individual or collective level distinguishes among individual (i.e., biologic, behavioral, and social characteristics, including maternal education), household (e.g., resources, overcrowding, family structure), and community (e.g., ecology, health system, accessibility to services) characteristics.

3. The third level, which is closest to morbidity, refers to the biomedical paradigm (i.e., exposure to infectious agents, vulnerability or susceptibility of the individual, and capacity to resist the disease).

Action may be conducted at any of these levels, but for Alberto Palloni, any vertical action related only to the third level cannot result in any sustainable improvement of children's health or in any long-term increase of their chances of survival. If the causes of individual differences (second level) in mortality can be identified, substantial reduction of mortality among the less-privileged social group may lead to a radical decrease in total mortality, but that is unlikely to occur without reinforcing social policies and horizontal interventions (first level).

2. In Developed Countries

In most developed countries, the stagnation of infant mortality is recent, and it is probably artificial, at least partly, and linked to the evolution of birth notification practices (Masuy-Stroobant and Gourbin, 1995), as well as to the fact that very low levels have

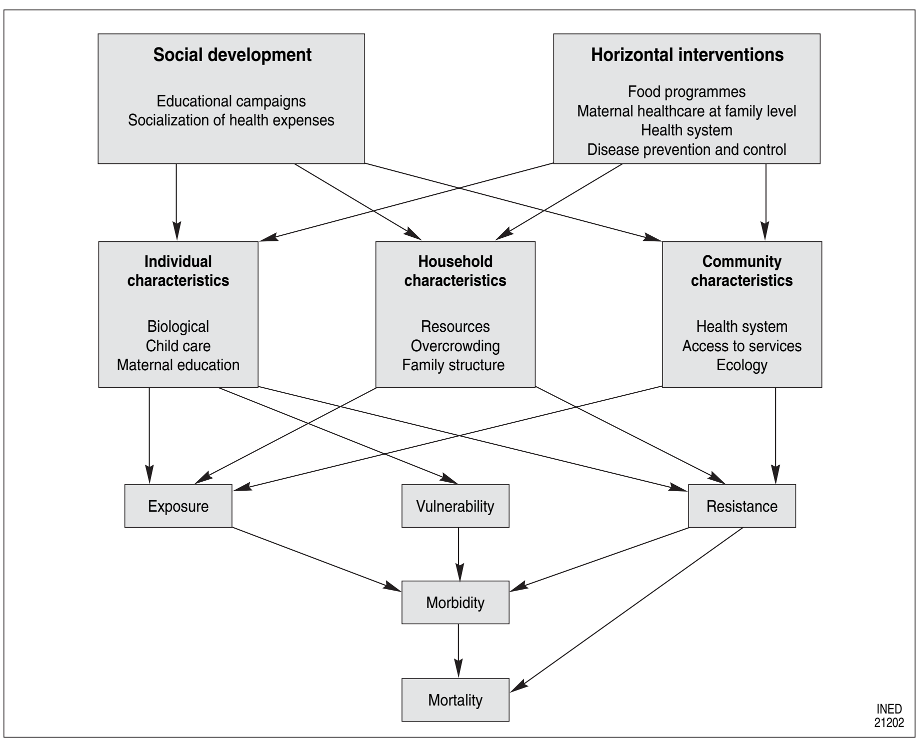

FIGURE 56–3 Analytic framework for the study of child survival, third example. Derived from the framework developed by Alberto Palloni (1985).

been achieved. As a social phenomenon, however, infant mortality in developed countries is not a solved problem—significant social inequalities are still observed, even when fetal mortality is considered. The believe that causes of fetal or neonatal mortality are mainly endogenous should be revised.

Whereas demographers are traditionally more interested in identifying mortality differentials (i.e., by maternal age, birth order, legitimacy, or the mother's social class and education), epidemiologists have repeatedly sought *factors* and *markers* of preterm birth or low birth weight. When risk factors are vulnerable to medical intervention, markers, among which most social and economic variables are included, are useful in identifying at risk groups, but they cannot be changed through medical intervention. The cause and effect relationship between preterm birth and those factors has seldom, if ever, been proved: "Many factors—more than 100—have been brought out. But the question of whether those factors play any causal role has not yet been investigated. . . . Efficient measures then might well be taken for high risk women, though no action was taken against the risk factors, since their causal role is ignored, and some of them cannot even be changed" (Schwartz, 1989, p. 138). The fact that infant mortality is a statistically rare event has also contributed to particular attention being paid to measures of a child's vulnerability at birth, such as preterm birth or the risk of low birth weight—which, like malnutrition, are not specific to any given disease—as dependent variables.

Beyond identifying risk criteria, a few attempts have been made to classify variables, as was done for developing countries. However, such attempts were definitely situated at the individual level; the social, health, and ecologic circumstances in developed countries are very different from those in developing ones. Concerning the United States, Charles Nam and colleagues (1989) draw a clear distinction between independent or basic variables (i.e., ethnic group, maternal education, marital status, and place of residence), intermediate variables (i.e., weight at birth, prenatal care, last birth interval, age of the mother, previous experience of death, sex of the child, and twin births), and immediate factors (i.e., age at death and medical cause). For Belgium, I have established a classification of social identification variables (i.e., occupation, education, nationality, and marital status of the child's parents) and intermediate variables (i.e., past fertility behavior, behaviors and preventive attitudes about the health system and in daily life) "in order to gain a better understanding of the mechanisms through which the social and cultural class determines unequal survival in early infancy" (Masuy-Stroobant, 1989, p. 48).

The process of systematizing available knowledge is ongoing, and the stage of developing one or several infant and childhood mortality theories has not been reached for developing or developed countries. Similar approaches are applied; social and cultural factors admittedly play a more extensive part, although they are nonspecific and must be used in combination with biologic factors to account for infant or child mortality. However, the persistent social component in children's health and mortality, even in the most developed countries, remains largely unaccounted for. The time or process dimension also needs to be inserted into the theorization attempts, which are still exceedingly static, so that that this essential aspect of the child mortality process can be considered.

The Health Transition: Trends and Prospects

FRANCE MESLÉ AND JACQUES VALLIN

Institut national d'études démographiques (INED), Paris, France

For thousands of years and up until the mid-18th century, human life expectancy rarely exceeded 25 or 30 years, with limited variations according to time or place. This does not mean that the epidemiologic profile did not change during that time. On the contrary, research has shown that since prehistoric times, there has been a succession of *pathocenoses*, periods marked by a specific epidemiologic development involving specific pathologic combinations (Biraben, 1999). However, from the mid-18th century on, a new era began in Europe during which the shift from one pathocenosis to the next also went along with a decisive and lasting lengthening of life expectancy. This marked the beginning of the *demographic transition*, a term coined to designate the historical process that enabled mankind to shift from an older demographic regime, in which high fertility rates balanced the losses due to high mortality, to a new regime, in which mortality between birth and the end of reproductive life dropped to such an extent that generation replacement could be ensured with barely more than two children per woman (Notestein, 1945; Kirk, 1944; Landry, 1934).

Mortality and fertility declines have their roots in the economic, social, and political transformations that led to the Industrial Revolution.[1] However, to each of these declines corresponds a specific set of factors. The dynamics of the factors leading to these long-term advances in life expectancy were given the name of *health transition* (Frenk *et al*., 1991).

These advances resulted from a decline in the spread of certain diseases, which deeply modified the epidemiologic profile of the population; however, unlike the other changes involved in pathocenosis, for the first time, the decline affected all infectious diseases, and these were no longer replaced by others in such a way as to maintain mortality globally at the same level at a given age. Age at death has risen, and life expectancy has increased. The term *epidemiologic transition* is used to designate the shift from one dominant pathologic structure to another and a radical transformation process in ages at death.

The epidemiologic transition was first theorized at the end of the 1960s (Omran, 1971). This research elucidated the reasons why life expectancy had begun to increase, how this increase accelerated, and how, beginning in the 1960s, it reached a threshold in the most advanced countries.

Omran's theory was soon undermined by the dramatic decrease in cardiovascular diseases in Western countries. The concept of epidemiologic transition, which focuses on trends in the spread of diseases, turned out to be too narrow, and as a result, in the first issue of the *Health Transition Review*, founded in 1991 by John Caldwell, Julio Frenk, and others, the term *health transition* was chosen. Health transition refers to changes in the epidemiologic characteristics of the health situation, and it reflects society's response to this state of health.

[1] This question is dealt with in Chapters 68 and 69, devoted, respectively, to Europe's demographic transition and to the globalization of the transition.

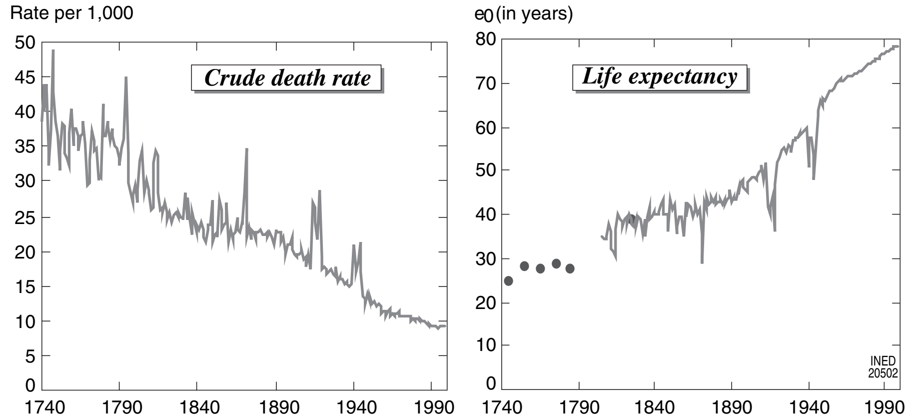

FIGURE 57–1 Crude death rate and life expectancy at birth in France: trends since the middle of the 18th century.

We face two important issues for the future. After 30 years of decline in mortality due to cardiovascular diseases, can we expect any further advances in life expectancy? It is probable that the new epidemiologic situation will change, because causes of death will be changing, and these developments probably carry new potential in terms of life expectancy gains. However, one question remains: Will these advances soon reach their limit, or is this limit still remote or uncertain?

Regardless of possible life expectancy gains in the future, existing gains have already and necessarily entailed the aging of the population. What is the relationship between aging and the state of health of populations? Our task is to determine for a given age whether the state of health has remained the same, is improving, or is deteriorating.

I. FROM THE EPIDEMIOLOGIC TRANSITION TO THE CARDIOVASCULAR REVOLUTION

In the demographic regimes of the past, mortality was very high, and there were strong fluctuations due to epidemics and famines. In a country such as France in the middle of the 18th century, when national statistical series began to be drawn up on a more or less regular basis, the crude death rate was still about 40 per 1000, hovering between 30 and 50 per 1000, as it had been in the past. By then, these fluctuations were much lower than they had been in previous times. The plague, for instance, which devastated Europe between 1347 and 1352, killed up to one-half of the population in some regions (Biraben, 1975). In Finland during the 1868 famine, the crude death rate rose to 80 per 1000 (Pitkänen, 1993).[2] In France in the space of 2 centuries, the crude rate dropped to less than 10 per 1000, and the fluctuations completely disappeared (Fig. 57–1). In the 20th century, such wide-scale disasters were caused only by the two World Wars, in violent contrast to the steadiness of the generally declining trend. The annual variations of life expectancy can be observed only since the beginning of the 19th century (Meslé and Vallin, 1989), but 10-year estimations are also available from the middle of the 18th century (Blayo, 1975). The average life span was about 25 years around 1740 and is about 80 years today. In Figure 57–1, we can see only the more recent fluctuations of the 19th century, but it is easy to imagine their scope in earlier times.

1. Epidemiologic Transition or Health Transition?

Abdel Omran (1971, 1983) attempted to synthesize the different factors at play in these secular mortality trends, in his theory of *epidemiologic transition*, based on three epidemiologic ages, with the second age corresponding to the *transition* between the first age, the age of high mortality, and the third age, that of the new epidemiologic regime. He determined the following stages:

[2] In Europe during peace time, the only country that reached a crude death rate of that scope during the 20th century was Ukraine, during the famine of 1933; that year, 2.5 million persons died in a population of about 30 million (Vallin *et al.*, 2002). Contrary to the Finnish famine, this famine was not caused by climatic conditions but was the consequence of Stalin's policy of forced collectivization of agriculture.

1. The *age of pestilence and famine*, in which mortality was high and fluctuating and life expectancy was less than 30 years on average
2. The *age of receding pandemics*, during which life expectancy increased strongly, rising from less than 30 to more than 50 years
3. The *age of degenerative and man-made diseases*, in which mortality, after a continuous decline, tends to stabilize at a very low level

The first age was marked by the predominance of infectious diseases; large-scale endemics determined the average level of the death rate, and epidemics and famines were responsible for the fluctuations. John Graunt, who studied death certificates in the city of London, showed that in the 17th century, three-fourths of the mortality in London was caused by infectious diseases, malnutrition, or complications of childbirth. In France, the first age lasted until the mid-18th century.

During the second age, epidemics became less frequent, and endemic infectious diseases began to decline; mortality decreased, and the fluctuations diminished. The "transition" began in the 18th century in northwestern Europe (around 1750 in France) and gradually spread to the rest of Europe, reaching the south in the 20th century. In Europe, cholera replaced the plague epidemic, although with far less violence, and this new disease was curbed much faster than previous ones. Among major endemic diseases, tuberculosis, which first spread considerably due to industrialization and urban crowding, began to recede near the end of the 19th century. In France, the development of industrial capitalism during the Second Empire went along with a pause in the decline of mortality, but beginning in the 1880s, mortality resumed a sharp decline, with a massive and widespread decline in infectious diseases. This decline continued throughout the 20th century, with two interruptions due to the two World Wars.

According to Omran, during the third age, the progress of life expectancy slows down and tends to reach a threshold. Numerous traditional causes of death continue to decrease, but the benefits of this new situation are countered by the rise of new endemic diseases, whether they are degenerative diseases (e.g., cardiovascular diseases, cancers, diabetes, metabolic disorders) or man-made diseases. Omran includes in this category "radiation injury, accidents, occupational hazards, carcinogens in the environment and in industry, and food additives." It is debatable whether mortality due to degenerative diseases has really increased globally. In France, the mortality increase attributed to cardiovascular diseases is deceptive, because if deaths due to ill-defined causes are realistically distributed going as far back in time as possible (1925), cardiovascular mortality is receding (Vallin and Meslé, 1988; Meslé and Vallin, 1988). There is no doubt that these diseases proportionally weigh more and more in calculating the total death rate. For man-made diseases, mortality has genuinely increased—or rather skyrocketed. However, the elements mentioned by Omran are not necessarily the determining factors. Smoking and alcoholism, which he does not even mention, are prime factors; most accidents are traffic accidents, and domestic or workplace accidents are declining.

Notwithstanding this criticism, Omran's division into three ages accurately reflects reality up until the end of the 1960s, when he wrote his first article. At that time, in all the industrialized countries, the progress of life expectancy was beginning to slow down, even stagnate, and in some cases (Eastern Europe), it began to decrease (Vallin and Chesnais, 1974). In France, a distinct pause can be observed among males, and progress in life expectancy was slowing among females (Meslé and Vallin, 1993). Many investigators believed at the time that life expectancy in the most advanced countries was close to the maximum limit imposed by human nature (see Chapter 48). Jean Bourgeois-Pichat (1952) calculated in the early 1950s a *maximum biologic life table*, showing that the maximum life expectancy was 76 for men and 78 for women. Similarly, to establish the first world population forecasts, the United Nations stated in the early 1980s that all populations were converging toward a life expectancy of 75 years (i.e., a little less for males and a little more for females) (United Nations, 1985).

However, events very soon belied this model. In all the Western countries, the advances of life expectancy accelerated again in the early 1970s because of a massive decline in cardiovascular diseases. At that time, Jay Olshansky and Brian Ault (1986), followed by Richard Rogers and Robert Hackenberg (1987), began to speak of a "fourth stage of the epidemiologic transition."[3] For the former, the diseases remained the same; only the ages at death had grown older. For the latter, we were dealing with a new era, in which great advances were and would be occurring because individuals were acquiring healthier habits. This notion of a fourth stage, which can be added on to Omran's epidemiologic transition, is rather unconvincing. Omran's idea was based mainly on the shift

[3] This was a "fourth stage of the epidemiologic transition" for Jay Olshansky and Brian Ault; it was a "new stage," also qualified as "hybristic," for Richard Rogers and Robert Hackenberg.

from an old permanent regime to a new permanent regime, after a transition toward lower mortality. It was therefore possible to say that the transition phase has grown longer and still retain the same three-phase explanatory model. However, this would not account for the fact that the new era of progress beginning in the 1970s was based on a major epidemiologic change, the cardiovascular revolution, which is not linked in any way with the end of the era of infectious diseases, even though it did follow closely. For this reason, it seemed preferable to us (Vallin, 1993) to adopt the semantic shift proposed by Julio Frenk *et al*. (1991) and include within the wider concept of health transition an initial phase (that described by Omran) of life expectancy gains, attributed mainly to the decline in mortality due to infectious diseases, followed by a second phase dominated by the decline in cardiovascular diseases, leaving open the possibility of identifying later phases, such as that suggested by Shiro Horiuchi (1999) for cancer and perhaps senescence.

2. Changes in Causes and Ages at Death

Two important phases in health advances can be distinguished based on the control of two very different types of diseases that have had an impact on different ages at death. If we take the example of France, we can divide the life expectancy gains obtained during a given period between those due to the changes in the different causes of death and those due to the probability of dying at different ages.[4] It is difficult to closely follow cause-specific mortality trends due to the breaks periodically introduced into statistical series by successive changes in the nomenclature of diseases. France, like most developed countries, uses the International Classification of Diseases (ICD), which was adopted by the International Institute of Statistics (IIS) in 1893 and by the World Health Organization (WHO) after World War II. This classification was revised 10 times within the space of a century, sometimes with wide-ranging modifications (see Chapter 42). The main reason for taking France as an example is that we have at our disposal reconstructions of historical series of deaths, classified by cause of death, on the basis of a constant definition (Vallin and Meslé, 1988, 1998). Nonetheless, this series only goes back to 1925, and we can therefore measure with precision the role of epidemiologic changes in the life expectancy trends only over the past 75 years of the period of health transition. However, we can obtain a good idea of it by identifying three periods: 1925 to 1948, when the decline of infectious diseases was still the dominant pattern; 1948 to 1968, during which this decline was less productive and partly countered by the rise of man-made diseases; and 1968 to 1996, when the advances in life expectancy gained new impetus with the control of man-made diseases and the decline of cardiovascular diseases.

Figure 57–2 represents a breakdown of life expectancy gains obtained in France during these three periods, between the different effects due to the trends of six large groups of causes:[5]

1. Infectious and respiratory diseases (i.e., Chapters 1 and 8 of the ICD, 9th revision)
2. Other cancers (i.e., Chapter 2 of the ICD, except bronchial and lung cancer)
3. Cardiovascular diseases (i.e., Chapter 7 of the ICD)
4. Man-made diseases (i.e., bronchial and lung cancers, alcoholism,[6] car accidents, suicide, and homicide)
5. Other diseases (i.e., all other items except those in Chapters 16 and 17 of the ICD)
6. Other violent deaths (i.e., other items of Chapter 17 of the ICD).

From 1925 to 1948 in France, of the 10.8 years of life expectancy gained by males, almost three-fourths (7.4 years) of the years were gained because of the decline in infectious and respiratory diseases. Among females, the proportion (7.5 of 12.2 years) is a little smaller because of the significant decline in cardiovascular diseases. From 1948 to 1968, the total life expectancy gain is twice as low (5.1 and 6.6 years, respectively), and the fact that the time interval is shorter (20 years instead of 23 years) does not alone explain it. There are probably two reasons. The impact of the decline of infectious diseases is decreasing, the impact of man-made diseases is decisively negative. During the following period (1968 to 1996), life expectancy gained once again—6.5 years for males and 6.9 years for females—but for entirely different reasons. The decline in mortality due to infectious diseases, which was still continuing, produced almost nothing in terms of life

[4] Different methodologies are available, including those developed by Evgueni Andreev (1982) and John Pollard (1982), which are based on the same principle and provide almost identical results (see Chapter 16).

[5] We first performed a proportional distribution of deaths due to ill-defined causes (i.e., Chapter 16 of the ICD) to avoid the considerable bias from the fact that the proportion of deaths due to ill-defined causes has dropped from more than 35% in the 1920s to less than 6% today.

[6] This category includes items 291 (alcoholic psychoses), 303 (alcohol dependence syndrome), 305.0 (alcohol abuse) and 571.0 to 571.3, and 571.5 (cirrhosis of the liver) in the 9th revision of the ICD.

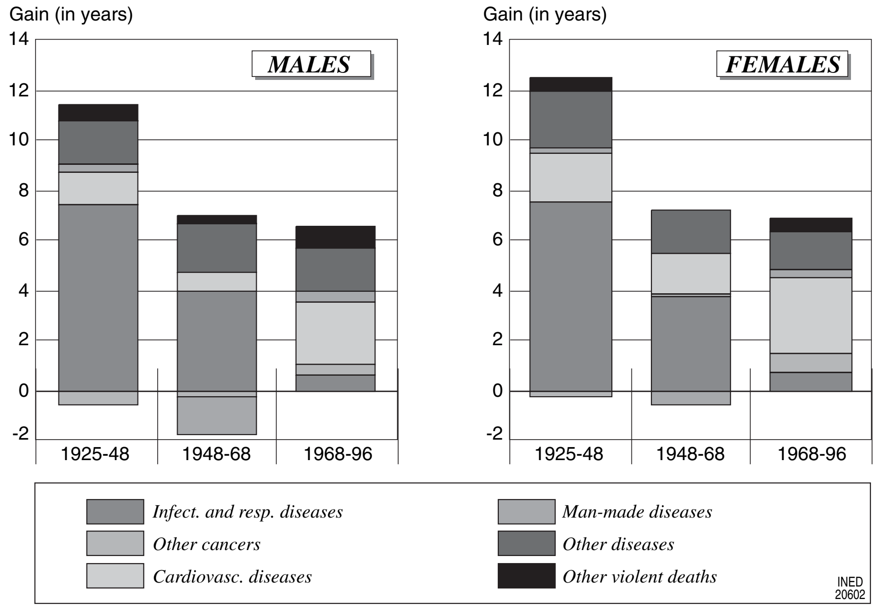

FIGURE 57–2 Contribution of the six large groups of causes of death in life expectancy gains according to sex during three periods in France.

expectancy gains because the level of this type of mortality was already very low. However, the decline in man-made diseases reversed the impact of this new trend on life expectancy and especially the decisive decline of cardiovascular mortality increased life expectancy by 2.6 years among males and 3.1 years among females. Moreover, for the first time, the category "other cancers" played a role in the lengthening of life expectancy.

The 1960s were marked by an important turning point in the health transition, when cardiovascular diseases replaced infectious diseases as the main source of life expectancy gains. The stage where Omran's epidemiologic transition left off is now far behind. However, there is another point concerning which Omran's pessimism is outdated: Not only has the rise in man-made diseases been curbed, but these causes of death have to a large extent been reduced. This is particularly clear among males, who are more affected by these diseases than females. Figure 57–3 shows how in France, from the 1960s on, these causes of death were gradually overcome.

The reversal of the tendency occurred first for alcoholism, beginning in the mid-1960s. For this cause of death, the losses in life expectancy turned into gains beginning in 1968–1978. The phenomenon occurred again a little later for traffic accidents. We know that the reversal of mortality trends due to traffic accidents began in 1974; for this reason, in Figure 57–3, life expectancy gains appear substantial only as of 1978–1988. The negative impact on mortality due to bronchial and lung cancer ceased only in the more recent period. This decline began in the early 1990s and should lead to life expectancy gains among males in later decades.

This extensive redistribution of the impact of different death causes on life expectancy trends went along with a radical transformation of the distribution of different age-specific death rates. From this point of view, available statistics make it possible to follow the effects of the health transition since it began. Figure 57–4 represents life expectancy gains due to the mortality decline of six age groups during six periods since the mid-18th century, in France. The three most recent periods are the same as those used in Figure 57–2 for causes of death, and we simply divided the two previous centuries into three periods.

For 2 centuries and up to the 1920s, the increase in life expectancy was almost entirely accounted for by the decline of infant and child mortality. From 1740–1749 to 1925, the life expectancy of males gained 29 years and that of women gained 32 years. In both cases, 23 years can be ascribed to the mortality decline of children younger than age 15 years. Between 1817 and 1885, the life expectancy gains are much lower than during the preceding and following periods, and this reflect the fact that the decline of child mortality slowed down at that time. A temporary increase in child mortality was observed in France during the Second Empire. The decisive impact of infant and child

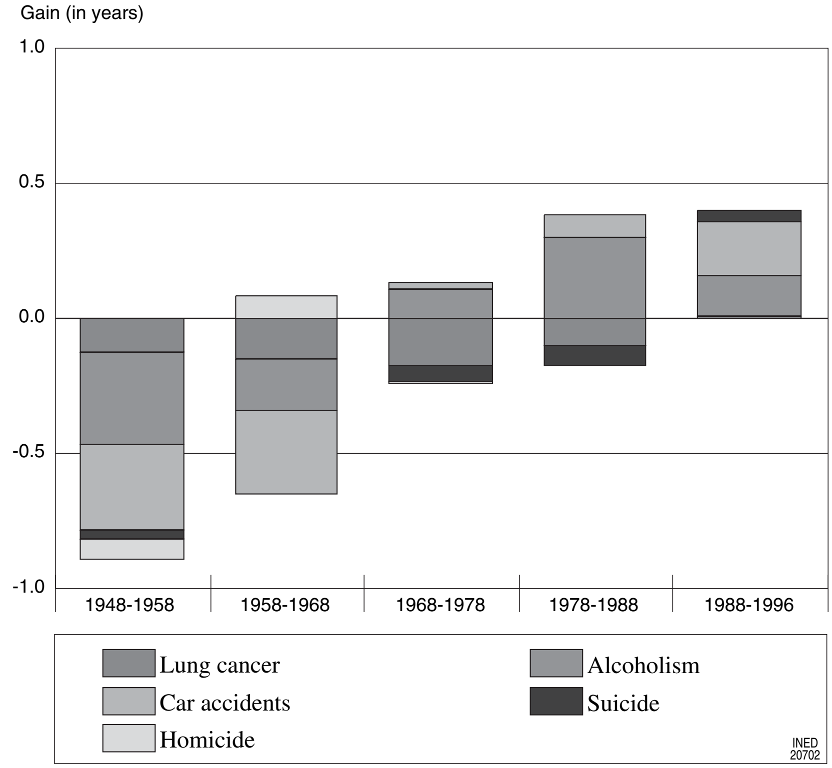

FIGURE 57–3 Contribution of five types of man-made diseases to gains or losses in life expectancy for males during three periods in France.

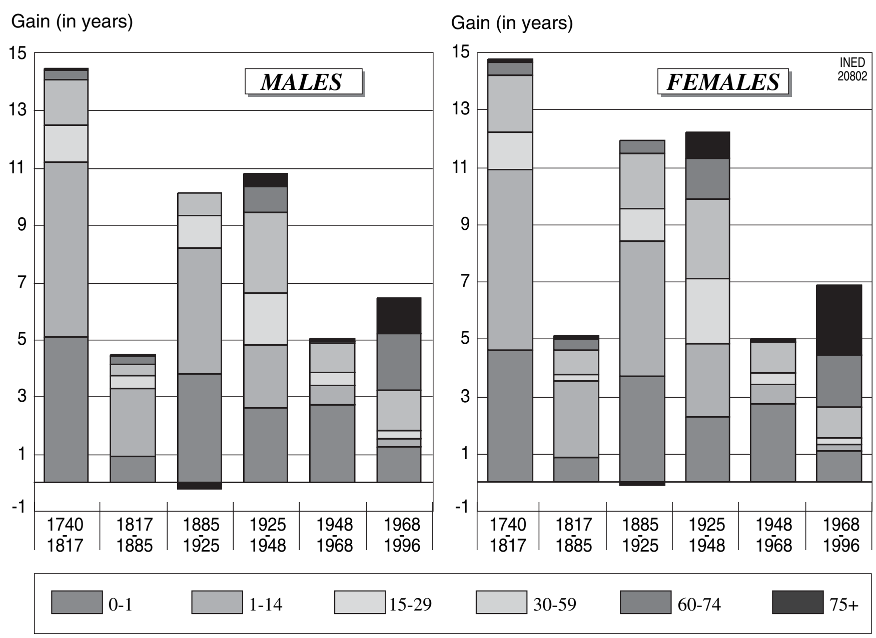

FIGURE 57–4 Contributions of six age groups to the gains or losses of life expectancy for each sex during three periods in France.

mortality trends corresponds to that of childhood infectious diseases.

The period between 1925 and 1948 appears to be quite different. The decline of child mortality led to still more gains in life expectancy, but substantial gains were also caused by the decline of adult mortality, particularly between at age 30–59 years. The decline of infectious diseases led to gains at all ages. Tuberculosis in particular began to recede, and maternal mortality from infectious causes began a steep decline with the arrival of sulfamides. Very soon, thanks to vaccines and antibiotics, the decline in child mortality led again to most of the life expectancy advances after World War II, whereas the rise of man-made diseases deprived adults of most of the advantages resulting from these medical advances.

The situation radically changes when we move to the last period (1968 to 1996). The decline of child mortality produced only marginal effects, whereas that of elderly persons began to play an unprecedented role. Among females in particular, the decline in mortality after age 60 represents a gain of 4.2 years, for a total of 6.9 years or more than 60%. Among males, the proportion is 50%. The decline in mortality at age 75+ represents on its own a 2.4-year gain among females and 1.2-year gain among males.

3. Health Transition Factors

There has been much debate concerning the factors responsible for the health transition, particularly about the respective roles of medical advances and social and economic development (Vallin, 1989). Other points of view have also stressed the importance of cultural and social changes (Tabutin, 1995; Caldwell, 1986, 1990).

In the 1960s, most researchers agreed that medical advances were mainly responsible for the health transition. From Pasteur to antibiotics, effective weapons against infectious diseases had been discovered, and after World War II, the effectiveness of these techniques were tested among the populations of the developing countries, still very much affected by infectious diseases. Paul Demeny (1965) went so far as to deny the impact of economic and social progress in the decline of world mortality during the 3 decades that followed the war, whereas Colin Clark (1967) believed that medical progress was the only factor responsible for the increase of life expectancy in England in the 18th and 19th centuries. At that time, however, Thomas McKeown (McKeown, 1965, 1976; McKeown and Record, 1962) held an opposite view, because he believed that the mortality decline observed in England in the 19th century was for the most part attributable to advances in nutrition; this opposing view led to violent disputes. Today, these disputes have lost their relevance, because it appears that these two factors do not suffice alone or together to account for health advances. Reality is far more complex, and factors have also varied to a large extent in time and space.

In Europe, during the 18th century, mortality began to recede thanks to the double impact of the control of the widespread epidemics that were so frequent in the past (not so much through medical advances but through measures taken to protect populations) and the increase of available food, which was attributed to the development of agriculture and the improvement of transport and storage conditions. In France, life expectancy rose from less than 30 years in the mid-18th century to a little more than 40 years in the 1840s. During the Second Empire, economic progress based on industrialization and the development of uncontrolled capitalism led to an interruption of the life expectancy increase during 3 decades (from 1850 to 1880) because of the concentration of an ever-larger proportion of the population in insalubrious urban zones and unhealthy working and living conditions, particularly for children.

Life expectancy began to increase again because of the discoveries of Louis Pasteur and their implementation through new health policies. However, even if medical progress played a very important role, it was not the only factor involved. Pasteur's ideas had to be concretely applied in daily life, particularly through rules of hygiene and food preserving techniques. Medical and health advances were spread mainly through educational progress, because education became free and compulsory at that time thanks to Jules Ferry. This double progress, both medical and sociocultural, largely contributed to the control of infectious diseases in a general context of economic and social development. More progress in medical techniques was made in the 1930s with the invention of sulfamides, and the decisive moment occurred in the 1940s with the invention of antibiotics and new vaccines. At that time, these advances made their way to the population thanks to the gradual implementation of generalized health insurance systems after World War II. In France, life expectancy rose from 43 years in the early 1880s to almost 60 years on the eve of World War II and 70 years in the early 1960s.

This considerable increase in life expectancy, due to two centuries of progress in nutrition and to the victorious struggle against infectious diseases, although first limited to Europe and North America, rapidly spread during the 20th century to the rest of the world. Significant advances were made in some regions of

Latin America and Asia in the first half of the century, but it is mainly after World War II that these advances reached the developing countries. The question of the spread of health advances to these countries led to the development of numerous theories and explanatory schemes of the mortality decline. These naturally involved multiple factors (Palloni, 1985; Mosley and Chen, 1984). The medical techniques developed in Europe and North America played a determining role, enabling some poor countries (e.g., Sri Lanka, Cuba, Costa Rica, Kerala) and even the largest among them, China, to reach life expectancy levels in the 1970s or 1980s that were quite close to those of the wealthy countries, even though these countries had not experienced major economic development (Preston, 1975). Nonetheless, efficient health policies still remained to be implemented so that the majority could benefit from these advances. After World War II, the success of vaccines and antibiotics led some to believe that it would be enough to organize eradication campaigns targeted at the main endemic diseases (Coale and Hoover, 1958). Indeed, because of the efforts of the WHO, some campaigns were very successful, the most famous case being the eradication of malaria in Sri Lanka whereby life expectancy in that country gained 12 years within 2 years (Molineaux, 1985a, 1985b; Meegama, 1967; Frederiksen, 1960). However, it was soon found that to spread health progress to the population in a lasting and effective way, health care policies had to account for these numerous factors. The WHO completely revised its action by adopting in 1978, at the Alma Ata conference, the strategy of "primary health care," which involves the dissemination at the local level of a number of simple and efficient medical techniques; the development of food production, drinking water, and environmental measures; and educational progress and improvement of the status of women. This strategy of primary health care has often been criticized, but the reason why it has often been unsuccessful is that its implementation requires political reforms that few governments are willing to implement (Mosley, 1985a, 1985b; Suarez-Ojeda and Yunes, 1985a, 1985b; Rosera-Bixby, 1985a, 1985b). The factors that determine health progress are doubtless a complex combination of technical, socioeconomic, cultural, and political factors in which each element interacts with the others.

What was true for the first phase of the health transition based on the control of infectious diseases is even truer for the next phase, in which the increase of life expectancy depends more and more on the decline of other diseases, particularly cardiovascular diseases. The issue is much more complex in terms of medical aspects. There are no miracle drugs such as vaccines and antibiotics to treat cardiovascular diseases, only various forms of treatment such as anticoagulants, beta-blockers, pacemakers, and coronary bypass surgery; treatment also includes the organization of medical emergency services. Medical prevention is more difficult to organize, because in this case it is not possible to vaccinate once and for all, but only to monitor certain risk indicators (e.g., blood pressure, cholesterol levels). In the case of infectious diseases, global policies are enough to improve environmental factors (e.g., environmental clean-up, drinking water distribution), but the context favoring cardiovascular disease can be modified only through the complex interaction of global policies and changes in individual behavior. In the case of smoking, for example, the decision to stop smoking is an individual matter, but this decision will more likely not be taken if smoking remains valued in the social culture. Political action and individual awareness are interdependent. Such changes are even more difficult in the realm of eating habits. In this case, the problem is not the consumption of one specific, clearly identified food item, but the subtle balance of quantity, quality, and the type of ingredients that make up daily meals. At the political level, the message is much harder to convey, and on the individual level, it is very difficult to change a person's eating habits. Beyond the obvious impact of advances in medical technology, as concerns the cardiovascular revolution and the initial successes in the struggle against cancer, public awareness of the fundamental importance of behavioral risk factors is a crucial element. It is the driving force of the second phase of the health transition, on a par with the role of Pasteur's discoveries and the use of antibiotics during the first phase.

This combination of factors came together quite late in the history of economic and social development in industrial countries. True, infectious diseases had to be dealt with before cardiovascular diseases could be addressed, but a high degree of economic and social development was also needed to ensure the necessary material and cultural means for these advances. This is what happened in the 1970s in most developed countries, and as a result, life expectancy in France rose from 72 years in 1970 to almost 79 years in 1999, crossing the 75-year barrier that the United Nations in the early 1980s still considered to be the upper limit of life expectancy. However, this new stage of health progress did not occur in all industrialized countries (Bourgeois-Pichat, 1985a, 1985b). The most notable exception is Eastern Europe, which instead of following the path of decline in cardiovascular disease, combined all the disadvantages of the third age of Omran's epidemiologic transition: pandemic of degenerative diseases and expansion of man-made diseases (Shkolnikov *et al*., 1995, 1996; Meslé, 1991).

II. THE HEALTH TRANSITION AND FUTURE PROSPECTS

The future developments of the health transition increasingly depend on the relationship between life expectancy and longevity, which so far has not been studied in depth. Until now, researchers have focused on life expectancy, with the implicit idea that longevity is an intangible fact; however, as demonstrated in Chapter 48, the question of longevity has become extremely important. Depending on whether the upper limit of human life can be extended, the potential increase of life expectancy can vary considerably. If it is intangible, life expectancy can still significantly increase, but if it is not, it can increase indefinitely. In any case, we must raise the question of the consequences of the health transition on the quality of the years gained.

1. Rectangularization of the Survival Curve?

Since the middle of the 18th century, the increase in life expectancy has mostly resulted from the fact that deaths that occurred at earlier ages began to occur at older ages, even if this extension does not necessarily go beyond the age limit biologically imposed on human life. As described in Chapter 48, as mortality declined, the survival curve of the population became increasingly "rectangularized" (Fig. 57–5).

The life tables for the years 1740–1749 show that the proportion of survivors dropped suddenly at very early ages due to the high level of child mortality. At the age of 1 year, it was down to 70%, and before the age of 10, one-half of the cohort had already died. Some exceptional individuals did come near or even exceeded 100 years. The life table of French women in 1996 showed that there were still 50% of survivors at 85, but even if living more than 100 years is becoming less and less unusual, it is still an exceptional feat.

On the basis of this observation, it can be concluded that there is a limit to the human life span. This limit is well over 100 years, although it cannot be precisely defined because our only reference is the empirical value of a record that will always remain temporary and whose validity depends on the probability of its happening again and the effectiveness of the administrative and statistical system. This record is held by Jeanne Calment, who was a little older than 122 years when she died in 1997. Observation shows that only very few individuals have come anywhere near such a record and that most people die before or very little after 100 years. The available space for such an increase in life expectancy is limited overall to the area situated between the present survival curve and the top right angle of the rectangle defined by a vertical line at 100 years or a little more than 100 years (see Fig. 57–5).

If we take into account the heterogeneous nature of the population and individual life stories, it would be unlikely that all individuals would live until 100 and that afterward all or almost all immediately die. We can easily conceive that the limit survival curve should

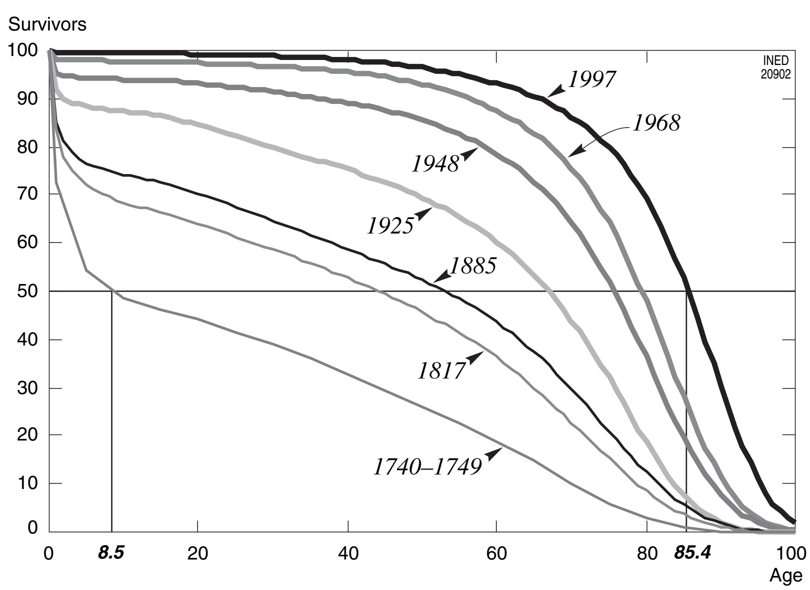

FIGURE 57–5 Rectangularization of the survival curve of French females.

be situated somewhere between the present curve and a perfect rectangularization. However, opinions diverge about the location of this "somewhere."

Certain demographers believe that we are very close to this limit. Jay Olshansky (1990), drawing his inspiration from the very pessimistic views of biologist James Fries (1980), shows that, on the basis of the 1985 life table of the United States, to reach a life expectancy of 85 years, it would be necessary to reduce by 43% the age-specific death risk of females and by 65% that of males. Because, according to this researcher, it would be very improbable that higher reductions might be obtained, he believed it most unlikely that life expectancy could ever exceed 85 years. Other researchers are more optimistic. Josianne Duchêne and Guillaume Wunsch (1990), for example, using the age limit of 115, on the basis of research carried out by several gerontologists (McGinnis, 1985; Medvedev, 1975; Korenchevsky, 1961) and taking a modal age at death of 95 years, suggest, after having conducted different types of modeling, a limit life table yielding a life expectancy of 91.4 years. In a more empirical fashion, we extrapolated the particularly stable and regular trends of the different age-specific death risks observed in France over the last 20 years and observed that within the next century, life expectancy could reach 91 years for males and 95 years for females (Vallin and Meslé, 2001). It seems quite probable, and in any case possible, that life expectancy will continue to increase well beyond the 85-year age limit suggested by Jay Olshansky. Nonetheless, if human longevity is finite, it would be very difficult to reach a life expectancy of 100 years.

2. Or a New Expansion of Ages at Death?

The second issue is to find out whether the limit of the human life span, which is today a little more than 120 years, is really intangible. In the early 1950s, Paul Vincent (1951) had suggested the idea of determining the upper limit of human life by extrapolating the trends of exponential mortality increase with age until the death risk reaches 100%. He then found, on the basis of French data, that the maximum duration of human life was 107 years. Twenty years later, using the same method but applying it to more recent data, Françoise Depoid (1973) estimated this maximum age to be 115 years. Did this mean that the age limit had really increased? As seen in Chapter 48, the data of five countries that have long had vital statistics enabled John Wilmoth and Hans Lundström to show that since statistics have become reliable, particularly in recent decades, the highest age at death has increased every year. The fact that the population is growing increases the likelihood that some will reach a very advanced age, especially given the increase in the proportion of persons reaching old age due to the decline of mortality among children and adults. Nonetheless, it is probable that part of the observed phenomenon actually reflect an extension of the human life span. This idea is also suggested by the recent acceleration of the mortality decline at more advanced ages. In France, this acceleration occurred in the early 1970s for mortality between 65 and 75 and in the early 1980s for mortality between 75 and 85 (Meslé, 1995). Even more significant, life expectancy at the age of 100 has also been increasing in the past decades. Among French females, it rose from 1.5 years in the mid-1950s to 2.2 years in the early 1990s (Allard *et al.*, 1996; Meslé and Vallin, 1998). The more reliable data on mortality at very advanced ages we have, the more it seems that the mortality increase with age slows down, contrary to the Gompertz model, which until recently was universally accepted. The explanation seems to be the very strong selection due to high mortality at these ages among a population that is very heterogeneous to begin with but becomes more and more homogeneous, being made up of the more resistant individuals (Barbi *et al.*, 2003; Vaupel *et al.*, 1979, 1998). Given these facts, the idea that recent health advances may partly reflect the slowing of biologic aging becomes more credible. This would obviously represent a new phase in the health transition, radically different from the previous ones. Without reaching the extreme conclusions of André Klarsfeld and Frédéric Revah (1999), who suggest that if immortality does not exist, the reason is not biologic necessity as always believed, but only the fact that it was not selected by evolution because it had no biologic purpose, we may nevertheless recall that in the early 1980s, Roy Walford (1984) did come to believe that a life expectancy of 150 years could be reached in the 21st century.

If, after the cardiovascular revolution, advances in cancer research should bring about the end of the second phase of the health transition—that of the decline of degenerative diseases, mainly thanks to the prevention of risk factors—it is too soon to find out whether a third phase will ever occur, such as through the control of genetic factors responsible for biologic aging.

Whether the third phase will ever happen, it is now certain that the second phase of the health transition—which, unlike the first, is no longer based on the decline of mortality at young ages but on that of mortality at advanced ages—will lead to new societal issues tied to the aging of the population, with mortality at advanced ages representing a major factor in the latter phenomenon. At the heart of this issue, paradoxically, lies the question of the health of the population.

3. Aging of the Population, Biologic Aging, and State of Health of the Population

In the past, during the phase when the health transition concerned mainly the control of infectious diseases of infants and children, the gains in terms of life expectancy at birth were almost exclusively gains in years of good health. However, because most of the years gained have resulted from the struggle against degenerative diseases, we may wonder whether health progress does not result in large part in making it possible for people with health problems to live longer. This question is more extensively discussed in later chapters,[7] but it is useful to say a few words about it at this stage.

Numerous surveys have been devoted to this issue during the past 2 decades in developed countries. The first results, mainly from predominantly Anglo-Saxon countries (e.g., Australia, Canada, United States), seem to indicate that the years of life that go along with disabilities and deficiencies have increased at a faster pace than total life expectancy. However, initial French surveys have partly contradicted these pessimistic results. If we make a distinction between moderate or slight disabilities and severe or very severe disabilities, we observe that years of life without severe disability everywhere increase as fast as the total life expectancy (Mormiche, 1999; Robine, 1993). These apparently contradictory results reflect the fact that in this field, there is no really objective measuring system to assess health and that as health improves globally, individual demands also rise, and along with these demands, the level of discomfort felt or declared. This phenomenon is particularly noticeable in cases of slight or moderate disabilities, which used to be considered normal. It is much less visible in cases of severe disabilities. For a given age, it would seem that health is improving, which is the logical conclusion, to the extent that the aim of health care is first and foremost to fight disease and suffering, and the fact that people die later than they used to is only a consequence of this effort.

However, if, at a given age, health improves while life expectancy increases, this does not necessarily mean that the average health situation of the population has improved. On the contrary, it may be deteriorating. In the current stage of the health transition, the life expectancy increase depends mainly on the decrease of mortality at advanced ages, which itself has become a major factor in the aging of the population. However, even if health improves at each age, there is no person whose health does not deteriorate with age. The question is to find out whether the improvement of health at a given age is enough to offset the deterioration of the global health situation caused by the aging of the population. If we retain present assessments of severe disability, we could be led to believe that for the time being, a certain balance has been created between these two phenomena, because the proportion of years spent in good health compared with the total number of years of life that have been gained remains about constant. However, this reasoning supposes that the population count does not change, and this is not the case. In the real context of most developed countries, we must expect in the next decades a significant increase of the disabled population, both in absolute figures and in proportion to the rest of the population.

II

DETERMINANTS OF MIGRATION

Introduction

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

Section I of Volume I considered population dynamics and its three components; Section II of Volume I and Section I of Volume II began to explore the determinants of fertility and mortality, respectively. Section II of Volume II now turns to the determinants of migration. Subsequent volumes investigate history and future perspectives of population settlement, the relations between population and society, population policies and theories, and the methods of data collection and complementary tools of analysis.

Within the general system formed by these four volumes, Section II of Volume II deals only with the determinants of migration. Issues concerning sources and analytic techniques were covered in Section I of Volume I. Chapter 13 on longitudinal analysis of population exchanges, Chapter 14 on period analysis, and Chapter 22 on mobility and spatial heterogeneity surveyed the available sources and methods of analysis used to study migration. More specific aspects of sources, concepts, and methods are explored in Section II of Volume IV. Any further elements of analysis or descriptions of sources essential to understanding the determinants are referred to as needed in the various chapters that make up Volume II.

The history of migration is discussed Section I of in Volume III, which includes Chapter 67, written by David Coleman, on the key role of migration in population processes from prehistory to the modern period. Chapters 68 and 69 of Volume III review the internal and external population changes connected with demographic transition and its spread worldwide. Section II of Volume II offers a practical introduction to the study of determinants through a review of the distinguishing characteristics of one of the major migration streams of the past century.

Similarly, the many different consequences of migration, including population genetics, societal impacts (i.e., integration of migrants), economics (i.e., population and development), environmental effects, and the strictly demographic consequences already considered in Volume I in relation to population dynamics, fall within the scope of Section II of Volume III.

It is trivial to say that migration involves the movement of a person from a place of departure to a place of arrival, but the possible types of movement vary widely according to how the investigator defines the places of arrival and departure, the length of absence from the place of departure, the duration of stay in the place of arrival, and the reasons for the move. All of these different characteristics interact with one another. One possible approach to a study of the determinants of migration may be to establish a typology of migration as the basis for a thorough study of the determinants of each type of migration. Such typologies have been posited by many demographers, not least David Coleman, who in Chapter 67 describes a typology for analyzing migration in prehistory or ancient and medieval history. In a different context, Antonio Golini (2000) also developed a typology to account for modern migration. To do so, he argues, means referring to "criteria—distance, recurrence, duration, causes, and legality—that are prevalent in the literature, but generally taken discretely, when they should be combined."

For the first of these criteria, there is no minimum distance for migration, and any change of house, building, neighborhood, municipality, region, country, continent, or any other defining area is a geographic migration that lends itself to analysis, but it will vary in the nature of its determinants and consequences.

Recurrence and duration, two inseparable aspects, may also vary widely. Daily, weekly and seasonal migrations tend to be of short duration, whereas migration stays of longer than a year, several years, or decades are more rarely cyclical, even though they can never be described as permanent during the individual's lifetime.

The type of migration also varies, admittedly widely relative to the preceding criteria, with the cause of the move: labor migration; training; family changes and disunion; the search for housing; a desire or need to live closer to the place of work; education; catastrophes and other acts of nature (e.g., floods, earthquakes); war; repression; military occupation; pressure of political, ideological, or religious events; job requirements (e.g., sales representatives or other mobile occupations, professional or scientific meetings, exploratory missions); tourism; and cultural or religious activities.

Migration is more or less tightly controlled by law—invariably in the case of international migration and frequently so in some countries for some types of internal migration. A distinction may therefore be drawn between legal and illegal migration.

Working from the third criterion, Antonio Golini first distinguishes between three types of territorial mobility: migratory mobility (i.e., any non-involuntary change of place of residence), pseudomigratory mobility (i.e., compelled by natural catastrophes or pressure of political or religious events), and nonmigratory mobility and other territorial moves (i.e., vacationing, occupational, and other moves). He cross-references these three types of mobility with the three other criteria (i.e., geography, time, legality) to obtain the full typology sought.

Sound as its rationale is, this typology is only one classification among others advanced by other investigators who place varying emphasis on different criteria or refer to others more relevant to the aspects they wish to focus on. The concept of migration or mobility varies enormously in different societies and at different times in the long history of humankind and is likely to evolve further in the future. Starting by drawing up a full and final typology of spatial mobility may not be the best way of accounting for the determinants of migration, and it is probably an unachievable goal. In the words of Daniel Courgeau (1988), "the study of spatial mobility involves identifying the changes occurring over time in the relations between an individual or social group, and space."[1] It is a definition that counsels against attempts to develop a universally valid full and final typology of migration, because it does not exist. If it did, it would lock the phenomenon into a rigid framework that could not accommodate the emergence of unforeseeable new kinds of mobility or the disappearance of older ones. The less lofty aim in the following chapters is to discuss the determinants of different types of migration, both spatial (i.e., internal and international migration) and temporal (i.e., from permanent changes of residence to daily commuting), without claiming to give the whole picture.

The propensity to migrate, like the propensity to procreate, depends on a very complex, often interacting set of individual and collective economic, political, social, cultural, ecological, psychological, and other factors that vary in time and space. As with fertility and mortality, a theoretical reference model needs to be constructed as a basis for analyzing and explaining migration and for identifying the singular or conjoint linkages between the migration process and its various factors. Explanatory analysis must be informed by the historical context in which the process takes place and by information about the geographic unit concerned, which encompasses the places of departure and arrival for each migrant.

Because of the complexity of explanatory analysis applied to migration, demographers have often confined themselves to collecting data and developing models of various degrees of sophistication to recreate unreliable or missing information with which to describe migration dynamics (discussed in Section I of Volume I). This is a large area to cover, because economic and political overtones have made migration a popular field of study for other disciplines, especially economics and sociology.

Part I of this section focuses mainly on international migration. Chapter 58 introduces the topic by considering Western migration trends over the past century, and Chapter 59 systematically reviews the main current theories on international migration.

Part II considers the main factors of migration. Migration often originates in a living environment where scarce economic resources compel some individuals to seek better prospects in other lands nearby or far away. From this perspective, migration is arguably a process needed for financial well-being, which may not, however, always be attained (see Chapter 60).

Migration may also be seen as something other than a financially motivated rural-to-urban move. Individuals are not always attracted to towns in search of easier or

[1] "L'étude de la mobilité spatiale consiste à mettre en évidence les changements au cours du temps, qui sont à l'œuvre dans les rapports entre un individu ou un groupe social et l'espace."

better-paid work. They may instead seek better social, cultural, and public health amenities; opportunities for claiming a better place in society; and easier access to basic public services for themselves and their families. These aspirations drive the process of urbanization everywhere in the world, and they are more than ever a major component of spatial mobility in all populations (see Chapter 61).

Whole pages of the history of migration in the 20th century have been written by the victims of medium- or large-scale population flights caused by political crises. Repression, war, ethnic cleansing, and genocide have been behind the forced migration of individuals under threat and seeking refuge or political asylum in nearby or distant countries that were willing to accept them for various periods (see Chapter 62).

Along with what can be broadly described as socioeconomic and sociopolitical factors is the wide range of personal motivations that push migrants toward neighboring countries or distant regions (see Chapter 63).

Part III of Section II looks at two particular types of migration: daily commuting and return migration. These situations vary widely in space and in the interval of time in which the departure and return moves take place. Simple cases are travel between the place of residence and the place of work or education. Such movements may be of very short duration, occurring daily in most cases. Daily commuting is a significant aspect of migration issues and the analysis of spatial interactions (see Chapter 64). On a different scale, return migration after a stay abroad for various periods is a little explored but hugely important field of research because of the total numbers of people concerned (see Chapter 65). Because of their singular characteristics, the two concluding chapters give extensive consideration to issues concerning sources, methods of measurement, and analysis.

I

MAJOR MIGRATION STREAMS AND THEORIES OF INTERNATIONAL MIGRATION

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

Accounting for the many facets and different phases of migration dynamics is a daunting challenge. The emigration decision is a supremely subjective one, based on an individual or family's assessment of the comparative advantages and disadvantages of a temporary or permanent move to another country or elsewhere in the country of residence. However, a migration that involves a large number of people over a vast geographic space and long period enters into the common history of a territory, and the determinants that shape it are of a different order. The introduction to Section II of Volume II stressed the importance of the historical and economic contexts in which migration occurs to help identify the factors that determine migration streams and enable them to be set within a theoretical framework of references that help elucidate the phenomenon.

In Chapter 58, Graziella Caselli surveys international migration developments in the 20th century, focusing on the developed countries, where big surges in immigration occurred especially in the first half of the century. She first describes the main migration routes of the late 19th and early 20th centuries, when Europe lost millions of population to the New World, and then analyzes that singular phase of international migrations for which the interwar period was known and the specific characteristics of the migrants compared with those of the departure and arrival countries. Detailed consideration is given to the history of migration in the latter half of the 20th century, when the phenomenon changed to gradually become all embracing in terms of the size of migration streams and their demographic and social composition. From the 1970s in particular, the coexistence of very different demographic groups and stages of economic development, along with the increasingly complex relations between cultural, social, and political systems, wrought radical changes in migration, imprinting the flows of the last 30 years with very different characteristics from those that prevailed in the first half of the 20th century. The chapter concludes with some considerations on the future of international migration and considers how wealthy countries can help immigrants to fit satisfactorily into society in the country of arrival. This chapter does not attempt to give a comprehensive history of mass migration movements. These are covered in some chapters of Volume III, where particular consideration is given to historic migration movements (see Chapter 67) and those that arose with the European demographic transition (see Chapter 68) and its spread across the rest of the world (see Chapter 69). The main aim of Chapter 58 is to introduce the reasons that may prompt mass migration movements.

In Chapter 59, Hania Zlotnik discusses the theories of international migration. She first reviews the main principles of the different theories, frameworks of analysis, and hypotheses from different fields of study and then offers a comparative analysis of their strengths and limitations. Based on the main thrust of her report to the United Nations in 1998, she examines how economic and sociologic approaches, as well as demography and political science, have informed the fundamentals of the various theories.

International Migration in the 20th Century: The Case of the Western Countries

GRAZIELLA CASELLI

Dipartimento di Scienze Demografiche, Università degli Studi di Roma "La Sapienza," Rome, Italy

The economic and social changes that accompanied the industrial revolution were at the roots of another revolution: the demographic transition. The transition from a natural population (i.e., high mortality and high fertility) to a controlled population (i.e., at a low level of both components) was a phase of unprecedented population growth. For hundreds of thousands of years, natural factors had regulated the number of births and deaths and thereby the progression of population numbers. However, from the middle of the 18th century, humans began to change the conditions of mortality without, in the first instance at least, changing those of fertility, thereby provoking an exceptional increase in the population as a result of the growing gap between the two phenomena. The first populations to experience the effects of this demographic trend were those of the northern and western countries of Europe; the southern and eastern countries began the same process a century later, as did the rest of the world after the First World War and particularly after the Second World War.

In the long century that lasted from the beginning of the 1800s until the First World War, Europe's population multiplied by almost 2.5, increasing from 188 to 458 million inhabitants (Livi Bacci, 1998a). An exceptional growth, which did not always go hand in hand with an equally rapid economic and social development and which eventually found an outlet in the great transoceanic migration that lasted about a century, from the middle of the 19th century to the 1930s.

To say that this remarkable population growth was the basis of this great migratory wave is to simplify the explanation of this phenomenon. Reasons for the departure of millions of people from their homelands are more complex. Uneven industrial development was not able to absorb the surplus workforce, which resulted as much from demographic growth as from the departure of part of the population from rural areas, where the increase in productivity made possible by the introduction of the first technologic tools from industry had caused significant unemployment. European cities and early industrial settlements were not able to absorb all the surplus workforce, while on the other side of the ocean, the scarcity of human resources, the extension of available land, and the numerous activities that needed to be developed resulted in a great demand for those looking for work and better living conditions. It is not easy to summarize the reasons for this veritable mass exodus in a few sentences. When emigration, which is a subjective decision taken after a personal and family assessment of its costs and benefits, involves such a large number of people in a collective historical act, the imbalance between resources and population appears in all its complexity (Birindelli, 1989). This is possibly the fundamental reason why some tens of millions of Europeans from the middle of the 19th century to just before the Second World War exiled themselves overseas, thereby lightening the demographic load of the Old Continent and contributing to the population growth of the New World.

During the first decades of the 20th century, the conditions that had led to this great wave of European emigration began to diminish. In this era, northern European countries were already entering a phase of advanced development in which the workforce had declined due to a decrease in the proportion of the population of working age, which itself resulted from the decline in fertility that started a few decades earlier. However, the problem of surplus population and insufficient development remained in the countries of southern and eastern Europe, but their emigrants could also find work in the more developed European countries, given that the demand for foreign labor in the traditional receiving countries had progressively declined. The rules of the labor market had nevertheless reacted very slowly to the drying up of the transoceanic flow of migration; a sudden interruption in migration was caused by the World War I, and after the 1920s, its revival was restrained by the new American policy regarding migration. Ten years later, around the time of the Great Depression in 1929, other northern countries and Latin American countries likewise adopted measures limiting immigration. The time of the great transoceanic migration came to an end quite quickly during the second half of the 1920s.

European migratory flows (not including the forced migration that preceded or followed the Second World War) resumed, with less intensity, in the 1950s. In the meantime, the connotation of the phenomenon and the global context had changed. The new flows directed to the Americas involved mainly family reunification and the systematic reception of war refugees and exiles. In Europe, the economic and political context resulting from the Second World War led the victorious countries (the richest) to look for labor in the poorer countries of the south for reconstruction purposes and then for the development process, which culminated in the economic boom of the 1960s.

From the 1970s, the decline of demographic growth in the European population paved the way (slowly but progressively) to immigration in all the countries of the Old World, a path taken mainly by the inhabitants of the poorest regions of Africa and Asia, who arrive today at the ports from which the Europeans departed a century earlier. All the countries of the world, rich and poor, have had to deal with problems created by migratory movements, whether internal, within their own borders, or external with the arrival of populations from neighboring countries or other continents. The largest of these movements, notably internal migration, was provoked by the technologic revolution and the profound transformations in the global economy that affected most populations of the world, to the benefit of some and to the detriment of others. To these fundamental circumstances, exceptional events have been added and superposed, such as natural disasters (e.g., drought, food shortages), civil wars, and nationalist and ethnic conflicts, which have given a new profile to the movements by upsetting the motives and the traditional structure of different societies, modifying as much their direction as their characteristics.

In recent decades, all internal and external migration has undergone substantial changes; international migration has acquired a global dimension, as much by its new scale as by its demographic and social characteristics (Collison, 1994). The widening of the differences in demographic growth between countries has played a major role in the explosion of the phenomenon and its rapid transformation. Whereas in the highly industrialized countries (notably in Europe), births have progressively fallen to very low levels, rates unimaginable at the end of the 19th century and even in the first half of the 20th century, in the developing countries, the speed of the demographic transition has for several decades resulted in very high growth rates, despite the efforts by international organizations to accelerate the decline in fertility by promoting the adoption of birth control measures.

As in the past, differences in economic growth and the conditions of poverty in which a significant part of the world's population find themselves lead to imbalances in demographic growth and constitute one of the major factors encouraging a growing number of individuals to emigrate from the poor countries to more economically developed countries. Violent internal conflicts add to the difficulties of remaining in regions that offer only minimal survival conditions due to lack of development and compel many people to flee, sometimes to distant lands. Moreover, the recent expansion of modern rapid mass transport have made long distance travel (formerly long and expensive) much more accessible.

These initial considerations suggest that the profound changes that have affected the phenomenon of international migration in the past few decades are caused by worsening of the problems in the poor countries of the planet. However, numerous studies show that these changes are mainly rooted in the development of the economic system of the most developed countries and the balance of international policy that results from it. The impact of the economic recession of the 1970s and 1980s on international migration led to a revision of internal and external economic policies by the rich countries.

The coexistence of different demographic systems and very different levels of economic development, without mentioning the growing complexity of cultural, social, and political relations, have profoundly changed migration and given very different characteristics to the flows of the last 30 years compared with the characteristics of migration in the first half of the 20th century. Because the object of this analysis is the development of international migration in the 20th century, I provide a framework that allows the identification of the different stages of this change. The importance of the great transoceanic migration, which has been the focus of numerous studies, is recalled in its broad outlines, with particular attention to its intensity and characteristics. The analysis then focuses on the past few decades, emphasizing especially the experience of European and North American countries.

TABLE 58–1 Flow of Total and Average Annual Departures from the European Countries and Italy toward Overseas Countries between 1876 and 1915

Period	Total flow[a]		Average annual flow[a]	
	Whole of Europe	Italy[b]	Whole of Europe	Italy[b]
1876–1880	1555	154	311	31
1881–1885	3357	320	671	64
1886–1890	3784	670	757	134
1891–1895	3437	751	68	150

I. THE GREAT MIGRATION AT THE TURN OF THE NINETEENTH AND TWENTIETH CENTURIES

Europe, which for 3 centuries, with Iberian and then English imperialism, dominated the rest of the world politically, economically, and demographically, experienced an unprecedented mass emigration in the 19th century. It is estimated that between 1846 and 1932, more than 55 million individuals left the continent in the direction of North America (more than 34 million to the United States and 5 million to Canada) and Latin America (about 7 million to Argentina and Uruguay and 4 million to Brazil). Among the countries that most contributed in populating the Americas are Great Britain and Ireland, with 18 million people; Italy, with 11 million; and Spain and Portugal, with almost 7 million. Significant numbers also departed from Germany (about 5 million) and from the Scandinavian countries (2 million from Sweden and Norway) (Livi Bacci, 1998b).

The phenomenon of the great migration reached its peak during the 40 years straddling the 2 centuries (from 1876 to 1915) when almost 34 million Europeans (including 11 million Italians) crossed the ocean to look for work (Table 58–1). During this period, there was no reduction in the number of departures. In the first 14 years of the 20th century alone, there were about 19 million departures, with a particularly high intensity between 1906 and 1910; the annual average surpassed 1.3 million (of whom 585,000 were Italians). At the same time, more than 9 million people (28% of departures) made the return journey within 40 years (Table 58–2).

The route to America was not the only one for the European populations. While vast hordes were crossing the Atlantic ocean, more than 5 million Europeans crossed the Urals headed for Siberia, and more than 3 million left to inhabit Soviet Central Asia. This emigration that began in Russia after the liberation of the serfs in 1861 ceased only when the fertile lands were totally occupied, and it began again between the end of the 19th and the beginning of the 20th century with the construction of the trans-Siberian and the industrial development of the Asian part of the Russian Empire, which later became the Soviet Union (Livi Bacci, 1998a).

In the years before World War I, the source of the European migratory process changed, from northwest to southeast; whereas previously most emigrants to America (70%) came from countries in the northwest of Europe, from the end of the 19th and the beginning of the 20th century, the Mediterranean, Balkan, and eastern countries of Europe supplied, in the same proportion, the transoceanic migration (Fig. 58–1). A change in the factors of migration and the characteristics of the migrants corresponded to this change in areas of departure, so much so that the flows recorded from the end of the 19th century can be called a "new wave of migration."

Migrants of the previous wave lived mainly in the northern and central countries of Europe and belonged to the intellectual and artistic classes (and were usually very well educated). They were driven by a desire to increase their well-being or by idealism; they were generally accompanied by their families (with both sexes more or less equally represented); and they

settled in agricultural regions. Later migrants left from the poorest regions of Europe, and they were of humble origins, generally rural, and mainly illiterate; they settled in towns where they looked for work in the nascent industries, and usually being men on their own, they had the intention of returning to their country as soon as they had put enough money aside. Return migration was much higher in this new wave than in the previous wave. In some periods, returns even exceeded the departures. Among the Italians between 1905 and 1915, for 5 million departures to America, 2 million returns (40%) were counted (Assante, 1978). However, the ratio of return journeys over departures increased considerably; between 1907 and 1911, it reached 70% (Foerster 1919, and 1968). According to the *Bollettino dell'Emigrazione* (1908, no. 6, page 4), in December 1907, while 5033 Italians were disembarking at the port of New York, 52,532 embarked to return to Italy. It was difficult to live in a distant country, unable to speak the language and especially separated from their families. They departed alone and remained so. As can be seen in Figure 58–2, the number of females in the great Italian migration was very low, never surpassing 20% of the total number of migrants (generally 22 to 23 women for 100 men).

The lateness with which the Mediterranean and eastern countries of Europe participated in the great migration can be explained by their delayed entry into the demographic transition. At the end of the 19th century, the countries of southern and eastern Europe experienced rapid demographic growth, whereas establishment and development of the industrialization process were delayed. These countries entered into the movement at a time when the development

process had already reached its peak in the northern and western countries of Europe, for whom the phase of high growth was already over. In these much richer countries, the demand for foreign labor was progressively increasing, to the point that many of them had become, by the turn of the century, the most frequent destination for the poor populations of neighboring countries. Between 1876 and 1915, 6 million Italians emigrated to Austria, Switzerland, and Germany, and 4 million Poles and Russians left for Germany (Table 58–3). As can be seen in Table 58–3, in the 40 years preceding the First World War, while about 34 million Europeans headed for the New World, 13 million others changed countries within Europe. For example, the total number of departures from Italy during this period was close to 15 million.

II. THE NEW MIGRANTS: BETWEEN REGULATION AND PROHIBITION

If the new migratory wave included an important internal component in Europe, it was not only because of the proximity of the more developed countries;

it was also because of the increasing difficulty of entering the American territories, especially the United States, where poor, uneducated immigrants were undesirable. At the beginning, during the first 15 years of the 20th century, this new migration, although undesirable, ended up surpassing the previous one, with 8 of 10 arrivals, because America still needed immigrants, and the new migrants were about the only ones available on the European market.

The Anglo-Saxon and Germanic bourgeoisie that held the economic power and dominated the ethnic and cultural landscape of the United States did not appreciate the new arrivals and saw danger in the introduction of these workers of humble origins, who were unspecialized, poorly educated, and inclined to organize themselves politically and into unions (examples of this had already been seen in Canada and Argentina) (Paris, 1975). Pressure on the political leaders to adopt measures limiting entries was strong and recurrent, and in 1907, the U.S. Senate created a commission (i.e., the Dillingham Commission, named after its chairman) that at the end of 3 years of assiduous work, produced a report suggesting that the new migration had been one of the causes of the economic and social crises of 1893 and 1905 (Paradisi, 1979). Moreover, in the numerous intermediate reports dealing with the issues of immigration, members of the commission insisted on the extremely negative influence that these new migrants would have. Migrants were accused, among other things, of being the cause of increasing overpopulation, public security problems, and decreased viability of urban zones (Tonizzi, 1999).

As early as 1907, a federal law was adopted prohibiting the entry of persons with mental problems or physical deficiencies that could impede on their professional activity and prohibiting unaccompanied children; another law, which foresaw the withdrawal of citizenship from American women married to foreigners, was aimed at limiting Japanese immigration. The work of the Commission and the laws of 1907 toughened the measures already adopted in previous years. The Literacy Act of 1897 (revised and modified to be more restrictive in 1917) stopped the entry of adults of 16 years or older who could only read and write their mother tongue, and a law adopted in 1903 prohibited the entry of anarchists and other subversives into the United States. These initiatives were intended more to establish quality control than to set a true quantitative limit. At the beginning of the 20th century, the United States was experiencing an accelerated phase of industrial development that made immigration necessary. Despite all this, the bourgeoisie and the economic leaders were opposed to this type of development and, in particular, did not share the excessively open attitudes of the democratic presidents on the issue of migration.

Despite these obstacles, between 1901 and 1915, of about 12 million immigrants arriving in the United States, almost 10 million came from the Mediterranean and eastern European countries (Table 58–4). These flows ceased only with the onset of the First World War, but they returned with greater intensity at the end of the war: 0.5 million between 1916 and 1920 and 2.5 million between 1921 and 1925, of which 1.5 million settled permanently in New York.

In 1921, faced with this huge inflow, a quota system was put in place for the first time (i.e., the National Origin Act, better known as the Quota Act), which fixed the maximum annual number of foreign entries

at 357,000. The 1924 law (i.e., the Immigration Act) again reduced the annual number of authorized entries to 164,000. However, the effects of the postwar depression and the approach of the great economic crisis of 1929 hindered foreign labor (and not only undesirable foreign labor) in an even more discriminatory way than the laws themselves. The new legislation foresaw quotas by nationality, thereby indicating a clear preference for the previous inflow, especially the one from the United Kingdom. Table 58–4 shows the annual quota granted to Anglophone countries from 1924 as 50.8%, whereas the total entries from these countries between 1901 and 1915 was only 10.5% of the total. The quota granted to Italy at only 11.6% was not in any way realistic, because in previous years, the Italian immigration had supplied 70% of arrivals.

In the years before the First World War, about 12 million Europeans departed for the United States, and another 10 million headed for other overseas destinations (Franzina, 1995): approximately 2 million to Canada, more than 3.5 million to Argentina and Brazil, and more than 1 million to Oceania (Table 58–5). At the time, immigrants to Canada and Australia were mostly Anglophone, and they were the first settlers to inhabit these new territories, seeking improved well-being rather than fleeing from economic necessity or demographic pressure in their home country. The Italians, on the contrary, forced to migrate by poverty, chose to settle in the United States and Latin America, notably in Argentina (Federici, 1979; Rosoli, 1978).

From 1920 to 1930, immigrants to Canada (where the population was a little more than 10 million) exceeded 5 million. At that time, like the United States, the Canadian government was taking hostile measures against immigration from south and east Europe and east Asia, which at the same time as the great crisis of 1929, led to practical closure of borders. Between 1931 and 1935, there were only 72,000 entries, and between 1936 and 1940, the departures exceeded the arrivals.

At the beginning of the 1930s, Brazil and New Zealand established immigration quotas, decreeing laws inspired by those of the United States that clearly discriminated against undesirable populations. The huge masses that had formerly filled the embarkation and disembarkation quays vanished from both sides of the Atlantic. Ellis Island, which was headquarters for receiving immigrants in the port of New York and where the poor third-class passengers had to complete all the necessary formalities to obtain permission to disembark, was almost completely deserted.

At the same time, the West Coast witnessed the departure of millions of Chinese, undesirable immigrants wherever they went. Most of them ended up on the Asian continent itself, few of them finding refuge elsewhere: 5 million people went to the mining regions of Manchuria, almost the same number to Formosa, and about 10 million to Thailand, Indochina and Malaysia, compared with only 300,000 to Brazil, Cuba, Peru, and the United States.

III. FORCED MIGRATIONS FROM THE END OF THE FIRST WORLD WAR TO THE 1950s

The end of the First World War was marked by an exceptional migratory process. In Europe, revolutions, the war, and a series of border changes caused significant transfers of populations from one country to another. About 2 million Russians, Ukrainians, and Byelorussians left the Soviet Union; more than 1.5

[a] Figures for emigration are given in thousands.

million Greeks left Turkey; important flows of Magyars left Rumania, Yugoslavia, and Czechoslovakia; and there was a forced exchange of about 2.5 million people between Poland and Germany.

During the 1930s and 1940s, the transoceanic borders remained closed to the most economically disadvantaged European populations, but internal migrations on the continent did not cease. During these 2 decades, France, Switzerland, and Germany were the preferred destinations of 2 million Italians. This is an impressive number, considering that the fascist laws of 1928 and 1931 were intended to limit, if not prohibit, departures from Italy. After agreements between Mussolini and Hitler for the placement of permanent and seasonal labor, approximately 800,000 Italian workers had emigrated to Germany, whereas 250,000 had left Italy to escape the fascist persecutions.

In the years preceding the Second World War, between forced migration, deportations to Siberia (about 5 million), and fugitives from dictatorial regimes, about 15 million Europeans left their countries. This is nothing compared with what happened in the following decade. During the Second World War, 30 million people were deported or exterminated, and in the following years, 35 million others (i.e., East Germans, Baltics, Poles, and Soviets) were transferred out of their countries, whether they had been expelled or were compelled to leave for the Western countries (Paradisi, 1979). Ethnic zoning in Eastern Europe in itself resulted in the displacement of more than 15 million people (Table 58–6).

Europe came out of the conflict impoverished, burdened with millions of refugees, and struck by unemployment. The situation was dramatic in the countries of the Soviet bloc and in the Mediterranean countries, where population problems as acute as those that existed before the war made it even more difficult to recover from the crisis. Emigration again seemed to be the solution. In May 1950, the foreign ministers of the three main Western powers (i.e., Dean Acheson, Ernest Bevin, and Robert Schuman) adopted a resolution in which they declared, “The overpopulation suffered by a number of European states is one of the most important factors in the world’s difficulties and imbalances. A systematic study of the possibilities of emigration could greatly contribute in solving such a problem.” A commission of experts appointed by the Council of Europe in 1950 estimated the surplus population at 5 million and advised that emigration from Europe was the only way to resolve the problem (Paradisi, 1979).

Interest in migration by political leaders favored the reopening the borders of the countries across the Atlantic to European immigrants. Without changing the quota laws, the United States authorized family reunification and lifted all limits on the entry of political exiles. Immigration to the United States therefore increased from 1 million in the 1940–1950 period to 3 million in the 1950–1960 period. For its part, Canada allowed 800,000 European immigrants to enter between 1951 and 1955 (about one-half million entered immediately after the end of the War) by permitting the entry of exiles and technicians capable of integrating the rapid industrialization process started after the war. Even Australia accepted an increased number of immigrants (more than a million between 1947 and 1954), striving to integrate them as soon as they arrived. To this end, the immigrants were chosen according to their origins, age, and physical condition: 48% were British, and the remaining 52% were Polish, German, Italian, Yugoslav, Russian, or from other countries (Reinhard *et al.*, 1968).

The period that followed the Second World War was significant by the birth of the new Israeli state, toward which headed hundreds of thousands of Jews who had survived the Nazi camps or who had been exiled all over Europe, as well as in the Muslim countries of North Africa. In December 1955, the inhabitants of Jewish origin numbered about 1.6 million, 88.5% of the total.

At the end of the 1950s and at the beginning of the 1960s, European emigration slowed down, and a new chapter in international migration began.

IV. THE GLOBALIZATION PROCESS AND INTERNATIONAL MIGRATION

The expansion of the global economy and the development of communication methods have contributed to changing the mobility conditions of populations between different regions of the world. From the 1950s, the nature of migration changed progressively, acquiring, like the flow of goods and capital, a global character, as much from the point of view of volume as from that of space and structure. After 1945 to 1950, during which some countries (including France and Great Britain) had to resort to immigration for their postwar reconstruction, several phases in the evolution of international migration can be identified over the course of the last 50 years (Salt, 1989). The first, which occurred approximately from 1950 to 1973, coincides with the period when the main economic strategies of large transfers of capital were decided by the richest countries of Europe and North America (and by Argentina, Venezuela and Australia). It was toward these countries that hordes of workers from the least-developed countries of the south and west coasts of Mediterranean Europe headed (Fassmann and Münz, 1994; Castles and Miller, 1993; King, 1993). At the same time, France and Great Britain opened their borders to immigrants from their former colonies, and in America, significant south-to-north migration was developing (Fig. 58–3). Access to the wealth of oil-producing Arab countries created in certain Gulf states an attraction for North African and Asian populations, encouraging the development of a new immigration destination.

The 1973 oil crisis radically changed the picture. It initiated a period of recession that led the developed countries to modify their economic strategies. To overcome the crisis, they were obliged to restructure their production systems and modify their working methods, to such an extent that the global economy was completely transformed. This caused a profound change in migration policies and consequently in the nature, volume, and direction of the flows (Fig. 58–4). In this way, a new phase of internal and international migration began, which saw some southern European countries, traditionally exporters of emigrants, become receiving countries. From the 1970s onward, these effects accentuated a process already underway in the poorest countries of the world, with millions of people leaving the poor rural areas to settle in towns, opening the way to a migratory chain, which by increasing over time, resulted in a decisive change in the intensity and direction of international migration flows. The arrival of large masses of population in towns still devoid of economic, social, and sanitary structures caused a dramatic crisis, even at the level of social values, forcing

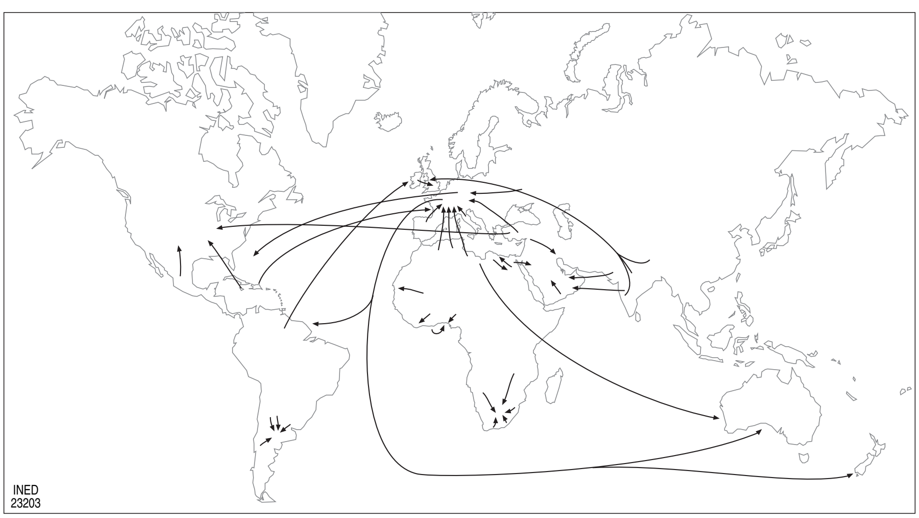

FIGURE 58–3 Direction of global migratory flows from 1945 to 1973. The dimensions of the *arrows* do not indicate the intensity of the movements. (From Castles and Miller, 1993.)

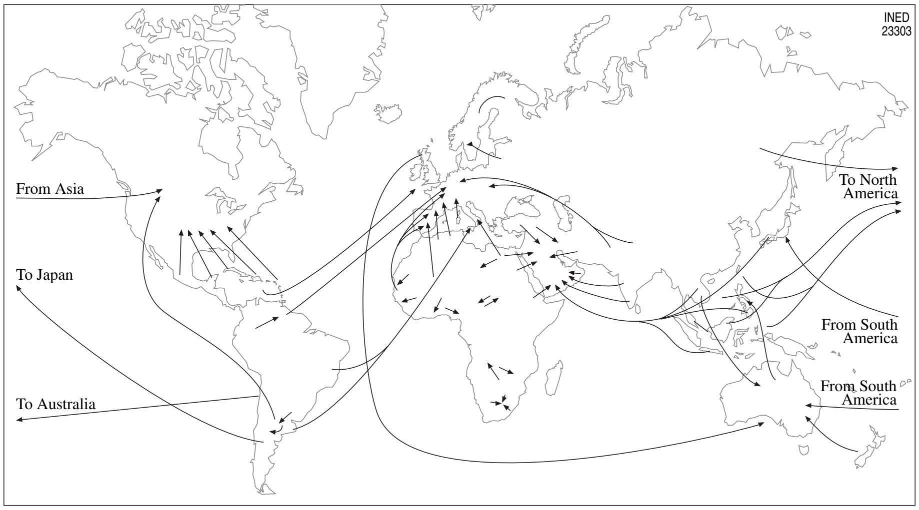

FIGURE 58–4 Direction of global migratory flows since 1973. The dimensions of the *arrows* do not indicate the intensity of the movements. (From Castles and Miller, 1993.)

a growing number of people to look for a better life in countries distant but better developed economically (whether traditional immigration countries or countries considered up to that time as countries of emigration, but sometimes of easier access).

From the second half of the 1980s and particularly at the beginning of the 1990s, international migration underwent new changes. While maintaining the same direction as in the preceding years, migratory flows became more associated with the political and economic globalization process that began at the end of the Cold War. The political and economic events of 1989 to 1996 that overturned the old political order and its economic relations opened the way for new migratory flows (Gould and Findlay, 1994). In effect, the political collapse of the Soviet Union and the creation of new independent states that significantly interrupted the internal trade exchanges in the Soviet bloc and the resulting economic crisis affecting all the countries in the region propelled the populations to look for work in the richest countries or the nearest countries from an ethnic and geographic point of view (Kupiszewski, 1994).

This crisis also affected nonmember countries (e.g., Yugoslavia, Somalia, Eritrea) that had privileged business relations with the Soviet bloc. In some of these countries, the wish to emigrate was increased by internal ethnic, religious, or political conflicts that obliged many minorities to leave their countries to seek political asylum in the Western countries. Often, a significant number of refugees, sometimes difficult to distinguish from economic migrants, were added to the normal flow of labor migrants (the volume of which is sometimes difficult to estimate). The case in recent years of migrants from Albania and the former Yugoslavia is emblematic.

Generally, these problems are also those of migrants from several countries in the Third World, where political and social conflicts in the context of a demographic explosion exacerbate the disastrous effects of the collapse of an economy that never really got off the ground. Today's events suggest that a new stage in migration history is beginning. The gap between rich and poor countries and between north and south is widening. While Eastern Europe's economy is experiencing difficulty emulating that of the rest of Europe, the economic barrier that separates the United States and Mexico and the one across the Mediterranean between Europe and North Africa continue to create enormous migratory pressure on the world's richest regions, sometimes contributing to the conversion of traditional emigration zones into immigration zones, as is the case in southern Italy. The old social and economic problems are exacerbated, and new ones appear. The emergence of new economic rivalries sometimes favors the adoption of protectionist measures, justified ethically by the necessity for self-protection.

Nevertheless, the migratory flows resulting from the globalization process are minimal compared with those produced by regional conditions. If it is true that the economy is becoming more and more international, it is no less true that a geographic polarization of investments is occurring, by virtue of which migration between neighboring countries and countries that have a shared history or culture is much more widespread. The migratory processes derive part of their momentum from political and economic treaties established between countries in the same geographic zone. This was one of the functions of the European Union, just as for other economic treaties such as the North American Free Trade Agreement (NAFTA), which was negotiated in the 1990s among the United States, Canada, and Mexico (Werner, 1994).

Among the new characteristics of international migration is its feminization, not only as a result of the policies developed in the last decades in favor of family reunification, but also because of the evolution in the social roles of both sexes and the *status* of women (Zlotnik, 1995). Formerly, the number of female immigrants was low (see Fig. 58–1), and they were mostly women following their husbands, but today, the decision to emigrate is their own, and they migrate to find work in countries where female labor is needed or to obtain permission to enter as refugees. In Italy, for example, asylum seekers from the former Yugoslavia are mainly women.

V. ACCELERATION OF MIGRATORY MOVEMENTS IN EUROPE AND NORTH AMERICA

The availability of data is the preliminary condition for any analysis or consideration regarding the political and social actions that affect migration, but collecting data on the volume and characteristics of the phenomenon causes serious problems. Even in the countries where a migrant registration system is in place, migrants from one zone to another do not always declare their transfer; the same is true for those going back to their country of origin, who do not always declare their return. The provisions in this area vary from one country to another, and this often makes comparative analyses impossible. The main problem is that the flows toward receiving countries often occur illegally, so that the registered migration is only part of the real migration. The literature on this aspect is abundant (Salt, 1998; CMS/IUSSP, 1987), and it does not seem helpful to review the regulations of each country nor to refer to all the definitions of migration here (see Chapter 13). We must content ourselves with an evaluation of the migratory movements based on existing information, national and international, concerning recorded migration and the indirect estimates of illegal migration and entries by requests for asylum.

Before going into detailed analysis, it may be useful to define the background of population movements since the Second World War for the geographic zones discussed here. From 1950 to 1989, Western Europe had a migratory net balance of approximately 8 million people, and North America had almost 25 million (Table 58–7). Almost two-thirds of this balance was acquired after 1960. In both cases, the speed is obvious, even though they occur differently: in North America, after doubling in the 1970s compared with the 1960s, the balance was reduced by one-half in the 1980s compared with the 1970s, whereas among the European countries as a whole, the balance has been doubling roughly every decade since the 1960s.

The European situation is, however, far from homogeneous. We know that the southern countries had a negative net migration total until the 1970s as a result of more than 3 million departures per decade. In Italy, for example, more than 5 million people departed over a period of 20 years from 1950 to 1970, and more than 3 million returned home; the final net migration was 2.5 million (Rosoli, 1978). The migratory balance became positive in southern Europe in the 2 decades that followed.

Western Europe had a positive migratory balance of more than 14.5 million people between 1950 and 1989. The Federal Republic of Germany and France were the main beneficiaries, with net immigration rates, particularly for the Federal Republic of Germany, of 4% annually on average, while natural growth was only 2% (Macura, 1994).

At the same time in North America, while an increase in the population had always been guaranteed by natural growth, the contribution from migration was 4% in Canada and 3% in the United States, supplying one-fourth of the population growth of both countries.

The most recent data, even if incomplete or fragmentary and not always comparable to preceding data, show a new growth in migratory movements for the first years of the 1990s. In Canada between 1990 and 1996, 231,000 people entered on average each year, compared with 138,000 between 1985 and 1989. In the United States each year, an average of more than 1 million foreigners legally entered the country, compared with 606,000 between 1985 and 1989 (UN/ECE, 1994). European countries were not left out; between 1990 and 1996, it is estimated that more than 2 million net annual immigration entries occurred in Western Europe, compared with 500,000 per annum in the 5 preceding years. The average annual estimate for Germany is about 900,000 between 1990 and 1996, compared with 332,000 per annum between 1985 and 1989. In the same period, net immigration for Italy was estimated at about 140,000 per year, compared with 66,000 per annum in the 5 preceding years.

Migration evolved differently in Eastern Europe (i.e., the former Soviet Union and the central and eastern European countries). After the Second World War, migration developed differently from that of the other European countries (Table 58–8). The Cold War period strengthened the Soviet regimes and contributed to maintaining a positive migratory balance in favor of the USSR until the end of the 1960s, despite the departures of members of certain specific ethnic or religious groups. In the 2 decades that followed, the entries were not sufficient to counterbalance the departures. Almost 700,000 people left the Soviet Union between 1950 and 1989, notably 370,000 Jews between 1973 and 1979, and a significant number of people followed during Gorbachev's presidency between 1986 and 1987 (Münz, 1995). The other countries in the region belonging to the Soviet bloc had a permanently negative balance during the whole of the Cold War period, on the order of 6 million during the first 2 decades (1950 to 1969) and 3.2 million in the following 2 decades (1970 to 1989), of which a significant part crossed from East to West Germany.

A veritable exodus accompanied the fall of Communism and the economic crisis that affected all the countries in the Soviet influenced zone. In only 4 years (1990 to 1993) the whole of Eastern Europe lost more than 3.5 million inhabitants through emigration, of which 1.4 million left from the former Soviet Union and 2.3 from the rest of the region. In the next 4 years (1994 to 1997), Russia alone lost almost 1.2 million people (Salt, 1998).

On the threshold of the 21st century, there are two contrasting Europes: all the Western countries that receive immigrants and all the Eastern countries that are experiencing a growing exodus of their population, who head mainly for the rich countries of Western Europe.

VI. IMMIGRANTS IN EUROPEAN COUNTRIES AT THE END OF THE TWENTIETH CENTURY

If the scale of the two components of the migratory balance (i.e., immigration and emigration) is often unknown, we do know that it depends mainly on three types of flow that are difficult to separate: migrants seeking work, political asylum seekers, and family reconciliation.

In recent decades, the issue of refugees has been added to the problem of the continual increase in

TABLE 58–8 Evolution of Migratory Balances in Europe, from 1950 to 1993

numbers of workers from the Third World. For the receiving countries, it is essential to know the volume of these inflows to construct legislative measures that are adapted to the new characteristics of the phenomenon. To obtain the required statistics, it is necessary to regulate the different flows while taking several factors into consideration, such as the needs of the national labor market, the integration of the immigrants, the ability to cope with the costs engendered by increasing demands for service from the foreign population, and the means to prevent immigration from becoming a catalyst for social conflicts and confrontations (Golini and Bonifazi, 1987). Despite the countless registration difficulties, official bodies and individual researchers on a national and international level have produced numerous and detailed estimates of migration by type of flow, destination, and migrants' characteristics.

Before examining estimates of flows, a few words should be said about the volume of foreign presence in the territory, as seen through official available data that, although only partially representative of real migration, are an interesting reference point on the evolution of the phenomenon. These data do not include children born in the receiving country to foreign parents, naturalized refugees, citizens of former colonies who have obtained citizenship of the receiving country, nor illegal immigrants, whose numbers are relatively high in the more recent receiving countries of Mediterranean Europe. Table 58–9 shows that the ratio of the foreign population to the native population has practically doubled every 20 years since the end of the Second World War in the whole of Western Europe, from 1.3% to 2.3% between 1950 and 1970 and from 2.3% to 4.5% between 1970 and 1990, with more sustained growth rates in recent years. Today, more than 19 million foreigners live in these countries, compared with 5 million in 1950 and 11 million in 1970.

In 1998, the western European countries with the highest proportion of foreigners were Luxembourg and Liechtenstein (34.9% and 34.3%, respectively), even though the numbers are very low (148,000 and 11,000 people, respectively), especially comparison with Germany (more than 7 million) or France (more than 3.5 million in 1990). Germany holds the European record for the total number of foreigners reached between 1960 and 1970, with the entry of refugees from

East Germany. This position was reinforced at the beginning of the 1990s with the arrival of migrants from the Soviet bloc. From 1970 to 1998, the number of foreign residents rose from 3 million to more than 7 million. In France and the United Kingdom, the number of foreigners is lower because it does not include the arrivals from former colonies that came in large numbers to their parent state in the first decades after the Second World War, at the end of the colonial era of the 20th century.

Closer reading of Table 58–9 shows the variations in the trends of the phenomenon. Decelerations and reversals in trend appear clearly during the 1970s. Numerous developed countries reacted to the economic recession that followed the 1973 oil crisis by adopting measures to restrict the entry of immigrants. However, in countries such as France, the decrease in the number of foreigners was above all the result of the increase in naturalizations. In Switzerland and Sweden, a decrease in foreign presence was observed. In Switzerland, the proportion of foreigners fell from 17.2% between 1970 and 1971 to 14.7% in 1982; in Sweden, it fell from 5.1% to 4.9%. In France and Great Britain, the same reversal in trend occurred in the following decade; between 1980 and 1990, the proportion of foreigners fell from 6.8% to 6.4% in France and from 3.9% to 3.4% in Great Britain. This shift, in France at least, was a result of the introduction of policies promoting family reunification that allowed entries, even during a period of economic crisis, and beyond the response to immigration needs (Fig. 58–5). These policies were beneficial from a demographic point of view; by increasing the number of women and children, the age and sex structure of the immigrant population became more homogeneous with that of the native population.

From the 1970s onward, the southern countries of Europe, traditional emigration zones, became immigration zones. In Italy particularly, the combination of the effects of the border closures of northern European countries and rapid economic growth resulted in the return of many emigrants (i.e., returns quickly exceeded departures) and the beginning of immigration from the poor Mediterranean countries, sub-Saharan Africa, and Asia and, from the second half of the 1980s onward, from the countries of the former Soviet bloc.

Tables 58–10 and 58–11 give an estimate of immigrant entries, and political asylum seekers in some European countries between 1980 and 1996. Despite the paucity of information on illegal migration and the diversity of data collection methods used in different countries, which limit comparison, these estimates give an idea of geographic differences resulting as much from each country's legislation as from the political and economic events that affected the whole continent. In the 1980 to 1985 period, in almost every country with traditionally high migration, a decrease in entries was observed, as mentioned previously in the cases of France and Great Britain, followed by a resumption of previous levels with the increase in requests for political asylum. At the end of the 1980s and at the beginning of the 1990s, for France and Sweden, the increase in migration seems entirely attributable to the entry of asylum seekers (Fig. 58–6).

For certain countries, this demographic profile is not surprising, considering that between 1980 and

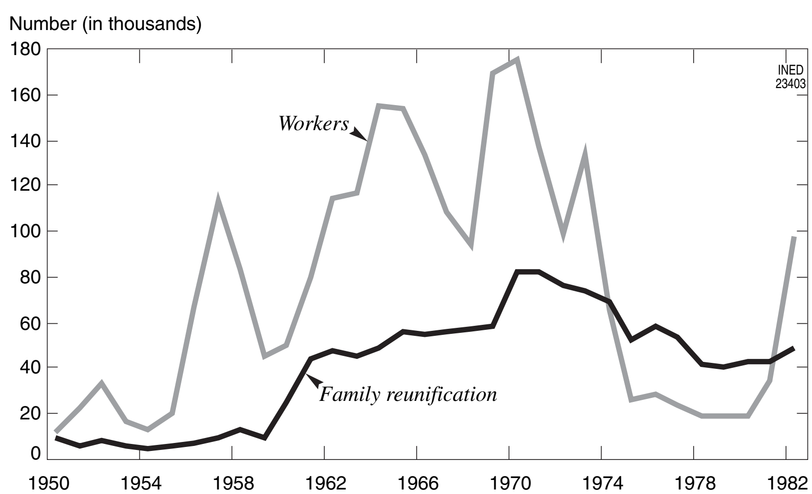

FIGURE 58–5 Annual trend in the number of immigrants in France from 1950 to 1982 according to the two main motives for entry.

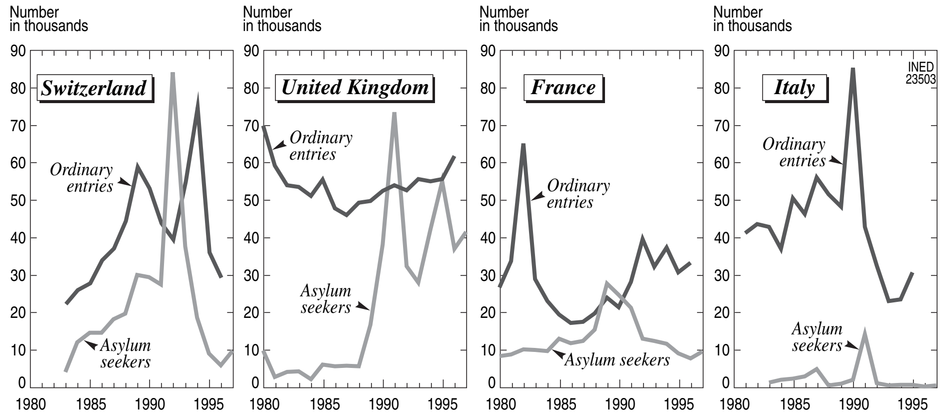

FIGURE 58–6 The trend of ordinary flows (not including asylum seekers and seasonal or border workers) and entries for asylum seekers in some European countries, with numbers given in thousands. (Data from ISTAT, 1999; Salt, 1998; OECD, 1992, 1995 1998.)

1993, more than 6 million people left Eastern Europe and the Soviet Union (net balance), of whom 3.6 million left between 1991 and 1993 alone, and that a very high proportion of them headed for Western Europe. Between 1985 and 1992, for Germany alone, the flow of labor migrants from the East was about 1.5 million, as well as 1 million asylum seekers (Fassmann and Münz, 1994). Table 58–12 completes this general view with a distribution of immigrants in 1992 by country of origin. In the first place, it confirms the previous statement regarding Germany, where, in that year immigrants from the former Communist countries made up more than one-half the total immigration figures, but the table also shows that it is different for the other countries that receive mostly nationals from Western European countries. Only Portugal, France, and Italy (for this country, see Natale and Strozza, 1997) are exceptions to this rule. In France, 44% of immigrants in 1992 came from Africa; in Italy, 53% came from African and Asian countries; and in Portugal, 52% came from America. Asylum seekers cannot be considered as permanent immigrants because most of them stay only for a short period in the receiving country because refugee status is granted to few of them.

The situation is different (at least concerning inflows from the countries of the former Communist bloc, Africa, and Asia) from what is seen from the data that do not include illegal immigration. The proportion of illegal immigration varies significantly from one country to another. In southern Europe, notably in Italy, illegal immigration is much higher than elsewhere, as numerous factors (e.g., border geography, proximity to countries of emigration, legislative tardiness, lack of adequate policies, weakness of control measures) have contributed in facilitating their entry. Numerous estimates confirm, for example, that in southern European countries, illegal flows from the poor Mediterranean and sub-Saharan countries are far higher than official flows. According to a Council of Europe estimate, in 1995, there were approximately 1.5 million illegal immigrants in Italy, Spain, Greece, and Portugal from non-European countries, and more than 0.5 million of these immigrants were from North Africa (Schoorl *et al.*, 1997). The same source also provides estimates of the trend in African migratory flows into several European countries, distinguishing between the two components, legal and illegal. In 1985, the African population in European countries, calculated using data from census data was about 2.3 million, and the estimate obtained by adding illegal immigrants was as high as 2.7 million. Only 9 years later, the gap between these two figures had more than doubled. In Europe in 1994, there were more than 3 million registered immigrants, but by adding illegal immigrants, the estimate was 4 million; the largest gap between registered immigrants (288,000) and the total number including illegal immigrants (935,000) was observed in Italy (Schoorl *et al.*, 1997).

In Italy, the issue of the number of illegal immigrants has caused lively debates because of the inability to agree on an estimate of the number of illegal immigrants. The complexity of the Italian administrative system makes it difficult, if not impossible, to correctly estimate this component of migration; the subdivisions of "regularized," "nonregularized," and "illegal" immigrants confuse rather than clarify the issue. Until the end of 1999, foreigners residing in Italy could be in order regarding their residence permit but not registered with the *anagrafe* (as is stipulated by

law), or they could be registered with the *anagrafe* (and even registered on the list of job seekers) without having a residence permit and therefore considered nonregularized or illegal. According to the new legislation, foreigners cannot register with the *anagrafe* unless they have a residence permit, but the *anagrafe* services, which are supposed to check the validity of each permit every year, rarely make these checks, at least not in the large cities. The application of legislation also varies from one region to another. Fortunately, in recent years, the problems and incoherencies introduced by legal and administrative complications have not prevented researchers from producing several estimates that appear to tally on several important points (Strozza, 1994). According to the first estimate, the number of immigrants in Italy between 1997 and 1998 should be about 1.2 or 1.4 million, more than double the number estimated using data from the 1991 Census (ISMU, 1995; ISTAT, 1994; CENSIS, 1993a; Natale, 1990) but quite close to the number of foreigners registered with the *anagrafe* in 1998 (about 992,000 according to ISTAT, 1999) and close to the number of residence permits issued in the same year (a little more than a million) (Caritas, 1999).

In Italy, more than 80% of the immigrants identified live in the central and northern regions (51% in the northern regions alone). More specific estimates show that in the *Mezzogiorno* region, immigration is lower and has different characteristics, so much as to suggest a hypothesis of temporary migrations. The southern regions may constitute an easily accessible first stage for immigrants intending to move further (Ferruzza *et al*., 1997). The statistics for residence (residency) permits issued in 1997 confirm the trend of progressive growth in the foreign population in the north and the center of the country, with proportions of more than 50% (Table 58–13).

According to a recent estimate, more than 30% of the permits were issued in Milan and Rome (Bonifazi and Strozza, 2003; Bonifazi, 1998); 65% of the 649,000 residence permits at the end of 1991 were issued for the purpose of seeking employment, a trend at odds with that of most of the traditional European immigration countries (Fig. 58–7).

The characteristics of migration have changed in recent years in many European countries as a result of measures taken to limit the entry of labor migrants. In Italy, because of the incoherencies and delayed adaptation, the effects are not yet evident, but in the countries where policy measures have been in place for a certain length of time, the impact on the flows is significant. In France, the long-term trend has been to limit new entries, with the exception of family reunification (see Figure 58–7B). This example was partially emulated elsewhere, which is partly responsible for one of the most significant changes in the structure of migrant populations: its feminization. In all the northern European countries, women currently make up about 45% to 46% of the total immigrant population, even though the phenomenon varies quite significantly according to the country of origin. Although it is true that the emigration of women depends on the sociocultural context in which they live, including events and circumstances at the time (e.g., war, food crisis, political repression), emigration reflects even more so the situation in the receiving country, as much because of policies favoring family reunification as the opportunities offered by the employment market. Figure 58–8 shows, for example, the heterogeneity of female presence according to country of origin (for five nationalities) and according to the receiving country (for five countries plus Europe).

The number of women from Mauritius is greater than the number of men (values more than 1000) in

Data from Ferruzza *et al*., 1997; ISTAT, 1997.

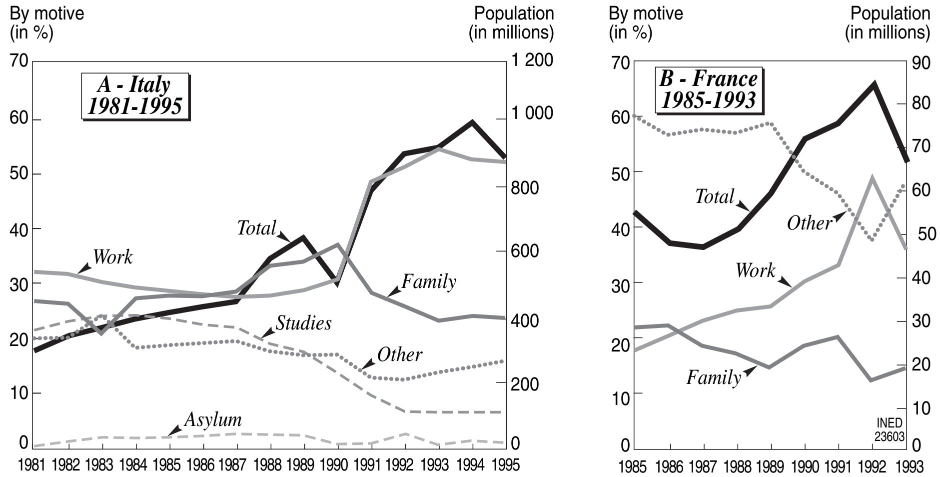

FIGURE 58–7 Distribution of foreign populations according to motive of entry and total foreign population. **A:** Italy, 1981 to 1991. **B:** France, 1985 to 1993. For Italy, the residence permit data are from the Ministry of the Interior, and the values for 1995 are from the August 31, 1994, inventory; from 1989, the work category includes those registered at registry offices. For Italy, the distribution concerns the movement of the "stock" of the foreign population, estimated from valid permits, and for France, it concerns the net "flow" evolution of foreign entries, estimated from permits issued annually. All values are expressed in thousands. (From Schoorl *et al*., 1997).

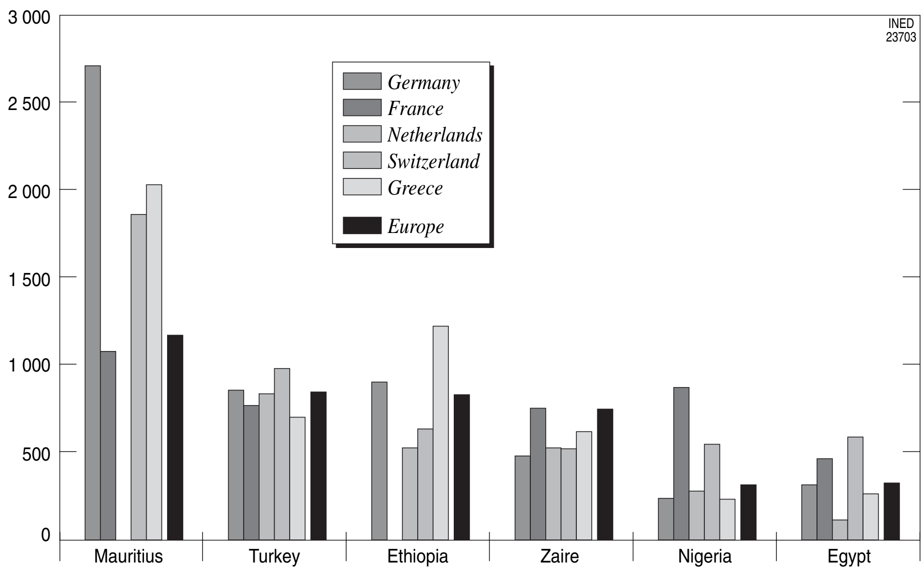

FIGURE 58–8 Sex ratio for each foreign population residing in different European countries in 1990 (number of women per 1000 men). The data are only for legal residents. (From Schoorl *et al*., 1997.)

each receiving country, and it is almost three times greater in Germany. This may indicate that they have autonomy from men regarding the migration project or that there are employment opportunities for women in some sectors in the receiving country. The emigration of Egyptian women is significantly lower than that of Egyptian men; the decision is generally made within the family and often includes women giving up their wish to emigrate.

VII. RECENT IMMIGRATION TO CANADA AND THE UNITED STATES

To estimate the number of foreigners in Canada and the United States, we can refer to the most recent censuses. In Canada, the number of immigrants was more than 4 million in the 1990 census, which is 16% of the total population. In 10 years, it had grown by approximately 400,000, but its proportional increase in the total population was only 0.7% (from 15.4% to 16.1%). The trend has been more distinct in the United States, where according to the most recent censuses, the number of immigrants increased from a little more than 14 million in 1980 to almost 20 million in 1990, which is an increase from 6.2% of the total population to 7.9%. This increase is even more surprising when compared with the 9 million immigrants recorded in the 1970 census; the immigrant population has doubled in a period of only 20 years (Table 58–14).

Detailed analysis of the annual flows reveals the migratory differences and similarities of both countries. In the United States in the 1970s, 450,000 entries were registered annually on average, close to values of the preceding years, and in the 1980s (Table 58–15, last row), the flow of entries was higher, with about 650,000 per year (Castles and Miller, 1993). In Canada, the 1970s was a period of higher immigration, with the entries, which in preceding years were about 100,000 annually, doubling before falling in the first half of the 1980s and stabilizing for several years at a lower level than that of previous years (see Table 58–15). These differences in trend are associated with different migratory histories, reflecting different political and administrative decisions (Papademetriou, 1994).

It is only in the second half of the 1980s that a real convergence between the two countries is observed, with resumption in the increase of migratory flows at the beginning of the 1990s, exceeding 200,000 per year in Canada and 1 million in the United States. This convergence is the consequence of policy measures adopted by both countries, such as those in favor of family reunification, the regularization of illegal immigrants, and the entry of certain categories of refugees. At least for the United States, a revival in the economy also contributed to a wider opening of the borders.

Measures for the regularization of illegal immigrants and the authorization of family reunification allowed more detailed information to be collected on the degree of the migratory movements and particularly on the composition of the foreign population.

TABLE 58–14 Immigrants Recorded in Various Censuses

Censuses	United States		Canada	
	Number[a]	%	Number	%
1970	9,619.3	4.7	—	—
1980 (to 1981)	14,079.9	6.2	3,908.0	15.4
1990 (to 1991)	19,767.3	7.9	4,342.9	16.1

[a] All population figures are given in thousands and percent of the total population.

From OCDE, 1995.

Figure 58–9 illustrates the effect of these measures on the increase in the number of immigrants, and Table 58–15 shows the role it played in the distribution of immigrants according to country of origin.

In Canada from 1980 to 1991, the flows from Africa and the Middle East increased from 6% to 18% of the total, whereas in recent years, they have decreased to 16%, with almost 30,000 entries per year. At the same time, the proportion of South Americans increased from 9% to 16%, only to decrease to 8% in more recent years. Despite a constant increase in the flows, the proportion of immigrants from Europe decreased between 1980 and 1996 (from 29% to 20%). The distribution of the flows also changed in the United States (particularly in the years after the regularizations of 1986 and 1990). From 1980 to 1991, the proportion of Mexicans increased from 11% to 51%, whereas that of Europeans, despite the increase in immigration, fell from 14% to 7%. The proportions of Europeans, Asians, and Latin Americans, which at the end of the 1970s were 18%, 44%, and 35%, respectively, changed to 11%, 38%, and 47% after the regularizations of 1986 (i.e., Immigration Reform and Control Act) and to 7%, 22%, and 67% after the regularizations of 1990 (i.e., Immigration Act).

The U.S. Congress did not have to wait long for the results expected from the new legislation of 1990. With the regularizations, the 1 million immigrants observed in 1989 grew to more than 2 million in 1991. The succession of legislative measures favoring immigration should have improved on the previous situation and regularized or eliminated illegal entries. This did not happen. On the contrary, it is estimated that the number of illegal immigrants is currently about 3.5 million (of which 80% to 90% are Mexicans) and that despite border control, 200,000 illegal immigrants enter annually. In the absence of new legislative measures, the number of legal immigrants has decreased, falling more or less to the levels observed in the 1980s (see Table 58–15). With regard to asylum seekers, at the end of the Second World War the United States favored the entry of numerous European immigrants, especially those from the Communist bloc countries. From 1946 to 1980, it is calculated that about 2 million refugees entered the United States to settle there permanently. A comparison with data from recent years is practically impossible, because new legislation in 1980 radically changed the definition of a refugee. However, it can be stated that entries by asylum seekers have made up for about one-sixth of the total flow each year from 1980 onward (see Fig. 58–9).

In 1990, the United States and Canada adopted migration policies setting a maximum number of immigrants for 1995 based on a significantly higher quota than that of preceding years. Canada basing

[a] All immigrant population figures are given in thousands.
[b] The high number of immigrants to the United States after 1990 is due to regularizations.
[c] From 1992, figures include Caribbean and Central America.
Data from OCDE, 1992,1995, and 1998.

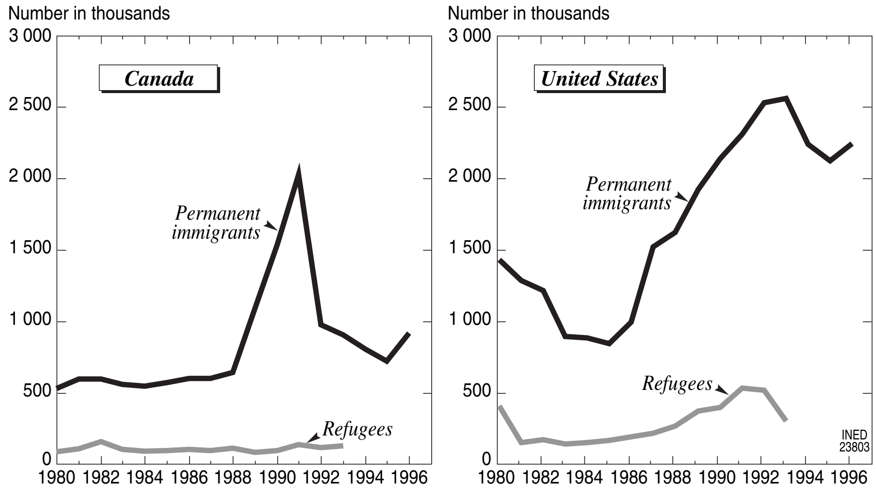

FIGURE 58–9 Evolution in the number of permanent immigrants (except refugees) and refugees in North America, in absolute figures. (From OECD, 1992, 1995, 1998.)

its quota on migration observed in 1990 fixed the maximum number at 250,000 immigrants per year, with the stipulation that labor migrants should not make up more than 50% of this number. Meanwhile, the United States set the average number of entries for the 1992 to 1994 period at 714,000, and the maximum number at 738,000 for 1995. In this same year, the proportion of labor migrants was restricted to 16% to 17% of the total in order that family reunification could constitute 70% of the total. It was possible to verify *a posteriori* whether the legal entries surpassed the limits set. In 1993, about 256,000 entries were recorded in Canada, whereas in the United States, 975,000 were recorded in 1992 and 904,000 in 1993. In the latter case, it appears that the number of entries respected the quota in 1995 but not in the following year, when the number of immigrants increased to 916,000.

VIII. INTEGRATION: THE END OF THE JOURNEY

The American experience calls into question the certitude of a guaranteed control of movement through the programming of entries. The historical reality and the current social, political, economic, and demographic situation show that the rich countries will continue to be the target for a growing number of emigrants. Sufficient economic growth in the Third World countries cannot be counted on to bridge the gap between them and the rich countries. Even at the level of international cooperation and despite efforts made in recent years, the innumerable interventions have not produced tangible results. Current economic agreements that allow the free flow of goods and capital are not sufficient to combat the demographic pressure in the least-developed countries, even if they can have an indirect effect in limiting the free flow of illegal workers. Moreover, if natural population growth cannot ensure a sufficient population of working-age people for development needs, there will be no choice but to resort to foreign labor in the future in many rich countries, notably in Europe. Numerous European countries that are today declaring their desire to close their borders may tomorrow be obliged to continue their economic development through immigration.

The objective of the governments regarding immigration on the other side of the Atlantic is different from that of the European countries. The United States is more concerned with blocking the entry of goods and capital than that of immigrants, contrary to European countries that, although pursuing different policies, converge around a basic position aimed at controlling the quantity and quality of immigration flows (Bonifazi and Gesano, 1994). The significant migratory pressure of African populations and the inexorable flood of people from the countries of the former Communist bloc have contributed to reinforcing the wish to restrict the entry of new immigrants. There are, however, different attitudes according to the type of flow and particularly about the necessity of at least favoring family reunification for foreigners already residing legally in the territory and the admissibility of asylum seekers.

Beyond their differences regarding migration policy, all the European governments are in agreement about the fact that conditions must be created for the complete economic, political, and social integration of immigrants who have been residing in the country for a long time (Salt, 1998; Tapinos, 1994). This is merely an agreement in principle, and the issue of the strategies for achieving this objective remains very controversial between different countries and within each of them. Total integration depends on equal opportunities for each individual within each society, without any cultural, religious, or racial discrimination. The process leading to integration is nevertheless extremely complex, and as Corrado Bonifazi and Giuseppe Gesano (1994) stated,

> Different ways of evolving the reference models exist on the basis of which the relation between the immigrant and the host society is organized and structured. It is a fundamental policy goal of the migratory process, but also a major problem which remains despite numerous efforts, as shown by the fact that the different approaches selected up to now in receiving countries, in Europe or elsewhere, have not fully achieved their objective, generally leave immigrants facing significant integration problems.[1]

In the failure of the integration models developed in the different countries, the main objective of legislation seems to be to favor the integration of legal immigrants, taking care to preserve their native culture and traditions in harmony with those of the receiving country (Bonifazi, 1998; Cagiano de Azevedo *et al.*, 1993, 1994). Among the fundamental points, the legislation is based (this is the case in Italy since 1986) on the recognition that immigrants have a right to be treated in the same manner, to have the same working conditions, to have the same access to social and health services, and to have the same schooling and accommodation as the native population (Coleman, 1993, 1994).

Even if measures are adopted to guarantee migrants at least satisfactory integration, if not complete immersion, we know that they vary greatly from one country to another, as much in their definition as in their application. Difficulties in intervention do exist, even in those areas where integration policies would seem to have broken all the barriers. Examples of discomfort are numerous. As in the past, immigrants are generally employed in the toughest employment sectors and usually have the most insecure jobs (Entzinger, 1990), without mentioning circumstances (as is underlined in the last OECD [1998] report on international migration) that resulted in unemployment rates increasing more rapidly for immigrants than for the native population in all the Western countries until 1996.

If employment facilitates the immigrant's integration into the host society, access to decent housing is an equally important factor. We know, however, that in all the countries of the world, housing for most immigrants is often very precarious and far from meeting the standards of a modern society. Unfortunately, this problem is not easy to resolve in countries where a large proportion of the native population is facing the same housing problems as the immigrants (CENSIS, 1993b).

Education is a fundamental element of integration. The first measures concern the immigrants' learning of the receiving country's language and setting up of special programs for their children. In all the receiving countries, the level of education of second-generation children is inferior to that of the local population. In countries that have not been receiving immigrants for a long period, the right to education for immigrants' children is rarely guaranteed, and even when it is, mediocrity is often the rule rather than the exception (Coleman, 1994). It may be thought that this poor education is the result of linguistic difficulties and the poor cultural context in which the children live. However, it depends greatly on factors such as the teachers' lack of preparation and the lack of multicultural education programs.

Recognition of citizenship (or of nationality) possibly constitutes the most fundamental stage in the integration process, because it is the conclusion of the migration process and is a major element in the acquisition of political rights, without which the immigrant's access to a full participation in the civic life of the receiving country is not possible. In Italy, for example, acquiring citizenship is a particularly complicated problem because the procedures in force are particularly restrictive and dissuasive, as much because of the duration of permanent residence required as the cumbersome nature of the administrative process, which culminates with a decree by the President of the Republic, on the suggestion of the Ministry of the Interior, after recommendation by the Council of State. Certain countries, even without naturalization, aim at encouraging the political integration of immigrants by giving them voting rights in local elections; this already appears in the provisions of the Maastricht Treaty for nationals of countries in the European Union, but it would be timely to offer this possibility to other nationals, at least for immigrants who have been resident in the receiving country for a long time, to allow them to exercise the democratic principle of participating in collective decisions and to protect their own interests.

The ideal conclusion of the migration process for recent generations of immigrants is still far away. The present climate of economic crisis and unemployment

[1] "Ha diversi esiti possibili al mutare dei modelli di riferimento in base ai quali viene organizzato e si struttura il rapporto tra immigrati e società d'arrivo. Un nodo politico fondamentale del processo immigratorio, ma anche un problema ancora aperto e dalle molteplici soluzioni, come dimostra il fatto che delle diverse strade scelte in passato dai paesi d'immigrazione europei ed extraeuropei, nessuna ha realizzato pienamente i suoi obiettivi, mentre generali rimangono le difficoltà di inserimento per gli immigrati."

make its achievement even more difficult, even improbable, as the immigrants' problems coincide with those of the native population. The immigrant can be considered by the most disadvantaged citizens as being a potential rival, and the actions of public authorities on his behalf can result in dangerous xenophobic and racist feelings that lead to aggressive and violent behavior and that are in contradiction with the fundamental principles of democracy. In this case, we lose sight of the basic problem: the search for a solution to control the flows without harming anyone. This is especially true for recent receiving countries (especially Italy), which must face the traditional problems of immigration and those resulting from the unavoidable globalization process of migratory movements. Two-thirds of humanity have access to less than one-third of global wealth, and this proportion of the planet's population is expected to increase rapidly for several decades before achieving its demographic transition, whereas the rich countries are experiencing an enormous reduction in births.

In the years to come, the developed world will not easily escape migratory pressure from the poor countries. Attempts to solve this through border closure policies will only aggravate the problem of illegal immigration. From now on, it appears evident that nothing will be done to improve cooperation between the north and the south, because the trend of the employment market in the developed countries does not provide any hope for mass recruitment of foreign workers. It is equally certain that numerous factors that could limit migratory flows are associated with the integration and globalization processes of the economy, a process capable of encouraging the movement of capital from the rich countries to the poor countries, where the labor force is based, and increasing international business (Malacic, 1996; Tapinos, 1996). Although such a prospect is no doubt desirable, it is not feasible in the long or short term as long as all the countries of the world are not working together toward the same goal.

Theories of International Migration

HANIA ZLOTNIK

Population Division, United Nations, New York, United States

Attempts to establish a theory of international migration have a long history. In the late 19th century, E. G. Ravenstein (1885, 1889) formulated the *laws of migration* on the basis of empirical analysis of migration in England and established the first theoretical framework for the analysis of the phenomenon. Although some of the laws formulated by Ravenstein do not have the universality that the term *law* suggests, they nevertheless encapsulate the principles that were to guide most of migration research during the 20th century. Ravenstein stated that "the major causes of migration are economic" and that "the major direction of migration is from the agricultural areas to the centres of industry and commerce," foreshadowing the attention that 20th century researchers would accord to the study of rural-urban migration and of the economic aspects of migration in general. Today, at the beginning of the 21st century, there is still no comprehensive theory of migration, but considerable progress has been made in devising explanatory frameworks that are useful in understanding the determinants of migration and that permit the derivation of testable hypotheses. Given the multifaceted nature of migration, it is not surprising to find that several disciplines have focused on its study and that each has posited some theoretical explanation about the nature, genesis, and development of specific types of migration. This chapter reviews the main tenets of the different theories, frameworks, or hypotheses that have been proposed within the various disciplines and then offers a comparative analysis of their strengths and limitations. The chapter draws on material prepared for the 1997 World Population Monitoring of the United Nations (United Nations, 1996).

I. THE ECONOMIC APPROACH

From the economic perspective, international migration is a mechanism to redistribute labor. Consequently, international migrants are equated with workers and existing economic theories are aimed at explaining *labor migration*, meaning the international movement of economically active individuals. Perhaps the oldest theory seeking to explain the occurrence of labor migration is that based on the thinking of Adam Smith and other economists of the period who suggested that the migration of workers is caused by differences in the supply of and demand for labor in different locations. Adam Smith observed that the laws in England that hindered the poor from moving from one locality to another, as well as those that prevented people from changing trades, served only to maintain inequality between places. He therefore argued in favor of dismantling barriers to the free circulation of labor to permit the natural tendency of workers to move from low-wage to high-wage areas to express itself and consequently to facilitate the economic progress of the areas of origin and those of destination and the progress of the migrants themselves. Adam Smith advocated the promotion of the completely unfettered international movement of capital, goods, and labor so that market forces could ensure maximum economic expansion and a reduction of poverty.

1. The Neoclassic Theory of Migration

Modern scholars (Todaro, 1976; Harris and Todaro, 1970; Sjaastad, 1962) have modified the classic theory, developing the *neoclassic theory of migration*, which posits that countries with a large endowment of labor relative to capital will tend to have a low equilibrium market wage, whereas countries with a limited labor endowment relative to capital will tend to have high market wages. The resulting wage difference entices workers from low-wage countries to move to high-wage countries. As a result of that movement, the supply of labor decreases and wages rise in the countries of origin, and the supply of labor increases and wages fall in the countries of destination, leading eventually to a new equilibrium at which wage differences reflect only the costs of migration. At that point, international migration ceases.

The macroeconomic formulation presented has a microeconomic counterpart that focuses on individual migrants acting as rational actors and deciding to migrate on the basis of cost-benefit calculations (Todaro, 1976; Harris and Todaro, 1970; Sjaastad, 1962). People are seen as choosing to move to wherever they can be most productive given their skills. However, to attain higher productivity, they must invest in their migration, which involves tangible and intangible costs (e.g., the costs of travel, of job search, of adaptation to a new environment). When applying this theory to actual case studies, the benefits of migration are measured in terms of net returns at the individual level discounted over a certain time horizon. Net returns are estimated as the difference between expected earnings in the country of destination and expected earnings in the community of origin. Expected destination earnings are the earnings at destination estimated on the basis of an individual's skills multiplied by the probability of that individual getting a job at destination. Similarly, expected earnings in the community of origin are the observed earnings multiplied by the probability of employment at origin. Net returns are summed over the time horizon discounted by a factor that reflects the greater utility of money earned in the present than in the future, and the sum is taken as an estimate of the benefits of migration (Massey *et al*., 1993; Todaro, 1976; Harris and Todaro, 1970; Sjaastad, 1964). The subtraction of estimated costs leads to a measure of the expected gains from migration. This approach to the quantification of the expected gains from migration implies that its occurrence depends on wage differences between countries and on differences in unemployment levels between the country of origin and that of destination. Because expected earnings depend on an individual's characteristics (including human capital), factors leading to the selectivity of migration are explicitly taken into account. Any factor that reduces the costs of migration tends to increase its likelihood of occurring. In practice, the problem of measuring costs is far from straightforward, because it is not easy to attach a value to preferences, personality traits, family constraints, or perhaps more importantly, to the obstacles faced by prospective migrants when trying to secure entry to countries characterized by restrictive admission policies.

The neoclassic theory of international migration has well-known limitations, including its failure to take into account the international political and economic environment, as well as the effects of state-level economic and political decisions that influence individual decisions regarding migration (Papademetriou and Martin, 1991). The macroeconomic model assumes that there is homogeneity of skills between areas of origin and destination (i.e., that labor is completely interchangeable) and that full employment is maintained in both areas during the migration process. Because those assumptions are generally not fulfilled in practice, the effects of labor migration tend not to conform to those predicted by neoclassic theory (Martin, 1991). The microeconomic model has generally not been put to a rigorous test in explaining international migration (Massey *et al*., 1994). However, there is ample evidence that wage differences play a significant role in determining the size of migration flows in many settings, so that it is widely accepted that the existence of such differences is a necessary, albeit not a sufficient, condition for the migration of labor to occur.

2. The New Economics of Migration

Recognition of the limitations of neoclassic theory has led to the proposition of alternative theories. The most recent, known as the *new economics of migration*, focuses on the microeconnomic level, but instead of assuming that migration decisions are made by individuals acting largely on their own, it assumes that people act collectively, typically within households or families, to maximize expected income and to minimize risks and loosen constraints associated with a variety of market failures that are particularly common in developing countries, where crop insurance markets, futures markets, or unemployment insurance do not exist or are beyond the reach of most people (Stark, 1991). According to this approach, households attempt to minimize risks to their economic well-being by diversifying the allocation of family labor. From this perspective, sending certain family members to work in another country where wages and employment conditions are largely independent of local economic conditions is a form of insurance against the deterioration of the latter. International migration and the remittances it generates can also allow households to obtain the capital needed to increase the productivity of assets in the community of origin. Such a function of migration is considered to be particularly important in developing countries where capital markets are weak, many people do not have access to banking services, and families lacking adequate collateral find it virtually impossible to borrow at reasonable interest rates.

The approach to the new economics of migration also questions the assumption that income has a constant effect on utility for different actors across socioeconomic settings. Instead, it argues that households send family members to work abroad to improve income in absolute terms and to increase income relative to other households in a reference group (Stark, 1991; Stark and Taylor, 1989). If in a community the income of affluent households increases, whereas that of poor households remains unchanged, the relative deprivation of the latter increases, and their incentive to participate in international migration rises as well, even if no change in expected wages takes place.

The theories derived from the new economics of international migration have important implications for the interrelations between international migration and development. First, they imply that migration can occur even in the absence of wage differentials between areas of origin and destination, because migration may be fueled by the desires of households in the place of origin to diversify risks. Second, because there are strong incentives for households to engage in international migration and in local economic activities, an increase in the return to the latter may heighten the attractiveness of migration as a means of overcoming capital and risk constraints on investment in local activities. Successful economic development within areas of origin need not reduce pressures for international migration (Massey *et al*., 1993). Third, international migration will not necessarily stop once wage differentials between countries of origin and destination have been eliminated, because as long as other markets within countries of origin are nonexistent, imperfect, or inaccessible, incentives for migration may continue. Fourth, governments of countries of origin can influence migration through labor-market policies and through those that shape insurance and capital markets. Government policies and economic changes that modify the income distribution will change the relative deprivation of some households and will affect the incentives to migrate. In particular, when poor households in areas of origin do not share equitably in the income gains of other households, their propensity to send some family members abroad will increase.

Evidence supporting the premises and the implications of the new economics of international migration has been growing steadily. However, most of it relates to cases of long-standing migration processes linking rural areas in developing countries to developed countries (Massey *et al*., 1994). The migration involved is usually temporary and precludes the relocation of complete households that, were it to occur, would largely reduce to a minimum the economic nexus between migrants and the community of origin. Typically, the studies available focus on the experience of just a handful of rural communities, which are not selected to be representative of the whole population, and in all cases, large wage differentials between areas of origin and destination continue to exist. Nevertheless, the evidence supports several of the conclusions predicted by the theory, including that remittances increase productive investment in the areas of origin (e.g., greater use of machinery, land, and hired labor) and promote the acquisition of income-producing assets (e.g., livestock, equipment, education). As a result, remittances can raise household income over time by more than the value of the remittances themselves (Taylor, 1992).

3. Family Migration and the Selectivity of Migration

Although not formally a part of the new economics of migration, extensions of the neoclassic migration model have been proposed to take into account that a large part of migration consists of the movement of complete families, not just of workers. Mincer (1978) considered the effects of earnings differentials across space on family migration. Such an approach is more realistic because, in many contexts, one family member may anticipate gains in potential earnings while another expects losses in the place of destination. To the extent that a family includes more than one person that is economically active, the possibility of conflicting goals exists. Assuming that a family consists of at least two married adults, with or without dependent children, Mincer (1978) shows that migration can create "tied movers" or "tied stayers" and that the difference between the individual's and the couple's optimal strategy depends on the degree of correlation in the gains from migration of the husband and wife. Only when there is a perfect correlation do the optimal strategies of the individual and the married couple coincide.

Borjas and Bronars (1989) use Mincer's approach to analyze the selectivity of migration to the United

States. Based on a model involving only individual migrants, Borjas (1987) shows that the extent of income inequality between the places of origin and destination influences the type of person that migrates. If income inequality is greater at the place of destination, people with higher than average skills have an incentive to migrate because they can earn a higher relative wage in the area of destination, other things being equal; conversely, if income inequality is greater in the place of origin, such persons have less incentive to migrate than those with lower skills. However, when married couples are considered, the selectivity effect weakens because some low-skilled migrants who would not have migrated on their own to a place with a high level of income inequality may do so if they are married to skilled persons. Such tied migrants with low skills are not likely to fare as well in the labor market of the area of destination and therefore may reduce the average wage for migrants as a whole, as Borjas and Bronars (1989) show in the case of married-couple migration to the United States.

4. The Dual Labor Market Theory

The neoclassic economic theory of migration and the new economics of migration assume that migration is mainly the result of rational choices made by individuals or families. In contrast, other economically based theories take a macroeconomic perspective and argue that international migration is mainly the product of international forces that transcend individual choice and set constraints on it. The *dual labor market theory* posits that international migration results from a permanent demand for foreign labor that is inherent to the economic structure of developed countries (Piore, 1979). Several factors contribute to create such structural demand for foreign workers. First, wages not only reflect conditions of supply and demand; they also confer status and prestige. Consequently, to preserve an established occupational hierarchy, wages cannot respond freely to changes in the supply of workers. Under those conditions, employers seeking to attract unskilled workers for jobs at the bottom of the hierarchy cannot simply raise wages, because by so doing, they would change the socially defined relationships between status and remuneration: An increase of wages at the bottom would put pressure to increase wages at other levels of the occupational hierarchy. To avoid such pressures in times of labor scarcity, employers have strong incentives to seek a cheaper solution: the importation of foreign workers willing to work for low wages.

A second factor against the use of local workers to fill in jobs at the bottom of the occupational hierarchy relates to the motivational problems associated with jobs that provide few avenues for upward mobility. Employers need workers who see bottom-level jobs simply as a means to earn an income and who disregard status implications or the lack of upward-mobility prospects. Foreign workers from low-income countries, especially those having a tentative migration status (as legal temporary workers or as undocumented migrants), are usually willing to satisfy that need because even a low wage in a developed country can be several times greater than the average wage in a developing country.

The third factor contributing to the existence of an unmet structural demand for unskilled labor in advanced industrial societies is the development of a dual economy characterized by the coexistence of a capital-intensive primary sector and a labor-intensive secondary sector and by a segmented labor market. Workers in the primary sector usually hold stable, skilled jobs that allow them to accumulate firm-specific human capital. Workers in this sector tend to be unionized and to work under contracts that require employers to bear a substantial share of the costs of any idle periods (through severance pay and unemployment benefits). They are expensive to let go and become in that sense more similar to capital. In contrast, workers in the secondary or low-productivity sector generally hold unstable, unskilled jobs and may be laid off at any time with little or no cost to the employer. They become the means of adjustment during cyclical downturns, when they can be forced to bear the costs of their own unemployment. Because native workers have no incentive to take the unstable jobs characterizing the secondary sector, shortfalls in labor supply in that sector are common and are often filled by having recourse to foreign labor. That is most likely to happen in societies where other sources of labor for the secondary or low-productivity sector—women and teenagers—are in short supply because of social constraints or better occupational opportunities in the case of women or because of declining cohort sizes and increasing years of schooling in the case of teenagers.

Although studies aimed at validating the existence of segmented labor markets and at identifying the primary and secondary sectors have been common, few have addressed the linkages between the existence of a segmented labor market and international migration. If, as the theory suggests, migrant workers were mainly recruited into the secondary labor market, we would expect to observe lower returns to education, skills, and work experience among migrants than among nonmigrants. Evidence supporting that expectation has been found with respect to Mexican migrants in the United States (Massey *et al*., 1994). Studies of other migrant groups in the United States (e.g., Cubans, Chinese) have shown, however, that urban labor markets are segmented, but particularly in cities with large migrant populations, they appear to be divided into three sectors rather than two: a primary sector, a secondary sector, and an ethnic enclave. The existence of ethnic enclaves facilitates the incorporation of migrants to the labor force, and although the jobs they initially get in the enclave pay low wages and lack prestige, the enclave provides greater opportunities for advancement than the secondary sector (Portes and Bach, 1985).

According to Piore (1979), foreign labor recruitment is the principal means through which unsatisfied demand in the secondary sector of the labor market is expressed. This assertion is validated mostly by the experience of the labor-importing countries of Europe during the late 1950s and 1960s, when the hiring of foreign workers was often done through official recruitment programs. Recruitment, whether through official channels or private ones, was also instrumental in initiating the flows of Mexican and Filipino workers to the United States and of workers from some Eastern and Southeastern Asian countries to Japan and some newly industrializing economies. However, despite the undeniable importance of recruitment in starting and building the momentum of international labor migration flows, it is not necessarily the case that, as Piore (1979) postulates, such migration is largely demand driven. In statistical analyses of the determinants of migration flows that include variables relative to both the country of origin and that of destination, those relative to the country of origin appear to have greater explanatory power (Massey *et al*., 1994). However, the analyses considered were not meant to test Piore's assertion and consequently do not test the effect of labor demand in the country of destination.

5. The World Systems Theory

A fourth approach to explain the causes of international migration is based on the thoughts of Marx regarding the functioning of international capitalism (Papademetriou and Martin, 1991; Wallerstein, 1974). Known as the *historical-structural model* or the *world systems theory*, this approach posits that the origins of migration can often be traced to the institutional and sectoral imbalances brought about by a state's incorporation into the world capitalist system. The world's labor is seen as divided into three geographically distinct zones: core, semi-periphery, and periphery. The nature of political and economic interdependence between the three zones, as well as the direction and nature of capital and commodity flows, structures the patterns of labor movements between the zones (Portes, 1995; Sassen, 1988; Petras, 1981). In core countries, the demand for migrant labor is not uniform because it usually reflects the relative scarcity of persons prepared to work for low wages. Demand for cheap labor arises in sectors, such as agriculture, that cannot rely on productivity increases to maintain profit levels. It is also linked to the overall shift of the economies of core countries from a manufacturing to a service base, coupled with the downgrading of jobs in the manufacturing sector, especially in high-technology industries (Grasmuck and Pessar, 1991). In peripheral countries, the commercialization of agricultural production generally leads to land consolidation, the substitution of cash crops for staples, the intensive use of modern inputs to produce high crop yields, mechanization and the consequent reduction of labor demand. Such changes result in the displacement of labor from the land and an increase in rural-urban migration, which contributes to producing a surplus labor force in urban areas. Typically, the growing urban labor force cannot be fully accommodated by the creation of new urban employment and high rates of unemployment and underemployment ensue, being accompanied by a growing number of persons in informal and low-paying service-sector occupations. Many families become marginalized, even during periods of rapid economic growth, and income inequality increases. The coexistence of such developments with the unmet demand for low-cost labor in core countries results in the international migration of workers from the periphery, a migration that is facilitated by the cultural and ideologic bonds between countries in the core and certain countries in the periphery and by the transportation and communication links between them, both of which are the by-products of the capitalist penetration of the periphery by core countries.

According to world system theory, migration is more likely to occur between past colonial powers and their former colonies and is facilitated by the cultural, linguistic, administrative, transportation, and communication links existing between the two. Within core countries, the management of the world economy is concentrated within a relatively small number of urban centers where banking, finance, professional services, and high-tech infrastructure coalesce. Given the strong demand for services from unskilled workers and the decline of heavy industrial production in those cities coupled with their highly developed transportation and communication links with peripheral countries, they are likely to attract a large proportion of international migrants (Sassen, 1991).

II. THE SOCIOLOGIC APPROACH

Although economic factors are almost always important, if not dominant, in migration decisions, the economic theories of international migration have often been viewed as too narrow because they cannot account for movements triggered by other considerations, including the need to flee life-threatening situations, the desire to move to a better climate, or the intention to search for a spouse in a better marriage market. Recognition of the relevance of a broader range of factors in explaining migration decisions and the fact that migration is not always voluntary underlie the approach proposed by Lee (1966), according to whom migration is caused by positive factors in possible areas of destination and by negative factors in the place of origin or current residence. Both areas of origin and destination are characterized by sets of positive factors, or forces of attraction or retention (i.e., pull factors), and negative factors, or forces of repulsion (i.e., push factors). The greater the perceived difference in the net forces of attraction (i.e., positive minus negative factors) in places of origin and destination, the more likely migration is to occur. Lee observed that migrants who respond primarily to pull factors in the place of destination tend to be positively selected, whether by age, education, skills, or motivation, whereas those responding primarily to push factors in the area of origin tend to be negatively selected. The former group is more likely to migrate voluntarily than the latter. An implication of this theory is that emigrants from a given origin are likely to be characterized by a bimodal distribution according to certain characteristics (e.g., educational attainment, skill levels). Such a bimodal distribution has been observed in many empirical studies.

Lee's approach built on the work of Stouffer (1940, 1960), who suggested that migration was a function of the relative perceived attractiveness of areas of origin and destination and that migration flows were limited by the existence of intervening opportunities and obstacles, both of which increased with the distance separating origin and destination. Despite the declining costs of travel, distance continues to be an important factor reducing migration propensities or, as the economic models would put it, increasing the tangible and the intangible costs of migration.

As in the case of economically based theories of international migration, those based on sociologic considerations have evolved toward recognizing the important role played by the family as a decision-making unit or as an institution providing the needed support for migration to take place. Migration often involves family groups, not just workers, as posited by economic theory. Family units may move simultaneously or in stages, with one family member relocating first and others following. The migration policies of countries of destination condition whether family migration can take place and the manner in which it can occur. Evidence showing that migrants often rely on kin already established in the country of destination to obtain accommodation, find a job, or secure financial and other types of support during an initial period of adaptation implies that kinship ties between potential migrants in the country of origin and residents of the country of destination can reduce the costs of migration, lower the risks involved, and increase the returns of migration. The concept of a migration network, which encompasses all interpersonal ties that connect migrants, former migrants, and nonmigrants in areas of origin and destination, provides a generalization of the kinship group because the ties considered include those based on kinship and those resulting from friendship or shared community origin (Massey *et al*., 1993; Gurak and Caces, 1992). Network connections can be considered as a form of social capital that people can draw on to gain information, material, or psychological support to facilitate migration and the adaptation process. Key elements of a migration network are the ties between migrants already established in the area of destination and persons remaining in the area of origin. Because of the assistance provided by the former to the latter, the costs and risks of migration decrease and the probability of further migration increases. Migrant networks contribute therefore to maintain the migration momentum even after the factors responsible for initiating the flow have lost their relevance. As the costs and risks of migration decline, the flow becomes less selective in socioeconomic terms, and migrants become more representative of the sending community as a whole. Because of the efficient operation of migration networks, governments may have difficulty in controlling the size of migration flows, particularly when their migration policies reinforce the operation of networks by facilitating family reunification or the admission of new migrants on the basis of kinship ties with previous migrants.

III. THE MOBILITY TRANSITION

At a time when demographers were positing that the path to modernization brought with it specific patterns of demographic change (i.e., the so-called demographic transition from high to low mortality and then from high to low fertility), Zelinsky observed that modernization generally was associated with specific changes in the patterns of mobility. He posited the hypothesis of the mobility transition (Zelinsky, 1971), which is a model associating patterns of variation of different types of spatial mobility with the phase in the path to modernization in which a society finds itself in. One valuable aspect of Zelinsky's approach is that it considers explicitly the existence of different types of migration: international migration; migration to the frontier areas of a country (frontierward); rural-urban migration; urban-urban and intra-urban migration; and a whole set of short-term types of mobility that he called *circulation*. According to Zelinsky, the five types of mobility identified vary in relative importance over time but remain correlated with the stage of the demographic transition as suggested by the diagrams presented in Figure 59–1.

Zelinsky also considered the likely impact of better transportation on mobility. As transportation improves, people can stay in their places of origin and commute to work, whereas during phases in which transportation was poor, they would have had to move. As modernization advances, some forms of migration are "absorbed" by circulation (Fig. 59–1, diagram F). As electronic communication improves, more people may be able to work at home, avoiding the need to commute altogether, as is suggested by diagram G in Figure 59–1.

Skeldon (1997) observes that Zelinsky's mobility transition has several weaknesses, two of which stem

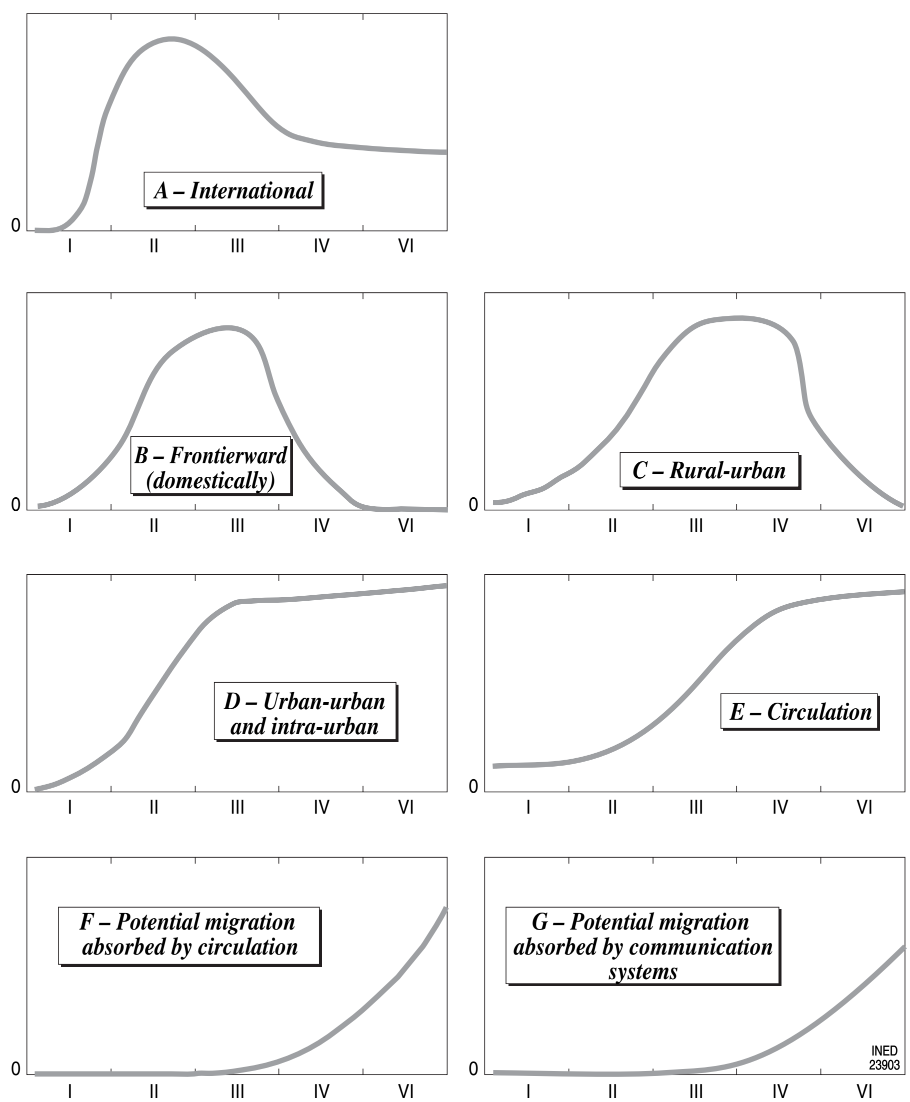

FIGURE 59–1 Variation of different types of migration in the course of the mobility transition. (From Zelinski, 1971.)

from problems in the basic assumptions made. Zelinsky's model assumes that mobility is almost nonexistent or rare in premodern societies, an assumption that is not validated by the evidence. The model assumes that the modernization process is unilinear—that societies move steadily toward ever-higher levels of prosperity. To be fair, that assumption is also at the basis of the theory of the demographic transition. However, today it is better known that there is no single path through the transition from high to low fertility and mortality. It is therefore unlikely that migration, which is an even more varied phenomenon, will change in similar ways in all development contexts.

Despite its drawbacks, Zelinsky's idea of the existence of specific migration patterns related to the stage of development or the stage in the demographic transition, which is reminiscent of the attempt by Ravenstein to establish laws of migration, has had sufficient appeal so as to be echoed in other attempts to provide explanations for the changes observed in international migration. For instance, in the 1990s, the concept of the *migration transition* was evoked when trying to identify the factors that had brought about the transformation of labor-surplus economies of emigration into labor-deficit economies of immigration among the newly industrializing countries of Eastern and Southeastern Asia (Abella, 1994; Fields, 1994). However, as Skeldon (1997) amply documents, despite the attractive simplicity of the model, it seldom fits well with actual experience. In the case of the Asian countries, inflows and outflows of migrants coexist; even the cases of Hong Kong or Malaysia, there has been no lengthy period since 1960 in which net migration has remained negative, so it is hard to argue that they have passed from being countries of emigration to being countries of immigration.

IV. THE CONTRIBUTION OF POLITICAL SCIENCE

As Zolberg (1981) observed, theories that model migration as the response of individuals to unevenly distributed opportunities make no significant distinction between internal and international migration, according secondary importance to factors such as barriers restricting exit or entry, deliberate recruitment efforts, or forced departures. Such theories cannot explain why most of the world's population, which should rationally opt to move to another country, does not migrate internationally. To explain the low international mobility of people, it is necessary to take account of the organization of the contemporary world into mutually exclusive and legally sovereign states, each containing some approximation of a single society, whose social boundaries coincide, by and large, with the frontiers delineated by international law as those of the state. In this context, international migration can be seen as an interaction between states, whereby there is a transfer of jurisdiction so that international migrants cease being members of one society and become instead members of another. From this perspective, international migration constitutes an exception from the prevailing norm of current social organization, which holds that society is a territorially based, self-reproducing cultural and social system whose human population is assumed, tacitly or explicitly, to renew itself endogenously over an indefinite period. The exceptional character of international migration is further buttressed by the fact that, whereas international instruments enshrine the right to leave any country including one's own, there is a universal and unambiguous consensus on the very opposite principle, that every state has the right to restrict the entry of foreigners, a right that is essential to maintain the integrity of society.

The analysis of the factors giving rise to international migration must be approached through a framework that takes the anomalous aspect of international migration as a point of departure rather than merely as an incidental feature. The world can be conceived as consisting, on the one hand, of individuals seeking to maximize their welfare by exercising a variety of choices, including that of transferring from one political jurisdiction to another and, on the other, of mutually exclusive societies, acting as organized states to maximize collective goals by controlling the exit and entry of individuals and their ultimate membership in society through nationality and naturalization laws. International migration is related to a fundamental tension between the interests of individuals and those of societies. However, the emphasis on tension does not preclude the possibility that individual and collective interest may coincide under particular circumstances, as with respect to the freedom to stay in, leave, or return to one's own country. The key point is to approach the study of the determinants of international migration in terms that consider to what extent individual and societal interests coincide or are antagonistic to one another, as well as to consider the interests of the state of destination and those of the state of origin and the societies each represents.

With respect to labor migration, this approach focuses on the conflicting interests of receiving societies (to maximize the labor supply and to protect cultural integrity), which lead to a dilemma with a limited number of possible solutions, the most common of which is to confine foreign workers strictly to their economic role by reinforcing barriers against their integration in society. Such barriers may include the physical isolation of migrants by concentrating them in special areas, legal restrictions on their length of residence or on the employment they may hold, constraints on family reunification, restrictions on their access to social services, barriers to their naturalization, and other legal devices that imply the erection of a societal boundary within the territorial confines of the receiving society, a boundary that is meant to offset the consequences of physical presence. In some countries, tolerance of unauthorized or illegal migration can be seen as another way of maintaining a separation between international migrants and the host society, given that the very status of those migrants ensures that they will work but not become incorporated (Zolberg, 1981).

With respect to forced migration, although refugees constitute a pervasive presence in the contemporary world, the processes that produce refugees have received little attention from theorists of international migration. Refugees are often the product of the nation-building process, whereby states try to conform to the nation-state model, according to which the state represents a homogeneous society with a uniform culture. Societies that are culturally or ethnically heterogeneous face the problem of increasing their homogeneity to conform to that model. Cultural homogeneity becomes an indivisible public good whose attainment may require the transformation of individuals through, for instance, religious conversion or linguistic assimilation. When transformation is impracticable or does not succeed, the state may expel or segregate the individuals involved (Zolberg, 1981). Because such actions by the state are tantamount to persecution, if the targeted individuals manage to leave their country, they normally become refugees.

State building entails regime construction, which stresses political uniformity or ideologic conformity (Zolberg, 1981). Because ideologic orientations are usually founded on objective interests related to position in the social structure, those evincing heterogeneity or lack of conformity are often strata or classes, or at least segments of them. Sometimes, the groups targeted are constituted by the descendants of migrants originally brought in by the colonizing power to serve as commercial intermediaries. When a political strategy of uniformity and an economic strategy of autarchy are simultaneously espoused by emerging states, migration policies preventing the exit of most citizens are likely to be adopted simultaneously with measures that force members of certain groups to leave (Zolberg *et al.*, 1989; Dowty, 1987). Although on the surface such policies appear as contradictory, expulsions of selected groups and prohibitions against the exit of the remainder of the population are complementary techniques of control. A comprehensive model of the causes of international migration should allow for their coexistence.

V. THE SYSTEMS APPROACH

Each of the approaches previously described presents a partial explanation of the causes and likely dynamics of international migration. In an attempt to combine the different approaches and recognizing that there is considerable interdependence between the migration experiences of groups of countries of origin or between that of groups of countries of destination, an approach focusing on migration systems has been proposed. Although the idea of using a systems approach to study migration can be traced back to the work of Mabogunje in the early 1970s (Mabogunje, 1970), its implications for the study of international migration began to be explored only in the late 1980s, and its formalization as a framework for analysis is still in the formative stages. The most comprehensive specification of what constitutes the systems approach resulted from the work of the Union for the Scientific Study of Population (IUSSP) Committee on International Migration, which published the results of its activities in 1992 (Kritz *et al.*, 1992). However, the IUSSP Committee's work marked only a first step in promoting the use of the systems approach in the study of international migration and left considerable space for more precise specification of models, hypotheses, and related measurement and estimation issues that must be addressed for the systems approach to fulfill its potential as a useful analytic tool.

The systems approach is based on a number of premises. The first is that migration creates a unified space, encompassing both the place of origin and that of destination. To understand migration and its causes and impacts, consideration of this unified space is necessary. The second is that migration is but one of the processes linking areas of origin and destination and is closely associated with those processes, often of long historical gestation. Consequently, most migration flows occur between areas that already have some historical, cultural, political, or economic linkages. The third is that the processes linking areas of origin and areas of destination modify, over time, the conditions in both areas, giving rise to feedback mechanisms likely to transform the initial processes. Migration will most probably change in magnitude and characteristics because its impact on the area of destination and the linkages it implies with the areas of origin varies over time. The fourth is that the state plays a crucial role in determining international migration flows through explicit policies to shape migration or by fostering economic, strategic, or political linkages with other states that may indirectly lead to migration. The fifth is that it is necessary to identify the mechanisms through which the macroeconomic-level forces that influence migration flows are translated into the determinants of migration at the level of the actual, individual decision-makers. One of the mechanisms identified is the operation of migrant networks, which are constituted by migrants, their relatives, friends, and acquaintances, whose social and kinship relationships act as links at the microeconomic level between the communities of origin and those of destination. Migrant networks help channel resources and information between communities, facilitating the further migration of individuals. Other mechanisms of interest include the operation of labor recruiters, multinational corporations, training and educational institutions, the military, and others engaged in fostering international flows of people. Consequently, the systems approach is based on "the conceptualization of a migration system as a network of countries linked by migration interactions whose dynamics are largely shaped by the functioning of a variety of networks linking migration actors at different levels of aggregation" (Kritz *et al*., 1992, p. 15).

Central to the use of the systems approach is the identification migration systems. A group of countries may be considered as generating a system if they satisfy the following conditions:

1. They have a similar position relative to migration; they can be identified as attraction poles for migrants or as sources of migrants.
2. If the countries concerned are mainly countries of destination, the migration flows converging to them should show considerable overlap in terms of the countries of origin involved.
3. The countries concerned should have the same level of development, a high degree of cultural affinity, and similar institutional structures.
4. They should also show some degree of coherence in the policies that they use or have used to control migration, and they should be linked by strong economic or political ties.

Given that migration creates a unified space encompassing the places of origin and those of destination, it is necessary to focus on a system as a whole to understand migration dynamics. Because international migration is generally just one of the processes linking areas of origin and those of destination and is closely associated with other processes, it is important to take into account the impact that the other processes may have in shaping migration. To do so, use of a combination of macroeconomic and microeconomic variables is necessary. Similarly, macroeconomic-level considerations are imperative to take account of the role that states play in initiating and molding migration flows. The appropriate methodology needs to be developed to ensure that the effects of feedback mechanisms are an explicit part of any model used.

Until now, the use of the systems approach to analyze international migration has mostly remained at a descriptive level. General observations have been made about the similarity of linkages among the countries generating the system (i.e., core countries) and among countries of origin, but the relevance of such linkages has not been formally or quantitatively tested. A major obstacle in advancing further the use of the systems approach is the lack of comparable and comprehensive data on international migration. Even for systems containing only a few core countries in the same part of the world, such data are generally not available. Exploring the relative strength of possible macroeconomic-level factors determining migration flows also demands that comparable indicators on a variety of socioeconomic issues be available for most countries of the world. Data limitations are likely to constrain the types of models that can be examined, although attempts at the examination of a partial system have been carried out (Kritz, 1995, 1996).

VI. COMPARISON OF EXISTING THEORIES OF MIGRATION

Table 59–1 compares the theories of migration previously discussed. A key point that the table makes clear is that most of the theories available relate to both internal and international migration without, in general, making any explicit differentiation between the two types of flows (the only exception is Zelinsky's mobility transition, which deals explicitly with internal and international migration separately). All the economic theories that focus on migration at the microeconomic level make no distinction between migrants moving within the borders of their own countries and those moving internationally, although the models proposed by the neoclassic theory and the economics of family migration can make some allowance for the difference between internal and international migration through higher wage differentials or through the increased costs usually involved in international migration. In the case of the new economics of migration, the emphasis the theory puts on the institutional constraints that prompt people to move is based on the

TABLE 59–1 Comparison of the Theories of Migration

Theory type	Theory	Main proponent	Type of migration		Level of analysis	Unit of analysis	Type of constraints explained	Part of the process
Economic	Neoclassic (1)	Harris-Todaro	Internal or international	Labor	Macro	Community or country	None	Initiation, maintenance, and end
	Neoclassic (2)	Harris-Todaro	Internal or international	Labor	Micro	Individual	Costs of migration and probabiliy of employment	Initiation
	New economics of migration	Stark-Taylor	Internal or international	Labor	Micro	Family	Lack of adequate financial or insurance institutions	Initiation and maintenance
	Economics of family migration	Mincer	Internal or international	Labor	Micro	Family/couple	Migration to the same destination	Initiation
	Segmented labor market	Piore	International	Labor	Macro	Community or country	Structural constraints at destination reduce socal mobility	Initiation and maintenance
	World systems	Wallerstein	International	Labor	Macro	Country	Constraints imposed by position in the capitalist system	Initiation and maintenance
Sociologic	Push/pull	Lee	Internal or international	All types	Micro	Individual	Some constraints may be interpreted as push factors	Initiation
	Networks	Various authors	Internal or international	All types	Micro >> macro	Individual/ family	None	Maintenance
Transition	Mobility transition	Zelinsky	Internal and international	All types, excluding forced	Macro	Countries	None	Process
Political	Political science	Zolberg	International	All types, including forced	Macro >> micro	State in relation to individual	Those imposed by States of origin and destination	Process
Systems	Systems approach	Kritz *et al.*	International	All types	Macro >> micro	State, community, and individual	Those imposed by states of origin and destination, by the structure of production, and by institutions	Process including feedback mechanisms

premise that areas of origin lack the financial institutions typical of the advanced market-economies so that the theory implicitly restricts its explanatory power to flows of migrants from developing and relatively backward communities to more advanced ones. This is somewhat of a simplification, because the theory's premise about the importance of risk diversification in determining the decision to migrate can be applied to a wide range of circumstances, but there is no denying that the most likely scenario in which the theory may be relevant is in cases where migration originates in developing countries or countries with economies in transition where people cannot normally rely on local institutions to diversify risk, obtain insurance, or get access to capital.

Table 59–1 shows that all theories that focused exclusively on international migration have devised explanatory frameworks at the macroeconomic level and have emphasized the constraints that migrants face in terms of the global capitalist system (Wallerstein) or the economic system of the community of destination (Piore) or the state (Zolberg). When the state is considered explicitly, it is recognized that the interplay between the state of origin and that of destination is relevant in determining the constraints actually faced by a migrant. The political science and the systems approach emphasize that in understanding migration at least three players need to be considered simultaneously: the state of origin, the state of destination, and the migrant. No other theory makes explicit mention of the state, although constraints emanating from the relation between migrant and state can be accommodated by the push-pull approach proposed by Lee.

As expected, all theories using an economic approach focus their explanatory power on the dynamics of labor migration (i.e., the movement of economically active individuals). The normal premise of such theories is to consider that workers are unattached individuals that can make decisions based entirely on the workings of the labor market (e.g., Harris-Todaro, 1970) or whose decisions are conditioned by the workings of the labor market (e.g., Piore, 1979). In such a context, the issue addressed by Mincer adds a welcome dose of realism to the theory and illustrates the complexity of incorporating a decision-making in which the interests of several individuals are at stake. Mincer's approach was developed to analyze the constraints faced by migrants moving within advanced market-economy countries. Only in that context did it seem necessary to attach equal importance to the economic goals of husband and wife. In general, by being gender blind, existing theories of migration tend to disregard the specificity of female migration and do not necessarily reflect the realities of the opportunities and constraints that women face when they engage in international migration.

In a similar vein, although there are several theories that do not explicitly delimit their universe of interest to specific types of migrants, they do not necessarily accommodate with equal ease the dynamics of voluntary migration and those characterizing forced migration. The political science approach is the only one providing a specific framework for the analysis of forced movements, although the push/pull approach has been used to assess the factors leading to such movements and both systems and networks theory can be used to understand how forced migration arises or may be maintained.

Massey and colleagues (1993, 1994) have argued that it is important to distinguish between theories that provide explanations for the initiation of migration and those that provide reasons for the maintenance or continuation of migration flows once they have started. Most of the available theories fail to state explicitly whether their focus of concern is the genesis of migration or its maintenance over time, but according to my interpretation, many of them address the processes triggering migration and those sustaining it after it has started. The new economics of migration, for instance, suggests that migration starts as a risk minimization strategy and to palliate the negative effects of the lack of local financial institutions or the limitations of existing ones. However, because migration is unlikely by itself to transform local institutions or to eliminate existing risks, it generally needs to be maintained in order for those left to keep on benefiting from its palliative effects. The appropriate word is not *maintained* but rather *expanded*, because as the theory itself expounds, as migrants become successful in improving the well-being of those that they have left, others will want to emulate that success by migrating. The development of migrant networks is the logical next step to ensure that the required expansion happens in the most efficient way possible. In this sense, the networks theory that was presented earlier is really part of the complex process that is part and parcel of migration. It is that holistic approach that is embodied by the systems approach.

Another important distinction that can be made between theories is that some refer explicitly to migration as a process whose characteristics change through time or, as Zelinsky (1971) put it, according to the different stages in which society finds itself in. Zolberg's framework (Zolberg, 1981) for the generation of forced migration also posits that the likelihood of such migration depends on the stage that the state of origin has reached in the nation-building process. The sense of the existence of some sort of evolution or life cycle of migration streams influences the idea that flows start, are maintained, and end. The key difference between considering a single stage in the "life" of a flow and addressing likely changes through time or in relation to the evolution of other processes, as the systems approach suggests, is that the second strategy is likely to provide a richer and more comprehensive understanding of the feedback mechanisms through which migration interacts with other factors. That is the essence of the dynamic framework that the systems approach attempts to provide.

The theories available suggest that it is generally more straightforward to address the mechanisms shaping migration at the macroeconomic level and their interactions than to stipulate the modes of articulation between the macroeconomic and the microeconomic levels. Only three approaches attempt to describe such modes of articulation, and in all cases, the description of the process involved remains too vague to be a useful tool for furthering understanding. The systems approach posits that social networks are one of the mechanisms for the translation of macroeconomic effects to the microeconomic level, but in the systems and the networks approaches, the networks themselves are described as a set of transnational relations between individuals that are not easily amenable to analysis through standard social science instruments. To be more precise, existing instruments have been successful in documenting the existence of networks and in elucidating some of the functions that networks perform, but they have not gone much beyond providing descriptive information on the issue. Theories need to go beyond mere description.

One particularly important aspect of the micro-macroeconomic articulation is the interaction between the state and the individual. The political science approach emphasizes the importance of such interactions, and the systems approach suggests that they become operationalized through institutions. The types of institutions and their mode of action depend on the nature of the state. In the case of a powerful state that is responsive to public demands, it is likely that institutions can work in partnership with the state, participating in the process of policy formulation in ways open to them. However, if the state is weak or authoritarian, institutions need to set parallel mechanisms of operation to supply the functions that the state has failed to undertake or to combat those that the state has put in place. The important role that institutions may play in influencing international migration has been underscored by Massey and colleagues (1993), who have gone so far as to claim that the operation of institutions produces yet another approach to the understanding of migration. In contrast, the systems approach suggests that institutions provide another mechanism for translating macroeconomic processes to the microeconomic level.

This overview suggests that, although considerable progress has been made in elucidating the mechanisms that give rise and maintain migration flows and in establishing their interrelations, there is a need for a more holistic approach to the issue, especially because of the importance of interactions among the main actors in the international migration process (i.e., the state of origin, the state of destination, and the migrant) and with a series of "intermediaries" that mediate the interactions between the main actors and are themselves players in the process and therefore have an impact in shaping flows. The systems approach tries to provide a framework for the analysis of the interactions involved but has not been fully successful in integrating the various elements that need to be taken into account. Consequently, its analytic usefulness remains largely untested. Other, more partial theories about specific aspects of international migration have been more successful in providing useful insights about the functioning of the process but their limited perspective reduces the generality of their findings. There are still major lacunae in the realm of theory, especially in regard to the integration of the role of the state or the analysis of forced migration. Without expanding existing theories further, we may discover that most our laws of migration have questionable validity.

THE PRINCIPAL DETERMINANTS OF MIGRATION

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

The review of theory in Chapter 59 provides the basis for identifying the main determinants of migration dynamics. Historical population growth inequalities that reflect the economic growth and poverty differentials affecting most of the world's population are still among the main reasons why a growing number of individuals move from poor countries to economically more developed ones. Radical changes in economic systems and the balance of international political power between developed countries prompted an overhaul of internal and external economic policies, which caused a backlash of economic crises in some developing countries that seemed poised in the 1970s and 1980s to make an early exit from poverty.

Economics was and remains a key variable in international migration dynamics. In Chapter 60, Marc Termote sets out to clarify the fundamental importance of these variables and to provide a general theoretical framework for analysis of the different kinds of migration that are found and to isolate the main methodologic implications for each.

Although many parallels are readily found in the theoretical concepts between this and the previous chapter, both were included despite the inevitable overlap, because they set the theoretical foundations of economic migration in very different contexts. Chapter 59 dealt with the theories of international migration only on a comparative basis of economic versus more sociologically or culturally oriented theories. Chapter 60 considers only economic migration, but it is confined neither to the theoretical aspects nor international migration alone, dealing also with internal migration.

The introduction to this volume referred to the importance of urbanization as a factor of spatial mobility. This process may over the centuries have been responsible for more population shifts than all international and inter-regional migration movements together. Denise Pumain addresses this idea in Chapter 61, working from a suggested definition of rural and urban areas to concepts of counting the urban population in developed and Third World countries, followed by an analysis of some aspects of the phenomenon that depart from economic theories of migration that are likely to explain away urban development as a simple aggregation of individual migration decisions.

Political migration is a special case within the general situation of international migration, but almost all of the host countries acknowledge it a legitimacy often denied to other forms of migration. During most periods in the history of migration, repression, war, genocide, and a wide range of political factors have resulted in forced movements of millions of people. In Chapter 62, Luc Legoux examines the roots of such movements, discusses the scale and reasons for their development worldwide, and assesses future prospects. He defines and clarifies the distinction between asylum seekers and refugees, and he shows how the official categorization as an asylum seeker or refugee can be influenced by migration policies. Tightening of regulations for economic migration prompts some potential migrants to seek entry as asylum claimants, and restrictive entry policies result in asylum being refused to claimants genuinely at risk in their countries of origin.

Analyzing the origins of migration behaviors requires consideration of the contexts in which individuals live, including the demographic and social characteristics, and consideration of all possible interactions among the different variables in the equation. Daniel Courgeau and Éva Lelièvre, who co-authored Chapter 63, analyze the determinants of migration through this prism, and they expand the field of study, moving from the macro approach at the aggregate level to the micro approach at the individual level. By combining these two approaches, they produce a theory of migration behaviors that brings into sharper focus the roles of the different levels of aggregation.

The Economic Determinants of Migration

MARC TERMOTE

National Institute of Scientific Research, University of Quebec, and Department of Demography, University of Montreal, Canada

The aim of this chapter is threefold: to present the fundamental significance of migration within the workings of the economic system, to construct a general theoretical framework that will make it possible to analyze the contribution of various migration theories and models already in existence, and to establish the main methodologic implications of this second analysis.

In economic theory, migration is a condition on which the system's optimal performance depends. This is demonstrated by two theoretical approaches, each representing one side of a single mirror: trade theory, which studies optimal trade flows between given production locations, and localization theory, which studies the optimal localization of production activities. Although migration appears to be a necessary process in finding economic equilibrium within a given space (whether defined in terms of regions or countries), it does not follow that this equilibrium is necessarily reached. A succinct presentation of the workings of a spatially defined labor market helps to demonstrate this.

This spatial version of the labor market model is enhanced to take into account the set of economic factors determining migratory movements. Rather than enumerating the various migration models and theories, which would only be incomplete and fastidious, it seems preferable to construct a general framework that makes it possible to identify each model's contribution and clarify its meaning.[1] Instead of a critical review of the various existing models, this chapter offers a theoretical grid of analysis of these models and theories. The methodologic implications of these approaches are discussed.

I. MIGRATION AS AN EQUILIBRIUM PROCESS

"Although the resource of emigration seems to be excluded from such perfect societies as the advocates of equality generally contemplate, yet in that imperfect state of improvement, which alone can rationally be expected, it may fairly enter into our consideration", wrote Malthus 2 centuries ago (1803, Book III, Chapter IV) in his famous *Essay on the Principle of Population*.

It is not really because our societies are in an imperfect state of improvement that migration needs to be introduced into the demographer's or the economist's language, but because migration represents a necessary process in spatial economic equilibrium. For too many years, economists, like most other researchers in

[1] This generalization encompasses countries said to be underdeveloped as well as developed countries. Very few models have been elaborated specifically for underdeveloped countries; Todaro's model (1980) is the most notable exception. In most cases, a model designed for developed countries has been applied to a context of underdevelopment.

the social sciences, have considered migration between countries or within a single country to be the result of a malfunction of the economic social system. The migrant has been seen as an outcast, as the reflection of some unbalance; on the contrary, migration constitutes, according to economic theory, a necessary condition to the optimal functioning of the economic system.

There are two ways of attaining spatial economic equilibrium: by the localization of production factors or by trading goods (material and immaterial) produced by these factors. Economists have mainly studied the second process. By developing trade theory, they tried to bring to light the optimal flows of goods and services between given localizations of production factors, but they rarely studied the question of the optimal localization of production factors. In other words, they postulated that an economic spatial optimum would automatically be attained simply by trading goods, without it becoming necessary to delocalize production factors, that is without having to envisage the migration of these factors.

Trade theory itself demonstrates this postulate's invalidity and therefore, the need for the migration of production factors. For the simple trading of goods to cause the equalization of the remuneration of production factors and thereby eliminate the need for any factor migration, the Hecksher-Ohlin theorem conditions, as made explicit by Samuelson, must be filled (Samuelson, 1949; Ohlin, 1935; Heckscher, 1919). This entails (1) that demand functions be homogeneous and identical in all places (i.e., identical tastes and consumer preferences, whatever the place of residence); (2) that mobility (e.g., by sector, by profession) within each spatial unit be perfect and without any cost attached; (3) that perfect competition and full employment reign everywhere; (4) that, for any given good, the production function be linear and homogeneous (with no economies of scale) and identical in all places (i.e., production conditions should be the same everywhere); (5) that the marginal productivity of factors be always positive and decreasing; (6) that there be no "excessive" specialization anywhere; (7) that the trading of goods be completely free; and (8) that the transportation costs of goods (in the broadest sense) be nil.

If all these hypotheses are simultaneously respected, the localization of production factors is of little importance, because the simple act of trading of goods and services will make it possible to reach spatial economic equilibrium and the spatial equilibration of factor remuneration. Migration is of no use in such a world because there are no remuneration disparities. Unfortunately, all of these hypotheses are unrealistic. The eighth hypothesis even leads to a sort of tautology. If we suppose the absence of any transportation costs, of any spatial friction, we negate the existence of space. In that sort of nonspatial world, the question of the delocalization of factors (i.e., the migration of labor and capital) becomes superfluous.

Rather than studying spatial economic equilibrium through the trading of goods between given locations (as in trade theory), it is possible to touch on the question by determining these locations themselves by explicitly introducing space and transportation costs. This is precisely the aim of localization theory, which provides a second demonstration of the need for migration as a process for reaching spatial economic equilibrium using a Löschian framework.

August Lösch[2] begins by posing a series of hypotheses concerning spatial uniformity. Production factors, population and natural resources, are evenly distributed across space; the transport conditions are always the same (i.e., the cost of transporting one unit of goods over one unit of distance is the same whatever the place of origin, and this rate does not depend on the overall distance); and the production and consumption functions are the same at every point.

The key feature is that, despite these hypotheses concerning spatial uniformity, according to Lösch's theory, a spatial concentration of production in the form of a hierarchical pyramid of *central places* is reached by taking transportation costs into consideration. This way of thinking leads to a contradiction. The population in its role as consumer is distributed evenly over space, but this same population in its role as producer of goods is concentrated in a hierarchy of central places. The only way of resolving this contradiction is to introduce migration, but by breaking the spatial uniformity of consumption, this reinforces the movement toward the concentration of production.

If instead trade theory proves the need for production factors to migrate, a final question remains: Can the equalization of the remuneration of the labor factor not be obtained by exchanging goods along with a capital transfer? The mere migration of capital (i.e., without labor migration) is not enough for at least three reasons. First, several types of capital exist. Doubtless, *liquid capital*, or financial capital, is very mobile, but like all production factors, it flows toward places where remuneration is highest. This optimal localization is seldom a place with low wages (e.g., even if the interest rate is sometimes high, the real return is often quite low, possibly even negative, due

[2] An English translation of Lösch's book (*Die räumliche Ordnung der Wirtschaft*, 1940) was published in 1954 (*The Economics of Location*, New Haven, CT, Yale University Press, 520 p.)

to uncertainty, devaluation risks), and it can vary quickly and in such a way that capital will seldom be reinvested to become a true production factor. *Immobilized capital* is made up of equipment (it is then difficult to move, and when it is moved toward a poor destination, its use often requires the parallel displacement of qualified workers) or human capital. In both cases, labor migration becomes necessary.

Human capital (e.g., scientific and technologic, progress of knowledge, know-how) leads us to the second reason, which takes into account the dynamic character of the economic process. This type of production factor is increasingly important, and capital transfers in their traditional form cannot replace them, except possibly in the long term. A third reason is related to the existence of production factors that are immobile or those that can be moved only at great expense. More precisely, the link between labor and land or natural resources must be considered. Capital migration cannot replace low reserves of natural resources, except in a few specific cases.

The fact that labor migration is a necessary process in the optimal running and equilibrium of the spatial economic system does not, however, mean that it necessarily leads to equilibrium. Contrary to the beliefs of neoclassic thinkers, economic theory provides no *a priori* solution concerning the effect of economic migration.

Most classic 19th century theoreticians thought migration represented an economic equilibrium process in so far as the subjacent fall in labor supply that it implied for the place of emigration caused an increase in this factor's remuneration. "All possible help should be accorded these poor unfortunates who . . . sacrifice themselves for their brothers by distancing themselves from them," affirmed Sismondi in 1817 in his *New Principles of Political Economy, or Wealth in its Relationship with Population*.[3] For John Stuart Mill (*Principles of Political Economy*, 1848), migration is a means of fighting the tendency of diminishing returns of the land, it is a remedy for low wage rates and for the decline in the profit rate ("the more . . . we send away, the more we shall possess and be able to retain at home").

Not everyone shares this opinion. Malthus remains consistent when, in his laws of population, he insists on the inadequacy of emigration as an answer to overpopulation. Even if emigration caused the wage rate to rise above subsistence level among the population who had stayed in the country, the subsequent natural population growth would soon neutralize the beneficial effects of emigration. Marx adopts this idea by stressing that the agricultural revolution and the natural growth rate of the non-emigrating population can neutralize the positive effects of emigration, as he points out was the case in Ireland, where the production of a *relative overpopulation* more than compensated the *absolute depopulation*.

Classic investigators were essentially concerned with the consequences of migration on the economy experiencing the emigration, and they thought that the advantage for the place of immigration (which was often a colonial country) was somehow self-evident. However, to study the role of migration as a "equilibrium engine," the effects of the place of emigration and immigration need to be studied simultaneously. To systematize this analysis, we can use a spatial model of the labor market.

Let us consider a place (region or country, depending on whether it is an internal or international migration) named *A*, where labor supply by workers is low and very sensitive to wage levels (because there are few workers and there is no labor reserve) and where labor demand is high and equally sensitive to wage levels (because there are quite a few production units and they are all highly capitalized). In this case, the meeting point between the labor supply curve (which has a positive slope, because the higher the wages, the greater the number of workers offering their production capacities) and the labor demand curve (with a negative slope) fixes a high wage level. Consider a second place, *B*, which is densely populated but has relatively few production units and where the meeting point of the supply and the demand of labor leads to a much lower level of wages. If the difference is significantly higher than the cost of migrating between these two localities, workers will emigrate from *B* to *A*.

According to neoclassic theory, this migration will lead to decreased wages in *A*, because the arrival of immigrant labor implies a rise in labor supply; in other words, the curve representing labor supply will cross the labor demand curve at a much lower point. In *B*, the decrease in labor supply resulting from this emigration will cause an increase in wages. Overall, the level of wages will rise in the poorest place and fall in the richest place. Migration from *B* to *A* will continue for as long as the wage gap is higher than the cost of migrating. Migration will have made the equalization of wages possible; it will have fueled an equilibrium process within the interregional and international economic system.

Many theories and models have been inspired by and continue to be based on this framework, and despite 200 years of international migration (some

[3] Nouveaux principes d'économie politique, ou de la richesse des nations dans ses rapports avec la population.

massive) and almost constant rural depopulation, what is observed is the persistence of or increase in wage differences between rich and poor regions or countries. Many elements help to explain the classic model's lack of relevance as far as migration is concerned (the introduction of technologic progress with the aim of producing the needed dynamization of the previously mentioned theory, is not the least of these elements). However, one fundamental weakness invalidates the classic framework: the nonintegration of the delocalization of consumption resulting from migration.

In the neoclassic model, migration is only seen as a means of delocalizing labor, and its effect on wages reflects only to the displacement of the labor supply. However, the migrant is both a producer and a consumer. He is a producer because he is a consumer. The migrant who moves from a poor locality to a rich one contributes to an increase in labor supply and to the rise in the demand for goods and services and therefore to a further increase in labor demand on the part of firms producing these goods and services. In the emigration site, the fall in labor supply is accompanied by a fall in the demand for goods and services and by a fall in labor demand.

Because of this double delocalization of production capacity and consumption capacity, to determine the economic consequences of migration on the emigration and immigration sites, it is not enough to state the production functions (i.e., technical production conditions) in each of the locations. It is also necessary to consider the consumption functions (without forgetting that these functions are not usually the same for migrants and nonmigrants) and to establish the relationship between these consumption functions and labor demand that will make it possible to fill consumption demand.

According to the framework described, there will be an increase in labor supply in the place of immigration, and there will be an increase in labor demand after an increase in consumption linked to immigration. It is impossible to know beforehand whether this supplementary labor demand will be greater than or less than the supplementary labor supply resulting from the immigration. It all depends on the immigrants' consumption function (more precisely, on their propensity to consume local goods and services), the relationship between the demand for goods and labor demand, and on the level and elasticity of labor supply and demand compared with wage levels. The same can be said of emigration. In other words, it is impossible to determine the effects of migration on the places of emigration and immigration without knowing the consumption and production functions, as well as the functions for labor supply and demand.

Given these conditions, migration can be a disequilibrium process for the international and interregional economic system, as well as an equilibrium process. It can reduce spatial wage disparities, but it can also increase them. The theory and the model now appear undetermined.

This theoretical conclusion is accompanied by an important methodologic implication. Migration as an answer to a spatial disparity can aggravate the condition as easily as it can reduce it. An analysis of the causes of migration runs the risk of being biased if it does not simultaneously include a study of its consequences. In other words, migration is both a dependent and an independent variable, and an analyst should be wary of models based on a single equation. Only a system of simultaneous equations makes it possible to obtain theoretically well-founded results.

This interdependence needs to be studied within a spatially disaggregated system, making it possible to identify the consequences of migration, wherever they may be. This is particularly important in the case of international migration. If we study the effect of international immigration at the global national level, we run the risk of underestimating it, because international immigration is most often concentrated in a few metropolitan regions. Almost all studies concerning the economic consequences of international immigration indicate a negligible effect or none at all, at least for the receiving country. This finding reflects the fact that the studies have been carried out within a spatial framework that is far too wide and in which the consequences are diluted. The causes and consequences of migration need to be analyzed at the level of the spatial units, where the phenomenon manifests itself.

II. IN SEARCH OF A GENERAL THEORETICAL FRAMEWORK

The conclusion that migration does not necessarily lead to spatial equilibrium was based on a simplified model in which only worker migrations exist and in which the only determinant of these migrations is wage levels and their only consequence is to modify wages. This framework needs to be extended.

In addition to wage levels in each location, the model must consider the probability of finding a job (which will make it possible to take advantage of these wages) or the unemployment rate. However, it is not enough to compare the present level of wages (i.e., income thesis), weighted by the probability of receiving a salary (i.e., job vacancy thesis). The migrant must also bear in mind the likelihood of being able to count on this salary in the future; he will estimate a discounted value of this weighted salary, taking into account the anticipated evolution of wages and unemployment. This approach characterizes Todaro-type models, developed to analyze internal migrations (rural-urban) in Third World countries; curiously, it has seldom been adopted for use on industrialized countries.

The future value of wages is discounted because migration is seen as an investment whose gain should be maximized. The length of time during which this investment can be made profitable is important. This naturally leads to the introduction of age as a determinant of migration. An elderly worker will not have much time to take advantage of his migratory investment compared with a young worker, who will have his entire working life to profit from migration or to correct the effects of a bad migratory calculation by a new migration.

This first addition to the model concerns only worker migrations that are exclusively motivated by wage levels (weighted against unemployment levels). To continue enriching the model, factors linked to the individual seen as a consumer need to be added. When the price of goods and services varies significantly over distance, wage rates need to be deflated to take into account disparities in the cost of living, established in real wage terms rather than in monetary wage terms.

In the same vein, local, regional, and national (in the case of international migrations) tax levels can also be pertinent. It is, however, important to tread carefully because wage levels may already incorporate this type of factor, in the same way that they may already take price levels into account.

For the same worker-consumer factor, it makes sense to consider the availability and the cost of some special goods and services, such as *land*, *housing*, and *public services*. Similarly, immaterial goods, such as *environmental and climatic conditions*, or even certain negative goods, such as *crime rates and pollution*, may be taken into account by some migrants. It is necessary to check that wage levels do not already reflect the level of housing costs, the availability of public services, or even the presence of negative goods.

Taking into account these nontraded goods leads to a new theoretical approach. The initial assumption in the neoclassic model (and therefore for all generalizations in this model) is that migration is a response to disequilibrium. Toward the end of the 1970s, when the evaluation of the environmental costs of large industrial projects became a research priority, a key question was whether a theoretical, but empirically verifiable, link existed between the value of compensation offered to residents negatively affected by such projects and the amplitude of migrations that might result from these negative effects. If compensation is insufficient, migration will ensue. However, under the terms of traditional microeconomic theory, measuring compensation requires the hypothesis of initial equilibrium (before the shock caused by the project) and a subsequent equilibrium, after the agents have adapted their behavior to the modifications caused by the project.

Based on this new approach, spatial wage disparities are presumed to be equilibrium disparities (i.e., the difference between wages is explained entirely by migration costs) or possibly compensatory disparities for the presence of nonmarket goods (i.e., *location-specific amenities*), whether they are positive goods, such as a pleasant climate, or negative goods, such as pollution. This sort of spatial wage disparity should not cause migratory movements. Migration should happen only when equilibrium is broken to correct the effects of a previous bad migratory calculation by making a new migration.

Location-specific amenities cause migration. Variations in demand can come from a change in income or a modification of the relative prices of certain market goods that can neutralize the effects of nonmarket goods (e.g., a fall in the cost of air conditioning units in regions with hot, humid climates). The only way for an individual or a household to satisfy a change in the demand for such goods is to migrate. The intensity of migratory relations between two localities does not, however, depend on the absolute difference between the exogenous variables being studied, but on changes in the absolute value of exogenous variables that produce a modification in the demand for nonmarket goods.

The demand for nonmarket goods that makes certain locations particularly attractive is closely linked to individuals' personal characteristics and the stage reached by them in the life cycle. The availability of microdata becomes an important condition for carrying out empirical studies based on this approach. Because this type of data remains uncommon, the use of this new theoretical approach is not yet widespread despite promising initial results.

Because migration has a cost, there will always be spatial disparities between wages, even in equilibrium situations. However, this cost of migration covers more than the cost of the simple physical displacement of people. Other than the *monetary cost* associated with displacement (of the migrant and his belongings), migration also has a *temporal cost* (the preparation of a migration takes time; for example, the person's housing needs to be sold and new housing found at the immigration point) and a *psychological cost* (i.e., linked to the loss of a support network of family and friends or difficulties in adjusting to the new environment, to cultural, linguistic, or even religious differences that need to be faced).

An often-neglected cost is that linked to the process of collecting information concerning utilities or disutilities offered by various points in space. This *information cost* depends on individuals' locations (e.g., a migrant candidate living at a spatial system's center of gravity will have access to better quality information at a lesser cost than a person living on the outskirts). Regardless of the initial localization, there will usually be a considerable quantitative and qualitative inequality between the information concerning the point of departure and the information relative to the destination point. The use of this asymmetric information is a relatively new and useful way of understanding a system of migratory flows.

Because information is expensive and takes time to collect, the migratory answer to a modification in the socioeconomic context will become noticeable only after a certain *time lag*. The migratory reaction of individuals is characterized by a strong dose of inertia. (Adam Smith [1776] remarked that "a man is, of all sorts of luggage, the most difficult to be transported"). It becomes necessary to enrich the model by introducing *explanatory variables* for migration integrating a time lag, with migration observed at *t* being, for instance, a function of the wage rate and the unemployment rate observed at *t-n*. Because the lag (value of *n*) is seldom longer than 1 or 2 years (several models obtain highly satisfactory results using a lag expressed in terms of a few months), this type of development requires chronologic series based on population registers or administrative files, which very few countries can provide.

After a certain number of people have emigrated, information flows from the place of immigration to these migrants' place of origin become richer, more trustworthy, and less expensive. A chain reaction of migrations takes place. One method sometimes used to study this "multiplier effect of parents and friends" (Nelson, 1959) consists of making the migration observed in *t* a function of the migration observed in *t-n*. We should be wary of this approach because we run the risk of uncovering only the temporal stability of migratory flows by using this type of model specification. We find that the model is more descriptive than explanatory.

Having defined a first series of generalizations linked to the migrant in his production role, a second series of generalizations linked to the migrant in his consumer role, and a third linked to the generalization of the spatial system to a system in equilibrium rather than in disequilibrium, this fourth series of generalizations, which refers to the various cost dimensions of migration, turns out to be particularly rich. However, faced with the multiplicity of the different costs that have an impact and the difficulty in obtaining adequate statistical data, we can try to simplify the problem by using a single variable capable of summarizing to some extent all those linked to migration costs.

The various migration costs are related to *distance*. It is understandable that a considerable investment has been made to try to uncover the mathematical function that best expresses the relationship between the intensity of migratory movement and distance. In this regard, we cannot ignore the considerable success obtained by the *gravitational approach*. Inspired by Newtonian physics, this type of model takes as its starting point the idea that the number of migrants moving between two places is a direct function of the mass (i.e., population) present in each of these places and is inversely proportional to the distance separating them.

The key problem resides in the definition of these masses. When talking about the migratory relationship between two places of population rather than the relationship between two celestial bodies, this mass needs to be specified in economic terms and not in physical terms. It becomes necessary to weight the numbers using the level of income, the unemployment rate, and other factors. By doing this, we are led back to the classic framework, as presented previously, in such a way that we could question the theoretical significance of this type of approach (Le Bras, 1990).

The reference to the law of gravity allows us to introduce a fifth type of generalization. Newtonian physics does not study the relationship between two specific masses, but rather a *system* of masses. Until now, we have thought only about the migratory relationship between two places (i.e., regions or countries). However, a candidate for migration does not make his migratory decision based solely on one possible destination. He studies a system of locations and chooses the one that will most easily provide employment opportunities or a higher income (i.e., Zipf's law of least effort [1949], which directly inspired several migration models). The key feature is not so much the distance separating two places, *i* and *j*, but the set of opportunities offered between these two places. The more opportunities that are lost in *i*, the more candidates for emigration among the inhabitants of this place and the more migrants there will be from *i* to *j*. A candidate emigrating from *i* is not alone in trying to improve his life by leaving *i*; he finds himself competing with other migration candidates (including some in a better position because they are closer to *j*), who are also looking for employment or higher wages. The combination of these various ideas led Stouffer to his celebrated model of *intermediate opportunities and competing migrants*.

The problem with this model resides in the difficulty of measuring the number of opportunities lost and offered. The simplest solution (and it is also the one adopted by empirical applications) consists in approximating the number of lost opportunities by the number of emigrants and the number of opportunities offered by the number of immigrants. After all, if the number of emigrants from a given place is high, it is because the number of jobs lost (or jobs at low wages) is high, and if there are many immigrants in this place, it is because the number of employment opportunities there is high. By proceeding in this manner, we are reduced to explaining migration by migration.

This type of circular reasoning is common in migratory analysis. It can be found in a number of theories on rural depopulation that aim to explain rural-urban migration by the attractiveness of cities, although that fact is precisely what needs to be explained. It is true that Stouffer's model has the advantage of being easy to apply while giving impressive empirical results. The coefficient of determination is often close to 0.9, which is rare in social science. Moreover, the model makes it possible to estimate origin-destination flows based on the total emigration and immigration flows for each place. However, we are far from an explanatory analysis.

Moreover, in this model of intervening opportunities and competing migrants, the spatial system only functions on a local basis (for each origin-destination pair). The model does not cover all flows in the entire system simultaneously. It does not take into account the *interdependence between various* regional labor *markets*. To cross into this new area of generalization, we need to use matrix formulation. This provides an immediate advantage over the statistical formulation implicit in the models discussed previously (i.e., models in which the migratory variable depends on a series of independent variables) because it forces the user to respect a certain number of accounting identities. The most obvious identity is the requirement that the sum of all regional migratory balances in a closed system must be nil (i.e., migration is a zero-sum game; what one place loses, another gains).

This *zero-sum constraint* implies that in a statistical analysis of interregional migratory flows, the sum of each variable's coefficients, as well as those of the regression constants, should be equal to zero when the various equations are all added up (one equation per region). This condition is necessary for the sum of the estimated values for the dependent variable (migratory flows from *i* to *j*) to be nil for the overall regional system. Few models respect this constraint, but neglecting it can lead to serious errors of econometric inference. This is all the more astonishing because the procedures for resolving the equations have existed for decades.

We can also study the entire space by constructing a *composite indicator of attractive and repulsive forces* that effects migration from *i* to *j*; this is a measurement in which the value of one variable in each place is weighted by the distance between this place and each of the other places. This weighted value is sometimes summed for all the points of origin (i.e., the global attractive force of *j*, or the relationship between *j* and the rest of the spatial system) and sometimes for all the destinations (i.e., the repulsive force of *i*, or at least the relationship between *i* and the rest of the system). This approach, suggested by Alonso (1978), adopts an idea developed by the gravitational school, the concept of potential, and is a part of the *family of spatial interaction models* (Wilson, 1970) that incorporates systemic variables of the same nature.

We still need to examine a sixth area of generalization concerning the basic framework. Until now, we have implicitly supposed that all migrations were labor factor migrations and that the population concerned was homogeneous.

The introduction of the cost of migration into the model (and thereby the approach by which migration is a sort of investment in space) naturally leads to the rejection of the homogeneity hypothesis, because the migrant's age (and therefore the length of time over which the migrant will be able to write off the cost of his migration and gain a profit from his investment by receiving higher wages) is a fundamental determinant in the migratory calculation. Likewise, the level of education determines information costs for utilities and disutilities offered by each place in the spatial system. Not every person migrating for economic reasons necessarily participates in the labor market, as is the case for members of a household accompanying a migrant worker or for migrations of retired people.

These considerations lead us to take account of the *life cycle*. This concept is not new, but its application to the study of migrations is relatively recent, although Hägerstrand (1963) did use the *life line* concept at the beginning of the 1960s to study migrations in Sweden. Although the different stages of the life cycle (i.e., marriage, divorce, finishing education, labor market entrance, giving birth, education and departure of children, and retirement from activity) are crucial to migratory decision, their importance was ignored for many years. The first models explicitly incorporating life cycle stages were formulated at the end of the 1970s. Three reasons explain this neglect.

The first reason is related to the fact that the necessary microdata have been collected for only a decade or two and that the collection of microdata implies costly surveys. We should, in this regard, underline the pioneering work carried out in France in 1981 by Daniel Courgeau and his team in their survey of "family, professional, and migratory biography" (Courgeau, 1985).

The second reason is methodologic. The biographic analysis raises the problems of the interaction between phenomena and the homogeneity of the population that the traditional demographic analysis tended to brush aside and to which are added the problems inherent in all retrospective surveys (e.g., incorrect or incomplete data) and the search for appropriate econometric techniques for microdata (e.g., probit or logit analyses).

A third reason is of a theoretical nature. The introduction of life cycle stages transfers the decision-making unit for migration from the individual to the household. The study of the economic causes and consequences of migration have traditionally been formulated in a context of maximization of individual utilities (based on the usual vision of microeconomic theory). The change from the individual to the household considerably complicates the theoretical analysis and the resulting models. The same type of problems can be found when household forecasts are attempted rather than population forecasts.

The links existing between household members imply negative personal external factors that are generally internalized by the household and that normally tend to slow down migration. "Tied people" (Mincer, 1978) include those for whom the gains resulting from migration are dominated (in absolute terms) by gains (or losses) obtained by the other members of the household. Mincer showed that by increasing these links, the increased participation of women on the labor market leads to a fall in the propensity to migrate, while increasing the household's (matrimonial) instability. This instability encourages migration and female labor market participation.

The complexity that results from using the household rather than the individual as the basic unit can be seen in the case of interregional and international migrations and in the context of intraregional or urban mobility (metropolitan). The simultaneous determination of the optimal location for the household's (single) residence and the optimal location for each household member's place of work constitutes a considerable analytic challenge.

III. METHODOLOGIC IMPLICATIONS

We can identify a few methodologic lessons from the preceding theoretical analysis. A first conclusion concerns the way in which to define the migratory problem. Too often, we tend to analyze the causes and consequences of migration separately. However, what determines migration is affected by migration. Using a system of simultaneous equations is the only way of grasping the set of interdependencies between migration and socioeconomic variables. This conclusion is particularly valid when migration is measured over a relatively long period, as is the case for countries that do not have a register for recording migratory events.

When the migratory analysis is directed at a closed system, the sum of regional migratory balances is necessarily zero. It is important to introduce a constraint aimed at maintaining this accounting identity in the specification of any explanatory model of internal migration. Few models respect this requirement.

The study of the various enhancements needed in the basic model (obtained from the spatialization of the labor market) clearly shows that the number of socioeconomic factors that should be taken into account and the complexity of the links between them are so overwhelming that no model could possibly incorporate them all at the same time. In this regard, the specification of the migratory variable is at least as important as the choice of independent variables. The effects directly related to the measurement of migration often are neglected. Too much attention is paid to the specification of the independent variables, when the latter specification should be a function of the way in which the phenomenon to be explained is measured.

The classic example of this carelessness is the use of net migration. Many studies (including some recent ones) try to identify the socioeconomic determinants of regional migratory balances. This begs the question of what is the rationality behind the migratory calculation of a net migrant! What would be said of a theory and a model that tried to uncover the determinants of the balance of births and deaths? The use of the concept of net migration runs the risk of leading to rather dubious interpretations.[4] The only sensible analysis of migratory balances must be aimed at the macroregional level; by doing so, a region's (or country's) demographic-economic dynamism (or the lack of dynamism) is studied rather than individual migratory behavior.

The set of problems and the model need to be specified in different terms, depending on whether

[4] On this point, the article by Andrei Rogers (1990) significantly entitled *Requiem for the Net Migrant* is required reading.

migration is expressed in absolute numbers or rates. To obtain impressive results in terms of coefficients of determination, the absolute number of migrants should be chosen as the dependent variable, and the population of origin (and destination, if origin-destination migratory flows are being studied) will therefore be introduced as an explanatory variable. This said, all we have done is introduce a size effect (mass, as we would say in the gravitational approach), and we have barely moved beyond the descriptive level.

If origin-destination flows are used as the dependent variable, the contents of the "costs of migration" variable will be completely different compared with a model that is defined in terms of total emigration and immigration flows; the way in which the overall spatial system is taken into account will also be different. Likewise, the fact that migration is measured in terms of events (as provided by registers and administrative files) or in terms of people having experienced certain events (surviving migrants obtained in a census) is significant. In the explanatory analysis of migration, we tend to neglect the fact that migration is a renewable phenomenon. The existence of multiple migrations and return migrations, however, significantly complicates the interpretation of results based on data mixing various periods of migration together.

If no longitudinal microdata are available (obtained from retrospective surveys), the analysis in terms of life cycle cannot easily be developed (even if several authors have tried to proceed using period data). However, retrospective surveys that produce data covering the set of crucial stages in the life cycle are rare, not to mention seldom sufficiently trustworthy or statistically significant. The sample size is an obstacle often underestimated. To pass this obstacle and ensure the sample's homogeneity with regard to exogenous events that can affect the behavior of the sample's members, it is probably inevitable to limit the sample to one single cohort (as in the case of the previously mentioned French survey).

With the exception of the first conclusion, which states that the causes of migration can be studied only at the same time as their consequences, the various methodologic implications derived relate mainly to the specification of the dependent migratory variable. This does not occur by chance. Before drawing up a set of problems, before constructing a theory and specifying a model, it is first necessary to define what we intend to analyze. In the study of the causes and consequences of migration, the means used to measure migration and those used to explain it often are inadequate. The slow advancement made in the demographic analysis of migration is related to the difficulties and weaknesses associated with economic analysis in this field.

The Urbanization Process

DENISE PUMAIN

Institut national d'études démographiques (INED), Paris, France

Urbanization is an important factor in the spatial mobility of populations. It is likely that urbanization has displaced many more persons than the interregional and intercontinental migrations that have gradually shaped the world's population settlements. Urbanization is a universal process that has modified and is still modifying the spatial distribution of population settlements in all parts of the world, and this process seems to be irreversible.

Even though cities began to appear several thousand years ago, their predominance, to the extent that they have become the most common form of human settlement, is a phenomenon that is only 2 centuries old. In developed countries, urban habitat has dominated for 50 years, and urban population now represents 80% of the population. According to estimates, in the year 2000, more than one-half of the world's population was living in cities. Historical and comparative analyses of urbanization processes reveal regular patterns, making it possible to predict in part future trends and their impact on population movements.

The urbanization process can be globally defined as the transformation of a rural type of settlement made up of villages—small settlements of no more than a few hundred or a few thousand inhabitants, located not far from each other, and spread over the territory and rather homogenous in terms of size—into an urban type of settlement, which is concentrated, organized on a hierarchical basis, and made up of cities—dense population clusters of very unequal size, from 1000 to 100,000 times larger than a village. The shift from one type of settlement to the other corresponds to the transformation of agrarian economies to industrial and tertiary economies. This change occurred relatively quickly on the broad scale of human history, although with variable intensities and durations, depending on the region of the planet.

The urbanization process led to a specific type of migration called *rural exodus*, whereby villages were drained of their populations by the cities. The urban system also encompasses more ordinary forms of migration, such as migrations between cities, a phenomenon that maintains differential growth rates and modifies, sometimes rather selectively, the population composition of a city, and migrations toward urban peripheries, which do not correspond to a return to the countryside but to spreading urbanized zones over the surrounding rural environment.

I. CITIES AND URBANIZATION

To measure and analyze urban migrations, clear definitions are needed for *city* and *countryside* in terms of rural space and urban space. Practically and theoretically, it is a difficult question.

1. Interpreting Urban Phenomena

A definition of the city must be based on a theoretical interpretation of the urbanization process. Cities, however, are complex social and geographic entities, and it is difficult to confine them to a global definition. Urbanization is a multifaceted phenomenon that cannot be reduced to what the theoretical apparatus of a single discipline has to offer. Urban phenomena can be considered from anthropologic, cultural, economic, geographic, political, legal, religious, and social viewpoints, and depending on the choice, the definition of the city can vary considerably.

From a demographic point of view, the city is a large and extremely dense population cluster, permanently grouped together on a limited area. The city also is defined morphologically by the permanence and continuous nature of its constructions and by the presence of urban planning rules underlying their organization. Such a conception implies that within the limited space it occupies, the city is unable to produce the total amount of food needed to feed its inhabitants. Their survival depends on the exchange of the goods and services they produce for the necessary agricultural products. The result is a functional, social, and economic definition of the city as a center of nonagricultural activity and innovation through the development of a more or less complex social division of labor; this enables it to support itself and grow because of a diversified economic basis.

Exchanges between city and countryside are always unequal, because a much higher value is attributed to manufactured products than to food products (Camagni, 1993; Braudel, 1979). The advantage held by cities is linked to their legal status as centers of power. Whether religious or political, this power always goes along with economic and territorial privileges, and city authorities exert this power over the population of neighboring localities. This specialized city occupies central functions for the surrounding region; it is a center through which all exchanges must pass. Unlike villages, which develop the resources of their immediate environment, cities develop their importance within a network, the scope of which depends on the size of the city and its type of specialization (Reymond, 1981). In this respect, a city is never isolated but always belongs to a network of cities; it is a node in a settlement system that changes according to coherent trends and in conjunction with the other elements of the system (Pumain, 1992).

Through the urbanization process, cities have become prevalent as a form of human settlement. This historical process has been interpreted in as many ways as there are definitions of cities. Several researchers have underscored the importance of symbols and of the sacred in the emergence of social forms organized on the basis of centralized power and exceeding in size all other forms of hunter-gatherer or sedentary agricultural societies (Racine, 1993; Weatley, 1971); others have highlighted the links between the development of cities and the political organization of the territories they control (Duby, 1985). Urbanization also can be explained by the change in the nature of economic activity. According to Paul Bairoch (1985), only the accumulation of agricultural reserves and of a surplus that can be sold can explain the almost simultaneous and independent emergence of cities in various regions of the world approximately 2000 to 3000 years after the Neolithic revolution. At the same time, the powerful urban growth of the 19th century cannot be separated from industrialization, even though a closer look at the phenomenon demonstrates that the links between urbanization and industrialization are quite complex. Henri Pirenne (1925) underscored the importance of trade and the possibilities for urban development offered by its expansion. In the current context of globalization, particularly the globalization of trade and the rapid development of international exchanges, this factor must again be taken into consideration because it may help to determine the nature of future urbanization processes.

Over the centuries, the same terms, *city* and *urban population*, have been used all over the planet to designate realities that are qualitatively and quantitatively very different, regardless of whether the point of view is social, cultural, environmental, political, or economic. What is there in common between a Greek *polis* and the cities of the Silk Road, between African mud towns and Manhattan skyscrapers, between medieval cities corseted behind their walls and sprawling Los Angeles, or between a small provincial town and a huge buzzing metropolis? Urban populations are by definition heterogenous, because the urban environment defines itself through the invention of new activities and new ways of life, in contrast to those of the rural world. The use of identical terms to designate such diverse forms has one advantage—it enables us to address the issue of the universal nature of urban phenomena and the uniqueness and coherence of their historical development. It also shows how important it is to develop relevant measuring tools for the purpose of comparison.

2. Defining the Urban Population

In practice, modern states have set up statistical instruments to distinguish between rural and urban populations or classify localities as towns or villages. Comparisons between one country and another are very difficult because official definitions are based on different criteria, which do not necessarily reflect the specificity of the local forms of urbanization but do reflect the complexity of urban phenomena. The *Demographic Yearbook* of the United Nations (UN) refers to these official definitions of urban populations, whose noncomparability was evaluated in two recent publications concerning countries of the European

Union (Pumain *et al.*, 1991) and concerning all countries of the world (Moriconi-Ebrard, 1993). The criteria adopted by the national institutes of statistics refer to the numerous concepts of city:

1. The *administrative status* of the city is derived from the legal definition of the city, often quite ancient. Localities are declared urban by political or administrative authorities. This criterion is applied, for instance, in Germany, in the United Kingdom, in Egypt, and in Tunisia.
2. An arbitrarily determined *population threshold* (e.g., 10,000 inhabitants in Spain or Italy) defines urban localities. Minimum thresholds vary considerably throughout the world, from 250 in Denmark to 50,000 in Japan, even though these differences may not reflect a systematic variation in the distribution of the population. In France, the threshold of 2000 inhabitants has not been modified since 1856. In other countries, the density threshold is used (e.g., in the Philippines, localities are considered urban if the population exceeds 1000 per square kilometer).
3. *Socioeconomic criteria* generally refer to a maximum threshold of the proportion of population in agriculture is retained, but this proportion can vary from 10% to 50%, depending on the country. The presence of typically urban infrastructures may sometimes be a determining factor, such as urban planning networks (in Bangladesh) or various service establishments (in Czechoslovakia).
4. Many *mixed criteria* are applied, such as size and urban planning as in Panama, size and legal status in India, or size and importance of nonagricultural activities in Zaire and in Zambia.

These criteria are generally applied within the framework of administrative subdivisions of limited size (e.g., the *communes* in France or local units in Europe). These vary considerably from one country to another. For example, in China, an urban *commune* always includes the population of a large rural territory, which often comprises several towns, and only partially corresponds to the reality of the population's spatial distribution. Defining the limits of urban entities is an essential issue, particularly for the detailed analysis and interpretation of migratory movements.

II. DEFINING THE LIMITS OF URBAN ENTITIES

As long as urban constructions were contained behind walls and as long as difficult traveling and transport conditions prevented towns from becoming too large, the town as a notion could be assimilated in the municipal territory of a *commune* or locality. When the town spread beyond the walls or the legal borders of the urban territory, these borders were periodically readjusted to correspond to the continuity of the built-up area, because urban growth remained slow.

With the industrial revolution and the urban explosion of the 19th century, the suburbs of cities extended, engulfing neighboring localities. Only after World War II did statistical institutes begin to consider the problem of the increasing difference between the city taken as a legal, political, and municipal entity and its sociologic, economic, and geographic reality. In several countries, as in Japan, Sweden, or West Germany (where the number of municipalities fell from 24,000 to 8500 between 1968 and 1978), some towns merged, or more often, new statistical entities that did not correspond to administrative limits were created.

The notion of an urban entity made up of several *communes* is based on the morphologic criterion of the continuity of buildings, which is used to define coherent urban entities. There are elementary urban forms regrouping a certain amount of population within a continuous built-up area as observed on maps or photographs (and sometimes on satellite images). According to the 1978 UN recommendation, an urban agglomeration is defined as a group of neighboring constructions separated by a space not exceeding 200 meters (500 meters in Latin America, where settlements are not as dense). Public areas, areas used for industrial or commercial purposes, as well as rivers with bridges crossing over them, are not taken into account to calculate this distance.

A population grouping that is continuously spread over several administrative units forms a *multicommunal agglomeration*. These agglomerations are usually adjusted according to communal limits, so that they coincide with a whole number of administrative entities. In France, the notion of multicommunal agglomeration appeared around 1954 (Marpsat, 1986). Communes with a population cluster of at least 2000 inhabitants are called *isolated towns*. If the agglomeration covers several communes, the multicommunal urban agglomeration is defined by identifying all the built-up zones regrouping at least 2000 inhabitants. Among the communes linked together, those in which the population cluster represents at least one-half of the total population of the commune are multicommunal urban agglomerations.

With minor variations, the concept of urban agglomeration—in the sense that the city is defined as a morphologic entity perceived in terms of the coherence of the urban fabric—is used by about 50 countries in the world. To the extent that the administrative networks of different countries can vary considerably in size and regularity, urban agglomerations defined in such terms are more comparable than cities defined as municipalities. In countries where settlements are very ancient, as in Europe, most urban activities, functions, and jobs are concentrated in the agglomeration; the latter can be considered a relevant framework for measuring the importance and impact of a city from a demographic or economic point view and for establishing national or international comparisons.

In many countries, the concept of urban agglomeration does not exist. The large-scale comparative studies of world urbanization conducted by Tertius Chandler and Gerald Fox (1974) or by Kingsley Davis (1969, 1972) were faced with the problem of the diversity of sources, as concerns the definition of a city. For this reason, the historical databases established for Europe between 1500 and 1800, on the basis of a single concept of urban agglomeration, by Jan de Vries (1984) are extremely useful, as are those of Paul Bairoch and colleagues (1988) for Europe from 800 to 1850 and Geopolis, the world database developed by François Moriconi-Ebrard (1994), in which the concept of morphologic agglomeration represents the first harmonized definition, applicable to the population of all cities of more than 10,000 inhabitants in the world from 1950 to 1990 (updated to 2000 on the web site www.geo.univ-avignon.fr).

From Cities to Urban Population Areas

According to the previously explained concepts, the city and the fact of living in it is what defines the urban population. With the spread of urban lifestyles to the rest of the territory, it is more and more the urban population itself, defined by its occupations and movements within an area of daily contacts, that determines the limits of the zones considered urban. The less compact urban forms observed in countries of more recent settlement, such as the United States, have encouraged some to suggest a more extensive definition of urban spaces, particularly around large cities. The use of cars and the preference for single-family houses and for a more rural type of environment have promoted the development of extensive residential suburbs, while city centers remain very dense employment areas with *central business districts* (Dupuy, 1995). This distribution has reinforced the dependence between the center and the peripheral zones of the city, with people massively commuting between home in the periphery and work in the center. The expression *daily urban systems* has been used to describe these configurations. Beginning in the 1950s, this model spread to many other countries, with the development of *banlieues* or immediate suburbs (i.e., entirely urbanized peripheral zones), followed by the creation of more distant suburban or peri-urban zones (i.e., population settlements in rural localities situated in the periphery of cities). Unlike classic suburbs, these peri-urban zones still have agricultural activities and non–built-up areas; sometimes called *rurban*, these forms of settlement reflect complex social transformations.

The Standard Metropolitan Statistical Area (SMSA) was created by the United States Census Bureau in 1949. An SMSA is centered on a city (or two contiguous cities) with a population of at least 50,000. It includes the entire surrounding county and the neighboring counties that do not have a large working population of farmers and where a certain proportion of residents commute to the city center for work. Several countries have used this definition to extend the concept of city to that of *employment area* or *functional urban area*. The aim is to include in the definition of an urban entity the peripheral zones polarized by a center that they depend on for employment and population growth. The center is defined as a composite entity made up of the central municipality and its immediate suburbs, and the urban area includes an urban unit or central city and the peripheral municipalities that are directly linked to it.

In Europe, four countries have officially defined functional urban areas: Belgium, France, Luxembourg, and the Netherlands. In Belgium, the area has a center called the *operational agglomeration*, and in Luxembourg, the center is an *urban agglomeration* of at least 50,000 inhabitants. In the Netherlands, the central nucleus of the agglomerates is made up of two contiguous municipalities with a population of at least 100,000. In France, the central nucleus of the *industrial and urban settlement zones* (ZPIU, as defined from 1962 to 1990) can be a multicommunal urban unit or an isolated town or a rural commune with an industrial activity (more than 100 jobs grouped in businesses employing at least 20 persons). To these centers are added the neighboring municipalities that have preferential commuting links with this center and that have characteristics that are considered specifically urban. The minimum population level determining an urban area varies greatly from one country to the next. An urban area must have a population of at least 100,000 in Luxembourg and in the Netherlands, 80,000 in Belgium, and only 2000 in France. Since 1990, a new definition of *urban areas* has replaced the ZPIU, which had become too extensive. These areas are situated around centers with at least 5000 jobs and regrouping communes, from which more than 40% of the residents commute to the center or any other commune dependent on the latter.

Employment areas or functional urban areas are more relevant as entities than morphologic agglomerations, and they are extremely useful for the study of current urbanization processes, including changes in land use, the extension of urban property, and the decentralization of residences or of certain types of occupation that have moved to peripheral zones not necessarily linked to the main agglomeration through continuously built-up surfaces. However, given the size of these areas and the difficulty of determining their limits with simple criteria (because there can be discontinuous parts or enclaves) and given their uneven status in terms of development, these entities are difficult to use in terms of their global weight in national and international comparisons.

The different types of statistical description of spatial forms can be grouped into four categories covering the huge variety of urban population conglomerations in different countries:

1. *Urban localities* are defined by administrative limits or by legal status.

2. *Urban agglomerations* or *urban units* group together urbanized centers made up of continuous built-up areas, covering a portion of an administrative unit or grouping together several units.

3. *Functional urban regions*, which include a central city and its sphere of influence, often are defined on the basis of commuting patterns.

4. *Polynuclear urban regions* or *conurbations* can represent a continuous built-up expanse but contain several polarizing centers. They often represent the combination of several agglomerations or urban regions that are initially distinct but that later merge as they spread in space.

III. THE URBAN TRANSITION

During the centuries before the industrial revolution, some cities were born while others disappeared. Their appearance and function underwent many transformations. The size of urban populations fluctuated, sometimes to a considerable extent, as for example during the great plague of the 14th century in Europe, which killed one-half the population of cities. However, throughout that period, the urbanization rate—the proportion of urban dwellers among the total population—remained relatively stable. Even though it may have varied from one period and one region to the next, on average, the rate remained about 10%, within a range that only exceptionally reached 30% or even 40%, for example in 17th century Netherlands (Bairoch, 1985).

The industrial revolution caused extensive changes in the organization of economic activities, lifestyles, and social structures, and it completely modified the organization of settlements in space. During a major transitional period, which in developed countries lasted about 2 centuries, the settlement system completely changed, and only about 20 years ago was a new balance apparently reached. The relationship between city and countryside has been totally reversed. Even though agricultural activities remain dominant in terms of land use and landscape, the population and its living conditions, activities, and lifestyles have become to a large extent urban, including in most communes still considered rural.

This major transition has been called *urban transition* by some researchers (Zelinski, 1971) by analogy with the demographic transition (see Chapters 68 and 69), which occurred at different times in the history of different countries of the world. Several aspects of the historical urbanization process can be linked to the way innovations are spread in space. A first hint is given by the specific shape of the curve describing the trend in the proportion of urban population within the total population, which takes on everywhere the shape of a logistic curve, similar to the curve of the proportion of population that adopts a given innovation (Hägerstrand, 1953). This simple indicator is called the *urbanization rate*. It measures the proportion of the population that has chosen to live in the city; it describes the relative weight of cities in the settlement pattern. This rate underwent specific variations during the period of urban transition. The settlement systems of the pre-industrial period showed a relatively low rate of urbanization; they remained quite stable, with a slow pace of progress and occasional small fluctuations. The urban growth of the 16th and 17th centuries in Europe, which led to a significant increase in the size of the urban population and in the number of cities, went along with a very slight increase in the relative share of the population living in towns of more than 5000 inhabitants. This proportion grew from 10% to 11.5% around 1500 to only 12% to 13% in 1700 (Bairoch, 1985; de Vries, 1984). The transitional phase began at a time when the urbanization rate began to increase faster than during previous periods and especially when this increase persisted steadily over several successive periods; thus began an irreversible process which in the space of a century led to an urban population of 80%. The end of the urban transition was marked by the stabilization of the urbanization rate, which meant that the industrial settlement system had reached a certain level of development.

This stability corresponds to a new balance in the spatial distribution of the population. However, this balance is a dynamic one, because each component of the settlement system continues to change. Even if some cities grow while others stagnate or decline, globally the ratio between city dwellers and country dwellers remains stable. A simple criterion such as the urbanization rate measures only one aspect of urban growth; it is a global measure that describes the organization of the system as a whole. The spatial extension of cities, for example, is another aspect of urban growth whose consequences are felt mostly on a different scale, that of local planning. The latter process is ongoing, and it has even gained momentum in recent years.

The relationships between migration and urbanization are complex. Although it is true that the overpopulation of the countryside can generate migration flows toward the city, overall, on that scale, it cannot be said that migrations are the cause of growing urbanization. The surplus of farming production, the emergence of new types of activity, and the intensification of exchanges are the decisive factors in the skyrocketing growth of urban populations, and they have an influence on country-city migrations. Conversely, on a local scale, residential migrations are the cause of recent transformations in the urbanization process in regard to its morphologic aspects, even if these are due to improved living standards and the generalization of automobiles, which must be taken into account but are not sufficient to explain the urban sprawl.

Globally, the urban transition appears to be a universal phenomenon in world history. However, a detailed study of the history of the urbanization process shows that there are many variants to this phenomenon, because its characteristics, pace, and explanatory factors seem to differ from one continent to the other and especially between developed countries and Third World countries (Fig. 61–1). Overall and over time, a general relationship is observed between urbanization and economic development, which is also reflected in technical progress, industrialization, and the social division of labor. The openness of the country to exchanges also seems to be a necessary condition, as shown by the decline of urbanization between 1500 and 1850 in China despite high demographic growth. At that time, the country was undergoing a period of total isolation, whereas during the 15th century, its situation had been comparable to that of Europe in terms of development level and urbanization rate (Bairoch, 1985).

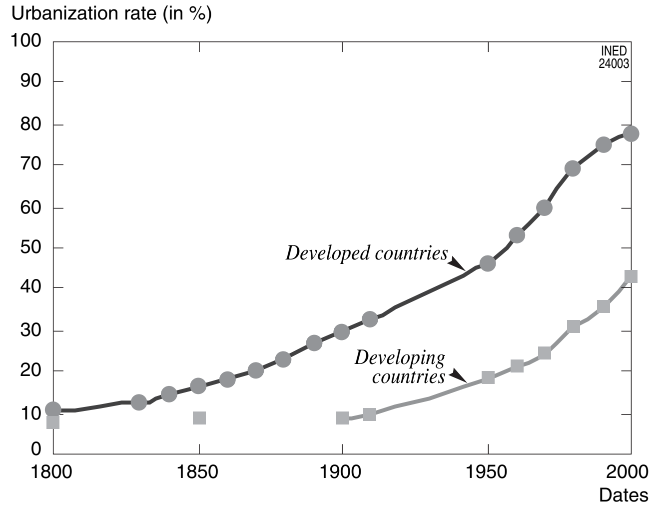

FIGURE 61–1 Urbanization rate since 1800 in developed and developing countries. (Data from Moriconi-Ebrard, 1994; Bairoch, 1985.)

1. The Urban Transition in Developed Countries

Toward the end of the 18th century, the urbanization rate in Europe began to increase and rose from about 20% to 80% in about 150 years. At that time, the average annual rate of growth of the urban population was close to 2% annually, about twice as high as that of the total population. During the 19th century, the increase in agricultural productivity drove unemployed farm hands to the city, and these migrations were responsible for one-half to two-thirds of the urban growth. At the same time, the population was beginning to increase at a very high rate due to the demographic transition, and this phenomenon also fueled urban growth. Nonetheless, urban dwellers had lower fertility and higher mortality rates than rural inhabitants (prompting the phrase *man-eating cities*); this mainly resulted from higher population density, resulting in a higher risk of epidemics, which at the time were difficult to control.

The urban transition first appeared in Great Britain, which at that time was not the most urbanized country, but it was the country where agricultural productivity had increased most and the first to have experienced the industrial revolution. In France, where the demographic transition preceded the urban transition, urbanization began later and at a slower pace, with an average rate of growth of the urban population of about 1% per year during the entire 19th century. This explains why in France the major part of the population was still rural until 1950, whereas in Great Britain, this had ceased to be the case at the turn of the century. Overall, the progress of urbanization followed that of the industrial revolution; it began first in northwestern Europe, was very rapid in the United States and in other "new" countries, and was somewhat delayed in some countries of southern Europe, even though these were the most urbanized at the start of the process.

After World War II, thanks to strong economic growth and to the baby boom, urbanization processes accelerated, especially in countries where they had been delayed. Migrations from the countryside to cities also fueled urban growth in the 1950s and 1960s; they later stabilized and even slightly declined in the 1980s. In these countries, the countryside—whose population had reached its maximum level in the last third of the 19th century but had since then consistently been declining—lost a considerable part of its population. In the space of 1 century, between 1866 and 1975, the French countryside lost one-half of its population, more than 12 million persons, mainly due to emigration. However, certain rural localities situated in the periphery of large cities increased their population thanks to urban expansion and the spread of the urban population. The suburbanization process, which began in the 1950s in the United States, spread to Northern European countries in the 1960s and 1970s, and this suburban spread continued throughout Europe during the 1980s and 1990s.

2. The Urban Explosion in Developing Countries

In 1950, the urban transition had not yet begun in developing countries; the urbanization rate was then only 15% on average. The urban population explosion that then took place was far more intense than anything ever experienced in industrialized countries. Between 1950 and 1990, the urban population increased each year by 4.5%, a rate almost 2.5 times higher than that observed in developed countries during the same period and twice as high as that witnessed in developed countries in the 19th century during the most intense moments of the urban transition. The pace of increase of the urbanization rate in developing countries is now twice as high as that of the developed countries in the last century. Instead of lasting about 150 years, it is likely that the urban transition will last only about 50 years in developing countries (see Fig. 61–1).

This unprecedented urban growth does not have the same causes. Migrations from country to city only account for one-half of this growth. The fertility rate of urban populations remain identical to that of rural populations, and the mortality rate is lower because health care facilities are more numerous. As Paul Bairoch (1985) said, "The city has ceased to be an impediment to its own growth." Instead of declining as in Europe during the urbanization process, the rural population continues to increase, and demographic pressure is strengthening.

There is a controversy concerning the factors that determined the urbanization process in developing countries. If we compare them with industrial countries during the past century, it seems that in the former, industrialization and agricultural productivity did not progress at the same pace as the urbanization rate. The causes of urban expansion are rooted in the very high rate of demographic growth, unprecedented in nature and linked to the rapid pace of the demographic transition in the Third World (see Chapter 69). The wide gap between urban and rural incomes, with the former twice to three times as high as the latter (compared with differences of 15% to 30% in 19th century Europe), can also be ascribed to the development of international relations and of links with the developed world, which generate dual economic systems. This wide gap, along with a broader reach of information and education, may explain the strong impact of the "urban mirage" (Bairoch, 1985).

Foreseeable population movements will be massive. For example, in China, during the first 2 decades of the 21st century, about 300 to 400 million persons will be compelled to leave the countryside to find employment in the city. The several million persons who have already moved to the city to find work represent an unstable population group, whose status remains unclear. Whatever its origins and given its momentum and very rapid pace, the urban transition in the Third World is different from that of industrial countries, or at least it represents a specific variation of this process. This new form is marked by a much higher concentration of the urban population in very large cities, much higher than that observed for the same urbanization rate in developed countries. It is not surprising that the distribution of large cities in the world has been completely reversed. In 1900, only 1 of 16 cities with a population of at least 1 million was in a developing country; by 1950, the figure had risen to 32 (37%) of 86 and to 174 (58%) of 298 in 1990 (Moriconi-Ebrard, 1993).

IV. THE DYNAMICS OF SETTLEMENT SYSTEMS

A settlement system on a given territory is defined by the inhabited areas (e.g., villages, towns, cities) and by communication networks (i.e., transport and information networks) that connect these areas of settlement. The notion of territory is understood here in its administrative or political sense, as a portion of the earth's surface that has been appropriated by a group.

This implies a certain degree of homogeneity of socioeconomic conditions and global control over the possibilities of circulation within that territory. The networks are created by the population of the different settlements and make possible numerous forms of interaction: exchanges of material and monetary goods (i.e., trade), exchanges of persons (i.e., migrations) or information. Throughout history, the system's environment, made for the most part of the mining and agricultural resources of the given territory, became less and less dependent on its natural characteristics and increasingly built-up as the industrial and urban society developed and took over the environment.

Settlement systems throughout the world have very powerful characteristics, which are relatively invariant depending on period or place. These systems are strongly hierarchical structures, reflected in the difference in size of the elements of the system, from a population of a few dozen living in small hamlets to over 10 million in large, modern metropolises. The general model that accounts for this organization is a reverse geometric progression of the number of cities according to their size (Zipf, 1949) or a log-normal distribution of the size of the settlement units (Pumain, 1982; Gibrat, 1931). Historical studies (de Vries, 1984; Carroll, 1982) and archaeologic studies (Fletscher, 1986), as well as very recent international comparisons (Guérin-Pace, 1993; Moriconi-Ebrard, 1993), all show the universal nature of this model in space and time.

This hierarchical structure is marked by regular patterns in the distance separating the settlement units; the larger the cities, the longer the distance between them. The theory of central places (Christaller, 1933; Reynaud, 1841, quoted by Robic, 1982) explains this configuration by way of the centrality principle, according to which the production of services situated at the same level and designed for a population dispersed in the surrounding region (or zone of influence) is regrouped in a center that attracts the client population. The centers are organized hierarchically because there are several different levels of services, defined by their spatial scope (i.e., the distance the consumer is willing to cover to obtain the service) and by thresholds of demand that determine the creation of a given service (i.e., the volume of clientele necessary to ensure that the production of the service remains profitable). The zones of influence of the different centers overlap, because the higher-level centers usually offer all the services that can be found at the lower levels. The consequence of this competition between centers is a regular pattern of distance between cities, and the hierarchy of service levels is reflected in the smaller number and longer distance between centers as we go up in the hierarchy.

Another important characteristic is the very high level of interdependence in the development of elements belonging to the same settlement system. Changes in morphologic configuration (e.g., city planning), in activity types (e.g., industrialization, tertiarization), in the social composition (e.g., development of salaried work, increase in the level of qualification), and in the number of inhabitants (e.g., rural exodus, urban growth) very seldom appear as isolated or sporadic phenomena happening in a single place. On the contrary, detailed analyses of the changes occurring in all the cities of a given territory show that the transformations pertaining to a given period were taking place simultaneously and in a very homogeneous way (Sanders, 1992; Pumain and Saint-Julien, 1978). Because these changes occur with practically the same intensity everywhere, the inequalities and differences that exist at a given moment between cities persist for periods. Over a given period, cities that belong to the same system shift in the socioeconomic space, and the settlement system adapts to this shift without modifying its structure.

The only way to modify in a deep and lasting way the structure of these city systems, as well as the urban population's ability to survive by adapting to the endless innovations that are part of urbanization dynamics, is through the selective adoption of innovations (e.g., when they are based on the development of sporadic mining fields, such as cities built around coal and iron mines during the industrial revolution, or towns built on the Riviera with the development of tourism) or, on the longer term, through major changes in political and economic organization (e.g., those that gradually displaced the centers of world economies, according to Fernand Braudel's concept).

If we observe in each city the growth of urban populations, encouraged during the urbanization process by these systemic dynamics, we distinguish two major types of development. In countries where settlements are ancient, they can be for a large part described by Robert Gibrat's (1931) stochastic model, which explains the log-normal distribution of city sizes through a random distribution of their growth rates in space and time. To this overall process, it must be added that over the long term, large cities tend to grow more than smaller ones, and this tends to reinforce contrasts in the hierarchy of city sizes within the system. This tendency can be explained by the fact that innovations spread according to a hierarchical pattern whereby overall development first takes place in large cities, which benefit more from the initial advantage. However, it is also explained by the historical tendency to reduce duration of travel with increasing speed of communication, which hampers the development of smaller towns. The urban network of these countries continues to develop along the same patterns; contrasts between city sizes are increasing, and hierarchy is simplified at the lower levels (Fig. 61–2).

In countries of more recent settlement, urban growth takes on other forms. In a country being colonized, there is a negative correlation between urban growth and the size of cities because of the continuous emergence of new towns on frontiers and the phenomenon of mushroom towns. This type of development continues until the territory is saturated. It seems that distances between cities are on average longer and much less regular in newer countries settled at times when means of communication were more rapid than they were at the time settlements were created in older countries. The average distance between two cities of more than 10,000 inhabitants in the European Union is of about 13 km; it is 17 km in India, but it exceeds 60 km in North America (Moriconi-Ebrard, 1994). In

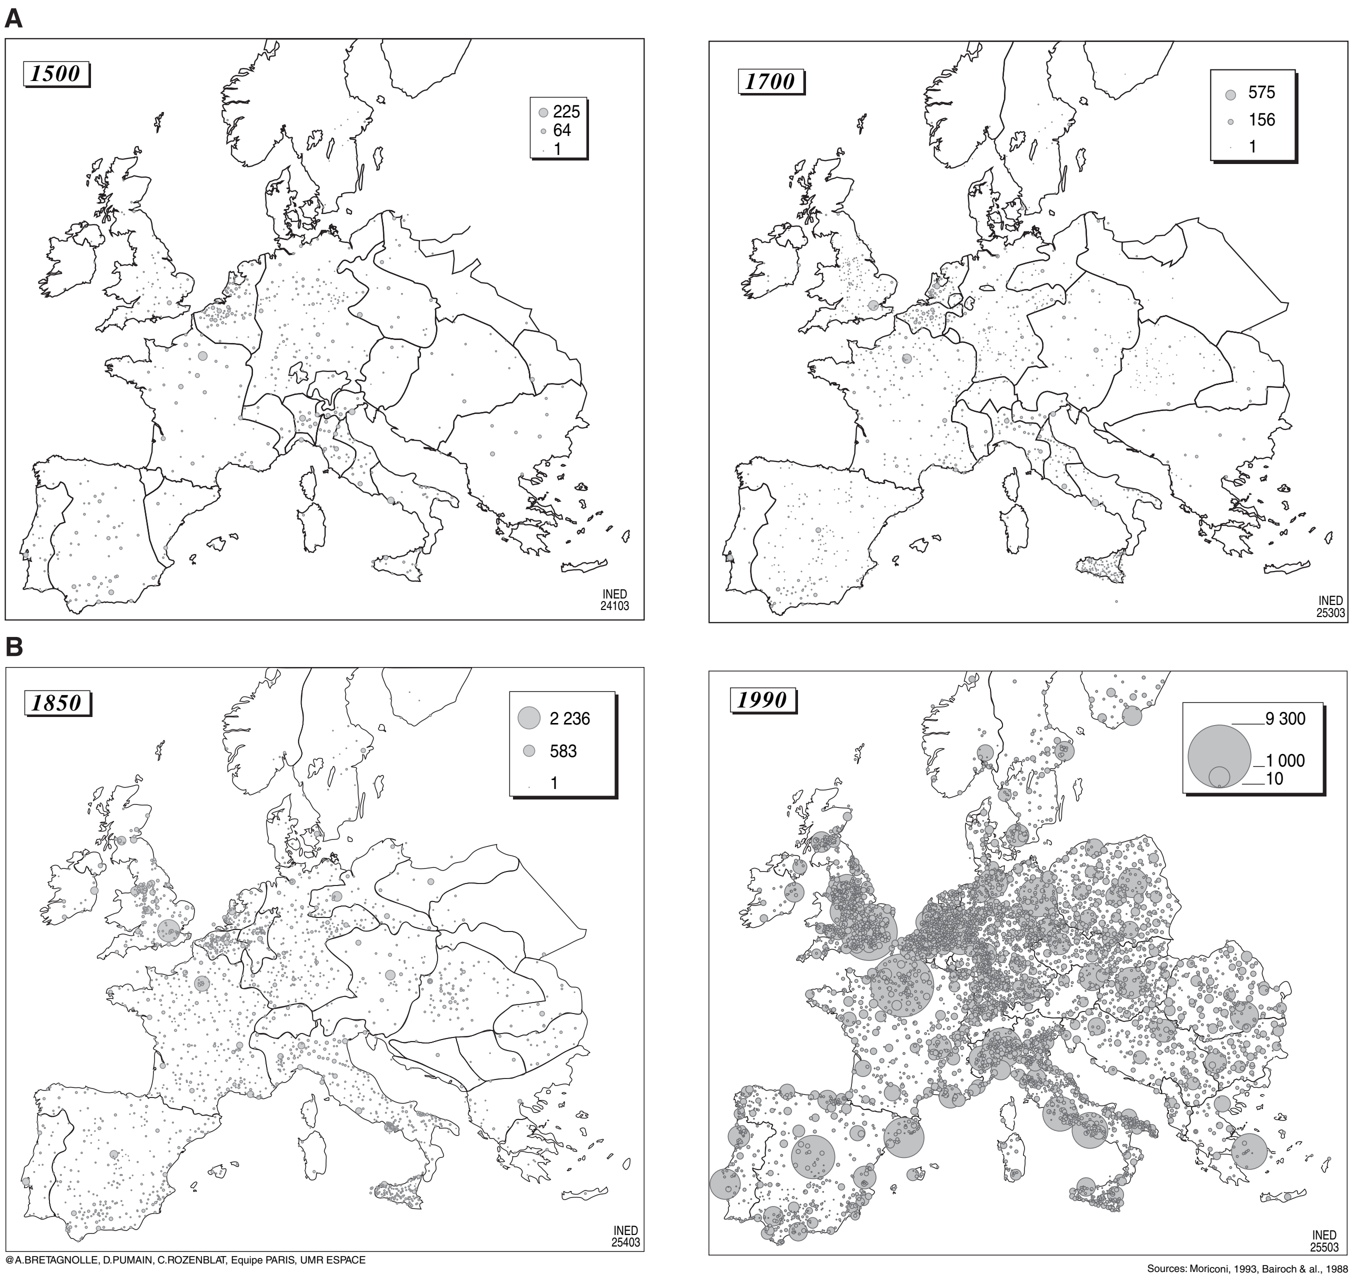

FIGURE 61–2 **A:** Population growth in the European city system in 1500 and 1700 (figures given in thousands). **B:** Population growth in the European city system in 1850 and 1990 (figures given in thousands).

America, the volume and density of the population is much lower, but big cities are much larger than European big cities, and the total number of urban units is much smaller. In Europe, the differences in distance patterns correspond to different types of settlement: more dense in countries along the Rhine, less dense and more contrasted in the western and northern periphery, and more regular in the eastern marshes, which were colonized later (Fig. 61–3).

Given the strong regularity of such patterns, researchers studying and analyzing urban populations must always consider two geographic scopes of investigation and interpretation: that of individual characteristics and of a person's position within the set of relations linking him or her to the rest of the city's inhabitants, with the city being a relatively autonomous subentity, and that of the variables that describe this conglomeration (i.e., the system formed by these persons), depending on its relative position (mostly represented by size, specialization, location, image, and other factors) in the system of cities. These two levels of organization have an undeniable impact on individual characteristics and movements, in the same way as a city cannot emerge as a coherent entity without going through a long history of formation of interaction networks. For this reason, newer approaches to explaining cities and city systems are based on evolutionary theories (Pumain, 1997).

V. MIGRATIONS AND URBANIZATION

Inequalities of urban growth more often result from the variable intensity of the city's power to attract migration than differences in the natural growth of the nonmigrating population. Although according to economic theory the explanatory factor of urban development would be the individual decision to migrate, it seems that migrations are very much influenced by the structural characteristics of the urban system in which they occur and that the latter's own dynamics highly influence individual movements.

1. Centripetal Migration: The Rural Exodus

In all countries where the urbanization process took place, it led to significant population movements.

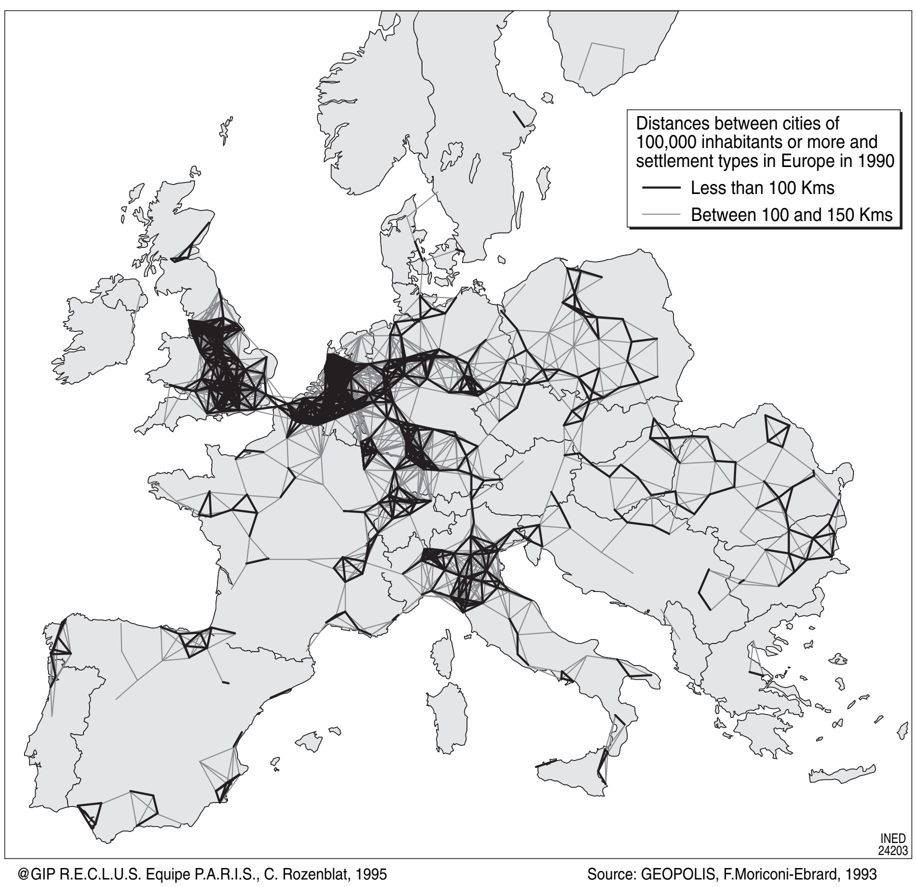

FIGURE 61–3 Distances between cities of 100,000 inhabitants or more and settlement types in Europe in 1990.

Although Edward Ravenstein's *laws of migration* (1885) established that all migrations occurring between different parts of a territory were made up of a flow and a counterflow that were more or less equivalent in volume, the rural exodus has been persistently asymmetric, because the flow from country to city has long exceeded the flow going the other way. These flows follow the gravitational model; if we measure the flows between two areas, we find that they are roughly proportional to the product of the populations located in the departure and arrival areas and inversely proportional to the distance separating the two zones. For a long time, the gradient of the decrease in the intensity of migrations from areas around cities remained very sensitive, reducing the relative volume of migrations coming from farther away than several tens of kilometers (Courgeau, 1970). The area around the city from which population moved to the city grew gradually larger, but today still, the more intense migratory exchanges, such as around French regional capitals (i.e., cities of 250,000 to 1 million inhabitants), do not extend beyond the first circle of *départements* surrounding the city.

The population migrating into cities mainly comes from the city's immediate surroundings. Many studies have shown that migrations from country to city most often occur in several stages, either during the life of a single individual or over successive generations, and that these stages generally correspond to a move upward in the urban hierarchy. Small and medium-sized cities often play the role of an intermediary stopover stage in the journey from country to city (Courgeau, 1983).

The rural exodus was also a selective process. Those who left the countryside first were those with the weakest ties to the land, because artisans and shopkeepers migrated before farmers. Results of studies underscore persistent differences in the individual characteristics of those who move to the city and those who remain in the country (Courgeau, 1987).

2. Migrations between Cities

During the urbanization process, because of the distribution of migratory processes into separate stages and to the positive net migration of larger cities compared with smaller towns, migrations between cities played a part in the concentration of population in the larger cities and in the development of urban hierarchies. Although this pattern was first considered valid for migrations in general, it was later limited to the working population when the urbanization process reached a phase of saturation. This selective process based on urban hierarchy remains nonetheless very significant.

When the rural exodus ended, migrations between cities increasingly contributed to the differential growth of the urban population. Although the cities' rates of natural increase are becoming more and more homogenous, their net migrations remain very uneven (although their overall contribution to urban growth is declining), and their impact is selective. This impact is more significant from a qualitative than from a quantitative viewpoint. Populations migrate differently depending on age. Young adults, students, or persons looking for their first jobs prefer big and dynamic cities, whereas older adults prefer medium-sized cities, and senior citizens prefer small towns. However, the social or economic composition of migratory flows seems to be determined to a higher extent by preexisting urban specializations. Workers are attracted to working-class towns but also leave them, and the composition of the population arriving in and leaving tertiary cities is just about similar to that of the resident population (Pumain and Saint-Julien, 1989). The role of migrations in urban dynamics is rather difficult to determine. Their impact on the rejuvenation of urban populations and the concentration of the young, working population in big cities is important, but it is less significant as concerns social or economic modifications in cities, because these factors seem to be determined mainly by endogenous factors (Baccaïni and Pumain, 1998). At the most we may observe, as a recurrent phenomenon, a selective emigration of senior-level professionals trained in the universities of large cities, who then move back to smaller towns.

3. Centrifugal Movement: The Urban Sprawl

The distribution of urban populations in urban space, usually observed in the area of residence, follows general processes such as competition for the occupation of the most accessible areas, and these often are the most central areas. This distribution also depends on technologic factors (i.e., speed and transport systems) and on social, legal, and cultural issues. Even though population densities vary considerably, from several hundred to more than 100,000 inhabitants per square kilometer, they usually follow rather systematic patterns. The density of cities varies, as does the general population density of the territory as a whole; on average, it is lower in the United States than in Europe, and it is higher in Asia. Within a single territory, the larger the city, the higher the average density. Within a single city, density decreases very strongly when moving from the center to the periphery, following an exponential or power function according to the distance from the center. Historically, urban densities first increased during an initial phase lasting from the Middle Ages, when the walls surrounding cities restricted their spatial extension, until the invention of urban streetcars. From then on, urban peripheries began to extend in space, and the density of suburbs increased faster than that of the center, reducing density gradients. In parallel, competition for land use on the part of economic activities, top-level services in particular, has created a central crater in big cities where residential density is lower (although the daytime density of the working population is very high).

The growing use of cars also generated specific population movements and urban forms that continue to influence migration.. Automobiles, along with single-family housing and very nonrestrictive land use standards, have led to the emergence of specific urban forms on the American suburbia model. However, extreme forms can be found in other new countries. In Australia, for example, Sydney's population of 3 million shares an area the size of greater New York City, which has a population of 24 million. From the 1960s on, the suburbia phenomenon began gaining momentum in the United States and spread to Europe in a slightly different form, called *urbanization of the countryside* and *peri-urbanization*. It first appeared in 1970 in Scandinavia and Great Britain, and it later occurred in France, reaching southern Europe in the 1980s. This phenomenon gave rise to pessimistic interpretations. Some came to believe that the end of cities, a process they called *counter-urbanization* (Champion, 1989; Berry 1976), was near (Chombart de Lauwe, 1982). However, the consequence of the urban sprawl, which led to a loss of population in city-centers and the migration of households toward rural peripheries, was not so much the revitalization of rural zones as the extension of the urban influence in terms of employment and services. These residential migrations went along with the development of commuting practices, because rather than take advantage of increased speed to reduce time spent in transport, urban populations preferred to increase the distance covered and gain access to more spacious and cheaper housing in a more natural and less urbanized environment.

This trend will probably continue, and it seems to have begun in the big cities of the Third World. On the part of urban populations, rather than being a sign of defiance faced with the generalization of the urban way of life, it appears to be a manifestation of the wish to take advantage of both the nearness of facilities and services made possible by concentration and of improved living spaces and a natural environment. This aspiration is not new and explains in part the fragmented, fractal aspect of urban settlement configurations (Frankhauser, 1993). Does this mean that cities that are more adapted to automobile traffic and that now have the highest living standards represent a universal urban model toward which all cities tend to converge? Let us not forget that cities are complex entities, the result of long-standing historical processes, and that the various processes that have influenced urban forms explain contemporary diversity and can guarantee the sustainability of cities.

CONCLUSIONS

The study of the long history of the urbanization process enables us, with a reasonable degree of certainty, to make a few predictions concerning the future of cities. Urbanization belongs to the category of processes involving the spread of innovations, and in that sense, it is possible to determine, especially in developing countries, which stage has been reached—all the while taking into account the country's specific historical characteristics—to determine how to go about facing the later phases of urban growth. The distribution of urban population growth among cities and the modifications of urban hierarchies are relatively foreseeable in the medium term if we apply what we know about the dynamics of city systems.

It is more difficult to foresee the future of this process after the populations have been more or less completely urbanized. Some believe that urban forms are linked to available technologies and to the economic activities they make possible; in their view, it is possible that new information technologies may undo previous population concentrations. The information society may return to more dispersed forms of settlement, and rural regions may be repopulated. Others insist on the strength of the links tying current urban systems to their past history. The networking of cities, which is a powerful phenomenon in Europe (Cattan *et al*., 1994) and which goes along with the growing internationalization of exchanges, corresponds to the relative concentration and the selection by large cities of the most skilled population and the most modern activities. These trends have been observed in the past, occurring at the beginning of every large cycle of innovations. Over the centuries, the city system has constantly reacted by adapting its structure to successive qualitative and quantitative changes in human activities, and it may very well adapt again to the innovations brought about by the *information society*.

CHAPTER

62

Political Pressure

LUC LEGOUX

Institut de démographie de l'université de Paris (IDUP), Paris, France

Whether it is repression, war, ethnic cleansing, or genocide, the political reasons for the forced movement of population seem innumerable. On the contrary, possible destinations are far fewer; they are limited to neighboring countries whose hospitality is often forced and to developed countries that are becoming increasingly hostile toward immigration. However, political immigration has a separate status in international immigration because most countries acknowledge its legitimacy over other types of migration. Consequently, if political violence determines the pressure to leave, the magnitude and destination of political migration depends on the receiving country's translation of this into a formal acknowledgment of the right to migrate. There is a wide gap between the theoretical right to look for political asylum in democratic countries and the effective possibility of actually doing it. Today, the major obstacle facing asylum seekers is no longer the defunct Iron Wall but Western policies of limiting immigration. Judging from the difficulties facing asylum seekers in Europe, these policies are effective. However, should this be called effectiveness when it is associated with a growth in tolerated illegality? Legal measures allow for the legitimate refusal of asylum, but they do not authorize the expulsion of asylum seekers to their countries if such countries are in the middle of violent conflict.

I. THE ROOTS

Violence has always been at the origin of forced movements of population. Twenty-five centuries ago, Aeschylus' oldest play, *The Suppliants*, depicted a perfectly contemporary request for asylum. The 50 daughters of Danaos requested and obtained asylum from the people of Argos to escape forced marriage. Today, recognition of refugee status for this type of human rights abuse is not always the case in Europe, although Canada recognizes gender persecution. Escape from wars and religious persecution has existed in all of human history, but until the 16th century, asylum was only for common law offenders. Sacred sanctuaries of antiquity and, later, Christian churches were asylums placed under the protection of the gods, where criminals could obtain temporary protection from the private vengeance of victims. The function of this asylum was to correct the weaknesses of the state justice system, and in reducing private violence, it indirectly reinforced the monopoly of legitimate violence detained by the lords. Because the Prince's interests took precedence over those of society, the inviolability of sanctuaries was often transgressed in political cases (Bettati, 1985). From the 16th century, the development of monarchies and civil justice questioned the basis of asylum for common law delinquents. Protection from the gods was no longer necessary for maintenance of order, and because it cast a shadow on the absolute power of the king, it had to disappear. In the opposite direction, political asylum found its own roots in the relativity of crimes of opinion, as the states, becoming increasingly powerful and protective of their territorial prerogatives, were no longer all condemning the same convictions at the same time. The exile of about 200,000 Huguenots in the 17th century and their generous welcome in France's neighboring states marked the beginning of the modern tradition of asylum in Europe.

When subjected to reason of the state, the political asylum of foreigners was very controversial, and the legitimacy of the protection given to the politically persecuted established itself very slowly. The French Revolution was a new stage that exalted resistance to oppression and placed political asylum in the constitution of 1793: "The French people shall provide political asylum to foreigners banished from their fatherland for the cause of freedom. It shall refuse asylum to tyrants" (article 120). This proclaimed right to asylum remained purely virtual because France at that time was no more a land of asylum than its neighbors, and the construction of national identities was progressively imposing a control of international migration (Noiriel, 1991).

II. THE INTERNATIONAL SYSTEM FOR MANAGING REFUGEE MIGRATION

The need for an international system for managing refugee migration appeared forcefully after the First World War. In a few years, Europe had had to cope with the resettlement of war refugees, the influx of about 1 million refugees of the Russian Revolution, and the consequences of the Armenian massacres in Turkey. Under the auspices of the League of Nations, a series of ad hoc international agreements were signed to regulate the status of the various groups of refugees. In 1921, the Nansen passport,[1] ancestor to the travel document of current refugees, was created to provide Russian refugees with an identity document to enable them to travel. The provision of this passport was then extended to other groups of refugees.

Before the Second World War, the mass arrival of Spanish and German refugees fleeing the Franco and Nazi regimes increased the necessity for a concerted management of these populations. The League of Nations consequently set up the Intergovernmental Committee for Refugees (ICR) in 1938, which adopted a very general definition for refugees and consequently for political immigration. After the Second World War, the United Nations Organization succeeded the League of Nations and created the International Organization for Refugees (IOR), which managed the resettlement of more than a million persons in a few years.

[1] Taken from the name of the President of the Norwegian delegation to the League of Nations. Founder of this travel document, he was an Arctic explorer and a renowned activist for refugees.

In 1951, the United Nations High Commission for Refugees (HCR) replaced the IOR, and during the same year, the Geneva Convention on the status of refugees was drawn up during the Cold War (Table 62–1). The jurisdiction of this convention, initially limited to events that took place before 1951 in Europe,[2] was extended to the whole world without restriction by the additional New York protocol of 1967.[3] This convention, ratified by more than 120 nations, has become the fundamental text for modern asylum. It defines a refuge as a person who "owing to well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group or political opinion, is outside the country of his nationality and is unable or, owing to such fear, is unwilling to avail himself of the protection of that country; or who, not having a nationality and being outside the country of his former habitual residence as a result of such events, is unable or, owing to such fear, is unwilling to return to it."[4] It also defines the rights of refugees in their host countries and specifically stipulates that they must at least enjoy the rights of non-refugee foreigners. It also protects refugees against expulsion or transfer to a country where they may be threatened.

The large number of civil wars in Africa and the ambiguity of the Geneva Convention concerning persecution related to this type of situation[5] led the Organization for African Unity (OAU) to write its own convention in 1969, which explicitly includes in the definition of a refugee, victims of all types of persecutions, irrespective of the circumstances. Latin America did the same with the Cartagena Declaration in 1984. Since then, political migration is managed by a dual system; in the Third World, the legal definition of a political refugee corresponds to the classic sociologic definition that considers all persons fleeing persecution,[6] whereas in developed countries, legal recognition of refugees giving them residency rights are

[2] From the beginning, the signatory countries had the possibility of extending the effects of their membership to events in Europe or elsewhere.

[3] Often called the Bellagio Agreement, it was named after the city where it was written.

[4] See HCR 1979, for the text of this convention accompanied by its interpretation.

[5] According to certain restrictive interpretations of the Geneva Convention, it does not apply to any person who is not individually persecuted by his or her own country, which effectively excludes civil war, whose victims are not individually persecuted.

[6] We should not see in this the evidence of more generosity; because refugees were already present in the Third World, recognizing them did not lead to more migration while enabling them to benefit from international aid if necessary.

TABLE 62–1 Major Texts Cited on the Protection of Refugees

Texts	Date	Supporting institution	Territories concerned	Subject
Geneva Convention on Refugees	1951	United Nations	Initially Europe, then the world since 1967	Definition of the refugee and protection against expulsion at the border
New York Protocol	1967	United Nations	World	Extension of the Geneva Convention to the rest of world
Organization for African Unity Convention	1969	Organization for African Unity	Africa	Explicit recognition of generalized violence in the definition of a refugee
Cartagena Declaration	1984	Government of Colombia	Latin America	Explicit recognition of generalized violence in the definition of a refugee

subjected to constraints of migration policies, which are very restrictive in Europe.

III. GROWTH IN THE NUMBER OF REFUGEES IN THE WORLD

At the creation of the HCR in 1951, the problem of refugees was perceived as temporary[7]; it would disappear with the integration of all exiles in the first host or resettlement countries. In the 1960s, the question of refugees still existed but changed location. If movement toward Western countries was low, new waves generated by conflicts associated with the Cold War begin to appear in Third World countries. It is the strategic importance of an international management of these movements (HCR, 1995) that made possible a lifting of the limitations in time and space initially prescribed by the Geneva Convention.[8] A few years later, unending growth in the number of refugees began. First from Latin America and then Asia (e.g., 1 million Boat People from South East Asia, 5 million Afghans), Africa (i.e., from Mozambique to Liberia through Somalia and Rwanda), and Europe (4 million ex-Yugoslavs), all the continents successively contributed their share of refugees. Despite the wish of the international authorities to encourage a return at the end of every conflict, the number of refugees and other persons under the authority of the HCR rose from 2.4 million in 1975 to 27.4 million in 1995, a quasi-regular increase of 25 million in 20 years. Since then, new conflicts have succeeded the ones that are ending, but the number of persons under HCR authority has been on the decline, falling below the figure of 20 million on January 1, 2002 (Fig. 62–1).

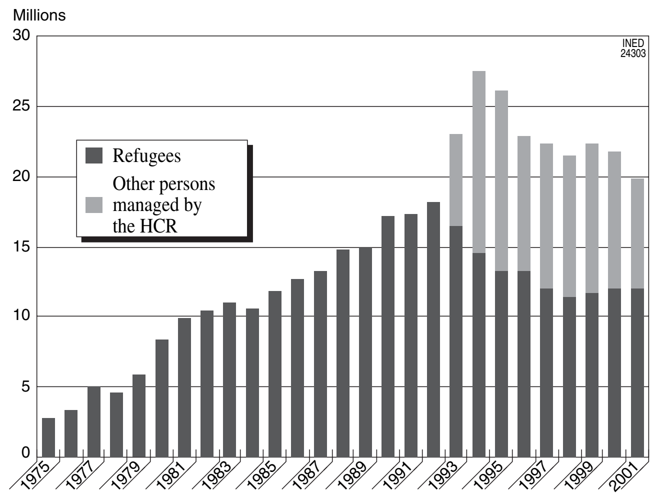

FIGURE 62–1 Trends in the number of persons managed by the United Nations High Commission for Refugees.

These figures do not include the 3 million Palestinian refugees registered by the United Nations Relief and Works Agency for Palestine Refugees in the Near East (UNRWA). This office was created in 1949 to cater originally for 750,000 Palestinian refugees, and one-half century later, this problem remains unresolved, and the number of refugees has increased because of the continuation of the conflict (Israeli-Arab war of 1967) and especially because of natural demographic growth.

The estimate of the number of persons displaced by conflict within their own country and not under the control of the HCR, which by nature is even less precise than that of refugees, is greater than 20 million persons. Currently, political migration may be between 40 and 50 million persons in the world.

[7] The initial mandate of the HCR, drawn up to be very temporary for three years, has since been regularly renewed for 5 year periods.

[8] France ratified the New York Protocol in 1971, after speculating for a long time whether there was a risk of refugees from Africa arriving.

IV. DATA QUALITY

Between the political implications of the number of refugees, the materially difficult conditions of data collection, and the absence of standards in definitions, the available figures on refugees can hardly be better than gross estimates.

The political implications take many forms. Certain countries do not like to recognize the fact that their nationals are fleeing persecution. Others find it useful to attribute a large number of departures to their opponents. For others, misinformation on the number of refugees is an integral part of their political strategy, as was the case in the debate concerning the number of Hutu refugees in ex-Zaire and what became of them during the Kabila offensive.[9] In the host countries, diplomatic considerations sometimes bar access to information on the real figures. To admit receiving refugees from a country with which one maintains very good economic and political relations may be seen as embarrassing. There are also economic implications for the host countries, because most often, the amount of international assistance given to refugees depends on the media coverage of events accompanied by the most shocking images and the most impressive figures possible.

In the zone of origin, conditions do not often allow a precise count of the refugee population. When the situation is unstable and camps move frequently, estimates become even more approximate. The use of indirect methods becomes more common. For example, Médecins sans Frontières (Doctors without Borders) estimated the population of camps in the region of the African Great Lakes by calculating their surface with the aid of the global positioning system (GPS)[10] and then multiplying this figure by a coefficient determined through a survey of enumeration areas. Identification by aerial and satellite photography is also used.

Even in host countries with a strong statistical tradition such as in Western Europe, statistics are not reliable. Even if the validity of data provided by the national authorities is not in doubt, enormous progress remains to be made in the standardization of estimates. For example, until 2002, French figures were based on the number of files of asylum requests, which did not include child minors, whereas German figures often included all members of the family. France still makes available only figures concerning statutory refugees as strictly defined by the Geneva Convention, whereas the German figures include all refugees, whether or not they have obtained the status of refugee according to the Geneva Convention.[11] Another example shows that integration within the host population does not make political refugees disappear from statistics at the same pace in all countries. France more easily naturalizes refugees than Germany. If in the past few years, the European Union has been trying to standardize statistics on asylum seekers (i.e., entries within the common territory); it is totally uninterested in the exits and makes no effort to measure the number of statutory refugees present in the territory every January 1. The European Union does not publish global statistics on this population. It is improbable that this relative ignorance of the total number of refugees protected by the Geneva Convention in Europe is fortuitous, and such a strategy is unfortunate. In France, statistics on statutory refugees, confidential for a time, show that their number has been on the decrease in recent years.

The number of refugees in the world depends equally on the notion employed; the population covered by the HCR includes conventional refugees (recognized within the Geneva Convention, the OAU Convention, the Cartagena Declaration, or HCR Statutes) and various other categories of persons whose definition changes regularly. On January 1, 1995, the 27.4 million persons depending on the HCR consisted of 14.5 million conventional refugees, 3.9 million recently repatriated refugees, 3.5 million other persons, and 5.4 million internally displaced refugees. On January 1, 2002, there were 12 million refugees (but these now included the various precarious or humanitarian sub-statuses created in Western Europe), including almost 1 million asylum seekers, 500,000 repatriated refugees, 5 million internally displaced persons, 240,000 internally displaced repatriated refugees, and 1 million "others." Even independently of these changes in definition, a time-series study of the HCR statistics is very problematic. For example, the distribution between conventional refugees and "others" in the German figures is stunning. At the end of 1999, 2000, and 2001, the number of conventional refugees was, respectively, 252,000, none, and 518,000; the category "others" was, respectively, 723,500, 906,000, and 385,000. The total, however, seems more coherent with, respectively, 975,500, 906,000, and 903,000.

[9] In this case, Western countries supporting rival parties are equally responsible for the misinformation.

[10] Equipment initially designed for aerial and sea navigation which provides a precise position in space based on calculation according to several satellites.

[11] The way of identifying nonstatutory refugees sometimes varies. Between January 1, 1995, and January 1, 1996, the number of refugees in the German statistics compiled by the HCR declined by more than one-half after a change in definition.

The category "conventional refugees" in the strict sense is far from homogeneous. The 14.5 million refugees estimated in 1995 were based on two very different notions. In the Third World, they were defined as victims of persecution of all origin, whereas in Europe, the restrictive interpretation of the Geneva Convention excluded the victims of general violence.[12] If this restrictive definition were to be applied all other the world, the number of refugees in the strict sense of the word would be much less.

V. THE CAUSES OF GROWTH

The increase in the number of refugees in the world since the mid-1970s goes hand in hand with the evolution in the nature of conflicts. A very high level of political instability and a certain "inward withdrawal" of Western Europe marked the second half of the 1970s (Rufin, 1996). Within a few years we witnessed the fall of Saigon; the arrival of new Marxist regimes in Angola, Mozambique, Guinea Bissau, Nicaragua, and Ethiopia; the entry of Vietnam into Cambodia; the invasion of Afghanistan by the USSR; the Lebanese war; the crisis in the Western Sahara; the Tamil insurrection; the Iranian revolution; and the invasion of East Timor by Indonesia. All these upheavals were accompanied by interminable guerrilla warfare whose first victims were civilians. The major characteristic of these so-called low-intensity conflicts is that direct combat between armies is rare, but civilians and economic infrastructures are systematically chosen as targets, thereby leading to an increasing number of refugee movements.

The collapse of the USSR at the beginning of the 1990s reopened a new period of great instability. As observed by Jean-Christophe Rufin (1996), "Since 1990, the possibility of a radical definition of territorial demarcations is no longer taboo, thereby opening a new pathway for the action of armed movements." The disintegration of ex-Yugoslavia is a perfect example of a redefinition that resulted in almost 4 million refugees and displaced persons in Europe. In Africa, the end of the Cold War opened up new political and economic perspectives[13] to guerrillas abandoned by their Western or Communist tutors, and the disintegration of certain countries such as Somalia or Liberia is almost complete. In Rwanda, the Tutsi genocide by the Hutus, followed by the military victory of the Tutsi guerrillas, led to the displacement of 4 million persons, of whom 2.2 million were Hutu refugees outside the country.

Major refugee movements are brought about by civil war. Even if persecutions and individual infringements of human rights are extremely high in the world, victims of collective violence are responsible for most of these movements.

VI. THE DESTINATION OF THE FLOW OF REFUGEES

Refugee movements in the world are extremely local. According to refugee statistics by country of asylum and country of origin published by the HCR, more than 95% of refugees in Africa and Asia found refuge in a neighboring country. Even in Europe, reputed for receiving refugees from all continents, more than one-third of refugees have been European since the wars in ex-Yugoslavia and the disintegration of USSR. These figures concern *stricto sensu* refugees or people recognized as such by a country or by the HCR.[14] It excludes essentially all local movements of "persons displaced within their own country," who are almost as many.

Beyond the neighboring countries and on a worldwide scale, Western Europe and North America (i.e., United States and Canada) are essentially the only destination for Third World refugees.[15] They receive a little more than 1.5 million non-European refugees, who make up about 13% of the total number of refugees and roughly two-thirds of the total in Europe. Migration of refugees is growing equally in all of Eastern Europe. Most of it is purely a local response to the collapse of frontiers in the former Eastern Bloc, but there are also arrivals of refugees from the Third World. For the latter, Eastern European countries are generally only one step toward Western European countries, whose direct access has been made very difficult by restrictions on immigration.

If the destination of "neighboring country" can be immediately understood, the logic governing the destination of "Western country" is much more complex, and an analyst does not systematically perceive the nationalities that have the highest number of refugees in the flows toward developed countries.

[12] Because Europe could not alienate itself from exiles present in its own territory, most of the victims of the conflict in ex-Yugoslavia are recorded in the category "others" of the HCR.

[13] For many leaders of armed movements, profits from illegal goods allowed by a war situation are at least as high a motivation as ideology.

[14] In Europe, Germany includes in its statistics protected war refugees who are not protected by the Geneva Convention.

[15] The other very developed democracies accept only a marginal number of refugees (e.g., 3200 in Japan; 55,000 in Australia; 5300 in New Zealand).

For example, if Afghanistan, Iraq, and Somalia, which were, respectively, the first, third, and sixth country of origin of world refugees at the end of 2001, were the main nationalities of refugees in Western countries; Burundi, Sudan, and Angola, which were, respectively, the second, fourth, and fifth, do not figure. We could also compare the 122,000 refugees from Sri Lanka in the world at the end of 2001, who were mostly present in Western countries, with the 111,000 refugees from Bhutan present at the same time but almost nonexistent in the same countries.

Explanatory factors are multiple and interrelated. First is the very nature of disorder that generates refugees. If most of the movements are purely local, this is because they are of victims of collective violence and that fleeing from massacre leaves no choice of destination. Absolute famine sometimes created by predator guerrillas themselves does not leave a choice either. These major collective movements of flight correspond to the logic of minimum displacement as the destination is generally fixed by the geography of the zones of conflict and refuge is found behind the first international boundary. It is this same logic of minimum displacement that is equally at the origin of the high number of "displaced persons," those who find refuge in another region of their own country and live in the same precariousness as refugees who succeed in reaching a neighboring country. In emergencies, these refugees or displaced persons, even if they wanted to, have absolutely no means of reaching Western countries. The major movements of refugees given the widest media coverage contribute little to the migratory pressure in Europe, except when these movements last a long time.

The destination of individual departures is more complex. Emergency flight in the wake of individual persecution, whether by a dictatorial state or armed groups, is common, but contrary to common opinion, all individual departures are not totally improvised. On the contrary, when the consequences of conflict in social organization is at the source of exile or when the state is deliquescent and the resulting arbitrariness, corruption, and generalized violence make the situation dangerous and life impossible, people start to leave. Not everybody leaves at the same time; the departure date depends on the level of each person's fears, the level of saturation, and especially the level of available resources. These financial and human resources, especially knowledge of migration networks or previous ties with a foreign country, determine to a large extent the chosen destination. Depending on available means, the possibility of choice for refugees will be limited to neighboring countries (i.e., individual movements in the region of origin) or will extend to rich countries. The itinerary to developed countries is most often indirect because of difficulties in the country of origin, particularly the lack of freedom to leave the country if it is run by a dictatorship, and because of restrictions on immigration in the developed countries themselves.

Preexisting organized migratory networks, or those created in recent globalization exchanges[16] (Angoustures, 1996), play a major role in the destination of movements toward the West. In this case, the notion of political asylum and economic immigration slowly blend to become one among asylum seekers.

VII. ASYLUM SEEKERS

The term *asylum seeker* was coined in the 1970s to differentiate refugees who had obtained their status from the mass of persons awaiting the decision that was becoming more and more negative. This expression, which had previously not been used, became necessary when statistically the asylum seekers stopped being potential refugees to become potential rejected asylum seekers.

If certain justified applications for asylum based on indisputable individual persecution have for a long time been rejected because of restrictive jurisprudence that is progressively being abandoned in European countries (France was the last to abandon this at the end of 2002), there are also asylum applicants whose motivations are purely economical. However, these requests are fewer than Western countries would like to make people believe, and in the many cases in which the economic component is strong, it is by no means unique. China is not a model of democracy; the most elementary human rights are often contravened, torture has been institutionalized, and the death penalty is common. One-fourth of the requests for asylum from Asians in 1996 in France came from Chinese. However, it would seem that political opposition members cannot come to France because a major part of the applications come from the Province of Zhejiang, especially the city of Wenzhou, and that the only persecution expressed is that of the one-child policy. According to asylum seekers from Wenzhou, they come to France to improve their conditions of life and escape the control on number of births, especially when their first child is a girl. This predominance of applicants from the city of Wenzhou has historical

[16] The control of commercial migration networks is sometimes in the hands of armed opposition movements, such as the Kurdish groups that control the bus companies and the Tamil groups that manage the networks of travel agencies.

roots going as far back as the First World War. France invited about 140,000 Chinese, almost all repatriated at the end of the war, with the exception of a little group among whom were people from Wenzhou. The latter then initiated a network of migration that prospered between the two wars, was interrupted during the Second World War, and was stopped during the Mao regime, but which took off again with the opening of China since 1979 (Porquet, 1997). France now considers that economic motivations are confirmed and that French society can no longer accept limitless Chinese immigration. The French policy is that limitation of births is not persecution, and consequently, France cannot but systematically reject all Chinese asylum requests. However, major world conferences on population have all affirmed that individuals have "the fundamental right to freely decide in all responsibility and without constraint the number and spacing of their children" (Mexican Declaration on Population and Development). It is true that this declaration aims at promoting family planning and birth limitation programs, but does a fundamental right have to be relative to the country in question? According to the perfect structure of all tragedies, the asylum seekers whose requests have been rejected by OFPRA and OFPRA[17] itself have the law on their side.

There are more examples for which economic factors coexist with political factors, and they show the importance of migratory networks. In effect, the existence of migratory networks has become more and more inevitable with the beginning of very restrictive migratory policies in Europe that practically refuse any legal arrival of asylum seekers.

VIII. ASYLUM POLICY

Speaking of asylum policy in the singular is no doubt excessive, because European countries have not harmonized their methods. However, the dominant attitude, which is clearly repressive, has led to a certain uniformity in practice.

The policy of restrictive asylum is based on two pillars. The first consists in refusing asylum seekers so as not to have to refuse them asylum (Marie, 1996). The second one is based on an interpretation of the Geneva Convention that disconnects the status of refugees from that of the need for protection. In democratic countries, asylum seekers are not refused as such; they instead suffer from measures of general immigration control whose first aim is to prevent them from reaching Western countries and then to transfer them to another country if they arrive.

1. Retention

Retaining asylum seekers at the borders of developed countries is the objective of two complementary measures: imposition of visas on all nationals of potential asylum-seeking countries and fines on transporters of persons not traveling with obligatory travel documents (i.e., visas). The aim is to retain these illegal immigrants at their source by delegating the power of the police to the transport firms (Julien-Laferrière, 1996). These measures have the advantage of replacing the refusal of admission at the borders and the costly and difficult procedures of expulsion with that of refusing embarkation at the country of origin. The effectiveness of these measures lies in the level of the fines imposed and on the list of countries subjected to visas. Currently, 126 nationalities are subjected to visas by all the countries who signed the Schengen Convention.[18]

France provides an example of how general migratory measures affect political immigration. The combined measures of visas and fines on transporters (the two measures are effective only when combined) distort the spirit of the Geneva Convention (Legoux, 1995). A person persecuted in his or her country can expect to encounter difficulties in obtaining all the necessary travel documents, and article 31 of the Geneva Convention stipulates that irregular entry or stay should not bar refugees. In France, article 10 of the 1952 law on the right to asylum (2002 version)[19] confirms this general disposition: "admission may not be refused for the sole reason that the foreigner does not have the documents or visas mentioned." However, article 20b of the ordinance of 1945 on the entry and stay of a foreigner in France[20] indicates that the fine on transporters is not inflicted in two cases only: if the foreigner "who asks for asylum has been admitted into French territory or if the application is not obviously

[17] The French Office for the Protection of Refugees and Stateless Persons (OFPRA) is the organization responsible for recognizing the status of refugee.

[18] France adds 21 other states to a common list of Schengen nations, and the fines for transporters is 10,000 francs (about $1500) per irregular passenger transported. According to a parliamentary report on underground immigration, called the Philibert-Sauvaigo report, the fines inflicted on Air France alone in 1995 amounted to 5 million francs ($750,000), to which was added 6 million francs ($900,000) of charges for the return and the escort of illegal immigrants.

[19] This article borrows extensively from the former article 31b of the 1945 ordinance in its 1993 version.

[20] The ordinance of November 2, 1945, modified version, on conditions of entry and residence of foreigners in France (2002 version).

unjustified" or "if the transport firm establishes that the necessary documents were presented to it at embarkation or if the presented documents do not have any obvious irregularity." Because the agents of the transport firm cannot determine that the border police will recognize the obviously unjustified nature of the asylum request nor the quality of the documents presented, they tend to refuse any passenger without a visa, even if she or he declares wanting to seek asylum on arrival in France. Formally, the absence of a visa is not a condition for refusing asylum requests, but in practice, an asylum seeker cannot use regular transport firms and is forced to enter France illegally. These measures were very effective for the first few years they were in effect, and the number of requests fell from 61,422 in 1989 to 17,405 in 1996. Since then, the networks of irregular entries have adapted themselves, and the applications increased to 47,291 in 2001.

2. Expulsion

When asylum seekers manage to reach a country that signed the Schengen Convention, expelling them is the objective of re-admission agreements. Because of the policy of visas, direct itineraries between the asylum seekers' country of origin and Western countries have become rare and have been replaced by complex itineraries ending with a land entry through the borders of Schengen countries. These countries "have thereafter instrumentalized these itineraries and developed concepts of 'third-party host' or 'secure third-party country' " (Créach, 1997). According to the London resolution of 1992,[21] third-party host countries are those in which the life or liberty of asylum seekers is not threatened and where they have already obtained some protection or *have had the possibility to ask for it*. As soon as it is possible to send an asylum seeker back to such a country, the examination of their request may be refused. Consequently, any country in which the asylum seeker has stayed, even if it is in transit for a couple of hours, may become a destination to return him or her to, if it is considered safe and if it accepts to readmit the asylum seeker. The readmission agreements are precisely aimed at obtaining the agreement of these countries and are sometimes accompanied by financial compensation. The agreement between Germany and Poland provided 120 million German marks (60 million dollars) to the police of Poland, and another between Germany and the Czech Republic provided 60 million German marks (30 million dollars) to the Czech security forces involved with guarding the borders.

The generalization of readmission agreements[22] gives rise to the possibility of true "expulsion chains" resulting from cascading readmissions from third-party country to third-party country, pushing asylum seekers to the periphery of Western countries. The ultimate objective of the readmission agreement is to constitute "a network of third-party countries promoted to the grade of advanced border-guards of the Schengen plan of action. . . ." The major consequence of this "advance protection" is to remove all meaning from the principle of "non-refoulement" or nonexpulsion of the Geneva Convention by replacing it with the principle of nonentry (Marie, 1996).

3. Interpretation of the Geneva Convention

After asylum seekers have reached a Western European country, applied for asylum, and are not the object of a readmission agreement, the final obstacle is the analysis of their request by the competent authorities. The level of rejection is very high, about 90% of requests in most countries in the Schengen area.[23] This rejection is based on an extensive use of the notion of "obviously unjustified request" and on the systematic doubt concerning persecutions not proved beyond reasonable doubt. The notion of "obviously unjustified" makes it possible for most countries to use procedures of rapid and expeditious judgment that often dispense with providing temporary residence rights to the seeker. The proof of persecution is not formally demanded, but the benefit of the doubt is never to the advantage of the asylum seeker. Illegal entries due to visa refusals and the fear of being expelled oblige asylum seekers to lie about their itinerary, which increases the doubt.

In total opposition to the HCR understanding of the Geneva Convention, France and Germany, followed by other European countries, wanted to reduce the number of refugees by excluding all nonstate persecutions from the Geneva Convention. Persons recognized as being in danger in their countries but whose request for asylum had been rejected could nevertheless, in certain cases, obtain the right to a more or less protective residence for humanitarian reasons. This is

[21] "Resolution on a harmonized approach of issues relative to third party host countries" was adopted in London on December 1, 1992, by the Ministers of Member States of the European Committee in Charge of Immigration.

[22] The asylum section of the Schengen agreement is already a readmission agreement between all the member states.

[23] The proportion of recognition displaced by France is higher (up to 20% in 1996), but close to one-half of the recognition considered relates to purely official requests of children of refugees already present in France and approaching 18 years old.

called subsidiary protection, humanitarian status, or B status. This restrictive interpretation of the Geneva Convention, which contributed significantly to the development of subsidiary protection in the past 10 years, has been abandoned, but the sub-status designations remain.

IX. NEGATIVE CONSEQUENCES

Effectively prohibiting the regular arrival of asylum seekers provokes fraudulent commercialization of assistance to cross the borders of developed countries, which itself has serious negative effects. The first consequence is the selection by money; the cost of introduction into Western Europe by Mafia-type professionals is between 20,000 French francs ($3000) for Turks to 100,000 francs ($15,000) for Chinese from Zhejiang; the trip between Shanghai and the United States can cost as much as $50,000 (Porquet, 1997; Marie, 1996). Even if a large part of this amount is payable on arrival after having found an illegal job, the victims of persecution forced to hastily leave their country are not in a position to employ these indispensable networks to cross the borders of developed countries. Another penalizing effect for political asylum seekers is that the authorities consider the use of immigration networks as an indicator of economic motivation for the asylum request. The sale to candidates of false papers and stereotyped asylum requests along with the trip contributes to this disqualification of request, especially because the necessity of dissimulating the conditions of their arrival pushes them to tell unconvincing tales. The traffic of persons is often accompanied by that of legal and illegal products, and this association highly discredits political immigration in public opinion. The cost of access to the asylum request provokes indebtedness, which makes return immigration impossible and imposes an underground life for asylum seekers whose applications have been rejected.

The measures designed to hold back the incoming flow of asylum seekers create the conditions for rejecting numerous requests, thereby creating a vicious circle in which a lack of respect for the right to asylum is self-justified.

X. INFORMAL ASYLUM

Before immigration restrictions were implemented in Europe in the mid-1970s, numerous political exiles found refuge in the Western democracies under the cover of the status of economic refugee. Consequently, the political immigration of Greeks and Portuguese hardly used the status of refugee, and many Republican Spaniards who arrived in France in 1939 after the Franco regime took power did not ask for refugee status until 10 or 20 years later. At that time, economic immigration was a possible alternative to political immigration, and it offered the advantage of not breaking ties with the country of origin. In France, even after 1974, many refugees from Chile did not ask for asylum until many years after their arrival, when the status became indispensable to avoid being expelled. When immigration for work was stopped, these incoming flows of political exiles very logically transformed themselves into those of asylum seekers. Currently, it is political asylum that is less accepted, and political exiles use the latest avenues possible: temporary protection provided by the duration of the examination of the asylum application and underground immigration.[24]

Confronted with massive rejections of their asylum requests, these exiles have obviously developed alternative strategies using the request for asylum as a means of temporarily regularizing their situation. Multiple applications in many countries (i.e., asylum shopping) have been a strong justification for the asylum section of the Schengen plan of action and then of the Dublin Convention, but this plan of action does not seem to be dissuasive. In France, the example of Romanians is very instructive about the use of asylum procedures to obtain protection normally refused by the host country. After the fall of Ceausescu, France decreed that Romania had become a democratic country and undertook to remove asylum status from all previously recognized Romanian refugees; under these conditions, new applications for asylum have been systematically rejected. In 1996, there were more than 4000 Romanian applications, amounting to 23% of the total applications from all nationalities. Apparently, the geographic proximity reduces the efficiency of procedures for holding back the flow. According to many studies,[25] it seems that these applicants, often Gypsies, have assimilated the fact that their applications would be rejected, but they have continued to use the asylum procedure in a sort of circular migration that provided them the financial resources necessary to fight against the social and economic discrimination

[24] In certain cases, it may be preferable to speak of illegal immigration. In France, the public struggle of the Sans-Papiers (those without papers) has shown that they are not illegal aliens in the strict sense of the word.

[25] Studies were directed by Olivier Brachet, an economist and the director of Forum-réfugiés (Refugee Forum, formerly Comité rhodanien d'accueil des réfugiés et de défense du droit d'asile), which is based in Lyon.

of which they were victims in Romania. Since 2002, Romanian nationals are exempted from the visa obligation to enter France, and the requests have greatly diminished.

Underground existence is the most precarious form of protection, but it is the ultimate refuge for many seekers whose applications have been rejected and who are awaiting a hypothetical regularization of their papers. Depending on the country, the presence of illegal aliens is more or less accepted. In France or in Italy, this seems to be a quasi-normal way of managing persons (Brachet, 1997), and this informal extralegal asylum contributes to the debate around conventional asylum.

XI. TRENDS

Even though it takes place in the context of democratic countries, the subjection of asylum policy to migration policy leads to negative practices that are shaking the whole edifice of the right to asylum. The retention of refugees outside developed countries, the legal controls that promote the nonrecognition of the status of refugee, and the multiplication of substatus designations and informal asylum show that the great principles of the protection of victims of political persecutions, at one time recognized for its universal nature by the Geneva Convention, are not respected in European democracies. For many years, the fear of a decline in the protection of human rights in the case of renegotiation of what is sometimes called *The Geneva Regime* (Zolberg, 1992) has led defenders of asylum rights to affirm the unsurpassable character of the 1951 Convention. However, the Geneva Regime is being progressively eaten from the inside by its very founders, and it is now time to explore new solutions.

1. Temporary Protection

For many years, provision has been made for resorting to temporary protection. A former director of international protection at the HCR already mentioned this in 1992 as a possible solution for Europe (Moussalli, 1992). In abandoning the right to permanent residence for statutory refugees, temporary protection makes a partial disassociation between asylum policy and migration policy possible. During the Kosovo crisis, most countries in the European Union set-up temporary *de jure* or *de facto* protection. France created a special plan of action for people from Kosovo, offering them temporary residence rights and the right to work if they did not ask for conventional asylum. Because this crisis had exposed evidence of differences in the treatment of temporary refugees in the European nations, the European Council in 2001 adopted a directive on temporary protection meant for massive incoming flows of displaced persons. It is an exceptional mechanism that offers a 1-year renewable protection and the right to work and to social benefits. It can be set in motion by the Union's Council of Ministers. The principle of double accord, that of the persons concerned and that of the host country, preserves the sovereignty of states in this European procedure.

Subsidiary protections are also a form of temporary protection. In France, territorial asylum was created in 1998 because of the issue of Algerians persecuted by groups of armed Muslim militia who could not be recognized as refugees because of jurisprudence excluding nonstate persecution from the protection of the Geneva Convention. At the end of 2002, France gave up this jurisprudence but retained territorial asylum, which was meant to be renamed subsidiary protection and administered by OFPRA[26] in a new reform of asylum planned for 2003. This temporary asylum is explicitly subjected to the interests of the host country in the very text of the law:

> In the conditions compatible with the country's interests, territorial asylum may be accorded to a foreigner by the Minister of Interior after consultation with the Minister of Foreign Affairs, if the foreigner establishes that his or her life or liberty is threatened in his or her country or that she or he is exposed to treatment contrary to article 3 of the European Convention of the protection of human rights and fundamental freedom. The decisions of the Minister do not have to be motivated.[27]

Statistics show a rapid growth in territorial asylum: 6984 applications in 1999; 11,810 in 2000; and 31,000 in 2001, according to figures cited in the asylum reform project (but only 15,700 in the preliminary statistics of the Interior Ministry). The number of residence permits delivered is very low: 292 in 1999, 351 in 2000, and approximately the same in 2001.

The major problem in using temporary protection is the duration of the temporary period. In the case of quick repatriation, obliging refugees to return to their countries if all security conditions are met. However, when conditions at the origin of exile cease after many years, certain refugees who are well integrated in the host society may see possible expulsion as a new form of persecution based on their nationality. The principle of temporary protection therefore separates asylum from the hazards of the migration policy only very

[26] Communication of the Minister of Foreign Affairs during the Council of Ministers meeting of September 25, 2002.

[27] The law on asylum rights of July 25, 1952, was modified by law no. 98-369 of May 11, 1998.

imperfectly, especially if the motivation for exile is perceived as resulting from a long-term situation. For example, persecutions based on sex are associated with cultural considerations that are reputed to evolve only very slowly, and it is unlikely that protection given for such a reason can be considered really temporary.

2. Defense of the Right to Remain in One's Own Country

A statement from the HCR perfectly summarizes the evolution in United Nations doctrine on the problem of refugees:

> During the years of the Cold War, the determination of Eastern countries to prevent the departure of their citizens led the international community to concentrate most of its attention on the right to leave one's home country. . . . Those who succeeded were transformed into heroes, an attitude which reflected and conditioned the exile-oriented approach as a response to the problem of refugees. . . . But since the collapse of the Soviet Bloc, the wheel has turned such that it is more a question today of the right to remain in one's own country and that of not being displaced (HCR, 1995).

The fine-tuning of the human rights issue is glaring. From an instrument in the East-West conflict, acceptance of refugees has become a liability that henceforth must be borne by the countries of origin. This total inversion of perspectives explains the current interest in the prevention of refugee movement and consequently the prevention of conflict.[28] At the same time, we discover the negative effect of resettlement programs or the prolonged assistance of refugee populations that have sometimes been an obstacle to the search for solutions in their countries of origin.[29]

The HCR firmly states that actions in the country of origin must not be transformed into arguments to justify the closure of borders to refugees nor used as a means of locking them in their countries under the pretext that international humanitarian organizations have created zones of security within these countries, because these zones are more often virtual than real, as has been shown by the massacres in the humanitarian enclaves of Bosnia.

The new paradigm of the right to remain in one's country cannot be conceived without political development. Respect for all individual freedom is necessary for the exercise of the right to remain. It cannot be conceived without economic development, because economic exploitation is at the origin of many conflicts, and periods of economic regression are the most conflicting ones because of the increase in competition for the control of resources (HCR, 1993). This paradigm therefore revisits the old problem of development as an alternative to purely economic migration and encounters the same limitations. At the first stage, a certain freedom regained from the emergence of a new way of life may increase migration instead of reducing it. At a second stage, development as a solution to migration implies a very strong reduction in inequalities between countries, whereas the process of globalization tends to amplify them.

While recognizing the declared wish of the United Nations to attack the causes of political migration, it is impossible not to recognize its chronic impotence, whether in Sarajevo, Grozny, or the catastrophic extermination of Rwandan refugees in the forest of Zaire. The right to remain in securely within one's own country is still an elusive objective like that of a better world permanently rid of war. Before that great day arrives, political pressure will remain a strong determinant of international migration.

[28] This interest is not new; in 1985, the UNO affirmed "the causes of refugee movements constitute an essential aspect of the solution and international efforts must also be geared toward the elimination of these causes. We also should be more interested in the causes and the prevention of refugee movements" (Michel Moussalli 1992).

[29] "Currently, it is believed that the international community's response to refugees in the 70s and 80s is perhaps not foreign to the level of the problem in the 90s" (HCR 1995).

Individual and Social Motivations for Migration

DANIEL COURGEAU AND EVA LELIÈVRE

Institut national d'études démographiques (INED), Paris, France

Any study of the motivations for migration behavior must also examine those that cause individuals to stay in the same place. Moreover, there is no reason to suppose that these motivations are the same for people who move short distances (e.g., intracommunal migration) as for people who move longer distances (e.g., interregional migration) or for nonmigrants, who do not change residential location. In this chapter, therefore, we examine both nonmigrants and migrants according to the type of *mobility* that they experience.

As a general rule, the term *mobility* is used here to denote all the moves undertaken by the individuals in the group being studied. Depending on the type of study to be conducted and the data available, it is possible to consider some moves as *migrations* while excluding others from analysis.[1] However, the individual lives in a space where administrative boundaries (e.g., communes, departments, and regions in France) often play a limited role in mobility within the country while possibly playing a more important role in international migration.

An analysis of the motivations for migration behavior also needs to consider them in interaction with all the other elements in the life of the individual. The reasons that "push" individuals to move, like those that cause them to stay in their group of origin or current dwelling, can only be understood when related to their past experience and present circumstances in the domains of family, work, and so on. The attraction of a higher income powerfully favors a move for a young adult living alone, whereas it has far less impact for an older individual with a wife who works and children, because of the risk of losing the wife's income and a reluctance to uproot the children from their school. In these conditions, motivations cannot be spoken of in absolute terms, but always with reference to the context of individuals in domains such as family life and career.

It is also necessary to introduce the information available to the potential migrant about the advantages and disadvantages of the choices between different destinations. Individuals are more likely to choose a destination region about which they have ample information through an extensive network of contacts than one about which their information is limited and obtained merely though the press. However, an individual who is well integrated in a neighborhood or town or city where most of his friends and relatives live has little incentive to move to another place.

The definition and measurement of motivations can vary greatly depending on the level of aggregation at which we are working. When survey data are being used, the motivations for migration can be introduced directly, if the survey subjects have been questioned about them. It is also possible to examine the dependencies between residential relocations and the individual's other life-history processes. The latter

[1] The definition of migration depends on two criteria—distance and period of residence—which are determined in the context of each individual study (see Chapter 22).

approach, less subjective than the former, is better suited for identifying the nature of the reasons for moving. Rather than working at the individual (micro) level, an aggregated (macro) level can be adopted when using census data, for example. Stronger assumptions then have to be made about the migration flows observed and about the various characteristics measured for each zone. A model of individual migration behavior underlies such an analysis (Puig, 1981). Validation of these underlying models calls for a more detailed analysis of the linkages that exist between micro-level and macro-level models.

I. THE COMPLEXITY OF MIGRATION BEHAVIOR

Before considering the individual reasons that affect mobility decisions, we need to take another look at the complexity of the analysis of geographic moves and the influence on them of other events. This analysis, i.e. an examination of the endogenous factors that motivate moves, only becomes meaningful if we envisage the interactions between multiple processes. For although a move can be motivated by a family event, another event affecting the family can be a cause of nonmigration or be the consequence of a move.

There are two elements to consider: mobility just as much as immobility and the implications of mobility for the demographic processes occurring in the other life domains of individuals. The latter aspect is not the subject of this chapter and is therefore not discussed further. Nonetheless, we felt it important to stress the need to envisage reciprocal dependencies in the analysis of individual behavior (Lelièvre, 1992).

1. Another Look at the Effect of Age

Migration rates by age based on data from the French 1999 Census exhibit a highly characteristic profile (Fig. 63–1). These are annual rates for residential mobility (movers) and for interregional migration.[2] This is a relatively universal profile, very close to that observed in other national contexts. Up to age 17, individuals' mobility parallels that of their parents, i.e. that of economically active adults between the ages of 30 and 47 years. Between ages 18 and 30, a sharp increase in mobility is observed, which is attributable to young people entering the labor market, leaving the parental home, moving into first union—in short, the mobility corresponding to the transition to adulthood. A small rise is observed around retirement (between ages 60 and 70), followed by an increase in mobility in old age, especially for women, corresponding to moving into care accommodation or to being looked after by one's children. The differences between the sexes reflect the age differences at which family and occupational transitions are made by individuals of opposite sex.

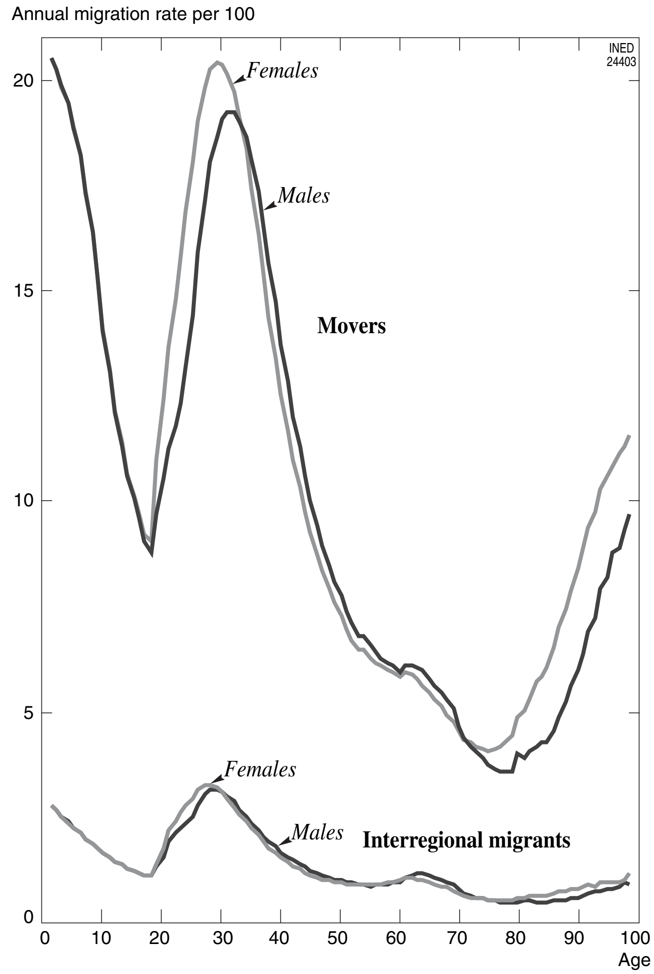

FIGURE 63–1 Residential mobility and interregional migration by age and sex (1999 French census). These estimates differ from those given by Baccaïni (2001) because of the inclusion of changes made between 1982 and 1990 and between 1990 and 1999 in the parameters used to convert inter-census data to annual data (Courgeau, 1973, 1979). These new estimates were produced using results from the French Labor Force Surveys for 1990 to 1999 and from the Jeunes et carrières (i.e., Young People and Careers) survey (INSEE, 1997) by Franck L'Hospital (2001). They are also consistent with data from France's electricity supply company (EDF) (Courgeau *et al.*, 1999, 2000).

The curves for residential relocation and interregional migration have broadly the same form, with just a difference in the multiplying factor. This confirms the choice made in the introduction of considering mobility as comprising the set of all spatial moves, with the

[2] In the case of France, this is a division into 22 regions. The direction of the flows is not discussed here (see Baccaïni, 2001).

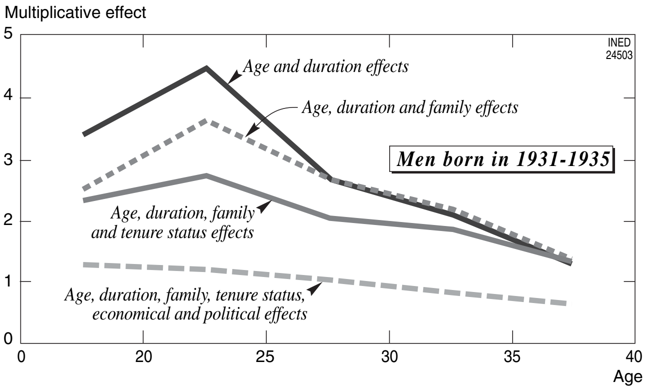

FIGURE 63–2 Multiplicative effect of age on male mobility by variables in the model used in the French Triple Biography survey of family, employment, and migration histories.

option then of considering only some of these as migratory moves. We shall see that the motivations involved are the same, some having greater impact for long-distance migration, others for short-distance moves.

In addition to a discussion of this classic distribution, a description based on analysis of individual-level data is now possible. Figure 63–2 shows the distribution (for the male population) of the effects of age, as estimated by a Gompertz type regression, modelling age at last move and duration of stay (Courgeau, 1985). A series of models are estimated, into which are introduced an increasing number of variables controlling the stages reached by the individual in his or her various life domains.

The age effect, controlling for the duration of stay, is very similar (disregarding the scales) to the curves in the previous diagram: a peak of mobility observed around age 22.5 gives way to stability. This time, however, the successive models make it possible to separate clearly what corresponds just to an age effect from what is the result of the variables characterizing the stages in the individual trajectories.

By first introducing the variables controlling for the stages of the family life-course trajectory (essentially marriage, divorce, and successive births), the effect of age alone is seen to be reduced between ages 15 and 28. Introducing the move into owner-occupation brings a further reduction in the age effect, this time across all the ages considered. In the full model, which introduces variables characterizing labor force status (military service, economically active, unemployment), type of job held, and macroeconomic conditions (e.g., period of wartime, crisis of 1931 or of 1974), the age effect disappears completely.

Age is clearly a proxy variable that captures, combines, and synthesizes the effects of the other processes at work in individual trajectories. It is therefore pertinent to try to identify the specific influence on mobility. Empirical distributions suggest that these effects occur at particular points in the trajectory and modify mobility over the lifetime of individuals. This leads us to favor, when the data are available, a longitudinal event history approach (see Chapter 23), which is the only satisfactory method for studying these changes.

2. Measurement of Mobility over the Individual Life-Course Trajectory

Event history data are extremely rich and allow mobility to be studied in a variety of ways that produce results that could be thought contradictory. It is therefore necessary to review these approaches whose implicit assumptions have a powerful influence on the results.

First, event history data files enable the changes in the migration behavior of individuals to be observed in relation to changes in, for example, marital status and work histories. For the case of marriage or divorce, both of which correspond to times of high residential mobility, it can be shown that these events also initiate new and highly specific periods of mobility. After the initial residential changes, marriage has a powerful stabilizing effect on individual mobility; divorce, by contrast, marks the start of a period of residential instability (Bonvalet and Lelièvre, 1991).

Second, at the time of the survey a summary statement of mobility (in the form of the number of dwellings) of the individuals questioned is obtained. This can be broken down according to the available characteristics, such as marital status at the time of the survey, family size, and occupational status at the time of the survey.

Because the key events in family life (e.g., entry into union, birth of children) and in occupational life (e.g., first job, changes) are very likely to be accompanied by a residential relocation, we can safely predict a higher number of dwellings for those with the most status changes in their family and occupational lives. The presentation of such a migration history provides the basis for valuable comparisons (Lelièvre, 1990a, 1990b; Bonvalet and Lelièvre, 1989).

One way of using these categories defined on *a posteriori* criteria is to differentiate, for example, the parents of three children or the permanently single at any point in the life course. This technique, although potentially highly instructive in a later phase of the analysis, produces results that must be used with caution, and for this reason, it is not recommended for an initial approach. It involves differentiating before family formation has even begun the future parents of three children from those who will have only one child

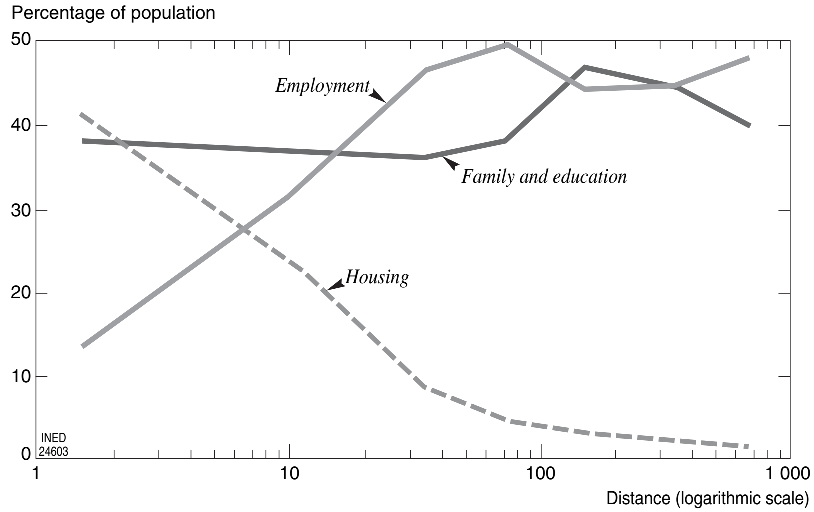

FIGURE 63–3 Reasons for migrations relative to distance (in kilometers) as found in the French Triple Biography survey of family, employment, and migration histories.

or the permanently single from those who will later form a union. It can be used, however, to test for possible selection processes. In the study of migration to France's principal metropolitan areas,[3] it could be shown that the fertility regime of migrant women was different from that of nonmigrants outside the metropolitan areas even before they moved to the highly urbanized regions. In other words, a definite selection process was at work. In the case of migration away from the metropolitan areas, no selection occurred because no distinction could be made between the fertility of future movers and nonmovers in the metropolitan areas (Courgeau, 1987; Courgeau and Lelièvre, 1989, 1992, 2001).

Although summary statements should not be ignored, they give an overly aggregate view of the different facets of individual life course trajectories. An average value for the number of moves per status at the time of the survey cannot take account of a fall followed by a rise in the propensity of individuals to move over their lifetime. Such summaries can only be established for groups exposed to the risk of moving over periods of the same length. An average number of dwellings for individuals in a 10-year age range lumps together in a way that varies with age group people who are in a phase of intense mobility with others who are in a period of stability. This biases the summaries.

The procedure whereby selective behavior is tested by examining the differential behavior of future categories must remain an empirical exercise to be used with caution.

[3] The regions of Paris, Lyon, and Marseille (see Courgeau, 1987; Courgeau and Lelièvre, 1989, 1992, 2001).

When longitudinal data are available, an analysis by duration of stay (if the data permit) can alone reveal the changes in mobility behavior over the lifetime of individuals.

3. The Motivations for Mobility

Determining the relative importance of the motivations quoted by individuals to explain their moves is a particularly difficult exercise. In part this is because these moves are very likely to be distributed differently depending on cultural context and historical period. Family-related reasons appear to dominate, at least for residential mobility, and work-related reasons dominate for longer-distance migrations. In the American context, Peter Rossi (1980) finds "the major function of mobility to be the process by which families adjust their housing to the housing needs that are generated by the shifts in family composition" (Rossi, 1980, p. 35). For France, Brigitte Baccaïni (1991) has shown how the reasons invoked to explain or justify a residential relocation vary with migration distance (Fig. 63–3). Over short distances (i.e., intracommunal moves), housing factors (e.g., entry to owner-occupation, home improvement, or enlargement) are the most important, whereas employment factors are negligible. The latter rapidly become more important with migration distance and form the majority of migrations at medium distances (i.e., intraregional moves), whereas family-related reasons remain at the same level up to a distance of 100 km. For the longer distance interregional migrations, housing factors account for a very small minority, and family and employment factors are on the same level. All of these motivations have a role, regardless of migration distance, but their importance varies with this distance.

Although the stages of the family life-course trajectory have a direct impact on the propensity of individuals to migrate, these stages occur within a context in which motivations are evaluated and acted on differently by individuals. Gary Sandefur (1985) has shown that the importance of motives for migrating depends strongly on the stage individuals are at in their life-course trajectory. Also, these reasons are reconstructed, often *a posteriori* as is the case in a retrospective survey, and only have the value attributed to them by the individuals required to justify or explain a move in the interview.

When event history data are available, a less subjective way to determine the nature of the motives for migration is to test the dependencies between mobility and other processes. The moves considered can be diverse in kind, ranging from simple residential relocations or even daily home-to-work journeys, up to interregional migration, depending on the level of precision of the data collection.

Despite the pertinence of event history methods, their application has limits that first need to be identified. Although a study of the interactions between marriage and migration proves particularly suited to this approach, we might want to carry out such a study between divorce and migration, and this is less straightforward. In the former case, selecting an origin that is common to both processes[4] presents no problem; for example, we could examine first marriage and the move into an independent dwelling. In the case of divorce, it appears virtually impossible to give an unequivocal definition of the specific move (which will be the same for all the individuals) from among the migration events to associate with the divorce, without making explicit reference to the breakdown of the couple. However, if we choose the move that precedes or follows the divorce, a study of interaction becomes meaningless.

Another difficulty, less trivial than it appears at first sight, stems from the structural transformations affecting relations between individuals. Although living as a couple still concerns the majority of individuals, the growth of cohabitation makes it harder to identify the entry into union. In the same way, well-defined events like divorce do not necessarily correspond to the point in time when the partners actually separated.

To illustrate these various points we now give a brief overview of the results obtained using event history data.

[4] This is one of the conditions for implementing the analysis (Courgeau and Lelièvre, 1989, 1992, 2001).

4. Some Significant Results

The following results are derived mainly from the analysis of data from the French Triple Biography survey of family, employment, and migration histories (also known as the 3B survey), conducted by the Institut National d'Études Démographiques (INED) in 1981. This highly innovative survey took the form of a retrospective collection of longitudinal event history information on individuals born between 1911 and 1935. The sample was nationally representative and contained 4602 individuals (Courgeau, 1985). These data allow us to examine the residential trajectories of these cohorts using the approaches described previously. We begin with the case of the different effects of marriage on individual mobility, which we believe is very explicit.

a. Marriage, a Factor of Mobility and of Greater Residential Stability

The survey data capture the mobility linked to this key event in the family trajectory of individuals. For the cohorts born between 1911 and 1935, marriage was associated with a move to a new residential location (Table 63–1). Marital status at the time of entry into a first independent dwelling explains the differences observed by sex. Forty-seven percent of men moved into an independent dwelling before they married, whereas women in these cohorts, who moved out of the parental home on average a year earlier than the men, more often moved at the time of their marriage (51% of women versus 39% of the men in the French 3B survey). Women are clearly more likely to change place of residence at the time of their marriage, and this move corresponds more often for them than for their partner with leaving the parental home.

Residential mobility is closely related to family events. Marriage usually results in a move by at least one of the partners, whereas divorce works in the opposite direction, resulting in the departure of at least one of the former partners. The results in Table 63–2 confirm these tendencies. Individuals who were single at the time of the survey were the least mobile, with

TABLE 63–1 Proportion of Individuals Changing Residence when They Married as Reported in the French Triple Biography Survey

Group	Cohort 1911–1925	Cohort 1926–1935	Total
Men	44.9	50.8	47.8
Women	64.8	66.4	65.5
All	55.6	58.7	57.4

TABLE 63–2 Average Number of Dwellings at Age 45 Years by Marital Status at the Time of the French Triple Biography Survey

Marital status	Average number of dwellings (standard error, 95% level)	Number
Single	2.13 (± 0.34)	189
Married	3.15 (± 0.12)	1385
Remarried	3.87 (± 0.48)	86
Divorced or separated	0.80 (± 0.13)	164

TABLE 63–3 Average Number of Dwellings Occupied for More Than 1 Year according to Marital Status at Each Age and at the Time of the French Triple Biography Survey

Marital status by age and at time of survey	Average number of dwellings (standard error, 95% level)	Number of people surveyed
25 Years		
Single–single	0.80 (± 0.13)	396
Single–married	0.90 (± 0.10)	1017
Married–married	1.55 (± 0.06)	1959
30 Years		
Single–single	1.19 (± 0.17)	396
Single–married	1.34 (± 0.20)	367
Married–married	2.06 (± 0.06)	2609
35 Years		
Single–single	1.52 (± 0.19)	396
Single–married	1.42 (± 0.30)	134
Married—married	2.51 (± 0.06)	2842

one in three of this group having never moved out of the parental home (many were farmers); these were usually individuals who never married and had very limited migration histories, and whose behavior contrasted sharply with that of single people who were not yet married. Next came married people, and the highest mobility was observed for the divorced and remarried. However, these results in no way take account of changes in mobility in the course of the trajectory.

As part of the attempt to measure the effect of marriage, Table 63–3 presents a description by current marital status and that observed at the time of the survey to capture the mobility of single people and the impact of marriage. At the three ages considered (25, 30, and 35 years), individuals who are single have practically the same mobility whatever their subsequent marital outcome. For married individuals, the average number of dwellings occupied is markedly higher at each age, revealing an effect of marriage on residential mobility.

This set of three tables is characteristic of the descriptive results commonly presented. Table 63–1 measures mobility at the time of marriage, Table 63–2 gives a summary comparable to that we would obtain with period data, and Table 63–3 is an attempt to capture mobility across the life-course, which turns out to be not very convincing.

Event history analysis is alone able to take into account the changes in the migration behavior of individuals, and its application reveals the second characteristic of the longer-term influence of marriage, the stabilizing effect (Courgeau, 1985), which is particularly clear, corresponding to a large slowdown that reduces mobility by one-third (Fig. 63–2). We see that an average value for the number of residential locations cannot reflect a rise followed by a fall in the migration propensity of individuals over their lifetime. Information derived only from this type of result is therefore completely inadequate for capturing the influence of an event on the mobility of individuals, and an event history analysis of such data has become indispensable. Implementing such an analysis is straightforward using widely available software.

b. Individual Mobility and the Arrival of Children

An event history analysis of the interactions between mobility and parenthood reveals in a few precise instances an effect associated with the birth of children. The increase in mobility that would be expected after successive births is observed only for women who married before age 22 (Courgeau, 1985). It can be assumed that these couples have had to adjust the size of their housing *a posteriori* to that of their family. This contrasts with couples who married later and who probably already had a dwelling more adapted to their desired future family size, which would explain the absence of any significant increase in mobility after the births. For the couples who married later, a solution employed by these cohorts to have more dwelling space was the move to home ownership, whose stabilizing effect has been combined with that of marriage.

In this case, when a summary is prepared showing the average number of dwellings occupied according to family size reached at the time of the survey, we find that childless couples have on the whole moved less than the others, but the differences observed thereafter

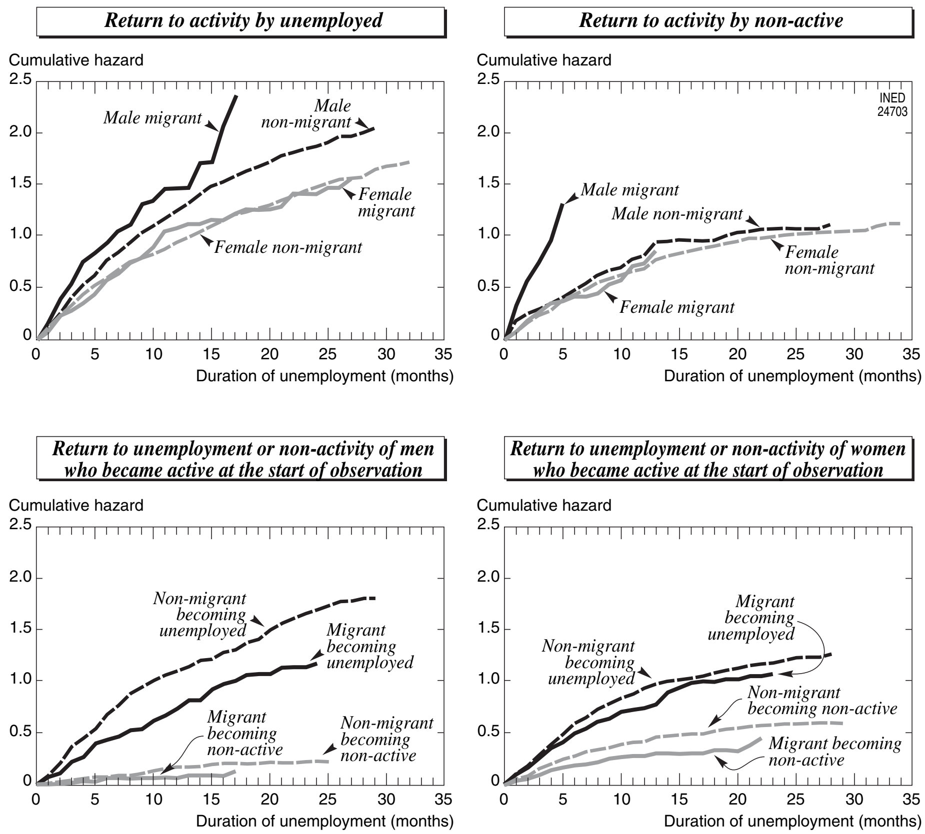

FIGURE 63–4 Mobility and economic activity in France between 1991 and 1995 as found in the Labor Force survey (INSEE). (From Courgeau and Meron, 1995, p. 22.)

are not statistically significant. In this information, we capture the description of the mobility of very specific categories and not the effect of births over the lifetime of individuals.

A similar analysis of the interactions between intraregional or interregional mobility and the birth of children was also conducted for Norway using data from the Population Register (Baccaïni and Courgeau, 1996). For the cohorts born in 1948 and 1958, the birth of a first child leads to increased short-distance mobility in the year of this birth and the following year. After this 2-year period, this mobility is reduced for interregional migrations or for higher-order births. In this country, the adjustment of housing size, when it is necessary, occurs after the first birth, and it is not observed for subsequent births.

c. Mobility and Economic Activity

Spatial mobility also has complex links with employment. In France in the early 1990s, it was observed that migration by a couple was more likely to lead to unemployment of one partner, usually the woman, the greater the distance moved (Courgeau and Meron, 1995; Figure 63–4). Twenty-seven percent of economically active women who were employed and who changed region became unemployed, compared with only 4% of those who did not move. For economically active men, these rates are 8% and 2%, respectively, which shows that they are also subject to this effect but to a lesser degree. It might be thought that because these migrants are cut off from some of their existing networks for integrating the labor market, they would have more difficulty finding work. However, this is not what is observed. Male migrants more often find work than nonmigrants, and no difference in behavior is found for female migrants. Moves are not made to a region picked at random, but to a region where the individual already has well-established relational networks.

Unemployed and economically inactive persons are more likely to find work when they are migrants than nonmigrants. Among nonmigrants, 41% of unemployed persons and 14% of the economically inactive find employment in the course of the year, and these percentages rise to 57% and 47%, respectively, among movers. Turning next to examine the stability of the work found by these individuals, we see that the return to unemployment or nonactive status is much slower for men and women who moved than for the nonmigrants. We can conclude that persons who have moved to find a job are better placed to keep it than those who took what was available in their existing place of residence. The cost of migrating must be evaluated in relation to the more stable nature of the work obtained after moving. The small numbers of individuals who take this course are clear evidence of the difficulty associated with such a reorientation.

5. Choice of Destination: The Role of the Personality of the Individuals and the Information Available to Them

Humans do not live in a homogeneous space about which they have all the relevant information necessary to decide about a possible migration. They inhabit a heterogeneous space about which they possesses information that is imperfect and that changes over time. The same applies to the means for acquiring this information through relational networks, through the press, or by any other means of diffusion.

One way to get a clearer view of this information is to capture it using surveys that identify the mental maps of individuals living in various locations, according to their age (Gould, 1975). Research on this subject has shown the construction of mental maps during an individual's childhood through adulthood. These maps reflect a sharply contrasted knowledge of the zones studied, with a maximum of information around the place where the individual lives and with relative maxima around the most densely populated centers. This information can then be modeled as a function of the distance of the individual and the populations from the different places in the country. Variables other than age can usefully be introduced; educational level, occupation or nonactivity, and the rural or urban milieu in which the individual lives are all characteristics with the potential to modify these mental maps. It is easy to imagine the complexity of the information that must be collected to facilitate understanding of these various maps.

A second method is to model this information in a more *macro* approach to individual behavior. Let us assume that the individual in a given region has perfect information about the other regions to which he can migrate. The probability for him of choosing region j is equal to the attractiveness specific to this region, divided by the summed attractiveness of all regions. Such attractiveness can be measured as a function of the various characteristics of region j: its unemployment rate, average income levels, the proportion of the population working in the agricultural sector, and so on. However, we must take account of the fact that the choice of the region of destination is not independent of the region of origin. The information the individual may have about the different destinations is a function of the proximity of the places, his or her occupation, income, and other factors. This means that we can write the probability of choosing destination j, knowing that the individual lives at i, in the following form:

$$\text{Prob. (choose } j/\text{living at } i) = \frac{p_j q_{ij}}{\sum_{k=1}^{r} p_k q_{ik}} \qquad (1)$$

In Equation 1, p_j is the attraction specific to region j independently of the origin, and q_{ij} is a measure of the information that pushes an individual present at i to move to j (Ginsberg, 1972). Depending on the characteristics introduced, this formulation produces various models of migration behavior in general use. If we measure the specific attractiveness of a region by its population, P_j, and the information by a function of the distance separating regions i and j, d_{ij}, we can write the migration flow between these regions:

$$M_{ij} = \frac{P_i P_j f(d_{ij})}{\sum_{k=1}^{r} P_k f(d_{ik})} = k P_i P_j f(d_{ij}) \qquad (2)$$

We obtain a model belonging to the class of gravity models, based on a behavioral theory. These models can introduce various other measures of the information between these zones and many other characteristics of both origin and destination zones: distance in terms of intermediate jobs, cost of living, income, leisure facilities, climate, and density of population in both origin and destination zones (Cadwallader, 1992; Rogers, 1967). These models can be estimated using linear regression methods when the logarithms of the two sides of the equations are taken. It is necessary to verify the conditions of application of such a model (Poulain, 1981).

This approach assumes that individual behavior derives from choices that depend on perception of aggregate characteristics. An individual will prefer the regions whose living conditions he or she knows best relative to other regions, while at the same time comparing it with living conditions in his or her region of residence. The logic and estimation of the model can then deal with flows and characteristics measured at the *macro* level, under the assumption that individual behavior based on rational choices is not simultaneously influenced by personal characteristics. However, we saw earlier that this assumption was not verified.

In the next section, we need to synthesize these two approaches.

Having presented the complexity of migration phenomena and the various approaches employed for their analysis, we now turn our attention to the more innovative lines of inquiry that can offer deeper insights into mobility.

II. TOWARD A BROADER UNDERSTANDING OF MIGRATION BEHAVIOR

The need to understand the decision-making mechanisms that lie behind the migration decisions and locational choices of individuals has led many researchers to look for a framework that allows individual strategies to be situated in their spatial context. Two main currents of research are presented here. These are currently undergoing major methodologic developments and are contributing, from very different perspectives, to the integration of the study of migration into a broader context.

In the study of urbanization processes, Véronique Dupont and Françoise Dureau (1988) directed their attention not at the abstract entity of the city, but at the actors of the processes of urbanization. For their analysis of urban dynamics, they found it simplistic to focus uniquely on the population living in the urban space delimited by its built environment and necessary to go beyond the usual practice of linking individuals to a single place of residence.

Another line of research allows the inclusion of more complex parameters derived from widely available data to analyze the interactions between the results obtained at different levels of aggregation. In particular, we need to try to identify the interaction between the individual level and the aggregate level. These two approaches are examined in order.

1. The Life Space and Its Modification

An initial means of going beyond the study of simple individual motivations is by situating the actors of mobility in their life space, defined as "that part of space in which an individual carries out all his or her activities . . . not only the places of transit and residence, but also all the places with which he or she interacts" (Courgeau, 1980). This concept issues from the conjunction of work in cognitive psychology and sociology, and it was first applied in demography by Daniel Courgeau (1972) for exploring and mapping the networks of relations between persons. The objective in this research was to use these networks to study individual mobility. Its basic postulate is as follows: migration by individuals or by households is not just the result of economic and social conditions but also depends heavily on the ties that individuals form, the advice they receive and the information to which they have access. In this perspective, a survey was conducted in a rural setting (followed by another in an urban setting). In this way were traced the first steps for operationalizing the life-space concept in a quantitative experiment. When the network of relations is considered, the exact location of its members gives its spatial distribution at a given point of time. Any modification over time in this set of places constitutes a change in the life space, causing it to undergo a contraction, an extension, a shift, or a complete redefinition.

Definitions of the life space are varied, ranging from a space structured by a network of relations to a space defined by a set of places corresponding to functions rather than to persons. In the generally available statistics, individuals are identified at a single place, that of their residence, and changes in this place over time define their migrations. In the context of a quantitative analysis, which applies a narrower definition of the life space, we can assume that it comprises the place of residence and place of work of an individual at a point in time, for example.

A study carried out in India (Dupont and Lelièvre, 1993) operationalized a specific definition of the life space of the migrant. Taking as their starting point the possible separation of place of work and place of residence, the researchers decided to incorporate the plurality of places of residence and work for any given individual. This allowed them take into account the fact that a migrant of rural origin can combine a job in the town with doing agricultural work and can consider his village of origin as a more important place of residence than his dwelling in the town, with the village remaining the main locus of emotional, familial, and social investment. In the study in question, "la dynamique d'une ville moyenne en Inde" (i.e., the dynamics of a medium-sized town in India), the objective was to "apprehend the town beyond the space of human concentration, such as to relate it to the rural dynamics that are its constituent parts." India presents the paradox of having a low rate of urbanization (25.7% of the population was urban in the 1991 census) even though it has the world's second largest urban population (218 million in 1991) after China. Using this approach also allows for the possible reversibility of migration flows. The preference accorded at any given point in time to one of the constituent poles of the life space can be modified, causing the movement to change direction. This approach to the actors of the urbanization processes and their life space led us to invert the classic view of the town as a pole possessing its zone of influence and to propose a new perspective, particularly revealing in the case of the small and medium-sized towns in India: The town appears more as an outpost of the village, a locus of investment and of diversification of the activities of country dwellers. The concept possesses considerable analytical power.

In the Population, Espace de Vie, et Environnement (Population, Life Space, and Environment) survey conducted by INED in 1991, Philippe Collomb and France Guérin-Pace collected data intended to identify the representations and practices of French people regarding the environment, for which purpose they introduced the life-space concept. Applied in a concrete approach to the spatial practices of the respondents, this concept enabled the authors to gain insight into the universe of individual representations and to get access to the larger notion of collective environment (Guérin-Pace, 1994). The life space the researchers observed with this survey is more accurately the space that is frequented and moved through, and around which individual existence is constructed and which structures daily life (Di Meo, 1991), which is also referred to as the *daily-life environment* (i.e., *spazio utilizzato*) (Barsotti and Bottai, 1994). A large part of the survey is devoted to the journeys made on foot in the vicinity of the dwelling, with a distinction being made between the familiar territory where the respondent goes with pleasure and the more functional and utilitarian territory where he or she goes from necessity. Information is also collected on the reasons why places are frequented, those that determine the attraction of some places or the repulsion or lack of interest for other zones.

The data from the Biographies et Entourage (Event Histories and Contact Circle) survey conducted in France between 2000 and 2001 opened up new and particularly promising perspectives for the study of the individual's life space and its evolution over the lifetime (Lelièvre *et al.*, 2002). The survey catalogues the mosaic of places that makes up the respondent's geographic universe, each place corresponding either to a *function* (i.e., place of residence and work, regularly visited places: school boarding facilities, barracks, weekend cottage, place of holiday) or to a *bond* maintained with the contact circle (i.e., places of residence of parents, siblings, uncles or cousins). The location of the kinship group at the time of the survey and at different stages in the respondent's lifetime, allows us to study the spatial dynamics and strategies at the level of the contact circle and to re-examine the analysis of diverse forms of mobility in interaction. Description can embrace commuting journeys (e.g., residence or work, family home or hall of residence) and international migration (e.g., place of origin or place of destination), and it can shift from residential mobility to space experienced and structured by networks of relations or space defined by personal mobility. By rethinking the temporal dimension of the processes and by placing individual strategies in their spatial context, we can avoid the single criterion of distance and the view of individuals as having a single reference point, while achieving a more balanced view of the economic determinants of migration decisions and envisaging mobility in its entirety rather than migration events in isolation.

We have gone from a narrow definition of migration as a change of residential location to a more general definition of migration as a change of life space. The former definition, elaborated on the basis of classic demographic statistics, is replaced by a definition that is more general and multiform in its quantitative operationalizations. Both of these definitions include the physical space in which the movements occur, which makes them familiar to geographers (Frémont, 1974). They differ from other definitions that are more tied to the conceptual and emotional space of individuals (Mangalam, 1968; Eisenstadt, 1953). This concept offers countless possibilities, because its flexibility of application means it can be adapted to the diverse problems associated with the range of types of mobility and immobility present in the field of migration.

2. Individual and Aggregate Approaches: The Need to Integrate the Different Levels Simultaneously

We saw earlier how various individual characteristics can influence migration behavior; this is possible with event history analysis. We also saw how different characteristics of the origin and destination areas, measured at the aggregate level, can influence the percentages of migrants; this is a task for which regression analysis is well adapted. The next step is to explore the relations that exist between the results produced by these two analyses.

In 1950, William Robinson showed that a correlation measured at an aggregate level is not necessarily the same as a correlation measured at the individual level. This introduced the concept of the ecologic fallacy, which occurs when we want to measure an individual correlation using aggregate data, the most often available. Almost 30 years later, Glen Firebaugh (1978) related the problems of aggregation to the theory of group effects and confirmed that an aggregate-level variable often measures a different characteristic than that measured by the same variable defined at the individual level. In 1992, Michael Von Korff and colleagues showed that analyses that relate aggregate-level characteristics to outcome variables measured at the aggregate or individual level do not inherently produce ecologic bias. The ecologic bias is the result of improper interpretation of the correct relationship measured at the aggregate level.

A broader perspective then becomes possible with a multilevel analysis, which acknowledges the importance of individual and aggregate characteristics in determining migration behavior. We need to examine in more detail the theoretical and practical associations that exist between these different levels and to demonstrate the value of this type of multilevel approach (Courgeau and Baccaïni, 1997, 1998; Courgeau, 1994, 1995, 2003).

Without going into the detail of the demonstrations, we have verified that for the study of migration behavior, the effect of aggregate characteristics was virtually independent of that of individual characteristics in the cases of French and Norwegian interregional migration. It follows that it is entirely legitimate to introduce individual-level and aggregate-level characteristics simultaneously to get a more comprehensive explanation of migration behavior.

The effect of some of these characteristics, depending on whether they are treated as aggregate or individual, can lead to apparent paradoxes that have to be explained through a more detailed examination of the situations. Let us take as an example the case of French women working in farming, whose migration probability is much lower than that of the other occupational groups. However, the fact of living in a region where women working in farming are more numerous increases the probability of moving out of that region (Courgeau, 1994, 1995).

This apparent paradox is explained by subdividing the population at risk into two distinct groups: women in farming and women not in farming. Regression is then used to estimate the logarithm of the probability of leaving the region as a function of the proportion of women in farming in the various regions (Fig. 63–5).

Women in farming have a consistently lower migration probability, regardless of the proportion they represent in the region. This confirms the negative parameter obtained at the individual level (–0.333). At the same time, we see that the migration probability for all women, whether in or not in farming, increases as the proportion of women in farming increases. The result is a positive value (+3.785) for the parameter associated with this aggregate variable. This illustrates the danger of inferring assumptions about individual behavior from results obtained at the aggregate level. A high proportion of women in farming is associated with a higher migration probability for all categories of the population, partly because of the scarcity of nonagricultural employment in these regions. This does not mean that women working in farming have a higher probability of migrating than others; at the individual level, the exact opposite is observed. This result holds regardless of the region of origin.

This suggests that to analyze migration behavior correctly, we need to introduce simultaneously the

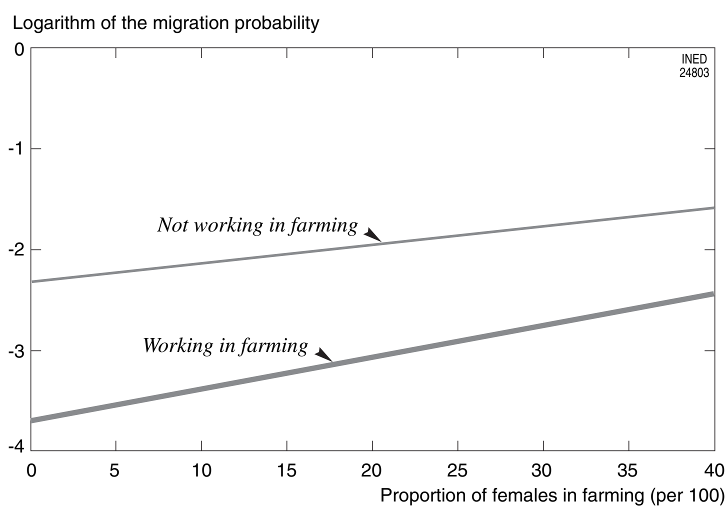

FIGURE 63–5 Logarithm of the migration probability for women working in farming and for other categories as a function of the proportion of women in farming in each region as found in the French Triple Biography survey of family, employment, and migration histories. (From Courgeau, 1994, p. 22.)

characteristics defined at different levels of aggregation: at the individual level and at the level of larger geographic units (e.g., regions, towns). At the same time, more far-reaching inquiry is essential into the significance of the different levels considered to identify the most relevant levels of aggregation for inclusion in the analysis. Does a choice have to be made between spatial divisions, such as that by communes, departments, or regions, or should they all be treated as relevant for inclusion in the analysis? Only further research in this field can provide the answer to such questions.

CONCLUSIONS

Our study of the motivations for migration has led us to broaden the scope of analysis by moving from an approach at the *micro* level to one at the *macro* level and then by attempting a synthesis of these two approaches.

The individual-level approach is a valuable tool for determining the motivations associated with the family and work domains of potential migrants, either through direct questioning about the reasons for migrating or by means of an event history analysis of migrations in interaction with a range of family- and work-related events. We have found this second approach preferable to the first, which in the case of retrospective surveys risks producing reasons reconstructed *a posteriori*. Event history analysis makes possible a very detailed analysis of these motivations, which are reconstituted from the succession of life stages of the respondents, such as marital migration, migration associated with divorce or widowhood, migration related to the birth of children, and work-related migration.

The aggregate-level approach is valuable for examining the motivations associated with the position of the individual in a space that is both social and geographic. The social space of origin is formed by the milieu in which the individual lives, which is apprehended through various aggregate characteristics of the place of origin. From this origin, there are various social spaces of destination that are more or less well known to potential migrants as a function of the physical or social distance that separates them. The attraction of these different spaces can then be modeled by introducing their various characteristics captured more or less precisely according to the distance between origin and destination zones. This approximate modeling results in aggregate migration models, which explain the flows in relation to the characteristics of the origin and destination areas and to a measurement of the information exchanged between these areas.

These approaches then must be generalized to give a more detailed view of migration in the form of change in life space and to attempt a synthesis linking the micro and macro levels. The first generalization involves conducting surveys with which to track the individual's contact circle (*entourage*), a concept whose complexity and value for social science we have already demonstrated (Bonvalet and Lelièvre, 1995; Lelièvre *et al*., 1997 and 1998). The second generalization leads to formulating models in which the characteristics measured at different levels of aggregation are introduced simultaneously. Such multilevel models can be used to test the independence between the effects of the characteristics measured at different levels. They show that in some cases the effect of the individual characteristic can run counter to that of the aggregate characteristic, although because of this independence, there is no paradox.

Much remains to be done to develop a theory that explains the role of the different levels of aggregation in migration behavior. The effect of individual characteristics can be taken to measure migration propensity according to personal situation while allowing for individual freedom of choice. Social constraints operate at a more aggregate level and influence the migration flows in a different way from the characteristics of the individuals who are going to migrate. The question then must be asked whether some levels of aggregation are more relevant than others for an understanding of migration behavior. This constitutes an entire field of research, both theoretical and empirical, which has only begun to be explored and for which many more studies will be needed.

III

SPECIFIC APPROACHES TO TWO TYPES OF MIGRATION

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

In Chapter 22, Daniel Courgeau wrote, "The study of spatial mobility involves identifying the changes occurring over time in the relations between an individual or social group, and space."[1] This spatially focused definition of mobility sees individuals as continually mobile and focuses on the need to analyze all time-bound movements. This makes all forms of movement material, including repetitive, short-duration commuting movements and comparatively permanent return movements after a relatively long time spent far away from the place of departure. The time aspect enables a link to be made between mobility and other population and economic processes and to identify how all an individual's life events connect with one another.

Daily commuting, the subject of Chapter 64, is a key issue for migration analysts engaged in the vast field of spatial interactions, studying the spaces in which individuals live. In this chapter, Marco Bottai and Odo Barsotti give a detailed description of the theoretical and methodologic aspects of the phenomenon and analyze it through complementary macro and micro approaches.

On a different scale, return migration after a comparatively long stay abroad is a relatively unexplored but highly important field of research because of the size of the populations concerned. In Chapter 65, Jean Louis Rallu explains the instruments and methods of analysis and applies them to survey data.

[1] "L'étude de la mobilité spatiale consiste à mettre en évidence les changements au cours du temps, qui sont à l'oeuvre dans les rapports entre un individu ou un groupe social et l'espace."

Daily Travel: Approaches and Models

MARCO BOTTAI AND ODO BARSOTTI

Dipartimento di Statistica e Matematica all' Economia, Università di Pisa, Pisa, Italy

Although daily travel merits its own category, it is not fundamentally different from other types of *spatial interaction*. We begin by defining what we mean by daily spatial interactions and describe how this type of spatial interaction is related to other forms of mobility. We present a macro-level perspective on daily travel before turning to a micro-level perspective. We conclude with a discussion of the challenges that face a unified theory.

I. SPATIAL INTERACTIONS AND LEVEL OF ANALYSIS

By *daily spatial interactions*, we mean the travel of individuals that ends within a single day, excluding all movements of merchandise, capital, data, and similar items.

Residential changes or migration are omitted by this definition. However, all these types of interaction are inextricably intertwined because daily travel depends on residential choices, and frequent round trips between the same destinations influence the decision to migrate. The link is so close that the approaches and models for studying daily *moves* are substantially the same as for other types of spatial interactions.

In particular, let us consider the spatial mobility of workers, which can be interpreted as an economic response (i.e., as a way to describe how workers adapt in their roles as factors of production and as consumers), and as a spatial equilibrium constraint (i.e., as a process constraining the overall localization pattern).

Because labor is mobile, workers can offer their labor services anywhere, and these offers can result in regular (daily) movements from residence to workplace or in changing the place of residence, or both.

Three processes of spatial adaptation in the individual's role as a factor of production can be identified (Termote, 1969):

1. Modification of the individual's spatial behavior as a result of a change in residence or workplace
2. Regular (periodic) movement from one locality to another
3. A combination of the two

Consider two geographic areas, A and B, with excess labor demand in A and excess supply in B. This situation can generate migration from B to A, commuting from B to A, or even migration from B to an alternative intermediate point C with associated commuting from C to A. Migratory and daily spatial interaction are linked by *spatial conjunction*.

After a period of commuting from B to A, a change of residence to A can follow, eliminating the commuting trips. In this case, migratory and daily spatial interactions are linked by *temporal conjunction*. There is also a hybrid case when a worker, after having moved to C, subsequently moves again to A, illustrating a *spatial-temporal conjunction* between permanent and daily moves (Termote, 1969).

Depending on the kinds of responses to spatial disequilibria, migrations and daily trips can be concurrent, sequential, or both concurrent and complementary.

Spatial adaptation of labor supply and demand can be formalized by the following matrix model:

Let M be an origin-destination matrix of order k (i.e., the number of regions in the spatial system) of migratory flows between time t and time $t + 1$ of the employed labor force, divided by the employed resident labor force in the region of origin.

Let L_t be the vector of the employed resident labor force in each locality at time t.

Then, $L_{t+1} = L_t \times M$ is the vector of the employed resident labor force in each locality at time $t + 1$.

If, in addition, N is the origin-destination matrix of commuters at time $t + 1$ divided by the employed resident labor force in each location of origin, then

$$D_{t+1} = L_{t+1} \times N$$

This is the vector of labor demand (jobs) among regions at time $t + 1$.

In essence, by using the two transition matrices M (for residential changes) and N (for commuting) for the employed labor force, we can measure over a specified period of time the combined effects of these two types of mobility in response to the demand for labor (Barsotti *et al*., 1976).

The model described above is oversimplified and should be viewed as only a framework because it is based on the classic view of labor force residential choice. Modern approaches view residential choices as a way to minimize work-residence distance and as a response to other criteria and constraints. An individual working and residing in location A may decide to move to B, thereby generating a daily trip from B to A where none previously existed. The classic model would not account for this, but current models recognize that the trade-off between work and residence locations is not entirely determined by the characteristics of the place of residence and that reducing the commute to work is not always the primary motivation for deciding where to live and how one uses the surrounding space.

An individual's place of residence is at the center of a widespread and interlinked network crossed by numerous pathways. Trips and travel along these paths are a way to use space to satisfy the diverse daily demands faced by each individual, and the resulting network defines a person's *life space*.

In analyzing daily travel, we often limit ourselves to trips such as to work or to school because of the relative abundance of data for these two types of travel compared with others. In the literature on gravitational analysis, shopping trips are occasionally taken into account, but travel based on free-time activities for leisure, social contacts, and health are generally ignored. Although the frequency of this type of travel may not be daily, it is becoming increasingly important because the number of such trips can exceed work or school trips and can be decisive in defining the life space and determining the quality of life.

A survey we took in Tuscany (Bottai and Barsotti, 1994) found that daily travel for work reasons represented barely 28% of the total number of trips. Adding trips to school raised the total proportion to 37%. These two types of travel formed only a little more than one-third of the volume of daily mobility. If we had only examined work and school travel, almost two-thirds of daily mobility would have been missed. Leisure trips (17%) and visits with family and friends (14%) form almost another one-third of the total, with the remainder (32%) attributed to shopping trips (15%) and, less frequently, travel for health, companionship, religion, volunteerism, and other reasons. If we distinguish between trips that must occur and those that are elective, we find that 40% of trips are for reasons of personal choice and not out of need. By ignoring these types of trips in studies of spatial interaction and territorial gravitation, we lose quantitative and qualitative information. It is as if we were ignoring the trips that most closely reflect spontaneous choices of mobility and use of space and tell us the most about individual attitudes.

The different spatial-interaction approaches can be split into two large classes at the macro level or micro level. At the macro level, attention is focused on territorial units (e.g., zones, communities, regions), and at the micro level, the units of observation are the individuals. The macro approaches comprise *gravitational models*; micro approaches are based on *behavioral models*.

In macroanalyses, spatial interactions are envisioned as the response to locational disequilibria between needs (the demand) and opportunities (the supply) under a cost function (distance), whereas in microanalyses, it is the individual's probability of movement that determines the volume of flows.

The choice of approach is often conditioned on availability of data. The greatest diffusion of macro approaches is probably due to the amount of information supplied by official sources, notably the censuses. In contrast, micro approaches most often use *ad hoc* surveys.

II. MACRO APPROACHES

1. Social Physics

Macro models are generally referred to as gravitational models. Historically, they antedate micro models. When positivism was at its zenith in the 19th century, social scientists competed to uncover hidden natural laws that guided human behavior in the field of mobility, as well as in other areas. They held the leibnitzian conviction that a natural law capable of determining the principles at the foundation of spatial interaction had to exist, and they believed that the laws of newtonian mechanics could be applied to human behavior.

They thought that spatial interactions were the result of demographic masses exerting gravitational attraction forces toward each other, as if variability in individual behavior was not determined by subjective choice, but rather that individual discretion was transcended by gravitational laws. In general, their assumption was that interactions (T_{ij}) between two nodes i and j were directly proportional to their sizes (P_i and P_j) and inversely related to the distance (d_{ij}) between them:

$$T_{ij} = P_i\, P_j\, f(d_{ij})$$

In this equation, $f(d_{ij})$ is a friction function of the distance between i and j.

From Quetelet and Carey to Reilly, proponents of social physics believed that they could apply the principles of newtonian astrophysics to determine the volumes of interactions between two nodes, as in the following equation:

$$T_{ij} = P_i\, P_j\, d_{ij}^{-2}$$

Recognizing that a strict analogy to physical laws may be too severe, a subsequent modification was made to allow flexibility by replacing the fixed exponent of 2 by an empirically estimated parameter β:

$$T_{ij} = P_i\, P_j\, d_{ij}^{-\beta}$$

Carroll and Bevis (1957) extended this gravitational model by adding a stochastic component (Isard, 1960, p. 494–499), but even in this case, important concessions had to be made: structural homogeneity in the sending and receiving "masses," friction that was independent of distance, and the modeling of individuals as particles without will. To each individual is attributed the same probability function for interactions that includes the probability of moving from node *i* (estimated by the ratio of all movements to the total population) and the probability of moving to node *j* (estimated by the ratio of the population at node *j* to the total population). Multiplying these two ratios together produces the expected number of interactions by any individual in the entire system with node *j*. Multiplying again by the population of *i* produces the total number of expected interactions from *i* to *j*, neglecting the impedance of distance:

$$pr(t_{ij}) = \frac{T}{P}\frac{P_j}{P}$$

Therefore,

$$T_{ij}{}^{*} = pr(t_{ij})\; P_i$$

In the previous equation, $pr(t_{ij})$ is the probability that a resident of *i* moves to *j* in the absence of friction due to distance; *T* is the number of overall commuting trips; *P* is the total "mass" of the system (i.e., the total population); and T_{ij}* is the number of trips expected between *i* and *j* in the absence of friction due to distance.

The ratio between the observed and expected interactions for each pair of nodes in the system is variable. Classic gravitational theory defines this variability as being a function solely of distance. By plotting each of these *ij* ratios and the distance between them on log-log axes, it is possible to find the function that best represents the friction due to distance. Generally, this function is assumed to be linear.

It can be shown that this approach is equivalent to the classic gravitational model:

$$\ln\left(\frac{T_{ij}}{T_{ij}^{*}}\right) = a - b \times \ln(d_{ij})$$

Therefore,

$$T_{ij} = \frac{\left(e^{a} \times T_{ij}^{*}\right)}{d_{ij}^{b}}$$

and

$$T_{ij} = \frac{e^{a}\,\dfrac{T}{P}\,\dfrac{P_j}{P}\,P_i}{d_{ij}^{b}}$$

Assuming that

$$G = e^{a}\,\frac{T}{P^{2}}$$

produces the following:

$$T_{ij} = G\,\frac{P_i P_j}{d_{ij}^{b}}$$

This pseudo micro approach leading to a macro model ignores individual behavior and treats individuals as homogeneous particles without preferences, undermining the usual point of micro models. A model cannot be considered as a micro model if it lacks the essential characteristic of allowing individuals to behave individually.

Isard, a disciple of the classic gravitational model, recognized the limitation and rigidity of using a law from physics as a model of trips. In reality, the exponent that modeled the friction of distance on the possible interactions combines too many different and non-negligible effects; the result is that the empirical data and the expectations based on the gravitational hypothesis are not close. Isard and geographers of the Chicago school sought a more flexible general law by introducing additional weights or coefficients to model mass, and exponents to model location-specific characteristics of accessibility and attraction. This becomes clearer when examining specific masses (i.e., groups of individuals) and their specific interactions; the friction of distance would be very different, depending on whether the groups were men or women, young or old, workers or retirees, and similarly, if work-related travel, leisure-related travel, shopping, or even weekends and weekdays are examined.

Isard's model presumes that the mass weights or coefficients and the exponents, estimated from empirical studies and exogenous to the model, vary according to the type of mass and the type of interaction; the distance exponent is estimated from the model:

$$C_{ij} = \frac{w_i P_i^a w_j P_j^b}{d_{ij}^{\beta}}$$

Bramhall (Isard, 1960, p. 543–544) hoped to sidestep this expansion of parameters:

> We prefer to maintain the point of view that the gravity model as defined by equation . . . applies to whole, integral masses; that is, to migration of all income, occupational, and racial classes and not to migration of Puerto Ricans alone; to passenger trip of all classes by all media over all distances and not to airline trips between New York and Miami; to all shipment of all commodities over all distances through all types of media and not to the shipment of Maine potatoes alone. To reiterate, the incorporation of all cases in the analysis cancels out the peculiarities, irregularities, and idiosyncrasies of interaction within a special sector or category of population or along a selected channel. Just as the brownian movements of any given microscopic particle are reduced to insignificance by the process of averaging over a multitude of particles, so are the capricious movements of any unit or small subgroup of units of population or other relevant social mass.

Because the masses of interest are population sizes, the weights should reflect a series of structural variables that influence the propensity to create or attract movements. It has not been clearly elucidated whether the interactive phenomena should be viewed globally or separately. If all movements, of whatever type, had to be viewed globally, the mass weights would be extremely complex because the variables that affect the different types of movements are multiple and diverse. Whichever we choose, it can only be arbitrary and approximate. Suppose in contrast that flows are decomposed into separate components (at least at the level of motivation or means of transport) and take, for example, work-related commuting. The total population is clearly too gross a measure of the actual population at risk. A young population with high activity rates will exhibit more travel than an older one with lower activity rates; a locality with large mass and a surplus of demand (i.e., jobs), compared with one with a surplus of labor, should have a larger weight.

The list of potential variables that characterize how a mass generates or attracts movements could be very long. This is why much more attention ought to be focused on describing a function that combines all of them into a single weight.

The sign and the magnitude of the mass exponents are unclear. Should they be parameters that depend only on specific characteristics of the mass (e.g., its geographic accessibility) or a simple control parameter permitting flexibility and a good model fit?

The measurement of distance also deserves attention. Imagine several reasonable measures:

Physical distance: distance as the bird flies, driving distance, travel time, the frequency of connections
Economic distance: transport cost
Social distance
Psychological distance

The hypothesis of a linear relationship in the logarithms of distance and the ratio of expected to observed interactions is often empirically unsupported. Other forms of functional relationship better represent the friction of distance. Several functions have been proposed for the distance component (Carrothers, 1956; Anderson, 1955). In particular, Carroll and Bevis (1957) found that a quadratic function seemed to fit well, which is consistent with more recent findings of our own (Bottai and Barsotti, 1994; Barsotti *et al*., 1990). Nonetheless, choosing a form for the distance function leads us away from the earliest models of gravitational physics without bringing us any closer to a theoretical alternative.

Even the most ardent supporters of the gravitational model admit imperfections in the theory and in its empirical performance, and it is not realistic to assume social masses behave according to the laws of physics. Particulate matter is devoid of will, and its behavior answers to an immutable law; human behavior and interactions answer to mechanisms that are far more varied, subtle, and complex.

2. Travel and the Structure of Opportunities

Another approach that models the distance-decay effect on interactions is Stouffer's (1940) theory of *intervening opportunities*. Travel from node i to node j is directly proportional to the volume of potential travelers in i and the opportunities in j that could satisfy their needs, and it is inversely proportional to the number of intervening opportunities available between i and j. Although distance is not an explicit variable in this model, it is obvious that as distance increases, so do intervening opportunities. Stouffer's model has rarely been applied because of the practical difficulties in collecting data on intervening opportunities. However, the model does have the virtue of moving beyond a strictly mechanistic view of the effect of distance, and it implicitly introduced the concept that opportunities to satisfy needs and preferences are not located at a single location but are geographically dispersed.

In effect, presuming that frequency of travel decreases with distance (with a maximum at the shortest distances) implies that destinations satisfying individual needs are uniformly distributed in space. In that case, the distance one travels depends only on the costs of travel; the probability of travel necessarily decreases with increasing distance. Consider a homogeneous space in which there is a constant distance (k) between destinations where needed services can be found (i.e., the supply), with an equally uniform but denser distribution of residences (i.e., the demand for those services); then trips to these destinations increase in frequency up to the distance $k/2$. In like manner, suppose that the demand is distributed in concentric rings around each supply point, with larger and larger radii. In the deterministic framework, this implies that the frequency of travel varies linearly from 0 to $k/2$ (with slope π), which determines the point of indifference between two points of attraction. The modal distance $k/2$ varies with how far apart the points of attraction are; this measurement depends on whether they are workplaces, schools, food or shopping opportunities, and so on.

The assumption of a homogeneous and uniform distribution of opportunities and residences is not realistic. Residences are clustered in some areas and absent in others, as are job opportunities. For each type of move, the distance k between pairs of destinations is variable, and the frequency of moves of a given type depends on numerous factors such as those described earlier.

3. Statistical Mechanics

Wilson (1968, 1971) refined the model by applying the concept borrowed from physics of *entropy*, which describes the tendency of a system to enter a more probable state. Suppose we have a regional system for which we can write down an origin-destination (O-D) matrix of flows (e.g., work commutes), for which rows represent destinations and columns represent origins, with fixed row and column marginal totals, and the added constraint of constant transport costs (or equivalently, travel distance). Our goal is to find the trip distribution that maximizes entropy (Tocalis, 1978, offers more details).

Wilson showed that the most probable pattern of trips between nodes i and j is directly proportional to the trips produced by i, to the trips directed toward j, to the ability of j to attract trips, to the ability of i to produce trips, and inversely to transportation costs (and therefore to distance) between i and j. This may seem no different from the gravitational model, but it is based on a model of statistical mechanics that provides a more solid fundamental theory than that of the gravity model.

Wilson showed that the trip matrix that maximizes entropy and produces the least-biased estimate of the trips between pairs of nodes is given by the following doubly constrained gravity model:

$$C_{ij} = A_i B_j O_i D_j f(d_{ij})$$

In this equation,

$$A_i = \left[\sum_j B_j D_j f(d_{ij})\right]^{-1}$$

$$B_i = \left[\sum_j A_j O_j f(d_{ij})\right]^{-1}$$

and, in general,

$$f(d_{ij}) = e^{-\beta d_{ij}}$$

In addition to its theoretical offering, the value of Wilson's model lies in its introduction of constraints that ensure consistency between expected trips and the marginal totals of the trip matrix. The introduction of constraints significantly improves the agreement between theoretical and observed trip flows compared with the unconstrained newtonian gravitational models.

4. Validation of Wilson's Model

To calibrate and estimate Wilson's model with actual data we must have a trip matrix between different nodes (O and D) and the corresponding distance matrix (Stillwell, 1991).

The main goal is to estimate the parameter β, which measures the friction of distance in the function $f(d_{ij})$. Because the parameters A_i and B_j are defined jointly and simultaneously, there is no closed-form solution, and we must resort to iterative methods of estimation.

We start with an initial arbitrary value for β and calculate the vector A after initializing B at unity; subsequently, we calculate values of B based on the estimated A and repeat the process until convergence. This gives the matrix of expected trip flows. Then we calculate the mean distances in the matrix of expected trips and check for convergence to those of the observed data. If, in absolute value, the difference is larger than the convergence threshold, we change the value of β and try again. At the end, we obtain an estimate of β and a trip matrix that maximizes entropy while maintaining constraints on the marginal totals and with a mean distance implied by the theoretical trip matrix not significantly different from that of observed trips.

We can also construct models constrained only for marginal row or column totals by replacing the omitted constraint by a proxy (i.e., population or workplaces). Relaxing one of the constraints results in a poorer fit to the data, but it allows the examination of alternative scenarios on the unconstrained variable.

5. Subsequent Models

The fundamental difference between Isard's model and Wilson's model is that Isard's poses only an overall constraint on total number of trips in the system and exogenously determines (i.e., by empirically calculated and arbitrarily chosen weights and coefficients) the pushing and pulling forces of each node. In contrast, Wilson's model binds the system to a fixed total cost (distance) and can include constraints on the vectors of trip flows and, by tracing these flows, can endogenously determine the push or pull forces.

Other variations based on the assumption that marginal row or column totals are allowed to vary within a given interval (i.e., "relaxed models") have been proposed as a way to add greater flexibility to the entropy model (Hallefjord and Jörnsten, 1985). Alonso (1978) proposed a general model from which it is possible to derive four typical variants on the Wilson model, ranging from the total absence of all constraints to the doubly constrained model. Alonso described his model as an integration of two submodels: a push-pull model of spatial interactions and a model of their distribution. This results from the role that systemic or relational variables (A and B) play as normalization factors and as explanatory variables.

Dorigo and Tobler (1983) have proposed a model similar to Wilson's, except for the fact that the relation between the normalization factors A and B is additive rather than multiplicative.

Ledent (1985) gives a more general formulation of doubly constrained models, in which an additional parameter provides the flexibility to allow for all variations of both the Wilson and Tobler models as special cases.

In an article, Tobler (1995) mused whether Ravenstein's migration laws, formulated more than a century ago, were still valid. He concluded that the analogy to physical laws remains useful for explaining spatial interactions. A fundamental continuity exists between successive macro models for which the gravitational principle is the common thread. However, there have been refinements that improve the predictive value of the models and, from this perspective, one can distinguish pre-Wilson from post-Wilson models: The latter models are able to integrate the internal structure of the trip matrix and to estimate all of its parameters endogenously. By doing so, those models are more coherent and consistent.

6. Trends in Social Context and Interpretive Paradigms

Gravitational models have played and continue to play an important role in the migration field. However, they have not been much used in the study of daily travel, especially for commuting.

That so little attention has been paid to daily trips seems less due to theoretical shortcomings or practical difficulties than as a kind of atonement for the original sin that stains the gravitational model. The gravitational model was born in an era (the second half of the 19th century) characterized by centralization in activities of production, which stimulated vast migratory flows toward cities, where residences and workplaces were closely situated. Work-to-home travel was not perceived as a problem. Work hours expanded, and individual differences and needs contracted. Freedom of choice was limited by structural constraints. The common man could be reduced to a molecule without will or volition.

With time, the rise of the capitalist system led to a more complex social structure. Progressive improvement in living standards and the transition to a postindustrial society have resulted in stratification in the social fabric, variations in consumption patterns, geographic differentiation, and rise of polycentric urban patterns.

This differentiation also applied to spatial use. Residential location is no longer dictated by job location. Other factors, often of a subjective nature, come into play. Structural constraints still hold sway, and individuals cannot dispense with them; sometimes, the constraints dominate, but in the end, it is the individual who, weighing social context and consequence in dialectic battle, must make the final decision.

An individual's life space expands with diversification and the multiplication of spatial interactions. Daily mobility has become increasingly important as a way to equilibrate labor supply and demand and as a way to satisfy personal needs and requirements, including personal care, developing a network of friends, leisure time, sport, shopping, studying, and voluntary activities.

When making the choice about where to live, individuals no longer view the job market and the place of work as monolithic constraints, but as part of a rich web of other constraints and opportunities. The housing market, the neighborhood environment, transportation, and communication networks are all evaluated for their ability to satisfy specific needs that depend on family composition and the stage of the life cycle.

7. Huff and *Homo economicus*

A clear weakness of gravitational models is that they ignore the effect of freedom of choice on more than one possible interaction (i.e., they cannot distinguish from among different ways to satisfy the same need). To address this other aggregated models have been developed to include theories of behavior.

Huff (1960, 1962), building on concepts drawn from behavioral psychology, developed a theory of individual choice based on trade-offs between the need to move (as a function of economic, social, cultural, and demographic characteristics) and psychological and physical barriers in the spatial structure of opportunities. His spatial interaction model was based on a behavioral approach in which individuals, to satisfy their needs, choose the location that maximizes expected utility. For each decision, individuals behave as if they perform a cost-benefit analysis (Berry, 1978, pp. 99–108).

This model could have led to a micro approach, but Huff's model remains a macro one. Because constructing utility matrices for each individual is difficult, Huff's approach was to combine individuals into the most homogeneous (from a socioeconomic perspective) groups possible. For example, in looking at shopping trips, principal factors in the model must include the type of merchandise offered, travel cost, income, and the size of the locality.

Each node in the system can be described by a series of macro variables that reflect an individual's utility and requirements, and the probability of spatial interaction for a particular node will depend on how this utility is achieved in comparison to other nodes.

The multinomial logit model followed the path blazed by Huff. That model rests on the assumptions that individuals exhibit economically rational behavior and that the utility functions that guide their rational behavior have random variable components that are independent and identically distributed. Refinements of the model have targeted the unrealistic assumption of independence; some alterations (Fotheringham, 1983; Gaudry and Degenait, 1979) relate to deterministic behavior, whereas others (McFadden, 1978) focus on risk.

Based on principles of behavioral science, this approach to the analysis of social interaction provided a way to escape the bonds of the gravitational model that so tightly linked individuals together. Interaction was no longer a mechanical response to structural disequilibria but rather the result of individual choices aimed at maximizing utility by avoiding costs and embracing opportunities afforded by macro-structural factors.

Although this step represents an important advance in the understanding of the process and the probabilistic approach adds predictive value, there are still some limitations. First, the underlying ideas of *discrete choice* and *rational expectations*, borrowed from microeconomics, presume abstract rationality of *Homo economicus*. Real-world behavior rarely conforms to that of *Homo economicus*. Economic rationality is only one of the behaviors (and rarely the most important) in a decision sequence that must weigh psychological, emotional, social, and cultural imperatives. It is only slight exaggeration to say that we have merely traded the bear trap of physical laws for the iron fist of economic rationality. Second, although the theoretical approach seems to fit within a micro-level model, it employs the macro-level instruments of ecologic variables and proxies for the way that individuals evaluate the value of differing locations.

In a complex society where situations and behaviors are so varied, we should not force behavior to match unrealistic and abstract theories. It is better to focus on less ambitious goals and to ask of our models only that they provide a true picture of the relationships that link the variables and a limited and current description of the interaction system, without pretensions to generality in time or space.

8. Applications of Macro Models

In the latest literature, gravitational models focus on the different factors that segment trips into different types of travel. There are two general approaches. The first applies separate models to homogeneous subgroups that share the most important defining characteristics; the other is based on classic linear models with additional explanatory factors. These models generally take a log-linear form.

The segmentation approach is used, for example, in a study by Cervero and Wu (1997). The authors considered four different combinations of the gravitational model by combining two worker categories (i.e., professional and nonprofessional) with two categories of work destination (i.e., traditional work destinations and newer, rapidly expanding employment zones). Their model included the usual variables: spatial impedance (i.e., travel time) and mass (i.e., labor supply at the origin and labor demand at the destination), and it included other explanatory variables, such as the destination's employment rate and the housing characteristics at both the origin and the destination.

The coefficients on these explanatory variables were statistically significant and of the expected sign, but overall goodness-of-fit was meager. This indicates that their model omitted key variables at the heart of the mechanism that generates daily trips, that the log-linear formulation was inappropriate, or that stochasticity dominated the decision-making process. This last point would mean that even within supposedly homogeneous subgroups, there is no universal behavioral response with respect to the use of space. However, we must not overlook the fact that the region studied (i.e., San Francisco bay area) has a polycentric urban structure that may have affected the results.

We may be in the middle of a transitional period between an historical phase of monocentric urban development in which work mostly determines travel and a new era characterized by polycentric urban patterns in which diverse demands for the daily usage of space influence the choice of where to live.

To evaluate the explanatory value of a gravitational model we must take into account the size of the geographic units for which data are available, because the larger the unit, the fewer the number of cross-boundary trips. This point, although critical, is often overlooked. In particular, it appears that the distance-decay parameter in gravitational models is not uniform with distance. Indirect support for this can be found in the positive coefficient on the index of urban contiguity in Baccaini's gravitational model (1997), which demonstrates that the friction of distance does not vary linearly with travel time (Barsotti and Bottai, 1994). More support can be found in a comparison of the Baccaini study with that of Cervero and Wu. Both are similar in that they update classic gravitational models by introducing explanatory variables reflecting polycentric urban patterns; however, only 33% of variance is explained by Cervero and Wu's model, whereas Baccaini's accounts for 96%.

Vickerman (1984) focused on the suburbanization processes in the London metropolitan area and observed that they led to an increase in the number of commutes. The direction of travel flows also changes as productive activities and jobs are dispersed toward the suburbs. Residential dispersion precedes job dispersion—or at least it occurs more quickly. Travel through the center of the urban system can increase even as the number of jobs located there decreases. City center residents are pushed out in a residential diaspora by rising housing prices, exacerbated by competing nonresidential land use, and by the increasing role of subjective and noneconomic factors in residential choice. Because of this, people no longer move to reduce home-to-work travel; instead, a residential move generates new commute trips.

The choice of the place of residence and type of housing are factors that strongly influence daily travel. Although this is obvious, the exact mechanism by which this operates is much less so. Both the housing market and urbanization policies have shown a weak ability to adjust to disequilibria between places of work and residence, which is important quantitatively and qualitatively. The housing market is increasingly segmented to the extent that almost everywhere (especially in Italy), it is dominated by the dream of owning one's own house, which tends to favor the migration of families with specific characteristics (e.g., income) to specific areas. If, in contrast, home-ownership status (i.e., renter or owner) and housing characteristics are satisfactory, migration incentives are greatly weakened, even in the face of job commuting. The housing market itself can raise barriers, as in the case of rent control. Such barriers can result in gentrification and segregation in urban and suburban centers.

It is difficult to imagine how we could disentangle the interdependencies of daily travel. Migration, residential location, job location, and travel costs are all factors jointly influencing daily mobility.

III. MICRO APPROACHES

The growing complexity of daily travel has given rise to the use of micro models. Even as macro models became more disaggregated and targeted, interest began turning to individual behavior as a key to understanding the travel behavior of groups. The goal of this approach was to highlight the ways in which structural factors are perceived and evaluated by individuals, depending on their demographic, social, occupational, and cultural characteristics. Surveys are the typical instrument needed to conduct this type of microanalysis.

As for all multivariate analyses, the most critical aspect is the selection of explanatory variables, because unexplained heterogeneity can bias the estimation of model parameters.

Gender is one of the factors most commonly studied. Gender differences in attitudes toward daily travel are so strong that it is often better to apply separate models to each sex than to introduce it as an explanatory variable in a single model (Baccaïni, 1997; Tkocz and Kristensen, 1994). It has been observed (Johnston-Anumonwo, 1992; White, 1977) that women are less likely to move long distances. This also appears to apply to daily travel; compared with men, women prefer shorter commutes.

The difference between single- and dual-worker families has also been studied. When both spouses work, family strategies seem to favor the husband's career, even if the resulting residential choice makes him commute longer. The wife then seeks employment closer to home, even if the resulting career opportunities are more limited. Even in the most advanced societies, there is asymmetry between male and female roles of production and reproduction (Madden, 1981).

The stage in the family life cycle is an intervening variable that can modify the effects of the two previous factors. The presence or absence of children in the household is commonly used as a proxy for the family life cycle stage. It has been shown that if the wife continues to work after the birth of children, she will try to bring workplace and home closer together. More precisely, she will try to minimize the distances between home, workplace, and the additional services (e.g., schools, shopping) needed to support the new family situation even though overall distance traveled and time taken may increase with the additional trips to school or shops (Camstra, 1996; Barsotti and Bottai, 1994; Rosenbloom, 1989).

Marital status seems to have the greatest influence on men's daily travel. Bachelors appear to commute shorter distances because it is easier for them to find housing in city centers or close to work (Baccaïni, 1997; Tkocz and Kristensen, 1994; Vickerman, 1984). However, the effect of marital status is not unambiguous and provides a good example of the way that the behavior of specific subgroups can differ. Although bachelors are more likely to live near work because of greater flexibility in housing size, characteristics, and cost, they are also less bound by familial or non–work-related constraints and therefore have the option to commute farther.

For adults, daily travel, like migration, tends to decline with age. According to some demographers, it also tends to be redirected toward urban centers. If one examines the entire age pattern and includes work and school travel (as perhaps we should, considering that they share the characteristics of both being compulsory and occurring on a daily basis), a graph of the relationship between age and daily travel resembles an inverted U (Barsotti and Bottai, 1994).

Taking income into account poses a number of problems. Should we consider household income or, especially when focusing on work travel, individual incomes of each family member? No matter how it is defined, commute distances and frequencies increase with income.

Socioeconomic status has considerable effect on daily travel. Home workers and farmers, for example, work close to or within their place of residence. The self-employed typically have low mobility. When controlling for other explanatory variables (e.g., sex, age, education, and home ownership status), the most mobile groups are supervisory white-collar workers. However, as shown by some of the studies we have discussed, blue-collar and office workers are among those with the longest commutes. This greater amount of daily travel (which has been rising in recent years) has resulted from the dispersion of residences to the suburbs.

Trends in daily commuting also depend on changes in home ownership status. Rising rates of home ownership reduces the propensity to change residence when changing the place of employment (Bottai, 1995).

Analysts can continue to add to the list of explanatory variables, including education (i.e., daily travel increases with the level of education) and modes of transport (e.g., cars, buses, trains, bicycles), which are determined by individual needs and by the existing transportation infrastructure and land use policy. All things considered, careful exploratory analysis is always well advised.

IV. THE CHALLENGES FACING A UNIFIED APPROACH

The need to reconcile the micro and macro approaches is clear. Two of the studies we have mentioned take two alternative paths in that direction.

Baccaïni (1997) supplements a micro model of individual-level variables with the addition of two variables that capture the regional context: one that takes into account spatial characteristics (geographic zone) and anotherthat measures the balance between labor supply and demand (i.e., employment rate) in the location of residence.

Tkocz and Kristensen (1994) build a polycentric spatial model in which the relationship between work-home distance and home-center distance is represented by a third-degree polynomial. In this model, the coefficients are replaced, following the method described by Casetti (1972), by a series of sociodemographic variables validated in a micro model.

Baccaïni's model begins as a micro model to which macro variables are added, and Tkocz and Kristensen's model begins as a macro model to which micro variables are added.

Courgeau (1999) carefully analyzes the biases that aggregated (macro) models can favor because they ignore how individual characteristics influence the likelihood of moves. These biases can be categorized as an ecologic fallacy arising from the reliance on large-scale empirical data. He also explores how biases arise in micro models by erroneous specification of individual-level variables and especially by discounting the influence macro variables have on the micro variables themselves. This bias is a type of atomistic fallacy. The probability of moving from one location to another for work reasons does not depend only on the type of job that an individual has (a micro-level characteristic) but also on the occupational structure of the area where the individual lives (a macro-level characteristic).

It seems more promising to tackle the problems of spatial interaction, as well as all similar problems of collective behavior, beginning from a micro perspective and adding macro variables of different levels of aggregation as needed. In any event, the macro-micro dichotomy seems too manichaean. In studying residential mobility, it may be better to begin at a point in the middle (i.e., with the household) because the choice of where to live concerns the household standing together rather than each individual standing alone. In this case, the problem, which several researchers are currently investigating, is how to handle characteristics of each member of the household (i.e., variables at a less aggregated level than the household itself).

The increasing preference for multilevel micro models implies a rejection of the typical macro approach of formulating laws that govern spatial interaction. The underlying reasons for this epistemologic evolution are the profound changes that have rendered modern and postmodern society more complex and differentiated. These changes have sparked the transition from monocentric spatial patterns to polycentric ones; an expansion of life space; a multiplication and increasing diversification of the reasons for using space; and the social fragmentation of mobility.

That we take recourse in microanalyses is as much due to the growing importance of individual choice as to the need to uncover by survey data the processes and mechanisms that give us insight into spatial behavior. We are witnessing a change of logic, and the transition from the cold deductions of macro models to the recognition that potential laws of interaction may only be discoverable by induction.

Studying Return Migration: Data from Censuses, Surveys, and Registers

JEAN LOUIS RALLU

Institut national d'études démographiques (INED), Paris, France

Return migration has not been extensively studied, even though it can affect significant numbers of people. Although some data are available, there are difficulties in defining return migrants, and there is prejudice about most of them being retired and therefore of secondary economic interest. The issue of migrants' retirement pensions to be paid in their native countries, if they choose to return, is beginning to cause some concern. According to the data available, most return migrants are not retired, and many are middle-aged adults. As a consequence, return migration should not be defined as a move for good, but in a wider circulation perspective. A return migrant is a person who goes back to his or her starting point (or even to one of his or her previous residences) and who may or may not migrate again in the future.

The study of return migration is based on data from censuses, surveys, and registers. Because simultaneous censuses and surveys have been conducted in these places, the examples are taken from migration between Guadeloupe and Martinique, the French overseas departments in the West Indies, and mainland France.

I. CENSUS DATA

Using census data, return migration can be defined from information obtained by the questions on previous residence and birthplace. A *return migrant* is defined as a native of the country or region where she or he was interviewed at a census or survey, and has lived in a different country or region at a previous time. If the contribution of foreigners (i.e., of people who were born abroad) to migration is to be measured based on such information, then it seems necessary to establish two categories among the migrants who were spotted by means of the question on their previous residence: those who were born in the country or region (i.e., return migrants) and those born outside the country or region.[1] This applies particularly to countries with formerly high out-migration rates and therefore potentially high rates of return migration, such as Spain, Portugal, and Italy.

In the case of censuses, it is of limited interest to calculate the proportion of return migrants in the population by simply comparing the number of return migrants with that of the natives or of the total population, because migration can be accounted for only partly through the question on previous residence. The return of people who were away at the time of previous residence and had returned some time in the n years between that date and the census is measured, but the people who migrated and then came back in that period, although they are included in the census, are ignored. The limitation also applies to the measurement of migration by means of the same question—those migrants who came and went away again

[1] For the sake of simplicity, only countries are used subsequently in the text as entities.

between the date of previous residence and the census are ignored, but in that case, non-enumerated migrants do not appear in the census.

1. Return Rate

The return rate is the ratio of return migrants to the emigrant population at the time of previous residence.[2]

$$\text{Return rate} = R_{i\,j}^{t\,t-a} \;/\; P_{ij}^{t-a} \qquad (1)$$

In Equation 1, $R_{i\,j}^{t\,t-a}$ equals the migrants who were born in *i* and appeared in the census in *i* at time *t and* resided in *j* at the time of previous residence *t* − *a*, and P_{ij}^{t-a} equals the population who were born in *i* and were enumerated in country *j* at the time of previous residence. Because new migration between the date of previous residence and that of the census represents a bias, *a* should be quite small (ideally, about 1 year).

Mortality is a disturbing event and should be taken into account through an estimate of the survival rate between *t* − *a and t*. However, its effect is insignificant among young and middle-aged adults, although it is different at later ages, such as when considering migration about retirement age.

Age was not included in the notations to keep the formulas as light as possible; however, those rates should be calculated by birth cohort and consequently require detailed age data when censuses are not conducted at 5-year intervals. This results in unconventional age groups (Table 65–1).

Using Equation 1, it is possible to calculate the return rates for different *j* countries of previous residence, provided those denominators can be derived from censuses in the countries of previous residence if they took place at the date or at a date close to the reference date for the question of previous residence or, if that is not the case, from estimates of the native population who have emigrated to the relevant *j* countries.

2. Periodicity and Simultaneousness of Censuses

It appears that simultaneous censuses in the European countries make it possible to measure international (and internal European) migrations in much better circumstances than censuses conducted at different dates. Previous residence had best be measured at the date of the last census. However, in a closed or all but closed area, denominators can be calculated again based on the population enumerated in the census and on the migration that was observed (from the census or from a different source) during the same period. It then seems better to use, as some countries do already, several questions about previous residence 1 year before the census to calculate rates for 1 year and 5 years before, to get more significant numbers for the analysis of the social and demographic characteristics of the migrants, and if necessary, at the date of or at a date close to the last census, for an assessment during the period between the censuses. The further back in time the previous residence is sampled, the more unobserved moves there are.

TABLE 65–1 Rates of Return Migration from Mainland France to the West Indian French Overseas Departments According to Censuses

Age (years) in 1990	Guadeloupe		Martinique	
	Men (%)	Women (%)	Men (%)	Women (%)
18–22	8.0	9.3	6.6	9.3
23–27	8.7	13.4	10.0	13.8
28–32	14.0	15.7	15.2	16.6
33–37	13.2	13.1	12.0	12.7
38–42	12.5	11.4	10.8	10.4
43–47	10.4	8.1	9.3	7.6
48–52	8.8	7.7	8.1	7.0
53–57	8.5	8.9	9.6	8.0
58–62	10.6	12.1	11.6	12.4
63+	11.1	12.2	9.6	10.3

Calculated from the 1982 census in Mainland France and the 1990 census in the French Overseas Departments.

In the frame of simultaneous censuses, it is also possible to check the results of migration from the question on previous residence by using the method of expected population. The expected population in a given *i* country at *t* + *a* provides, by difference with the population counted in the census in *t*, an estimate of migration that can be compared with that obtained from the question on previous residence in the *j* country. If the migration estimated through the expected population method in the *i* country is higher than that observed in *j*, it is (if there are no variations in the completeness of enumeration of successive censuses) because migrants who left country *i* did not necessarily go to country *j* or later remigrated to other destinations. If the migration observed in *j* is higher than the estimate from data in country *i*, it is a sign that there were errors in the data; some statements about previous residence were wrong, or under-enumeration affects the first census conducted in *i*. Such errors may happen in one or the other country, and the results of those comparisons should be very carefully interpreted. Whenever data are available, the moves between *i* and all the other *j* countries should then be

[2] The rates are computed with the initial population as denominator and are actually probabilities.

considered. Where return migration is concerned, an estimate of the expected number of migrants originating from i in the j country is made and then compared with the returns observed in i.

3. Extensions of the Method

What has been studied hitherto is a single question about previous residence. Several countries have multiple questions about residence 1 year and 5 years before the census (e.g., Portugal) and about 10 years before the census (e.g., Spain). Those questions make it possible to study, based on the various previous residences, such facts as the circulation of migrants between the various foreign countries and where they stopped on the way home (including internal migration after their return), which are an important aspect of the migrants' re-localization—the towns where they choose to settle, depending on the latter's size, the region, and other factors. Those data should not be neglected, mainly because the cost is so low, because they are products of the census; however, the various situations are revealed only at various points—as in some registers, such as the PDS in France,[3] not complete biographies; as a result, data from surveys should be used preferably for this type of studies.

Another extension of the method consists in measuring second-generation migration. In that case, the parents' birthplace is enough to spot the children born to migrants in a host country—those who were residing abroad at the time of previous residence are second-generation return migrants. Then they do not exactly return, but migrate, individually or with their parents, to the country where the latter were born.

Some censuses include a question about the year of arrival in the country (or of the latest migration). The question, although more awkward to use in itself (see Chapters 22 and 23), makes it possible, by simultaneously using the flow data from the migration statistics offices, to calculate the return rates, or rather the rates of remigration; the census then provides the number of people who are still present by immigration cohort, excepting persons who were temporarily away and were not counted in the census (Péron, 1977). Based on a series of censuses, the intercensus probabilities of departure from the country of residence can be calculated, but the fact that some people return after they have left the country takes much of the significance away from those probabilities.

[3] Permanent Demographic Survey (INSEE) that includes census and civil registration data.

4. Limits and Use of Census Data

The main flaw about census data is that they do not take into account the migration that took place between the date of $t - a$ previous residence and that of census t. The return migration measured is then bound to be affected by unknown re-emigration (and so is the migration measured through the same question); besides, the two-way trips made between the two countries, between $t - a$ and t, are ignored. These represent visits that are usually shorter than those of the migrants counted in censuses, but there is a bias if the reintegration of people who have come back in the past 5 years, for example, is to be measured.

The theory of return migration has been little developed, as has the study of the phenomenon itself. Two main reasons for returning are distinguished in it: failure or success in migration. Based on that very rough framework, the characteristics of return migrants can be studied, using all the information made available during the censuses (and the surveys), such as sex, age, educational level, labor force participation, and occupation. By calculating the rates by sex and age, it has emerged that the rate of return migration is high among young adults, then it decreases, and it goes up again at retirement age (see Table 65–1). In a study of returns conducted in Portugal and Spain (Rallu *et al.*, 2000), it was revealed that return rates vary depending on the level of skills. The educational level of return migrants is usually higher than that of the native population as a whole,[4] although it appears on analysis that there are also groups of manual workers with little education behind them. Return migrants are usually working people, sometimes employers. This is a means of providing part of the answers to the following questions. Do return migrants create companies and jobs, and what part do they play in the economy and in development?

II. SURVEY DATA

Through surveys, unlike censuses, complete migratory biographies can be recorded. All migratory moves are then made available. It is possible to calculate the proportion of people by birth cohort who have been abroad at least once for a minimum stay of x months or years for a reason given as an answer to an ad hoc question (which may reflect the cause of departure, but

[4] When using census data, we prefer to compare return migrants with the total native population rather than with nonmigrants, because among the latter are included migrants who were not counted through the question on previous residence.

not the reason for the visit nor for extending it) or according to their actual occupation over there (e.g., studies, employment). Surveys are also useful because the number of visits abroad can be calculated along with their total duration and other aspects. In that case, it is important not to forget that in a survey conducted in a given country, only return migrants will be captured, whereas migrants presently abroad are ignored, although some may well have returned before their current migration. Likewise, in a survey conducted in the host country, the migrants who have returned or remigrated are ignored.

1. Return Rates by Cohort and by Rank Order

A survey makes it possible to know the departures to j per year and calculate the return rates by year (cohort) of departure:

$$T_{ij}^{t,a} = R_{ij}^{t,a} \;/\; E_{ij}^{a} \qquad (2)$$

In Equation 2, $R_{ij}^{t,a}$ represents the migrants who have returned from j to i in the year t and who went from i to j in the year a, and E_{ij}^{a} represents the number of migrants from i to j in year a (i.e., cohort of outgoing migrants). The intensity of the return migration from j to i among the cohort of year a of outgoing migrants is the sum of annual rates.

In a survey, it is possible to choose to calculate rates or probabilities in building attrition tables with the usual methods (Fig. 65–1). However, the intensity of returns by cohorts calculated does not provide the proportion of people who migrated to j in a and came back to i at the date of the survey for the cohort under study, because they may have re-emigrated. It is then possible to calculate the re-emigration and return rates by rank for every first-migration cohort or by latest previous migration (the latter may be re-emigration or return) (Fig. 65–2A), and therefore to get a measure of the circulation by combining the probabilities (Fig. 65–2B). It appears that although the migrants in the second half of the 1960s did frequently have a first return, many went away again later in the great wave of migration to mainland France in the early 1970s. It is different with the 1975–1984 cohorts; among them first returns are highest, and re-emigration is low compared with the previous cohorts. The last cohort observed is characterized by low circulation between the overseas departments and mainland France. The 1970–1974 cohort is peculiar in that it shows growing probabilities at every new migration, an effect of the selection of the most mobile people, which results in greater circulation. If the data are to be unbiased, migrants should be interviewed in their native (return) country and in the host country, with a view to securing a total picture of migration per year.

The wide array of opportunities offered by surveys in providing migratory biographies are revealed in this manner. However, the surveys must be conducted in both countries when the migration from a given country is mainly directed to another or several other countries. The cost of such surveys is high, but one large, well-designed survey is better than several imperfect ones or even a number of small-scale ones.

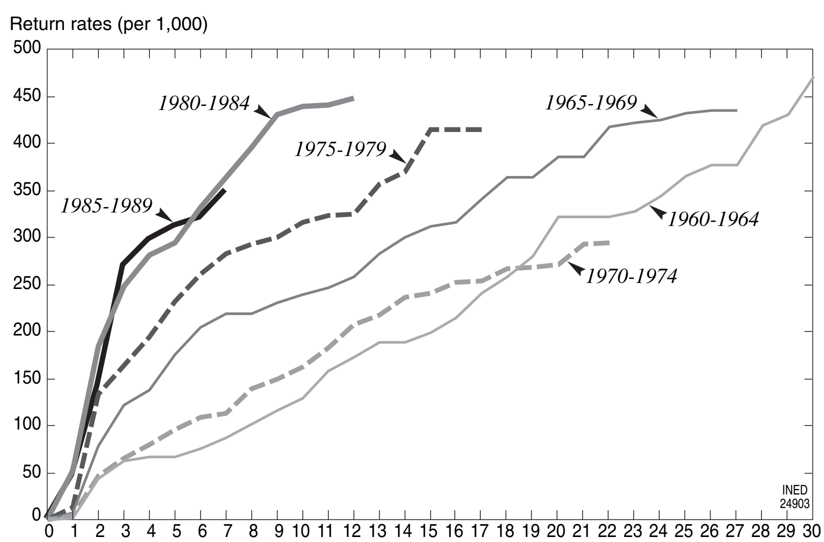

FIGURE 65–1 Total returns in the West Indian Overseas Departments by duration of stay and period of arrival in mainland France, from the probabilities of return (per 1000). (From INSEE survey on migration between the overseas departments and mainland France [Aziz and Lavertu, 1994].)

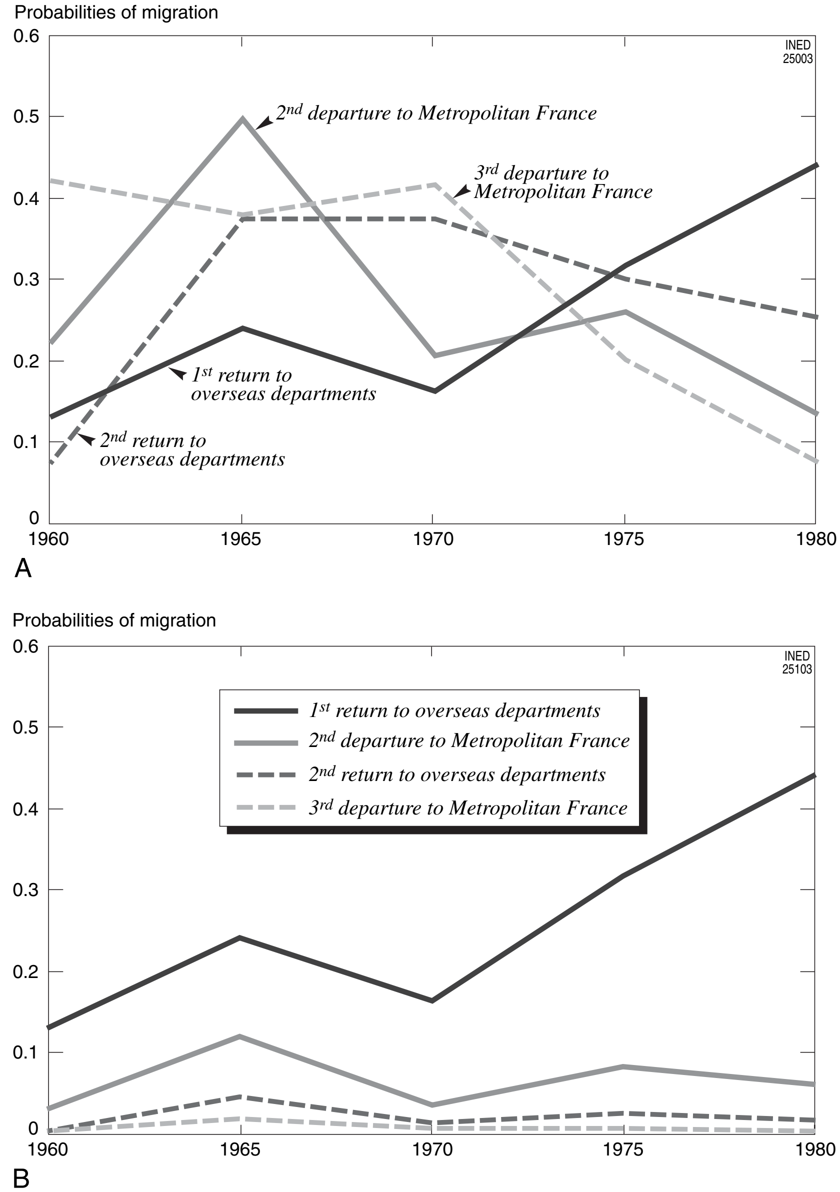

FIGURE 65–2 **A:** Probabilities (migrations n + 1/migrations n) of different types of migration (up to 9 years' duration) between the French West Indies and mainland France by cohort of first migration to mainland France. **B:** Probabilities of the different types of migration (migrations n/first migrations to mainland France) between the French West Indies and mainland France (at 9 years' duration) by cohort of first migration to mainland France. (From INSEE survey [Aziz and Lavertu, 1994].)

Simultaneous or quasi-simultaneous surveys have been conducted, such as the survey on the migration of natives of or residents in the overseas departments conducted by the French Institute of Statistics (INSEE) in 1991 to 1992 (Aziz and Lavertu, 1993, 1994) or the Research Network on Urban Migration in Western Africa (REMUAO) surveys by the ORSTOM (now IRD, French Research Institute on Development) on migration in West Africa.

2. Assessing the Productivity of the Sample

Though it is possible through surveys to measure migration over a long period, as with censuses, surveys may record such past migration as may be of limited interest for analyzing the present situation, particularly the social and economic aspects of migration. For example, a survey may yield information on migrants who returned when they were young adults several years or decades ago, who are presently older and now consider migration as only remotely linked, if at all, to the present situation.

The same applies to the study of the determinants of return migration. To compare the situation of a person who returned at age *a* in year *t*, it is necessary to know the situation of a person who stayed in the country of residence at the same age, in the same year, which implies that work biographies are available. Knowing the situation of the persons in the country of residence at the date of the survey makes it possible to compare the return migrants with the emigrants only in the year of the survey. It appears that the "productivity" of the sample may be considerably reduced if the information gathered is limited only to the current economic situation. Analyzing migratory biographies concurrently with work biographies provides all the resources offered by analyzing that type of data (see Chapter 23).

III. POPULATION REGISTERS

The study of return migration, as well as of migration in general, can be done using population registers. Such studies have been conducted, particularly in the field of historical demography (Tedebrand, 1976).

A distinction should be drawn between two types of registers: those that provide continuous observation of migratory moves—and are very much akin to biographic data—and those that provide truncated data or information relating to certain dates (e.g., the French Permanent Demographic Survey, which is based on censuses) or at the time of certain events (e.g., the respondents' personal address at the time of the vital events recorded by civil registration). Registers that provide biographic data can be analyzed by the methods of biographic data analysis. Registers that provide truncated data can be analyzed using methods similar to that presented for the study of censuses or, more systematically, using the particular methods appropriate for this type of incomplete data, such as have been presented in this book. Registers and surveys are used mainly for a longitudinal study of phenomena, whereas censuses offer mainly cross-sectional analyses. However, in the case of migration, censuses and certain registers provide a longitudinal fragment only, between the date of previous residence or arrival and the census, and that fragment is affected by the cross-sectional enumeration of the population in the census, in which the persons who were temporarily absent were excluded and the migratory moves between the dates under study were ignored.

CONCLUSIONS

The study of return migration must be freed from the idea that it is just a question of aged persons returning for good at retirement. It is part of the study of migration, defined as the circulation of persons between various places, in its various possible forms, including circular migration between two or several places or with more complex routes. In that sense, it is also a necessary element in measuring migration using the question about previous residence. In that circulation and through its age structure, it has significant effects on employment, skills of the labor force, and the economy.

For a complete, unbiased study of migration and of the migrants' characteristics, it is necessary to have data about all migratory moves, based on surveys or censuses simultaneously conducted in the various countries involved. The question about previous residence (usually 5 years before the census to limit the loss of information that may happen if the period is too long) should be asked, as is the case already in several countries, along with questions about the respondents' residence 1 year before the census and at the time of the last one. The countries involved would then have better data at their disposal to study migration.

SECTION

I

POPULATION IN TIME AND SPACE

History of Population and Population Forecasts: Introduction to Volume III

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

Volume I, Section I looked at the central study of the discipline–the in-built mechanisms of population dynamics. Volumes I, Section II, and Volume II, respectively, addressed the determinants of the three big forces of those dynamics (fertility, mortality and migration). This gives us the essential foundations for a better understanding of the historical and geographical forces driving population, and for a consideration of future prospects. It is this complex of issues that are the subject of this section, leaving the remaining text to examine population and society, population thought and policies, and methods of observation and corresponding tools for demographic analysis, as originally planned.

Between the time when the first *hominidae* appeared on Earth some 2 or 3 million years ago–or on a smaller timeframe, in the hundred thousand years since the most recent human species, *Homo sapiens*, entered the frame–and the mid-18th century, the history of the population of this planet has been a very long sequence of phases of slow expansion interspersed with crises and declines. A history in which the balance of births and deaths has been decisive for the future of each group, but also a history in which, for the most dynamic and ultimately successful groups at least, migrations have been a major determinant of human expansion across the continents. In the 18th century, however, the driving forces of that history changed radically. The industrial revolution led to unprecedented population growth, while relentless forces made the world population a reality as civilizations interacted with one another, and demographic behaviors in particular grew more uniform. Population growth has thus become a supremely global issue and its future, a big political issue.

The four chapters of Part I will attempt to give a broad outline of the history of the human population. Part II will look at the geography of population: the distribution of humankind across the surface of the Earth and the diversity of current population characteristics, for behind the converging trends, each population and group has its own history and differing timelines that give rise to a very wide range of point-in-time situations. Part III concludes the volume with an overview of the methods, and especially the hypotheses that offer avenues for an exploration of the future of a specific population, and ultimately the world population. It readily becomes clear that although the short and medium term future may be easily visualized, if not predictable, the same cannot be said for the long-term future, where the range of possibilities is very much wider.

PART

I

THE HISTORY OF THE HUMAN POPULATION

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

The history of humankind which Jean-Noël Biraben describes as "short," unfurling over "the last 3 million years at most" is indeed an eye-blink compared with the time that distances us from the first appearance of life on Earth, let alone that which elapsed between the formation of the universe and the emergence of life, which runs into billions of years. Even so, very little is known about most of those 3 million years, until the dawn of history with the invention of writing, probably around 4000 BC. What little we do know of the history of the human population, however, is enough for specialists in prehistoric demography to venture approximations of the possible sizes of the human groups who began to settle the planet even before we–*Homo sapiens*–emerged. It is this long period of prehistory in particular to which Jean-Noël Biraben devotes much of the opening chapter of this section (Chapter 66), painting a fascinating panorama which encompasses the human population "from the first beginnings to the present day." But although this chapter also deals fairly comprehensively with the historical period, it can clearly only skim the surface of the past 2 or 3 centuries–a time of unprecedented developments on the population front, which will be dealt with in greater detail in the following chapters.

Before that, however, David Coleman gives over much of Chapter 67 to a consideration of prehistory and ancient or medieval history in order to clearly delineate "the major role played by migration in the history of the human population." The population pattern of human groups has in fact long depended on their ability to exploit technical advances in order both to achieve natural increases through a surplus of births over deaths and to cope with the resulting pressure either through further technical progress or migration.

From the mid-18th century onward, however, humans–who had hitherto sought to adapt to the natural conditions of their environment and striven to tame nature for their benefit (such as, in the Neolithic era, turning from hunting and gathering to agriculture and stock rearing) had nevertheless remained wholly subjugated to the harsh equation of balance between their natural increase and the increase in available resources–finally began to liberate themselves from this ancient law and bring both the time of their death and the force of their fertility under their own dominion. In the space of 2 centuries, the demographic system, which had governed humankind for millennia, changed completely in Europe. It was what Adolphe Landry was to call the "demographic revolution," the *transition* from an old to a modern demographic regime (the pretransitional to post-transitional stages), with far-reaching consequences for European countries themselves in the first instance and for the rest of the world. The "European Demographic Transition" is considered by Jacques Vallin in Chapter 68.

The same author concludes this section on the history of the human population in Chapter 69, focusing on the half-century since the European demographic transition. This was a period of contrasts that saw the "theory of demographic transition," devised by writers in the late 1940s to account for the origins and consequences of the system change, come to fruition with the *globalization* of the vast historical movement initiated in Europe and the rise of uncertainties–first for Europe and its North American and Pacific Rim offshoots and then for the longer-term future of the other continents–so little does the "completion of transition" resemble the emergence of a stable and permanent demographic regime in which uncontrolled growth finally gives way to permanent stability.

CHAPTER

66

The History of the Human Population from the First Beginnings to the Present Day

JEAN-NOËL BIRABEN
Institut national d'études démographiques (INED), Paris, France

INTRODUCTION

This is the most recent in a series of exploratory estimates begun in 1979 (Biraben 1979). These tentative studies, as the name suggests, make no pretence to give the final picture of the demographic history of humankind. It, as did its predecessors, aims merely to review current thinking and move a step forward in the unending quest for more knowledge of our demographic past. It is also more comprehensive in considering humankind from the beginnings to the present day.

Significant advances both in the sciences of prehistory and in historical demography over the past 20 years make the case for these ongoing endeavours. This exploration, as did those before it, is purely tentative in simply taking stock of the state of early 21st century knowledge.

I. THE FIRST HUMAN POPULATIONS

The short history of humankind—the past 3 million years at most in the long life of the planet Earth—is both very unlike that of other living and extinct species and very alike in terms of the evolutionary pattern of all other species. It is hard to pinpoint when humankind first appeared and depends on the criteria used. What most distinguishes its lifestyle from that of the other great anthropoid apes may be less the fashioning and systematic use of tools (from wood, flint, bone, etc., which their anthropoid progenitors also used at times) than the quality of their manufacture, and even more important is the existence of a sufficiently permanent encampment where the gathered or hunted food was brought back for consumption by the group. Three million years would seem the very outside for the origination of such human beings in east Africa.

Little skeletal evidence remains of these *Homo habilis*, taking them as the earliest human beings, and is concentrated in regions where fossil remains could be recovered. The traces of their earliest industries, by contrast, have been better preserved and afford some evidence of the *oecumene*, or scale of distribution of these assemblages. It extended over nearly 4 million square kilometers of tree and bush savannah between Ethiopia, the Central African Republic, and Zimbabwe, i.e., approximately the same surface area as the mainly forest region between Guinea and Congo occupied by chimpanzees in around 1930 before the encroachment of agriculture. The number of chimpanzees around 1930 was estimated at approximately 200,000 individuals divided between five main species. But this population, unlike that of the other great anthropoid apes, was also thought to have increased significantly since the turn of the century, especially on the fringes of banana plantations where they lived commensally with humans by plundering the fruit.

When he addressed this issue in an article, Janos Némeskéri (1974) estimated these first humans as numbering approximately 100,000 individuals. Assuming the savannah-dwellers to be more carnivorous in their diet than were the chimpanzees of 1930, their number could be conservatively estimated as between 100,000 and 200,000 individuals, already divided into different types of hominid.

At that time, however, the Earth's prevailing quite uniformly hot climate (no polar ice-sheets) began to cool down and entered a major glaciation comprising at least six main glacial advances and retreats, each lasting tens of thousands of years, as well as countless smaller pulses of glacial advance alternating with periods of retreat of no longer than a few millennia each. There have only been four of these major glaciations in the 4.5 billion-year-old history of the Earth. Each has lasted only a few million or tens of millions of years, but each has been accompanied by an evolutionary spurt, with many species disappearing and many more appearing during each stage. One such evolutionary spurt, based on all the evidence, occurred in the human species, whose brain, in particular, expanded by a full kilogram in under 3 million years—one of the most rapid evolutions known for an organ that initially weighed substantially less than 500 g. It is hard to resist the conclusion that the capacities of this new organ gave its possessors such a selective advantage as to accelerate their evolution, leading to the elimination of all their nearest rivals. The result was the extinction at each stage of the preceding less sophisticated species of the genus such as *H. habilis* and *H. rudolfensis*, which were supplanted by *H. ergaster* in Africa, spreading across Southern Asia and Europe as its close relative *H. erectus*, and later in Europe as *H. neanderthalensis* and in Indonesia as *H. javanicus*.

Prehistoric demography sets out to study three aspects of these populations through different investigative methods of varying accuracy:

Population measurement
Mortality
Causes of death

II. THE PREHISTORIC POPULATION AND METHODS OF MEASUREMENT

The total prehistoric population has been extensively researched by many interesting methods, none of them, unfortunately, wholly satisfactory. Research has followed two lines: (1) that into the total population of large unit areas—regions, countries, and even continents; and (2) that into the size of a localized group such as an encampment, village, or small community.

1. Four Estimation Models

Essentially, four main methods have been used to estimate total populations. Briefly, they are as follows:

1. For the earliest periods (those of *H. habilis*), estimation of the population is determined by estimation of *biomass*—either the direct biomass of the primates deduced from their interaction with their environment, or biomass indirectly determined from the mass of available and accessible edible big animals and plants.

Although this method may have some value for other mammals, it offers no more than a tentative approximation for even primitive humankind, for which cultural changes, be it hunting techniques or social organization, significantly and rapidly affected the relationship between a population and the accessible biomass.

2. By measuring the *oecumene*, that is, the size of the area inhabited by humans of a particular culture; the calculated surface area is then multiplied by the density of historically recorded populations with ostensibly similar natural and cultural living conditions.

This method cannot be used for any of the very long Lower Paleolithic Age, for which there is no recorded evidence of a population living in comparatively similar conditions.

It also presupposes that populations live in equilibrium with their environment, which is only the case after a protracted period of adaptation, and even nowadays, countries with comparable climates and living standards, such as England and New Zealand, have very different population densities.

Finally, it also predicates long-term stability of the ecological environment, which has been approximately the case for the past 10,000 years, but such a protracted period of comparative climatic stability has been very uncommon since the appearance of human beings—that is, the start of the current glacial period marked by frequent, sudden climatic fluctuations every 2000 or 3000 years as a rule in the preceding 120,000 years—and probably also during earlier periods for which less evidence is available.

These shortcomings notwithstanding, this is by far the most popular method and can, if used with caution, give a valid crude approximation of the prehistoric population of a vast area for a particular period. However, in more recent terms, it is akin to back-calculating the population of the 16th century Iberian peninsula based on a rough idea of that of 19th century Turkey.

3. Denis Peyrony (1949) devised a completely different method for estimating the total population of a regional unit area, even for very remote periods of history. It involves a fairly forensic, uniform exploration of all the archaeological layers for each period in the area of study before a careful investigation of the geological conditions of layering and erosion in the Quaternary Period in that area to assess what proportion of the strata may have vanished through erosion, agriculture, or earthworks (given that this process follows an approximately logistic law) to reconstitute the number of layers for each culture in that area. Finally, it requires a fairly exact knowledge of the chronology for calculating the relative number of stratified deposits per millennium for each ancient culture (or per century for the most recent ones). This per-millennium stratigraphy, it is argued, then gives a relative scale of the population in each period.

Although pleasing in theory, this method does not pass muster in practice. An exhaustive exploration over a very large area is not possible or desirable, and estimating vanished layers is always an uncertain business. The few known cases in which it has been used are limited in scope, but the method could be substantially improved by systematic or random sampling exploration, which would enable the population to be more forensically tracked than by other methods, even for cultures with no known contemporary equivalent.

4. For more recent periods (the Mesolithic, Neolithic, and Chalcolithic eras), the assumption was that, because the population was divided into small groups, the total population could be estimated by counting the number of groups, that is, encampments for nomadic peoples or villages for sedentary communities, multiplied by the average estimated size of each group.

As in the previous method, this is limited by archaeological exploration and estimating average group numbers, which can be very difficult given that the smallest groups, which far outnumber all others, are most likely to be missed by exploration.

Its accuracy could now be considerably improved, however, by using lognormal distribution of groups, which allows the number and total population of groups to be fairly accurately approximated from just the most easily identifiable groups—the largest. Obviously, that involves using the greater range and variety of group size measurement methods, which, as will be seen, yield results equally variable in quality as did the previous methods.

2. Eight Methods of Measurement

Eight methods for measuring a local prehistoric population group are reviewed.

1. The idea of estimating the size of a group—say a clan—by measuring its hunting ground came to Dr. Louis Pradel (1954) while he was studying the area of distribution of flint from a very small jaspoid deposit used only over a relatively short period by a small group of Neanderthals of the Mousterian plateau culture a little over 70,000 years ago. This hunting and fishing ground, not far from the confluence of the Vienne and Creuse rivers at Fontmaure-en-Vellêche, is only a hundred square kilometers in size, and seven approximately similar assemblages along the Vienne and Clain rivers have been identified for the same period, spaced approximately 15 to 30 km apart. It can be deduced from this that each group could have consisted of between 10 and approximately 30 individuals, but it would certainly be wrong to extrapolate these results areawide across a region that is far from being as favorable to hunting and fishing as are these valleys, and it only offers an approximation based on an educated guess as to the number of groups or number of inhabitants.

By using the same method, Henri de Lumley (1976) demonstrated from the dispersal fan of more than 100,000 objects found around the Caune de l'Arago cave site that the hunting ground of this *H. erectus* clan of the Tayacian culture, which inhabited Roussillon a little more than 250,000 years ago in the Mindel-Riss interglacial stage, was approximately 500 km^2 in area for a group that, year in, year out, could also have consisted of between 10 and about 30 individuals.

2. Livio Livi (1941) conjectured that genetic survival required a minimum size for these basic population groups and that small islands holding only one group assumed to be fairly strictly endogamous and so forming a true isolate in the real sense, would give the size of these groups. In fact, this population of seafarers, which often roamed far and wide in quest of wives, was very much exogamous, and the lower limit of these island populations was predominantly dictated by the economy of the time.

3. For more recent epochs, the Mesolithic Period in particular, attempts have been made to calculate the size of certain population groups from the size of

kitchen-midden accumulations apparently belonging to the same group over a specific period (Boone 1976). The volume of refuse divided by a presumed average individual daily consumption would give the number of individuals in the group. Such calculations have been attempted on the shell mounds of the Californian and Portuguese coasts, the Azilian on the Basque and Cantabrian coasts, the kjöken-möding in Denmark, and the Tunisian snail mounds.

Unfortunately, these calculations are little more than "best guesstimates." Assessments of what constitutes age- and sex-specific average daily consumptions differ widely, whereas the actual duration of site occupation is still more arbitrarily estimated. It is just about possible to identify seasonally-returning groups but not groups returning only occasionally or even sporadically, nor is it easy to say whether the spot was a feeding center for the whole group or reserved for part of the community, such as women or children.

4. For even more recent periods—such as the Neolithic Period and Chalcolithic, Copper, Bronze, and Iron ages—attempts have been made to estimate village populations by the conjectured yield of surrounding cropped areas in each period. Sherburne Cook and Woodrow Borah (1963) used this method to estimate the pre-Colombian population of certain Maya cities.

But this method of calculation is very tentative for production and consumption, as it disregards the contributions of gathering, hunting, and fishing, not to say that of trade, by presuming villages to be completely self-sufficient, surely a very uncommon occurrence.

5. In recent sedentary culture periods, extensive research into the living environment, its sizes, capacity, dispositions, and layout (see Petrequin *et al.* 1969) has made it possible to conjecture approximate, but only likely, population sizes, which certainly vary with time and within a fairly broad range. Aggregated for each dwelling in a village, it gives an estimated order of magnitude of the village population. It is this method, first propounded by M. Jindrich Matiegka in 1911 (Matiegka 1927), that was the first used in prehistoric demography.

With the caveat that certain buildings within sites may be used not for dwelling but other purposes (places of worship, cattle sheds, barns, storehouses, etc.), which must be established, this method can yield fairly good results.

6. The study of some major collective structures has led to suggestions that the size of the societal group responsible for them can be inferred from the estimated number of contributors involved in creating them (Nougier 1959). The huge Locmariaquer menhir, which when whole weighed 368 tons, or the giant statues of Easter Island are examples.

However, experiments to validate this in 1979 showed that the number of contributors was much less important than were the lifting and rolling techniques used, and that, even with very crude techniques such as using logs and saplings for leverage, no more than 200 people were needed to erect a monumental 150-ton standing stone (Rouzé 1982). The same applies to the largest tumuli that 200 people can build in a few days, some of which, moreover, were added to by successive generations.

7. Mesolithic burials found grouped together in large burial grounds or cemeteries afford a much more accurate approximation of populations. Two Hungarian authors, Acsadi and Némeskéri (1970), devised and implemented a formula for the direct reconstruction of a village population from burial evidence.

Let t be the duration of the burial ground, D the number of reference skeletons, e_0 the mean estimated lifespan based on age at death from skeletal evidence, and K the estimated number of skeletons no longer extant. If, for example, $K = 10\%$, then

$$K = 0.1 \times D.\ e_0/t,$$

and the population

$$P = K + D.\ e_0/t$$

So, a cemetery containing 500 skeletons, in use for 200 years, would represent a village with an average population of 69 inhabitants.

Although the theory is scientific enough, especially compared with preceding ones, the method is nevertheless marred by uncertainties, especially as regards the completeness of the death totals: some who may have died in fighting or hunting accidents far from the village may not have been buried in the communal burial ground, whereas estimating the number of nonextant skeletons is particularly hazardous, especially those of very young infants, who were generally buried close to the surface and whose remains may have long been ploughed over. A statistical estimate of these can be ventured by plotting the age-specific cumulative distribution curve of deaths and comparing it with that of the closest model life table, but a degree of uncertainty remains (Biraben 1969).

Claude Masset (1982) devised a statistical method by which to reconstruct the total number of individuals buried in a rock tomb or ossuary where the skeletal remains have been secondarily moved and mixed.

This method, too, although satisfactory on the theoretical level, has serious drawbacks in practical application, which can only partly be overcome by the application of significant material means.

8. In the case of an incineration ground, finally, accurate dating of the ashes in each burial urn could give a distribution of deaths by broad blocks of years, that is, a trend pattern of deaths over the period of use of the entombment ground. The method was devised by Odette Taffanel (1976) to study the Mailhac burial ground, for which she estimated the 30-year death trend over 170 years, from 870 to 700 BCE. Assigning to this population maximum and minimum life expectancies enables the trend range of change in the population of that village to be calculated in 30-year cycles over the period.

This method, ostensibly quite precise, likewise unfortunately suffers from uncertainties, because there can be no certainty that all individuals in the village were incinerated, and particularly because of the unresolved practical issues surrounding accurate dating of incineration ashes.

After this rapid overview of methods of counting prehistoric populations, a very tentative outline account can now be ventured of the key results achieved or, put differently, the orders of magnitude within which prehistoric populations may possibly have fallen.

III. ESTIMATES OF PREHISTORIC POPULATIONS

When dealing with the world population, only the second method is usable, and that is the one that will be used to postulate some estimates, or rather, as stated above, what are still tentative orders of magnitude.

1. From the Earliest Hominids to *Homo Sapiens*

The only extant evidence from the very long Paleolithic Era about developments in hunting or gathering technologies of the time is what may be deduced from the flint or wooden artifacts found. It may therefore be assumed that they evolved correspondingly slowly, and that the number of human beings was for long much more closely linked to the size of the *oecumene* (area of distribution and historical movement) and to climatic variations, which govern the biomass (i.e., the annual quantity of plants or animals likely to form a direct or indirect part of the human food chain), than to any improvement in hunting or gathering techniques.

It is, however, worth noting that changes in the *oecumene* at these remote eras are also arguably connected with the physical changes in humankind, which may themselves be related to the sweeping climate changes of the main glacial advances. So, the appearance of *H. ergaster* at least quadrupled the *oecumene* of its predecessors, *H. rudolfensis* and *H. habilis*, stretching across northern and southern Africa, south and east Asia, the Middle East, and southern and central Europe, found in its form of *H. erectus*.

Technological leaps, although few and far between, also occur. The taming of fire, almost half a million years ago, enabled the cooking of some foodstuffs that were inedible raw, significantly reduced the parasites in the food that was cooked, and kept predators away from encampments. Much later, Levalloisian flaking of flint gave much improved tool quality and a better output of cutting edge per kilogram of raw flint. It also enabled diversification, so a greater variety of stone tools developed. On the basis of this, the total number of *H. erectus* on the planet can be conjectured at between 500,000 and 700,000.

During the penultimate ice advance, the Riss Glacial Stage in Europe, at both ends of the *oecumene*, i.e., in Indonesia and Europe, different physical types gradually began to emerge that, long kept apart by the rising sea levels during the following much warmer Eemian Interglacial, caused three distinct hominid population groups to develop at the same time—Java man in Indonesia, Neanderthal man in Europe, and *H. sapiens*, who, probably making his first appearance in Ethiopia and the surrounding areas, slowly spread first toward southern Africa, then to the Arabian peninsula, Levant, Iran, India, Indo-China, and China, where he supplanted *H. erectus*.

Slow progress in hunting and gathering technologies, improving the productivity of subsistence activities (the development of the Mousterian culture in Europe), suggests the possibility of a fresh population spurt. A midrange assumption for the number of humans at this period of optimum climatic conditions may be 800,000 for *H. sapiens* in the Afro-Asian area, 250,000 for Neanderthal man in Europe, and 100,000 for Java man in Indonesia.

The last ice advance, known as the Würm glacial stage in Europe, beginning toward 72,000 BCE, changed the world order. The ice-sheet across the northern half of Europe and falling sea levels, which restored communications between Europe and Asia and between Indonesia and Asia, would enable vast population migrations to occur.

Neanderthal man first abandoned the North European Plain, and the harsh climate, combined with the very significant decline in plant and wildlife, would lead to a drastic fall in their numbers to perhaps 50,000, when analogized from the established numbers of Eskimo or Chukchi populations living in the same climatic conditions in the 18th and 19th centuries but with a markedly more developed cultures. Then, from 70,000 BCE onward, they very rapidly spread east into as-yet-unpopulated Turkestan and southeast through Asia Minor, made accessible by the falling sea level, as far as to Palestine, where they lived alongside *H. sapiens*. At the same time, in southeast Asia, *H. sapiens* entered Indonesia, then part of the Indo-Chinese peninsula, squeezing out Java man within some 10 thousand years.

In a second stage, from 50,000 BCE perhaps, *H. sapiens* crossed the Timor Strait from Indonesia into then-uninhabited Australia and New Guinea (reunited by the falling sea level).

In a third stage, from about 42,000 BCE, the Middle Eastern branch of *H. sapiens* in Asia Minor gradually spread across Europe via the Caucasus and the Balkans, where a new culture—Proto-Aurignacian—developed. Despite the attempts of the Mousterian culture (i.e., Neanderthal man) to emulate it, this was to give *H. sapiens* a decisive superiority. Around 30,000 BCE, they spread through the Danube valley, Po River plain, and Provence to occupy all of Central Europe, Italy, most of France, and the Cantabrian mountains area of Spain. The last traces of the Mousterian culture offer presumptive evidence that the last Neanderthal men died out in northwestern France and in England around 29,000 BCE and in Andalusia about 28,000 BCE.

It was also probably somewhat before 40,000 BCE that humans crossed the Bering Strait and spread across North American and then South America. These vast lands, which, similar to Australia, were not everywhere habitable, nevertheless very soon added at least 500,000 individuals to humankind.

Twice—first around 23,000 BCE, then around 18,000 BCE during the last two lowest sea levels, *H. sapiens* migrated from Sicily (then attached to Italy, as were Malta and Pantellaria) to Tunisia via the less than 20-km-wide strait that separated them, rapidly ousting the very scattered people of the Aterian culture descended from *H. erectus*, who were still living there and relatively cut off by the desert. Their rapid advance westward would take them to the Canary Islands; their eastward move, into Egypt and Arabia. In the Maghreb, the population may have risen from 10,000 in the Aterian period to 50,000 for the Oranian culture and 70,000 for the Capsian culture.

In the same era, others left the Ukrainian and Russian plains, spreading eastward to become the Palaeosiberian peoples, and on into the Yenisei and Lena basins, Kamtchatka, Chukotka, and Japan (Ainu). They were very few in number at first, and even several millennia afterward, these vast spaces were probably inhabited by fewer than 50,000 people.

Later, around 12,000 BCE, a population drift from eastern Asia would again cross the Bering Strait, swamping the indigenous populations and driving them to seek refuge in a handful of sites, this becoming the majority population of America south of the Rio Grande River. The Eskimos would comprise the third population migration from Asia, where a very few can still be found. But another final, later-occurring and more miscegenous Palaeosiberian population movement was to invade the great plains and Rocky Mountains of North America, driving the occupants south of the Rio Grande River.

The vast forested tracts of sub-Saharan Africa and the Congo basin excluding the Sahel, which was relatively populous between 9000 and 4000 BCE (conjecturally, between 200,000 and 400,000 people), remained very sparsely populated. The earliest population of Pygmy inhabitants living in scattered groups was joined perhaps much later (perhaps 15,000 or 10,000 BCE) by a black population arriving in several waves, the first of which now remain only in a handful of refuge-habitats (similar to the Dogons in their rocky hills), and the last of which seem to be the Fulani (or Peul) people.

It is worth noting in this broad-brush picture that even before the development of navigational technology, humans seem to have crossed stretches of ocean that were not too wide—70 or 80 km at most—and that a systematic investigation into the periods at which channels such as the Bering Strait emerged add little to population research. Crossing conditions, by contrast, are more decisive than is width, and the strong current of the Strait of Gibraltar explains the late and still infrequent crossings of the Early Neolithic era.

2. The Prehistoric Population of Europe

In the work *Histoire de la population européenne* (Bardet and Dupâquier 1998), the authors described the method used to estimate the population of the European continent—the best explored from an archaeological standpoint—at between 140,000 and 170,000 inhabitants in the earliest period of habitation, that of *H. sapiens*, between 32,000 and 16,000 BCE, rising perhaps to nearly 200,000 at the height of the Magdalenian and Epigravettien cultures between 10,000 and 8700 BCE. It should also be noted that nomadism did not by any means produce a uniform pattern of human distribution: they wandered in small groups but almost always in the same regions, which were presumably most suited to their diet and activities and where almost all of the archaeological sites relating to them are now found.

The lognormal distribution of these groups suggests that both small (2 to 8 people) and large encampments (50 to 250 people) are uncommon, with most falling between 10 and 50 people. With some slight adjustment, this distribution is found among all populations in all parts of the world. Such a structure, even allowing for traditional exogamy (i.e., where marriages are prescribed with a nearby group), favors genetic drift. Where, by chance or design, a group is isolated from the outset, as it is always too small to be representative of the general population from which it originates, there is a significant founder effect, and within the space of a dozen generations, the genetic, cultural, and linguistic drift is so significant that, coming back into contact with the general population, it appears alien. This is the cause of differentiation and diversification in human types and ethnic groups, some of which are very old and many others comparatively recent, at least in prehistorical terms.

The sudden climatic warming which occurred in Europe between 8700 and 8650 BCE (when the average temperature of western and central Europe is estimated to have risen by 13°C in 50 years!) cut short the then pan-European Magdalenian and Epigravettien cultures. The southern steppes, hitherto teeming with herds of large animals, became overgrown by dense forest inhabited now only by packs of smaller animals and the odd solitary animal (wild boar, deer). Adaptation to the new plant and animal resources was initially reflected in a significant population decrease. By contrast, the northern tundra became forested, but less densely, interspersed with vast clearings where large herds of aurochs and bison continued to roam, and in Scandinavia, the reindeer population increased, as did the human population, under the effect of the climatic amelioration. Broadly, it may be conjectured that after a slight drop to perhaps 180,000 inhabitants around 8000 BCE in response to the sudden climate change, the population learned to adapt, began to rise again, and doubled around 7000 BCE to something approaching 400,000 inhabitants.

At this time, people from Anatolia established a first Neolithic village settlement in Greece, near Thessaloniki, growing hand-hoe—cropped cereals and pulses; rearing dogs, goats, sheep, oxen, and pigs; and living in stone-built, timber, and cob houses. This proto-Sesklo culture would rapidly evolve into the Sesklo civilization around 6800 BCE, making pottery and living in brick-built houses. Two courses developed from this.

In the south, along the Mediterranean coast, a seaborne course—the Cardial culture—characterized by impressed ware decorated by patterns made with a cockleshell, usually *Cardium edule*. Although not a colonizing people, they were culturally expansionist and moved from the seaboards inland to invest the Mesolithic (Epipalaeolithic) populations, each of which evolved in their own way from seminomadic hunter-gatherers into sedentary pastoralist and farming peoples. The civilization reached the Strait of Gibraltar before 6000 BCE and, after a pause, moved on to the Atlantic seaboard around 5000 BCE, where from 4 200 BCE the civilization ended up on the southern coasts of England, separated even then from the continent for 2500 years by the rising sea level (the civilization also, with difficulty, sporadically crossed the Strait of Gibraltar and established a few scattered settlements strung out along the coast of the Er-Rif mountain range and the Oranie region).

Somewhat later, around 6000 BCE, a course thrust northward across land, settling in the central Balkans, a civilization characterized by fine-painted ceramic ware, and diversifying into a wide variety of local cultures. About 5500 BCE, in Hungary, the Starcevo culture underwent a surprising population surge and moved up the Danube to occupy all the European hinterland from the Paris basin to Poland and Moldavia, driving back or absorbing the nomadic Tardenoisian hunters and then meeting and merging with the seaborne course around 4000 BCE in central France or in the Alps.

When another Neolithic course, which around 5000 BCE spread along the east coast of the Black Sea, the Kuban river, and the Ukraine, is added, then by around 4000 BCE almost the whole of Europe had moved into the Neolithic period with a population that may have stood at 2 million.

3. The Prehistoric Population of the Middle East and the Rest of the World

Among extra-European populations, the only one known with comparative certainty is that of the Middle East, where the Neolithic stage of development was attained around 10,000 BCE in the Fertile Crescent with cereal farming (mainly corn) and animal domestication—goats, sheep, and oxen. It was consolidated around 8000 BCE, with the appearance of pottery, and rapidly spread to Egypt, Anatolia, the Iranian plateau, and thence to the Caucasus, the plains of Punjab, Nubia, Ethiopia, and Yemen. The population for the entire Palestine, Lebanon, Syria, and Iraq region may have increased from 200,000 around 10,000 BCE to 500,000 in 8000 BCE and 1.5 million by 4000 BCE.

India was to be far and away the most populous region, but its population size is unfortunately very difficult to determine, because it seems to have been ignored by prehistorians and studied only by historians who have deduced utterly impossible totals for these ancient times from the purple passages of legendary tales. So, Pran Nath (1929) calculated the size of the armies engaged in the Mahabharata war—placed by Chandra (cited in Pran Nath, 1929) as at around 3100 BCE—at 1.97 million soldiers, which infers a total population size of between 29.6 and 39.4 million inhabitants! This number seems overstated, given that only the northwest of the country (present-day Pakistan) had attained the Neolithic culture, and the entire east and south of the country remained at the Mesolithic stages of development. If the population of India in these periods absolutely had to be conjectured, then reasonable orders of magnitude might be from 600,000 around 4000 BCE, 2 or 3 million around 3000 BCE, and an absolute maximum of 20 or 25 million around 2000 BCE, when virtually all the peninsula—India, Pakistan, Bangladesh, and Sri Lanka—had attained the Neolithic culture.

Around 8000 BCE, a Neolithic culture also developed in the plains of the Huang Ho River basin, rapidly developing to produce the glorious Chinese civilization. Originally confined to an area of just 600,000 km^2, it spread rapidly, first eastward to the China Sea and then southward, where corn gave way to rice cultivation. The population of China was of the same order of magnitude as that of India, perhaps a little faster-growing, with 800,000 inhabitants around 4000 BCE, 3 or 4 million around 3000 BCE, and an absolute maximum of between 15 and 20 million around 2000 BCE.

Somewhat later, another Neolithic culture in the Tehuacan valley in Mexico began to grow maize, tomatoes, and beans and to domesticate dogs and turkeys; yet another culture on the high plateaus of Peru grew potatoes and domesticated llamas and alpacas.

Elsewhere, in Neolithic cultures at various stages of completion, pottery appeared from 10,000 BCE in Japan and from 8000 BCE in a huge swathe of the African Sahel, followed by the Middle East, India, China, and Europe, and finally Mexico, Ecuador, and Peru.

So, by around 4000 BCE, not only in the Middle East and Europe but also in the African Sahel, Sudan, Ethiopia and Yemen, northwest India, China, Japan, and the high plateaus of the two Americas, the populations had evolved from hunter-gatherers to agro-pastoralists. With these eight Neolithic population centers, the world population had risen from just 6 or 7 million at 2000 years before to nearing 30 million and, 2000 years after that, when the hand-hoe was supplanted by the swing-plough, which vastly increased yields, it would be close to 100 million.

In seeking to chart the long rise of the human population, authors have long stopped short at estimating populations at a given date in Prehistory, Antiquity, the Middle Ages, and, more often still, the Renaissance or modern times and the contemporary era. This point-in-time approach has tended to give the impression of more-or-less uninterrupted exponential growth. Of the many published works on this subject, those of John Durand (1974) seem to have the most cogently argued case.

Prehistory, however, more suggests sharp growth spurts interspersed with long periods of stagnation or even decline. Does that paradigm still hold good for historical periods? The only way we have of knowing is to calculate the world population at a sufficiently large number of dates close enough together to plot the trends. Arguably, this idea is lent credence by the long, wide fluctuations in the long population curves of regions as populous as China or Europe, which according to the period each account for a fifth or sixth of humankind.

Until recently, humankind had remained segregated in large, comparatively hermetic cultural spaces, which Pierre Chaunu (1974) has dubbed "enclaved universes." Conceivably, the population within the same cultural space presents overall changes that reflect boom-bust cycles, but there is no circumstantial evidence from which to conclude that the populations of discrete or even far-apart cultural spaces evolve at the same pace, except by pure chance.

Similar to any plant or animal population, humankind is concentrated at points of the *oecumene* that are most suited to its subsistence and activities. So, it is clear that from Antiquity, China, India, and the European and Mediterranean countries accounted for between two-thirds and three-quarters of humankind between the three of them; in other words, the evolution of people in these areas determined that of all human populations.

IV. FROM ANTIQUITY TO MODERN TIMES

The table compiled (Table 66–1) shows that, significant divergences aside, there has been a correspondence of some favorable and unfavorable long periods in all three regions since Antiquity (although obviously not just between these three regions, since it may obtain generally almost worldwide). To show this

TABLE 66–1 World Population by Broad Regions at Different Dates

*Community of Independent States (CIS) + Baltic states.

clearly, however, the points have been increased by aggregating the population of all countries, first in blocks of 2 centuries at a time between 400 BCE and 400 CE, then in single-century blocks up to the 17th century, and in half-century blocks from 1700 to the present day; finally crucial dates that were watershed moments for humankind's population development are indicated: in 1250 (just after the Mongol invasions) and in 1340 (just before the Black Death).

None of these numbers lay any claim to accuracy: even for the year 2000, as for 1950 and 1900, international yearbooks (chiefly those of the International Statistical Institute, League of Nations, and United Nations) are uncertain and may vary between editions; they are probably accurate for total world populations to within 5%. For periods further back, estimates have to be even more approximate, say 7% or 8% around 1700 and 10% around 1500. Further back than this, the scant, almost always indirect, statistics available enable one to work only within very uncertain ranges. The key thing is that the direction of variations and magnitude of fluctuations tend to more than compensate for the uncertainties.

1. Asia

The data for China are taken from Michel Cartier (Cartier 1973; Cartier and Will 1971), adjusted for current borders. The vicissitudes of China's history will not be rehearsed again in detail here, apart from one arguably key episode in which Chinese censuses report a loss of nearly one-third of the population in 49 CE. From this date until 73 CE, China called a halt to the reconquest of its territory, embroiled in battle as it was with the Yueh-chih from the west. The probable key to this puzzle is offered in the writings of a Chinese doctor of the time, Ko-Hong, in the form of the first description of smallpox, which he reports to be a new disease brought by the Yueh-chih horsemen in 49 (Ming Wong 1974). The same disease was similarly to ravage the West, i.e., the Roman Empire in 168 (where it was known as the Antonine plague) (Bakfalouni 1983, 1984) and the Aztec Empire in 1521 (Biraben 1992).

The data for India are taken from Ajit Das Gupta (1972), except for the pre-16th century era, where he merely argues that the population of India could have reached 100 million at the zenith of the Maurya empire (between 321 and 185 BCE), during the Gupta empire (320 to 470 CE), and under the reign of Harsha (612 to 627 CE). This very round figure of 100 million obviously requires qualification. It must be remembered that in all these periods, vast tracts of the interior were still tribal lands, governed by a very antiquated economic system (some still a Mesolithic culture almost until modern times), certainly with very low population densities. It was therefore thought preferable to estimate populations of 50 to 60 million for these periods, which are still within the bracket accepted by John D. Durand (1974), who argues for 75 million, but they could have been put 10 or 20 million higher without affecting the results. A later detailed study by Shireen Moosvi (1984) using two different methods estimates the population of India at approximately 145 million in 1595, tallying with Ajit Das Gupta's estimate taken for 1600 in preference to the 100 million conjectured by Moreland with little supporting evidence.

Southwest Asia includes the Arabian peninsula, Jordan, Palestine, Israel, Syria, Iraq, Turkey, Iran, and Afghanistan (Bachi 1974). Studies on the population in Antiquity exist for several of these countries; all of the countries are covered for the 19th and 20th centuries (Benham and Amani 1974). However, there are few (Israel, Syria, Turkey, Iraq) estimates for the Middle Ages (Bakfalouni 1983) or the Renaissance period (Barkan 1958, 1969; Erder 1979; Panzac 1981; Karpat 1985; Lacquerer 1987). The trend has therefore been plotted by reference to the flourishing and turbulent periods of their history, which, although of doubtful validity, broadly lines up with trends in which ignorance less outweighs knowledge. Additionally, it was only in Antiquity that the population of the Middle East influenced that of the world to any significant extent.

The figures for Japan follow the revised estimates of Akira Hayami (1987), reported in an article in *Population* (Biraben 1993).

Pre-19th century data for the rest of Asia is scant, except for Korea, Vietnam (Cartier 1973), Kampuchea (Meng-Try 1980), and Thailand in 1700 (Vallin 1976). Although several other countries in the region—Sri-Lanka, Burma, Champa, and Indonesia—reached apogees of civilization in the Middle Ages, their demography remains almost an unknown quantity and all that can be offered is pure conjecture. But the small population sizes of these countries made little contribution to the world total.

2. Europe

The data for Europe are drawn partly from volume 1 of the *Histoire des populations de l'Europe* (Bardet and Dupâquier 1998; although this arguably relies too heavily on McEvedy 1978, which is not the best authority) and partly from unpublished personal records. Broadly, rapid population growth in Antiquity was interrupted by smallpox (Antonine plague in 168) and then measles epidemics, giving way to a population decline. This decline gathered pace after the appearance of St. Cyprian's plague (a severe epidemic of an unknown type) and deepened with the successive waves of Germanic invasions in 251, 276, 375, and especially 407–412, when the economy was crippled by a general decline in trade. Although the late 5th and early 6th centuries seem to show an upturn, the Justinian plague of 542–543 and the reappearance of smallpox 10 years later completed the population loss. This was followed by stagnation and a very slow return to growth owing to the insecurity created by the Slavic, Avar, and Bulgarian invasions in the east and the Saracen, Norman, and Hungarian raids in the west. With these tribulations at an end, a strong population surge occurred in the 10th century, continuing through until the early 14th century, with only a slight blip caused by the Mongol expansion in 1242–1243. The Black Death, which appeared in 1347–1352 and turned into a new epidemic, caused a population loss of at least 20% in the space of a century. With the plague vanquished, another population surge occurred between 1450 and 1550. The late 16th, mid-17th, and early 18th centuries were also periods of stagnation or loss owing to wars, religious strife, and climatic deterioration, but most striking of all is the spiraling population growth from the mid-18th to early 20th century, which abated under the sharp check delivered by two world wars and slowed even further by fertility decline accentuated by the economic recession from 1973. In 2000, almost all of Europe was in a phase of population stagnation or even decline, despite continuing life expectancy gains, except in Eastern Europe, where life expectancy has even shortened slightly.

For the countries of the former Soviet Union, there is sparse evidence from the 13th century and relatively copious data from the 17th century to the modern day.

3. Africa

North Africa from Egypt in the east to the Maghreb in the west experienced Middle East—like periods of great prosperity in Antiquity, but the large body of research has produced no overall data or data too discrete to carry conviction owing to the continuing great uncertainties even about the best-researched periods. This chapter produces a tentative synthesis, which arguably best summarizes the achievements of the past 20 years.

The rest of Africa poses major problems, because only point data exist for most countries before the 20th century. An attempt has been made to estimate the population based on what is known of its economic and political history, outlined in the author's first publication in 1979.

4. America and Oceania

Although there are no statistical data for America predating the 16th century, archaeological research is beginning to yield a large body of much older local evidence. Also, close examination of the Spanish census documents from Peru and Bolivia showed that the population recorded by the quipu-camayoc in the Inca period and kept on the quipus (accounting apparatus) had often been recorded by the Spanish agents. The population decline seems not to have been as sharp as has been claimed on the basis of work skewed by a faulty methodology. I concur with John Durand (1974) that the population is likely to be somewhere between the two extremes argued for, at around 40-odd million in 1500.

It should also be noted that, after a slight retreat, the population grew rapidly from the mid-14th century, in stark contrast to the population of the Old World, on which the Black Death had inflicted serious losses at the same time.

For Oceania—excluding Australia, which has been populated since prehistory—population growth has only been hypothesized from the 10th century onward, when the Polynesians began to occupy the Pacific islands and, much later, New Zealand.

5. World Total

Turning now to the world population as a whole, it is clear that, notwithstanding the sometimes crude approximations used, the human population has not experienced the uninterrupted exponential growth that some studies affirm as an accepted truth. The more probable explanation is successive phases of growth or decline varying in length and rate. Before the recent rapid growth phase from the 16th to 20th century, it had been in decline for a good 100 years after the sudden emergence of the plague in the mid-14th century and a series of economic tribulations and wars. This peak around 1340 had followed a trough in the 5th and 7th centuries, itself preceded by a peak in the 2th century. There is a suspected trough around the 9th century BCE, preceded by a peak in the 11th century and so on.
